Preface

A new Handbook of Nuclear Engineering is indeed a rare event, although the engineering sciences – and especially nuclear engineering – have progressed immensely during the fifty-two years that have passed since the publication of the first handbook of this kind. Even if the basic principles of nuclear engineering have remained unchanged for decades, it is compelling to note that the professional practice in this sector has enjoyed great progress during this period.

Professor Dan Cacuci has embarked on an ambitious task: to edit a new Handbook of Nuclear Engineering, aiming at making it as all encompassing as possible. He successfully carried out this huge task in a very short time span, bringing together specialists of the highest international reputation.

Primordially, nuclear engineering draws its roots from the nuclear sciences, a field founded on the most fundamental advances in the physics of the 20th century. This is an exacting field conceptually, demanding knowledge not only of the intimate structure of matter, but also of the mathematical formalisms that represent this structure. A field that is, regrettably, increasingly more neglected in the general education.

At the same time, nuclear engineering is also about engineering at the highest level of exigency for harnessing the extremely high power density in nuclear systems, intertwined with the absolute necessity to control and operate these systems in conditions of maximum safety and economic feasibility.

Last but not least – and this is probably the source of its unique characteristics – nuclear engineering is anchored in time, in its own history, first and foremost, and especially in the extent of time over which the responsibility of nuclear engineers must last – from designing, constructing and operating reactors to the management of the ultimate destination of decommissioned reactor plants.

These exceptional stakes are becoming critical now – at a time when the “third-generation” of nuclear engineers needs to be educated, a generation which is to succeed the “master-builders”, who themselves had, in turn, succeeded the “pioneers”. This third-generation of nuclear engineers is already being called upon to fulfill a new demand – that of integrating all of the knowledge produced by its predecessors in the quest for meeting an increasing demand for energy production under enhanced safety requirements and optimal economic conditions.

Energy is a major stake of the 21th century. Humanity will imperatively need to manage the sustainable production, transportation, and applications of energy. Nuclear power will inevitably play a decisive role in this quest.

Needs for energy, needs for competences, needs for education and training, needs for reference books in nuclear engineering: I do make the wish that the present work would contribute its share towards satisfying these needs, enlightening the young generations to which we are passing on great responsibilities. In view of the contents of this Handbook, covering widely

and deeply the vast field of nuclear engineering, and the outstanding quality of this coverage – guaranteed by the worldwide reputation of the authors – I have no doubt that this wish will come true.

About the Editor

Dan Gabriel Cacuci

Institute for Nuclear Technology and Reactor Safety
Karlsruher Institut für Technologie (KIT)
Gotthard-Franz-Str. 9
76131 Karlsruhe
Germany

Dan Gabriel Cacuci has received his Ph.D. degree in applied physics and nuclear engineering from Columbia University, New York, in 1978. His career has bridged activities in the academia and multidisciplinary national research centers. His teaching and research experience as a full professor at leading academic institutions includes appointments (tenured, part-time, visiting, or adjunct) at the University of Tennessee (1983–1988), University of California at Santa Barbara (1988–1990), University of Illinois at Urbana-Champaign (1990–1993), University of Virginia (1993–2000), University of Michigan (1995–2000), University of California at Berkeley (2001–2006), Royal Institute of Technology Stockholm (2003), the French National Institute for Nuclear Sciences and Technologies in Paris (since 2006), and the University of Karlsruhe (since 1992). Professor Cacuci has also served as a group leader and section head at Oak Ridge National Laboratory (1976–1988), Institute Director at the Nuclear Research Center Karlsruhe in Germany (1993–2004), and acted as Scientific Director of the Nuclear Energy Directorate, Commissariat à l’Energie Atomique, France (2005–2009).

Professor Cacuci’s scientific expertise encompasses several areas in nuclear engineering (reactor multi-physics, dynamics, safety and reliability), predictive best-estimate analysis of large-scale physical and engineering systems, and large-scale scientific computations. He has authored 3 books, 7 book chapters, and over 180 peer-reviewed articles.

Since 1984, Professor Cacuci has been the Editor of “Nuclear Science and Engineering –The Research Journal of the American Nuclear Society” (ANS). He is a member of the European Academy of Arts and Sciences, Honorary Member of the Romanian Academy, ANS Fellow, and has received many awards, including four titles of Doctor Honoris Causa, the Alexander von Humboldt Prize for Senior Scholars (Germany), the E. O. Lawrence Award and Gold Medal (US DOE), the Eugene P. Wigner Reactor Physics Award (ANS), and the Glenn Seaborg Medal (ANS). Professor Cacuci has served on numerous international committees, was founding coordinator of the EURATOM-Integrated Project NURESIM (European Platform for Nuclear Reactor Simulation, 2004–2008), and founding coordinator (2004–2007) of the Coordinated Action for establishing a Sustainable Nuclear Fission Technology Platform (SNF-TP) in Europe.

Table of Contents

Preface	v
About the Editor	vii
Contributors	xiii
Biographies of Contributors	xxi
Introduction	li

Volume 1 Nuclear Engineering Fundamentals

1 Neutron Cross Section Measurements	1
<i>Robert C. Block · Yaron Danon · Frank Gunsing · Robert C. Haight</i>	
2 Evaluated Nuclear Data	83
<i>Pavel Obložinský · Michal Herman · Said F. Mughabghab</i>	
3 Neutron Slowing Down and Thermalization	189
<i>Robert E. MacFarlane</i>	
4 Nuclear Data Preparation	279
<i>Dermott E. Cullen</i>	
5 General Principles of Neutron Transport	427
<i>Anil K. Prinja · Edward W. Larsen</i>	
6 Nuclear Materials and Irradiation Effects	543
<i>Clément Lemaignan</i>	
7 Mathematics for Nuclear Engineering	643
<i>Dan Gabriel Cacuci · Mihaela Ionescu-Bujor</i>	

Volume 2 Reactor Design

8 Multigroup Neutron Transport and Diffusion Computations	751
<i>Alain Hébert</i>	
9 Lattice Physics Computations	913
<i>Dave Knott · Akio Yamamoto</i>	
10 Core Isotopic Depletion and Fuel Management	1241
<i>Paul J. Turinsky</i>	

11	Radiation Shielding and Radiological Protection	1313
	<i>J. Kenneth Shultis · Richard E. Faw</i>	

12	High Performance Computing in Nuclear Engineering	1449
	<i>Christophe Calvin · David Nowak</i>	

Volume 3 Reactor Analysis

13	Analysis of Reactor Fuel Rod Behavior	1519
	<i>Paul Van Uffelen · Rudy J.M. Konings · Carlo Vitanza · James Tulenko</i>	

14	Noise Techniques in Nuclear Systems	1629
	<i>Imre Pázsit · Christophe Demazière</i>	

15	Deterministic and Probabilistic Safety Analysis	1739
	<i>Mohammad Modarres · Inn Seock Kim</i>	

16	Multiphase Flows: Compressible Multi-Hydrodynamics	1813
	<i>Daniel Lhuillier · Meng-Sing Liou · Theo G. Theofanous</i>	

17	Sensitivity and Uncertainty Analysis, Data Assimilation, and Predictive Best-Estimate Model Calibration	1913
	<i>Dan Gabriel Cacuci · Mihaela Ionescu-Bujor</i>	

18	Reactor Physics Experiments on Zero Power Reactors	2053
	<i>Gilles Bignan · Philippe Fougeras · Patrick Blaise · Jean-Pascal Hudelot · Frédéric Mellier</i>	

Volume 4 Reactors of Generations III and IV

19	Pressurized LWRs and HWRs in the Republic of Korea	2185
	<i>Nam Zin Cho · Han Gon Kim</i>	

20	VVER-Type Reactors of Russian Design	2249
	<i>Sergei B. Ryzhov · Victor A. Mokhov · Mikhail P. Nikitenko · George G. Bessalov · Alexander K. Podshibyakin · Dmitry A. Anufriev · Janos Gadó · Ulrich Rohde</i>	

21	Sodium Fast Reactor Design: Fuels, Neutronics, Thermal-Hydraulics, Structural Mechanics and Safety	2321
	<i>Jacques Rouault · P. Chellapandi · Baldev Raj · Philippe Dufour · Christian Latge · Laurent Paret · Pierre Lo Pinto · Gilles H. Rodriguez · Guy-Marie Gautier · Gian-Luigi Fiorini · Michel Pelletier · Dominique Gosset · Stéphane Bourganel · Gerard Mignot · Frédéric Varaine · Bernard Valentin · Patrick Masoni · Philippe Martin · Jean-Claude Queval · Daniel Broc · Nicolas Devictor</i>	

22	Gas-Cooled Reactors	2711
	<i>Bertrand Barré</i>	

23	Lead-Cooled Fast Reactor (LFR) Design: Safety, Neutronics, Thermal Hydraulics, Structural Mechanics, Fuel, Core, and Plant Design	2749
	<i>Luciano Cinotti · Craig F. Smith · Carlo Artioli · Giacomo Grasso · Giovanni Corsini</i>	
24	GEM* STAR: The Alternative Reactor Technology Comprising Graphite, Molten Salt, and Accelerators	2841
	<i>Charles D. Bowman · R. Bruce Vogelaar · Edward G. Bilpuch · Calvin R. Howell · Anton P. Tonchev · Werner Tornow · R.L. Walter</i>	
 Volume 5 Fuel Cycles, Decommissioning, Waste Disposal and Safeguards		
25	Front End of the Fuel Cycle	2895
	<i>Bertrand Barré</i>	
26	Transuranium Elements in the Nuclear Fuel Cycle	2935
	<i>Thomas Fanghänel · Jean-Paul Glatz · Rudy J.M. Konings · Vincenzo V. Rondinella · Joe Somers</i>	
27	Decommissioning of Nuclear Plants	2999
	<i>Maurizio Cumo</i>	
28	The Scientific Basis of Nuclear Waste Management	3253
	<i>Bernard Bonin</i>	
29	Proliferation Resistance and Safeguards	3421
	<i>Scott F. DeMuth</i>

Biographies of Contributors

Dmitry A. Anufriev

Dmitry A. Anufriev was born on June 28, 1946, in Krivandino, Moscow region. He graduated in 1969 as an engineer in thermal physics from the Moscow Power Engineering University. Since 1969, he has worked at OKB “GIDROPRESS” in positions of increasing responsibilities, as head of group, and deputy head of the department. His professional interests are focused on VVER-1000 reactor plant design development, elaboration of the schemes and processes of reactor plant operation, protection and control system operation algorithms, and safety analyses.

Carlo Artioli

Dr. Ing. Carlo Artioli, received his degree in nuclear engineering (*summa cum laude*) at the University of Bologna, Italy, in 1975. He joined the former CNEN (Nuclear Energy National Committee) where he worked as core designer for fast reactors. He took part in the European activities for the harmonization of nuclear codes and in the programs for Plutonium management and Minor Actinides reduction. Currently serving as researcher for the Italian National Agency for New Technologies, Energy and Sustainable Economic Development (ENEA, former CNEN) in Bologna, he has been core design leader for the ADS EFIT within the European IP EUROTRANS and core neutronic design for the ELSY reactor, as well as in charge of definition and designing of the DEMO LFR in the Italian program. Also, he is professor of Neutronic Design of the Reactor in the Postgraduate Master on Advanced Nuclear Systems in the Bologna University. He is author of several papers; mainly about new concepts related to LFR and lead coolant ADS, in international conferences.

Robert Bari

Dr. Robert Bari has over 35 years of experience in the field of nuclear energy. He is a senior physicist and a senior advisor at Brookhaven National Laboratory and has directed numerous studies of advanced nuclear energy concepts involving subjects such as nuclear energy technology performance, safety, nonproliferation, economics, and waste management. He has lectured widely on nuclear technology and has published more than 100 papers. For over 25 years, Dr. Bari has served at various levels of management at Brookhaven National Laboratory and has directed numerous programs for the US Department of Energy and the US Nuclear Regulatory Commission. Dr. Bari is currently international cochairman of the working group that has developed a comprehensive methodology for evaluation of proliferation resistance and physical protection of new nuclear energy concepts proposed within the multinational Generation IV International Forum. He has served on the Board of Directors of the American Nuclear Society, and is the past president of the International Association for Probabilistic Safety Assessment and Management. He has served as an adjunct faculty member and advisor to several major universities in the field of nuclear technology and received his doctorate in physics from Brandeis University (1970) and his bachelor's degree in physics from Rutgers University (1965).

Bertrand Barré

Bertrand Barré is the scientific advisor to the Chairperson of the AREVA group. He is also professor emeritus of nuclear engineering at the Institut National des Sciences et Techniques Nucléaires, INSTN. From 1994 to 1999, he was the head of the Nuclear Reactor Directorate of the French Atomic Energy commission, CEA, and from 1999 to 2002, he was Vice-president in charge of R&D in COGEMA (now AREVA NC).

Past President of the European Nuclear Society (ENS) and of the International Nuclear Societies Council (INSC), Past chairman of the Standing Advisory Group on Nuclear Energy of the IAEA, Bertrand Barré has just left the Chair of the International Nuclear Energy Academy (INEA). His recent publications include *Nuclear Power, understanding the future* (with P.R. Bauquis – Hirlé, 2007. *Atlas des énergies – Autrement 2007. Les 100 mots du nucléaire* – PUF 2009. His personal Web site (French/English) is www.bertrandbarre.com.

Charles G. Bathke

Dr. Charles G. Bathke is a staff member in the D-5 “International and Nuclear Systems Engineering” group at Los Alamos National Laboratory (LANL). His knowledge of the nuclear fuel cycle derives from his past work on Accelerator Transmutation of Waste (ATW) and its successor the US Advanced Fuel Cycle Initiative (AFCI), where he developed the Nuclear Fuel Cycle Simulation (NFCSim) code that is used to simulate the civilian nuclear fuel cycle from cradle (mining) to grave (waste repository). In the course of his career, he has performed systems analyses of reactors based upon various magnetic fusion confinement schemes, proton accelerators used to generate tritium, electron accelerators used for X-ray radiography, and terrorist-induced biological events. For the past three years, his research interests have gravitated to the nonproliferation arena, where he has been analyzing the material attractiveness of nuclear materials associated with reprocessing. He received his Ph.D. in Nuclear Engineering from the University of Illinois in 1976, followed by a postdoc at the Princeton Plasma Physics Laboratory. He has been at LANL since 1978.

Georgy G. Bessalov

Georgy G. Bessalov was born on September 27, 1931, in Skopin, Ryazan region. He was graduated in 1955 as a mechanical engineer from Moscow Power Engineer University. Since 1955 he held the following positions at OKB “GIDROPRESS”: engineer, head of group, and head of department. Reactor plant design development, commissioning tests at NPPs with VVER-440, and safety analyses are his professional interests.

At present, he is a leading engineer on reactor plants with VVER-440 reactors.

Gilles Bignan

Gilles Bignan earned his Ph.D. in nuclear physics and instrumentation from the Caen University of Sciences (1989) and the degree of Engineer in nuclear energy from the Institute of nuclear sciences in Caen. He started his career at CEA in the development of nuclear measurement devices for various applications (online power estimation of a power reactor, fuel monitoring for safety-criticality risk assessment, and nuclear material control for Safeguards). Since 2000, he is working in the Research Reactor field for neutron physics and Safety test and he is currently involved in the new International Material Testing Reactor Project called Jules

Horowitz Reactor as the User Facility Manager. He is an expert for the IAEA in the field of research reactors.

Edward G. Bilpuch

Edward G. Bilpuch is a Henry W. Newson professor of Physics at Duke University. He did his undergraduate studies at the University North Carolina at Chapel Hill and earned a Ph.D. degree in physics from University of North Carolina at Chapel Hill in 1956. He began his career at Duke in 1956 as a research associate, subsequently was appointed to the faculty, and was promoted to professor in 1971. He was director of the Triangle Universities Nuclear Laboratory from 1978 through 1992, and named Henry W. Nelson professor of Physics in 1987.

Professor Bilpuch perfected high-resolution techniques in nuclear physics using linear accelerators. These endeavors culminated in an experiment that set new standards for measurements of properties of atomic nuclei.

Professor Bilpuch has authored or coauthored 122 articles published in professional journals and has given many seminars in the USA and throughout the world. He has directed or codirected over 40 Ph.D. graduate students associated with the nuclear laboratory. He was a guest professor at the University of Frankfurt, Germany, 1972 and 1973, and at Fudan University of Shanghai, China, 1983 and 1985. He was the recipient of a Senior US Scientist Humboldt Award in Germany in 1983. In 1986, he was named an honorary professor at Fudan University and in 1988 he was the recipient of the Distinguished Alumnus Award from the University of North Carolina in Chapel Hill. In 1992, he was awarded an honorary doctorate by Frankfurt University in Germany.

Patrick Blaise

Patrick Blaise, Ph.D., is an industrial engineer in Nuclear Energy from Brussels, and got his Ph.D. in reactor physics from Marseille University in 1996. He was involved in designing and conducting experimental programs in the EOLE critical Facility in Cadarache from 1997 to 2007, mainly in the frame of 100% MOX LWRs, and responsible for international collaborations in experimental reactor physics. Since 2007, he is a senior expert in Reactor Physics Experimental programs. He is currently in charge of code qualification for Advanced LWRs at the section for reactor physics and cycle at Cadarache.

Robert C. Block

Dr. Robert C. Block is professor emeritus of Nuclear Engineering at Rensselaer Polytechnic Institute (RPI). During his 40-year career at RPI, he served as Director of the Gaertner LINAC Laboratory, Chairman of the Department of Nuclear Engineering and Engineering Physics, and Associate Dean of Engineering. Before joining RPI, he was a staff member at the Oak Ridge National Laboratory. He has had sabbaticals at the AERE Laboratory at Harwell, UK; the Kyoto University Research Reactor Laboratory in Kumatori, Japan; and the Sandia National Laboratory. He is currently employed by the Knolls Atomic Power Laboratory and is a consultant to national laboratories and industry.

Dr. Block has served on numerous advisory committees and has almost 300 publications in journals and conference proceedings to his credit. He was awarded the ANS Seaborg Medal in

2005 from the American Nuclear Society, the Glenn Murphy Award in 1991 from the American Society for Engineering Education, and the William H. Wiley Distinguished Faculty Award in 1995 from RPI.

Bernard Bonin

Dr. Bernard Bonin has a background in fundamental research in high energy physics and materials physics. Between 1996 and 2000, he was head of a Service of Research and Studies on Nuclear Waste, within CEA's Institute for Nuclear Protection and Safety. His studies then aimed at obtaining an overall view of the scientific basis for nuclear waste management, with special interest in the migration of radioactive contaminants in the underground environment. In 2000, he was appointed assistant to the Director of Research and Development in COGEMA, in charge of the organization of the R&D on the front end of the nuclear fuel cycle, and on future nuclear energy systems. He received the Areva Innovation Award in 2002 for the development of a radon detection system. Since 2003, he is Deputy Scientific Director in the Nuclear Energy Division of the Commissariat à l'Énergie Atomique and professor at the French Institute for Nuclear Sciences and Techniques.

Stéphane Bourganel

An engineer and researcher at CEA/Saclay, Stéphane Bourganel earned a Ph.D. from the INPG School in Grenoble, France and contributes to R&D in the field of the PWR lifetime. He is involved in design and analysis of experiments dedicated to decay heat issues. He worked on the first fluence calculations for the fourth reactor generation lifetime. Furthermore, he takes part, as a teacher, in training course on the Monte Carlo computer code TRIPOLI-4.

Charles Daniel Bowman

Dr. Charles Daniel Bowman was awarded a Ph.D. from Duke University in 1961 in neutron physics. He led the development of world-class accelerator-based neutron sources and their application to basic and applied science at Lawrence Livermore National Laboratory, the National Institute of Science and Technology, and the Los Alamos National Laboratory. In 1970, he became a Fellow of the American Physical Society; in 1982, he was awarded the U S Department of Commerce Silver Medal; and in 1993, he was honored as a Fellow of the Los Alamos National Laboratory.

In 1993, Dr. Bowman became Project leader for the Los Alamos Accelerator-Driven Transmutation Technology (ADTT) program. When the US-funded International Science and Technology Center (ISTC) was formed in Moscow in 1993, Dr. Bowman also led Project 17 of the ISTC, which employed about 500 Russian scientists on the ADTT concept. In 1997, he organized ADNA Corporation (Accelerator-Driven Neutron Applications) to pursue the application of accelerator sources of neutrons in nuclear energy culminating in GEM*STAR.

Christophe Calvin

Christophe Calvin is leading a laboratory in the Nuclear Energy Division of the French Atomic Commission (CEA) in charge of the development of reactor physics simulation codes. He

received a Ph.D. in applied mathematics and parallel computing and worked, at CEA Grenoble, in a CFD code development team in charge of the code parallelization. He has also led the development of a new generation of reactor physics simulation code at CEA Saclay. He currently has an expert position in HPC at CEA Nuclear Energy Division, participating to international collaboration with European research institutes and with Japan academic laboratories and institutes in reactor physics simulation and high-performance computing. He has published more than 10 papers in international conferences or journals on scientific code architecture, parallel algorithms, and scientific code parallelization.

P. Chellapandi

An outstanding scientist of repute, P. Chellapandi is the director of Safety Group and associate director of Nuclear Engineering Group. He joined the Indira Gandhi Centre for Atomic Research, Kalpakkam, (IGCAR) in 1979. Since then, he has been working on the design and development of 500 MWe prototype fast breeder reactor (PFBR), over a wide spectrum of design, namely, conceptualization, development of sophisticated computer codes, detailed analysis, design validation, preparation of preliminary safety analysis reports, execution of R&D activities involving national academic institutions, and R&D establishments in the country. He is also the convener of a task force, which is coordinating for the manufacture and erection of reactor assembly components. He earned his B.E. (Hons.) in Mechanical Engineering from Madras University in 1978 securing the first rank, and M.Tech. in Engineering Mechanics (Gold Medalist with CGPA 10), and Ph.D. in Applied Mechanics from IIT Madras. He is a professor at the Homi Bhabha National Institute, and adjunct professor of PSG college, Coimbatore, and Sathyabama University, Chennai. He has guided more than 50 postgraduate students and published about 460 papers in journals, national and international conferences. He is a Fellow of Indian National Academy of Engineering.

Nam Zin Cho

Prof. Nam Zin Cho received his B.S. in nuclear engineering from Seoul National University and Ph.D. in nuclear engineering from University of California at Berkeley. He worked at Science Applications, Inc. in Palo Alto from 1980 to 1982, and at Brookhaven National Laboratory in Long Island from 1983 to 1987. In 1987, he joined the faculty at Korea Advanced Institute of Science and Technology (KAIST) in Korea, where he is mostly involved in teaching and research in reactor physics and neutron transport computation.

He is Fellow of American Nuclear Society and Associate Editor of Nuclear Science and Engineering. He was the Technical Program Chair for the PHYSOR 2002, a series of the ANS topical meetings on reactor physics, held in Seoul, Korea. From 2003 to 2006, he served as Commissioner of the Atomic Energy Commission of the Republic of Korea. From 2007 to 2008, he was President of Korean Nuclear Society.

Luciano Cinotti

Luciano Cinotti has been student at the Scuola Superiore degli Studi Universitari e Perfezionamento S. Anna, the renowned School linked to the University of Pisa, Italy, where he received his Dr. Ing. degree in 1975. He has served 5 years in France in the French-Italian Ansaldo-Novatome

team in charge of the development of the large sodium-cooled fast reactors. After returning to Italy, he has led the Ansaldo Nucleare activities for the improved European fast reactor (EFR) and the innovative reactors PIUS and PRISM, while conceiving ISIS, a full-passive reactor for the combined generation of electricity and heat. He has been responsible of the department of Nuclear Technology of Ansaldo Nuclear Division till 2006 and has been the coordinator of the ELSY STREP in the proposal preparation phase. He is currently involved in the development and promotion of the LFR and Euratom Representative and is the chairman in the GIF LFR Provisional Steering Committee. He is author of several papers on new reactors published in learned journals.

Giovanni Corsini

Giovanni Corsini received his degree of Dott. Ing. in chemical engineering in 1970 at the University of Pisa. After 10 years as a chemical project engineer in Foster Wheeler Italy, he joined Ansaldo in 1981, where he has gained experience in the field of pressurized heavy water reactors and in the field of fast reactors (SPX1 and particularly EFR, where he has been coleader of the decay heat removal subsystem). Subsequently, he has participated in the ECC-funded TACIS project for the safety improvement of the Russian VVER 430-type Novovoronezh and Kola power plants.

He worked in the Ansaldo team for the design of the experimental accelerator-driven system (XADS), in particular for issues relevant to corrosion protection in LBE. While continuing the participation in the ADS field, and in the European ELSY project, since 2002 he also worked as project engineer of the Intermediate Cooling Loop of Heat Removal System and the Cover Gas System of Megapie. At the end 2008, he left Ansaldo Nucleare but continues to work as an independent professional in the field of lead technology.

Dermott E. Cullen

Dermott E. Cullen earned his Ph.D. in nuclear engineering from Columbia University, New York City, in 1967. From 1967 through 1972, he worked at Brookhaven National Laboratory, Long Island, New York as a nuclear physicist. From 1972 through 1979, he worked at Lawrence Livermore National Laboratory, Livermore, California. From 1979 through 1987, he worked at the Nuclear Data Section, International Atomic Energy Agency, Vienna, Austria. From 1987 through 2009, he worked at Lawrence Livermore National Laboratory, Livermore, California. He is now retired and lives in Livermore, California. He has more than 40 years of experience with nuclear and atomic data, involving its preparation and use in particle transport calculations. He is the author of over 200 papers on this subject, as can be seen in his online resume located at <http://home.comcast.net/~redcullen1/RESUME.pdf>

Maurizio Luigi Cumo

Full professor of nuclear plants in the University of Rome Sapienza since 1976, Maurizio Luigi Cumo was engaged in experimental and theoretical research in the field of thermofluidynamics of nuclear plants systems and components in the ENEA Research Centre, Casaccia. He has published 10 books and over 200 scientific publications. Furthermore, he was engaged in nuclear safety researches as president of the Italian SOGIN Company for Nuclear Installations Decommissioning and chairman of the International Scientific Council of the Nuclear Energy Directorate of the French Commissariat à l'Énergie Atomique. He is a member of the Italian

Academy of Sciences, said of the forty, and of the European Academy of Sciences and Arts, leading as president the Italian Society for the Advancement of Sciences.

Yaron Danon

Dr. Yaron Danon is a professor in the department of Mechanical Aerospace and Nuclear Engineering at Rensselaer Polytechnic Institute (RPI) in Troy, New York. He is also the director of the Gaerttner Electron Linear Accelerator (LINAC) Laboratory at RPI. Dr. Danon is a member of the US Cross Section Evaluation Working Group and chairman of the Measurements Committee. He is also a member of the Nuclear Data Advisory Group (NDAG), which advises the US Nuclear Criticality Safety Program (NCSF) on issues relating to nuclear data. Dr. Danon has over 120 publications in archived journals and conference proceedings.

Christophe Demazière

Christophe Demazière (Ph.D. in reactor physics, Chalmers University of Technology, Sweden, 2002; Engineering degree, Hautes Etudes d'Ingénieur, France, 1996) is an associate professor in the department of Nuclear Engineering, Chalmers University of Technology, Gothenburg, Sweden, lecturing in nuclear reactor physics (reactor physics and nuclear thermal-hydraulics) and nuclear reactor modeling (deterministic methods). He is a member of the American Nuclear Society (Reactor Physics Division, Mathematics and Computation Division, Thermal Hydraulics Division, Education and Training Division) and of the Swedish Nuclear Society.

His research interests include pressurized water reactor and boiling water reactor physics, reactor dynamics applied to both critical and subcritical systems, power reactor noise and noise diagnostics, signal processing and data analysis (linear, nonlinear, wavelet, and fractal analysis), nuclear reactor modeling and calculations, (including coupled neutronics/thermal-hydraulics), and computational methods applied to nuclear reactor modeling.

Scott DeMuth

Dr. Scott DeMuth has a Ph.D. in chemical engineering and has been a staff member at Los Alamos National Laboratory for the past 20 years. Prior to Los Alamos, he was a research engineer at Oak Ridge National Laboratory for 10 years. His specialty is nuclear materials processing and safeguards. He has worked for research and development in all areas of the nuclear fuel cycle, including uranium enrichment, fuel fabrication, thermal and fast reactors, fuel reprocessing, and waste management. Currently he is on assignment in Washington, DC working for the US Department of Energy's Office of International Regimes and Agreements (NA-243).

Nicolas Devictor

After receiving a Ph.D. in applied mathematics, Nicolas Devictor worked from 1997 to 2007 on structural reliability, probabilistic safety assessment, and risk management. He is one of the editors of *Uncertainty in Industrial Practice – A Guide to Quantitative Uncertainty Management*, published by Wiley in 2008. He was in charge of the coordination of the project "Safety and Reliability of the facility," a transversal project in support of the sodium fast reactor and gas-cooled fast reactor, and served as the CEA-representative in the Working Group RISK of OECD/NEA. From 2007 to 2009, Nicolas Devictor was head of the laboratory in charge of the preconceptual

design of sodium fast-cooled reactors, and related safety analysis. Since 2010, Nicolas Devictor has been project manager for the R&D led by CEA team in support to SFR and Astrid project.

Philippe Dufour

After graduating from “Ecole Centrale de Paris,” Dufour joined CEA (Commissariat à l’Energie Atomique) in 1974. The beginning of his career was devoted to thermal-hydraulical studies for the Superphenix fast reactor. Subsequently, he was involved in other fields such as, neutronics, safety, development of computer codes, economy, and optimization, for various reactor types. From 1998 to 2007, Philippe Dufour was head of the laboratory in charge of the preconceptual design of sodium fast-cooled reactors, and related safety analysis. He is currently project advisor at the Department for Reactor Studies at Cadarache (DEN/DER/SESI).

Mike Ehinger

Mike Ehinger has worked in the areas of safeguards and nuclear nonproliferation for 40 years. He is currently at Oak Ridge National Laboratory as a senior program development manager working principally in the area of International Safeguards. From 1999 to 2006, he worked at the International Atomic Energy Agency (IAEA) in Vienna on the development, installation, and implementation of equipment and procedures for IAEA inspections at the Rokkasho Reprocessing Plant in Japan. Prior to going to Vienna, he was manager of safeguards programs at Oak Ridge. While at Oak Ridge, the Russian Material, Protection, Control and Accounting (MPC&A) program was among his responsibilities and he actively participated in the tasks related to the Russian fuel reprocessing sites Mayak and Tomsk. He was also involved with the US and Russian HEU down-blend program serving as a monitor at enrichment facilities. He has broad international experience having participated in activities at many reprocessing facilities throughout the world including England, France, and India. Prior to joining Oak Ridge in 1983, he was a senior nuclear material control engineer at the Barnwell Reprocessing Plant where he installed the Nuclear Material Accountancy system and demonstrated its capabilities to US and international regulatory, development, and operating organizations. From 1968 to 1974, he was the accountability supervisor during the operating years of the West Valley Reprocessing Plant. During this period, he hosted the very first IAEA inspection at a reprocessing facility.

Thomas Fanghänel

Prof. Dr. Thomas Fanghänel currently serves as the director of the Institute for Transuranium Elements (ITU), which is one of the seven institutes of the European Commission’s Joint Research Centre located in Karlsruhe, Germany. It is ITU’s mission to provide the scientific foundation for the protection of the European citizen against risks associated with the handling and storage of highly radioactive elements. Research is focused on (1) basic actinide science and applications, (2) safety of conventional and advanced nuclear fuel cycle including spent fuel disposal, and (3) safeguards and nuclear forensics.

Since 2002, he is professor of Radiochemistry at the Ruprecht-Karls-University Heidelberg. Prof. Fanghänel has degrees in Chemistry (Diplomchemiker), a Ph.D. and Habilitation in Inorganic and Physical Chemistry from the Technical University Bergakademie Freiberg. Before he was appointed as the director of ITU, he had been director of the Institute for Nuclear Waste

Disposal (INE) of the former Forschungszentrum Karlsruhe (now Karlsruhe Institute of Technology, KIT), director of the Institute of Radiochemistry, Forschungszentrum Rossendorf, and professor of Radiochemistry at the University of Dresden. He has more than 25 years of research experience with special expertise in Actinide chemistry and long-term safety of nuclear waste disposal. Since 2003, he is a member of the Reactor Safety Commission of the German Federal Ministry for the Environment, Nature Conservation, and Nuclear Safety.

Richard E. Faw

Richard E. Faw, born in rural Ohio, was educated at the University of Cincinnati (B.S., Chemical Engineering, 1959) and at the University of Minnesota (Ph.D., Chemical Engineering, 1962). In 1962, he joined the nuclear engineering faculty at Kansas State University, where he served until 2000. Appointments at the university include department head, 1972–1977, director of the Radiation Shielding Laboratory, 1968–1980, and director of the Nuclear Reactor Laboratory, 1976–1996. He is licensed by the Nuclear Regulatory Commission as a senior reactor operator and by Kansas and Ohio as a professional engineer. He is a Fellow of the American Nuclear Society and recipient of university awards for teaching and research. Dr. Faw is author or coauthor of four textbooks on radiation shielding and radiological assessment. Two of these books are in second editions.

Temporary assignments include service in the US Army Combat Developments Command from 1963 to 1965, and research appointments at Argonne National Laboratory (1975), UKAEA Culham Laboratory (1977–1983), and Oak Ridge National Laboratory (1990). Research and teaching interests include radiation shielding and dosimetry, boiling heat transfer, and nuclear reactor accident analysis. Dr. Faw was employed part time with Black & Veatch in ABWR plant design from 1998 to 2004 and with GE-Hitachi in ESBWR safety analysis from 2006 to 2009. Dr. Faw now makes his home in Winston-Salem, North Carolina.

Gian Luigi Fiorini

Gian Luigi Fiorini graduated in nuclear engineering (Pisa, Italy 1975) and joined the CEA in 1979. His professional experience spans 30 years of activities related to the definition, the realization, and the management of experimental and theoretical activities concerning the operation and the safety of fission reactors. Since the beginning, until the 1980s he worked essentially on the sodium LMFBR. Since 15 years, he has been engaged within the innovation program at CEA addressing all the nuclear technologies, including ADS and ITER. He is a former member of the Gen IV Roadmap Integration Team, and currently serves as a “Chargé de Mission Generation IV” at the CEA Department for Reactor Studies (DEN/DER/SESI). Strongly involved within the Gen IV Initiative implementation, he was member of the “Gen IV Sodium Fast Reactor (SFR) Steering committee,” cochairman of the SFR Design & Safety Management board and of the Gen IV Expert Group. He is currently cochairman of the “Gen IV Risk & Safety Working Group,” and member of the French Advisory Group on Safety (GCFS – AREVA, CEA, EDF).

Philippe Fougeras

Philippe Fougeras received his Ph.D. in reactor physics from the Orsay Faculty of Science in 1992. He started his career at CEA as physicist in the code validation team for Pu recycling in light water reactors (LWRs). He was in charge of the EOLE Critical Facility from 1996 to 2000,

covering the MISTRAL program, and was head of the Experimental Programs Laboratory of the CEA Cadarache from 2000 to 2007, supervising programs on EOLE, MINERVE, and MASURCA facilities, also involved in international collaborations and development of new experimental techniques. He is currently deputy head of the section for reactor physics and fuel cycles at Cadarache.

János Gadó

Dr. János Gadó is director of the KFKI Atomic Energy Research Institute, Budapest, since 1990. The institute belongs to the Hungarian Academy of Sciences. Dr. Gadó graduated at the Roland Eötvös University, Budapest, as a physicist (1969). He started to work in the field of reactor physics, and later he moved to the area of nuclear safety. He was project manager of various projects related to the safety of the Paks NPP, and represents Hungary on several international committees and projects. Dr. Gadó became Doctor of the Academy in 1999. He was awarded various medals and prizes.

Guy-Marie Gautier

Guy-Marie Gautier graduated in 1977 from “Ecole Nationale Supérieure d’Electricité et de Mécanique de Nancy,” and has over 25 years experience on the management of experimental facilities and the definition of operating points for sodium fast reactor (SFR) and pressurized water reactor (PWR). Since 1994, Mr. Gautier has been involved in the definition of the French Atomic Commission (CEA) Innovative Program. He was the coordinator of the innovative activities of the safeguard systems of PWRs, and he was in charge of the definition of the design options of innovative concepts, especially of PWR and now for SFR, including economic assessment studies.

Jean-Paul Glatz

Jean-Paul Glatz received his Ph.D. in analytical and radiochemistry, and has been working since 1981 at the European Commission’s Joint Research Center (JRC) Institute for Transuranium Elements (ITU), in Karlsruhe, in various research fields. From 1998 to 2008, he was head of the “Hot Cells” department at ITU responsible for all postirradiation examination work on irradiated fuel and other highly active materials, related to the safety of nuclear fuel, spent fuel characterization in view of storage and partitioning and transmutation (P&T). Since 2007, he has been head of the “Nuclear Chemistry” department, responsible for projects on chemical characterization of irradiated fuel and other highly radioactive materials. The corresponding projects include reprocessing studies, the behavior of spent nuclear fuel under repository conditions, and the behavior of radionuclides in the environment and the use of short-lived alpha-nuclides for cancer therapy.

Dominique Gosset

After receiving a Ph.D. in 1985 in the Yves Quéré’s Irradiated Solids Laboratory, Dominique Gosset joined the Absorber Materials Laboratory in CEA. This laboratory was in charge of fundamental and project studies on the absorber materials to be used in PWR (Ag–In–Cd alloy, hafnium compounds) and mainly in FBRs (boron carbide, moderators) and was a support unit for development laboratories in CEA, including international collaborations (Russia, Japan,

and the USA). D. Gosset was especially involved in structural and microstructural analysis of the materials (microscopy, X-ray diffraction), development of new materials and concepts and postirradiation examinations. In the 1990s, his main interests shifted toward fundamental analysis of the behavior of nuclear ceramics under irradiation, focused on microstructure evolutions (e.g., phase transformation in Zirconia and in spinels), through a close collaboration with a CNRS-Ecole Centrale Paris laboratory. More recently, part of his fields of interest come back to the carbides (ZrC, SiC), as potential materials for Gen-IV reactors. He authored or coauthored over 50 referred papers and patents.

Giacomo Grasso

Giacomo Grasso received his MS degree in nuclear engineering (*summa cum laude*) from the University of Bologna, Italy, in 2006. Subsequently, he received his Ph.D. in nuclear reactor physics at the Nuclear Engineering Laboratory (LIN) of Montecuccolino, Department of Energy and Nuclear Engineering and of Environmental Control (DIENCA), University of Bologna, in 2010. He currently serves as researcher in the Italian National Agency for New Technologies, Energy, and Sustainable Economic Development (ENEA) in Bologna, Italy. He worked on the modeling of neutron transport in nuclear reactors, Generation IV nuclear reactor design, computational methods for particle transport, plasma physics and complex system dynamics, and nuclear fuel cycle scenarios. He participated in the ELSY project as a neutronics core designer, and also participated in several European projects for fuel cycle scenario studies. He has authored 20 technical papers and articles in international conferences and journals.

Frank Gunsing

Dr. Frank Gunsing is a research team leader in the Nuclear Data Measurements Group of the Nuclear Physics Division (Irfu/SPhN) at the “Commissariat à l’Energie Atomique et aux Energies Alternatives” (CEA) in Saclay, France. Following his Ph.D. degree in nuclear physics from Delft University in the Netherlands in 1995, he worked at the IRMM in Belgium and joined the French CEA in 1996. He obtained the Habilitation to Direct Research from the University of Paris VII in 2005. He is interested in nuclear data and measurement techniques for applications in nuclear technology, astrophysics, and nuclear structure. He is involved in experimental work among others at the IRMM in Geel and at the n_TOF facility at CERN. He is active in European Framework research programs and serves on several scientific advisory committees.

Robert C. Haight

Dr. Robert C. Haight is a research team leader in the Neutron and Nuclear Science Group of the Los Alamos Neutron Science Center (LANSCE). Following his Ph.D. degree in nuclear physics from Princeton University, he entered experimental neutron physics 40 years ago and has held various positions at Los Alamos and at the Lawrence Livermore National Laboratory. He has used neutron sources based on cyclotrons, Van de Graaff accelerators, intense 14-MeV neutron generators with rotating tritium targets, and the spallation neutron sources at LANSCE. He has concentrated on charged-particle production in neutron-induced reactions, fission neutron spectra, and the physics of polarized neutrons. He is interested in applications of nuclear techniques and nuclear data to defense, medicine, space, and fission and fusion energy. He is a Fellow of the American Physical Society.

Alain Hébert

Alain Hébert has been a professor of the Institut de Génie Nucléaire at École Polytechnique de Montréal since 1981. From 1995 to 2001, he worked at the Commissariat à l'Énergie Atomique, located in Saclay, France. During this period, he led the development team of the APOLLO2 lattice code, an important component of the Science™ and Arcadia™ packages at Areva. Back in Montréal, he participated in the development of the DRAGON lattice and TRIVAC reactor codes, both available as *Open Source* software.

Alain Hébert is the author of *Applied Reactor Physics* (2009), a reference textbook in the domain. He is also a contributing author in more than 43 full papers and 67 conference papers, published between 1981 and now.

Magnus Hedberg

Magnus Hedberg is a project manager for one of the European Commissions Safeguards actions; “Nuclear and Trace analysis for Safeguards Purposes (NTAS).” His special interest is in particle analysis for nuclear Safeguards purposes. Hedberg was previously, for a period of 7 years, the unit head for a mass spectrometry group at the International Atomic Energy Agency laboratories in Austria. Hedberg is originally from Sweden where he earned a M.Sc. degree in electrical engineering at the technical faculty of Lund University in 1987.

Michal Herman

Michal Herman earned his M.S. in nuclear physics from the University of Warsaw, Warsaw in 1973, Ph.D. in nuclear physics from the Institute of Nuclear Research in Warsaw, Warsaw in 1980. His scientific carrier is dedicated to low-energy nuclear reactions, and is best known for contributions to multistep compound reaction theory. He is the main developer of the nuclear reaction model code EMPIRE widely used as nuclear reaction data evaluation tool.

He worked as a research scientist in the Institute of Nuclear Physics Research, Warsaw in 1973–1984, research scientist in ENEA, Bologna in 1985–1996; nuclear data physicist in the Nuclear Data Section, IAEA Vienna in 1997–2002; in 2003, he joined the National Nuclear Data Center at BNL. In January 2010, he took over US nuclear data leadership as the head of the National Nuclear Data Center and chair of the Cross Section Evaluation Working Group.

Calvin R. Howell

Calvin R. Howell received his B.S. degree from Davidson College in 1978 and obtained his Ph.D. degree from Duke University in 1984. He is a professor of physics at Duke University and the director of the Triangle Universities Nuclear Laboratory. He holds adjunct professorships in the Medical Physics Program at Duke University and in the physics department at North Carolina Central University. He is a Fellow of the American Physical Society (APS). His research includes the study of fundamental properties of nuclear systems, plant physiology using radioisotopes, and applications of nuclear physics in the areas of national security, nuclear energy, and medicine. He has coauthored more than 110 articles in scientific journals and has held visiting scientist positions at Los Alamos National Laboratory, the Stanford Linear Accelerator Center, and Jefferson Laboratory. Since joining the faculty at Duke University in 1985, he has served as faculty coordinator for the Carolina Ohio Science Education Network, as the faculty coordinator for the Mellon Minority Undergraduate Fellowship Program, and as the academic coordinator for the Summer Medical and Dental Education Program at the Duke

University Medical Center. Professor Howell has served the physics community extensively as a Nuclear Physics Program Director at the National Science Foundation (NSF), as a member of the Department of Energy (DOE)/NSF Nuclear Science Advisory Committee, as a member of the Executive Committee of the Division of Nuclear Physics of the APS, as chair of the Executive Committee of the Southeastern Section of the APS, as chair of the APS Committee on Minorities, and as a member of numerous NSF and DOE review and planning panels.

John Howell

Dr. John Howell has been with the Faculty of Engineering, University of Glasgow in the UK since 1984. Prior to this position, he was with the Control and Instrumentation Division of the United Kingdom Atomic Energy Authority. He started his career as a control and dynamics engineer with responsibilities for the assessment, design, and development of control and measurement systems for the UK's prototype fast reactor and associated reprocessing plant, which were located at Dounreay. Dynamic modeling was a core component of these activities. His research focus over the past 20 years has been on the evaluation of monitoring data collected from process plants, in general. The emphasis has been on isolation and diagnosis. Although his roots are very much in model-based reasoning, he has also researched into approaches including ICA, rule-based reasoning, and signed-graph analysis. He has contributed to the development of a number of solution monitoring systems for the IAEA.

Jean-Pascal Hudelot

Jean-Pascal Hudelot received his Ph.D. in reactor physics from the Grenoble Faculty of Science (1998). He started his career at CEA as a physicist in the development of innovative neutron and gamma measurement techniques on experimental facilities. He was in charge of the MINERVE Facility from 1998 to 2006, covering the OSMOSE, HTC, VALMONT, and OCEAN programs, and was also involved in international collaborations. He is now head of the Nuclear Project Laboratory at CEA Cadarache, supervising the development, validation and qualification of neutronics, and photonics calculation tools for experimental and irradiation reactors, including JHR, OSIRIS, CABRI.

Mihaela Ionescu-Bujor

Mihaela Ionescu-Bujor received her Dr.-Ing. degree from the Institute for Nuclear Technology and Reactor Safety, Faculty of Mechanical Engineering, University of Karlsruhe, Germany, in 2000, with the grade of "Excellent with Distinction." For 5 years prior to her doctoral degree, she was a staff researcher at Siemens AG, KWU, Erlangen, working in the reactor physics and thermal-hydraulics section. During 2000–2003, she served as group leader for sensitivity and uncertainty analysis in the Institute for Reactor Safety at Forschungszentrum Karlsruhe (FZK), performing original research on and supervising the implementation of the adjoint sensitivity analysis procedure (ASAP) into various large-scale multi-physics computational code systems. Typical systems included the development of the coupled two-fluid and heat structure adjoint models for the reactor safety code system RELAP5/MOD3.2, and sensitivity and uncertainty analysis of dynamic reliability of large-scale systems modeled by Markov chains. During 2003–2006, she served as a task force leader in the FUSION Program at FZK, providing management and scientific leadership for the design and construction of the Helium Loop Karlsruhe (HELOKA) facility at FZK. Since 2006, Dr. Ionescu-Bujor has been program manager at

the Karlsruhe Institute of Technology/Forschungszentrum Karlsruhe (KIT/FZK), responsible for planning KIT/FZK fusion projects, including scheduling, resource allocation, cost control, budget management, and quality management.

Dr. Ionescu-Bujor has extensive expertise in sensitivity and uncertainty analysis of large-scale systems; consistent assimilation of experimental and computational data for obtaining best estimate results with reduced uncertainties, reliability analysis, numerical methods for multi-physics (thermal-hydraulics, structural, neutronics) code systems, and computer software. Dr. Ionescu-Bujor has coauthored 2 books, 2 book chapters, and over 40 peer-reviewed articles.

Frédéric Jasserand

Frédéric Jasserand is an engineer at CEA in the radioprotection field, performing shielding studies, including dosimetry studies for fabrication and recycling facilities, and the conception of transport casks.

Han Gon Kim

Dr. Han Gon Kim received his B.S. in nuclear engineering from Seoul National University and Ph.D. in nuclear engineering from Korea Advanced Institute of Science and Technology (KAIST). In 1997, he became a member of Korea Hydro & Nuclear Power Co., Ltd. (KHNP) as a senior researcher, where he is actively involved in research and development in nuclear reactor thermal hydraulics. From 2005 until now, he is a team leader being responsible for design of nuclear steam supply system (NSSS) of advanced nuclear power plants. He is a member of Korea Nuclear Society.

Inn Seock Kim

Inn Seock Kim received his Ph.D. from the University of Maryland in the area of process diagnostics for large technological systems such as nuclear power plants, and his work in this area has been acknowledged by many organizations, including the Halden Reactor Project of the OECD and the Korea Atomic Energy Research Institute. Dr. Kim served on the scientific staff of Brookhaven National Laboratory from 1988 through 1995, and also used to teach many courses related to reliability engineering and probabilistic analysis of systems safety while serving on the Nuclear Engineering faculty of Hanyang University in Seoul, Republic of Korea.

Inn Seock Kim is particularly interested in helping secure safety in both operating and future nuclear power plants. He has been involved in research activities for enhancing decision-making infrastructure, licensing framework, and regulatory effectiveness by use of both deterministic and risk-informed methodologies. He has consulted to numerous organizations throughout the world, such as the US Nuclear Regulatory Commission, Swiss nuclear regulatory body, Spanish nuclear regulator, European Space Agency, and Korean nuclear institutions including Korea Institute of Nuclear Safety. He recently founded International System Safety Analysis (ISSA) Technology, Inc., in Maryland, which specializes in probabilistic safety assessment and applications, accident management, instrumentation and controls, and human factors analysis.

Dave Knott

Dave Knott received his Ph.D. in nuclear engineering, from the Pennsylvania State University in 1991, for development of the lattice physics code KRAM to model the detailed depletion

of Gadolinium isotopes from boiling water reactor (BWR) fuel designs. He has also received a Master of Computer Science from Cleveland State University in 2002. His career includes employment at the Perry Nuclear Power Plant (1985–1987, in-core analysis); Studsvik of America, Inc. (1991–1998, development of the lattice physics code CASMO-4); First Energy Nuclear Operating Company (1998–2004, creation of the core design and physics support group at the Perry Nuclear Power Plant); Global Nuclear Fuels (General Electric, 2004–2007, development of the lattice physics code LANCER02); Studsvik Scandpower, Inc., (2007–Present, development of the safety-related software MARLA for optimizing fuel movement during refueling outages and during dry storage cask loading campaigns). In his current position as a senior nuclear engineer at Studsvik Scandpower, Inc., in Wilmington, North Carolina, he has focused on developing software for improving capacity factors at boiling water reactors (BWRs) and pressurized water reactors (PWRs). He has served as a research adjunct associate professor of nuclear engineering, University of Cincinnati, 2003–2007. He has also served as a visiting scholar in nuclear engineering, Ohio State University, 2004, and an external advisor, Ph.D. thesis committee, Pennsylvania State University, 2006.

Rudy J. M. Konings

Rudy J. M. Konings received his Ph.D. in chemistry from the University of Amsterdam in 1990, working since 1985 for ECN, the Energy Research Centre of the Netherlands, on various topics related to nuclear fuel, such as fission product chemistry and transmutation. In 1998, he became the manager of the product group Fuels, Actinides and Isotopes at the Nuclear Research and consultancy Group (NRG), a partnership firm created by the merger nuclear activities of ECN and KEMA. A year later, he left NRG for a position at the European Commission's Joint Research Centre (JRC), Institute for Transuranium Elements (ITU). There he continued working on nuclear fuels, with a strong interest in thermodynamic studies. Since 2006, he is head of the Materials Research department of ITU, focusing on scientific research in support of the development of safe advanced fuel. Rudy Konings was appointed editor of *Journal of Nuclear Materials* in 2009.

Edward W. Larsen

Edward W. Larsen is a professor in the department of Nuclear Engineering and Radiological Sciences at the University of Michigan. In 1971, he obtained a Ph.D. in Mathematics from Rensselaer Polytechnic Institute and joined the faculty of the Department of Mathematics at New York University. In 1976, he became an associate professor in the Department of Mathematics at the University of Delaware. In 1977, he joined the Transport Theory Group at Los Alamos National Laboratory, and in 1986, he became a professor in the Department of Nuclear Engineering and Radiological Sciences at the University of Michigan.

Professor Larsen's research involves the development of advanced mathematical algorithms for solving particle transport problems. His work has included neutron transport methods for nuclear reactor applications, thermal radiation transport methods, and charged particle transport methods for medical physics applications. His research has helped extend the theory and simulation of neutral and charged particle transport processes through, for example, the development of improved discretization methods for deterministic transport calculations, improved acceleration methods for speeding up the iterative convergence of deterministic calculations, and new hybrid Monte Carlo-deterministic algorithms.

Professor Larsen is a Fellow of the American Nuclear Society (ANS). For his contributions to nuclear engineering, he received the US Department of Energy E.O. Lawrence Award (1994), the ANS Arthur Holly Compton Award (1996), and the ANS Eugene P. Wigner Reactor Physicist Award (2009).

Christian Latge

Christian Latge received his doctorate in chemical engineering, and engaged in R&D related to sodium fast reactor technology and SuperPhenix start-up at CEA, in 1983. During the period 1988–1995, he was involved in the thermonuclear project ITER for the design of tritium systems. From 1990 to 1996, he was head of Laboratory “Process Studies and consultancy” for nuclear reactor technologies. During 1996–2001, he served as the director of the Sodium School, while during 2000–2003, he was head of service for Process studies for Decontamination and Nuclear Waste Conditioning. Since 2003, he has been a research director at CEA, serving also as project director (2003–2012) of the International Project Megapie (Spallation target for waste transmutation). In addition, he currently serves as professor and International Expert in liquid metal technologies, involved in various European projects, including education and training.

Clément Lemaignan

Clément Lemaignan is a research director at CEA and professor at INSTN on nuclear metallurgy, physics of fracture and material science. Prof. Lemaignan holds 4 patents, and has authored 3 books, 6 review book chapters, and over 80 peer-reviewed articles. He has been editor for the Journal of Nuclear Materials for more than 15 years. He is an officer of the Palmes Académiques and has received many other distinctions.

Daniel Lhuillier

Daniel Lhuillier is a senior researcher with the French National Center for Scientific Research (CNRS). After graduating from the Ecole Normale Supérieure, he obtained a Ph.D. in physics from the University Pierre and Marie Curie (Paris, France). He began his research work at the Laboratory of Aerodynamics (Orsay, France), then moved to the Laboratory for Modeling in Mechanics and is presently a member of the Institute Jean le Rond d'Alembert (IJLRA) of the University Pierre and Marie Curie. Dr Lhuillier is a specialist of thermo-mechanics of continuous media, with applications to superfluid helium, polymer solutions, suspensions of particles, two-phase mixtures, and granular materials. He received the bronze medal of CNRS and the E.A. Brun prize of the French Academy of Sciences.

Meng-Sing Liou

Meng-Sing Liou is a senior technologist of NASA Glenn Research Center. He received B.S. in mechanical engineering from National Cheng Kung University, Taiwan and Ph.D. in aerospace engineering from the University of Michigan. His research interest has been centered about computational fluid dynamics, including development of numerical algorithms and applications to topical areas of high-speed aerodynamics, air-breathing propulsion, and multiphase flows. Multidisciplinary design optimization for aeronautical systems is another interest currently. Dr. Liou has received several major NASA awards, including Abe Silverstein Medal (2006), Exceptional Achievement Medal (2004), and Exceptional Scientific Achievement Medal (1992).

Pierre Lo Pinto

Pierre Lo Pinto is a senior engineer with over 25 years experience in the area of nuclear safety and fast neutron reactor system. He worked on analyzing fast sodium reactors (Phenix, Superphenix, etc.), and coordinated international collaborations (Japan, Russia, etc.) on several innovative design or safety studies in particular in the fields of SFR (e.g., ECRA, CAPRA). More recently, he has been in charge of designing innovative SFR concepts at CEA, and safety-related topics, and is involved as a CEA representative in the SMFR (small modular fast reactor) project involving ANL, CEA, and JAEA.

Klaus Lützenkirchen

Since 2002, Dr. Klaus Lützenkirchen has been head of the Nuclear Safeguards and Security Department of the European Commission's Joint Research Centre Institute for Transuranium Elements in Karlsruhe, Germany. His activities are focused on nuclear forensics, nuclear safeguards, and nonproliferation. He has previously worked at GSI (Gesellschaft für Schwerionenforschung) in Darmstadt, Germany, at the Weizmann Institute in Rehovot, Israel, as an assistant professor at the University of Mainz, and as professor of nuclear chemistry at the University of Strasbourg, France. He holds a doctorate in nuclear chemistry from the University of Mainz, Germany.

Robert E. MacFarlane

Robert E. MacFarlane has received his Ph.D. from the Carnegie Institute of Technology in 1967 and then joined the Physics Division at Los Alamos National Laboratory, where he did experimental studies of the lattice dynamics of bismuth and antimony with inelastic neutron scattering. When that program shut down, he moved to the Theoretical Division to work on nuclear data. There he led the development of the NJOY nuclear data processing system and worked on the production of data libraries for a wide range of applications, such as fast reactors, thermal reactors, fusion systems, accelerator systems, weapons, and cold-neutron facilities. During this period, he also had several administrative positions, including a number of years as group leader, he managed the group's network of workstations on the side, and he provided his group with an early presence on the World Wide Web. MacFarlane was also active in the Cross Section Evaluation Working Group (CSEWG), which manages the US-evaluated nuclear data files (ENDF/B). He was involved in the ENDF/B-V, VI, and VII libraries. He worked on the development of a number of formats, including the ENDF-6 structure, energy-angle distributions, charged-particle representations, atomic data, and thermal scattering data. He was heavily involved in data testing for the various ENDF/B versions, and he also participated in the evaluation effort. Some significant components of this were his work on (1) improving the performance of ENDF/B for fast critical assemblies, including Godiva, Jezebel, and Bigten; (2) energy balance issues for heating and damage; (3) thermal neutron scattering data for important moderators. MacFarlane officially retired in 2005, but remains active by continuing to work part time.

Philippe Martin

Philippe Martin has received his degree of Doctor Engineer in 1972, and has spent his professional career (1973–2008) at the Atomic Energy Commission (CEA), France. He served as head of the Components and Structures Design Laboratory and a member of the French Committee

for rules to be applied to Fast Reactors Design (1986–1993); head of the life extension Project of the Phénix reactor (1993–1997); senior expert (1995–1999); head of the Innovative reactors & systems Section (1997–2000); head of the Simulation of fuel behavior Section (2000–2002); deputy head of the Fuel Department in charge of development of fuels for fourth-generation reactors; and CEA's representative to the Gen-IV SFR Project arrangement negotiation (2002–2006). He is a member of the GEN IV Sodium Fast Reactors Steering Committee of GENIV International Organization (2006–2007) and contributor to CEA's Nuclear Energy Division SFR program. Since 2008, he has served as an engineer-consultant for the Nuclear Energy Division of CEA.

Patrick Masoni

Patrick Masoni is an engineer at CEA specializing in thermo-mechanical analysis of structures. During 1981–1984, he analyzed the thermomechanical static behavior of the cores of the French fast breeder reactors Phenix and Superphenix. During 1984–1995, he performed theoretical and experimental dynamic mechanical studies of light water reactor (LWR) fuel pins and fuel assemblies, and the mechanical behavior of the Phenix reactor core (vibrations, shocks, and seismic calculations). Since 1995, he has performed theoretical and experimental thermomechanical studies regarding the behavior of fuel pins for future (Gen-IV) reactors (GFR and SFR), and also assessed the static thermomechanical behavior of existing French fast breeder reactors.

Klaus Mayer

Dr. Klaus Mayer obtained his Ph.D. in 1987 in the field of radiochemistry and analytical chemistry from the University of Karlsruhe, Germany. He then worked for 2 years at the Institute for Transuranium Elements (ITU) as postdoctoral researcher. In 1990, he started working with the European Commission at IRMM Geel (Belgium) on actinide isotopic reference materials, high accuracy mass spectrometric measurements of U, Pu, and Th, the organization of an external quality control program for nuclear material measurements, and the coordination of support activities to the Euratom safeguards office and to the IAEA. In 1996, he moved to ITU Karlsruhe (Germany) for working on the development and application of analytical methods for nuclear safeguards purposes. He is chair of the ESARDA (European Safeguards Research and Development Association) Working Group on Destructive Analysis. Currently, he is in charge of ITU's activities on combating illicit trafficking and nuclear forensics, and is cochairman of the Nuclear Smuggling International Technical Working Group (ITWG).

Frederic Mellier

Frederic Mellier is a research engineer at CEA. He started his career participating to neutron physic studies for SUPERPHENIX before moving toward activities in support of PHENIX operating and irradiation program. He was in charge of the development and maintenance of the PHENIX core management tools and was involved in experiments for absorber rod reactivity worth measurements. He joined the MASURCA facility in 2002 as the person responsible for experimental programs. He coordinated the MUSE-4 program (funded by the European Commission within the framework of the fifth EURATOM/FP) and is now involved in the GUINEVERE project (sixth FP), both programs aiming at studying the reactivity measurement issue in subcritical systems driven by an external source.

Gerard Mignot

Gerard Mignot obtained his Ph.D. in 1994 at the Aix-Marseille University, option energy science. He joined CEA as an engineer, working on thermal-hydraulics with applications on different nuclear reactor types: sodium fast reactor, pressurized water reactor, and high temperature reactor. From 2003 to 2006, he was in charge of studies on light water reactor innovative fuels and systems in the service of innovative reactor studies in Cadarache. In 2007, he changed fields and coordinated core design studies for the future sodium-cooled fast reactor. Since 2008, he serves as a project manager in the Reactor Studies Department, in charge of the core and reactor design for sodium fast reactor within the CEA SFR program.

Mohammad Modarres

Mohammad Modarres is a University of Maryland distinguished scholar–teacher, a professor and director of Nuclear Engineering, and director of Reliability Engineering at the University of Maryland; he is also a Fellow of the American Nuclear Society. He received his Ph.D. in nuclear engineering from MIT in 1980 and M.S. in mechanical engineering also from MIT.

Professor Modarres' research areas are probabilistic risk assessment, uncertainty analysis, and physics of failure degradation modeling. He has served as a consultant to several governmental agencies, private organizations, and national laboratories in areas related to probabilistic risk assessment. Professor Modarres has authored or coauthored over 250 papers in archival journals and proceedings of conferences, 3 books, 1 handbook, 4 edited books, and 5 book chapters in various areas of risk and reliability engineering.

Dr. Modarres' interests in energy technologies are in the next-generation nuclear reactors and nuclear fuel cycle safety, risk assessment, and management. These areas include research to advance probabilistic risk and safety assessment techniques and applications to complex energy technologies and addressing possible safety issues of the next generation of nuclear power designs in the context of the current combined risk-informed and traditional defense-in-depth regulatory paradigm. His research focuses on understanding safety and regulatory implications of the advanced nuclear reactors. Prof. Modarres is also performing research on the following areas: (1) technology-neutral nuclear power plant regulation; (2) hazard assessment of fire in advanced nuclear power plants; (3) fatigue and corrosion-based degradation assessment of reactor vessels and piping of advanced nuclear power plants using probabilistic modeling based on physics of failure with characterization of uncertainties; (4) best estimate thermal-hydraulic analyses of reactor transients using probabilistic methods to account for variability and uncertainties; and (5) risk and performance-based maintenance techniques for monitoring and assessing nuclear plant system health.

Victor A. Mokhov

Dr. Victor A. Mokhov was born on February 25, 1957, in Sverdlovsk. In 1980, he graduated as a mechanical engineer from the Bauman Moscow State Technical University and joined OKB "GIDROPRESS" as an engineer. His career progressed through the positions of design engineer, deputy head of department, and head of department. He is currently the chief designer of OKB "GIDROPRESS," and is an honored designer of the Russian Federation. His professional interests include the following: reactor plant design, accident analysis, probabilistic safety analysis, and the development of thermal-hydraulic codes for reactor plant transient analyses.

Said Mughabghab

Dr. Said Mughabghab received his M.S. in nuclear physics from the American University of Beirut, Beirut in 1959, followed by Ph.D. in nuclear physics from the University of Pennsylvania, Philadelphia in 1964. He dedicated his scientific carrier to physics of nuclear reactions in the low-energy region, and is best known for numerous contributions to physics of neutron resonances and reaction mechanisms. He has gained worldwide reputation as key author of compendia of neutron resonance parameters and thermal cross sections commonly known as BNL-325, its fifth edition published as *Atlas of Neutron Resonances* in 2006. He has been a research scientist in the National Nuclear Data Center at Brookhaven National Laboratory since 1963, involved in neutron physics research, high-flux beam reactor experiments, neutron resonances, neutron radiative capture and nuclear level densities, compilation of neutron resonance parameters and thermal cross sections. From 1987 to 1993, he worked in the BNL Reactor System Division with J. Powell on the Space Nuclear Thermal Propulsion program to determine the feasibility of using a small reactor for nuclear rocket propulsion for possible future mission to Mars.

Mikhail P. Nikitenko

Dr. Mikhail P. Nikitenko was born on July 1, 1947, in Mariinsk, Khabarovsk region, and graduated as a physical engineer from the Tomsk Polytechnical University, in 1971. He joined OKB "GIDROPRESS" as an engineer in 1971, and became head of group, and head of department. Currently he is the deputy chief designer of OKB "GIDROPRESS," and is an honored designer of the Russian Federation. His professional interests include reactor plant design development, safety analysis, and reactor process analysis.

David Nowak

David Nowak graduated from Rensselaer Polytechnic Institute with a B.S. degree in physics and from the University of Chicago with a Ph.D. in theoretical physics. His current position at Argonne National Laboratory involves working with the Department of Energy to develop a modeling and simulation effort in support of a revitalized nuclear enterprise in the USA.

Prior to Argonne, Dr. Nowak held a series of senior management positions at Lawrence Livermore National Laboratory (LLNL) which included a broad spectrum of highly visible national security responsibilities. Until June 2005, he was deputy associate director for Defense and Nuclear Technologies. He was a founding member of and the first LLNL Program Leader for the Department of Energy's Accelerated Strategic Computing Initiative (ASCI) Program. He led the team that developed the acquisition strategy that culminated in the 100-Teraflops Purple system and the 360-Teraflops Blue Gene system. He was one of the principals developing and executing the ASCI University Alliance Program. Dr. Nowak served as advisor to the Assistant Secretary for Defense Programs in the Department of Energy. Currently, Dr. Nowak splits his time between Chicago and Paris.

Pavel Obložinský

Pavel Obložinský received his M.S. in nuclear physics from the Czech Technical University, Prague, in 1967, and his Ph.D. in nuclear physics from the Slovak Academy of Sciences, Bratislava, in 1973. His scientific carrier has been dedicated to low-energy nuclear reactions,

focusing on studies of neutron-induced reactions. He is best known for numerous contributions to pre-equilibrium nuclear reaction theory and nuclear reaction data evaluation projects. Dr. Obložinský held positions as head of Nuclear Physics Department, Slovak Academy of Sciences, Bratislava (1973–1980); deputy head of Nuclear Data Section of the International Atomic Energy Agency, Vienna (1993–1999); head of the National Nuclear Data Center, Brookhaven National Laboratory (2002–2009); chair of the US Nuclear Data Program (2002–2009); chair of the US Cross Section Evaluation Working Group (CSEWG) (2001–2009). He was responsible for the release of the US-evaluated nuclear data library ENDF/B-VII.0 in 2006.

Laurent Paret

Laurent Paret graduated from the Département Génie mécanique, Université de Technologie de Compiègne, in 1996. After working at AREVA NC as the engineer in charge of deployment of a software to manage MOX fuel fabrication, he joined the CEA, in 1999, to work on MOX-fuels fabrication for experimental irradiations. Since 2001, he has been performing fuels studies for Gen-IV reactors (GFR and SFR). Currently, he is project manager in charge of the sodium fast reactor (SFR) fuels development.

Imre Pázsit

Imre Pázsit (M.Sc., 1971; Ph.D., 1975, Budapest, Hungary) is professor and chair of the Department of Nuclear Engineering, Chalmers University of Technology, Göteborg, Sweden. Former employments include the Central Research Institute for Physics, Budapest (1975–1983) and the nuclear research center Studsvik, Nyköping, Sweden (1983–1991). Imre Pázsit is a Fellow of the American Nuclear Society (2006), and a member of the Executive Committee on the Mathematics and Computation Division of ANS. He is a member of the Royal Swedish Academy of Engineering Sciences (2008) and a working member of the Royal Academy of Arts and Sciences in Göteborg (2005). Since 2009, he has also been an adjunct professor in the Department of Nuclear Engineering and Radiological Sciences of the University of Michigan, Ann Arbor, USA. Between 2000 and 2008 he was the head of the Section for Mathematical Physics of the Swedish Physical Society.

His research interests include the following: fluctuations in neutron transport; atomic collision cascades and fusion plasmas; reactor dynamics; neutron noise analysis applied to reactor diagnostics and nondestructive analysis in nuclear safeguards; transport theory of neutral and charged particles; intelligent computing methods such as artificial neural networks and wavelet analysis; diagnostics of two-phase flow and fusion plasma; positron annihilation spectroscopy and positron transport. He coauthored with L. Pál a book entitled *Neutron Fluctuations – a Treatise on the Physics of Branching Processes*, Elsevier Science Ltd., 2008. He has published over 160 articles in international journals; several book chapters, numerous reports, conference proceedings, popular science booklets, and articles. He is a member of the Editorial Board of the *Annals of Nuclear Energy*, the *International Journal of Nuclear Science and Technology*, and the *Nuclear Technology and Radiation Protection Journal*.

Michel Pelletier

Michel Pelletier received his Ph.D. from the University of Paris IX (Orsay), in materials sciences, in 1981, and joined CEA, Cadarache working in experimental fuel studies (definition of irradiation, PIE, and synthesis). During 1991–2000, he was a member of the SFR fuel-safety

working group (CABRI program). A senior expert since 1996, he is also lecturer at the “Institut National des Sciences et Techniques Nucléaires” and at the School of plutonium (Cadarache), specializing in the modeling and design of reactor fuel behavior.

Alexander K. Podshibyakin

Dr. Alexander K. Podshibyakin was born on June 30, 1938, in Podolsk, Moscow region, and graduated as an engineer in thermal physics from the Moscow Power Engineering University, in 1965. He joined OKB “GIDROPRESS,” and progressed through a sequence of positions of increased responsibility: leading engineer, head of department, first deputy chief designer of OKB “GIDROPRESS.” Currently, he is the chief specialist on VVER NSSS, and is an honored designer of the Russian Federation. His professional interests include the following: reactor plant design development, analytical and theoretical studies, elaboration of the schemes and processes of reactor plant operation, commissioning tests at NPPs, safety analyses.

Anil K. Prinja

Anil K. Prinja is a professor and associate chair in the Department of Chemical and Nuclear Engineering at the University of New Mexico (UNM), USA. He obtained his B.Sc. (“1st Class Honors,” 1976) and Ph.D. (1980) in nuclear engineering from Queen Mary College, University of London, UK, and held a research staff appointment at the University of California, Los Angeles (UCLA), before joining UNM in 1987. He has since held visiting professor’s appointments at Chalmers University, Sweden, and at UCLA, and has an ongoing affiliate appointment at Los Alamos National Laboratory, USA.

Professor Prinja’s research interests include development of efficient solution techniques for stochastic and deterministic computation of high-energy charged particle transport, formulating models for radiation transport in random media, application of stochastic methods to uncertainty quantification in radiation transport, and investigating neutron branching processes in multiplying media. Professor Prinja is a Fellow of the American Nuclear Society. From 1995 to 2005, he was the associate editor of *Annals of Nuclear Energy* and presently serves on the Editorial Boards of *Transport Theory and Statistical Physics*, and *Annals of Nuclear Energy*.

Jean Claude Queval

Jean Claude Queval, born in 1950, graduated as an aerospace engineer in 1972, has a very extensive experience in dynamic and seismic behavior of equipment and structures, for 30 years. He is in charge of the experimental part of the EMSI Laboratory at CEA Saclay. He is the author of many papers in R&D and seismic qualification tests, fluid-structure interaction computation, and fuel assembly modeling.

Baldev Raj

Dr. Baldev Raj (born in 1947; B.E., Ph.D., D.Sc.) holds memberships in the International Nuclear Energy Academy, German National Academy of Sciences; he is a Fellow of the Third World Academy of Sciences, and Fellow of all Engineering and Science Academies in India. He is a distinguished scientist and director, Indira Gandhi Centre for Atomic Research, Kalpakkam, Tamil Nadu. His specializations include materials characterization, testing and evaluation using nondestructive evaluation methodologies, materials development and performance assessment

and technology management. He has more than 750 publications in leading refereed journals and books. He has coauthored 12 books and coedited 32 books and special journal volumes. He has 5 Indian Standards and 18 patents to his credit. He is editor-in-chief of two series of books: one related to NDE Science and Technology and another related to Metallurgy and Material Science. He is on the editorial boards of national and international journals. He is the member of many national and international committees and commissions. He has been invited to deliver plenary and panel speeches in the most eminent international forums and more than 50 occasions in 30 countries. He has won many national and international awards and honors. He has a passion for teaching, communications, and mentoring. His other interests include science and technology of cultural heritage and theosophy.

Ulrich Rohde

Ulrich Rohde studied physics at the University of Minsk (Byelorussia), obtaining a master's degree in 1976. During 1976–1998, he worked as a research scientist in the Central Institute for Nuclear Research in Rossendorf near Dresden, the later Forschungszentrum Dresden-Rossendorf (FZD). In June 1987, he obtained a doctorate in physics in the field of two-phase flow modeling and boiling water reactor (BWR) stability analysis. Since 1998, he has been the head of the Safety Analysis Department of the Institute of Safety Research of the FZD, performing research in reactor dynamics, thermal hydraulics, and fluid dynamics.

Dr. Rohde gained particular experience in reactor dynamics and safety analysis of VVER-type reactors. He contributed to the development and validation of the Rossendorf reactor dynamics code DYN3D, which was initially designed for VVER type reactors, and is currently used as a transient-analysis tool in most of the countries with operating VVER reactors; the code is a part of the European software platform NURSIM. He has participated on scientific and management level in several international projects on safety analyses and validation of coupled neutronics/thermal hydraulics codes for VVER. From 1992 until 2009, he was a member of the Scientific Council of Atomic Energy Research (AER), an international association on reactor safety and reactor safety of VVER.

Gilles H. Rodriguez

Gilles H. Rodriguez (Engineer, chemistry, University of Lyon, France, 1990; Master of Science in chemical and process engineering, Polytechnic University of Toulouse, France, 1991) is a senior expert engineer at CEA/CADARACHE (French Atomic Energy Commission/Cadarache center). He is working on Generation-IV Fast Reactor research program. His areas of expertise are fast reactor technology, liquid metal processes, and process engineering. Since 2007, he has been a project leader of sodium technology and components, within the CEA SFR project organization, and is representing CEA/France on the GEN IV SFR Project Management Board (component design and balance of plant).

Vincenzo V. Rondinella

Vincenzo V. Rondinella has received his Ph.D. in materials sciences from Rutgers University, New Jersey. Currently, he is the head of the Hot Cells (HC) department at the Institute of Transuranium Elements (ITU), the European Commission's Joint Research Centre (JRC) located in Karlsruhe, Germany. The HC department performs postirradiation examinations on light water reactor (LWR) and advanced reactor fuels and cladding materials, focusing

on properties and behavior related to various stages of the nuclear fuel cycle, including fuel behavior in-pile, effects associated with different irradiation history (burn up, temperature, power, etc.) and behavior/evolution during storage and disposal. Dr. Rondinella's main areas of interest include the following: radiation damage, properties of high burn up nuclear fuels, mechanical properties of the fuel rod system (fuel + cladding/coatings), and the development and characterization of advanced fuels for new reactors.

Jacques Rouault

Jacques Rouault graduated in 1976 from Ecole Centrale de Paris, and joined CEA (Commissariat à l'Énergie Atomique) in 1980. He spent most of his career in the field of fast reactors. He was successively involved in the field of fast reactor fuel behavior (postirradiation examinations, modeling). From 1993 to 1996, he was the CAPRA project manager (Feasibility studies of a fast reactor optimized to burn Pu) in the context of a large international collaboration. From 1996 to 2000, he managed the Section of fuel development (FBR, PWR), covering postirradiation examinations, code development, experimental irradiation in Phénix and other reactors, and the material program for Minor Actinides transmutation. From 2001 to 2007, he directed the Section of Innovative Systems Study mainly focusing on GEN IV system design. Since 2007, he has responsibilities in the CEA Gen-IV program management with emphasis on the sodium fast reactor.

Sergei B. Ryzhov

Dr. Sergei B. Ryzhov was born on November 18, 1959, in Chekhov, Moscow region. He was graduated in 1982 as a mechanical engineer, from the Bauman Moscow State Technical University, and joined OKB "GIDROPRESS" as an engineer. Since then, he progressed through appointments as design engineer, head of group, head of department, and chief designer. Currently, he is the director-general designer of OKB "GIDROPRESS," and has been designated an honored designer of the Russian Federation. His professional interests include the following: reactor plant design development, and participation in research and experimental activities.

Mark Schanfein

Mark Schanfein joined Idaho National Laboratory (INL) in September 2008 as their senior nonproliferation advisor, after a 20-year career at Los Alamos National Laboratory (LANL). His current focus is on leveraging INL technology, facilities, and nuclear material to build an international safeguards program. He has over 30 years of experience in international and domestic safeguards. This includes his 20 years at Los Alamos National Laboratory where he most recently served as the program manager for Nonproliferation and Security Technology, a portfolio that included international and domestic safeguards and security. He also spent 10 years at the LANL Plutonium Facility as the team leader for all NDA measurements at this facility, and the Chemistry and Material Research facility, totalling over 100 instruments. He has over 8 years of experience working at the International Atomic Energy Agency, where he served 4 years as a safeguards inspector and inspection group leader covering inspections on a diverse set of facilities, and another 4 years as the unit head for Unattended Monitoring Systems.

J. Kenneth Shultis

J. Kenneth Shultis, born in Toronto, Canada, graduated from the University of Toronto with a BA.Sc. degree in engineering physics (1964). He gained his M.S. (1965) and Ph.D. (1968) degrees in nuclear science and engineering from the University of Michigan. After a postdoctoral year at the Mathematics Institute of the University of Groningen, the Netherlands, he joined the Nuclear Engineering faculty at Kansas State University in 1969 where he presently holds the Black and Veatch Distinguished Professorship. He teaches and conducts research in radiation transport, radiation shielding, reactor physics, numerical analysis, particle combustion, remote sensing, and utility energy and economic analyses. He is a Fellow of the American Nuclear Society, and has received many awards for his teaching and research. Dr. Shultis is the author or coauthor of six textbooks on radiation shielding, radiological assessment, nuclear science and technology, and Monte Carlo methods. He has written over 200 research papers and reports, and served as a consultant to many private and governmental organizations.

Craig F. Smith

Dr. Craig F. Smith earned his B.S. degree in engineering (*summa cum laude*) at the University of California, Los Angeles (UCLA) in 1971 and his Ph.D. in nuclear science and engineering, also at UCLA, in 1975. He is a Fellow of the American Nuclear Society (ANS) and of the American Association for the Advancement of Science (AAAS). He is currently serving on assignment as the Lawrence Livermore National Laboratory (LLNL) chair professor of Physics at the Naval Postgraduate School (NPS) in Monterey. He also serves as adjunct faculty at the Monterey Institute of International Studies.

In addition to his faculty role, Dr. Smith leads research efforts in nuclear energy technology at LLNL. He is the US member of the Generation IV International Forum (GIF) Provisional System Steering Committee on lead-cooled fast reactors, and has worked internationally in research related to nuclear energy technology, radiation detection, and automated systems. He has authored more than 50 technical papers and articles and 4 books, including the recently published *Connections: Patterns of Discovery*, (Wiley, 2008).

Joe Somers

Joe Somers hails from Dublin, Ireland, where he completed a chemistry degree at Trinity College Dublin in 1981. Thereafter, he concluded a Ph.D. on surface chemistry (1986), before joining the Fritz Haber Institut der Max Planck Gesellschaft in Berlin. There, his investigations centered on the use of UV and soft X-ray photoelectron and absorption spectroscopy at the synchrotron radiation source BESSY for the elucidation of geometric and electronic structure of adsorbates on metal and semiconductor surfaces.

In 1990, he joined the scientific staff of the European Commission's Joint Research Centre at the Institute for Transuranium Elements (JRC-ITU) in Karlsruhe, initially investigating the agglomeration of airborne particles using very high intensity ultra sonic waves. For the last 15 years, his research interests have concentrated on the development and testing of ceramic materials for nuclear fuel applications. This research has covered a wide variety of nuclear fuels (UO₂, MOX, Minor actinide fuels) for a variety of reactor systems (LWR, HTR, SFR, GFR, ADS), and has been performed through institutional and international programs. In addition, the local structure of actinide-bearing compounds and its evolution due to irradiation damage

has been a subject of particular interest. Currently, he is head of the Nuclear Fuels department at the JRC-ITU.

Ugo Spezia

Ugo Spezia has a master's degree in nuclear engineering, and has been active in the Italian nuclear industry since 1981, working on the Italian Unified Nuclear Project. Since 1999, he has been the secretary-general of the Italian Nuclear Association (AIN), advisor of the Italian Nuclear Regulatory Agency (ANPA), and, since 2003, technical manager of the Italian Nuclear Plant Management Company (SOGIN), the state-owned company charged of the Italian nuclear plant decommissioning. Since 2009, he has been technical manager of the SOGIN Safety Project Control. He is author of several publications on nuclear energy and nuclear technology and coauthor of the book *Nuclear Plant Decommissioning* (2002).

Theofanis G. Theofanous

Theofanis (Theo) G. Theofanous is professor in the Chemical Engineering and Mechanical Engineering Departments at UCSB, and founding director of the Center for Risk Studies and Safety (CRSS). He is a graduate of the National Technical University of Athens, Greece, and holds a Ph.D. from the University of Minnesota, both in chemical engineering. Prior to coming to UCSB in 1985, he taught at Purdue's Chemical Engineering and Nuclear Engineering Departments, where he was also the founding director of the Nuclear Reactor Safety Laboratory.

Professor Theofanous has worked on the physics and computation of multiphase flows and on methodologies for addressing uncertainties in risk management; he championed a key-physics-based approach to addressing complexity as a basis for decision making; and he brought applications to completion on important safety issues in both the chemical and nuclear industries, and as of recently in the domain of National Defense. He is consulted extensively, and internationally, for industrial and governmental organizations, and served on a number of National Research Council Panels, including the one that assessed the safety of the Nation's Research and Production (Defense, Nuclear) Reactors in the aftermath of the Chernobyl accident. His practical credits include the following: the Risk Oriented Accident Analysis Methodology (ROAAM), the In-Vessel Retention (IVR) design concept for PWRs, and the Basemat-Internal Melt Arrest and Coolability (BiMAC) device for BWRs and large PWRs.

He is a member of the National Academy of Engineering, a fellow of the American Nuclear Society, and was awarded an honorary doctorate from the University of Lappeenranta in Finland. In 1997, he received the E. O. Lawrence Medal from the US Department of Energy for his work on managing risks of severe accidents in nuclear power reactors.

Anton Tonchev

Anton Tonchev is an assistant research professor at Duke University. He received his Ph.D. degree in 1995 from the Joint Institute for Nuclear Research, Dubna, Russia. His main area of research is nuclear structure and nuclear astrophysics, in particular the study of the nuclear dipole response and the different low-energy modes of excitation. These low-energy modes of excitation address important issues such as how protons and neutrons arrange themselves

in neutron-rich nuclei under electric dipole absorption. His other research interests include nuclear forensics and neutron science related to national security.

Werner Tornow

Werner Tornow is a nuclear physics experimentalist who received his doctorate in 1972 from the University of Tuebingen, Germany. He is a full professor at Duke University and served as director of the Triangle Universities Nuclear Laboratory from 1996 to 2006. His expertise is in neutron-induced reactions ranging from few-body systems to heavy nuclei. More recently, he has also been involved in photon-induced reaction studies, and in neutrino physics and double-beta decay searches.

Ivo Tripputi

Ivo Tripputi is a nuclear engineer who is in the nuclear industry for more than 35 years. He played several roles in the engineering department of ENEL for the development of new reactor projects for the Italian utility. Later he was involved in the development of utility requirements for advanced plants in USA and in Europe with leading roles. Recently he was decommissioning manager for all Italian nuclear fuel cycle plants and manager for R&D, innovation and special projects. He has been IAEA expert for development of safety guides and on special assistance projects in various parts of the world. He is currently chair of the Working Party for Decommissioning and Dismantling of OECD/NEA.

James S. Tulenko

James S. Tulenko is emeritus professor in the Department of Nuclear and Radiological Engineering at the University of Florida (UF) in Gainesville, Florida and served as chairman of the Department for 16 years (1986–2001). He currently is the director of the Laboratory for Development of Advanced Nuclear Fuels and Materials at UF. Prior to his academic career, Professor Tulenko spent 23 years in the nuclear industry as manager, Nuclear Fuel Engineering at Babcock and Wilcox; manager of Physics at Nuclear Materials and Equipment Corp; and manager, Nuclear Development at United Nuclear Corporation.

Professor Tulenko has numerous fields of interest in the nuclear area, most of which involve nuclear fuel and the nuclear fuel cycle. He was presented with the Silver Anniversary Award of the American Nuclear Society (ANS) for his contributions to the nuclear fuel cycle in the Society's first 25 years. He received the Mishma Award of the ANS in recognition of his many contributions to nuclear material research. He also received the Arthur Holly Compton Award for his contributions to nuclear science and technology, and the Glenn Murphy Award of the American Society for Engineering Education for his outstanding contributions to engineering education. Elected a Fellow of the ANS for his contributions to the nuclear fuel cycle, Professor Tulenko is a past president of the ANS, having served from 2004 to 2005.

Paul J. Turinsky

Paul J. Turinsky is a professor of Nuclear Engineering at North Carolina State University, where he also services as coordinator of the Interdisciplinary Graduate Program on Computational Engineering and Sciences, and university representative to and chair of the Battelle Energy Alliance Nuclear University Collaborators, which is associated with the operation of Idaho

National Laboratory. His area of expertise is computational reactor physics, with a focus on nuclear fuel management optimization, space-time kinetics, sensitivity/uncertainty analysis, and adaptive core simulation. He is a Fellow of the American Nuclear Society and recipient of numerous awards including the Glenn Murphy Award (ASEE), E. O. Lawrence Award in Nuclear Energy (US Department of Energy), Eugene P. Wigner Reactor Physics Award (ANS), and Arthur Holly Compton Award (ANS). He serves on several advisory committees and retains an active consulting practice supporting industry and government.

Bernard Valentin

Bernard Valentin graduated with a master's degree in heat transfer from National Institute of Nuclear Science and Technic (INSTN), and joined CEA in 1983. He has worked on modeling and computations related to safety of SFR, particularly on PHENIX and SPXI reactors. He is now a specialist of SFR core and subassembly cooling, developing the ELOGE platform for design and thermo-hydraulics computations of such cores and subassemblies.

Paul Van Uffelen

Paul Van Uffelen studied nuclear engineering in Belgium and in France. He obtained his Ph.D. in the field of nuclear engineering at the University of Liège. Since he started his research career at the Belgian nuclear research centre (SCKCEN) in 1994, Paul has been involved in research for light water reactor (LWR) fuel, more precisely in the field of fission gas behavior and heat transfer. During 1996–1997, he was a visiting scientist at the OECD Halden Reactor Project in Norway, where he worked under the supervision of Carlo Vitanza and Wolfgang Wiesnack on in-pile experiments. Since 2002, Paul is leading the modeling team at the Materials Research department of the European Commission's Joint Research Centre (JRC), Institute for Transuranium Elements. His present research activities cover modeling of LWR fuel under normal operating and design basis accident conditions, as well as advanced fuel behavior modeling by means of the TRANSURANUS fuel performance code.

Frédéric Varaine

Frédéric Varaine has over 15 years experience in the area of nuclear physics and core design for fast reactor. He was involved in the restart of SUPER-PHENIX in 1994, having performed core physics calculation, safety, and neutronics tests. Subsequently he became responsible for irradiations studies performed in the PHENIX reactor for the transmutation demonstration. From 2000 to 2006, he was a project manager for transmutation studies under the 1991 French law on the management of radioactive waste. Since 2002, he has been a group leader of the core design laboratory, which is conducting all neutronics studies for reactor design of Generation-IV systems and especially gas and sodium fast reactor. He participates in several collaborative projects on SFR with Japan, India, the USA, Russia, and China.

Carlo Vitanza

Carlo Vitanza graduated in nuclear physics at the University of Milan, Italy, in 1971. Until 1975, he worked in a nuclear fuel company in Italy. He then moved to the OECD Halden Reactor Project, Norway, where he worked for 24 years, dealing primarily with the large nuclear fuel program carried out through the Halden reactor experiments. During 1989–1999, he was the director of the Halden research establishment.

In 1999, he moved to the OECD Nuclear Energy Agency (NEA) in Paris, France, where among others he was in charge of the international research projects conducted under the OECD sponsorship in the nuclear safety area. During his stay at the OECD-NEA 1999–2009 he initiated a number of such international projects, mainly in the area of thermal-hydraulics, severe accidents, and fuel safety. In 2009, he returned at Halden, where he is currently responsible for new development and marketing.

R. Bruce Vogelaar

Dr. R. Bruce Vogelaar received his Ph.D. in accelerator-based nuclear astrophysics from the California Institute of Technology in 1989, and then became head of cyclotron operations at Princeton University, where he later joined their faculty as an assistant professor. He subsequently moved to Virginia Tech in 1998 becoming a professor with research in fundamental weak-interaction physics, using ultracold neutrons at the Los Alamos National Laboratory and very large neutrino detectors at the INFN underground laboratory in Gran Sasso, Italy. He led a team to advance Kimballton as a potential national underground facility, and is currently the founding director of the Kimballton Underground Research Facility in addition to leading an active National Science Foundation (NSF)-funded research group.

Dr. Vogelaar encouraged and participated in some of the earliest neutron transport experiments underlying the foundations of GEM*STAR and conducted GEM*STAR's most recent neutron transport and fuel burn-up studies using the code MNCPIX.

Richard Wallace

Dr. Richard Wallace has a Ph.D. in nuclear astrophysics from the University of California. He has 28 years experience in nuclear weapons analysis, nuclear materials use and protection, nuclear safeguards systems, and technical program management. Currently, he is a group leader for the N-4 Safeguards Systems Group at Los Alamos National Laboratory (LANL), overseeing a staff of experts in advanced safeguards systems development, nonproliferation policy analysis, international engagement activities related to the nuclear fuel cycle and safeguards, and IAEA activities related to developing potential proliferation indicators. From 2002 to 2005, Dr. Wallace was a senior analyst with the International Atomic Energy Agency (IAEA) in Vienna, Austria, working to collect, evaluate and analyze open source and proprietary information to identify and assess indicators of potential clandestine nuclear weapons activities. He shared in the 2005 Nobel Peace Prize that was awarded to the IAEA. From 1995 to 2001, he was a project leader for the US–Russian Nuclear Materials Protection, Control, and Accounting program at LANL and acting program manager for Russian Nonproliferation Programs. In 1995, he provided technical advice to Department of Energy (DOE) during negotiations for the Comprehensive Test Ban Treaty. From 1981 to 2004, he was involved in nuclear weapons physics simulation modeling.

R. L. Walter

Prof. R. L. Walter is a full professor in the department of Nuclear Physics at Duke University, and conducted most of his research at the Triangle University Nuclear Laboratory (TUNL) in Durham, North Carolina. He is an international leader in polarization in nuclear physics, and has supervised over 30 Ph.D. students, performing theses (mostly) on this subject. His studies

include the production of polarized charged particles and neutrons, and the use of such particle beams in studies of nuclear structure.

Akio Yamamoto

Dr. Akio Yamamoto received his Ph.D. in energy science at Kyoto University, in 1998, for his work on loading pattern optimization methods for light water reactors (LWRs). During 1989–2003, he was in charge of in-core fuel management and related methodology development for commercial LWRs at Nuclear Fuel Industries, Ltd., Japan. Currently, he is an associate professor in the Graduate School of Engineering, Nagoya University, Japan. His research is focusing on the development of advanced nuclear design methods for current and Gen-IV reactors, large-scale simulations using parallel/distributed computing, in-core fuel optimizations, education of reactor physics and energy policy/strategies. He is a member of both the Atomic Energy Society of Japan (AESJ) and American Nuclear Society (ANS).

Introduction

In 1958, when nuclear engineering was at the dawn of becoming an international profession, McGraw-Hill Book Company published the first *Nuclear Engineering Handbook*, edited by Harold Etherington. It contained 14 chapters, contributed by 70 specialists, all from the USA, spanning 1,872 pages, and served, for decades, as the reference book for nuclear engineers worldwide. Following the role model provided by that pioneering work, but surpassing it considerably in depth and extent, the present *Handbook of Nuclear Engineering* comprises 29 chapters in 5 volumes, spanning over 3,600 pages. The Editor is very grateful to the 100 international experts who contributed to turning this handbook, in a very short time, from a paper project into a comprehensive and inspiring reference work, at a time when the field of nuclear engineering and technology appears to be at the dawn of a worldwide renaissance, after some 2 decades of stagnation and even decline, in some countries.

Each of the five volumes of this handbook is devoted to a representative segment of the field of nuclear engineering and technology, as indicated by their respective titles. They commence with a presentation of the fundamental sciences underlying nuclear engineering and move successively on to reactor design and analysis, fuel cycles, decommissioning, waste disposal, and safeguards of nuclear materials. As a whole, the handbook strives, of course, to cover all of the representative aspects of this field. The five volumes of this handbook are:

Volume 1, entitled *Nuclear Engineering Fundamentals*, comprising Chaps. 1 through 7

Volume 2, entitled *Reactor Design*, comprising Chaps. 8 through 12

Volume 3, entitled *Reactor Analysis*, comprising Chaps. 13 through 18

Volume 4, entitled *Reactors of Generations III and IV*, comprising Chaps. 19 through 24

Volume 5, entitled *Fuel Cycles, Decommissioning, Waste Disposal and Safeguards*, comprising Chaps. 25 through 29

Each chapter strives to be self-contained, covering the current state-of-the-art and open issues in the respective area of nuclear science and engineering. An expert reader could go directly to the chapter of interest. Graduate students, on the other hand, may wish to consult the chapters in the first volume, since knowledge of the contents of those chapters will greatly facilitate the understanding of the material presented in the subsequent chapters/volumes. To assist the reader, the remainder of this *Introduction* briefly summarizes the contents of the handbook's chapters.

Chapter 1, entitled *Neutron Cross Section Measurements*, gives an overview of neutron-induced cross-section measurements, both past and present. Neutron cross sections are the key quantities required to calculate neutron reactions (e.g., in reactors, shields, nuclear explosions, detectors, stars). This chapter presents the principal characteristics of time-of-flight and mono-energetic fast neutron facilities and explains the physics of typical neutron cross sections and their measurements. In particular, the chapter provides an overview of the *R*-matrix formalism, which is the fundamental theory for describing resonance reactions. The chapter ends with a brief overview of the current libraries of evaluated cross sections, mentioning not only the major general purpose libraries, e.g., the ENDF (USA evaluated nuclear data library), the JEFF (European joint evaluated fission and fusion library), the JENDL (Japanese evaluated nuclear data library), the CENDL (Chinese evaluated nuclear data library), and the BROND

(Russian evaluated neutron reaction data library) but also the most important special purpose and derived libraries.

Chapter 2, entitled *Evaluated Nuclear Data*, describes the status of evaluated nuclear data for nuclear technology applications. The chapter commences with a presentation of the evaluation procedures for neutron-induced reactions, focusing on incident energies from thermal energy up to 20 MeV, although higher energies are also mentioned. The status of evaluated neutron data for actinides is discussed next, followed by paradigm examples of neutron-evaluated cross-section data for coolants/moderators, structural materials, and fission products. Neutron covariance data characterizing uncertainties and correlations are presented next, highlighting the procedures for validating evaluated data libraries against integral benchmark experiments. Additional information of importance for nuclear technology, including fission yields, thermal neutron scattering, and decay data is also presented. The chapter concludes with a brief introduction to current web retrieval systems, which allow easy access to a vast amount of up-to-date evaluated data for nuclear engineering and technology, including the latest versions of the major libraries ENDF/B-VII.0, JEFF-3.1, and JENDL-3.3.

Chapter 3 is entitled *Neutron Slowing Down and Thermalization* and presents the theory underlying the generation of thermal cross sections, concentrating on the phonon expansion method. Paradigm examples are given for graphite, water, heavy water, and zirconium hydride. The graphite example demonstrates incoherent inelastic scattering and coherent elastic scattering for crystalline solids. The water example demonstrates incoherent inelastic scattering for liquids with diffusive translations. Heavy water adds a treatment for intermolecular coherence. Zirconium hydride shows the effects of the “Einstein oscillations” of the hydrogen atoms in a cage of zirconium atoms, and it also demonstrates incoherent elastic scattering. Steady-state slowing down is illustrated for typical cross-section data, highlighting slowing down by elastic scattering, inelastic scattering, and resonance cross sections in the narrow resonance approximation. Intermediate resonance self-shielding effects are introduced using the NJOY flux calculator and the WIMS implementation. The effects of time and space on slowing down are demonstrated using Monte Carlo simulations. Neutron thermalization is modeled first by using Monte Carlo simulations of several systems, followed by modeling using multigroup discrete-ordinates and collision-probability methods. The chapter also demonstrates size effects in thermalization and concludes by reviewing open issues that warrant further theoretical and experimental investigations.

Chapter 4, entitled *Nuclear Data Preparation*, focuses on data-processing codes that translate and manipulate the evaluated cross-section and other nuclear data (e.g., photon interactions, thermal-scattering laws) from the universally used ENDF/B format to a variety of formats used by individual particle transport and diffusion code systems for various applications. Data processing codes prepare nuclear data for use in continuous energy Monte Carlo codes as well as in multigroup Monte Carlo and deterministic codes. The main tasks performed by data processing codes are the reconstruction of energy-dependent cross sections from resonance parameters and Doppler broadening to a variety of temperatures encountered in practical systems. The chapter underscores the importance of the multiband method for enhancing the accuracy of reactor criticality and shielding computations.

Chapter 5 is entitled *General Principles of Neutron Transport* and highlights the theory underlying the forward and the adjoint transport equations as well as the scaled transport and neutron precursor equations. In particular, the chapter includes a discussion of the lack of smoothness of the angular flux in multidimensional geometries, which impacts negative numerical simulations. The chapter also presents the derivation of the time-dependent

integral transport equation as well as derivations of the transport equation in specialized one-dimensional (1D), two-dimensional, and three-dimensional geometries. Since the exact transport equation cannot be solved for large-scale reactor physics applications, various approximations have been developed in time, in parallel with the development of computational resources. The chapter also features, in a more rigorous manner than hitherto presented in the literature, derivations of the transport equation's approximate forms used for practical applications, highlighting: (1) an asymptotic derivation of the point kinetics equation, (2) an asymptotic derivation of the multigroup P_1 and diffusion equations, (3) derivation of the spherical harmonics (P_N) and simplified spherical harmonic (SP_N) approximations, and (4) an asymptotic derivation of the point kinetics equations. Computational neutron transport methods are also discussed briefly, underscoring the salient features of the most popular deterministic methods, Monte Carlo methods, and hybrid Monte Carlo/deterministic methods.

Chapter 6 is entitled *Nuclear Materials and Irradiation Effects* and highlights the physical transformations induced in materials by neutron irradiation. Irradiation damage is caused by (n, α) reactions, as well as by elastic interactions of neutrons with atoms, leading to displacement cascades and generation of point defects. In turn, the migration and clustering of point defects induce major changes in microstructures. The physical mechanisms leading to irradiation hardening, reduction of ductility, swelling, and irradiation creep and growth are described in detail for the alloys (e.g., structural and stainless steels, aluminum, zirconium, and vanadium alloys) and ceramics used not only in operating reactors but also envisaged for use in future fission and fusion reactors. The chapter also describes water radiolysis and changes in electrical properties of insulating ceramics.

Chapter 7, entitled *Mathematics for Nuclear Engineering*, summarizes the main mathematical concepts and tools customarily used in nuclear science and engineering, thus facilitating the understanding of the mathematical derivations in the other chapters of the handbook. The material presented in this chapter highlights the following topics: vectors and vector spaces, matrices and matrix methods, linear operators and their adjoints in finite and infinite dimensional vector spaces, differential calculus in vector spaces, optimization, least squares estimation, special functions of mathematical physics, integral transforms, and probability theory.

Chapter 8, entitled *Multigroup Neutron Transport and Diffusion Computations*, reviews the traditional methods for solving the steady-state transport equation, including the spherical harmonics expansion method, the collision probability method, the discrete ordinates method, and the method of characteristics. The chapter also highlights the most popular discretization methods for solving the neutron diffusion equation numerically.

Chapter 9 is entitled *Lattice Physics Computations* and presents a detailed description of the elements that comprise a so-called "lattice physics code." Lattice physics codes analyze axial segments of fuel assemblies, referred to as "lattices," to determine the detailed spatial and spectral distribution of neutrons and photons within and across the segment. The major components of a lattice physics code include a corresponding cross-section library, and various modules for performing computations in the cross sections' resonance region, fine-mesh transport calculations within the heterogeneous lattice geometry, and burnup computations. The flux distribution obtained from lattice computations is used to condense and homogenize the cross-section data into the structure needed for coarser-level "nodal" codes, in which each lattice is treated as a "node." The nodal codes are used to model the coupled neutronics and thermal-hydraulics behavior of the entire reactor core during steady-state and transient operation.

Chapter 10 is entitled *Core Isotopic Depletion and Fuel Management*. It commences by discussing numerical methods for solving the Bateman equation, which models the transient behavior of the isotopes (fissile, fertile, burnable poison, and fission products) produced during reactor operation. After introducing the concepts of breeding, conversion, and transmutation, the chapter discusses out-of-core and in-core nuclear fuel management, emphasizing fuel management for light water reactors (LWRs). Out-of-core fuel management aims at optimizing decisions regarding: (1) fuel cycle length; (2) stretch-out operations; and (3) feed fuel number, fissile enrichment, burnable poison loading, and partially burnt fuel to be reinserted, for each cycle in the planning horizon. On the other hand, in-core fuel management requires decisions for determining the loading pattern, control rod program, lattice design, and assembly design. The chapter continues with a brief review of in-core fuel management decisions for heavy water reactors, very high temperature gas-cooled reactors, and advanced recycle reactors. The mathematical optimization techniques and the tools for accomplishing the computations which are required to support decision making in nuclear fuel management are discussed with a view toward further enhancing the capabilities in these areas. The chapter concludes by summarizing the current state of fuel depletion and management capabilities, while discussing the avenues for further progress in these areas.

Chapter 11, entitled *Radiation Shielding and Radiological Protection*, deals with shielding against gamma rays and neutrons with energies up to 10 MeV, while assessing the health effects from exposure to such radiation. The chapter commences by describing the features of radiation sources and fields, including the mathematical modeling of the energy and directional dependence of the radiation intensity. The interaction of neutrons and gamma rays with matter is presented next, highlighting the computation of various types of radiation doses stemming from radiation intensity and target characteristics. This discussion leads to a detailed description of photon radiation attenuation and neutron shielding calculations, as well as corresponding dose evaluations. The chapter presents the basic concepts of buildup factors and point-kernel methodology for photon attenuation computations, as well as the established concepts and computational methods for designing shielding against fast, intermediate, and thermal energy neutrons. The chapter also highlights the special cases of albedo, skyshine, and streaming dose calculations and concludes with a discussion of shielding materials, radiological assessments, and risk calculations.

Chapter 12 is entitled *High Performance Computing in Nuclear Engineering* and comprises an introduction to high-performance computer and processor architectures, highlighting the current parallelism models. The chapter then presents the key concepts and requirements for designing parallel programs. This presentation is followed by presentations of paradigm applications of high-performance computing in reactor physics, nuclear material sciences, and thermal-hydraulic nuclear engineering. The chapter concludes with a discussion of open issues and possible paths forward in this rapidly developing field.

Chapter 13, entitled *Analysis of Reactor Fuel Rod Behavior*, focuses on the behavior of light water reactor (LWR) fuel rods. Following a presentation of the main properties of fuel and cladding materials, this chapter systematically describes the thermal and mechanical behavior under irradiation as well as the behavior of the fission gas produced in the fuel. The chapter also highlights the typical phenomena and issues of interest for the design and licensing of LWR fuels, namely: the high burnup structure, pellet-cladding interaction, pellet-coolant interaction, loss-of-coolant accidents (LOCA), and reactivity-initiated accidents (RIA).

Chapter 14 is entitled *Noise Techniques in Nuclear Systems* and deals with neutron fluctuations in nuclear systems. Such neutron fluctuations, called “neutron noise,” provide valuable

information regarding the behavior of the reactor system. This chapter focuses on the concepts and methodologies for extracting nonintrusive information from neutron noise, aiming at the detection, identification, and quantification of potential operational anomalies, at the earliest possible stage.

Chapter 15 is entitled *Deterministic and Probabilistic Safety Analysis* and highlights the evolution of deterministic and probabilistic safety analyses, which play a crucial role for assuring public health and safety in the peaceful uses of nuclear power. The chapter commences with a review of the origins of nuclear power safety analysis, comprising both deterministic and probabilistic methods. Deterministic approaches, including the defense-in-depth and safety margin concepts, provide methodologies for quantifying deterministically uncertainties associated with the adequacy of safety features. The chapter also discusses in detail probabilistic safety assessment methods and their uses in nuclear power safety analysis and safety-related decision making, reflecting the maturing and widening applications of such methods.

Chapter 16, entitled *Multiphase Flows: Compressible Multi-Hydrodynamics*, presents a conceptual framework for modeling three-dimensional multiphase flows in terms of a local disperse system description (bubbles/drops in a continuous liquid/vapor phase). This framework is based on a new, “hybrid” effective-field method (EFM) that incorporates features of a statistical approach and reveals more clearly the nature of phase interactions at the individual particle scale. The resulting multiphase flow formulation is amenable to numerical simulations based on the direct solution of the Navier–Stokes equations resolved at the particle scale. The basic constitutive treatment concerns pseudo-turbulent fluctuations of the continuous phase, and the resulting systems of equations are fully closed and hyperbolic (and hence directly usable for computations) even in their non-dissipative form, except for a non-hyperbolic corridor around the transonic region. The results thus obtained are discussed in relation to formulations that form the basis of current numerical tools (codes) employed in nuclear reactor design and safety analyses (mostly addressing bubbly flows) as well as the formulations found in other contexts. The numerical implementation of this new mathematical formulation emphasizes flow compressibility, focusing on capturing shocks and contact discontinuities robustly, for all flow speeds and at arbitrarily high spatial resolutions. A key role is played by “upwinding,” applied within the context of a scheme that emphasizes conservative discretization, extending thereby the ideas underlying the Advection Upstream Splitting Method to compressible multi-hydrodynamics (including the EFM).

Chapter 17 is entitled *Sensitivity and Uncertainty Analysis, Data Assimilation, and Predictive Best-Estimate Model Calibration*. This chapter provides the theoretical and practical means of dealing with the discrepancies between experimental and computational results and is therefore of paramount importance for validating the design tools used in all aspects of nuclear engineering. Such discrepancies motivate the activities of model verification, validation, and predictive estimation. The chapter presents the modern statistical and deterministic methods for computing response sensitivities to model parameters, highlighting, in particular, the adjoint sensitivity analysis procedure (ASAP) for nonlinear large-scale systems with feedback. Response sensitivities to parameters and the corresponding uncertainties are the fundamental ingredients for *predictive estimation (PE)*, which aims at providing a probabilistic description of possible future outcomes based on all recognized errors and uncertainties. The key *PE* activity is *model calibration*, which uses *data assimilation* procedures for integrating computational and experimental data in order to update (calibrate or adjust) the values of selected parameters (such as cross sections and correlations) and responses (such as temperatures, pressures, reaction rates, or effective multiplication factors) in the simulation model. This chapter also presents a

state-of-the-art mathematical framework for time-dependent data assimilation and model calibration, using sensitivities and covariance matrices together with the maximum entropy principle and information theory to construct a prior distribution that encompasses all the available information (including correlated parameters and responses), while minimizing (in the sense of quadratic loss) the introduction of spurious information. When the experimental information is consistent with computational results, the posterior probability density function yields reduced best-estimate uncertainties for the best-estimate model parameters and responses. Open issues (e.g., explicit treatment of modeling errors, reducing the computational burden, treating non-Gaussian distributions) are addressed in the concluding section of this chapter.

Chapter 18 presents *Reactor Physics Experiments on Zero Power Reactors*, performed in the EOLE, MINERVE, and MASURCA Zero Power Reactors (ZPRs), operated by the Commissariat à l’Energie Atomique (CEA), France. The experimental programs in these ZPRs have long played a crucial role in the validation of neutron physics codes and nuclear data by reducing the uncertainties of the experimental databases. These ZPRs also provide accurate data regarding: (1) innovative materials for reactor (fuels, absorbers, coolants, and moderators); (2) new reactor concepts (advanced BWRs, sodium and gas-cooled Generation-IV reactors, as well as hybrid systems, involving a subcritical reactor coupled to an external accelerator); (3) plutonium and waste management (involving heavy nuclides and long-lived fission products); (4) transmutation of long-lived nuclides; and (5) data for the new materials testing reactor “Jules Horowitz,” currently under construction in Cadarache.

Chapter 19 is entitled *Pressurized LWRs and HWRs in the Republic of Korea*. It describes Korean experiences and accomplishments in the design, operation, and construction of two Generation-III pressurized light water reactor (LWR) plants (OPR1000 and APR1400, respectively), which are currently in service and/or under construction in the Republic of Korea. The chapter also presents the Korean experience regarding the pressurized heavy water reactors (CANDUs) built and operated in the Republic of Korea.

Chapter 20, entitled *VVER-Type Reactors of Russian Design*, describes the design and technical layout of the Russian VVER-440 and VVER-1000 reactor plants. VVER reactors are a special design of pressurized water reactors, featuring a hexagonal geometry for the fuel assemblies, with fuel rods arranged in a triangular grid. The cladding for the fuel rods is manufactured from a zirconium–niobium alloy. The large-sized equipment can be advantageously transported by railway to enable a complete manufacturing process under factory conditions, but this design feature imposes a limit on the outer diameter of the reactor pressure vessel. The design of the horizontal steam generators with a tube sheet in the form of two cylindrical heads is also original. Reactors with the designations RP V-392, V-412, and V-428 are Generation-III reactors. Comprehensive sections are devoted to the primary circuit systems and equipment, reactor coolant system, reactor core, main circulation pumps, pressurizer, steam generators, chemical and volume control systems, and secondary circuit components (main steam line system, main feedwater system, turbine, generator, and moisture separator reheater), for both VVER-440 and VVER-1000 reactor plants.

Chapter 21 is comprehensively entitled *Sodium Fast Reactor Design: Fuels, Neutronics, Thermal-Hydraulics, Structural Mechanics and Safety*. The chapter highlights the fundamental motivations for building a fast reactor system: effective utilization of uranium resources through the judicious exploitation (transmuting, converting, or breeding) of fertile material and a sustainable closed fuel cycle, permitting a flexible management of actinides to minimize high-level

waste and reduce the burden on deep geological storages. These advantages had been envisaged as early as in 1946 by Enrico Fermi, who demonstrated the breeding principle and stated: “The people who will develop SFR technology will lead the world in the future.” The chapter provides a comprehensive review of the development of sodium fast reactors (SFR) in the USA, Russia, France, the UK, Germany, Italy, Belgium, the Netherlands, Japan, India, China, and Korea, highlighting the motivation and challenge underlying the two basic design choices, namely “pool design” and “loop design.” The objectives, scope, and levels of the “defense in depth” safety principles are emphasized, aiming at the “practical elimination” of initiating events and sequences leading to hypothetical severe plant conditions. The considerations underlying the choice of materials (for fuel, structures, absorbers, shielding) are presented in depth, since these are paramount for optimizing the reactor core design (including geometrical parameters, neutronics, thermal-hydraulics, structural mechanics, reactivity effects) and performance objectives. The chapter also underscores several important specific issues regarding the design and analysis of the mechanical integrity of the reactor (comprising thermal striping, stratification, seismic-induced forces, fluid–structure interactions, buckling of thin shells). Design basis and design extension conditions, including residual risks, are analyzed for typical anticipated transients without scram. The vast French licensing experience with the Phenix, SPX-1, SPX-2 sodium-cooled fast reactors is discussed with a view toward innovations, leading to enhanced safety of future innovative SFR designs. The chapter concludes with presentations of the ongoing SFR activities in France and India.

Chapter 22 is entitled *Gas-Cooled Reactors* and presents the main features of reactors that use a gas (carbon dioxide or helium) as the primary fluid for cooling the core. The oldest reactors of this type were the British Magnox and the French natural uranium graphite gas (NUGG) reactors, which used carbon dioxide as coolant in graphite-moderated cores fueled with natural uranium. The availability of low-enriched uranium fuel allowed the British to develop the advanced gas-cooled reactor as a successor to the Magnox reactor. In a world progressively dominated by the water-cooled reactors, mostly PWR and BWR, helium remained under consideration as coolant for the prismatic and pebble-bed high-temperature reactors (HTR) moderated with graphite. Both of these HTRs use a very innovative fuel element – the coated particle. As recalled in this chapter, the same type of fuel was also used in the NERVA US-program, which aimed at developing nuclear propulsion for rockets. Helium cooling is also used for two envisaged Generation-IV concepts, namely the very high temperature reactor (VHTR) system aimed at both electricity generation and hydrogen production and the gas-cooled fast-neutrons reactor (GFR).

Chapter 23 is entitled *Lead-Cooled Fast Reactor (LFR) Design: Safety, Neutronics, Thermal Hydraulics, Structural Mechanics, Fuel, Core, and Plant Design*. The lead-cooled fast reactor (LFR) has both a long history and a currency of innovation. Early work on such reactors, dating back to the 1950s, was devoted to submarine propulsion, as Russian scientists pioneered the development of reactors cooled by heavy liquid metals (HLM). More recently, there has been substantial interest in both critical and subcritical reactors cooled by lead (Pb) or lead–bismuth eutectic (LBE), not only in Russia (BREST-300, SVBR-75) but also in Europe, Asia, and the USA. This chapter reviews the historical development of the LFR and provides detailed descriptions of the current initiatives to design LFRs for various missions. Currently, the leading designs are for: (1) accelerator-driven subcritical (ADS) systems for nuclear materials management, (2) small modular systems for deployment in remote locations, and (3) central station plants for integration into developed power grids. The chapter describes: design criteria and

system specifications; specific LFR features regarding neutronics, coolant properties, and material compatibility issues; core and reactor plant design; and considerations related to the balance of plant and plant layout for Generation-IV LFR and HLM-cooled ADS concepts (SSTAR, ELSY, MYRRHA, EFIT).

Chapter 24 is entitled *GEM*STAR: The Alternative Reactor Technology Comprising Graphite, Molten Salt, and Accelerators*, and it illustrates conceptually the possible benefits of implementing supplementary neutrons from accelerators in a futuristic reactor concept called GEM*STAR (Green Energy Multiplier*Subcritical Technology for Alternative Reactors) by its authors. This chapter does not aim at providing a complete history of molten salt, graphite, and accelerator technologies but rather a description of how these elements of nuclear power development might be integrated to address the main barriers that constrain the full deployment of today's nuclear power technology. The basis for the GEM*STAR concept is a subcritical (initial multiplication factor = 0.99) thermal-spectrum reactor, operating with a continuous flow of molten salt fuel in a graphite matrix. If sufficient external neutrons are available, GEM*STAR may operate with natural uranium and un-reprocessed LWR spent fuel, recycling its own fuel several times without needing external reprocessing.

Chapter 25 is entitled *Front End of the Fuel Cycle* and describes the complete set of industrial operations needed to produce a functional fuel element ready to be loaded in a nuclear reactor. This chapter commences by providing data concerning the element uranium (its abundance and relevant properties) and continues by describing the uranium exploration, mining, concentration, and site rehabilitation processes. Light water reactors, which constitute the vast majority of currently operating and under-construction nuclear reactors, must use uranium enriched in the isotope U-235. The enrichment process requires that uranium be converted into a gaseous compound. The enriched uranium is subsequently fabricated into solid ceramic pellets and assembled into leak tight metallic pins, which are, in turn, assembled to form the fresh fuel element. The chapter also provides valuable information on mixed uranium-plutonium oxide (MOX) fuel assemblies for recycling plutonium in LWR as well as basic data on plutonium and thorium. The chapter also provides an explanation of the fascinating Oklo Phenomenon, which occurred almost two billion years ago in a particular uranium deposit in Gabon.

Chapter 26 is entitled *Transuranium Elements in the Nuclear Fuel Cycle*. The transuranium elements neptunium, plutonium, americium, and curium are produced from actinides through neutron capture processes and therefore arise mostly as by-products of fuel irradiation during the operation of a nuclear reactor. The nuclear properties of transuranium (TRU) elements significantly affect the nuclear fuel cycle, largely determining the requirements and procedures for handling, storing, reprocessing, and disposing the spent fuel and high-level waste. Socio-economical and political considerations have so far prevented the establishment of a standard, universally accepted route for the treatment of TRU-elements. In particular, it is still a matter of political debate if plutonium is waste or a resource for the production of energy. This chapter provides an overview of past and current experiences and perspectives regarding the recovery and incorporation of TRU-elements in fuels and targets for advanced nuclear fuel cycles, as well as the disposal of TRU-elements as the main components of high-level nuclear waste. In particular, this chapter highlights the main properties of TRU fuels, the specific requirements for their fabrication, their irradiation behavior, and their impact on the back end of the fuel cycle. For the latter, a major issue is the development of options for reprocessing and separation of TRU-elements from spent fuel, in order to make these elements available for further treatment. The chapter also discusses the effects on long-term storage and final disposal caused by the presence of TRU-elements in irradiated fuel and high-level nuclear waste. At this time,

the final destination for TRU-elements continues to remain an open issue, as various countries pursue a diversified set of options. The comprehensive understanding of the worldwide knowledge and experience presented in this chapter provides an essential basis for developing viable, safe, and technologically effective options for the treatment of TRU-elements, which, in turn, are crucial for ensuring that nuclear energy remains a key component in a sustainable mix of energy production.

Chapter 27 is entitled *Decommissioning of Nuclear Plants* and covers all aspects related to the closure of the operating life of nuclear plants, providing a description of all activities and tools involved in the decision-making and operative processes of decommissioning. The main stages involved in the decommissioning process include the termination of operations, the withdrawal of the nuclear reactor plant from service, and the transformation of the plant into an out-of-service state without radiological risks. In some cases, decommissioning leads to the complete removal of the plant from its original site. Nuclear plant decommissioning comprises a complex, long, and highly specialized spectrum of activities including technological tools, industrial safety, environmental impact minimization, licensing, safety analysis, structural analysis, short- and long-term planning, calculation of cash flow and financing, waste disposal, and spent fuel strategy. All of these activities must be performed in a cost-effective manner, assigning top priority to the health and safety of the workers on site as well as the public and the environment. In some countries, decommissioning is actually called “deconstruction,” because it resembles, in many respects, the construction activity. Unlike the construction activities, though, decommissioning also deals with partially activated and contaminated structures. The chapter draws technical information from the direct experience of nuclear operators as well as from the results produced by working groups, special studies, comparisons of technologies, and recommendations from the OECD-NEA, IAEA, US-NRC, and the European Commission.

Chapter 28 is entitled *The Scientific Basis of Nuclear Waste Management* and provides the scientific concepts and data underlying the management of the highly radioactive waste produced at various stages of the nuclear fuel cycle. In a context in which science and technology interact strongly with social and economical issues, the scientific basis for high-level radioactive waste management continues to evolve. Within a closed fuel cycle, the management of high-level waste, from its production to its final destination, appears as a chain, whose links are treatment, recycling, conditioning, storage, and disposal. When the fuel cycle remains open, the first two links (treatment and recycling) are absent. The chapter commences by describing the origin, nature, volume, and flux of nuclear waste, while briefly presenting various management options. Waste conditioning is addressed next, emphasizing the elaboration and long-term behavior of two important conditioning matrices: cement-like materials and glass. Since some countries consider spent fuel to be “waste” that must therefore be conditioned as such, the chapter devotes a special section to this controversial issue. The chapter also describes in detail the design and properties of installations for interim storage of long-lived waste, since such installations are already operational in several countries that exploit nuclear power plants. Since the definition of “ultimate waste” varies from country to country due to socioeconomical issues, the means and ways for the disposal of such waste in deep geological repositories is not universally resolved, even though the basic scientific concepts and technological issues involved are largely known. Therefore, this chapter also emphasizes the mechanisms, models, and orders of magnitude of the main physical and chemical phenomena that govern the long-term evolution of various types of possible geological repositories for high-level radioactive ultimate waste. The chapter concludes with a short description of the methodology used for evaluating the safety of radioactive waste disposal installations.

Chapter 29 is entitled *Proliferation Resistance and Safeguards* and presents the status of the international activities regarding these very complex issues. As is well known, the Nuclear Nonproliferation Treaty (NNPT or NPT) is the primary cornerstone of international efforts to prevent the proliferation of nuclear weapons. Currently, 189 countries are party to the treaty, with only four sovereign states abstaining: India, Israel, Pakistan, and North Korea. The NPT is broadly interpreted to comprise three pillars: nonproliferation, disarmament, and the right to the peaceful use of nuclear technology. This chapter addresses each of these NPT-pillars and commences by analyzing the significance of the Strategic Arms Reduction Treaty (START), which was signed between the USA and the former Soviet Union on 31 July 1991. This treaty, considered by many to be the largest and most complex arms control treaty in history, has led to a significant reduction in the number of deployed warheads for both the USA and Soviet Union. Furthermore, the US and Russian presidents signed a preliminary agreement on 6 July 2009 to reduce further the number of active nuclear weapons to between 1,500 and 1,675 by 2012. Although these treaties have been the backbone of joint US and Russian efforts toward nuclear disarmament, they have not addressed the discontinuation of weapons-grade fissile material production and disposition of excess weapons-grade materials. The current situation is that the USA, France, and the UK have ceased the production of weapons-grade materials. In 1997, the USA and Russia signed the Plutonium Production Reactor Agreement to cease the production of plutonium for weapons production. Although Russia still operates nuclear reactors used previously for production of weapons material, to generate heat and electricity, it does not reprocess the spent fuel correspondingly, and plans to decommission these reactors. While India and Pakistan apparently are still producing weapons-grade material, unsubstantiated reports indicate that China has also instituted a moratorium on production, while Israel's position is unclear. In September 2000, the USA and Russia, each formally agreed to transform 34 metric tons of excess military plutonium into a more proliferation-resistant form over the course of 20 years, by irradiating it in nuclear power reactors. Currently, Russia favors irradiation in a new generation of fast reactors yet to be developed, and the USA favors irradiation in their existing commercial LWR fleet. Additionally, a joint program has been developed by the USA and Russia to disposition excess highly enriched uranium (HEU) by blending it with natural uranium to produce low enriched uranium (LEU) for commercial power reactor fuel. This chapter presents a broad overview of experimental and statistical methods and tools for assessing nonproliferation compliance at declared facilities. In the broader nonproliferation context, monitoring for undeclared activities involves many difficult additional statistical issues. The chapter concludes by presenting a paradigm example of validating a safeguard design for the detection of abrupt diversion.

Although this handbook represents the most comprehensive snapshot of the current state of nuclear engineering and technology worldwide, several topics were not treated comprehensively as they could have been, due to scheduling constraints. Thus, the Editor believes that full stand-alone chapters would be warranted for presenting in adequate detail topics such as: Monte Carlo and variational methods for reactor physics and shielding computations, reactor dynamics and control, nuclear instrumentation, corrosion under irradiation, life extension of Generation-II LWRs, advanced supercritical water reactors, and research and materials testing reactors. The next edition of this handbook envisages a comprehensive exposition of these and related topics, along with updates of the topics covered in the present 29 chapters.

The Editor commenced work on this handbook in the fall of 2007, while serving as the Scientific Director of the Nuclear Energy Directorate of the Commissariat à l'Énergie Atomique (CEA), France. The extensive yet focused work required during 2010 to finalize this handbook

has been greatly facilitated by the support of Mr. Laurent Turpin, Director of the National Institute for Nuclear Science and Technology (INSTN) at CEA, and the Editor wishes to express his heartfelt appreciation for this support. The Editor also wishes to acknowledge with distinctive pleasure the very cordial and efficient collaboration with the publication team of Springer-Verlag, led by Mr. Alex Green (Editorial Director for Engineering) in the USA. The Editor also wishes to express special thanks to Dr. Sylvia Blago, Lydia Mueller, and Simone Giesler, for their particularly dedicated professional and very friendly collaboration in weekly interactions over the almost 3 years dedicated to this handbook project.

Abstract: This chapter gives an overview of neutron-induced cross section measurements, both past and present. A selection of the principal characteristics of time-of-flight and monoenergetic fast neutron facilities is given together with several examples of measurements. The physics of typical neutron cross sections and their measurements are explained in detail. Finally an overview of the R -matrix formalism, which is at the basis of resonance reactions, is given. The many references provide a starting point for the interested reader.

1 Introduction

When a beam of particles impinges upon a nucleus, the ratio of the reaction rate (in units of s^{-1}) to the incident flux (in units of $\text{cm}^{-2}\text{s}^{-1}$) is defined as the “cross section” (in units of cm^2 or barn with $1 \text{ barn} = 10^{-24} \text{ cm}^2$). The cross section is thus a measure of the strength of a reaction.

Neutron cross sections are the key quantities required to calculate neutron reactions taking place in reactors, shields, transmuters, nuclear explosions, detectors, stars, etc. Neutron cross sections have been measured over the past 70 years and techniques are being continually developed to improve the accuracy and completeness of neutron cross section data for both stable and radioactive nuclei. As new reactors, neutron sources, waste transmutation devices, and medical applications emerge, there is need for improved neutron cross section measurements.

There is an ongoing major international effort to provide a complete-as-possible compilation of evaluated cross section data for nuclear calculations. Major evaluation compilations are ENDF (USA evaluated nuclear data library) (Chadwick et al. 2006), JEFF (European joint evaluated fission and fusion library) (Koning et al. 2006), JENDL (Japanese evaluated nuclear data library) (Shibata et al. 2002), CENDL (Chinese evaluated nuclear data library) (Ge Zhigang et al. 2008), and BROND (Russian evaluated neutron reaction data library) (Ignatyuk and Fursov 2008). Since evaluated data can be no better than the measurements upon which they are based, thus there is an ongoing need for better measurements. In addition experimental compilations like references Mughabghab (2006), Sukhoruchkin et al. (1998) or the international database EXFOR (previously also known as CSISRS) Zerkin et al. and available on the websites <http://www.nds.iaea.org/exfor>, <http://www.nea.fr/html/dbdata/x4>, <http://www.nndc.bnl.gov/>.

It is a difficult task to review such a large effort as neutron cross section measurements without committing errors of commission or omission. If we erroneously reported on your laboratory and/or its publications, we apologize in advance as it was never our intent to be in error. Also, if we either left you out of our summaries or did not give as much attention to your contributions as you deem we should have, again we apologize with the excuse that it was impossible to present all the work that has been and is now going on. We admit that we presented many details from the laboratories that the authors are working with – this was only because the authors are more familiar with these works and does not imply that they are superior to other laboratory efforts. Finally, we did not include any “figure-of-merit” listings that were so popular in the past when comparing neutron sources. In retrospect, these figures-of-merit frequently wound up making one’s own neutron source look superior to another’s, whereas the total merit of a neutron source can never be summarized by a single number. It is the total impact of the cross sections measured, the number of published articles and conference proceedings, the impact on the field, etc. that need to be taken into account in evaluating a neutron source. To paraphrase British Prime Minister Benjamin Disraeli’s famous statement “There are lies, damned lies and figures-of-merit.” (“There are lies, damned lies and statistics” is attributed to Prime

Minister Benjamin Disraeli in the nineteenth century. Mark Twain again made it famous in the twentieth century. Wikipedia: http://en.wikipedia.org/wiki/Lies,_damned_lies,_and_statistics (2009).

2 History

The neutron was discovered by Chadwick in 1932 from the interaction of alpha particles incident on beryllium or boron (Chadwick 1932). Neutrons were soon recognized as excellent particles to probe nuclei since their lack of charge enabled them to readily penetrate deeply into matter and into the charged nucleus. Fermi and coworkers used neutrons generated from natural alpha sources to study nuclear reactions over a large range of nuclei and found that the strength of interaction varied greatly from nucleus to nucleus and that in many cases the interaction can be enhanced by moderating the neutron energy with hydrogen (Amaldi and Fermi 1936). Ultimately the neutron was discovered to produce fission in uranium and this led to the major effort in the 1940s to produce nuclear reactors and weapons. The design of these neutron devices critically depended on neutron cross section data from thermal to tens of MeV energy and major laboratories in the US and Europe were set up to make these measurements.

In the 1930s and 1940s cross section measurements utilized the neutrons from accelerators and early reactors. Activation with and without Cd covering and reactivity measurements using devices such as the pile oscillator provided thermal-spectrum-averaged cross sections. Crystal spectrometers, neutron velocity selectors, and neutron choppers using the time-of-flight (TOF) method provided sufficient energy resolution to measure resonance energy cross sections typically up to ~ 100 eV. In the 1950s positive ion accelerators utilized nuclear reactions to produce monoenergetic neutron beams and these provided cross section data from the keV to MeV energy range. Pulsed accelerators for electrons and protons were used to produce intense bursts of neutrons which enhanced the TOF measurements well beyond what fast choppers could provide. Even nuclear explosions were used to provide a very intense pulse of neutrons for time-of-flight experiments.

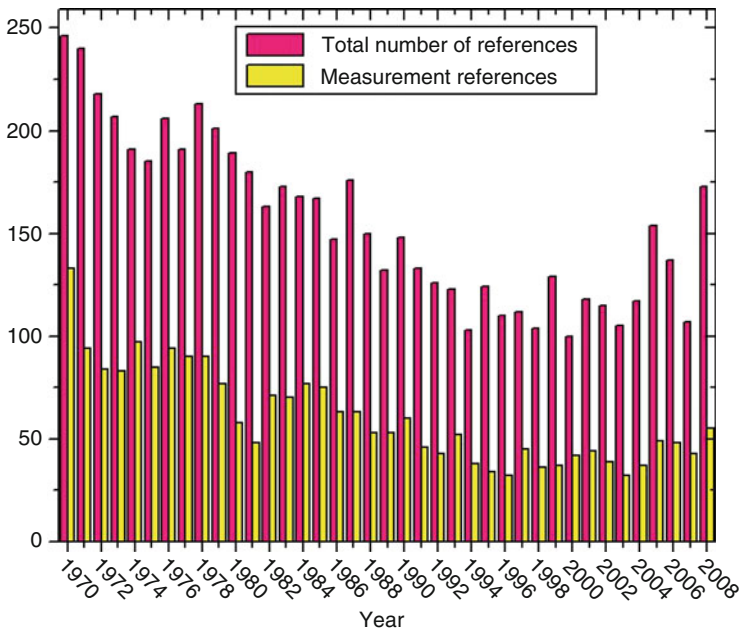

Since the 1970s cross sections were mainly obtained either by pulsed accelerator TOF methods (Ray and Good 1972) or neutrons derived from positive-ion-induced nuclear reactions. In the 1970s and 1980s neutron cross section measurement laboratories were set up in USA, Europe, and Japan. TOF measurements were carried out at the General Atomics Corporation (Orphan et al. 1969), Oak Ridge National Laboratory linac (Dabbs 1979) and Van de Graaff (Good et al. 1958), Rensselaer Polytechnic Institute (Hockenbury et al. 1969), the Lawrence Livermore National Laboratory (LLNL) linac (Behrens et al. 1982) and D-T source (Hansen et al. 1973), the LLNL cyclograff (Davis 1989), National Bureau of Standards (Carlson et al. 1983), the linacs at Harwell (Firk et al. 1963), Saclay (Blons 1973), and Geel (Kohler et al. 1985) the Karlsruhe cyclotron (Cierjacks et al. 1968) and Van de Graaff (Wisshak and Kappeler 1978, 1979), the Frascati Neutron Generator (Pillon et al. 1995), the pulsed reactor at Dubna (Frank and Pacher 1983), Kyoto University Research Reactor Institute (Fujita 1986) and the linac of the Japan Atomic Energy Research Institute at Tokai Mura (Asami 1973). Light-ion-based accelerator measurements were made at Los Alamos National Laboratory (Woods et al. 1974), Duke University (Farrell and Pineo 1968), Ohio University (Finlay et al. 1982), Lowell University (Kegel 1989), Argonne National Laboratory (Dudey et al. 1970), Bruyères-le-Châtel (Joly et al.

1978), the Forschungszentrum Jülich (Qaim et al. 1984; Grallert et al. 1993), Research Institute National Defence, Stockholm (Nystrom et al. 1971), the Institute of Physics and Power Engineering at Obninsk 14 MeV source (Lychagin et al. 1987), and pulsed Van de Graaff (Kononov et al. 1982; Kononov et al. 1987; Kornilov and Kagalenko 1995; Zhuravlev et al. 2007) and the DT source of Kossuth University at Debrecen, Hungary (Biro et al. 1975).

Recently the pulsed spallation sources at Los Alamos (Lisowski and Schoenberg 2006) and CERN (Borcea et al. 2003) have been utilized for TOF cross section measurements where their intense neutron pulses are well suited for both high resolution and high neutron intensity measurements. The high energy protons that produce these neutrons enables measurements up to 100s of MeV. Other initiatives concern the time-of-flight facility nELBE at the Forschungszentrum in Dresden-Rossendorf (Klug et al. 2007), the neutron source FRANZ at the Stern Gerlach Zentrum in Frankfurt (Petrich et al. 2008) and the neutron source JPARC at the Japan Atomic Energy Research Institute in Tokai (Futakawa et al. 2009) and in the future at SPIRAL2 at GANIL in Caen (Fadil and Rannou 2008).

The above list of laboratories is not exhaustive but the references will provide a good starting point for the interested reader.

Neutron cross section measurements increased rapidly into the 1950s and 1960s as many laboratories were set up throughout the world for these measurements. This activity peaked in the 1960s but decreased from 1970 to today, as shown in  Fig. 1. The upper bar graph

 **Figure 1**

The plot labeled “Total number of references” shows the total number of references published per year pertaining to neutron cross sections; these publications refer to both evaluation and experiments. The plot labeled “Measurement references” are for publications which contain information on neutron cross section measurements

is a plot of the number of journal references per year pertaining to neutron cross sections while the lower bar graph is a plot of the number which pertain to measurements of neutron cross sections. This plot was obtained by using the Engineering Village search program <http://www.engineeringvillage2.org>, Elsevier, Inc. (2009). Here we see that from 1970 to 2000 the “activity” in this field dropped by about a factor of two. This drop reflects the decrease in the funding in this field with the corresponding decrease in the number of laboratories working in this area. From 2000 to 2008 the activity increased $\approx 25\%$ and, with the renewed interest in new power reactors, it is predicted that this rate will continue to rise in the next decade or so.

3 Currently Active Laboratories

3.1 Time-of-Flight Laboratories

Major laboratories for time-of-flight cross section measurements are located in the USA, Europe, and Asia. All of these facilities utilize accelerators for electrons or protons to produce intense pulses of neutrons and typically have long flight paths to obtain good energy resolution. A non-exhaustive summary of these facilities is listed in [Table 1](#).

The three major laboratories in USA are the Gaertner LINAC Laboratory at Rensselaer Polytechnic Institute (RPI), the LANSCE Laboratory at Los Alamos National Laboratory and the ORELA Laboratory at Oak Ridge National Laboratory. The ORELA and Gaertner facilities utilize an electron linear accelerator while the LANSCE facility uses a high-energy proton linear accelerator. In Europe the GELINA facility of the Joint Research Center IRMM in Belgium has a long record of measurements. The new facility IREN in Russia is under construction but operational and has replaced the pulsed reactor IBR-30. The facility nELBE in Dresden-Rossendorf is a relatively new facility. The neutron source n_TOF at CERN, Geneva, is operational since 2001. For Asia we include PNF at PAL in Pohang, Korea, and KURRI in Kumatori, Japan. Also the neutron source MLF-NNRI at J-PARC has been put in operation.

Many of these laboratories have several flight paths such that several experiments can be set up and acquire data without interfering with each other.

The table lists the particle, its energy and the target used to generate the neutrons. Beam parameters like pulse width, beam power, and repetition rate are also given as well as the range of flight paths available. Finally the number of neutrons produced per pulse is given. Other parameters like the average current (beam power divided by the particle acceleration voltage, equivalent to its energy in eV), the pulse charge (average current divided by the frequency) or the number of neutrons per second (neutrons per pulse times frequency) are sometimes given in other facility descriptions, for example, in Koehler (2001); Lisowski and Schoenberg (2006); Klug et al. (2007). They can be easily derived from the listed parameters.

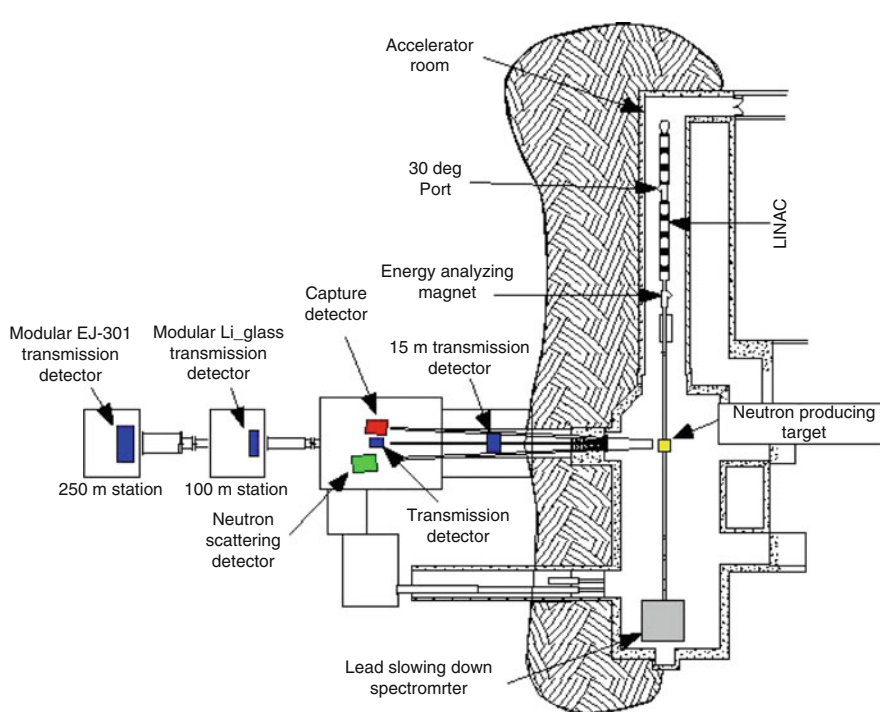

[Table 1](#) does not contain information about resolution components due to the target-moderator system. Neutron time-of-flight resolution reflects the distribution of the measured neutron time-of-flight for a given neutron energy. Its origin has several components, like the pulse width, the moderator geometry, and the detector used. This distribution known as the resolution function is usually highly non-Gaussian and changes with neutron energy. In the following some of the facilities are described in more detail.

Table 1
Parameters of several neutron time-of-flight facilities. For the new facilities parameters still may improve

Facility	Location	Particle	Beam energy (MeV)	Neutron target	Pulse width (ns)	Beam power (kW)	Pulse frequency (Hz)	Flight path lengths (m)	Neutron production (n/pulse)
RPI	RPI, Troy, USA	e-	60	Ta	5	0.6	500	15-250	3.6×10^9

3.1.1 The Gaerttner LINAC Laboratory

The Gaerttner LINAC Laboratory started its operation in December of 1961 and is since used for research and teaching at Rensselaer Polytechnic Institute (RPI). The laboratory and LINAC were designed and built in order to perform time-of-flight (TOF) measurements in the neutron energy range from thermal to 20 MeV. As such, it is a pulsed L band electron LINAC capable of delivering up to 100 MeV electrons at a repetition rate of up to 500 Hz and a pulse width that can vary from 5 ns to 5 μ s with up to 10 kW of average electron beam power.

The facility is equipped with several flight paths ranging from 15 to 250 m which enables measurements in a broad energy range and high energy resolution. In addition, it is equipped with a lead slowing-down spectrometer (LSDS) which provides a high neutron flux utilized for fission and (n, α) cross section measurements of small samples (< μ g) or samples with small cross sections (< μ b). A layout of the facility is shown in  Fig. 2.

Neutrons are produced by interaction of the electrons with a water- (or air-) cooled tantalum target which produces a high Bremsstrahlung flux that interacts with the tantalum to produce neutrons with an evaporation energy spectrum. Different neutron targets were constructed to produce tailored flux shapes for the different experiments (Danon et al. 1995; Overberg et al. 1999).

 Figure 2

Layout of the RPI LINAC and beam ports and detectors

■ Figure 3

A picture of a modular neutron detector for neutron transmission measurement at a TOF path length of 100 m

For transmission measurements in the neutron energy range from thermal to a few hundreds of keV, ^6Li -glass detectors are utilized (Barry 2003) at flight paths of 15, 25, 31, and 100 m. At the 100 m flight station, a modular ^6Li -glass detector shown in [Fig. 3](#) was installed to enable high energy resolution transmission measurements. In order to improve the detector resolution the design employs photomultipliers outside the neutron beam which reduces neutron scattering back to the ^6Li -glass. For measurements of neutrons with energies above 0.4 MeV a modular liquid scintillator is utilized at 100 m or 250 m flight path (Rapp et al. 2009). An example of Mo total cross section data measured with the liquid scintillator detector positioned at 100 m is shown in [Fig. 4](#).

A 16-section NaI multiplicity detector (Block et al. 1988) is used on one of the flight paths at about 25 m. Capture, scattering, and fission data are obtained as a function of the total energy deposited in the detector and the number of NaI segments which detect each event. Scattering events are detected from neutron interactions with a ceramic $^{10}\text{B}_4\text{C}$ liner surrounding the sample. The 477 keV gammas from ^{10}B ($n, \alpha\gamma$) interactions are used to provide a distinct signature of neutron scattering into the liner. [Figure 5](#) shows an example of natural Hf capture and transmission data obtained with this detector and a ^6Li -glass detector at 25 m (Trbovich et al. 2009).

A fast-neutron scattering detector system was installed at a 30 m flight path. The system includes eight liquid scintillator detectors surrounding a sample with a digital data acquisition system capable of pulse shape analysis to separate neutron from gamma events and has 1 ns TOF resolution (Saglione et al. 2006). Measurements with this system serve as benchmark data to qualify cross section libraries by simulation of the whole experimental setup (Saglione et al. 2009).

■ Figure 4

Transmission of 8 cm natural Mo sample and evaluated data. Left – showing cross section structure at the low energy range. Right – showing the high energy range

■ Figure 5

An example of ^{nat}Hf transmission (*top*) and capture (*lower*) data measured, respectively, with the ^6Li -glass and multiplicity detectors (Trbovich et al. 2009). Note that the results of four transmission and four capture measurements have been simultaneously fitted with one set of resonance parameters

A lead slowing-down spectrometer driven by the LINAC provides a neutron flux intensity which is about 3 orders of magnitude higher than a TOF experiment with a flight path producing an equivalent energy-time relation (5.6 m). The resolution of the spectrometer is about 35% (FWHM) in the energy range from 1 eV to 20 keV. Measurements with the LSDS include fission cross sections of small samples (< 1 μg) for actinides such as ^{254}Es , ^{250}Cf and ^{245}Cm (Danon et al. 1991). Recently the LSDS was used for neutron energy dependent fission fragment spectroscopy and demonstrated the method for ^{235}U and ^{239}Pu samples (Romano et al. 2008). In addition methods were developed for (n,α) and (n,p) measurement of samples with small cross sections and the (n,α) cross section of $^{147,149}\text{Sm}$ isotopes were successfully measured.

The large target room and flexibility of the facility were used to develop methods for high accuracy transmission measurements using an iron filtered beam (Danon et al. 2009a), and neutron resonance scattering to provide benchmark data for scattering kernel development (Danon et al. 2009b).

3.1.2 The Los Alamos Neutron Science Center

The Los Alamos Neutron Science Center (LANSCE) at the Los Alamos National Laboratory features three separate neutron sources that are used for nuclear data measurements. All are driven by 800 MeV protons from a linear accelerator, which bombard tungsten targets of different designs. The resulting spallation spectrum of neutrons is similar to a fission neutron spectrum with a high energy tail that extends in principle to 800 MeV and, in practice, has been used up to 600 MeV. This spectrum can be moderated to lower neutron energies by water or liquid hydrogen moderators (Lujan Neutron Scattering Center (MLNSC) facility), taken directly (WNR facility), or slowly moderated by an assembly of pure lead (lead slowing-down spectrometer). The beam lines and detector stations are shown in  Fig. 6.

The Lujan facility at LANSCE (LANSCE-MLNSC) provides white sources of neutrons based on a moderated spallation source (Mocko et al. 2008). The 800 MeV proton beam from the linac, which is several hundred microseconds long, is compressed by a proton storage ring into a 135 ns (FWHM) bunch and then is directed to a two-stage tungsten target. Spallation neutrons are moderated by water or liquid hydrogen moderators. The target-moderator-reflector system (TMRS) includes neutron reflectors to increase the neutron flux in the flight paths. The repetition rate of the source is 20 Hz with 3.7×10^{13} protons per burst, making approximately 1.4×10^{16} neutrons per second. Of the 16 flight paths, 3 are used for nuclear reaction experiments including neutron capture, fission, and fundamental neutron properties. The neutron energies span the range of cold neutrons (a few milli-electron volts) to several hundred keV. The detector for advanced neutron capture experiments (DANCE) is a nearly 4π highly-segmented calorimeter of BaF₂ scintillators with very high efficiency that permits neutron capture cross section measurements on samples of 1 mg or less (Jandel et al. 2008). Fission experiments are carried out on another flight path with parallel-plate ionization chambers.

The Weapons Neutron Research (LANSCE-WNR) facility is based on micropulses from the linear accelerator providing bunched 800 MeV proton bursts on a bare tungsten target. The macrostructure of the proton beam consists of trains of micropulses, approximately 625 μs long, with a macropulse frequency of 40 Hz. Internal to the macropulse are micropulses of up to 8×10^8 protons with spacings adjustable in units of 180 ns. Common micropulse spacings are 1.8 and 3.6 μs. The proton micropulse width is approximately 0.2 ns and therefore allows

Figure 6

The beam lines and detector stations at the Los Alamos LANSCE facility

high-energy experiments with excellent timing. The unmoderated spallation neutrons are collimated in six flight paths with production angles from 15° to 90° . Experimental stations at flight paths of 8–90 m are set up for high-resolution gamma-ray detection (GEANIE array with 26 HPGe detectors), neutron emission (FIGARO array with 20 liquid scintillation neutron detectors), charged-particle emission (NZ with four charged-particle telescopes), medium-energy few-nucleon research, long-flight path experiments, industrial irradiations of electronic components (ICEHOUSE), and fission cross section measurements. A representative measurement is shown in Fig. 7 for the ratio of the ^{237}Np to ^{235}U fission cross sections. Detailed information on the beams and research is given on the LANSCE web site and references (Tovesson et al. 2009; Bernstein et al. 2002; Rochman et al. 2004).

A lead slowing-down spectrometer is used for high neutron flux experiments. It is driven by the proton beam, either the micropulse beam usually used at WNR or the beam from the proton storage ring. The beam hits a tungsten target at the center of a 20-ton cube of pure lead, 1.2 m on a side. Materials and detectors are placed in channels in the cube and are subjected to very large fluxes of neutrons for cross section measurements as functions of neutron energy. The reaction rate is measured as a function of time, which can be converted into average neutron energy in the range 0.1 eV–100 keV. The conversion is equivalent to a time-of-flight experiment with a flight path of 6.2 m. The trade-off for this approach is that the energy resolution is only about 30% (FWHM) in $\Delta E/E$ (Rochman et al. 2005). With the very large neutron flux, cross sections have been measured with samples less than 10 ng.

3.1.3 The ORELA Laboratory at Oak Ridge National Laboratory

The Oak Ridge electron linear accelerator (ORELA) is a high power, high resolution, and highly versatile white neutron source (Dabbs 1979). Over the course of the last 30 years, ORELA

Figure 7

Ratio of fission cross section for ^{237}Np to that of ^{235}U over 10 orders of magnitude in neutron energy from data taken at LANSCCE (Tovesson and Hill 2007, 2008). The experimental values are compared with data in the JENDL3.3 and ENDF/B-VI libraries and were used to improve the data for ^{237}Np in the new ENDF/B-VII library

experiments have contributed the majority of neutron nuclear data that are used for applied and basic nuclear physics programs around the world such as nuclear criticality safety, nuclear reactor physics, neutron shielding, nuclear medicine, and nuclear astrophysics.

ORELA consists of a 180 MeV electron linear accelerator, neutron producing targets, underground and evacuated flight tubes, sophisticated detectors, and data acquisition systems. Simultaneous measurements are possible at 18 detector stations on 10 separate flight paths at distances between 9 and 200 m from the neutron source. An artist's view of the laboratory is shown in [Fig. 8](#).

Neutron capture, (n,γ) , measurements routinely are performed using a pair of deuterated benzene scintillation detectors on flight path 7 at the 40-m station. Improvement in this apparatus over the last few years has resulted in substantially reduced background from scattered neutrons and ORELA measurements with this new system have demonstrated that previous (n,γ) cross-sections are in error, sometimes substantially, due to this effect (see [Fig. 9](#)).

Total cross section measurements can be performed with an NE-110 plastic (above 100 keV) or ^6Li glass (below 100 keV) scintillator. The sample can be cooled to 10 K to significantly improve the resolution of closely spaced resonances by reducing the Doppler broadening as shown in [Fig. 10](#). Fission measurements have been performed using a variety of ionization chambers, such as a small hemispherical ion chamber for high alpha-activity rejection.

A new type of detector, called a compensated ion chamber, was pioneered at ORELA and made possible the first measurements of (n,α) cross sections on intermediate- to heavy-mass nuclides at astrophysical relevant energies. These data demonstrated that the latest nuclear models used to calculate astrophysical (α,γ) and (α,p) reaction rates for explosive nucleosynthesis studies are in need of serious revision.

3.1.4 GELINA at the JRC-IRMM in Geel

The neutron time-of-flight facility GELINA (Geel Linear Electron Accelerator) of the European Commission's Joint Research Center IRMM in Geel, Belgium, has been operational for more

Figure 8

Figure 9

Comparison of the ENDF/B-VI and recent ORELA ^{28}Si capture cross section from 50 to 75 keV (Guber et al. 2005). Due to the neutron sensitivity of the experimental set up the previous $^{28}\text{Si}(n,\gamma)$ experiments (on which ENDF/B-VI is based) seriously overestimated the capture cross section

Figure 10

Comparison of recent ORELA measurements with previous ^{233}U total cross sections. Using a cryogenically cooled sample significantly improved the resolution

than 30 years. Neutron-induced reaction data have been measured for a variety of applications related to nuclear technology and nuclear science.

The facility is based on an electron LINAC providing a pulsed electron beam of 100 MeV average energy and a typical power of 10 kW, impinging on a rotating uranium target cooled by a flow of mercury. Typical operation frequencies range from 40 to 800 Hz. The initial electron burst, consisting of a train of micropulses with energies from 70 to 140 MeV, is compressed by a

Figure 11
A schematic view of the neutron beam lines of GELINA

post-acceleration 360° bending magnet system to a bunch of less than 1 ns FWHM, preserving the average current. The Bremsstrahlung induced in the uranium target by the electron beam produces neutrons by (γ, n) and (γ, f) reactions. The neutron distribution emitted by the uranium target has a typical fission-evaporation spectrum peaked at around 1 MeV with a small intensity of low-energy neutrons.

Two moderators consisting of slabs of 4 cm thick water canned in beryllium are placed under and above the uranium target. They modify this fast spectrum to a partial moderated spectrum containing a Maxwellian peak at thermal energies and an approximate $1/E$ energy dependence at higher energies. At 800 Hz the average neutron production rate at the source is 3.4×10^{13} neutrons/s.

Twelve neutron flight paths leading to experimental stations at distances from 5 to 400 m depart from the neutron source under angles which are multiples of 9° , as is shown in [Fig. 11](#). Each flight path can be shielded either from the uranium neutron production target or from the water moderators by 30 cm long shadow bars consisting of lead and copper, in order to obtain a fast or moderated neutron spectrum. More details on the facility can be found, for example, in Tronc et al. (1985) and Flaska et al. (2004).

The experimental stations are equipped with measurement setups for neutron capture with Ge, BGO, or low neutron-sensitive C_6D_6 detectors in combination with the weighting function technique (Borella et al. 2007a; Schut et al. 2008), for transmission experiments using ${}^6\text{Li}$ -glass detectors (Kopecky and Brusegan 2006, Borella et al. 2007b), for fission measurements with dedicated fission chambers (Wagemans et al. 2008), and for $(n, xn\gamma)$ measurements HPGe detectors (Mihailescu et al. 2008) and other experiments.

In [Fig. 12](#) an example of a neutron capture and transmission experiment on an enriched ${}^{206}\text{Pb}$ sample is shown in the left panel. The capture yield shows the measured yield, the background contribution, and the measured scattered neutron contribution. The transmission factor and a zoom on the 66 keV s -wave resonance are shown in the right panel. Resonance parameters were obtained by a simultaneous analysis of the capture and transmission data (Borella et al. 2007b).

3.1.5 The n_TOF Facility at CERN

The construction and commissioning of the neutron time-of-flight facility at CERN, Switzerland, after an initial proposal (Rubbia et al. 1998), was finished in 2001 when the facility became operational.

Figure 12

The neutron capture yield spectrum of ^{206}Pb (left panel), together with the transmission factor (right panel), both measured at GELINA (Data are from Borella et al. 2007b)

The facility uses a 6 ns wide, 20 GeV/c proton beam with up to 7×10^{12} protons per pulse hitting a lead target, yielding about 300 neutrons per incident proton. A water slab surrounding the target serves as coolant and as moderator. At present a single flight path is available with an experimental station located at 185 m. A 1.5 T sweeping magnet is placed at a distance of 145 m from the spallation target to remove residual charged particles. One collimator with an inner diameter of 11 cm is placed at 135 m while a second collimator with a variable diameter of either 1.8 cm or 8 cm is situated at 175 m from the production target. The main elements of the neutron beam line are shown in Fig. 13. The repetition period of the proton pulses from CERN's PS accelerator is a multiple of 1.2 s, which allows to cover the energy range down to subthermal energies without overlapping of slow neutrons in subsequent cycles. A full description of the characteristics and performances of the facility is described elsewhere (Abbondanno et al. 2003). The facility is mainly used for capture and fission measurements. The energy distribution of the incident neutron flux is continuously measured during the experiments with an in-beam neutron flux detector (Marrone et al. 2004). The spatial distribution has been obtained with a MicroMegas-based detector (Pancin et al. 2004). The developed data acquisition system

Figure 13

A schematic view of the neutron beam line of n_{TOF} at CERN

(Abbondanno et al. 2005) uses sampling of the detector signals in order to extract the deposited energy and the time of flight.

In-house developed deuterated benzene C_6D_6 gamma-ray detectors contained in a cylindrical low mass carbon fibre housing (Plag et al. 2003) have been used for neutron capture measurements. Samples are kept in position by a carbon fiber sample changer. The low neutron capture cross sections of both carbon and deuterium assure a low contribution to the background from sample scattered neutrons. Since this detector does not measure the full gamma-ray cascade following neutron capture, it requires the use of weighting functions to reconstruct the neutron capture yield (Abbondanno et al. 2004; Borella et al. 2007a). Although the detection efficiency for a single detector is only about 3% for a 1 MeV gamma-ray, due to the gamma-ray multiplicity after neutron capture, in the order of 3–4 for medium and high mass nuclei, the efficiency to detect capture event is roughly 20% for the set of two detectors.

A second neutron capture detection system consists of a 4π 100% efficiency total absorption capture detector, made up of 40 BaF_2 crystals contained in ^{10}B loaded carbon fiber capsules, coupled to XP4512B photomultipliers equipped with (for this purpose) especially designed voltage dividers. Samples are surrounded by a $C_{12}H_{20}O_4(^6Li)_2$ neutron absorber which moderates and absorbs sample scattered neutrons.

Fission experiments have been performed with two different detector systems. Two fission ionization chambers (FIC) use deposits of fissile isotopes on 100 μm thick aluminum foils. The FIC-0 detector was used for the low activity samples while the FIC-1 detector was used for the samples with higher activity (Calviani et al. 2008, 2009).

As an example the $^{233}U(n,f)$ cross section measured at n_TOF with the FIC detector is shown (Calviani et al. 2009) in  Fig. 14. In  Fig. 15 the neutron capture spectrum of ^{232}Th measured with the optimized C_6D_6 gamma-ray detectors is shown (n_TOF Collaboration 2009).

The second type of fission detector is based on parallel plate avalanche counters (PPACs), developed with target deposits on 1.5 μm thin mylar or 2 μm aluminum foils, allowing to detect the two fission fragments in coincidence (Paradela et al. 2009).

 Figure 14

Part of the measured $^{233}U(n,f)$ cross section at n_TOF at CERN (Data from Calviani et al. 2009)

■ Figure 15

The count rate spectrum of the $^{232}\text{Th}(n,\gamma)$ reaction and the calculated background contribution from sample scattered neutrons. For comparison also the contribution of the natural radioactivity of ^{232}Th is shown (Data are from n_TOF Collaboration 2009)

The facility has been operating from 2000 to 2004 (phase-I) with neutron capture and fission measurements and was upgraded in 2008 with a new spallation target (phase-II). Future plans include the construction of a short flight path (phase-III).

3.1.6 The IREN Facility at Dubna

The pulsed neutron source research complex IREN is a new facility which will be realized in several stages. Eventually, the facility will comprise a 200 MeV electron linac delivering 10 kW beam power, and impinging on a tungsten electron-neutron converter located in the center of a subcritical neutron multiplying target. This target will consist of about 24 kg of highly enriched (more than 95% ^{239}Pu) metallic plutonium, resulting in a neutron yield of 10^{15} n/s and a pulse width of 600 ns.

These are target values that will be achieved gradually. By the middle of 2009 a 30 MeV electron linac together with a non-multiplying tungsten target had been put in operation, making the installation ready in the first stage for high resolution neutron spectroscopy experiments in the energy range up to several 100s of keV. Planned experiments are foreseen in the field of nuclear astrophysics, nuclear data, nuclear structure and fundamental symmetries, as well as neutron and gamma activation analysis and medical radioactive isotope production. The neutron source parameters of this first stage have been included in ► Table 1.

The neutron source has replaced the phased-out facility IBR-30, which was also an accelerator-driven subcritical assembly. IREN uses the existing flight path infrastructure of eight neutron beams with lengths from 10 to 1,000 m. In ► Fig. 16 a schematic view of the future subcritical core is shown.

An example of a measurement of the first stage is the $^{181}\text{Ta}(n,\gamma)$ reaction with both the IBR-30 and IREN neutron source, shown in ► Fig. 17, measured with a six times 351 segmented liquid scintillator detector located at the 60 m flight path.

■ Figure 16

A schematic view of the IREN facility (left panel) and its subcritical core (right panel) (Figure from Ananiev et al. 2005)

3.1.7 The PNF Laboratory at Pohang

The Pohang neutron facility (PNF) (Kim et al. 2002; Wang et al. 2008) consists of a 100 MeV electron linac, a water-cooled Ta target, and an 11-m long TOF path which has recently been set up in Pohang, Korea. The maximum electron energy for TOF measurements is 75 MeV, and the measured peak beam currents at the entrance of the first accelerating structure and at the end of linac are 100 and 50 mA, respectively. The duration of electron beam pulses are 1–2 μ s, and the pulse repetition rate is 12 Hz. The measured energy spread is $\pm 1\%$ at its minimum. The energy spread is reduced when optimizing the RF phase of the RF-gun and the magnetic field strength of the alpha magnet.

The neutron target is water cooled and composed of ten 4.9-cm diameter Ta disks with different thickness and a total Ta thickness of 7.4 cm. This target is set at the center of a cylindrical water moderator contained in an aluminum cylinder with a diameter of 30 cm and a height of 30 cm. The distributions of neutrons with and without water moderator are described elsewhere. The photoneutrons produced in the giant dipole resonance region consist of a large number of evaporated neutrons and a small fraction of directly emitted neutrons, which dominate at higher energies. The MCNP calculated neutron yield per kW of beam power for electron energies above 60 MeV at the Ta target is 1.91×10^{12} n/s (Nguyen et al. 2006), which is consistent with the calculated value based on Swanson's formula, $1.21 \times 10^{11} Z^{0.66}$, where Z is the atomic

Figure 17

Example of a measurement of the $^{181}\text{Ta}(n,\gamma)$ neutron capture reaction performed during the commissioning phase in 2009 with a six times 35 l segmented liquid scintillator detector located at the 60 m flight path using both the IBR-30 (lower panel) and IREN (upper panel) neutron source (Data from Belikov et al. 2010)

number of the target material. The total neutron yield per kW of beam power is measured to be $(2.30 \pm 0.28) \times 10^{12}$ n/s by using the multiple-foil activation technique.

Neutron flight tubes are constructed of stainless steel and placed perpendicularly to the electron beam. The collimation system is mainly composed of H_3BO_3 , Pb, and Fe collimators. Transmission measurements are made with a $^6\text{Li-ZnS}(\text{Ag})$ scintillator (BC702) with a diameter of 12.5 cm and a thickness of 1.6 cm . A typical TOF spectrum is shown in Fig. 18 where the upper curve is with no sample in the beam and the black curve has Co, In and Cd in the beam to determine the background at strong resonances.

A large volume bismuth germanate ($\text{Bi}_4\text{Ge}_3\text{O}_{12}$; BGO) detector is under construction for the measurement of neutron capture cross sections. This detector is an assembly of BGO bricks and will have a total volume of 2.25 l .

3.1.8 Electron Linac at Kyoto University Research Reactor Institute, KURRI

The electron linear accelerator (KURRI-LINAC) at the Kyoto University Research Institute in Kumatori, Japan, was installed in 1965 as a 23 MeV machine and subsequently upgraded to 46 MeV . The accelerator operates at L-band ($1,300\text{ MHz}$) and provides electron pulse widths from 2 ns to $4\text{ }\mu\text{s}$. The research covers a wide range of neutron measurements using the TOF

■ Figure 18

Background level determination with Co, In, and Cd samples in the beam at Pohang. The background was determined by fitting to the counts at the blacked-out resonances produced by these samples

method. Currently two flight paths are used for TOF experiments with detector stations at 10.0, 12.7, and 24.2 m. In particular, neutron capture measurements are made with a 4π total absorption BGO spectrometer, another BGO detector, a C_6D_6 liquid scintillation detector and a 4π Ge spectrometer (on loan from JAEA) (Kobayashi et al. 2002; Shcherbakov et al. 2005; Kobayashi et al. 2004; Hori et al. 2008).

► Figure 19 shows the BGO total absorption spectrometer where 12 blocks of BGO surround a ${}^6\text{LiF}$ shielded capture sample and ► Fig. 20 shows a measurement of the ${}^{127}\text{I}$ capture

3.2 Monoenergetic Fast Neutron Facilities

Cross section measurements in the energy range 10 keV to many MeV are frequently carried out with light-ion-induced nuclear reactions that lead to monoenergetic or quasi-monoenergetic neutrons. Typically, a source reaction is chosen to produce neutrons of one energy (with a small energy spread), and these neutrons can either be continuous in time or pulsed. For the latter type of source, TOF techniques can be used to reject parasitic neutrons of other energies. TOF is also commonly used in neutron scattering and neutron-emission measurements where the energy of the outgoing neutron is determined by the flight time from the sample to the detector. Data on the neutron source reactions are available from the International Atomic Energy Agency (IAEA) (Drosg 2005).

Many low energy accelerator facilities have produced monoenergetic neutron cross section data over the past 70 years. Although several of these facilities are no longer operational, some are still very productive. Facilities that specialize in TOF measurements typically have special capabilities including pulsed beams with time spreads approaching 1 ns and flexible pulse spacing. Most facilities feature relatively high beam currents in order to produce usable neutron fluxes, neutron-production targets that can withstand the high beam current, gas production targets with pressures of several atmospheres of ²H₂ or ³H₂, ⁷Li, ⁹Be targets, and experimental areas that have low-mass floors and large target rooms to minimize room back-scattering into the sample or the detectors. The available accelerator beams and beam energies determine the range of neutron energies. Unique detector capabilities at certain facilities give them a special status. Here, we give examples of facilities that are optimized for monoenergetic measurements with neutrons in the 10s and 100s of keV range, others in the range 1–26 MeV, specialized 14-MeV neutron facilities, and sources that produce neutrons in the 20–200 MeV range. A selection of monoenergetic neutron source facilities is given in [Table 2](#). Examples are given of measurements performed in this wide energy range.

3.2.1 Neutron Energies Below 1 MeV

Neutron capture reactions have been studied extensively in the keV region at the Van de Graaff laboratories at the Forschungszentrum Karlsruhe (FZK) and in Japan at the Tokyo Institute of

Technology and the Japan Atomic Energy Agency laboratory in Tokai. All of these facilities use the ${}^7\text{Li}(p,n)$ reaction with proton beams in the 1.8–4 MeV range to produce monoenergetic neutrons in the range 1 keV–2 MeV. Pulsed beams of ≈ 1 ns width can be used with TOF techniques to separate neutrons from gamma rays produced at the source. Although the FZK facility is no longer operational, an upgraded facility at the Goethe University, Frankfurt, Germany, is expected to begin operation soon with neutron fluxes increased by 2–3 orders of magnitude relative to the FZK flux.

Neutron capture is detected by a single, well-shielded NaI(Tl) gamma-ray detector at Tokyo, (Igashira et al. 1986), (● Fig. 23) and by a 4π calorimeter of BaF₂ crystal scintillators at Karlsruhe (● Fig. 24) (Wisshak et al. 1990). The former is used to measure discrete high energy gamma rays whereas the latter detects the full energy of the gamma-ray cascade, which is the Q -value of the capture plus the incident neutron energy in the center of mass, a specificity that can help distinguish capture in the sample from background captures in other materials. TOF techniques can be used to deduce the capture cross section or capture-to-fission ratio as a function of neutron energy, for example, (Beer and Kappeler 1979) and (Wisshak et al. 2004).

For activation experiments, a neutron continuum spectrum approximating a Maxwellian spectrum with $kT \approx 25$ keV can be produced with the ${}^7\text{Li}(p,n)$ reaction with 1.911 MeV protons on a stopping lithium target (Beer and Kappeler 1980). This approach has been used in favorable cases to measure the neutron capture cross section for radioactive isotopes such as ${}^{155}\text{Eu}$ (Jaag and Kappeler 1995). This particular temperature for the Maxwellian is of importance in understanding s -process nucleosynthesis in stars.

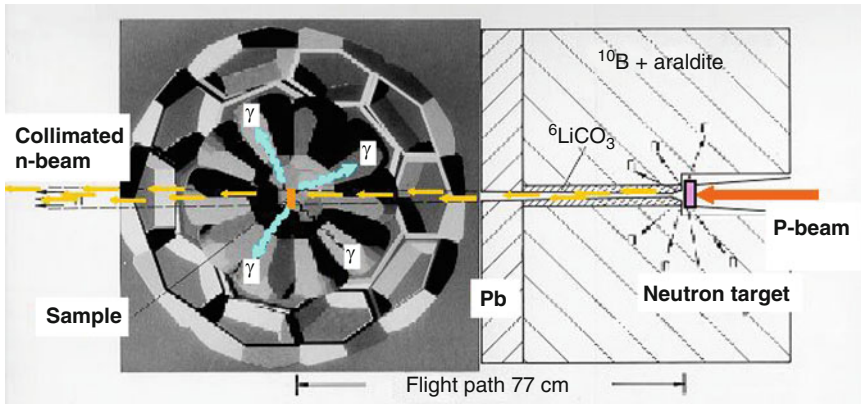

Figure 24

Calorimetric array of BaF_2 scintillators at Karlsruhe covering close to the full 4π solid angle. Neutrons produced by the ${}^7\text{Li}(p,n)$ reaction are incident on a sample in the middle of the array and the cascade of gamma rays following neutron capture is detected by the scintillators (Wisshak et al. 1990)

3.2.2 Neutron Energies in the MeV Region

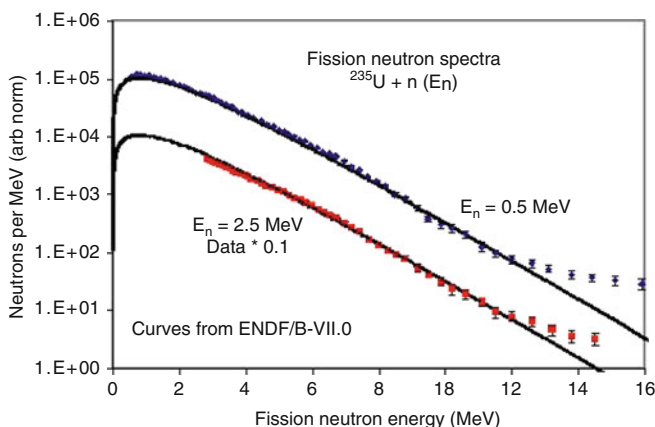

At the University of Kentucky, a vertical electrostatic accelerator, extensively rebuilt from its original Van de Graaff accelerator, provides beams of protons, deuterons, ${}^3\text{He}$ ions, and ${}^4\text{He}$ ions from 0.5 to 7 MeV. Neutron fluxes are provided by the ${}^3\text{H}(p,n){}^3\text{He}$ reaction from 0.5 to 5 MeV, by the ${}^7\text{Li}(p,n){}^7\text{Be}$ reaction from 0.05 keV to 0.5 MeV, by the ${}^2\text{H}(d,n){}^3\text{He}$ reaction from 5 to 9.5 MeV, and from 15 to 20 MeV by the ${}^3\text{H}(d,n){}^4\text{He}$ reaction. The Van de Graaff accelerator terminal provides continuous beams, those pulsed to 10 ns, and pulsed and bunched beams of 1 ns burst width at a repetition rate of 1.875 MHz. Almost all neutron-induced reactions have been done with ≈ 1 ns pulsed and bunched beams. For neutron-detection experiments, a post-acceleration buncher provides sub-nanosecond pulses. Most neutron experiments take place in a “neutron hall,” with a thin metal floor above a pit of 1.5 m depth, and an area $9.7\text{ m} \times 9.7\text{ m}$. Shielded detectors for pulsed-beam neutron detection are used for TOF detection with flight paths up to 4 m. Gamma-ray detection usually uses shorter flight paths of about 1.2 m. Gamma-ray detection is available with HPGe detectors, actively shielded with BGO annulus detectors. The whole assembly is housed in a large shield. A variety of liquid scintillation neutron detectors is available with diameters of 5.1 cm or 11.4 cm and thickness from 1.2 to 12.5 cm. Four large HPGe detectors are housed in a coincidence array (KEGS) for gamma-gamma correlation experiments. An example of inelastic scattering cross section data is shown in Fig. 25 where the excitation of specific levels as a function of incident neutron energy was determined by detecting their gamma-ray decay (Lesher et al. 2007). Analysis of the Doppler shift of the gamma rays gives information on the lifetimes of the states.

Another single-end Van de Graaff used for neutron research is at the University of Massachusetts Lowell Radiation Laboratory. A typical neutron source is produced by the ${}^7\text{Li}(p,n)$ reaction with a tightly bunched proton beam with a maximum energy of 5.5 MeV. Neutron emission is measured with this facility, an example being the spectrum of neutrons emitted

■ Figure 25

Data for the level at 2735.98 keV in ^{96}Mo are compared with statistical model calculations for three different spin possibilities. These data are from the University of Kentucky. The best fit for this level is $J = 3$ (Leshner et al. 2007)

■ Figure 26

in the fission of actinides. ➤ Figure 26 gives a result for the neutron emission spectra from neutron-induced fission of ^{235}U (Staples et al. 1995).

In the European Union, high intensity quasi mono-energetic neutron sources are produced at the Institute for Reference Materials and Measurements (IRMM) at Geel, Belgium, by a vertical 7 MV Van de Graaff accelerator with either continuous or pulsed ion beams (Reimer et al. 2009; Semkova and Plompen 2007). The installation has two pulsing systems: (1) a fast beam pulsing generating a minimum ion beam pulse width of 2 ns and pulse repetition rates of 2.5, 1.25 or 0.625 MHz, and (2) a slow pulsing system giving a minimum pulsing width of 10 μs at an

Figure 27

Cross sections for the $^{241}\text{Am}(n,2n)^{240}\text{Am}$ reaction with recent data from the VdG Geel (from Sage et al. 2009)

adjustable frequency up to 5 kHz. Neutron fields that have well-defined energies are produced by the nuclear reactions $^7\text{Li}(p,n)$, $^3\text{H}(p,n)$, $^2\text{H}(d,n)$ or $^3\text{H}(d,n)$ giving neutrons within the energy regions 0.3 to 10.0 MeV and 14.5 to 24 MeV. This facility houses six experimental set-ups in two large laboratory halls. In addition to TOF experiments, many neutron activation experiments have been carried out. An example of activation cross section results is shown in Fig. 27 for the $^{241}\text{Am}(n,2n)^{240}\text{Am}$ reaction (Sage et al. 2009).

At Ohio University, a high current tandem Van de Graaff accelerator with a terminal voltage up to 4.5 MV accelerates hydrogen ions to 9.0 MeV and other ions to higher energies. Beams of protons, deuterons, ^3He , ^4He , ^6Li , ^7Li , ^9Be , ^{10}B , ^{11}B , ^{12}C , and ^{13}C are produced. A central focus of the laboratory is neutron physics, and a pulsing and bunching system is available to produce beams of about 1 ns width for protons and deuterons, and 2.5–4 ns width for Li through O. A particularly important piece of experimental equipment is a “beam swinger,” which allows the beam incident on a target to be rotated through a range of angles (Finlay et al. 1982). One flight path with length of 4 to 30 m is used with the swinger to investigate neutron scattering from 0° to 160° . The laboratory is equipped with gas cell target assemblies that can be used with $^2\text{H}_2$ or $^3\text{H}_2$ gas. Solid targets containing tritium are also available. Efficiency calibrations of neutron detectors can be carried out with a ^{252}Cf source or with previously measured spectra from deuteron bombardment of stopping targets of B or Al (Massey et al. 1998; Di Lullo et al. 2008). This facility (Fig. 28) has been used for neutron elastic and inelastic scattering studies. An example of the angular distribution of elastic scattering of neutrons is shown in Fig. 29. The data from this facility have greatly improved the understanding of the neutron-nucleus optical model.

Somewhat higher neutron energies are provided by the Triangle Universities’ 10 MV FN tandem Van de Graaff accelerator at Duke University. It is equipped with a variety of ion sources,

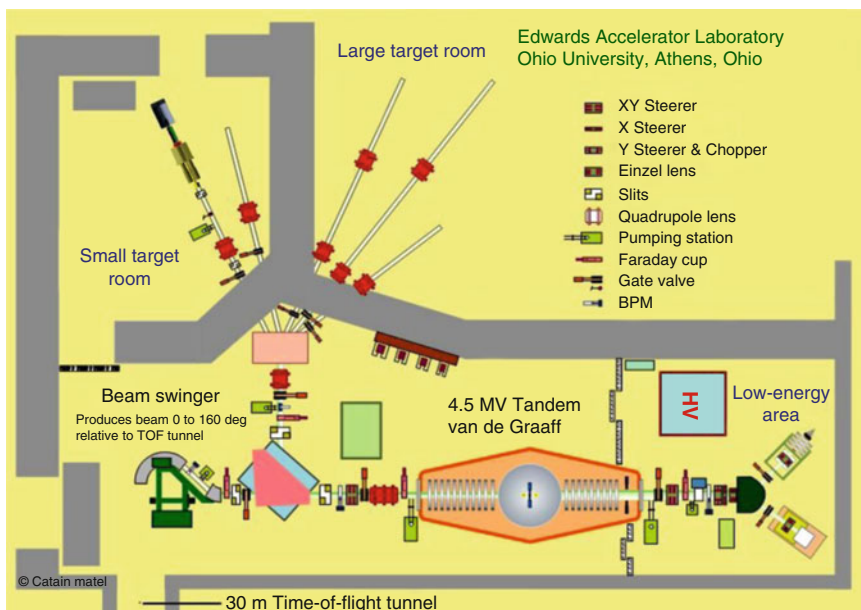

Figure 28

Schematic layout of the Ohio University Tandem Van de Graaff facility showing the accelerator, the beam swinger, the 30-m time-of-flight tunnel and other beam lines

beam lines, and target stations. The associated polarized ion source is the most intense source of dc polarized H^+ and D^+ ions in the world. Unpolarized beams of protons and deuterons are available from a direct-extraction negative-ion source. These beams are being used in a wide range of nuclear reaction studies including few-body reactions, radiative capture, and polarized neutron induced reactions. An example of neutron scattering from ${}^6\text{Li}$ is given in [Fig. 30](#) (Hogue et al. 1979).

At the Physikalisch-Technische Bundesanstalt (PTB) standards laboratory in Braunschweig, Germany, a cyclotron is used to produce standard neutron fields and to make basic cross section measurements of activation and differential scattering. High current beams of protons up to 19 MeV, deuteron beams up to 13.5 MeV and alpha particles up to 28 MeV are produced here. This very well characterized facility is unique in that the cyclotron is moved around the scattering sample in order to change the set of scattering angles ([Fig. 31](#)) (Mannhart and Schmidt 2002; Schmidt 2008).

A high-energy tandem Van de Graaff with a terminal voltage up to 13 MV is used at the Chinese Institute of Atomic Energy in Beijing, China. A multi-detector array of liquid scintillators detects the scattered neutrons. Another approach, the so-called “abnormal” TOF spectrometer is used to overcome difficulties of source breakup neutron interference in the ${}^2\text{H}(d,n)$ reaction in the 8–13 MeV region (Schmidt et al. 2005). In the latter, the neutrons are collimated to a narrow beam and the scattering sample is placed approximately 2 m from the source. Detectors for the scattered neutrons are located 50–100 cm from the sample. In this method, neutron emission from the sample can be studied down to 1 MeV in the emitted neutron energies.

Figure 29

Elastic differential cross section for neutron scattering from ^{54}Fe at three incident energies taken at Ohio University compared with phenomenological optical model fits (Mellema et al. 1983)

3.2.3 Neutron Energies Near 14 MeV

A special neutron energy is 14 MeV, where neutrons can be produced with high intensity by the $^3\text{H}(d,n)^4\text{He}$ reaction which has a large cross section near the wide resonance just above 100 keV and which is, therefore, accessible to low energy deuteron accelerators. This 14 MeV source reaction (also called a D-T source reaction for deuterons plus tritons) is also the most favorable for fusion energy, and therefore data at this energy are very important for those applications. Many laboratories, both small and large, have used 14 MeV neutrons for cross section measurements. An example is the Octavian facility at Osaka University and one type of measurement made there is neutron emission spectra and angular distributions (Fig. 32). Other types of measurements made at laboratories of this type are neutron activation (of importance to waste disposal for fusion reactors), hydrogen and helium production (important for radiation damage of structural materials), standard cross section measurements, and integral tests of neutron transport, such as the pulsed sphere measurements carried out at several laboratories (Hansen et al. 1980).

Figure 30

Angular distribution of elastic scattering of neutrons from ${}^6\text{Li}$ (Hogue et al. 1979). The data are from the Triangle Universities Nuclear Laboratory

For much higher neutron-production rates, rotating tritium-loaded targets are used to handle beam currents on the order of 10s or even 100 mA. Present facilities at the Japan Atomic Energy Agency (fast neutron source – FNS) can produce 14-MeV neutron fluxes well in excess of 10^{12} n/cm²/s for samples close to the source.

With a source of very high intensity, neutrons can be collimated in very narrow beams, sometimes called “pencil beams,” and still retain enough intensity for cross section measurements. The advantages of this approach are described in Kondo et al. (2006).

One special technique, referred to as “neutron-tagging” or “associated-particle” technique, is particularly appropriate for D-T neutron sources when the number of neutrons incident on a sample needs to be known precisely. The reaction at low incident neutron energy produces an alpha particle in addition to the neutron, and the two are correlated in angle by two-body kinematics. The alpha particle is usually detected at a back angle and the direction of the associated

■ Figure 31

Cyclotron and time-of-flight paths for neutron scattering experiments at PTB. Note that the cyclotron can be moved to change the set of scattering angles

neutron is known exactly, to within the angular resolution of the alpha particle detector. This technique is used to measure cross sections without the need to refer to another, so-called “standard,” reaction cross section. This technique is not limited to the D-T reaction and 14 MeV neutrons but other reactions, such as ${}^2\text{H}(d,n){}^3\text{He}$ also provide an associated charged particle in addition to the neutron. This technique is not used much at present due to the improvements in “standard” cross sections, but it is still very useful when very precise neutron detector calibrations or absolute cross section measurements are desired.

3.2.4 Neutron Energies Above 30 MeV

The Svedberg Laboratory (TSL) (Klug et al. 2002) at Uppsala, Sweden, is a good example of a laboratory using neutrons in the 10s of MeV region and higher. It consists of a cyclotron that can accelerate protons up to 180 MeV, deuterons up to 96 MeV, alpha particles up to 200 MeV and all the way up to ${}^{129}\text{Xe}$ to 1240 MeV. ● Figure 33 shows the neutron energy distribution for a quasi-monoenergetic peak around 96 MeV obtained from the ${}^7\text{Li}(p,n){}^7\text{Be}$ reaction. Approximately, half of the neutrons generated are in the peak. The low energy tail can be removed in the data analysis by TOF techniques.

■ Figure 32

Neutron emission spectra at 30° from 14.1 MeV neutron bombardment of carbon (data times 0.01), silicon (data times 0.1), and lead measured at Osaka (Takahashi et al. 1988). The data are expressed as double-differential cross sections. Elastically scattered neutrons are in the peaks near 14 MeV. Inelastic scattering to resolved levels in carbon with excitation energy of 4.43 MeV is observed with an emitted neutron energy of about 9 MeV. Other resolved states are seen in carbon and silicon, and to some extent in lead

■ Figure 33

The quasi-monoenergetic 96 MeV neutron beam distribution at the The Svedberg Laboratory (TSL) at Uppsala, Sweden, obtained from the ${}^7\text{Li}(p,n){}^7\text{Be}$ reaction. The upper histogram is for all the neutrons generated. For the lower histogram, time of flight was used to reduce the low energy tail. Approximately half of the neutrons are contained in the peak

Other facilities for neutrons in this energy range include the CYCLONE cyclotron (protons to 75 MeV, high mass particles up to Xe) at Louvain-la-Neuve, Belgium (Jongen and Ryckewaert 1976), the TIARA cyclotron ($K = 110$ AVF) at the JAEA Laboratory at Tokai-Mura, Japan (Baba et al. 2002; Ibaraki et al. 2000), the AVF cyclotron (90 MeV protons, 65 MeV deuterons and higher masses) at Tohoku University, Japan (Baba 2005), and the cyclotrons at the iThemba Laboratory for accelerator based sciences (LABS) at Faure, South Africa (up to 230 MeV protons) (<http://www.tlabs.ac.za>).

4 Neutron Cross Sections

4.1 Introduction

In the interaction between neutrons and nuclei, the kinetic energy of the neutron determines the nature of the interaction. A characteristic quantity is the reduced de Broglie wave length $\lambda = \hbar/2\pi$ of the neutron-nucleus center-of-mass system, defined by

$$\lambda = \sqrt{\frac{\hbar^2}{2mE}} \quad (1)$$

where m is the reduced mass, E the kinetic energy in the center of mass frame, and $\hbar = h/2\pi$ is the reduced Planck constant. If the nucleus has a mass A times that of the neutron m_n , then

$$m = \frac{A}{A+1} \times m_n. \quad (2)$$

At very low neutron energies, typically in the meV range and below, this wave length has a size of the order of the spacing between the nuclei in their material, for example, a crystalline structure. The neutron then does not see individual nuclei but interacts by scattering from the crystalline structure. Since this is a wave phenomenon one does not refer to the neutron kinetic energy, but rather to the neutron wavelength. This technique is commonly used in neutron diffraction.

In the energy range between roughly 1 meV and 10 MeV, the wave length varies from the distance between the atoms to the size of a single nucleon, therefore covering approximately the same order of magnitude as the size of the nucleus. Since the electrically neutral neutron has no Coulomb barrier to overcome, and has a negligible interaction with the electrons in matter, it can directly penetrate the atomic nucleus and interact with it.

For these energies, reactions often go through the formation of a compound nucleus. The compound nucleus model was introduced by Bohr (1936) to explain the observed resonances in neutron-nucleus reactions.

In this theory the formation of the compound nucleus is decoupled from its decay, such that the reaction cross section $\sigma_{n,x}$ can be factored into the product of the cross section for forming the compound nucleus, σ_c , times the probability of decay via reaction x as shown in the equation

$$\sigma_{n,x} = \sigma_c \frac{\Gamma_x}{\Gamma}. \quad (3)$$

Here Γ_x/Γ , the probability of decay via reaction x , is expressed as the partial width Γ_x divided by the total width Γ (of the resonance). In this picture, the neutron binding energy which becomes

available to the compound nucleus is rearranged among all nucleons, and gives rise to a complex configuration corresponding to a well-defined nuclear state with an energy, spin, and parity. Within Fermi's description of excitations of particle-hole configurations, such a state would correspond to an extremely complicated configuration of a many particle, many hole state.

At the high excitation energies above the neutron binding energies, for most nuclei the nuclear system is extremely complex and no nuclear model is capable of predicting the position and other properties of these excited states. For a heavy nucleus the level density in this region near the neutron binding energy is very high. A neighboring eigenstate can be excited by only a small change in excitation energy and may have a completely different wave function. This is a manifestation of what is also called chaotic behavior. Due to extreme configuration mixing, the nucleus in this regime above the neutron binding energy has a statistical behavior. This is expressed by the assumption that the matrix elements, relating nuclear states, have a random character, governed by a Gaussian distribution with zero mean. This statistical model of the compound nucleus is referred to as the Gaussian orthogonal ensemble (GOE) (Lynn 1968; Mehta 1960; Haq et al. 1982; Bohigas et al. 1984; Mehta 1991).

The statistical model has direct consequences on the observables of the reaction cross sections. The channel widths are proportional to the square of the matrix elements and have, therefore, a chi-squared distribution with one degree of freedom, also called the Porter-Thomas distribution (Porter and Thomas 1956). The observed gamma width of a resonance is the sum of many, for heavy nuclei, several tens of thousand, individual gamma widths, and each of these widths varies over the resonances according to a Porter-Thomas distribution. Therefore, the total radiation width for many heavy nuclei is of a similar order of magnitude. Observed fission widths correspond to a relatively small number of fission channels, at maximum three or four. The resulting distribution can be approximated by an effective chi-squared distribution with a small, fractional number of degrees of freedom.

With increasing excitation energy the Γ widths of the states start to overlap and the resulting cross sections become smooth. The properties of the eigenstates, like the decay widths, fluctuating from one state to another, become apparent as values averaged over many resonances. These average values now can be predicted by nuclear models, parameterized with average properties. Measured average cross sections can therefore finetune the parametrization of these models.

At even higher excitation energies, many more decay channels open up. Some reaction cross sections may only be accessible by nuclear model calculations.

► *Figure 34* shows some typical neutron-induced cross sections for the nucleus ^{238}U . In addition to the total, capture, and fission cross sections showing resolved resonances up to several keV, some threshold reactions are also shown. The cross sections for inelastic scattering leaving the nucleus in the first, second, and third excited state are shown, as well as three (n,xn) reactions with $x = 2, 3, 4$.

In the same ► *Fig. 34* typical neutron spectra are shown in the energy range from 10^{-5} to 10^9 eV. The energy region around a few tens of meV is called the thermal region and is of importance in reactor physics where the water moderated neutrons are in thermal equilibrium with the water and have Maxwell-Boltzmann distributed velocities peaked at an equivalent kinetic energy of $kT = 25.3$ meV. A different energy distribution is found for neutrons in certain stars where the synthesis of the isotopes heavier than about $A = 60$ takes place (Wallerstein et al. 1997). The neutrons are present as a hot gas and also have a Maxwellian kinetic energy distribution in the figure shown for temperatures with kT ranging from 5 to 100 keV in Asymptotic Giant Branch stars. The velocities of neutrons from ^{235}U thermal neutron-induced fission follow in good agreement a Maxwell-Boltzmann energy distribution, peaked at about 1 MeV as

■ Figure 34

Typical neutron-induced cross sections (upper panel) here for the nucleus ^{238}U over an energy range from 10^{-5} to 10^9 eV, together with on the same scale some typical neutron energy distributions (lower panel), from fully moderated neutrons, stellar spectra at several temperatures, fission neutrons, and a typical spallation spectrum (also see text)

shown in ► Fig. 34. A typical spallation neutron spectrum in an accelerator-driven subcritical system, in this case MEGAPIE at PSI in Switzerland (Panebianco et al. 2009), is shown as well.

But at excitation energies just above the neutron binding energy, usually just a few decay channels are open. In ► Fig. 35 the cross sections for $^{235}\text{U} + n$ are shown for incident neutrons up to 11 eV. Only the capture, elastic scattering, and fission channels are open for these energies. The eigenstates are visible as resonances at the same energy in each of the cross sections.

Since these states are not bound, the compound nucleus decays eventually through the emission of a gamma ray(s), a neutron, a charged particle, or the scission into mostly two fission fragments. The way of decay and the decay probability of the compound nucleus are considered to be independent from the way the compound nucleus was formed, but respecting conservation of energy and angular momentum. The decay probability through a decay channel c with width Γ_c is the branching ratio Γ_c/Γ (3). At low energy (in non-fissile nuclei) such a channel corresponds mainly to the emission of gamma rays or a neutron.

Typical widths Γ of measured resonances are in the order of electron volts. According to Heisenberg's uncertainty principle, the corresponding life time of the compound nucleus is in the order of $\tau = \hbar/\Gamma \approx 10^{-15}$ s, several orders of magnitude larger than the typical time needed by a neutron to cross a nucleus without interaction. In ► Fig. 36 a picture of the compound nucleus reaction is sketched. After the formation of the highly excited state by an incident neutron, the compound nucleus can decay by emission of gamma radiation, which is called radiative neutron capture, or by emission of a neutron, which is elastic scattering. If the kinetic energy

■ Figure 35

The neutron capture, elastic, and fission cross section for ^{235}U up to 11 eV, showing the resonance structure

■ Figure 36

Schematic view of the formation and decay of a compound nucleus with the orders of magnitude of the level spacing and neutron separation energy for a heavy mass nucleus. The resonances observed in the reaction cross section correspond to the excitation of nuclear levels

of the neutron is high enough, threshold reactions are possible, like inelastic scattering, leaving the target nucleus in an excited state.

Heavier nuclei are fissionable since the nuclear potential energy becomes lower than that of the ground state at large deformation. If the nucleus has an excitation energy higher than the barrier height, the nucleus can fission. This may be the case when a compound nucleus is formed, even with a neutron with nearly zero kinetic energy. But also when the compound nucleus is in a state below the fission barrier height, fission can occur through tunneling (subthreshold fission). If the nucleus in its ground state fissions, we speak of spontaneous fission.

In direct reactions, the opposite reaction mechanism to compound nucleus reactions, the incident neutron interacts directly with one or a few nucleons without forming a compound nucleus. The time scale of direct reactions is of the order of 10^{-22} s, a much shorter time than for compound-nucleus resonance reactions. Direct reactions become important for the heavier nuclei at neutron energies higher than about 10 MeV where the de Broglie wavelength of the neutron becomes comparable to the size of nucleons. But also at lower neutron energies, mainly for light A or closed shell nuclei, direct reactions may contribute significantly to the total cross section.

The width of an isolated resonance in a reaction cross section has in good approximation a Breit–Wigner shape (Breit and Wigner 1936), which is the typical shape for any quantum-mechanical state with a finite lifetime. This can be derived from the time dependence of the wave function $\Psi(t)$ of a non-stationary state with an energy E_0 and a lifetime τ . The time dependence of this wave function is

$$\Psi(t) = \Psi(0)e^{-iE_0t/\hbar} e^{-t/2\tau} \quad (4)$$

is observed as an exponential decay in time, like for example the familiar decay of the activity of a radioactive source. The squared absolute value of the Fourier transform of $\Psi(t)$, and defining $\Gamma = \hbar/\tau$ gives the energy distribution $P(E)$ having the Breit–Wigner form

$$P(E) \propto \frac{\Gamma}{(E - E_0)^2 + \Gamma^2/4} \quad (5)$$

This Breit–Wigner form is present in the formulas for resonance cross sections. Also the more exact R -matrix expressions result in Breit–Wigner shapes in the limiting cases.

4.2 Total Cross Section

In principle, the “simplest” cross section to measure is the total cross section using the transmission method.  *Figure 37* shows a typical transmission method setup where a neutron beam impinges on a detector and a sample of the nuclei of interest is cycled in and out of the beam. The neutron transmission T is given by

$$T = \frac{\text{sample in counting rate}}{\text{sample out counting rate}} = e^{-N\sigma_t} \quad (6)$$

where N is the areal sample thickness (in units of atoms/barn) and σ_t is the neutron total cross section (in units of barns, where 1 barn equals 10^{-24} cm²). It should be noted that this measurement does not require accurate knowledge of the neutron flux or the detector efficiency. It

■ Figure 37

The principle of the transmission experiment setup. The neutron detector is located far from the sample in order to detect only neutrons that have not undergone an interaction in the sample (sample in position). The neutron flux incident on the sample is measured by removing the sample from the beam (sample out position)

only requires a neutron source that is constant in time or one that can be normalized for equal numbers of neutrons for the sample-in and sample-out runs.

Atoms inside the target are in thermal motion so that the measured total cross section σ_t in (6) is actually a Doppler broadened cross section. Thus, the transmission at neutron energy E is

$$T(E) = \exp\left(-N \int \sigma_t(E') P_E(E', t) dE'\right) \quad (7)$$

where $T(E)$ is the transmission at incident neutron energy E ; $P_E(E', t)$ is the probability, the result of thermal motion of the target atoms at temperature t , that the interaction takes place with energy E' ; and the integral is over all energies. The integral is called the Doppler-broadened total cross section $\sigma_{\Delta, t}$.

For some materials like metals, the free gas model (Lamb 1939) with an effective temperature T describes in good approximation Doppler broadening by a Gaussian with a standard deviation

$$\sigma_D = \sqrt{\frac{Mm}{(M+m)^2} 2kTE} \simeq \sqrt{\frac{2kTE}{A}} \quad (8)$$

with M the mass of the target nucleus, m that of the incident neutron, and A the atomic number, close to M/m for medium and heavy nuclei. Note that in the literature we often see the Doppler width Δ_D defined as $\Delta_D = \sqrt{2}\sigma_D$. For other materials, like poly-atomic crystalline lattices, a more complicated description is sometimes needed (Meister 1994; Naberejnev et al. 1999; Dagan 2008). The Doppler broadening effect is symmetric and will, therefore, not result in an apparent shift of the resonance energy.

In most measurements the incident neutrons are not at energy E but rather have a distribution of energy about E . Thus, the measured transmission T_m at energy E and temperature t is

$$\begin{aligned} T_m(E, t) &= \int R(E, E'') T(E'') dE'' \\ &= \int R(E, E'') \exp\left(-N \int \sigma_t(E') P_{E''}(E', t) dE'\right) dE'' \end{aligned} \quad (9)$$

where $R(E, E'')$ is the resolution function and is the probability that at nominal energy E the neutron has energy E'' . Both integrals are taken over all energies.

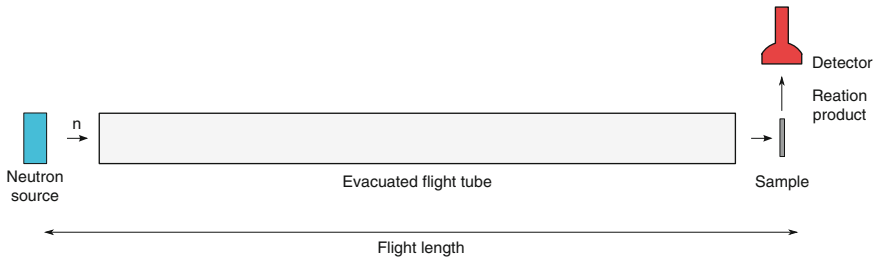

Figure 38

The principle of the reaction experiment setup. The detector for the reaction products may be in the beam together with the sample, for example, for (n,f) or (n,α) experiments, or outside the beam, like for capture or scattering reactions. The off-beam detector can be close to 4π configuration or cover a smaller solid angle

4.3 Partial Cross Section

The total cross section is the sum of all the partial cross sections such as scattering cross section, capture cross section, fission cross section, etc. A typical partial cross section experiment is shown in Fig. 38 where a beam of neutrons is incident upon a sample and the reactions of interest are observed in a detector. The yield for reaction x is defined as

$$Y_x = \frac{\text{number of } x\text{-reactions}}{\text{number of incident neutrons}} \quad (10)$$

Note that Y_x is the number of occurred reactions, not the number of detected reactions which depend largely on experimental factors as the detector efficiency and the solid angle covered. The primary yield Y_p is defined as the yield for first interactions. It is defined as the ratio of the reaction to total cross section σ_x/σ_t times the fraction of neutrons $(1 - T)$ inducing a reaction. Therefore,

$$Y_{x,p} = [1 - T] \frac{\sigma_x}{\sigma_t} = [1 - e^{-N\sigma_t}] \frac{\sigma_x}{\sigma_t} \quad (11)$$

where σ_x is the partial cross section. For simplicity, Doppler effects and resolution broadening are ignored in (11). The term within the brackets is the fraction of the incident beam, which interacts in the sample and the ratio of cross sections is the fraction of interactions which are of type x .

In addition to the primary yield there is multiple scattering in the sample which produces additional x reactions in the sample. Thus, the total yield Y_x is

$$Y_x = Y_{x,p} + Y_{x,m} \quad (12)$$

where $Y_{x,m}$ is the result of multiple scattering and subsequent reactions of type x in the sample.

For thin samples where $N\sigma_t \ll 1$, multiple scattering becomes negligible and $Y_{x,p}$ can be expanded as

$$Y_x = [1 - 1 + N\sigma_t - (N\sigma_t)^2/2! + (N\sigma_t)^3/3! + \dots] \frac{\sigma_x}{\sigma_t} \approx N\sigma_x \quad (13)$$

or

$$\sigma_x \approx \frac{Y_x}{N} \quad (14)$$

Thus, for thin samples the partial cross section is equal to the partial yield divided by the areal sample thickness.

For fission measurements, the sample can be very thin and the detector counts the fission reactions. For this case, the measured partial cross section of type x is merely the resolution broadened cross section. Applying both Doppler and resolution broadening, one obtains for thin samples the measured cross section at nominal energy E and temperature t

$$\sigma_m(E, t) = \int R(E, E'') \left[\int \sigma_x(E') P_{E''}(E', t) dE' \right] dE'' \quad (15)$$

4.4 Resonance Cross Section

Neutron cross sections exhibit many resonances in the energy region above thermal energies. The cross section of an isolated resonance can be described by the single-level Breit-Wigner formula. At low energies where the neutron has zero orbital angular momentum (s -wave), the partial reaction cross section of an isolated s -wave resonance is given by

$$\sigma_x(E) = \pi \lambda^2 g \frac{\Gamma_n \Gamma_x}{(E - E_0)^2 + (\Gamma/2)^2} \quad (16)$$

where E is the neutron energy (in the center of mass system), λ is the reduced neutron wavelength, g is the statistical weight factor, Γ_n is the neutron width, Γ_x is the reaction width, Γ is the total width (full width at half maximum), and E_0 is the neutron energy at the peak of the resonance. The statistical weight factor g is given by

$$g = \frac{2J + 1}{2(2I + 1)} \quad (17)$$

where J is the total angular momentum (resonance spin) of the compound nucleus and I is the total angular momentum (spin) of the target nucleus. The neutron width Γ_n is energy dependent and can be represented by

$$\Gamma_n(E) = \Gamma_n(E_0) \sqrt{\frac{E_0}{E}} \quad (18)$$

Equation (16) can be transformed by dividing numerator and denominator by $(\Gamma/2)^2$ and by introducing the peak cross section at resonance to become

$$\sigma_x(E) = \sigma_0 \frac{\Gamma_x}{\Gamma} \sqrt{\frac{E_0}{E}} \left(\frac{1}{1 + y^2} \right) \quad (19)$$

where the peak cross section σ_0 is given by

$$\sigma_0 = 4\pi \lambda_0^2 g \frac{\Gamma_n(E_0)}{\Gamma} \quad (20)$$

$\Gamma_n(E_0)$ is the neutron width at the resonance energy, λ_0 is the reduced neutron wavelength at E_0 , and y is given by

$$y = \frac{E - E_0}{\Gamma/2} \quad (21)$$

The total cross section is the sum of the scattering cross section and the sum of all the partial cross sections. The total cross section for an isolated s -wave resonance is

$$\begin{aligned} \sigma_t(E) &= \pi\lambda^2 g \frac{\Gamma_n\Gamma + 4\Gamma_n(E - E_0)R/\lambda}{(E - E_0)^2 + (\Gamma/2)^2} + 4\pi R^2 \\ &= \sigma_0 \sqrt{\frac{E_0}{E}} \left(\frac{1}{1 + y^2} \right) + \sigma_0 \sqrt{\frac{E_0}{E}} \left(\frac{y}{1 + y^2} \right) \frac{2R}{\lambda} + 4\pi R^2 \end{aligned} \quad (22)$$

where the last term is the potential scattering cross section and R is the potential scattering radius. The second term represents the resonance-potential interference and, in some cases, leads to almost zero total cross section.

Thus, the neutron cross section of an isolated resonance can be calculated from a set of parameters termed “resonance parameters.” These parameters are the resonance energy E_0 , total width Γ , neutron width Γ_n , reaction width(s) Γ_x , total angular momentum J , target nucleus spin I , and the orbital angular momentum of the neutron. For non-fissile resonances the only reaction width is the radiative width Γ_γ . From these parameters and the Debye temperature of the target nucleus the Doppler-broadened cross section can be calculated.

To account for nearby or overlapping resonances the Breit–Wigner formula is no longer valid and an R -matrix formalism, explained in more detail in [Sect. 6](#), is used to calculate the neutron cross sections. However, the same resonance parameters are used for these calculations. Thus, the measured transmission and/or partial cross sections which include the effects of Doppler broadening and resolution broadening can still be interpreted in terms of these resonance parameters. Originally, the Breit–Wigner formalism was used to fit the measured transmission and partial cross sections to obtain these parameters. Today, there are two major codes, REFIT (Moxon and Brisland 1991) and SAMMY (Larson 2006) based on the R -matrix formalism, which can extract resonance parameters from the measured data. These programs calculate the Doppler-broadened cross section, apply resolution broadening to simulate the observed transmission and partial yield data, and then determine the resonance parameters that provide the best fit to all of the measured data. It is these parameters that are used to calculate neutron cross sections for reactor and other applications.

4.5 High Energy Cross Section

With increasing neutron energy the average spacing between levels $\langle D \rangle$ decreases (the result of level density $\rho(E)$ increasing with energy) while the average resonance width $\langle \Gamma \rangle$ increases. In the energy region where $\langle \Gamma \rangle$ is comparable to $\langle D \rangle$ the cross section exhibits structure caused by unresolved clusters of partially overlapping resonances. This is a very difficult region to express analytically, so statistical representations based on average parameters are typically used in neutronic calculations. At higher energies where $\langle \Gamma \rangle$ is much larger than $\langle D \rangle$, the cross section is in a continuum region and is typically represented by optical and collective model expressions based on a Hauser–Feshbach description with width fluctuation corrections (see also [Sect. 6.3](#)).

■ Figure 39

The ENDF/B-VII.0 evaluated total cross section of ^{197}Au

5 Cross Section Measurements

Cross sections of interest to nuclear engineering cover the range from subthermal energies in the millielectron volts to tens of millions of electron volts. A typical example of a cross section is shown in [Fig. 39](#) where the ENDF/B evaluated total cross section of Au is plotted (Chadwick et al. 2006). For convenience this large energy span can be divided into four energy ranges: thermal, resolved resonance, unresolved resonance and continuum energy regions. In this figure the thermal region extends up to ~ 0.1 eV and the resolved resonance region falls between approximately 0.1 eV and 4.8 keV. Note that above 4.8 keV the cross section is represented as a smooth curve.

However, immediately above 4.8 keV the cross section is still dominated by resonance structure but is considered “unresolved.” This structure is considered unresolved because the experimental resolutions could not resolve individual resonances and/or, even if the experimental resolution were “perfect” and truly resolved all the structure in the cross section, the resonances partially overlap and cannot be clearly distinguished from each other. Even though this unresolved resonance region is represented in the evaluation as a smooth average cross section, the cross section fluctuations about the average result in fluctuations in self-shielding and must be taken into account in neutronic calculations in this energy region. In the MeV energy region the Au resonances have overlapped to the extent that the cross section is now a smooth continuum and here, we only see very wide optical diffraction peaks in the cross section above ~ 1 MeV; this is the continuum energy region.

The boundaries between the different regions, thermal, resolved resonances, unresolved resonances, and continuum, are different for each nucleus and depend on the level density of the

Figure 40

The neutron total cross section of several nuclei showing large differences in the resonance spacings

compound nucleus. In fact, resolved neutron resonances are an important source to obtain level density information.

In [Fig. 40](#) the neutron-induced total cross section is shown for several nuclei of increasing mass. Since the level density increases with mass, resonances are more closely spaced for heavier nuclei. But near a double closed shell nucleus like ${}^{208}\text{Pb}$, the level density is much lower, and we observe a much higher level spacing. Also nuclei with neighboring masses may show large differences in the level density due to shell effects.

As a result of the different structure in each of these energy regions, the cross section measurement techniques in each region can be quite different. These techniques are reviewed below.

5.1 Thermal Energy Region

This region typically extends from a fraction of an eV down into the meV region. The cross section here is equal to the sum of the scattering cross section and the absorption cross section. The absorption cross section typically varies as $1/v$ where v is the velocity of the neutron. This can be seen from (19) and (22), where at low energies the cross sections are proportional to $1/\sqrt{E}$ (or $1/v$); this is also seen in the low energy ^{197}Au total cross section shown in [Fig. 39](#). Some “famous” absorption cross sections at 0.0253 eV, which corresponds to the maximum at 2,200 m/s in the Maxwell–Boltzmann distribution of the neutron velocities at a temperature of 293.6 K, are 3,840 barns for the (n, α) reaction in ^{10}B , 25,200 barns for the (n, γ) reaction in $^{\text{nat}}\text{Cd}$, and 585 barns for the (n,f) reaction in ^{235}U . The scattering cross section can be more complex as solid state effects take place. Neutrons can undergo Bragg scattering by any crystalline material present, undergo paramagnetic scattering with the target nuclei and neutrons can be up-scattered or down-scattered in energy from the thermal motion of the nuclei they interact with.

Thermal reactors have been used for many of the early absorption cross section measurements. Samples of the material of interest were placed inside the thermal spectrum where the induced radioactivity in the samples or the change in reactivity of the reactor were interpreted in terms of the sample absorption cross section. Reactors were used to provide monoenergetic neutron beams using crystal spectrometers or velocity selectors for cross section measurements. Fast choppers were used to produce pulses of neutrons for TOF measurements. More recently, bent tubes have been used to provide extremely pure neutron beams in the millielectron volt range for precise sub-thermal cross section measurements.

For the past 30 years the energy-dependent cross sections in the thermal region have been measured predominantly by TOF techniques using pulsed accelerators. This technique provides good resolution well into the resolved resonance region so that in a single measurement, both thermal and resonance regions data can be obtained. Since the thermal absorption cross sections of most materials is the result of the tails of resonances, the accelerator time-of-flight method provides data over the whole energy region which contributes to the thermal cross section.

An example of a measurement of the total cross in the thermal region is shown in [Fig. 41](#) for ^{165}Ho (Danon et al. 1998). The TOF transmission method was used for the RPI measurement. A paramagnetic scattering cross section of 28.3 barns at 0.0253 eV was calculated for ^{165}Ho and this had to be accounted for in analyzing ^{165}Ho for both thermal absorption cross section and total cross section.

5.1.1 Thermal Flux Averaged Cross Section

The flux averaged cross section $\bar{\sigma} = \int \sigma(E)\phi_E(E)dE$ of a reaction is a useful quantity for irradiation experiments. If the cross section has a smooth shape of the form

$$\sigma(E) = \left(\frac{E}{E_r}\right)^\alpha \sigma_r \quad (23)$$

where σ_r is the cross section at energy E_r , then we can calculate the flux averaged cross section as

$$\bar{\sigma} = \frac{\int \sigma(E)\phi(E)dE}{\int \phi(E)dE} = \left(\frac{kT}{E_r}\right)^\alpha \sigma_r \Gamma(\alpha + 2) \quad (24)$$

■ **Figure 41**
Total cross section of ^{165}Ho in the thermal energy region

where $\Gamma(x)$ is here the gamma function. This is particularly useful at low, thermal energies where the cross section has a $1/v$ shape, so $\sigma(E_n) \propto E_n^{-1/2}$, that is, $\alpha = -1/2$. The flux averaged cross section becomes then

$$\bar{\sigma} = \sqrt{\frac{\pi}{4}} \sqrt{\frac{E_r}{kT}} \sigma_r \quad (25)$$

In this case we often choose E_r such that we have the cross section at $v = 2,200$ m/s, that is, at $E_r = 24.3$ meV.

5.2 Resonance Energy Region

This is the region in which resonances can be resolved by the technique being used for the measurement. This energy typically spans an energy region from ~ 1 eV to several MeV for light nuclei like Be and C, into the 100s of keV for the structural materials like Fe and Ni, into the keV region for rare earth nuclei like Ho or Gd and into the 100s of eV to keV region for heavy nuclei like U. It is in the resonance region where the TOF measurements at pulsed accelerators have made the major contributions.

Each resonance represents an excited state in the compound nucleus formed by the incident neutron. The focus of these measurements is the extraction of resonance parameters both for understanding the underlying science of nuclear levels and for the practical need of being able to calculate cross sections at any operating temperature (such as in a reactor). Typical resonance parameters are the resonance energy E_0 , resonance spin J , orbital angular momentum of the incoming neutron ℓ , resonance total width Γ , the always present neutron width Γ_n , and, if applicable, other, partial widths like the radiative width Γ_γ or the fission width Γ_f .

■ Figure 42

Capture yield and transmission of metallic Hf samples near the 2.39 eV resonance in ^{177}Hf

■ Figure 43

Cutaway view of the 16-section NaI multiplicity detector. A capture sample is placed in the center of the detector and the neutron beam is collimated along the detector axis

An example of data from a TOF measurement optimized to measure resonance parameters is shown in [▶ Fig. 42](#). These data were obtained from low energy capture and transmission measurements at the Rensselaer Polytechnic Institute LINAC with elemental Hf (Trbovich et al. 2009). A high-efficiency calorimeter-type detector was used for the capture measurements and is shown in [▶ Fig. 43](#). A ^6Li glass scintillator detector was used for the transmission measurements. Here, both transmission and capture measurements were performed on many sample thicknesses, and the Bayesian-based SAMMY code (Larson 2006) was used to obtain a single set of parameters to fit all the data. In this region the resonances are reasonably well separated

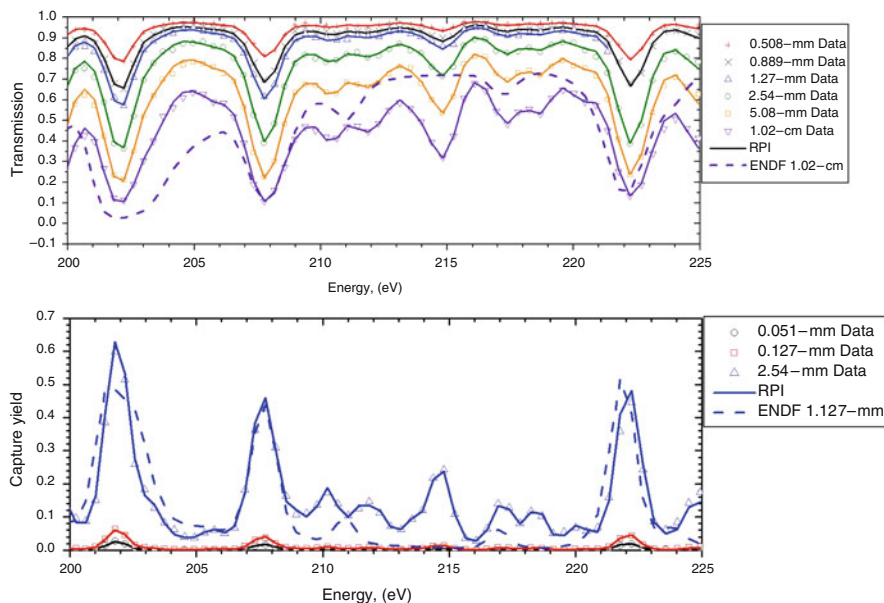

Figure 44
Transmission and capture yield from multiple samples of elemental Gd

and it is relatively easy to obtain a good fit. In the example of a higher-energy measurement, as shown in [Fig. 44](#) for elemental Gd (Leinweber et al. 2006), the resonances are beginning to overlap and it is more difficult to make the fit. Eventually, the resonances overlap so much that it becomes very difficult to resolve them from each other. In this case better TOF resolution and/or the use of separated isotopes can extend the energy range for clearer separation of resonances and ultimate determination of resonance parameters.

[Figure 45](#) shows an example of a capture measurement of isotopically-enriched ^{91}Zr at the n_TOF facility at CERN (Tagliente et al. 2008). This measurement spans the energy range from 1 eV to 100 keV and shows the transition from clearly separated ^{91}Zr resonances at lower energies to the keV region where the resonances are only partially resolved. These data were taken with a C_6D_6 scintillator detector that was designed with minimum absorbing material to reduce its sensitivity to neutrons scattered by the capture sample. Resonance parameters were determined up to 26 keV; above this energy the fluctuations in the yield clearly show the effects of unresolved resonances.

5.3 Unresolved Resonance and Continuum Energy Region

An example of the change from the unresolved to continuum energy region is shown by the recently measured (at RPI) total cross section of elemental Zr above 0.3 MeV shown in [Fig. 46](#). Here, we clearly see the effects of unresolved resonance structure up to ~ 3 MeV. Above ~ 3 MeV are seen the effect of nuclear optical structure with a very broad peak near 9 MeV;

■ Figure 45

Capture yield (black) and background (gray) of ^{91}Zr between 1 eV and 100 keV measured at n_TOF (Tagliente et al. 2008)

this is clearly in the continuum energy region. This type of structure below 3 MeV can be interpreted in terms of the fluctuations in the observed cross section; an excellent example of this type of analysis has been applied to total cross section measurements of ^{31}P , ^{32}S , ^{39}K , ^{51}V , ^{56}Fe , and ^{59}Co between 0.75 and 11.3 MeV (Abfalterer et al. 2000) to obtain average level densities and resonance widths as a function of excitation energy.

To represent the cross section in the unresolved resonance region for neutronic applications, two distinct approaches have been successful: ladders of pseudo resonances and probability lookup tables. Both of these approaches select resonances stochastically from a level spacing and a level strength distribution, which are based on the average spacings and strengths extrapolated from the resolved resonance region. In the ladder case a set of parameters is stochastically selected over a given energy range and a pseudo cross section is calculated from these parameters. The pseudo cross section is then used in neutronic calculations over this energy range. In the probability lookup case a pseudo cross is calculated over a given energy range and the probability distribution of a given value of cross section is determined over this energy range. For neutronic calculations, the probability of a given cross section is stochastically sampled from the probability distribution.

Figure 46

The measured and evaluated total cross section of ${}^{\text{nat}}\text{Zr}$ from 0.5 to 20 MeV

5.4 The Neutron Time of Flight Method

The principle of neutron time of flight measurements is based on the pulsed neutron source which produces at a time t_0 neutrons in a wide energy range. For reaction measurements a sample is put in the neutron beam at a well know distance L and the reactions are observed with a detector. The detection of the reaction determines the time of arrival t_n of the neutron at the sample and therefore its velocity $v = (t_n - t_0)/L$, which gives the kinetic energy of the neutron. The idea is illustrated in [Fig. 47](#).

Accelerator-based pulsed white neutron sources are in general either electron-based sources where the neutrons are produced via Bremsstrahlung on a high Z target, or proton-based sources where the neutrons are produced by spallation on a target of heavy nuclei.

The neutrons created by the pulsed source travel along the flight path with length L during a time t before possibly undergoing a reaction in a capture, scattering or fission setup, or before getting detected in a transmission experiment (see [Fig. 37](#)). The neutron kinetic energy is determined relativistically from the neutron velocity $v = L/t$ and momentum $p = mv$ as

$$E_n = E_{tot} - mc^2 = \sqrt{c^2 p^2 + m^2 c^4} - mc^2 = mc^2(\gamma - 1) \quad (26)$$

Figure 47

The principle of the neutron time-of-flight method

with $\gamma = (1 - v^2/c^2)^{-1/2}$ and where c is the speed of light. For low energies where $v \ll c$ and therefore $\gamma \rightarrow 1$, the relativistic expression can be conveniently written as a series expansion of γ

$$\gamma = 1 + \frac{1}{2} \frac{v^2}{c^2} + \frac{3}{8} \left(\frac{v^2}{c^2} \right)^2 + \frac{5}{16} \left(\frac{v^2}{c^2} \right)^3 + O\left(\frac{v^2}{c^2} \right)^4 \quad (27)$$

For resolved resonances the first two terms of the series expansion of the relativistic expression are usually sufficient, which results in the classical definition of kinetic energy

$$E_n \approx \frac{1}{2} m v^2 = \alpha^2 \frac{L^2}{t^2}. \quad (28)$$

Taking the definition of the speed of light $c = 299,792,458$ m/s and taking $m = 939.6$ MeV/ c^2 for the neutron mass, we get $\alpha = 72.3 \mu\text{s}\sqrt{\text{eV}/\text{m}}$ when using units eV, m, and μs for E_n , L , and t respectively.

See also, for example, Foderaro (1971), Krane (1987), Knoll (2000), and Reuss (2008) for a wider discussion on neutron physics and associated instrumentation.

5.4.1 Neutron Density and Flux Distributions at Thermal Energies

Fully thermalized neutrons behave like an ideal gas and can, therefore, be described in good approximation by Maxwell–Boltzmann statistics. The neutron density, that is, the number of neutrons per unit of volume, has a Maxwell–Boltzmann velocity distribution $n_v(v)$ of the form

$$n_v(v) = 4\pi \left(\frac{m}{2\pi kT} \right)^{3/2} v^2 \exp\left(-\frac{mv^2}{2kT} \right) \quad (29)$$

where k is the Boltzmann constant, m the neutron mass, and T the temperature.

This distribution shows a maximum at $v = \sqrt{2kT/m}$ corresponding to a kinetic energy of $E_{\text{max}} = kT$. For a velocity of 2,200 m/s, used as a reference for thermal neutrons, this gives $E_{\text{max}} = 25.3$ meV, $\lambda = 0.18$ nm, and $T = mv^2/2k = 293.6$ K, which is practically room temperature.

From the velocity distribution $n_v(v)$ we can obtain the distribution $n_E(E)$ of the kinetic energy E , the distribution $n_t(t)$ of the time-of-flight t , and the distribution $n_\lambda(\lambda)$ of the wavelength λ using the relations

$$n_v(v)dv = n_E(E)dE = n_t(t)dt = n_\lambda(\lambda)d\lambda \quad (30)$$

where dv , dE , dt , and $d\lambda$ are obtained from taking the derivatives of the expressions

$$E = \frac{1}{2} m v^2 = \frac{1}{2} m \frac{L^2}{t^2} \quad (31)$$

and

$$\lambda = \frac{h}{mv} = \frac{ht}{mL} \quad (32)$$

One is often interested in the distribution of the neutron flux. The velocity distribution of the neutron flux $\varphi_v(v)$ is related to $n_v(v)$ as

$$\varphi_v(v) = C_v \times v \times n_v(v) \quad (33)$$

where C_v is the appropriate normalization constant to normalize the integral to unity $\int \varphi_v(v) dv = 1$ ($C_v = \sqrt{8kT/(\pi m)}$ in this case). In a similar way as in (30) the kinetic energy, time-of-flight, and wavelength distributions of the neutron flux can be obtained using

$$\varphi_v(v)dv = \varphi_E(E)dE = \varphi_t(t)dt = \varphi_\lambda(\lambda)d\lambda \quad (34)$$

Applying this and by introducing the characteristic variables

$$v_T = \sqrt{\frac{2kT}{m}} \quad (35)$$

$$E_T = kT \quad (36)$$

$$t_T = L\sqrt{\frac{m}{2kT}} \quad (37)$$

$$\lambda_T = \sqrt{\frac{h^2}{2mkT}} \quad (38)$$

we obtain the expressions for the neutron density and neutron flux distributions as given in **Table 3**. This table is similar to the one in (Molnar 2004). Here, we also add the time-of-flight distributions which are analogous to the wavelength distributions with the characteristic variables.

Note from the equivalent maximum values that the energy distribution of the flux has a maximum at $E = E_T = kT$ and that the time-of-flight distribution, which is typically measured at a TOF facility, shows the maximum at flight time which corresponds to an energy of $E = (5/2)kT$. So a room temperature water moderated neutron source with a thermal peak of 25 meV has a peak in a time-of-flight spectrum at 63 meV.

5.5 Surrogate Reactions

A different approach to study neutron-induced reactions in some cases is to use surrogate reactions. This technique, developed by Cramer and Britt (1970) uses light charged particles, typically, but not only deuterons, tritons, ^3He or α particles, to form a compound nucleus by a few-nucleon transfer reaction. The target nucleus and charged particle is selected in such a way that the same compound nucleus is formed as in the neutron-induced reaction. In this way, the decay of the compound nucleus for a particular decay channel can be measured. The formation of the compound nucleus for the neutron-induced reaction has to be calculated using optical model calculations. The reactions are usually described using Hauser–Feshbach calculations, which in some energy ranges can be done in the Weisskopf–Ewing approximation where spin and orbital angular momentum are ignored (Weisskopf and Ewing 1940; Ait-Tahar and Hodgson 1987).

Table 3

Neutron density and flux distributions for Maxwell–Boltzmann distributed neutrons at temperature T , as a function of velocity v , energy E , wavelength λ , and time-of-flight t

Distribution	Most probable value	Equivalent in E_T	Mean value
$n_v(v) = \frac{4}{\sqrt{\pi}} \frac{v^2}{v_T^3} e^{-\frac{v^2}{v_T^2}}$	$v_{\max} = v_T$	E_T	$\langle v \rangle = \frac{2}{\sqrt{\pi}} v_T$
$n_E(E) = \frac{2}{\sqrt{\pi}} \sqrt{\frac{E}{E_T^3}} e^{-\frac{E}{E_T}}$	$E_{\max} = \frac{1}{2} E_T$	$\frac{1}{2} E_T$	$\langle E \rangle = \frac{3}{2} E_T$
$n_t(t) = \frac{4}{\sqrt{\pi}} \frac{t_T^3}{t^4} e^{-\frac{t_T^2}{t^2}}$	$t_{\max} = \frac{1}{\sqrt{2}} t_T$	E_T	$\langle t \rangle = \frac{2}{\sqrt{\pi}} t_T$
$n_\lambda(\lambda) = \frac{4}{\sqrt{\pi}} \frac{\lambda_T^3}{\lambda^4} e^{-\frac{\lambda_T^2}{\lambda^2}}$	$\lambda_{\max} = \frac{1}{\sqrt{2}} \lambda_T$	E_T	$\langle \lambda \rangle = \frac{2}{\sqrt{\pi}} \lambda_T$
$\varphi_v(v) = 2 \frac{v^3}{v_T^4} e^{-\frac{v^2}{v_T^2}}$	$v_{\max} = \sqrt{\frac{3}{2}} v_T$	$\frac{3}{2} E_T$	$\langle \varphi_v \rangle = \sqrt{\frac{3}{2}} v_T$
$\varphi_E(E) = \frac{E}{E_T^2} e^{-\frac{E}{E_T}}$	$E_{\max} = E_T$	E_T	$\langle \varphi_E \rangle = 2 E_T$
$\varphi_t(t) = 2 \frac{t_T^4}{t^5} e^{-\frac{t_T^2}{t^2}}$	$t_{\max} = \sqrt{\frac{2}{5}} t_T$	$\frac{5}{2} E_T$	$\langle \varphi_t \rangle = \frac{\sqrt{\pi}}{2} t_T$
$\varphi_\lambda(\lambda) = 2 \frac{\lambda_T^4}{\lambda^5} e^{-\frac{\lambda_T^2}{\lambda^2}}$	$\lambda_{\max} = \sqrt{\frac{2}{5}} \lambda_T$	$\frac{5}{2} E_T$	$\langle \varphi_\lambda \rangle = \frac{\sqrt{\pi}}{2} \lambda_T$

The method has gained renewed interest by several recent measurements, especially for fission and capture reactions. In [Table 4](#) a few examples of surrogate reactions and their equivalent neutron-induced reaction, are given.

Because of the different involved spins and orbital momenta, in some cases a different spin-parity distribution may influence the decay probabilities if the same compound nucleus has been formed by a neutron or by a charged particle. This effect can often be neglected (Younes and Britt 2003; Escher and Dietrich 2006). More details and references may be found in refs (Petit et al. 2004; Plettner et al. 2005; Boyer et al. 2006; Lyles et al. 2007; Hatarik et al. 2009).

In [Fig. 48](#) the surrogate reaction $^{232}\text{Th}(^3\text{He},\text{p})^{234}\text{Pa}^*$ is shown. From the measured gamma decay the $^{233}\text{Pa}(n,\gamma)$ cross section is derived and compared to evaluated data (Boyer et al. 2006).

The surrogate ratio $^{234}\text{U}(\alpha,\alpha'f)/^{236}\text{U}(\alpha,\alpha'f)$ is shown in [Fig. 49](#). These reactions are well above their thresholds and are in a range where the Weisskopf-Ewing approximation to a Hauser-Feshbach calculation is expected to represent the reactions rather well.

The comparison of the known $^{235}\text{U}(n,\gamma)$ and (n,f) cross section ratio as evaluated in ENDF/B-VII to that measured in the surrogate reactions $^{235}\text{U}(d,\text{p}\gamma)$ and $^{235}\text{U}(d,\text{p fission})$

■ Table 4

Some examples of surrogate reactions for actinides and their equivalent neutron induced reaction, where the asterisk denotes a compound nucleus

Neutron induced reaction	Surrogate reaction
$^{235}\text{U} + n \rightarrow ^{236}\text{U}^*$	$^{234}\text{U}(t,p)^{236}\text{U}^*$
$^{235}\text{U} + n \rightarrow ^{236}\text{U}^*$	$^{235}\text{U}(d,p\gamma)^{236}\text{U}^*$
$^{235}\text{U} + n \rightarrow ^{236}\text{U}^*$	$^{236}\text{U}(\alpha,\alpha')^{236}\text{U}^*$
$^{233}\text{Pa} + n \rightarrow ^{234}\text{Pa}^*$	$^{232}\text{Th}(^3\text{He},p)^{234}\text{Pa}^*$
$^{241}\text{Am} + n \rightarrow ^{242}\text{Am}^*$	$^{243}\text{Am}(^3\text{He},\alpha)^{242}\text{Am}^*$
$^{243}\text{Cm} + n \rightarrow ^{244}\text{Cm}^*$	$^{243}\text{Am}(^3\text{He},d)^{244}\text{Cm}^*$

■ Figure 48

The $^{233}\text{Pa}(n,\gamma)$ cross section measured with the surrogate reaction $^{232}\text{Th}(^3\text{He},p)^{234}\text{Pa}^*$ (Data are from Boyer et al. 2006)

(Allmond et al. 2009) is shown in [Fig. 50](#). This comparison shows the data obtained in surrogate reactions at equivalent low incident neutron energies.

In [Fig. 51](#) the $^{236}\text{U}(n,f)$ cross section as determined by the surrogate ratio method is compared with values from the ENDF/B-VII evaluated data (Lyles et al. 2007). This comparison shows that the surrogate method does well for fission cross sections a few MeV above threshold.

■ Figure 49

Results of the surrogate ratio $^{234}\text{U}(\alpha,\alpha'f)/^{236}\text{U}(\alpha,\alpha'f)$ compared to the ENDF-BVII ratio of $^{233}\text{U}(n,f)/^{235}\text{U}(n,f)$ (Burke et al. 2008)

■ Figure 50

Comparison of the known $^{235}\text{U}(n,\gamma)$ and (n,f) cross section ratio as evaluated in ENDF/B-VII to that measured in the surrogate reactions, $^{235}\text{U}(d,p\gamma)$ and $^{235}\text{U}(d,p$ fission) (Allmond et al. 2009)

■ Figure 51

The $^{236}\text{U}(n,f)$ cross section as determined by the surrogate ratio method (Lyles et al. 2007) is compared with values from the ENDF/B-VII evaluated data

5.6 Cross Section Standards

Many cross sections are measured relative to well understood, well measured, “standard” cross sections (Carlson et al. 2009). If the standard is measured along with the reaction of interest, then there is no need to measure the neutron flux. The particular reactions that are considered standards have been agreed to internationally and the standards data are maintained by the Nuclear Data Section of the International Atomic Energy (<http://www.nds.org/standards/>). Standards data include scattering, capture, and fission cross sections. In addition, for activation, there is the International Reactor Dosimetry File with recommended cross sections (not officially “standards”) (http://www-pub.iaea.org/MTCD/publications/TRS452_web.pdf).

6 Nuclear Resonances and the *R*-Matrix Formalism

6.1 Introduction

If the wave functions of the nuclear system before and after the reaction were known, one could calculate the cross section with the usual concepts of reaction theory. While the incoming waves are known, the reaction modifies the outgoing wave functions in a generally unknown way.

The idea behind the *R*-matrix formalism is to use the wave function of the nuclear system of two particles when they are so close that they form a compound nucleus. Although the wave function of the compound nucleus is extremely complicated, one can expand it in its eigenstates. Matching, then, the incoming and outgoing waves to the internal wave function provides a way to describe the cross section of the reaction in terms of the properties of the eigenstates of the compound nucleus. These properties are basically the energy, spin, parity, and a set of partial widths related to the widths of the decay modes of the compound nucleus.

This method of describing a reaction cross section using only the properties of nuclear excitation levels, is at the same time also the most important limitation. No information of the forces inside the nucleus is needed or can be extracted. The nucleus is treated as a black box of which the properties of the eigenstates have to be measured in order to describe the cross sections.

The binary nuclear reactions proceeding from one system of two particles to another system of two particles can be described with the general R -matrix theory. Not only in neutron-induced reactions, but also in other cases, such a reaction goes often through the formation of a compound nucleus X^* .

The R -matrix formalism does not only apply to compound nucleus reactions. Both direct and indirect reactions can be described with it. The inclusion of the Coulomb interaction allows us to use it also for charged particle reactions. But the theory is applicable only in a general way for binary reactions, which is appropriate for neutron-induced reactions up to energies of several tens of MeV.

In a very general way, the cross section of a two-body nuclear reaction could be calculated if the nuclear wave functions were known. The wave functions could be calculated by solving the Schrödinger equation for the nuclear system. This requires that the nuclear potential is known. When the two particles are far away, the interaction can be considered absent for neutral particles or to be the Coulomb interaction for charged particles. In these cases it is indeed possible to calculate the wave functions.

When the two particles are so close to each other that a nuclear reaction takes place, the potential of the interaction is extremely complicated. For certain energy ranges and reactions this potential can still be approximated or calculated (Bauge et al. 2001) and the wave functions and cross sections can be calculated. In other cases however, and especially in the resolved resonance region, the complexity of the reacting system does not allow this.

The first step is to consider that the reaction process can be split up geometrically into two regions for each channel where a channel is the precise constellation of particles and their spins. If the separation is smaller than the channel radius a_c , all nucleons involved in the reaction are close to each other and form a compound nucleus. Although the wave function of the compound nucleus is extremely complicated, it can be expanded as a linear combination of its eigenstates without solving explicitly the Schrödinger equation of the system. In the external region, at distances larger than a_c , the potential is zero for neutral particles or is the Coulomb interaction for charged particles and the Schrödinger equation of the system can be solved. The properties of the eigenstates of the compound nucleus are included in the R -matrix. Equating the values and derivatives of the wave functions at the boundary of the internal and external region assures a smooth wave function and the cross sections can be calculated as is illustrated in  Fig. 52. The exact internal wave function is not needed, only the values and derivatives at the nuclear surface.

In the following we describe in more detail the R -matrix formalism which links the properties of the nuclear states to the cross sections. The cross section in the thermal energy region is also described by the R -matrix formalism. Reaction cross sections at thermal energy are the sum of the contributions of all nuclear states, that is, the resonances but also the bound states, sometimes referred to as “negative energy” resonances. Other reaction formalisms have been used in the past, like the K -matrix formalism (Payne and Schlessinger 1970) still in use for particle physics (Shyam and Scholten 2008), but for neutron-induced resonance reactions the

Figure 52

Schematic view of the wave function of a channel as a function of the separation distance r . The wave function in the internal region $r < a_c$ is an expansion of the eigenstates of the compound nucleus. The full internal ($r < a_c$) wave function is not needed, only the value and derivative at $r = a_c$ where it matches the known external ($r > a_c$) wave function which is related to the Bessel functions

R -matrix formalism, and in particular one of its approximations, is nowadays the preferred formalism.

The R -matrix formalism was first introduced by Wigner and Eisenbud (1947). A most extensive and detailed overview has been given by Lane and Thomas (1958) and by Lynn (1968). Recently Fröhner (2000) summarized the R -matrix formalism together with other useful considerations on nuclear data evaluation. Other related references of interest can be found elsewhere (Humblet and Rosenfeld 1961; Vogt 1962; Schmittroth and Tobocman 1971; Foderaro 1971; Adler 1972; Feshbach 1991; Luk'yanov and Yaneva 1997; Brune 2002). A brief outline of the formalism will be given in order to understand its basic principles.

6.1.1 Channel Representation

It is customary to use the concept of channels in the description of nuclear reactions, which will be limited to two particle reactions in the following. The entrance channel c consists of a particular initial constellation of particles and all the quantum numbers necessary to describe the corresponding partial wave function. The type of the two particles α_1 and α_2 , with their spins I_{α_1} and I_{α_2} , and their states of internal excitation are denoted by α . Four quantum numbers are needed to include the spins of the particles in a channel. The most appropriate combination is the orbital angular momentum ℓ , the channel spin j , which is the combined spin of the two particles

$$\mathbf{j} = \mathbf{I}_{\alpha_1} + \mathbf{I}_{\alpha_2}, \quad (40)$$

the total angular momentum J

$$\mathbf{J} = \mathbf{j} + \boldsymbol{\ell} \quad (41)$$

and its projection on the z -axis m_j . So the entrance channel c can be designated by the set

$$c = \{\alpha, \ell, j, J, m_j\} \quad (42)$$

Similarly, the exit channel is given by

$$c' = \{\alpha', \ell', j', J', m_j'\} \quad (43)$$

The reaction $\alpha \rightarrow \alpha'$ may go through the formation of a compound nucleus, like often the case with neutron-induced reactions. The reaction can then be written as $\alpha \rightarrow A^* \rightarrow \alpha'$. The spin and parity are of course conserved in all stages of the reaction and the compound nucleus has its defined spin J and parity π . The conservation of spin and parity puts restrictions on the entrance channels that are open to form the compound nucleus or the exit channels open for the decay of the compound nucleus. For neutrons and protons the intrinsic spin is $1/2$ and the intrinsic parity is positive. Conservation of angular momentum gives the vector addition:

$$\mathbf{J} = \mathbf{I}_{\alpha_1} + \mathbf{I}_{\alpha_2} + \boldsymbol{\ell} = \mathbf{I}_{\alpha'_1} + \mathbf{I}_{\alpha'_2} + \boldsymbol{\ell}' \quad (44)$$

and conservation of parity gives, using $+1$ for positive and -1 for negative parity:

$$\pi = \pi_{I_{\alpha_1}} \times \pi_{I_{\alpha_2}} \times (-1)^\ell = \pi_{I_{\alpha'_1}} \times \pi_{I_{\alpha'_2}} \times (-1)^{\ell'} \quad (45)$$

The conservation of angular momentum has important consequences for cross section calculations based on channels. The total number of possible combinations to sum the spins and orbital momentum is $(2I_{\alpha_1} + 1)(2I_{\alpha_2} + 1)(2\ell + 1)$. Only $2J + 1$ orientations of them add up to J . For this reason in expressions for cross sections of the formation of a compound nucleus level with spin J for a given ℓ the statistical factor $g(J)$

$$g(J) = \frac{2J + 1}{(2I_{\alpha_1} + 1)(2I_{\alpha_2} + 1)} \quad (46)$$

is taken into account.

The boundary $r = a_c$ is the limit between the internal region, where all the nucleons interact, and the external region where the incident and target particles do not have a nuclear interaction, other than possibly a Coulomb interaction. Although there is no sharp limit, in practice the channel radius a_c can be taken just slightly larger than the radius $R' = R_0 A^{1/3}$ of a spherical nuclear volume with $A = A_{\alpha_1} + A_{\alpha_2}$ nucleons, and where for R_0 usually the value 1.35 fm is used. This scattering radius can be used as a first approximation of the low-energy potential scattering cross section σ_{pot} with the relation

$$\sigma_{\text{pot}} = 4\pi R'^2 \quad (47)$$

Experimental values of R' show larger structures around the smooth curve $R' = R_0 A^{1/3}$, which can be well described with optical model calculations. In evaluated nuclear libraries, the channel radius a_c can be defined to have either the numerical value of a possibly energy-dependent scattering radius R' , or an energy-independent, mass-dependent channel radius given by

$$a_c = 0.8 + 1.23A^{1/3} \text{ fm} \quad (48)$$

where A' is the ratio of the isotope mass to the mass of the neutron. The channel is defined in the center of mass and the reduced mass of the particles is

$$m_c = m_\alpha = \frac{m_{\alpha_1} m_{\alpha_2}}{m_{\alpha_1} + m_{\alpha_2}} \quad (49)$$

and the wave number k , related to the de Broglie wavelength λ , is

$$k_c = k_\alpha = \frac{1}{\lambda_c} = \sqrt{\frac{2m_\alpha E_\alpha}{\hbar^2}} \quad (50)$$

and the relative velocity is

$$v_c = v_\alpha = \hbar k_c / m_c \quad (51)$$

The dimensionless distance ρ_c is used to indicate the distance r_c in measures of de Broglie wavelengths.

$$\rho_c = \rho_\alpha = k_c r_c \quad (52)$$

6.1.2 The Wave Function in the External Region

The system of the two particles interacting through a central potential $V(r)$ can be described by the Schrödinger equation of the motion of the reduced mass particle. Also, using spherical coordinates, the solution $\psi(r, \theta, \phi)$ can, in case of a central potential, be separated in a radial and an angular part

$$\psi(r, \theta, \phi) = R(r)\Theta(\theta)\Phi(\phi) \quad (53)$$

The radial part $R(r)$ although still depends on the nonnegative integer solutions $\ell(\ell + 1)$ of $\Theta(\theta)$. The integers appearing in the solution of $\Phi(\phi)$ are $m_\ell = 0, \pm 1, \pm 2, \dots, \pm \ell$. The solutions of the angular part $\Theta(\theta)\Phi(\phi)$ do not depend on the central potential and are the spherical harmonics $Y_{m_\ell}^\ell(\theta, \phi)$. Only the solution $R(r)$ of the radial part depends on the potential $V(r)$. The radial Schrödinger equation

$$\left[\frac{d^2}{dr^2} - \frac{\ell(\ell + 1)}{r^2} - \frac{2m_c}{\hbar^2} (V(r) - E) \right] R(r) = 0 \quad (54)$$

can be solved for the case of the Coulomb potential $V(r) = -Z_{\alpha_1} Z_{\alpha_2} e^2 / (4\pi\epsilon_0 r)$. The general solution is a linear combination of regular and irregular Coulomb wave functions. In the special case that $V(r) = 0$, such as for neutrons, (54), after a rearrangement in dimensionless form, is called the spherical Bessel equation. The solution consists of a linear combination of spherical Bessel functions of the first type $j_\ell(\rho)$, and of the second type $n_\ell(\rho)$ (or Neumann functions). Two linearly independent complex combinations of j_ℓ and n_ℓ are known as spherical Bessel functions of the third type (or Hankel functions) $h_\ell^+(\rho)$ and $h_\ell^-(\rho)$ (Abramowitz 1965; Zwillinger 2003). These are functions of the dimensionless parameter $\rho = kr$. Although $n_\ell(\rho) \rightarrow -\infty$ for $r \rightarrow 0$, this irregular solution should be included because we only need this

■ Table 5

The spherical Bessel functions and the incoming and outgoing waves from equations (55) and (56). Derived quantities are given in ► Table 6

ℓ	j_ℓ	n_ℓ	$O_\ell = I_\ell^*$
0	$\frac{\sin \rho}{\rho}$	$-\frac{\cos \rho}{\rho}$	$e^{i\rho}$
1	$\frac{\sin \rho}{\rho^2} - \frac{\cos \rho}{\rho}$	$-\frac{\cos \rho}{\rho^2} - \frac{\sin \rho}{\rho}$	$e^{i\rho} \left(\frac{1}{\rho} - i \right)$
ℓ	$(-1)^\ell \rho^\ell \left(\frac{1}{\rho} \frac{d}{d\rho} \right)^\ell \frac{\sin \rho}{\rho}$	$-(-1)^\ell \rho^\ell \left(\frac{1}{\rho} \frac{d}{d\rho} \right)^\ell \frac{\cos \rho}{\rho}$	

■ Figure 53

The Bessel function $j_\ell(\rho)$ for $\ell = 0, 1, 2, 3$ is shown as a function of ρ and as a function of equivalent energy for a nucleus with mass $A = 238$

solution in the external region $r > a_c$. The appropriate solution for a channel c is a linear combination of waves corresponding to incoming $I_c(r)$ and outgoing $O_c(r)$ waves for a free particle, $R(r) = R_\ell(r) = y_\ell I_\ell(r) + x_\ell O_\ell(r)$, with

$$I_c(r) = I_\ell(r) = -iph_\ell^-(\rho) = -i\rho(j_\ell(\rho) - in_\ell(\rho)) \quad (55)$$

and

$$O_c(r) = O_\ell(r) = -iph_\ell^+(\rho) = i\rho(j_\ell(\rho) + in_\ell(\rho)) \quad (56)$$

The functions $j_\ell(\rho)$ and $n_\ell(\rho)$ together with $O_\ell(\rho)$ are given in ► Table 5. In ► Fig. 53 the function $j_\ell(\rho)$ is shown as a function of ρ and as a function of equivalent energy for a nucleus with mass $A = 238$.

6.1.3 The Collision Matrix U

The total wave function Ψ in the external region can be expressed as the superposition of all incoming and outgoing partial waves \mathcal{I}_c and \mathcal{O}_c , with amplitudes y_c and x_c , and summed over all possible channels c .

$$\Psi = \sum_c y_c \mathcal{I}_c + \sum_{c'} x_{c'} \mathcal{O}_{c'} \quad (57)$$

The complete wave functions in the channel, \mathcal{I}_c and \mathcal{O}_c , contain the radial parts I_c and O_c , but also the angular part of relative motion $Y_{m_\ell}^\ell$, as well as the internal wave functions of the particles and the channel spin, combined in φ_c , and are written as

$$\mathcal{I}_c = I_c r^{-1} \varphi_c i^\ell Y_{m_\ell}^\ell(\theta, \phi) / \sqrt{v_c} \quad (58)$$

and

$$\mathcal{O}_c = O_c r^{-1} \varphi_c i^\ell Y_{m_\ell}^\ell(\theta, \phi) / \sqrt{v_c} \quad (59)$$

The factor $1/\sqrt{v_c}$ normalizes the waves to unit flux. The physical process of the reaction will result in a modification of the outgoing waves. In the reaction, the coefficients x_c of the outgoing waves, depending on the details of the reaction which are observable in the cross section, have to be determined with respect to the coefficients of the incoming waves y_c . The collision matrix $U_{cc'}$ is now defined as the relation between the coefficients of the incoming and outgoing waves:

$$x_{c'} \equiv - \sum_c U_{c'c} y_c \quad (60)$$

All the physics of the reaction is contained in the elements of the collision matrix. The collision matrix has two important properties. From the conservation of probability flux in the reaction it follows that the collision matrix is unitary, which means that its complex conjugate equals its reciprocal, $\mathbf{U}^* = \mathbf{U}^{-1}$ or

$$\sum_c U_{cc'}^* U_{cc''} = \delta_{c'c''} \quad (61)$$

The second property follows from time reversal conservation and implies that the collision matrix is symmetric, $U_{cc'} = U_{c'c}$.

Finally, we can express the total wave function of (57) in terms of the collision matrix:

$$\Psi = \sum_c y_c \left(\mathcal{I}_c - \sum_{c'} U_{cc'} \mathcal{O}_{c'} \right) \quad (62)$$

which is a linear combination of the wave functions for each channel c , consisting of an ingoing wave and the modified outgoing waves summed over all channels c' .

6.1.4 The Relation Between the Cross Sections and the Collision Matrix U

The relation between reaction cross sections and wave functions, describing a probability, is based on the conservation of probability density. The probability density of an incident plain

wave, which is the flux of particles \mathbf{j}_φ is given by the quantum mechanical expression

$$\mathbf{j}_\varphi = \frac{\hbar}{2mi} (\psi^* \nabla \psi - \psi \nabla \psi^*) \quad (63)$$

The connection with the cross section is best illustrated by considering a flux of incident particles j_{inc} , represented by a plain wave ψ_{inc} , which can be expanded in a series of partial radial waves, scattering elastically at a point $r = 0$ because of an unknown physical process. The scattered wave, originating at $r = 0$ is a radial wave ψ_{sc} and far from the scattering center at a distance r in a solid angle element $d\Omega$ the current of scattered particles across the surface $r^2 d\Omega$ is j_{sc} . The total wave $\psi = \psi_{\text{inc}} + \psi_{\text{sc}}$ is a solution of the Schrödinger equation for this system. The cross section of this reaction, which is a differential cross section, is defined as

$$d\sigma = \frac{j_{\text{sc}}}{j_{\text{inc}}} r^2 d\Omega \quad (64)$$

Integrating over $d\Omega$ gives the total scattering cross section. If elastic scattering were the only process to occur, the total current of ingoing particles equals that of the outgoing particles. Any reaction, defined as any other process than elastic scattering, means that there is a difference in the absolute values of the ingoing and outgoing current.

In the more general description of channels the total wave function is (62). Elastic scattering means here that the entrance and exit channel are the same. A change of channel in the outgoing wave is considered as a reaction. With a similar approach, including the expansion of the incoming plane wave into an infinite sum of partial waves ℓ , and using the full description of the channel wave functions, the angular differential cross section for the reaction $\alpha \rightarrow \alpha'$ has been worked out by Blatt and Biedenharn (1952). For zero Coulomb interaction the expression is

$$\frac{d\sigma}{d\Omega} = \frac{1}{2j+1} \lambda^2 \sum_{\ell=0}^{\infty} B_\ell(c, c') P_\ell(\cos \theta) \quad (65)$$

The coefficients $B_\ell(c, c')$ are rather complicated factors and contain the collision matrix elements $U_{cc'}$ and relations containing Clebsch–Gordan coefficients for the spin bookkeeping, eliminating most of the terms in the infinite sum over ℓ .

The cross section for an interaction from channel c to channel c' is then

$$\sigma_{cc'} = \pi \lambda_c^2 |\delta_{c'c} - U_{c'c}|^2 \quad (66)$$

If the interaction occurs without a change in the channel c then the process is called elastic scattering. The cross section is, putting $c' = c$

$$\sigma_{cc} = \pi \lambda_c^2 |1 - U_{cc}|^2 \quad (67)$$

and the cross section for a channel reaction, i.e. any interaction which is not elastic scattering, is obtained by summing (66) over all c' except c

$$\sigma_{cr} = \pi \lambda_c^2 (1 - |U_{cc}|^2) \quad (68)$$

and the total cross section is obtained by summing all channels c'

$$\sigma_{c,T} = \sigma_c = 2\pi \lambda_c^2 (1 - \text{Re } U_{cc}) \quad (69)$$

In practice, channel to channel cross sections are not useful. One would like to have the cross sections of $\alpha \rightarrow \alpha'$ for the component of total angular momentum J . The total reaction cross section is obtained by integrating (65) over the full solid angle to obtain the total cross section for the component of total angular momentum J

$$\sigma_{\alpha\alpha'}(J) = \pi\lambda_\alpha^2 g(J) \sum_{j,j',\ell,\ell'} |\delta_{jj'\ell\ell'} - U_{j\ell,j'\ell'}|^2 \quad (70)$$

and the total cross section by summing over all α'

$$\sigma_{\alpha,T}(J) = 2\pi\lambda_\alpha^2 g(J) \sum_{j,\ell} (1 - \text{Re } U_{j\ell,j\ell}) \quad (71)$$

6.1.5 The Wave Function in the Internal Region

The complete wave function Ψ can be described as the product of the function of relative motion and the channel-spin function, giving the internal states of the particles α_1 and α_2 and their combined spin. From the function of relative motion the radial part $R(r)$ is separated and the remaining part is combined with the channel-spin function to give the channel surface function φ_c

$$\Psi = \sum_c \varphi_c R_c(a_c). \quad (72)$$

The surface functions φ_c have the property of orthonormality over the surface S_c given by $r = a_c$. This will be exploited to expand certain quantities in terms of surface functions. It follows immediately that

$$R_c(a_c) = \int \varphi_c^* \Psi dS_c. \quad (73)$$

The integration over a surface, instead of integrating over a volume, is particularly useful in deriving the R -matrix relation using Green's theorem, expressing a volume integral in a surface integral.

At the channel surface $r = a_c$ the radial wave function for the internal and external region should match. The value V_c and derivative D_c are defined with a normalization constant as

$$\begin{aligned} V_c &= \sqrt{\frac{\hbar^2}{2m_c a_c}} u_c(a_c) \\ &= \sqrt{\frac{\hbar^2}{2m_c a_c}} \int \varphi_c^* \Psi dS_c \end{aligned} \quad (74)$$

and

$$\begin{aligned} D_c &= \sqrt{\frac{\hbar^2}{2m_c a_c}} a_c \left(\frac{du_c}{dr} \right)_{r=a_c} \\ &= \sqrt{\frac{\hbar^2}{2m_c a_c}} \int \varphi_c^* \nabla_n (r\Psi) dS_c \\ &= V_c + \sqrt{\frac{\hbar^2}{2m_c a_c}} a_c \int \varphi_c^* dS_c \end{aligned} \quad (75)$$

In the internal region the wave function cannot be calculated readily by solving the Schrödinger equation since the nuclear potential is in general very complicated and the nucleus has many interacting nucleons. But the wave function can be expressed as an expansion in eigenfunctions X_λ and eigenvalues E_λ

$$\Psi = \sum_{\lambda} A_{\lambda} X_{\lambda} \quad (76)$$

and the coefficients A_λ can be expressed as

$$A_{\lambda} = \int X_{\lambda}^* \Psi d\tau \quad (77)$$

where the integration goes over the volume $d\tau$ of the internal region given by $r < a_c$.

The values and derivatives on the surface $r = a_c$ are defined, analog to (74) and (75), as

$$\gamma_{\lambda c} = \sqrt{\frac{\hbar^2}{2m_c a_c}} \int \varphi_c^* X_{\lambda} dS_c \quad (78)$$

and

$$\delta_{\lambda c} = \gamma_{\lambda c} + \sqrt{\frac{\hbar^2}{2m_c a_c}} a_c \int \varphi_c^* \nabla_n(X_{\lambda}) dS_c. \quad (79)$$

The boundary conditions to be satisfied on the channel surface are taken identical for all λ

$$B_c = \delta_{\lambda c} / \gamma_{\lambda c}. \quad (80)$$

Applying Green's theorem to (77) gives

$$\begin{aligned} A_{\lambda} &= \int X_{\lambda}^* \Psi d\tau \\ &= (E_{\lambda} - E)^{-1} \frac{\hbar^2}{2m_c} \int (X_{\lambda}^* \nabla_n(\Psi) - \Psi \nabla_n(X_{\lambda}^*)) dS_c \\ &= (E_{\lambda} - E)^{-1} \sum_c (D_c - B_c V_c) \gamma_{\lambda c} \end{aligned} \quad (81)$$

using (74), (75), (78), (79), and (80). The expression (76) for the wavefunction can now be written as

$$\Psi = \sum_c \left[\sum_{\lambda} \frac{X_{\lambda} \gamma_{\lambda c}}{E_{\lambda} - E} \right] (D_c - B_c V_c). \quad (82)$$

By multiplying each side of (82) by $\varphi_{c'}$, integrating over the surface $r = a_c$ and using (78) one obtains

$$V_{c'} = \sum_c R_{cc'} (D_c - B_c V_c) \quad (83)$$

with

$$R_{cc'} = \sum_{\lambda} \frac{\gamma_{\lambda c} \gamma_{\lambda c'}}{E_{\lambda} - E}. \quad (84)$$

The quantity $R_{cc'}$ is the R -matrix and contains the properties E_{λ} and $\gamma_{\lambda c}$ of the eigenstates λ . The boundary constant B_c can be chosen freely.

6.1.6 The Relation Between the R -Matrix and the Collision Matrix \mathbf{U}

The values and derivatives of the internal wave function are given by the R -matrix relation (83). The external wave function is given by (62) and is known except for the boundary conditions. The boundary condition is that both the internal and external wave functions have the same value and radial derivative at $r = a_c$ in order to have a smooth transition. By matching these conditions and after considerable rearrangements, the collision matrix $U_{cc'}$ can be given explicitly as a function of the R -matrix in matrix notation by

$$\mathbf{U} = \Omega \mathbf{P}^{1/2} [1 - \mathbf{R}(\mathbf{L} - \mathbf{B})]^{-1} [1 - \mathbf{R}(\mathbf{L}^* - \mathbf{B})] \mathbf{P}^{-1/2} \Omega. \quad (85)$$

The introduced complex matrix \mathbf{L} is given by

$$L_c = S_c + iP_c = \left(\frac{\rho}{O_c} \frac{dO_c}{d\rho} \right)_{r=a_c} \quad (86)$$

where real matrices S_c is called the shift factor and P_c the penetrability factor. The matrix Ω_c is

$$\Omega_c = \left(\frac{I_c}{O_c} \right)_{r=a_c} \quad (87)$$

which can be reduced for neutral particles, using (55) and (56), to

$$\Omega_c = \exp(-i\phi_c) \quad (88)$$

from which ϕ_c follows

$$\phi_c = \arg O_c(a_c) = \arctan \left(\frac{\text{Im } O_c}{\text{Re } O_c} \right) = \arctan \left(-\frac{j_\ell(\rho)}{n_\ell(\rho)} \right) \quad (89)$$

All matrices in (85) are diagonal matrices except \mathbf{U} and \mathbf{R} . A table of P_ℓ , S_ℓ , and ϕ_ℓ is given in [Table 6](#). They are directly related to the solution of the Schrödinger equation in the external region, which are the spherical Bessel and Neumann functions $j_\ell(\rho)$ and $n_\ell(\rho)$ for neutral particles, and can be derived from the quantities listed in [Table 5](#).

Table 6

The penetrability P_ℓ , the level shift S_ℓ and the hard-sphere phase shift ϕ_ℓ for reaction channels without Coulomb interaction, as a function of $\rho = ka_c$. These parameters are derived from the quantities in [Table 5](#)

ℓ	P_ℓ	S_ℓ	ϕ_ℓ
0	ρ	0	ρ
1	$\rho^3/(1 + \rho^2)$	$-1/(1 + \rho^2)$	$\rho - \arctan \rho$
ℓ	$\frac{\rho^2 P_{\ell-1}}{(\ell - S_{\ell-1})^2 + P_{\ell-1}^2}$	$\frac{\rho^2 (\ell - S_{\ell-1})}{(\ell - S_{\ell-1})^2 + P_{\ell-1}^2} - \ell$	$\phi_{\ell-1} - \arctan \frac{P_{\ell-1}}{\ell - S_{\ell-1}}$

Figure 54

The functions $P_\ell(\rho)$, $S_\ell(\rho)$, and $\phi_\ell(\rho)$ for $\ell = 0, 1, 2, 3$ shown as a function of ρ and as a function of equivalent energy for a nucleus with mass $A = 238$

If the boundary conditions B_c , defined by (80), are real, then the $\delta_{\lambda c}$ and the $\gamma_{\lambda c}$ are real and hence \mathbf{R} is real. In addition \mathbf{R} is symmetrical. A common choice is to take

$$B_c = S_c \quad (90)$$

which eliminates the shift factor for s -waves, but introduces an energy dependence. The choice $B_c = -\ell$ has also been proposed (Fröhner 2000). At low energy this is equivalent as can be seen in Fig. 54, where P_ℓ , S_ℓ and ϕ_ℓ are plotted as a function of ρ and as a function of equivalent energy for a nucleus with mass $A = 238$.

So (85) defines the collision matrix in terms of the parameters of the R -matrix, $\gamma_{\lambda c}$ and E_λ , representing the physical process of the reaction, and the quantities P_c , S_c , ϕ_c , describing the known incoming and outgoing waves I_c and O_c , outside a sphere with radius a_c . The values B_c determine the boundary conditions at the matching point of the internal and external region, and are free to be chosen. The unknowns of the R -matrix, $\gamma_{\lambda c}$ and E_λ , need to be determined in order to know the U -matrix and subsequently the cross sections.

6.2 Approximations of the R -Matrix

Several approximations of the R -matrix have been developed in the past in order to overcome the complications of inverting the matrix

$$[1 - \mathbf{R}(\mathbf{L} - \mathbf{B})]^{-1}$$

appearing in (85). Except in the case where only one or two channels are involved, the inversion is in general impossible without additional assumptions. The problem can be put in terms of the inversion of a level matrix \mathbf{A} of which the elements refer to the properties of the levels λ of the system. The problem of inverting a matrix concerning all channels is now put in a problem of inverting a matrix concerning levels.

The level matrix $A_{\lambda\mu}$ is introduced by putting the following form

$$([1 - \mathbf{R}(\mathbf{L} - \mathbf{B})]^{-1})_{cc'} = \delta_{cc'} + \sum_{\lambda\mu} \gamma_{\lambda c} \gamma_{\mu c'} (L_{c'} - B_{c'}) A_{\lambda\mu} \quad (91)$$

from which the elements of the inverse of \mathbf{A} are

$$\begin{aligned} (\mathbf{A}^{-1})_{\lambda\mu} &= (E_\lambda - E) \delta_{\lambda\mu} - \sum_c \gamma_{\lambda c} \gamma_{\mu c} (L_c - B_c) \\ &= (E_\lambda - E) \delta_{\lambda\mu} - \Delta_{\lambda\mu} - \frac{1}{2} i \Gamma_{\lambda\mu} \end{aligned} \quad (92)$$

with the quantities $\Delta_{\lambda\mu}$ and $\Gamma_{\lambda\mu}$ defined by

$$\Delta_{\lambda\mu} = \sum_c (S_c - B_c) \gamma_{\lambda c} \gamma_{\mu c} \quad (93)$$

and

$$\Gamma_{\lambda\mu} = 2 \sum_c P_c \gamma_{\lambda c} \gamma_{\mu c} \quad (94)$$

Now the collision matrix from (85) can be expressed in terms of \mathbf{A}

$$U_{cc'} = \Omega_c \Omega_{c'} \left(\delta_{cc'} + 2i \sqrt{P_c P_{c'}} \sum_{\lambda\mu} A_{\lambda\mu} \gamma_{\lambda c} \gamma_{\mu c'} \right) \quad (95)$$

Additional approximations have been formulated in order to simplify this expression. The most illustrative is the Breit and Wigner single level (SLBW) approximation where only one level is considered. It can be extended to several, independent levels, which is the Breit and Wigner multi level (MLBW) approximation. The formalism of Reich and Moore (1958) neglects only the off-diagonal contributions of the photon channels, which is an accurate approximation for medium and heavy nuclei. It takes into account the interference between levels and reduces to the SLBW approximation in the limit of a single level. These three formalisms will be described in some more detail. Other formalisms exist of which we mention here the formalisms of Kapur and Peierls (1938), Wigner and Eisenbud (1947), Adler (1972), Hwang (1973), and more recently Luk'yanov and Yaneva (1997).

6.2.1 The Breit–Wigner Single Level Approximation

The expression (92) can be simplified if only a single level is present. In that case the matrix contains only a single element. Therefore,

$$(\mathbf{A}^{-1})_{\lambda\mu} = A^{-1} = E_\lambda - E + \Delta_\lambda - i\Gamma_\lambda/2 \quad (96)$$

with

$$\Delta_\lambda = \Delta_{\lambda\lambda} = -\sum_c (S_c - B_c)\gamma_{\lambda c}^2 \quad (97)$$

and

$$\Gamma_\lambda = \Gamma_{\lambda\lambda} = \sum_c \Gamma_{\lambda c} = \sum_c 2P_c\gamma_{\lambda c}^2 \quad (98)$$

Substituting these expressions in (95) gives the collision matrix

$$U_{cc'} = e^{-i(\phi_c + \phi_{c'})} \left(\delta_{cc'} + \frac{i\sqrt{\Gamma_{\lambda c}\Gamma_{\lambda c'}}}{E_\lambda + \Delta_\lambda - E - i\Gamma_\lambda/2} \right) \quad (99)$$

From the collision matrix the cross sections can be calculated. For the total cross section this results in

$$\sigma_c = \pi\lambda_c^2 g_c \left(4 \sin^2 \phi_c + \frac{\Gamma_\lambda \Gamma_{\lambda c} \cos 2\phi_c + 2(E - E_\lambda - \Delta_\lambda) \Gamma_{\lambda c} \sin 2\phi_c}{(E - E_\lambda - \Delta_\lambda)^2 + \Gamma_\lambda^2/4} \right) \quad (100)$$

The first part of the total cross section is the potential scattering or hard sphere scattering cross section $\sigma_p = 4\pi\lambda_c^2 g_c \sin^2 \phi_c$. It is associated with the elastic scattering of the incoming neutron from the potential of the nucleus without forming a compound state. The term with the factor $\sin 2\phi_c$ is the interference of the potential scattering and the resonant elastic scattering through formation of a compound nucleus. Finally, the term with $\cos 2\phi_c$ describes the resonance cross sections of the channels.

In a more practical case, we can see what the cross sections becomes for a neutron entrance channel $c = n$. We assume that the only open channels are elastic scattering and neutron capture, $\Gamma_\lambda = \Gamma = \Gamma_n + \Gamma_\gamma$.

A series expansion of the trigonometric factors gives for $\ell = 0$ at low energy in good approximation $\sin \phi_c = \rho = ka_c$ and $\sin \phi_c = 0$ for $\ell > 0$. The cosine term can be approximated by $\cos \phi_c = 1$ for all ℓ .

In the same way, the reaction cross section is

$$\sigma_{cc'} = \pi\lambda_c^2 g_c \frac{\Gamma_{\lambda c}\Gamma_{\lambda c'}}{(E - E_\lambda - \Delta_\lambda)^2 + \Gamma_\lambda^2/4} \quad (101)$$

and the shift Δ_λ results from the boundary condition.

6.2.2 The Breit–Wigner Multi Level Approximation

Several resonances can be taken into account as a sum of Breit and Wigner single level cross sections. This is the most simple treatment of cross sections of many resonances. It neglects any possible interference between channels and levels (resonances).

The Breit and Wigner multi level (BWML) approach uses a sum over the levels in the collision matrix. In the inverse of the level matrix \mathbf{A} all off-diagonal elements $A_{\lambda}^{-1}\mu$ are neglected, which means neglecting all interference terms between channels, but not between levels.

$$(\mathbf{A}^{-1})_{\lambda\mu} = (E_{\lambda} - E + \Delta_{\lambda} - i\Gamma_{\lambda}/2)\delta_{\lambda\mu} \quad (102)$$

$$U_{cc'} = e^{-i(\phi_c + \phi_{c'})} \left(\delta_{cc'} + \sum_{\lambda} \frac{i\sqrt{\Gamma_{\lambda c}\Gamma_{\lambda c'}}}{E_{\lambda} + \Delta_{\lambda} - E - i\Gamma_{\lambda}/2} \right) \quad (103)$$

6.2.3 The Reich–Moore Approximation

In the approximation of Reich and Moore (1958) it is assumed that the amplitudes $\gamma_{\lambda c}$ are uncorrelated and have a Gaussian distribution with zero mean. This is a consequence of the chaotic behavior of the compound nucleus, except for the very light nuclei. This is known as the Gaussian orthogonal ensemble (Lynn 1968; Mehta 1960, 1991).

In medium and heavy nuclei, the number of photon channels is very large. And since the amplitudes are supposed to have a random distribution with zero mean, the expectation value of the product of two amplitudes is zero for $\lambda \neq \mu$, that is, $\langle \gamma_{\lambda c}\gamma_{\mu c} \rangle = \gamma_{\lambda c}^2\delta_{\lambda\mu}$. Summing over the photon channels gives

$$\sum_{c \in \text{photon}} \gamma_{\lambda c}\gamma_{\mu c} = \sum_{c \in \text{photon}} \gamma_{\lambda c}^2\delta_{\lambda\mu} = \Gamma_{\lambda\gamma}\delta_{\lambda\mu} \quad (104)$$

Therefore, the general expression for \mathbf{A}^{-1} , (92), can be simplified for the photon channels and becomes

$$\begin{aligned} (\mathbf{A}^{-1})_{\lambda\mu} &= (E_{\lambda} - E)\delta_{\lambda\mu} - \sum_{c \in \text{photon}} \gamma_{\lambda c}\gamma_{\mu c}(L_c - B_c) - \sum_{c \in \text{photon}} \gamma_{\lambda c}\gamma_{\mu c}(L_c - B_c) \\ &= (E_{\lambda} - E)\delta_{\lambda\mu} - \Gamma_{\lambda\gamma}(L_c - B_c)\delta_{\lambda\mu} - \sum_{c \in \text{photon}} \gamma_{\lambda c}\gamma_{\mu c}(L_c - B_c) \\ &= (E_{\lambda} - E + \Delta_{\lambda} - i\Gamma_{\lambda\gamma}/2)\delta_{\lambda\mu} - \sum_{c \in \text{photon}} \gamma_{\lambda c}\gamma_{\mu c}(L_c - B_c) \end{aligned} \quad (105)$$

Comparing this to (92), the approximation may be written as a reduced R -matrix in the sense that the photon channels are excluded and the eigenvalue E_{λ} is replaced by $E_{\lambda} - i\Gamma_{\lambda\gamma}/2$. This Reich–Moore R -matrix is

$$R_{cc'} = \sum_{\lambda} \frac{\gamma_{\lambda c}\gamma_{\lambda c'}}{E_{\lambda} - E - i\Gamma_{\lambda\gamma}/2} \quad c \notin \text{photon} \quad (106)$$

The number of energy levels, which may be over hundreds of thousands in heavy nuclei, determines the number of possible photon decay channels. Excluding them reduces largely the number of channels and, therefore, the matrix inversion needed in the relation between the R -matrix and the cross sections. In the often occurring case at low energy that only the elastic scattering and neutron capture channels are open, the number of channels in the R -matrix is one, namely, that of the neutron channel, the photon channels being excluded explicitly. The

total radiation width is present however in the denominator of (106). The R -matrix becomes in this case an R -function of which the inversion is trivial. Including other channels, like one or two fission channels, keeps the number of channels low and makes the inversion still feasible. This approximation of the general R -matrix is the most accurate one used.

6.3 Average Cross Sections

At higher energies the widths of the resonances overlap and the cross sections appear smooth and with a slow variation with energy. The total and scattering cross sections without sharply separated or observed resonances can be adequately described by representing the particle-nucleus interaction by a complex potential. This optical potential, so called because mathematically analogous to the scattering and absorption of light in a medium (cloudy crystal ball), results in the partial scattering or absorption of the beam. The solution of the Schrödinger equation, usually numerically, with a given potential gives the wave functions from which the cross sections can be obtained (Fernbach et al. 1949). Much progress has been made since in the theoretical development and parametrization of a suitable optical model potentials, see for example Camarda et al. (1989), Leeb and Wilmsen (2000), Bauge et al. (2001), Dietrich et al. (2003), Capote et al. (2005) and Quesada et al. (2007).

By making averages over resonances, the energy averaged collision matrix $\overline{U_{cc}}$ can be related to the energy-averaged cross sections $\overline{\sigma}$. The development of a given shape of the optical model potential results in a value for $\overline{U_{cc}}$. From the usual R -matrix expressions we can formulate a number of cross sections as follows. By analogy to (67) the average scattering cross section $\overline{\sigma_{cc}}$ can be written as

$$\overline{\sigma_{cc}} = \pi \lambda_c^2 g_c \overline{|1 - U_{cc}|^2} \quad (107)$$

which can be split up into an average shape elastic scattering cross section

$$\overline{\sigma_{cc}^{se}} = \pi \lambda_c^2 g_c \overline{|1 - \overline{U_{cc}}|^2} \quad (108)$$

associated with potential scattering, and an average compound elastic scattering cross section due to resonance scattering

$$\overline{\sigma_{cc}^{ce}} = \pi \lambda_c^2 g_c \left(\overline{|U_{cc}|^2} - |\overline{U_{cc}}|^2 \right) \quad (109)$$

and after (68) the average reaction cross section $\overline{\sigma_{cr}}$, corresponding to all nonelastic partial cross sections, as

$$\overline{\sigma_{cr}} = \pi \lambda_c^2 g_c (1 - |\overline{U_{cc}}|^2) \quad (110)$$

and following (69) the average total cross section $\overline{\sigma_{c,T}}$ can be written as

$$\overline{\sigma_{c,T}} = 2\pi \lambda_c^2 g_c (1 - \text{Re } \overline{U_{cc}}). \quad (111)$$

The sum of the average compound elastic scattering cross section $\overline{\sigma_{cc}^{ce}}$ and the average reaction cross section $\overline{\sigma_{cr}}$ can be considered as the cross section for the formation of the compound nucleus $\overline{\sigma_c}$, and can be written as

$$\begin{aligned} \overline{\sigma_c} &= \overline{\sigma_{cc}^{ce}} + \overline{\sigma_{cr}} = \pi \lambda_c^2 g_c \left(\overline{|U_{cc}|^2} - |\overline{U_{cc}}|^2 + 1 - |\overline{U_{cc}}|^2 \right) \\ &= \pi \lambda_c^2 g_c (1 - |\overline{U_{cc}}|^2) \end{aligned} \quad (112)$$

Then the sum of this compound nucleus formation cross section $\overline{\sigma_c}$ and the average shape elastic scattering cross section $\overline{\sigma_{cc}^{se}}$ equals the total cross section $\overline{\sigma_{c,T}}$, which can be checked by

$$\begin{aligned}\overline{\sigma_c} + \overline{\sigma_{cc}^{se}} &= \pi\lambda_c^2 g_c (1 - |\overline{U_{cc}}|^2 + |1 - \overline{U_{cc}}|^2) \\ &= \pi\lambda_c^2 g_c (1 - |\overline{U_{cc}}|^2 + 1 - 2 \operatorname{Re} \overline{U_{cc}} + |\overline{U_{cc}}|^2) = \overline{\sigma_{c,T}}\end{aligned}\quad (113)$$

From the above expressions, only the total, shape elastic, and compound nucleus formation cross sections $\overline{\sigma_{c,T}}$, $\overline{\sigma_{cc}^{se}}$, and $\overline{\sigma_c}$ contain the elements $\overline{U_{cc}}$, calculated by optical model, without other terms like $|\overline{U_{cc}}|^2$ which cannot be extracted from optical model calculations. For a direct comparison with experimental data, only the calculated average total cross section (111) can be used in a general way. The shape elastic scattering cross section cannot be distinguished from the compound elastic scattering. The calculated compound nucleus formation cross section (112) is also not directly observable, but can be used in combination with measured decay channels, like in the surrogate measurements.

Finally, the average cross section for a single reaction $\overline{\sigma_{cc'}}$ is

$$\overline{\sigma_{cc'}} = \pi\lambda_c^2 g_c |\overline{\delta_{cc'} - U_{cc'}}|^2 \quad (114)$$

which contains the nearly impossible averaging over $|U_{cc'}|^2$.

When we introduce the transmission coefficient

$$T_c = 1 - |\overline{U_{cc}}|^2 \quad (115)$$

the compound nucleus formation cross section (unaveraged) can be written as

$$\sigma_c = \pi\lambda_c^2 g_c T_c \quad (116)$$

Using the usual concepts in nuclear reaction theory (reciprocity, time-reversal invariance), the probability of decay through channel c' as $T_{c'}/\sum T_i$ the cross section for the reaction $c \rightarrow c'$ is then

$$\sigma_{cc'} = \pi\lambda_c^2 g_c T_c \frac{T_{c'}}{\sum T_i} \quad (117)$$

where the sum runs over all possible channels. Averaging over a small energy interval with many resonances, taking into account shape elastic scattering in addition to compound reactions and redefining T_c as

$$T_c = 1 - |\overline{U_{cc}}|^2 \quad (118)$$

results in the Hauser–Feshbach formula (see also Hauser and Feshbach 1952; Feshbach et al. 1954; Hodgson 1971; Moldauer 1975b,a 1976, 1980; Fröhner 2000; Sirakov et al. 2008 for more details)

$$\overline{\sigma_{cc'}} = \overline{\sigma_{cc}^{se}} \delta_{cc'} + \pi\lambda_c^2 g_c \frac{T_c T_{c'}}{\sum T_i} W_{cc'} \quad (119)$$

where the factor $W_{cc'}$ is factor that includes elastic enhancement and a correction for width fluctuations, which can be written as (see for example Moldauer 1976)

$$W_{cc'} = \left(\frac{\overline{\Gamma_c \Gamma_{c'}}}{\Gamma} \right) \frac{\overline{\Gamma}}{\overline{\Gamma_c \Gamma_{c'}}} \quad (120)$$

The width fluctuations can be calculated most accurately using the GOE triple integral (Verbaarschot et al. 1985; Verbaarschot 1986), but also with simpler approximations.

The transmission coefficients for particle channels are given by (118). Two other channels exist which are the photon and fission channels. Their transmission coefficients, related to the average widths and level spacing, are defined as

$$T_\gamma = 2\pi \frac{\overline{\Gamma}_\gamma}{D} \quad (121)$$

and

$$T_f = 2\pi \frac{\overline{\Gamma}_f}{D} \quad (122)$$

Dedicated modelizations on photon strength functions, level densities, and fission models, are used for the photon and fission transmission coefficients, but are beyond the scope of this overview. Good starting points for further reading are the user guides of specialized computer codes like EMPIRE (Herman et al. 2007), TALYS (Koning et al. 2007), and others.

7 Concluding Remarks

The importance of neutron-induced reaction data is evident in a wide variety of research fields, ranging from stellar nucleosynthesis and nuclear structure to applications of nuclear technology. The present chapter has sketched out an impression of neutron cross section measurements at time-of-flight facilities and at monoenergetic fast neutron sources. The principal measurement techniques have been summarized. Also details on the *R*-matrix formalism linking measurable nuclear properties to useable nuclear cross sections have been presented.

Many details were intentionally omitted but the provided references should form a good starting point for the interested reader.

Abstract: This chapter describes the current status of evaluated nuclear data for nuclear technology applications. We start with evaluation procedures for neutron-induced reactions focusing on incident energies from the thermal energy up to 20 MeV, though higher energies are also mentioned. This is followed by examining the status of evaluated neutron data for actinides that play a dominant role in most of the applications, followed by coolants/moderators, structural materials, and fission products. We then discuss neutron covariance data that characterize uncertainties and correlations. We explain how modern nuclear evaluated data libraries are validated against an extensive set of integral benchmark experiments. Afterward, we briefly examine other data of importance for nuclear technology, including fission yields, thermal neutron scattering, and decay data. A description of three major evaluated nuclear data libraries is provided, including the latest version of the US library ENDF/B-VII.0, European JEFF-3.1, and Japanese JENDL-3.3. A brief introduction is made to current web retrieval systems that allow easy access to a vast amount of up-to-date evaluated nuclear data for nuclear technology applications.

1 Evaluation Methodology for Neutron Data

The evaluated (recommended) neutron cross-section data represent the backbone of data needed for nuclear technology applications. The incident energies of interest cover an extremely broad energy range of 13 orders of magnitude. Thus, for fission and fusion reactor systems one needs neutrons from 10^{-5} to $2 \times 10^{+7}$ eV (20 MeV), to be extended up to about 200 MeV for accelerator-driven systems. If higher incident energies are needed, one resorts to on-fly calculations (not covered here) rather than to evaluated nuclear data libraries.

Such a large range of incident neutron energies represents an enormous challenge for developers of evaluated nuclear data libraries. This is coupled to another challenge that stems from the fact that nuclear technology applications need data for about 400 atomic nuclei, covering the atomic mass range of $A = 1-250$, from hydrogen to the actinides.

There is no simple way to describe the physics of neutrons interacting with atomic nuclei throughout this vast range of energies and different types of nuclei. Rather, nuclear physics uses different approaches and many different models to describe underlying physics. The role of experimental data in the evaluation process is absolutely crucial, with the understanding that measured data must be combined with physics-based models to fill in the gaps and to gain confidence in the judgment as to what is the best reflection of nature.

The goals for the evaluations are to comply as closely as possible with experimental microscopic (differential) data, and at the same time to accurately match results from simple benchmark (integral) experiments. The evaluation is a complex process, requiring a detailed knowledge of nuclear reaction physics, experimental databases, nuclear modeling, considerable experience, and attention to details. Once the whole set of isotopes (materials) is evaluated and a library is assembled, a validation of the entire library is performed against hundreds of benchmark experiments.

The description of evaluation methodology given below reflects the state-of-the-art methods used in the development of the latest US-evaluated data library, ENDF/B-VII.0. This library, released in December 2006, is described in detail in the extensive paper by Chadwick et al. (2006). The evaluated data are stored in the internationally adopted ENDF-6 format (Herman and Trkov 2009).

1.1 Basic Ingredients

Basic ingredients of the evaluation process for neutron cross-section data include the EXFOR database of microscopic experimental data, *Atlas of Neutron Resonances*, and nuclear reaction model codes. Consequently, the evaluation methodology consists of three parts:

- Careful analysis of microscopic experimental data. (“Microscopic” is the term used by nuclear data physicists to describe properties of individual nuclei and their interactions, which should be distinguished from properties of large-scale ensembles of nuclei. Thus, microscopic cross section is the interaction probability of one neutron incident on a single target nucleus.)
- The low energy region (thermal energy, resolved resonances, and unresolved resonances) is treated by methods developed to analyze neutron resonances.
- The fast neutron region is evaluated using methods based on nuclear reaction model calculations and experimental data.

Nuclear theory and modeling has played a central role in developing complete cross-section evaluations, by which we mean representations that cover all incident projectile energies, outgoing particle and photon energies, as well as angular distributions. Nuclear reaction theory codes provide a powerful tool to interpolate and extrapolate from the measured data, and naturally incorporate constraints such as unitarity, and energy and momentum conservation. A number of reaction physics codes have been developed that support this work:

- Statistical, preequilibrium, direct, and fission models, for use in modeling medium and heavy nucleus reactions, notably Los Alamos National Laboratory (LANL) code GNASH (Young and Arthur, 1977; Young et al., 1992, 1998) and code EMPIRE (Brookhaven National Laboratory, Herman et al., 2005b, 2007), often used in conjunction with coupled-channels optical model code ECIS (CEA Saclay, Raynal, 1994).
- R-matrix codes for light nucleus reactions, and for lower incident energy reactions on heavier targets, notably the Los Alamos code energy-dependent analysis (EDA) (Hale, 1992) and the Oak Ridge code SAMMY (Larson, 2006).
- Atlas code system (Oh et al., 2000) for analyzing neutron resonances in terms of multilevel Breit–Wigner (MLBW) formalism by Mughabghab at Brookhaven to produce a comprehensive evaluation of resonance parameters, thermal cross sections, and average resonance parameters for the *Atlas of Neutron Resonances* (Mughabghab, 2006).

➤ *Figure 1* qualitatively summarizes nuclear reaction models and related codes as used in the ENDF/B-VII.0 evaluations for various combinations of mass number and incident energy. In light nuclei, the excited states are generally sparse and well isolated. This feature necessitates the use of special few-body techniques that are feasible due to a limited number of nucleons in the system. We have used the explicit R-matrix theory, implemented in the Los Alamos code EDA, for evaluations of nuclides up to the atomic mass $A \approx 10$ (with a few exceptions). This approach, although formally strict, relies on experimental input. In ➤ *Fig. 1* the few-body regime is depicted as a vertical rectangle at the left of the picture. Note, that in this case the same methodology is applied throughout the whole energy range.

Increasing the number of nucleons in the target makes usage of few-body models impractical. On the other hand, the large number of excited states facilitates approaches that,

■ Figure 1

Schematic representation depicting the use of various evaluation techniques and related codes (in brackets) depending on target mass and incident energy. Arrows to the right of the figure indicate major reaction mechanisms in the fast neutron region and their energy range of applicability

to a certain extent, are built upon statistical assumptions. This “statistical regime” appears in [Fig. 1](#) to the right of $A \sim 10$. We have to deal with three distinct energy regions for these nuclei:

- Resolved resonance region (including thermal neutrons)
- Unresolved resonance region (URR)
- Fast neutron region

Since the density of neutron resonances increases with A , the upper limit of the resolved resonance region decreases when moving to heavier nuclei. A neighboring region is known as the URR in which overlapping resonances usually produce quite smooth cross sections. Each of these three regions needs different techniques and different reaction modeling.

Except for very light nuclei, there is no theory capable of predicting individual resonances. Therefore, realistic evaluations require experimental data for neutron resonances. In ENDF/B-VII.0, the Reich–Moore approach derived from the R-matrix theory, as implemented in the Oak Ridge code SAMMY, was utilized for the important actinides. For about 150 fission product nuclei, the MLBW formalism and statistical methods from the *Atlas of Neutron Resonances* (Mughabghab, 2006) were used at BNL.

The URR is a transitional region that could be treated with the methods from the resolved region as well as in the terms of the models used in the fast neutron region.

The fast neutron region involves a whole suite of nuclear reaction models with a strong statistical component resulting from the averaging over many resonances. The Hauser–Feshbach

formulation of the compound nucleus is a key model for any evaluation in the fast neutron region, although in the low energy range it must be corrected to account for the width fluctuation effects. At incident energies above some 10 MeV, preequilibrium emission has to be taken into account and one implements a variety of semiclassical and quantum-mechanical models.

While most of the nuclear reaction models used for the evaluations are predominantly phenomenological, their usage involves a huge number of input parameters. The development of the ENDF/B-VII.0 library largely benefited from the reference input parameter library (RIPL) (Ignatyuk et al., 1998; Young et al., 2005; Capote et al., 2009), an international project coordinated by the International Atomic Energy Agency (IAEA), Vienna.

1.2 Thermal and Resolved Resonance Region

Usually, the first step in neutron resonance evaluation is to inspect the well-known compendium of data produced over the years by Mughabghab, BNL, traditionally known as BNL-325. Its fifth and latest edition has been published in 2006 as *Atlas of Neutron Resonances: Resonance Parameters and Thermal Cross Sections* (Mughabghab, 2006), representing a considerable update to the 1981 (Mughabghab et al., 1981) and 1984 editions (Mughabghab, 1984). Often, one is satisfied with these data and adopts them as they are. Indeed, these latest thermal values and resonance parameters provided a basis for more than 150 new evaluations included in ENDF/B-VII.0. In many other cases, however, one performs additional evaluation by applying sophisticated R-matrix analysis to most recent experiments using the Oak Ridge code SAMMY (Larson, 2006).

1.2.1 Thermal Energy Region

Accurate knowledge of the thermal neutron capture and fission cross sections are of paramount importance for many applications and considerable experimental as well as evaluation effort was expended in obtaining precise and consistent constants at a neutron energy of 0.0253 eV (velocity $v_0 = 2,200$ m/s). The parameters under consideration are the absorption (σ_{abs}), radiative capture (σ_γ) and fission (σ_f) cross sections, the neutron yield data ($\bar{\nu}$, η), as well as Westcott factors g_w . Some of these quantities are interrelated as

$$\eta = \bar{\nu} \frac{\sigma_f}{\sigma_{\text{abs}}} = \frac{\bar{\nu}}{1 + \alpha}, \quad (1)$$

where $\bar{\nu} = \bar{\nu}_p + \bar{\nu}_d$ is the average number of neutrons emitted per neutron-induced fission obtained by the sum of prompt and delayed values,

$$\sigma_{\text{abs}} = \sigma_\gamma + \sigma_f \quad \text{and} \quad \alpha = \frac{\sigma_\gamma}{\sigma_f}. \quad (2)$$

When the scattering cross section (σ_s) is known, the absorption cross section can be determined absolutely to a high degree of accuracy from a measurement of the total cross section as $\sigma_{\text{abs}} = \sigma_{\text{tot}} - \sigma_s$.

The capture cross section for a single resonance is usually represented by the Breit-Wigner formalism. (“Capture” is the short-hand term used by nuclear physicists to describe

■ Figure 2

Neutron capture cross sections for ^{133}Cs in the thermal and resolved resonance energy region computed from Atlas are compared with experimental data. The calculated cross section is Doppler-broadened to 300 K; the experimental resolution is not included. Two bound levels were invoked in order to fit the thermal constants

radiative capture, i.e., (n, γ) cross sections. This differs from what nuclear engineers might consider “capture,” which is given by the sum of neutron removal cross sections, i.e., $(n, \gamma) + (n, p) + (n, \alpha) + \dots$. In the case of several s-wave resonances, the thermal capture cross section at $E = 0.0253$ eV is given by

$$\sigma_{\gamma}(E) = \frac{2.608 \times 10^6}{\sqrt{E}} \left(\frac{A+1}{A} \right)^2 \sum_j \frac{g_j \Gamma_{nj}^0 \Gamma_{\gamma j}}{\Gamma_j^2 + 4(E - E_{0j})^2}. \quad (3)$$

In this relation, Γ_{nj} , $\Gamma_{\gamma j}$, and Γ_j are the neutron scattering, radiative, and total width of the resonance j , respectively; E_{0j} is the resonance energy, A is the atomic mass number of the target nucleus, and g_j is the statistical spin weight factor defined as

$$g_j = \frac{2J+1}{2(2I+1)}, \quad (4)$$

where J is the resonance spin and I is the target nucleus spin. As an example, ► Fig. 2 shows the evaluated capture cross sections for ^{133}Cs in the thermal along with the low-energy resonance region compared with the available experimental data.

Similarly, the fission cross section can be described as a sum over positive and negative energy resonance contributions. In the framework of the Breit–Wigner formalism, the fission cross section can be obtained from

$$\sigma_f(E) = \frac{2.608 \times 10^6}{\sqrt{E}} \left(\frac{A+1}{A} \right)^2 \sum_j \frac{g_l \Gamma_{nj}^0 \Gamma_{fj}}{\Gamma_j^2 + 4(E - E_{0j})^2}, \quad (5)$$

where

$$\Gamma_j(E) = \Gamma_{nj}(E) + \Gamma_{\gamma j} + \Gamma_{fj}. \quad (6)$$

The formalism for neutron elastic scattering is more complicated. Thus, the elastic cross section for a single resonance can be expressed by the sum of three terms

$$\sigma_n(E) = 4\pi \frac{2I+1}{k^2} \sin^2 \phi_l + \pi \frac{g_l}{k^2} \frac{\Gamma_n \Gamma \cos(2\phi_l) + 2(E - E_0) \Gamma_n \sin(2\phi_l)}{(E - E_0)^2 + \frac{1}{4} \Gamma^2}, \quad (7)$$

where k is the neutron wave number, ϕ_l are the phase shifts determined by k , and the potential scattering radius R' . The first term describes potential scattering, σ_{pot} , which is nearly constant as a function of energy. The second term stands for the symmetric resonance cross section. The third term, containing $2(E - E_0) \Gamma_n \sin(2\phi_l)$ in the numerator, describes interference between potential (hard-sphere) and resonance scattering, which is negative at $E < E_0$ and positive at $E > E_0$. Note that Eq. (7) does not include resonance–resonance interference term.

In order to obtain the thermal scattering cross section, one should resort to an extended version of the above expression, such as provided by the MLBW formalism. We note that in the low-energy approximation simplified expressions can be obtained, including that for potential scattering

$$\sigma_{\text{pot}} \approx 4\pi R'^2. \quad (8)$$

The neutron scattering can also be expressed in terms of spin-dependent free nuclear scattering lengths, a_+ and a_- , associated with spin states $I + 1/2$ and $I - 1/2$, as

$$a_{\pm} = R' + \sum_j \frac{\lambda_j \Gamma_{nj}}{2(E - E_{0j}) - i\Gamma_j}, \quad (9)$$

where $\lambda_j = 1/k$ is de Broglie's wavelength divided by 2π . We note that a_{\pm} contain imaginary components and the summation is carried out over all s-wave resonances with the same spin.

The total coherent scattering length for nonzero spin target nuclei is then the sum of the spin-dependent coherent scattering widths, a_+ and a_- , weighted by the spin statistical factor, $g_+ = (I + 1)/(2I + 1)$ and $g_- = I/(2I + 1)$,

$$a = g_+ a_+ + g_- a_-. \quad (10)$$

The total scattering cross section can then be expressed as

$$\sigma_s = 4\pi (g_+ a_+^2 + g_- a_-^2). \quad (11)$$

If the results of the calculated cross sections do not agree with measurements within the uncertainty limits, then one or two negative energy (bound) levels are invoked.

The potential scattering length or radius, R' , is an important parameter, which is required in the calculation of scattering and total cross sections. It can be expressed as

$$R' = R(1 - R^\infty), \quad (12)$$

where R is the channel or interaction radius, and R^∞ is related to the distant s-wave resonance contribution. We note that R' can be determined to a high degree of accuracy from the measured coherent scattering amplitude by (9) when the resonance data are complete.

1.2.2 Westcott Factors and Resonance Integrals

In general, in the thermal energy region, capture cross sections follow the $1/v$ law, where v is the neutron velocity. Deviations from this behavior are due to the proximity of the first resonance to the thermal energy of 0.0253 eV, notable examples being ^{113}Cd , ^{149}Sm , and ^{155}Gd . Westcott factors, ideally equal to unity, can be used as a suitable measure of the validity of this law. They are defined as the ratio of the Maxwellian averaged cross section, σ , to the thermal cross section, σ_0 ,

$$g_w = \frac{\sigma}{\sigma_0} = \frac{1}{v_0 \sigma_0} \int_0^\infty \frac{1}{\pi^{1/2}} \frac{v^3}{v_T^3} e^{-v^2/v_T^2} \sigma(v) dv, \quad (13)$$

where $v_0 = 2,200$ m/s and v_T is the most probable velocity for Maxwellian spectrum at temperature T .

Resonance integrals represent useful quantities that characterize cross sections in the thermal and resonance region. For a particular reaction $\sigma_x(E)$, such as total, elastic scattering, capture, and fission ($x = \text{tot}, s, \gamma, f$), in a $1/E$ spectrum these are defined as

$$I_x = \int_{0.5 \text{ eV}}^\infty \sigma_x(E) \frac{dE}{E}, \quad (14)$$

where the low energy is determined by the cadmium cutoff energy usually set to 0.5 eV, while the upper energy is sometimes set to 100 keV (JEFF3, 2005). It is important to note that both the thermal energies and resonances contribute to the resonance integrals.

Often Westcott factors and resonance integrals are readily available in tabulated form, an example being JEFF-3.1 library (JEFF3, 2005). They can also be conveniently obtained from the web using retrieval systems such as Sigma (Pritychenko and Sonzogni, 2008) developed and maintained by the National Nuclear Data Center (NNDC) at Brookhaven.

1.2.3 Resolved Resonance Energy Region

Neutron time-of-flight techniques that employ accelerator facilities as neutron sources are used to perform high-resolution cross-section measurements in the resonance region. Then, the measured data are analyzed by a state-of-the-art tool such as SAMMY (Larson, 2006). This code combines multichannel multilevel R-matrix formalism with corrections for experimental conditions to fit experimental data using generalized least-squares fitting procedures.

Resolved resonances are described by the R-matrix collision theory, which is exact, and the resulting formalism is fairly transparent, though the expressions look rather formidable. In practical applications, several approximations are widely used. The most precise is Reich–Moore followed by the MLBW, while the least precise is single-level Breit–Wigner (SLBW). In ENDF/B-VII.0 library, Reich–Moore is mostly used for actinides, MLBW is adopted for majority of other materials, while SLBW was essentially abandoned and its use is restricted to the URR.

R-matrix channels are characterized by the two particles with spin i and I , the orbital angular momentum l , the channel spin s (where $s = i \pm I$), and the total spin J (where $\vec{J} = \vec{s} + \vec{I}$) and parity π . Those channels having the same J and π (the only two quantum numbers that are conserved) are collected in the same spin group. Resonances (which appear generally as peaks in the cross sections) are assigned to particular spin groups depending on their individual characteristics; initial assignments may be changed as knowledge is gained during the evaluation process. The goal of the evaluation is to determine those values for the resonance energy (peak position), channel widths, and spin for each of the resonances that provide the best fit to the measured data.

In general, partial cross sections can be obtained from a collision matrix U_{ab} , which connects entrance channels a with exit channels b . The formalism, applied to neutron reactions, implies $a = n$ and

$$\sigma_{nb} = \frac{\pi}{k^2} g_J |\delta_{nb} - U_{nb}|^2, \quad (15)$$

where k is the neutron wave number and δ_{nb} is the Kronecker delta symbol. These partial cross sections must be summed over the appropriate entrance and exit channels to yield observable cross sections. The statistical factor g_J is the probability of getting the correct angular momentum J from the spins of collision partners, and π/k^2 relates probability and cross section.

In the Reich–Moore formalism as implemented in ENDF-6, the only reactions requiring explicit channel definitions are total, elastic scattering and fission; capture is obtained by subtraction (although it is possible to obtain it directly from the collision matrix elements). Neutron channels are labeled by quantum numbers, l , s , and J .

The channel spin s is the vector sum of the target spin I and the neutron spin $i = 1/2$, and takes on the range of values $|I - 1/2|$ to $I + 1/2$. The total angular momentum J is the vector sum of l and s , and runs from $|l - s|$ to $l + s$. The fission channels $f1$ and $f2$ do not correspond to individual two-body fission product breakup, but to Bohr-channels in deformation space, which is why two are adequate for describing many neutron-induced fission cross sections.

If one sums over all incident channels n and exit channels b , and invokes unitarity, the resulting total cross section can be expressed in terms of the diagonal matrix elements as

$$\sigma_{\text{tot}}(E) = \frac{2\pi}{k^2} \sum_{lsJ} \sum_{l's'J'} g_J \text{Re}[1 - U_{lsJ,l's'J'}]. \quad (16)$$

The elastic cross section is obtained by summing the incident neutron channels over all possible lsJ values and the exit neutron channels over those quantities $l's'J'$ that have the same ranges as lsJ . The conservation of total angular momentum requires that $J' = J$; usually additional, simplifying conservation rules are imposed, namely, $l' = l$ and $s' = s$. The sixfold summation then reduces to the familiar form

$$\sigma_{nn}(E) = \frac{2\pi}{k^2} \sum_{lsj} g_J |1 - U_{lsj,lsj}|^2. \quad (17)$$

The absorption (nonelastic) cross section is obtained by subtraction

$$\sigma_{\text{abs}}(E) = \sigma_{\text{tot}}(E) - \sigma_{nn}(E). \quad (18)$$

Fission is obtained from the collision matrix by summing (15) over all incident lsj values and over the two exit fission channels, $b = f1$ and $b = f2$,

$$\sigma_f(E) = \frac{2\pi}{k^2} \sum_{lsj} g_J \left(|U_{nf1}^{lsj}|^2 + |U_{nf2}^{lsj}|^2 \right). \quad (19)$$

The level-matrix form of the collision matrix is given as

$$U_{nb}^J = e^{-i(\phi_n + \phi_b)} \left\{ 2[(1 - K)^{-1}]_{nb} - \delta_{nb} \right\}, \quad (20)$$

where

$$(1 - K)_{nb}^{-1} = \delta_{nb} - \frac{i}{2} \sum_r \frac{\Gamma_{nr}^{1/2} \Gamma_{br}^{1/2}}{E_r - E - i \Gamma_{\gamma r} / 2}. \quad (21)$$

Here, ϕ_b is zero for fission, $\phi_n = \phi_l$, and the summation is over those resonances r that have partial widths in both of the channels n and b ; E_r is the resonance energy; $\Gamma_{\gamma r}$ is the “eliminated” radiation width; Γ_{nr} and Γ_{br} are the partial widths for the r th resonance in channels n and b .

The shift factor has been set equal to zero in the above equations ($E_r' \rightarrow E_r$); hence they are strictly correct only for s-wave resonances. Originally, the ENDF Reich–Moore format was used for low-energy resonances in fissile materials, which are s-waves. However, it is believed that the “no-shift” formulae can be safely applied to higher l -values also, since the difference in shape between a shifted resonance and one that is not shifted at the same energy has no practical significance.

One of the tasks of the evaluator is to assign the orbital momentum, l , for resonances where this has not been done experimentally. In the *Atlas of Neutron Resonances* this was done by the Bayesian approach that assigns these values probabilistically. The first investigators to apply Bayes’ conditional probability for the determination of parities of ^{238}U resonances were Bollinger and Thomas (1968). Subsequently, Perkins and Gyullassy (1972) and Oh et al. (2000) extensively applied this procedure in the evaluation of resonance parameters.

For a resonance with a neutron width weighted by the spin statistical factor, $g_J \Gamma_n$, the probability that this resonance is p-wave is given according to Bayes’ theorem of conditional probability by

$$P(p|g_J \Gamma_n) = \left(1 + \frac{P(g_J \Gamma_n | s) \langle D_1 \rangle}{P(g_J \Gamma_n | p) \langle D_0 \rangle} \right)^{-1}, \quad (22)$$

where $\langle D_1 \rangle / \langle D_0 \rangle$ are the level-spacing ratio, and $P(g_J \Gamma_n | s)$ is the probability that the neutron width is $g_J \Gamma_n$ if the resonance is s-wave and similarly for p-waves. The Bayesian equation can be solved by taking into account the Porter and Thomas (1956) distribution and taking into account $(2J + 1)$ degeneration of nuclear levels.

■ Figure 3

Porter–Thomas distribution of reduced neutron widths, $g\Gamma_n^0$, for s-wave resonances of ^{133}Cs in the energy region below 3,400 eV

► Figures 3 and ► 4 illustrate the Porter–Thomas analysis as applied to the s- and p-wave resonances of ^{133}Cs . From this procedure also the average level spacings and strength functions for the s- and p-waves are determined, see (26) and (27).

1.3 Unresolved Resonance Region

In the URR, the situation is different than in the resolved resonance energy region. The experimental resolution is larger than the width of the resonances and individual resonance parameters can no more be extracted from cross-section fitting. The formalism used for cross-section treatment in URR is therefore based on average values of physical quantities obtained in the resolved resonance range. The values for statistical quantities are determined from the resolved energy region and used as starting values for the unresolved evaluation.

The theoretical basis for URR description is the Lane–Lynn approach (Lane and Lynn, 1957), which for capture gives

$$\langle \sigma_Y \rangle = \sum_{Jl} \langle \sigma_Y \rangle_{Jl} = \frac{2\pi^2}{k^2} \sum_{Jl} \langle \Gamma_Y \rangle_l S_l V_l E_n^{1/2} g_J \frac{F(\alpha_{Jl})}{\langle \Gamma_J \rangle}, \quad (23)$$

■ Figure 4

Porter-Thomas distribution of reduced neutron widths, $g\Gamma_n^1$, for p-wave resonances of ^{133}Cs in the energy region below 387 eV where the p-wave resonances are detected

where the averaged quantities are given in brackets $\langle \rangle$, V_l is the penetrability factor divided by kR ; $F(\alpha_{jl})$ is the fluctuation factor, α_{jl} being the ratio of mean radiative and neutron widths; summation is carried over partial waves l and spins J .

The URR is treated within the SLBW formalism, which requires the following parameters: the average level spacing, D_l , the strength functions, S_l , the average radiative widths, $\Gamma_{\gamma l}$, and R' . After the determination of l values for all resonances, the reduced neutron widths are analyzed in terms of the Porter-Thomas distribution (Porter and Thomas, 1956) if the number of measured resonances is large enough for a statistical sample.

Instead of working with the Porter-Thomas distribution, it is often much simpler to analyze the resonance parameter data with the cumulative Porter-Thomas distribution. Since resonances with small neutron widths are usually missed in measurements, it is necessary to exclude resonances whose reduced widths are smaller than a certain magnitude. By setting a cutoff value, that is, a minimum magnitude of reduced neutron width, the effect of missed small resonances on the resulting average parameters is reduced significantly. The result is

$$N(y) = N_r(1 - \text{erf}(y)), \quad (24)$$

where erf is the error function, N_r is the corrected total number of resonances, and $N(y)$ is the total number of resonances with reduced neutron width larger than a specified value y ,

$$y = \left(\Gamma_n^l / 2 \left\langle \Gamma_n^l \right\rangle \right)^{1/2}, \quad (25)$$

where Γ_n^l is the reduced neutron width for orbital angular momentum l and $\langle \Gamma_n^l \rangle$ is its average value. The two parameters N_r and $\langle g\Gamma_n^l \rangle$ are determined through the fitting procedure.

The resulting average level spacing D_l and neutron strength function S_l in a determined energy interval ΔE are then calculated by

$$D_l = \frac{\Delta E}{N_r - 1}, \quad (26)$$

$$S_l = \frac{\langle g\Gamma_n^l \rangle}{(2l + 1)D_l}. \quad (27)$$

The average radiative widths of neutron resonances are determined from measurements in the resolved energy region by calculating the weighted as well as unweighted values. For nuclei with unmeasured radiative widths, the systematics of s-, p-, and d-wave radiative widths as a function of atomic mass number are used (Mughabghab, 2006).

► *Figure 5* shows the evaluated capture cross sections in the unresolved energy resonance region, compared with the available experimental data for ^{133}Cs . The URR is extended up to the first excited level, which is 90 keV for ^{133}Cs . At higher energies (fast neutrons), the evaluations were done by the code EMPIRE. We note an excellent match of cross sections in the boundary of the two energy regions.

We note that in the code SAMMY, the unresolved resonance formalism is based on the methodology adopted by the statistical model code FITACS developed by Fröhner (1982). Values of the average parameters are found from fitting the calculated cross sections to experimental cross sections. The set of parameters that best reproduces the data cannot be reported directly to ENDF/B because the ENDF-6 format uses a less rigorous SLBW representation. SAMMY/FITACS parameters must therefore be converted into average widths before insertion into ENDF/B library.

1.4 Fast Neutron Region

Fast neutron region is defined as incident energies above the URR (materials with $Z > 42$) or above resolved resonances that vary between hundreds keV–MeV for light nuclei and eV–keV for actinides. The upper end of the fast neutron region is in general 20 MeV, though in about 10% cases in ENDF/B-VII.0 this has been extended to 150–200 MeV. In this energy range, several distinct nuclear reaction models are used to describe the interaction of fast neutrons with atomic nuclei.

1.4.1 Optical Model and Direct Reactions

Spherical optical model is usually used to calculate transmission coefficients for all ejectiles involved in a reaction. In the case of spherical nuclei, the same calculations also determined

■ Figure 5

Neutron capture cross section for ^{133}Cs in the unresolved resonance energy region extended up to the first excited level. The evaluation at higher energies was performed by EMPIRE. Evaluation adopted by ENDF/B-VII.0 is compared with experimental data

reaction (absorption) cross sections. For deformed nuclei, the incident channel is treated in terms of coupled-channels rather than the spherical optical model. In the latter case, proper coupling also provided cross sections for inelastic scattering to collective levels and related angular distributions of scattered neutrons. In certain cases we also included direct scattering to the collective levels embedded in the continuum. Generally, we chose optical model potentials from a vast selection available in the RIPL library (Capote et al., 2009), but in the course of ENDF/B-VII.0 development the original RIPL potentials were often adjusted to improve agreement with recent experimental data or to match the cross section obtained in the unresolved resonance evaluation, and in some cases totally new potentials were constructed.

1.4.2 Compound Nucleus Decay

The statistical model provides the basic underpinning for the whole evaluation procedure. The decay of the compound nucleus (CN) is modeled by the Hauser-Feshbach equations, using transmission coefficients and level densities to represent the relative probabilities of decay in the various open channels.

Schematically, the cross section for a reaction (a, b) that proceeds through the compound nucleus mechanism can be written as

$$\sigma_{a,b} = \sigma_a \frac{\Gamma_b}{\sum_c \Gamma_c}. \quad (28)$$

The summation over compound nucleus spin J and parity π , and integration over excitation energy E is implicit in (28). The decay width Γ_c is given by

$$\Gamma_c = \frac{1}{2\pi\rho_{CN}(E)} \sum_{c'} \int_0^{E-B_c} \rho_c(E') T_c(E - B_c - E') dE', \quad (29)$$

where B_c is the binding energy of particle c in the compound nucleus, ρ is the level density, and $T_c(\epsilon)$ stands for the transmission coefficient for particle c having channel energy $\epsilon = E - B_c - E'$. Again, for simplicity, we drop explicit reference to the spin and parity in (29) and the summation extends over all open channels c' . For low incident energies, (28) needs to be corrected for width fluctuation corrections. Since the evaluations extend at least up to 20 MeV, sequential multiparticle emission had to be included in the Hauser–Feshbach calculations, which in practice implies an energy convolution of multiple integrals of the type of (29).

In order to account for the competition between γ -emission and emission of particles along the deexcitation chain, our calculations always involve a full modeling of the γ -cascade that conserves angular momentum. The formalism for γ -rays transitions is based on the giant dipole resonance (GDR) model known as the Brink–Axel hypothesis (Alex, 1962; Brink, 1955, unpublished). GDR parameters are taken from the experimental compilation and/or systematics contained in the RIPL library. We note, that our calculations account for GDR splitting due to nuclear deformation. In GNASH, the γ -ray transmission coefficients are obtained from the γ -ray strength function formalism of Kopecky and Uhl (1990). EMPIRE allows for a suite of γ -ray strength functions. Typically, we used Mughabghab and Dunford’s prescription known as GFL (Mughabghab and Dunford, 2000) or Plujko’s modified Lorentzian referred to as MLO1 (Plujko and Herman, 2006). In both codes, the γ -ray strength functions can be, and often are, normalized to experimental information on $2\pi\Gamma_\gamma/D_0$ or adjusted to reproduce capture cross sections.

Nuclear level densities along with optical model transmission coefficients are the two most important ingredients of the statistical model. In GNASH, the description of the level densities in the continuum follows the Ignatyuk form of the Gilbert–Cameron formalism, including a washing out of shell effects with increasing excitation energy. Most of the evaluations performed with EMPIRE employed level densities that are specific to the EMPIRE code. The formalism uses the superfluid model below a critical excitation energy and the Fermi gas model at energies above it. Collective enhancements due to nuclear vibration and rotation are taken into account in the nonadiabatic approximation, that is, they are washed out when excitation energy increases. Differently from other formulations, EMPIRE-specific level densities explicitly account for the rotation-induced deformation of the nucleus and determine spin distributions by subtracting rotational energy from the energy available for intrinsic excitations.

1.4.3 Width Fluctuation Correction

At low incident energies, the statistical approximation that entrance and exit channels are independent (Bohr independence hypothesis) is not valid anymore due to correlations between entrance and exit channels. The Hauser–Feshbach equations have to be modified in order to include the so-called width fluctuation correction factors accounting for the coupling between the incident and outgoing waves in the elastic channel.

The GNASH code does not calculate these correction factors but rather imports them as the result from an auxiliary code (usually COMNUC, Dunford, 1971, which uses the Moldauer model). EMPIRE, by default, uses internal implementation of the HRTW approach (Hofmann et al., 1975) that can be summarized with the following equation:

$$\sigma_{ab}^{HRTW} = V_a V_b \left(\sum_c V_c \right)^{-1} [1 + \delta_{ab} (W_a - 1)]. \quad (30)$$

This formula is, essentially, equivalent to the Hauser–Feshbach expression (28) but the elastic channel is enhanced by the factor W_a . In (30) the quantities V_c replace optical model transmission coefficients that appear in the original Hauser–Feshbach formula.

1.4.4 Preequilibrium Models

The probability that a system composed of an incident neutron and a target nucleus decays before thermal equilibrium is attained becomes significant at incident energies above 10 MeV. In any preequilibrium model, the excited nuclear system (composite nucleus) follows a series of ever more complicated configurations, where more and more particle-hole (p-h) states are excited. In each stage, a possible emission of a particle competes with the creation of an intrinsic particle-hole pair that brings the system toward the equilibrium stage. Particle emission from the early stages is characterized by a harder spectrum and forward peaked angular distributions.

The exciton model is a semiclassical formulation of the preequilibrium emission that is used in GNASH and EMPIRE. The core of the model is the so-called master-equation that governs time dependence of occupation probabilities, P_n , for various p-h stages

$$\hbar \frac{dP_n}{dt} = \sum_m \Lambda_{n,m} P_m - \Gamma_n P_n, \quad (31)$$

where the total decay width of the stage n is given in terms of the partial transition widths $\Lambda_{l,n}$ and partial width $\Gamma_{e,n}$ for the emission of particle e by

$$\Gamma_n = \sum_l \Lambda_{l,n} + \sum_e \Gamma_{e,n}. \quad (32)$$

Due to the two-body nature of the nuclear force, intrinsic transitions occur only between neighboring stages, and the transition matrix Λ is tri-diagonal, the off-diagonal terms accounting for backward and forward transitions.

In GNASH, the preequilibrium phase is addressed through the semiclassical exciton model in combination with the Kalbach angular-distribution systematics (Kalbach, 1988). These systematics provide a reasonably reliable representation of the experimental database.

EMPIRE implements a suite of preequilibrium codes including two versions of the exciton model (PCROSS and DEGAS, Běták and Obložinský, 1993), and the Monte-Carlo approach DDHMS (Blann, 1996; Blann and Chadwick, 1998, 2000) in addition to the quantum-mechanical multistep direct (MSD) and multistep compound models.

A new Monte Carlo preequilibrium model allows unlimited emission of preequilibrium neutrons and protons, and is therefore well suited for the study of high-energy reactions up to a few hundreds of MeV. The model of choice in EMPIRE is the statistical MSD theory of preequilibrium scattering to the continuum originally proposed by Tamura, Udagawa, and Lenske (TUL) (Tamura et al., 1982). The evolution of the projectile-target system from small to large energy losses in the open channel space is described in the MSD theory with a combination of direct reaction (DR), microscopic nuclear structure, and statistical methods.

The modeling of multistep compound (MSC) processes in EMPIRE follows the approach of Nishioka et al. (NVWY) (1986). The formal structure of the NVWY formula resembles the matrix representation of the master-equation typical for classical preequilibrium models. However, the NVWY formalism is strictly derived from basic principles. Microscopic quantities that constitute ingredients of the NVWY formula were linked to the macroscopic, experimentally known, quantities in Herman et al. (1992), which was an essential step allowing for practical application of the theory.

1.4.5 Light Nuclei

In the case of light nuclei (from hydrogen to oxygen, $A = 1-18$, which mostly serve as coolants and moderators), the statistical approach cannot be applied and the above methodology should be replaced by the R-matrix approach. In the USA, this approach is pursued by Los Alamos and virtually all light nuclei evaluations in ENDF/B-VII.0 were performed by the EDA code developed over the years by Hale (1992, 2008), which is based on R-matrix formalism in its most general form.

R-matrix theory is a general framework for describing nuclear reactions that are particularly well suited for including resonances. It is the mathematically rigorous phenomenological description of what is actually seen in an experiment. This is not a model of neutron–nucleus interaction, rather it parametrizes measurements in terms of observable quantities. This theory properly describes multichannel nuclear reactions and builds in all the fundamental conservation laws, symmetries, and analytic properties of nuclear interactions. The experimental cross-section data from all relevant reactions, including neutron and charged particles, are taken into account and fitted simultaneously. This allows obtaining a single set of multichannel, multilevel R-matrix parameters that describe all the desired neutron-induced cross sections for light nucleus under consideration.

1.5 Fission

Nuclear fission remains the most complex topic in applied nuclear physics. Since its discovery, it has remained an active field of research, and from the evaluation point of view it poses one of the most difficult problems.

1.5.1 Fission Modeling

The status of fission modeling and related parametrization relevant to evaluation is summarized in the extensive paper dedicated to the RIPL by Capote et al. (2009). The main concepts of nuclear fission theory are based essentially on the liquid-drop model (Bohr and Wheeler, 1939; Frenkel, 1939). According to this model, when a nucleus is being deformed, the competition between the surface tension of a nuclear liquid drop and the Coulomb repulsion related to the nuclear charge leads to the formation of an energy barrier, which prevents spontaneous decay of the nucleus by fission. The penetrability of this barrier depends on its height and width and is a dominant factor in determining the fission cross section. Decrease in height and/or width results in an exponential increase in barrier penetrability, which leads to increased fission.

For most of the practical calculations, one-dimensional fission barrier is considered. The present knowledge indicates that the pre-actinides have single-hump barriers, while the actinides have double- or triple-humped barriers. Usually, the barriers are parametrized as a function of the deformation (β) by inverted parabolas,

$$B_i(\beta) = B_{fi} - \frac{1}{2}\mu\hbar^2\omega_i^2(\beta - \beta_i)^2, \quad i = 1, N, \quad (33)$$

where N is the number of humps, the energies B_{fi} represent maxima of the deformation potential, β_i are the deformations corresponding to these maxima (saddle points), the harmonic oscillator frequencies ω_i define the curvature of the parabolas, and μ is the inertial mass parameter approximated usually by a semiempirical expression.  Figure 6 illustrates the relationship among the above-mentioned quantities in a typical case of a double-humped fission barrier ($N=2$). The quasi-stationary states in the second well (the class II states) are also depicted in the plot.

 Figure 6

Energy of a double-humped fission barrier in function of the deformation β along with associated barrier parameters: B_{fi} is the height of the fundamental fission barrier i ; $\epsilon_i(KJ\pi)$ is the energy of the transition state i ; $E_{ci}(J\pi)$ is the cutoff energy, above which the continuum starts for a barrier i . Fission barriers associated with each discrete transition state are shown

Above each barrier hump there is a spectrum of excited levels commonly referred to as transition states. Close to the top of the hump these levels are well separated and can be treated individually while at higher excitation energies (above E_{ci}) the concept of level densities must be invoked, as indicated in  Fig. 6 with the shaded regions. The discrete transition states for all barriers i ($i = 1, 2$ for a double-humped barrier) are obtained by building rotational levels on top of vibrational or non-collective levels that serve as a base (bandheads). They are characterized by a set of quantum numbers (angular momentum J , parity π , and angular momentum projection on the nuclear symmetry axis K) with the excitation energies

$$E_i(KJ\pi) = B_{fi} + \epsilon_i(KJ\pi) = B_{fi} + \epsilon_i(K\pi) + \frac{\hbar^2}{2\mathcal{I}_i} [J(J+1) - K(K+1)], \quad (34)$$

where $\epsilon_i(K\pi)$ are the bandhead energies and $\hbar^2/2\mathcal{I}_i$ are the inertial parameters. A parabolic barrier with height $E_i(KJ\pi)$ and curvature $\hbar\omega_i$ is associated with each transition state.

The transmission coefficients through each hump are expressed in first-order approximation in terms of the momentum integrals for the humps

$$K_i(U) = \pm \left| \int_{a_i}^{b_i} \sqrt{2\mu[U - B_{fi}(\beta)]/\hbar^2} d\beta \right|, \quad i = 1, 2, \quad (35)$$

where a_i and b_i are the points indicated in  Fig. 6 and U is the excitation energy in the fissioning nucleus. The + sign is taken when the excitation energy U is lower than the hump under consideration and the - sign when it is higher. In the case of a single parabolic barrier, (35) yields the well-known Hill–Wheeler transmission coefficient (Bjornholm and Lynn, 1980a)

$$T_i^{HW}(U) = \frac{1}{1 + \exp[-(2\pi/\hbar\omega_i)(U - B_{fi})]}. \quad (36)$$

The total fission transmission coefficient for a given excitation energy U , spin J , and parity π is determined by summing the penetrabilities through barriers associated with all allowed transition levels, that is,

$$T_i(UJ\pi) = \sum_{K \leq J} T_i(UK\pi) + \int_{E_{ci}}^{\infty} \frac{\rho_i(\epsilon J\pi) d\epsilon}{1 + \exp[-\frac{2\pi}{\hbar}\omega_i(U - B_{fi} - \epsilon)]}. \quad (37)$$

The sum runs over all the discrete transition levels having the same spin J and parity π as those of the decaying compound nucleus, and the integration runs over the continuum of the transition levels described by the level densities $\rho_i(\epsilon J\pi)$. Usually the wells are considered deep enough so that the transmission coefficient can be averaged over the intermediate structures. For a double-humped barrier the fission coefficient becomes

$$T_f(UJ\pi) = \frac{T_1(UJ\pi)T_2(UJ\pi)}{T_1(UJ\pi) + T_2(UJ\pi) + T_{\gamma_{II}}(UJ\pi)}, \quad (38)$$

where T_1 and T_2 are the penetrabilities of the inner and the outer humps, respectively, calculated according to (37), and $T_{\gamma_{II}}$ is the probability for gamma decay in the second well.

Finally, the relation used in the statistical model for the fission cross section is

$$\sigma_{a,f}(E) = \sum_{J\pi} \sigma_a(EJ\pi)P_f(EJ\pi), \quad (39)$$

where $\sigma_a(EJ\pi)$ is the population of the fissioning nucleus in the state $EJ\pi$, and $P_f(EJ\pi)$ represents the fission probability computed for a specific representation of fission barrier. The fission probability is usually defined as the ratio of the fission coefficient T_f to the sum of all the transmission coefficients including the competing channels $\sum_d T_d$,

$$P_f(EJ\pi) = \frac{T_f(EJ\pi)}{T_f(EJ\pi) + \sum_d T_d(EJ\pi)}. \quad (40)$$

Similar definitions apply for other decay probabilities.

In GNASH, fission probabilities are calculated from the quantum-mechanical transmission coefficient through a simple double-humped fission barrier, using uncoupled oscillators for the representation of the barriers. The barrier penetrabilities are computed using the Hill–Wheeler formula for inverted parabolas. An additional parameter is used to account for level density enhancement due to asymmetry at saddle points (Young et al., 1998).

Version 2.19 (Lodi) of the EMPIRE code introduced an advanced fission formalism that is applicable to multi-chance fission induced by light particles and photons. It uses an optical model for fission, that is, allows for an absorption through the imaginary potential in the second well, to calculate transmission through coupled single-, double-, and triple-humped fission barriers. Such calculations can start from sub-barrier excitation energies. In the case of a double-humped barrier, the expression is generalized to account for multimodal fission. For light actinides, a triple-humped fission barrier with a shallow tertiary well, which accommodates undamped vibrational states, is employed. This fission model can provide a good description of experimental data, including gross vibrational resonant structure at sub-barrier energies.

As an example of the complexity of the fission channel modeling in EMPIRE, we show ^{232}Th fission cross sections in  Fig. 7. Fine details can be seen in the insert, revealing complex resonance-like structure of fission in the threshold energy region. These fine details are fully described by the model, with the caveat that the fission model parametrization was obtained from careful fits to data.

1.5.2 Prompt Fission Neutron Spectra

One of the most intriguing aspects of evaluation of actinides are prompt neutron fission spectra. The Los Alamos (Madland–Nix) model of the prompt fission neutron spectrum and average prompt neutron multiplicity is based upon classical nuclear evaporation theory and utilizes an isospin-dependent optical potential for the inverse process of compound nucleus formation in neutron-rich fission fragments (Madland and Nix, 1982). This model, in its exact energy-dependent formulation, has been used to calculate the prompt fission neutron spectrum matrix for the $n + ^{235}\text{U}$, $n + ^{238}\text{U}$, and $n + ^{239}\text{Pu}$ systems, and these appear in ENDF/B-VII.0 with the tabulated distribution (LF=1) law.

 Figure 8 shows the average prompt fission neutron emission energy as a function of incident energy for $^{235,238}\text{U}$ and ^{239}Pu for both the new ENDF/B-VII.0 evaluations and the old ENDF/B-VI evaluations.

Figure 7

Figure 8

First moments (average energies) of $^{235,238}\text{U}$ and ^{239}Pu prompt fission neutron spectra from ENDF/B-VII.0 calculated with the Los Alamos model (Madland and Nix, 1982) in comparison with those of ENDF/B-VI

1.5.3 Peculiarities of Fission Cross Section Evaluation

It is notoriously difficult to describe and parametrize the fission process. In particular, fission is extremely sensitive to fission barriers that are very difficult to predict and their actual values depend on other parameters such as nuclear level densities.

In view of this, in most cases fission cross sections are directly adopted from experiments. Then, the modeling is performed and used to evaluate all other reaction channels. This is the approach applied for years by Los Alamos, using the code GNASH. Most recently it has been used in the unprecedented evaluation of a complete set of ten uranium isotopes $^{232,233,234,235,236,237,238,239,240,241}\text{U}$ as well as ^{239}Pu by Young et al. (2007), from keV energies to 30 MeV. These evaluations can be seen as the core of the ENDF/B-VII.0 library, with more details provided in the subsequent part of this chapter.

Recent advances in fission modeling, gradually implemented into the codes such as EMPIRE, allow cautious bypassing traditional mantra of using purely experimental data for fission cross-section evaluations. An example would be ^{232}Th evaluation adopted by ENDF/B-VII.0. In that evaluation, the fission channel was based on modeling with parametrization derived from fits to data, see  Fig. 7.

2 Neutron Data for Actinides

In general, actinides are the most important materials (isotopes) in most of the nuclear technology applications. The “big three” actinides, ^{235}U , ^{238}U , and ^{239}Pu , usually play the dominant role. These three plus ^{232}Th constitute the major actinides; the remaining about 15 actinides including other isotopes of U and Pu as well as Np, Am, and Cm fall into the category of minor actinides.

It should be emphasized that major actinides are evaluated extremely carefully and attention paid to details is exceptionally high. The nuclear data community spent considerable amount of time on these evaluations (Young et al., 2007). What is shown below is a glimpse on progress made between 2001 release of the US library ENDF/B-VII.8 and 2006 release of the ENDF/B-VII.0 library (Chadwick et al., 2006).

2.1 ^{235}U Evaluation

The ENDF/B-VII.0 evaluation in the URR was performed by ORNL. This was complemented with the evaluation in the fast neutron region performed by LANL. The remaining data were taken over from ENDF/B-VI.8.

2.1.1 ^{235}U , Unresolved Resonance Region

The SAMMY code has been used to perform the unresolved resonance evaluation of the ^{235}U cross sections from 2.25 up to 25 keV (Leal et al., 2004). SAMMY generates average resonance parameters based on a statistical model analysis of the experimental average cross sections. The primary use of the average resonance parameters is to reproduce the fluctuations in the cross sections for the purposes of energy self-shielding calculations.

Figure 9
 Evaluated $^{235}\text{U}(n, \gamma)$ capture cross section compared with data and with the JENDL-3.3 evaluation

A good representation of the average cross section was achieved with the new evaluation as shown for the ^{235}U radiative capture in Fig. 9.

The thermal $\bar{\nu}$ value for ^{235}U , which was taken over from ENDF/B-VI.8, is $\bar{\nu} = 2.4367$. This value is slightly higher than that from the neutron standards, 2.4355, but within experimental uncertainties in order to optimize agreement with the critical assembly benchmarks.

2.1.2 ^{235}U , Fast Neutron Region

The new ^{235}U evaluation builds upon the previous ENDF/B-VI.8 file, with a number of improvements from Los Alamos. They include improved fission cross sections from the new standards, prompt $\bar{\nu}$ based on a covariance analysis of experimental data, $(n, 2n)$, $(n, 3n)$ cross sections based on new data, new prompt fission spectra taken from Madland, new delayed neutron time-dependent data, and improved inelastic scattering at 14 MeV and below.

The previous ^{235}U ENDF/B-VI.8 evaluation has performed reasonably well in integral validation tests based on simulations of critical assemblies. The principal deficiency the ENDF/B-VII.0 developers wanted to remove was an underprediction of reactivity. For instance, the calculated k_{eff} for Godiva, a fast critical assembly based upon highly enriched uranium (HEU) in a spherical configuration, was 0.9966, compared to experiment of 1.0000.

■ Figure 10

Evaluated fission cross section compared with measured data, as represented by a covariance analysis of experimental data (referred to as ENDF/B-VII.0 Standard). Our new evaluation follows the Standard evaluation of the experimental data. Other evaluations from joint evaluated fission and fusion (JEFF) and JENDL are also shown

The ^{235}U fission cross section is shown in [Fig. 10](#), with comparison to the previous ENDF/B-VI.8 evaluation, and to the latest joint evaluated fission and fusion (JEFF) and JENDL evaluations. This new result comes from the recent international standards project, and the evaluation follows the statistical analysis of the measured data. This evaluation is 0.5–1.5% higher than the previous ENDF/B-VI Standard in the 1–5 MeV region, and significantly higher above 15 MeV. The impact of the higher fission cross section in the fast region (a few MeV) is particularly important, having the effect of increasing the criticality of fast systems.

The Nuclear Energy Agency (NEA Paris) project studied the fission prompt neutron spectrum for ^{235}U . The final report (Weigmann et al., 2003) noted that significant uncertainties still exist in the prompt spectrum at thermal energies. Because of this uncertainty, adopted were Madland's new data for all energies except thermal, where the previous ENDF/B-VI evaluation was preserved.

In [Fig. 11](#), we show the prompt fission neutron emission spectrum, compared with measurements by Boykov et al. (1991) for 2.9 MeV neutrons on ^{235}U and plotted as a ratio to the $\sigma_c = \text{constant}$ approximation to the Los Alamos model (Madland and Nix, 1982). It is evident that the present ENDF/B-VII.0 agrees better with the data by Boykov et al.

The new $^{235}\text{U}(n, 2n)$ cross section comes from a GNASH code theory prediction, baselined against the measured data. A comparison with experimental data, and with ENDF/B-VI.8, JEFF-3.0, and JENDL-3.3 is given in [Fig. 12](#).

The previous ^{235}U evaluation was known to poorly model Livermore pulsed sphere data that measure the downscattering of 14 MeV neutrons, in the region corresponding to inelastic scattering (the 2–4 MeV excitation energy region in ^{235}U). The angle-integrated spectrum for

Figure 11

Prompt fission spectrum for 2.9 MeV neutrons incident on ^{235}U shown as a ratio to the $\sigma_c = \text{constant}$ approximation to the Los Alamos model. The data are from Boykov et al. (1991)

Figure 12

Evaluated $^{235}\text{U}(n,2n)$ cross section compared with data and with previous evaluations

14 MeV is shown in Fig. 13, and the oscillatory structure between 9 and 13 MeV emission energy is due to the new inelastic scattering to collective states. This is the first time that pre-equilibrium and DWBA mechanisms for inelastic scattering have been included high into the continuum for evaluated actinide databases. In ENDF/B-VII.0, this approach was followed for $^{233,235,236,238}\text{U}$, ^{239}Pu , ^{232}Th , and $^{231,233}\text{Pa}$.

■ Figure 13

Evaluated $^{235}\text{U}(n, xn)$ neutron production energy-spectrum compared with previous evaluations. No measured data exist, though our calculations were guided by measured data for ^{238}U

2.2 ^{238}U Evaluation

In natural uranium, ^{238}U is the dominant isotope, with 99.27% abundance and a half-life of 4.468×10^7 years. Although it is fast fissioner, not suitable for thermal systems, its high abundance stipulates that it must be evaluated very carefully.

2.2.1 ^{238}U , Resolved and Unresolved Resonance Region

Numerous criticality studies, involving low-enriched thermal benchmarks demonstrated a systematic k_{eff} underprediction of about -0.5% (-500 pcm) or more with ENDF/B-VI.8. International activity was formed to solve this problem. First, the ^{238}U capture cross sections were investigated using specific integral experiments sensitive to the capture resonance integrals:

- Correlation between k_{eff} and ^{238}U capture fraction
- Measurements of ^{238}U spectral indices and effective capture resonance integral
- Postirradiation experiments that measure the ^{239}Pu isotopic ratio as a function of burn-up

These tests (Courcelle, 2004) supported a slight reduction of the effective resonance integral between 0.5 and 1%. A new analysis of the ^{238}U cross section in the resolved-resonance range was performed at ORNL in collaboration with the CEA (Derrien et al., 2004). The SAMMY (Larson, 2006) analysis of the lowest s-wave resonances below 102 eV led to resonance parameters slightly different from those of ENDF/B-VI.8 as shown in [Table 1](#).

The $^{238}\text{U}(n, \gamma)$ thermal cross section, recently recommended by Trkov et al. (2005), $\sigma_0 = 2.683 \pm 0.012b$, was adopted. The scattering cross section at thermal energy was also

■ Table 1

Resonance parameters of the ^{238}U s-wave resonances in ENDF/B-VII.0 and ENDF/B-VI.8

Energy (eV)	ENDF/B-VII.0 $R' = 9.48$ fm		ENDF/B-VI.8 $R' = 9.42$ fm	
	Γ_γ (MeV)	Γ_n (MeV)	Γ_γ (MeV)	Γ_n (MeV)
6.673	23.00	1.476	23.00	1.493
20.87	22.86	10.09	22.91	10.26
36.68	23.00	33.55	22.89	34.13
66.03	23.31	24.18	23.36	24.60
80.75	23.39	1.874	23.00	1.865
102.56	24.08	70.77	23.40	71.70

Although the differences look small, they have a positive impact on performance

revisited and the effective scattering radius R_{eff} as well as the parameters of the external levels have been carefully assessed.

► *Figure 14* shows an example of the SAMMY fit of capture measurements in the keV energy range. As suggested by integral experiments, this new evaluation proposes a slight decrease of the effective capture resonance integral by about 0.6%, compared to ENDF/B-VI.8. One expected consequence of this new evaluation is an increase of the calculated multiplication factor for low-enriched lattices from about 0.1 to 0.15% (100–150 pcm), depending on the moderation ratio. The combination of the new LANL ^{238}U inelastic data in the fast neutron region with the ORNL resonance parameter set gave a satisfactory correction of the reactivity underprediction.

2.2.2 ^{238}U , Fast Neutron Region

The new ENDF/B-VII.0 evaluation is based upon evaluations of experimental data and use of GNASH and ECIS nuclear model calculations to predict cross sections and spectra. Prior to the present work, there were some long-standing deficiencies, as evident in critical assembly integral data testing. First, there was the reflector bias – the phenomenon whereby fast critical assemblies showed a reactivity swing in the calculated k_{eff} in going from a bare critical assembly (e.g., Godiva (HEU) or Jezebel (^{239}Pu)) to ^{238}U -reflected critical assembly (e.g., Flattop-25, or Flattop-Pu), whereas measurements showed $k_{\text{eff}} = 1$ for both assemblies.

Second, thermal critical assemblies involving ^{238}U have showed a calculated under-reactivity for ENDF/B-VI.8. Third, some intermediate energy critical assemblies involving large quantities of ^{238}U , such as Big-10, were modeled very poorly using ENDF/B-VI.8 data. The nuclear data improvements made for ENDF/B-VII.0 largely removed these deficiencies. Similar methods in the fast neutron region applied at the CEA/Bruyères-le-Châtel lead to similar improvements in the JEFF-3.1 library (López Jiménez et al., 2004).

■ Figure 14

Experimental capture data on ^{238}U (one sample measured by De Saussure and two samples by Macklin) compared to the results of the SAMMY fit in the range 5.5–6.0 keV

The fission cross section was taken from the new recommendations of the IAEA Standards group, based on a Bayesian analysis of measured data. As can be seen in [Fig. 15](#), the fission cross section differs from the previous ENDF/B-VI.8 cross section in some important ways, being $\approx 1.5\%$ larger in the 2–4 MeV region, and 1–5% larger in the 14–20 MeV region. Above 14 MeV, the principal reason for the change is newer and more precise measurements from various laboratories, which were not available for ENDF/B-VI.

The prompt fission spectrum in ENDF/B-VII.0 for ^{238}U came from a new analysis by Madland using the Los Alamos model. The average energies are compared with Los Alamos model predictions in [Fig. 16](#), and the agreement with experimental data is seen to be good.

Nuclear reaction modeling with the GNASH and ECIS codes played an important role for improving the treatment of inelastic scattering to discrete levels and to the continuum. This work impacts both the scattering in the fast region, as well as at 14 MeV and below. In the former case – inelastic scattering in the fast (a few MeV) region – our improved data for inelastic scattering result in significant improvements in the critical assembly validation tests, not just for fast critical assemblies, but also for more moderated and thermal assemblies (the LEU-COMPTHERM series).

An example of the secondary neutron emission spectrum at 6.1 MeV incident energy on ^{238}U is shown in [Fig. 17](#) for an emission angle of 45° . It is evident that the new ENDF/B-VII.0 evaluation provides a much more accurate representation of the secondary spectrum, and its angular distribution, than the earlier ENDF/B-VI.8 evaluation.

Figure 15 Evaluated ^{238}U fission cross section based on a covariance analysis of the experimental data from the Standards project (labeled Std)

Figure 16 First moment (average energies) of the $n+^{238}\text{U}$ prompt fission neutron spectrum matrix calculated with the Los Alamos model shown together with those extracted from earlier experiments and the more recent CEA/Los Alamos FIGARO measurements (Ethvignot et al., 2003)

Our evaluated neutron capture cross section is shown in [Fig. 18](#), and is compared with the result from the Standards project (which represents a Bayesian analysis of a large amount of experimental data). It should be noted that in the 10s–100s keV region, the evaluated cross section lies below the bulk of the measurements that one might find in the CSISRS (EXFOR) experimental database. This is intentional and represents the conclusions of evaluators who

■ Figure 17

Evaluated $^{238}\text{U}(n, xn)$ neutron production energy-spectrum, compared with data, and with different evaluations

■ Figure 18

Evaluated $^{238}\text{U}(n, \gamma)$ neutron capture cross section, compared with data (labeled Std), and with previous evaluations. The standards evaluation resulted in uncertainties less than 3% over the $E_n = 10^{-4}$ –2.2 MeV region

Figure 19
Evaluated $^{238}\text{U}(n,2n)$ cross section compared with data and with previous evaluations

have studied the various measurements and concluded that the lower measurements are most accurate. See, for instance, the NEA WPEC Subgroup-4 report (Kanda and Baba, 1999).

The neutron capture cross section of ^{238}U can be tested in an integral way by comparing the production of ^{239}U in a critical assembly for various neutron spectra in different critical assemblies, ranging from soft spectra to hard spectra. The results show that the evaluation reproduces integral capture rates reasonably well.

Like radiative capture, cross sections such as $(n,2n)$ and $(n,3n)$ are also important for production–depletion studies of uranium isotope inventories and transmutation. Our new evaluation of the $(n,2n)$ cross section is shown in Fig. 19 and is compared with ENDF/B-VI.8 and with measured data.

2.3 ^{239}Pu Evaluation

2.3.1 ^{239}Pu , Resonance Region

The evaluation by Derrien and Nakagawa of the resonance region was taken over from the ENDF/B-VI.8 library without any change.

2.3.2 ^{239}Pu , Fast Neutron Region

The upgrades made to the ^{239}Pu evaluation included improved description of $^{239}\text{Pu}(n,2n)$, adoption of fission cross section from Standards, new analysis of the prompt fission spectrum,

■ Figure 20

Evaluated ^{239}Pu fission cross section compared with measured data, as represented by a covariance analysis of experimental data (referred to as ENDF/B-VII.0 Standard). The new evaluation follows the Standard evaluation of the experimental data. Other evaluations from JEFF and JENDL are also shown

new delayed neutron time-dependent data, $\bar{\nu}$ modifications, and improved inelastic scattering at 14 MeV and below.

The earlier ^{239}Pu ENDF/B-VI.8 evaluation exhibited an under-reactivity, with the simulated Jezebel k_{eff} being ≈ 0.997 . The new evaluation is more reactive, mainly because of the higher fission cross section in the fast region, with $k_{\text{eff}} \approx 1.000$.

The new fission cross section is shown in [Fig. 20](#) and is compared with the older ENDF/B-VI.8 evaluation. Because the earlier ^{235}U ENDF/B-VI.8 standard fission cross section was too low in the fast neutron energy region, and has now been increased in ENDF/B-VII.0, this leads to an increased ^{239}Pu fission cross section in this energy region too, since the plutonium fission cross section is strongly dependent on $^{239}\text{Pu}/^{235}\text{U}$ fission ratio measurements.

The prompt fission neutron spectrum, as a function of incident neutron energy, was reevaluated using the Madland–Nix approach. An example of the prompt fission spectrum is shown in [Fig. 21](#), for 1.5 MeV neutrons incident on ^{239}Pu , compared with the data by Staples et al. (1995).

The new $(n, 2n)$ cross section was based upon a Livermore–Los Alamos collaboration, involving GEANIE gamma-ray measurements of the prompt gamma rays in ^{238}Pu , together with GNASH code theory predictions of unmeasured contributions to the cross section. Prior to this work, precision activation measurements had been made near 14 MeV by Loughheed et al. (2001). Other measurements based on measuring the two secondary neutrons were thought to be problematic and were therefore discounted in the evaluation ([Fig. 22](#)).

Figure 21 Prompt fission neutron spectrum for 1.5 MeV neutrons incident on ^{239}Pu . The data of Staples et al. (1995) are shown together with the least-squares adjustment to the Los Alamos model

Figure 22 Evaluated $^{239}\text{Pu}(n,2n)$ cross section compared with data, and with previous evaluations. The evaluation was based upon the GEANIE-GNASH data and the Loughheed et al. 14 MeV data (Loughheed et al., 2001). The ENDF/B-VII.0 evaluation (red line) is also referred to as the “GEANIE-project” evaluation

■ **Figure 23**

Evaluated $^{239}\text{Pu}(n, xn)$ neutron production energy-spectrum compared with previous evaluations. No fundamental experimental data exist for this reaction, although Livermore pulsed data for transmission do exist

As was the case for ^{235}U , the previous ^{239}Pu evaluation did not include enough inelastic scattering into the continuum for 14 MeV neutron energy and below, leading to poor performance in simulations of Livermore pulsed spheres in the 2–4 MeV excitation energy region. We inferred collective excitation strength from DR analyses of ^{238}U data by Baba et al. and assumed similar strengths for ^{239}Pu . ➤ *Figure 23* shows the new angle-integrated neutron spectrum data compared to the ENDF/B-VI.8 evaluation (no measurements exist). This procedure led to a much improved MCNP modeling of the pulsed-sphere data.

2.4 ^{232}Th Evaluation

Recent developments in innovative fuel cycle concepts and accelerator-driven systems for the transmutation of nuclear waste have created a new interest in nuclear data for light actinides, with fission being crucially important for the design of new reactor systems. Additionally, there is strong scientific interest in the “thorium anomaly” (Bjornholm and Lynn, 1980b), which implies that in the thorium region the second-order shell effects split the outer fission barrier giving the so-called triple-humped structure.

The evaluation of ^{232}Th was completed in 2006 (Trkov, 2003, 2006). The resonance parameters were obtained by Leal and Derrien (2006) from a sequential Bayes analysis with the SAMMY code of the experimental database including Olsen neutron transmission at

ORELA (Olsen and Ingle, 1981), not yet published capture data by Schillebeeckx (GELINA), and Gusing (n-TOF) in the energy range 1–4 keV. Unresolved resonance parameters (4–100 keV) were derived by Sirakov et al. (2006, ^{232}Th : evaluation of the average resonance parameters and their covariances in the URR from 4 to 100 keV, private communication).

Evaluation in the fast energy region (Capote et al. 2006, evaluation of fast neutron-induced reactions on ^{232}Th and $^{231,233}\text{Pa}$ up to 60 MeV, private communication) was fully based on nuclear model calculations using the EMPIRE-2.19 code (Herman et al., 2005a,b; Sin et al., 2004). A crucial point was the selection of the proper coupled-channel optical model potential. The direct interaction cross sections and transmission coefficients for the incident channel on ^{232}Th were obtained from the dispersive coupled-channel potential of Soukhovitskii et al. (2005) (RIPL 608). Hauser–Feshbach (Hauser and Feshbach, 1952) and HRTW (Hofmann et al., 1975) versions of the statistical model were used for the compound nucleus cross section calculations. Both approaches include fission decay probabilities deduced in the optical model for fission (Sin et al., 2006) and account for the multiple-particle emission and the full γ -ray cascade.

A new model to describe fission on light actinides, which takes into account transmission through a triple-humped fission barrier with absorption, was developed (Sin et al., 2006) and applied for the first time to fission cross section evaluations. This formalism is capable of interpreting complex structure in the light actinide fission cross section in a wide energy range. The agreement with experimental fission cross sections is impressive as can be seen in  Fig. 7 discussed earlier. The complex resonance structure in the first-chance neutron-induced fission cross section of ^{232}Th has been very well reproduced. Prompt fission neutron spectra and $\bar{\nu}$ values were calculated using a new PFNS module of the EMPIRE code. The calculated $\bar{\nu}$ values were normalized to BROND-3 values (Ignatyuk et al., 2006), which are based on an extensive experimental database and contain covariance information.

The EMPIRE calculations were merged with the resonance data, including resonance covariance file and the delayed neutron data from the BROND-3 file (Ignatyuk et al., 2006). Since the evaluation extends up to 60 MeV, exclusive spectra are only given for the first three emissions, such as $(n, 3n)$ and $(n, 2np)$, while all the remaining channels are lumped into $MT = 5$. The validation of the thorium file was carried out by Trkov and Capote (2006), showing improvement over previous evaluations.

2.5 Minor Actinides

Minor actinides are defined broadly as fissionable nuclei beyond the four major actinides. They include minor isotopes of U and Pu as well as isotopes of Np, Am, and Cm and ultimately also all heavier actinides. For example, advanced reactor systems are interested in 15 minor actinides, $^{233,234,236}\text{U}$, $^{238,240,241,242}\text{Pu}$, ^{237}Np , $^{241,242m,243}\text{Am}$, and $^{242,243,244,245}\text{Cm}$.

2.5.1 ^{233}U Evaluation

The latest evaluation for ^{233}U (Young et al., 2007) was specifically performed for ENDF/B-VII.0 library. The fission cross section is taken from a covariance statistical analysis of all experimental data, including $^{233}\text{U}/^{235}\text{U}$ fission ratio measurements converted using the ENDF/B-VII.0

■ Figure 24

Evaluated fission cross section that follows the measured data (shown as a covariance analysis of the experimental data). Other evaluations from JEFF and JENDL are also included

standard ^{235}U cross section, as shown in ► Fig. 24. The somewhat higher ^{233}U fission cross section in the fission spectrum region produces better agreement with fast critical benchmark experiments.

2.5.2 $^{232,234,236,237,239,240,241}\text{U}$ Evaluations

These evaluations were done by the well-established Los Alamos group led by Young et al. (2007). Depending upon the isotope, varying amounts of measured data are available. In some cases, the experimental database is extremely sparse. For example, for ^{237}U , there are no direct measurements of the fission cross section at monoenergetic incident neutron energies, and there are no capture measurements. However, for ^{237}U and ^{239}U , indirect information does exist on the fission cross section in the few-MeV region, using surrogate (t,p) “Decay Ratio” (DR) experiments from Los Alamos, which have recently been reanalyzed by Younes and Britt (2003) at Livermore and from a more recent Lawrence Livermore National Laboratory (LLNL) experiment by Bernstein et al. (Plettner et al., 2005). These data allow an assessment of the equivalent neutron-induced fission cross section, and Younes and Britt have shown that such surrogate approaches can be accurate to better than 15%.

In the case of ^{237}U , a measurement has been made of the fission cross section in a fast fission spectrum within a Flattop (fast) critical assembly, at two locations – the center region and the tamper region (where the spectrum is softer). This kind of measurement also provides indirect information on the fission cross section.

Table 2

Thermal (0.0253 eV) constants obtained from the standards evaluation, g_w^f and g_w^{abs} are the Westcott factors

Quantity	²³³ U	²³⁵ U	²³⁹ Pu	²⁴¹ Pu
σ_{nf} (b)	531.22 ± 0.25% (531.22)	584.33 ± 0.17% (585.09)	750.00 ± 0.24% (747.40)	1013.96 ± 0.65% (1011.85)
σ_{ny} (b)	45.56 ± 1.50% (45.24)	99.40 ± 0.72% (98.69)	271.50 ± 0.79% (270.33)	361.79 ± 1.37% (363.05)
σ_{nn} (b)	12.11 ± 5.48% (12.15)	14.087 ± 1.56% (15.08)	7.800 ± 12.30% (7.975)	12.13 ± 21.50% (11.24)
g_w^f	0.9956 ± 0.14% (0.9966)	0.9773 ± 0.08% (0.9764)	1.0554 ± 0.20% (1.0542)	1.0454 ± 0.53% (1.046)
g_w^{abs}	0.9996 ± 0.11% (0.9994)	0.9788 ± 0.08% (0.9785)	1.0780 ± 0.22% (1.0782)	1.0440 ± 0.19% (1.042)
$\bar{\nu}_{tot}$	2.497 ± 0.14% (2.497)	2.4355 ± 0.09% (2.4367)	2.8836 ± 0.16% (2.8789)	2.9479 ± 0.18% (2.9453)

The neutron sublibrary values are given in brackets. The nubar obtained from the standards evaluation process for ²⁵²Cf is $\bar{\nu}_{tot} = 3.7692 \pm 0.125\%$, comprised of $\bar{\nu}_p = 3.7606$ and $\bar{\nu}_d = 0.0086$. In ENDF/B-VI.8, $\bar{\nu}_{tot}$ was 3.7676, comprised of $\bar{\nu}_p = 3.759$ and $\bar{\nu}_d = 0.0086$

2.6 Thermal Constants

It is useful to summarize the thermal constants in the ENDF/B-VII.0 neutron sublibrary for important materials and compare them with the values given in the neutron cross section standards sublibrary. This is done in [Table 2](#). One can see that there are differences between the two sublibraries, though these are generally very small and within ≈ 0.5 standard deviation. The only item shown in this table that is considered a standard is the thermal ²³⁵U(*n, f*) cross section.

2.7 Nubars

The average number of neutrons per fission, also known as fission neutron multiplicity, represent quantities of exceptional importance. These quantities are evaluated with utmost care and high precision of data has been achieved. The total nubar (denoted as $\bar{\nu}$ or $\bar{\nu}_{tot}$) is obtained as a sum of prompt and delayed nubars,

$$\bar{\nu}_{tot} = \bar{\nu}_p + \bar{\nu}_d \tag{41}$$

For ²³⁵U, the energy dependence of the prompt $\bar{\nu}_p$ is shown in [Fig. 25](#). This new ENDF/B-VII.0 evaluation follows covariance analysis of the experimental data, generally within uncertainties, and includes renormalization of the measured values to the latest standard value for ²⁵²Cf.

■ Figure 25

Evaluated ^{235}U prompt fission neutron multiplicity, $\bar{\nu}_p$, compared with measured data, as represented by a covariance analysis of experimental data. Other evaluations from JEFF (Europe) and JENDL (Japan) are also shown

For ^{238}U , the energy dependence of prompt fission neutron multiplicity, the ENDF/B-VII.0 data are identical to ENDF/B-VI, except the energy range was extended from 20 to 30 MeV. The ENDF/B-VI data are based on an evaluation by Frehaut (2000). For the results and comparison see [▶ Fig. 26](#).

The ^{239}Pu evaluated prompt fission nubar is shown in [▶ Fig. 27](#), compared with statistical covariance analysis of all measured data (again re-normalized to the latest californium standard). In the fast region, our evaluation follows the upper uncertainty bars of the statistical analysis of the experimental data, allowing us to optimize the integral performance in criticality benchmarks for the fast Jezebel ^{239}Pu spherical assembly.

2.8 Delayed Neutrons

Delayed neutrons originate from the radioactive decay of nuclei produced in fission and hence they are different for each fissioning system.

2.8.1 Fission-Product Delayed Neutrons

Delayed neutrons, also referred to as temporal fission-product delayed neutrons, are stored in ENDF-6 formatted files as MF=1, MT=455. Related experiments typically report data as a series

Figure 26
 Evaluated ^{238}U prompt fission neutron multiplicity based on a covariance analysis of the experimental data

Figure 27
 Evaluated ^{239}Pu prompt fission neutron multiplicity, $\bar{\nu}_p$, compared with measured data, as represented by a covariance analysis of experimental data. Other evaluations from JEFF and JENDL are also shown

of exponential terms. An experiment includes measurements characteristically made for a set of irradiation, cooling, and counting periods. Integrally detected delayed neutrons, adjusted for efficiencies and assigned uncertainties, are fit for maximum likelihood with an exponential series.

The most common function used has been a series of six exponential terms emulating the sum of contributions of six uncoupled delayed-neutron precursors or precursor groups of differing time constants – hence the use of “six-group fits” in common parlance. This series is generally given in terms of $\bar{\nu}_d$ – the total number of delayed neutrons per fission – times the normalized sum of six exponential terms giving the temporal production at time t following a fission event.

The delayed neutron yields in ENDF/B-VII.0 were carried over from ENDF/B-VI.8, with the exception of the modifications to ^{235}U thermal $\bar{\nu}_d$ as described in the next subsection. Therefore, these yields are based on experimental data. The six-group parameters describing the time dependence of the delayed neutrons are discussed in more detail below. But we note that an explicit incident energy dependence is not given in the ENDF file as was also the case in the previous ENDF/B-VI.8 evaluation. The six-group values in the ENDF file correspond to fast neutron incident energies.

CINDER’90 calculations of a single fission pulse were replaced with a series of calculations for a variety of irradiation periods followed by decay times to 800 s, defining delayed neutron production in terms of irradiation and cooling times improving fits at very short and very long cooling times (Wilson and England, 2002). Subsequent improvements in P_n and half-life data were obtained using evaluated measured data of Pfeiffer et al. (2002) and NUBASE2003 (Audi et al., 2003). Use of the earlier systematics of Kratz and Herrmann was then replaced by results obtained with our own model.

A new CINDER’90 data library, including all delayed neutron data developed, now includes 534 delayed neutron precursors, with 477 precursors in the fission-product range $65 < A < 173$. Use of the fission product yields (FPY) data (England and Rider, 1993) results in the production of 281–440 of these precursors yielded in the 60 fission systems. These data have been used to produce new temporal delayed neutron fits for all 60 fission systems. Fits for some systems are included in this release of ENDF/B-VII.0; spectra, where present, are taken from the ENDF/B-VI.8 files using the new group abundances.

For illustration, in  Fig. 28 we show delayed neutron fraction emitted as function of the time following a ^{235}U thermal fission pulse. As shown in the inset, differences between ENDF/B-VII.0 and the other evaluations are smaller than 20% for times larger than 1 s.

2.8.2 ^{235}U Thermal $\bar{\nu}_d$

When Keepin (1965) measured delayed nubar ($\bar{\nu}_d$) for ^{235}U , he found a difference between thermal and fast values: 0.0158 ± 0.0005 and 0.0165 ± 0.0005 , respectively. Since second-chance fission was above the energy of his measurements, he assumed it was an experimental error, and recommended the cleaner fast data for kinetics applications, including thermal. This posed a problem for thermal reactor designers: use the more accurate fast value, or the more relevant thermal data. Mostly, they opted for the latter.

Experiments continued to send mixed signals. Conant and Palmedo (1971) and Tuttle (1975) supported a difference between fast and thermal values, and thermal reactor kinetics

Figure 28

Delayed neutron fraction as a function of time following a ^{235}U thermal fission pulse for ENDF/B-VII.0, ENDF/B-VI.8, JEFF 3.1, Brady and England (1989), and Keepin (1965). The inset shows the ratio of the delayed neutron fractions for the other evaluations to the ENDF/B-VII.0

calculations failed to show a problem with the lower value. Fast measurements and summation calculations tended to raise the 0.0167 value even higher.

Two recent developments provided a plausible resolution to this problem:

1. Fission theory allowed an energy-variation of delayed nuclide in the resonance region (Ohsawa and Oyama, 1999; Ohsawa and Hamsch, 2004). The change in ^{235}U delayed nuclide is a series of small dips, one at each resonance, but for engineering purposes, only the average value over the thermal region is important. As the energy increases, the fluctuations decrease and the value approaches the higher fast value.
2. Analysis of beta-effective measurements supported the view that thermal delayed nuclide is about 5% lower than the fast value (Nakajima, 2001; Sakurai and Okajima, 2002; van der Marck, 2005).

The ENDF/B-VII.0 ^{235}U delayed nuclide file is not a reevaluation of the data, but a minimum adjustment to ENDF/B-VI, which reflects current usage and recognizes the thermal-fast difference. An appropriate time to revisit this issue will be when the ANS-19.9 Standard is finalized. The delayed value at thermal energy ($\bar{\nu}_d = 0.01585$) was taken from JENDL-3.3. It then ramps linearly to 0.0167 at 50 keV. JENDL ramps to 0.0162, but 0.0167 minimizes the change to ENDF/B-VI. Above 50 keV, the ENDF/B-VI data are unchanged. To avoid disturbing thermal criticality benchmark results, which depend on total nuclide, the thermal prompt value was changed to keep total nuclide the same, $\bar{\nu}_{\text{tot}} = 2.42000-2.42085$.

2.9 Fission Energy Release

The ENDF/B-VII.0 library includes new information for the energy released in fission for the major actinides, $^{235,238}\text{U}$ and ^{239}Pu . A recent study by Madland (2006) found a new representation for the prompt fission product energy $E_{FR}(e_{\text{inc}})$, prompt neutron energy $E_{NP}(e_{\text{inc}})$, and prompt photon energy $E_{GP}(e_{\text{inc}})$ functions. Their sum, the average total prompt fission energy deposition, is given by

$$\langle E_d(e_{\text{inc}}) \rangle = E_{FR}(e_{\text{inc}}) + E_{NP}(e_{\text{inc}}) + E_{GP}(e_{\text{inc}}). \quad (42)$$

This expression is based upon published experimental measurements and application of the Los Alamos model (Madland and Nix, 1982), and it shows that, to first order, these quantities can be represented by linear or quadratic polynomials in the incident neutron energy e_{inc} ,

$$E_i(e_{\text{inc}}) = c_0 + c_1 e_{\text{inc}} + c_2 e_{\text{inc}}^2, \quad (43)$$

where E_i is one of E_{FR} , E_{NP} , or E_{GP} .

The recommended coefficients for $^{235,238}\text{U}$ and ^{239}Pu are provided in [Table 3](#). The average total prompt energy deposition $\langle E_d \rangle$ obtained using these coefficients in (42) and (43) is shown in [Fig. 29](#). Madland's recommended c_0 values for E_{FR} have been adopted in the new ENDF/B-VII.0 files for $^{235,238}\text{U}$ and ^{239}Pu .

2.9.1 Nuclear Heating

Nuclear heating is an important quantity in any nuclear system. It is a topic that should be explored in relation to the energy release presented above and its handling by the processing code NJOY. In general, heating as a function of energy, $H(e_{\text{inc}})$, may be given in terms of kinetic

Table 3
Madland's recommended energy release polynomial coefficients, in MeV

Nuclide	Parameter	c_0	c_1	c_2
^{235}U	E_{FR}	169.13	-0.2660	0.0
	E_{NP}	4.838	+0.3004	0.0
	E_{GP}	6.600	+0.0777	0.0
^{238}U	E_{FR}	169.8	-0.3230	0.004206
	E_{NP}	4.558	+0.3070	0.0
	E_{GP}	6.6800	+0.1239	0.0
^{239}Pu	E_{FR}	175.55	-0.4566	0.0
	E_{NP}	6.128	0.3428	0.0
	E_{GP}	6.741	+0.1165	-0.0017

See (43) for explanation

■ Figure 29

Average total prompt fission energy deposition as a function of the incident neutron energy. See (42) for explanation

energy released in materials (KERMA) coefficients (the International Commission on Radiation Units and Measurements in its document ICRU-63 (ICRU, 2000) recommends using the name “KERMA coefficient” instead of “KERMA factor”), $k_{ij}(e_{\text{inc}})$, as

$$H(e_{\text{inc}}) = \sum_i \sum_j \rho_i k_{ij}(e_{\text{inc}}) \Phi(e_{\text{inc}}), \quad (44)$$

where ρ_i is the number density of the i th material, $k_{ij}(e_{\text{inc}})$ is the KERMA coefficient for the i th material and j th reaction at energy e_{inc} , and $\Phi(e_{\text{inc}})$ is the scalar flux. A rigorous calculation of the KERMA coefficient for each reaction requires knowledge of the total kinetic energy carried away by all secondary particles following that reaction, data that frequently are not available in evaluated files. An alternative technique, known as the energy balance method (Muir, 1976), is used by NJOY. KERMA coefficient calculations by this method require knowledge of the incident particle energy, the reaction Q -value, and other terms.

The prompt fission reaction Q -value required for prompt fission KERMA including the energy-dependent prompt fission Q -value can be calculated as

$$Q(e_{\text{inc}}) = E_R - 8.07 \times 10^6 [\bar{v}(e_{\text{inc}}) - \bar{v}(0)] + 0.307 e_{\text{inc}} - E_B - E_{GD}, \quad (45)$$

where E_R is the total energy minus neutron energy, E_B is the total energy released by delayed betas, and E_{GD} is the total energy of delayed photons.

■ **Table 4**

Prompt fission Q-values in MeV obtained with ENDF/B-VII.0 data^a

Nuclide	Incident energy e_{inc}	ENDF/B VII.0	Madland	NJOY (old)	NJOY (45)
²³⁵ U	0.0253 eV	180.65	180.57	180.65	180.65
	1.0 MeV	180.19	179.68	179.84	180.19
	14.0 MeV	169.07	168.14	164.24	169.14
²³⁸ U	0.0253 eV	181.28	181.04	181.30	181.30
	1.0 MeV	181.02	180.15	180.68	181.03
	14.0 MeV	169.59	169.37	164.86	169.76
²³⁹ Pu	0.0253 eV	188.38	188.42	189.37	188.37
	1.0 MeV	187.58	187.42	187.24	187.59
	14.0 MeV	175.98	174.12	171.10	176.00

^a Given for the sum of prompt fission products, prompt neutrons, and prompt gammas
To get total energy deposition, add the incident energy to total Q-values tabulated here

Results based upon new ENDF/B-VII.0 are shown in [Table 4](#). We note that the prompt fission Q-value calculated with the traditional ENDF formulas are now in much better agreement with Madland's calculations.

3 Neutron Data for Other Materials

In addition to actinides, there are three other categories of materials of interest for nuclear technology applications. These are light nuclei that often serve as moderators and coolants, structural materials, and fission products.

3.1 Light Nuclei

Several light-element evaluations were contributed to ENDF/B-VII.0, based on R-matrix analysis done at Los Alamos using the EDA code. Among the neutron-induced evaluations were those for ¹H, ³H, ⁶Li, ⁹Be, and ¹⁰B. For the light-element standards, R-matrix results for ⁶Li(*n*, α) and ¹⁰B(*n*, α) were contributed to the standards process, which combined the results of two different R-matrix analyses with ratio data using generalized least-squares. Differences persisted between the two R-matrix analyses even with the same data sets that are not completely understood, but probably are related to different treatments of systematic errors in the experimental data.

Below we summarize upgrades that have been made for ENDF/B-VII.0. Where no changes have been made compared to ENDF/B-VI.8 (e.g., for *n* + ²H), we do not discuss reactions on these isotopes.

¹H: The hydrogen evaluation came from an analysis of the *N* – *N* system that includes data for *p* + *p* and *n* + *p* scattering, as well as data for the reaction ¹H(*n*, γ)²H in the forward (capture) and reverse (photodisintegration) directions. The R-matrix parametrization, which is

completely relativistic, uses charge-independent constraints to relate the data in the $p+p$ system to those in the $n+p$ system. It also uses a new treatment of photon channels in R-matrix theory that is more consistent with identifying the vector potential with a photon “wavefunction.”

In the last stages of the analysis, the thermal capture cross section was forced to a value of 332.0 mb (as in ENDF/B-VI.8), rather than the “best” experimental value of 332.6 ± 0.7 mb (Cokinos and Melkonian, 1977), since criticality data testing of aqueous thermal systems showed a slight preference for the lower value. Also, the latest measurement (Schoen et al., 2003) of the coherent $n+p$ scattering length was used, resulting in close agreement with that value, and with an earlier measurement of the thermal scattering cross section (Houk, 1971), but not with a later, more precise value (Dilg, 1975).

This analysis also improved a problem with the $n+p$ angular distribution in ENDF/B-VI.8 near 14 MeV by including new measurements (Boukharaba et al., 2002; Buerkle and Mertens, 1997) and making corrections to some of the earlier data that had strongly influenced the previous evaluation.

^3H : The $n+^3\text{H}$ evaluation resulted from a charge-symmetric reflection of the parameters from a $p+^3\text{He}$ analysis that was done some time ago. This prediction (Hale et al., 1990) resulted in good agreement with $n+t$ scattering lengths and total cross sections that were newly measured at the time, and which gave a substantially higher total cross section at low energies than did the ENDF/B-VI evaluation. At higher energies, the differences were not so large, and the angular distributions also remained similar to those of the earlier evaluation.

^9Be : The $n+^9\text{Be}$ evaluation was based on a preliminary analysis of the ^{10}Be system that did a single-channel fit only to the total cross section data at energies up to about 14 MeV. A more complete analysis should take into account the multichannel partitioning of the total cross section, especially into the $(n, 2n)$ channels. An adequate representation of these multibody final states will probably require changes in the EDA code. For ENDF/B-VII.0, the elastic (and total) cross section was modified to utilize the new EDA analysis, which accurately parametrizes the measured total elastic data, while the previous ENDF/B-VI.8 angular distributions were carried over.

Data testing of the file (including only the changes in the total cross sections) appeared to give better results for beryllium-reflecting assemblies, and so it was decided to include this preliminary version in the ENDF/B-VII.0 release.

^{16}O : The evaluated cross section of the $^{16}\text{O}(n, \alpha_0)$ reaction in the laboratory neutron energy region between 2.4 and 8.9 MeV was reduced by 32% at LANL. The $^{16}\text{O}(n, \alpha)$ cross section was changed accordingly and the elastic cross sections were adjusted to conserve unitarity. This reduction was based upon more recent measurements. We note that this led to a small increase in the calculated criticality of LCT assemblies.

3.2 Structural Materials

Structural materials play a prominent role in nuclear applications and hence neutron reaction data are evaluated very carefully.

In the ENDF/B-VII.0, the main evaluation effort was concentrated on the major actinides and the fission products ($Z = 31-68$) that together cover more than half of the ENDF/B-VII.0 neutron sublibrary. Outside of these two groups, only few materials were fully or partially evaluated for ENDF/B-VII.0, as described below.

3.2.1 Evaluations of Major Structural Materials

Structural materials fall into a category of priority materials in all major evaluated data libraries. The list is dominated by Cr, Fe, and Ni, the most important isotopes being major structural materials ^{52}Cr (natural abundance 83.8%), ^{56}Fe (91.7%), and ^{58}Ni (68.1%), followed by less abundant isotopes $^{50,53}\text{Cr}$, $^{54,57}\text{Fe}$, ^{60}Ni , etc.

In the USA, considerable attention to evaluations of structural materials has been devoted in the past. These evaluations have been performed by the highly experienced team at ORNL up to 20 MeV in the 1980s, in particular in reference to the celebrated ENDF/B-V library. We note that ORNL supplied complete evaluations in the entire energy range, combining the capabilities in the thermal and resonance region (code SAMMY) with the then advanced nuclear reaction modeling code TNG in the fast neutron region. An example would be the 1986 update for iron by Fu et al. (1986). Since then, virtually no updates below 20 MeV have been made. In view of the data need for accelerator driven systems in the 1990s, the evaluations of structural materials have been extended to 150 MeV by Los Alamos and incorporated into the ENDF/B-VI library. Then, these have been adopted without any change by the latest version of the ENDF/B-VII.0 library, which was released in 2006.

3.2.2 New Evaluations for ENDF/B-VII.0

^{nat}V : Cross sections for the (n, np) reaction were revised at BNL (Rochman et al., 2006) by adjusting the EMPIRE-2.19 calculations to reproduce two indirect measurements by Grimes et al. (1978) and Kokoo et al. (1999) at 14.1 and 14.7 MeV, respectively. This resulted in the substantial reduction (about 350 mb at the maximum) of the (n, np) cross section. Similarly, the (n, t) reaction was revised to reproduce experimental results of Woelfle et al. (1990). The inelastic scattering to the continuum was adjusted accordingly to preserve the original total cross section.

$^{191,193}\text{Ir}$: These are two entirely new evaluations performed jointly by T-16 (LANL) and the NNDC (BNL) in view of recent GEANIE data on γ -rays following neutron irradiation. The resolved and unresolved resonance parameters are based on the analysis presented in Mughabghab (2006). New GNASH model calculations were performed for the γ -rays measured by the GEANIE detector, and related (n, xn) reactions cross sections were deduced (Kawano et al., 2006). We also include an evaluation of the $^{193}\text{Ir}(n, n')$ reaction to the isomer. The remaining cross sections and energy-angle correlated spectra were calculated with the EMPIRE code. The results were validated against integral reaction rates.

^{208}Pb : A new T-16 (LANL) analysis with the GNASH code was performed over the incident neutron energy range from 1.0 to 30.0 MeV. The Koning–Delaroche optical model potential (Koning and Delaroche, 2003) from the RIPL-2 database was used to calculate neutron and proton transmission coefficients for calculations of the cross sections. Minor adjustments were made to several inelastic cross sections to improve agreement with experimental data. Additionally, continuum cross sections and energy-angle correlated spectra were obtained from the GNASH calculations for (n, n') , (n, p) , (n, d) , (n, t) , and (n, α) reactions. Elastic scattering angular distributions were also calculated with the Koning–Delaroche potential and incorporated in the evaluation at neutron energies below 30 MeV.

This new ^{208}Pb evaluation led to a significant improvement in the lead-reflected critical assembly data. This is especially true for fast assemblies, but some problems remained for thermal assemblies.

3.3 Fission Products

Fission products represent the largest category of nuclei (materials) in the evaluated nuclear data libraries. Defined broadly as materials with $Z = 31\text{--}68$, in the latest US library ENDF/B-VII.0 they supply 219 nuclei. We follow this definition with the understanding that it covers also several other important materials such as structural Mo and Zr, and absorbers Cd and Gd.

Many fission product evaluations in ENDF/B had not been revised for nearly 30–35 years. Not surprisingly an analysis performed by Wright (ORNL) and MacFarlane (LANL) in 2000 revealed considerable deficiencies in ENDF/B-VI (Wright and MacFarlane, 2000).

In this situation, fission product evaluations in ENDF/B-VI.8 were completely abandoned and ENDF/B-VII.0 adopted new or recently developed evaluations. For a set of 74 materials, including 19 materials considered to be of priority, entirely new evaluations were performed using the Atlas-EMPIRE evaluation procedure (Herman et al., 2007) including those by Kim et al. (2006, 2008). For the remaining 145 materials, evaluations were adopted from the recently developed International Fission Product Library of Neutron Cross Section Evaluations completed in December 2005 and described in the 2009 report (Obložinský et al., 2009b).

3.3.1 Priority Fission Products

New evaluations were performed for materials considered to be priority fission products. The list includes 19 materials,

- ^{95}Mo , ^{99}Tc , ^{101}Ru , ^{103}Rh , ^{105}Pd , ^{109}Ag , ^{131}Xe , ^{133}Cs , ^{141}Pr , ^{153}Eu , $^{143,145}\text{Nd}$, $^{147,149,150,151,152}\text{Sm}$, $^{155,157}\text{Gd}$.

This selection (Oh et al., 2000) was based on the analysis by DeHart, ORNL, which was performed in 1995 (DeHart, 1995). It was motivated by the need to improve existing evaluations for materials of importance for a number of applications, including criticality safety, burn-up credit for spent fuel transportation, disposal criticality analysis, and design of advanced fuels.

3.3.2 Complete Isotopic Chains

As a part of modern approach to evaluation, complete isotopic chains were evaluated for several fission products, including Ge, Nd, Sm, Gd, and Dy.

A simultaneous evaluation of the complete isotopic chain for a given element became possible thanks to tremendous progress in the development of evaluation tools in recent years. This includes highly integrated evaluation code systems such as EMPIRE, coupled to experimental database EXFOR and to the library of input parameters RIPL. Complete isotopic chains for Ge,

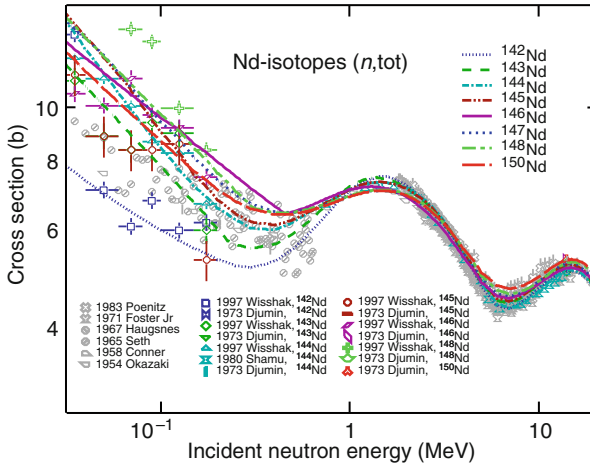

Figure 30

Total cross sections for Nd isotopes. Note the consistency among different isotopes resulting from the simultaneous evaluation of the full chain of neodymium isotopes

Nd, Sm, Gd, and Dy, totaling 37 materials were evaluated for ENDF/B-VII.0. As an example, we discuss isotopes of Nd.

A set of neodymium evaluations include two priority fission products, $^{143,145}\text{Nd}$, another five stable isotopes, and the radioactive ^{147}Nd . Neodymium is one of the most reactive rare-earth metals. It is important in nuclear reactor engineering as a fission product that absorbs neutrons in a reactor core. A new evaluation was performed by Kim et al. (2008). In Fig. 30, we show total neutron cross sections of all Nd isotopes in comparison with available data measured on isotopic samples as well as on elemental samples.

Of special interest to radiochemical applications is the radioactive ^{147}Nd for which no data exist in the fast neutron region. A good fit to available data on other stable isotopes gives confidence that predictions for ^{147}Nd cross sections are sound. This is illustrated in Figs. 31 and 32 where we show $(n, 2n)$ and neutron capture cross sections, respectively, for all Nd isotopes.

3.3.3 Specific Case of ^{90}Zr

Zirconium is an important material for nuclear reactors since, owing to its corrosion-resistance and low absorption cross section for thermal neutrons, it is used in fuel rods cladding. Benchmark testing performed at Bettis and KAPL showed an undesirable drop in the reactivity when the beta version of ENDF/B-VII.0 was used. Taking into account the importance of zirconium in reactor calculations, BNL undertook an entirely new evaluation of the fast neutron region in ^{90}Zr using the EMPIRE code. A good description of the total cross section of ^{90}Zr confirmed the higher elastic scattering cross section, see Fig. 33. The new file met expectations when validated against integral measurements at KAPL.

Figure 31 $(n,2n)$ cross sections for Nd isotopes. Good fit to the available data justifies prediction of cross sections for the radioactive ^{147}Nd

Figure 32 Neutron capture cross sections for Nd isotopes. Good fit to the available data endorses prediction of cross sections for the radioactive ^{147}Nd

■ Figure 33

Comparison of ^{90}Zr elastic cross sections calculated with various optical model potentials. The preliminary ENDF/B-VII evaluation (denoted ENDF/B-VIIb2) yields the lowest cross sections. The ENDF/B-VII.0 evaluation is considerably higher as suggested by the integral experiments

3.3.4 Remaining Fission Products

Recognizing a need to modernize the fission product evaluations, an international project was conducted during 2001–2005 to select the best evaluations from the available evaluated nuclear data libraries. Evaluated nuclear data libraries of five major efforts were considered, namely, the USA (ENDF/B-VI.8 and preliminary ENDF/B-VII), Japan (JENDL-3.3, released in 2002), Europe (JEFF-3.0, released in 2000), Russia (BROND-2.2, released in 1992), and China (CENDL-3.0, made available for this project in 2001).

As a result, the International Fission Product Library of Neutron Cross Section Evaluations (IFPL) was created for 219 materials (Obložinský et al., 2009b). Afterward, IFPL was adopted in full by the ENDF/B-VII.0 library, see 📍 Table 5 for a summary.

4 Covariances for Neutron Data

A covariance matrix specifies uncertainties and usually energy–energy correlations of data (cross sections, $\bar{\nu}$, etc.) that are required to assess uncertainties of design and operational parameters in nuclear technology applications. Covariances are obtained from the analysis of experimental data and they are stored as variances and correlations in the basic nuclear data libraries.

Early procedures for generating nuclear data covariances were widely discussed in the 1970s and 1980s (Smith, 1991). Accordingly, many of the presently existing covariance data were developed about 30 years ago for the ENDF/B-V library (Kinsey, 1979; Magurno et al., 1982). This earlier activity languished during the 1990s due to limited interest by users and constrained resources.

■ **Table 5**
Summary of 219 fission product evaluations included in the ENDF/B-VII.0 library

Library (data source)	Full file	Resonance region	Fast region
ENDF/B-VI.8, released in 2001	1	3	13
New evals for ENDF/B-VII.0	74	74	–
JEFF-3.1, released in 2005	1	–	–
JENDL-3.3, released in 2002	47	7	56
CENDL-3.0, released in 2001	11	–	15
BROND-2.2, released in 1992	1	–	–
Total number of materials	135	84	84

Full files were taken over from single libraries (data sources) for 135 materials; the remaining 84 files were put together from two different data sources

■ **Table 6**
Summary of methods used for the ENDF/B-VII.0 covariance evaluations

Energy region	Evaluation method	Material
Resolved resonances	Direct SAMMY	^{232}Th
	Retroactive SAMMY	$^{152,153,154,155,156,157,158,160}\text{Gd}$
	Atlas-KALMAN	^{89}Y , ^{99}Tc , $^{191,193}\text{Ir}$

Distinguished are three energy regions: resolved resonances, unresolved resonances, and fast neutron region

More recently, intensive interest in the design of a new generation of nuclear power reactors, as well as in criticality safety and national security applications has stimulated a revival in the demand for covariances as demonstrated at the major Covariance Workshop held in 2008 (Obložinský, 2008).

4.1 Evaluation Methodology

New covariance data in the ENDF/B-VII.0 neutron sublibrary were produced for 13 materials using the evaluation techniques summarized in [Table 6](#).

4.1.1 Resonance Region

Covariances in the resonance region can be produced by three different methods. The most sophisticated approach is based on the code SAMMY (Larson, 2006), which uses generalized least-squares fits to experimental data. The intermediate Atlas method propagates resonance parameter uncertainties (Mughabghab, 2006) to cross-section covariances. The simplest and most transparent method uses uncertainties of thermal cross sections and resonance integrals as estimate of covariances (Williams, 2004).

SAMMY Covariance Method

This method is normally applied to actual experimental data as the integral part of simultaneous evaluation of both resonance parameters and their covariances (files MF2 and MF32 in ENDF-6 format terminology, Herman and Trkov, 2009). However, out of practical necessity an alternative retroactive procedure is often used. One proceeds in three steps:

First, one either starts with actual experimental data or these are artificially (“retroactively”) generated using R-matrix theory and known resonance parameters. In the latter case, usually transmission, capture, and fission is calculated assuming realistic experimental conditions. Then, realistic statistical uncertainties are assigned to each data point, and realistic values are assumed for data-reduction parameters such as normalization and background.

Afterward, initial covariance matrix is established. Let D represent the experimental data and V the covariance matrix for experimental/retroactive data. Values for V (both on- and off-diagonal elements) are derived from the statistical uncertainties of the individual data points, v_i , and from the uncertainties of the data-reduction parameters, in the usual fashion

$$V_{ij} = v_i \delta_{ij} + \sum_k g_{ik} \Delta^2 r_k g_{jk}. \quad (46)$$

In this equation, $\Delta^2 r_k$ represents the uncertainty on the k th data-reduction parameter r_k , and g_{ik} is the partial derivative of the cross section at energy E_i with respect to r_k . Then, the covariance matrix V_{ij} describes all the known experimental uncertainties.

Finally, the generalized least-squares equations are used to determine the set of resonance parameters, P' , and associated resonance parameter covariance matrix, M' , that fit these data. If P is the original set of resonance parameters (for which we wish to determine the covariance matrix), and T is the theoretical curve generated from those parameters, then, in matrix notation, the least-squares equations are

$$P' = P + M + G^t V^{-1} (D - T) \quad \text{and} \quad M' = (G^t V^{-1} G)^{-1}. \quad (47)$$

Here, G is the set of partial derivatives of the theoretical values T with respect to the resonance parameters P ; G is sometimes called the sensitivity matrix.

The solutions of (47) provide the new parameter values P' and the associated resonance parameter covariance matrix M' , fitting all directly measured/retroactive data simultaneously and using the full off-diagonal data covariance matrix for each data set.

Atlas Covariance Method

This method combines the wealth of data given in the *Atlas of Neutron Resonances* (Mughabghab, 2006) with the filtering code KALMAN (Kawano et al., 1999; Kosako and Yanano, 1999). Atlas

provides values and uncertainties for neutron resonance parameters and also integral quantities such as capture thermal cross sections, resonance integrals, and 30-keV Maxwellian averages. The procedure consists of two major steps:

- One starts with the resonance parameters and their uncertainties and uses MLBW formalism to compute cross sections along with their sensitivities.
- Uncertainties of resonance parameters are propagated to cross sections with the code KALMAN. Uncertainties of thermal values are obtained by suitable adjustment of resonance parameter uncertainties, if necessary, inferring anticorrelation with bound (negative energy) resonances.

An alternative approach would be to take resonance parameter uncertainties, put them into file MF32, and leave the job of propagation of these uncertainties into cross-section covariances to well-established processing codes.

Low-Fidelity Covariance Method

This simple, yet extremely transparent and useful method, provides an estimate of covariance data using known uncertainties of thermal cross sections and integral quantities. It was proposed by Williams (2004) and later used extensively in the “Low-fidelity Covariance Project” by ANL-BNL-LANL-ORNL collaboration that was completed in 2008 (Little et al., 2008).

4.1.2 Fast Neutron Region

EMPIRE-KALMAN Covariance Method

EMPIRE-KALMAN methodology can serve as an example of recently developed covariance methods in the fast neutron region. The KALMAN filter techniques are based on minimum variance estimation and naturally combine covariances of model parameters, of experimental data, and of cross sections. This universality is a major advantage of the method.

The key ingredient of the method is the sensitivity matrix, which represents complex nuclear reaction calculations. If we denote the combination of nuclear reaction models as an operator \hat{M} that transforms the vector of model parameters \mathbf{p} into a vector of cross sections $\sigma(\mathbf{p})$ for a specific reaction channel, then the sensitivity matrix \mathbf{S} can be interpreted as the linear term in the expansion of the operator \hat{M} ,

$$\hat{M}\mathbf{p} = \sigma(\mathbf{p})$$

and

$$\hat{M}(\mathbf{p} + \delta\mathbf{p}) = \sigma(\mathbf{p}) + \mathbf{S}\delta\mathbf{p} + \dots, \quad (48)$$

where \hat{M} is the operator rather than a matrix. In practice, the elements $s_{i,j}$ of the sensitivity matrix are calculated numerically as partial derivatives of the cross sections σ at the energy E_i with respect to the parameter p_j ,

$$s_{i,j} = \frac{\partial\sigma(E_i, \mathbf{p})}{\partial p_j}. \quad (49)$$

In case of covariance determination, the initial values of the parameters, \mathbf{p}_0 , are already optimized, that is, when used in the model calculations they provide the evaluated cross sections.

Their covariance matrix \mathbf{P}_0 is assumed to be diagonal while the uncertainties of the parameters are estimated using systematics, independent measurements, or educated guesses. The model-based covariance matrix (prior) for the cross sections, \mathbf{C}_0 , can be obtained through a simple error propagation formula,

$$\mathbf{C}_0 = \mathbf{S}\mathbf{P}_0\mathbf{S}^T, \quad (50)$$

where superscript T indicates a transposed matrix.

The experimental data, if available, are included through a sequential update of the parameter vector \mathbf{p} and the related covariance matrix \mathbf{P} as

$$\mathbf{p}_{n+1} = \mathbf{p}_n + \mathbf{P}_n\mathbf{S}^T\mathbf{Q}_{n+1}(\sigma_{n+1}^{\text{exp}} - \sigma(\mathbf{p}_n)), \quad (51)$$

$$\mathbf{P}_{n+1} = \mathbf{P}_n - \mathbf{P}_n\mathbf{S}^T\mathbf{Q}_{n+1}\mathbf{S}\mathbf{P}_n.$$

Here,

$$\mathbf{Q}_{n+1} = (\mathbf{C}_n + \mathbf{C}_{n+1}^{\text{exp}})^{-1}, \quad (52)$$

where $n = 0, 1, 2, \dots$ and $n + 1$ denotes update related to the sequential inclusion of the $(n + 1)$ th experimental data set. In particular, the subscript 1 $\equiv 0 + 1$ denotes updating model prior ($n = 0$) with the first experiment. Vector \mathbf{p}_{n+1} contains the improved values of the parameters starting from the vector \mathbf{p}_n , and \mathbf{P}_{n+1} is the updated covariance matrix of the parameters \mathbf{p}_{n+1} . The $\mathbf{C}_{n+1}^{\text{exp}}$ is the cross-section covariance matrix for the $(n + 1)$ th experiment. The updated (posterior) covariance matrix for the cross sections is obtained by replacing \mathbf{P}_0 with \mathbf{P}_{n+1} in (50),

$$\mathbf{C}_{n+1} = \mathbf{S}\mathbf{P}_{n+1}\mathbf{S}^T. \quad (53)$$

The updating procedure described above is often called Bayesian, although (50)–(53) can be derived without any reference to the Bayes theorem as shown in Muir (1989).

The experimental covariance matrix, $\mathbf{C}_n^{\text{exp}}$, is usually non-diagonal, due to the correlations among various energy points E_i . Assuming that systematic experimental uncertainties are fully correlated, the matrix elements are expressed through the statistical, $\Delta^{\text{sta}}\sigma_n^{\text{exp}}$, and systematic, $\Delta^{\text{sys}}\sigma_n^{\text{exp}}$, experimental uncertainties. This yields

$$c_n^{\text{exp}}(i, i) = (\Delta^{\text{sta}}\sigma_n^{\text{exp}}(E_i))^2 + (\Delta^{\text{sta}}\sigma_n^{\text{exp}}(E_i))^2 \quad (54)$$

and, for $i \neq k$,

$$c_n^{\text{exp}}(i, k) = \Delta^{\text{sys}}\sigma_n^{\text{exp}}(E_i) \times \Delta^{\text{sys}}\sigma_n^{\text{exp}}(E_k). \quad (55)$$

The quality and consistency of the evaluated cross sections can be assessed by scalar quantity

$$\chi^2 = \sum_{n=1}^N (\sigma_n^{\text{exp}} - \sigma(\mathbf{p}_N))^T (\mathbf{C}_n^{\text{exp}})^{-1} (\sigma_n^{\text{exp}} - \sigma(\mathbf{p}_N)), \quad (56)$$

where \mathbf{p}_N is the final set of model parameters corresponding to the inclusion of N experiments. A value of χ^2 per degree of freedom exceeding unity indicates underestimation of the evaluated uncertainties. It is a fairly common practice to multiply such uncertainties by a square root of χ^2 per degree of freedom to address this issue.

4.2 Sample Case: Gd

Covariance evaluation of Gd isotopes was produced as a sample case for ENDF/B-VII.0. There are seven stable Gd isotopes, $^{152,154,155,156,157,158,160}\text{Gd}$ and the radioactive ^{153}Gd . All covariances were produced by SAMMY retroactive method in the resolved resonance region and EMPIRE-KALMAN at higher energies.

► *Figure 34* shows uncertainties for ^{155}Gd capture cross sections at low energies. The thermal cross section and its uncertainty in the *Atlas of Neutron Resonances* (Mughabghab, 2006) are very well reproduced. The particular feature that ^{155}Gd shares with ^{157}Gd is a very close vicinity of the first positive resonance to the thermal energy. Therefore, the thermal cross section is determined by the first resonance rather than $1/v$ dependence typical for other nuclei.

► *Figure 34* also demonstrates anti-correlation between uncertainties and cross sections in the resonance region. The highest uncertainties are being found between the resonances, that is, at dips of cross sections. This feature is clearly visible although it is, to some extent, obscured by the groupwise representation that lumps close resonances together.

■ **Figure 34**

Relative uncertainties for $^{155}\text{Gd}(n, \gamma)$ obtained with the retroactive SAMMY method plotted along with the cross sections to show anti-correlation between the two quantities. The experimental cross section (60,900 b) and its uncertainty (0.82%) at the thermal energy (Mughabghab, 2006) are well reproduced

Figure 35

Relative uncertainties in the unresolved resonance and fast neutron range for the total, elastic and capture cross sections on ^{157}Gd obtained with the EMPIRE-KALMAN method

The covariances for the unresolved resonance and fast neutron regions were produced with the EMPIRE-KALMAN method. In [Fig. 35](#) we show relative uncertainties for $^{157}\text{Gd}(n,\text{tot})$, $^{157}\text{Gd}(n,\text{elastic})$, and $^{157}\text{Gd}(n,\gamma)$ cross sections for incident neutron energies above 1 keV. [Figure 36](#) shows the correlation matrix for the $^{157}\text{Gd}(n,\gamma)$ cross section. This matrix reveals complicated structures with strong correlations aligned within a relatively narrow band along the diagonal.

4.3 Major Actinides

Covariances for major actinides play a crucial role in many applications. There was insufficient time to complete new covariance evaluations for these important actinides prior to the release of the ENDF/B-VII.0 library in 2006. This work was completed in 2008, but it has not yet been officially approved by Cross Section Evaluation Working Group (CSEWG) (status at the end of 2009).

One of the issues that has been resolved was conversion of huge multimillion line long resonance parameter covariance matrices (MF32 files) into cross-section covariances (MF33 files). Such a conversion reduced the size of the files considerably, though the ^{235}U and ^{239}Pu covariance files still remain very large (about 50 and 30 MB, respectively).

Figure 36

Correlation matrix for the $^{157}\text{Gd}(n,\gamma)$ neutron capture cross sections in the fast neutron region obtained with the EMPIRE-KALMAN method

4.3.1 $^{233,235,238}\text{U}$ Covariances

The evaluation of $^{233,235,238}\text{U}$ covariances was performed by ORNL-LANL collaboration. ORNL covered the resonance region and LANL supplied covariances in the fast neutron region.

Due to the huge size of the resonance parameter covariances (MF32), the files were converted into cross-section covariances (MF33). Still, the size of the largest ^{235}U file is considerable, in excess of 52 MB.

The preliminary version of these evaluations are available in the recently reestablished ENDF/A library, which contains candidate evaluations for the next release of ENDF/B-VII library. It is expected that all these files will be included into ENDF/B-VII.1 release. As an example of these evaluations, $^{235}\text{U}(n, f)$ covariances are shown in [Fig. 37](#), see also discussion later in this chapter under the advanced fuel cycle initiative (AFCI) covariance library.

4.3.2 ^{239}Pu Covariances

The evaluation of ^{239}Pu covariances was also performed by ORNL-LANL collaboration. ORNL covered the resonance region and LANL supplied covariances in the fast neutron region.

The file was also converted into cross-section covariances (MF33), its reduced size is 32 MB. The preliminary version of this evaluation is available in the ENDF/A library and it is expected that the file will be included into ENDF/B-VII.1 release.

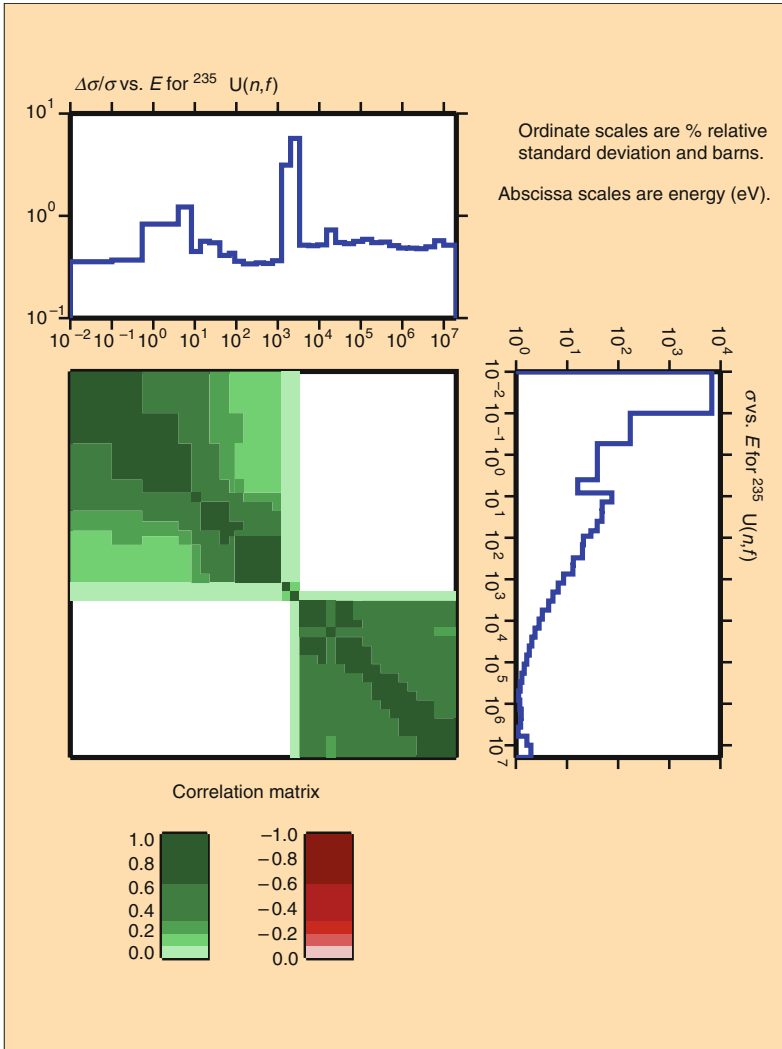

Figure 37

Covariances for $^{235}\text{U}(n, f)$ taken from ENDF/A (November 2009), which collects candidate evaluations for the next release of ENDF/B-VII. Data are given in 33-energy group representation adopted by the advanced fuel cycle initiative (AFCI) covariance library: *top* – cross-section uncertainties, *right* – cross sections, *middle* – energy–energy correlations

4.3.3 ^{232}Th Covariances

The covariance evaluation for ^{232}Th includes the resolved resonance, unresolved resonance, and the fast neutron regions as well as $\bar{\nu}$. In the resolved resonance region, a Reich–Moore evaluation was performed (Derrien et al., 2006) in the energy range up to 4 keV using the code

■ Figure 38

Correlation matrix for ^{232}Th neutron radiative capture cross sections in the thermal and resolved resonance region

SAMMY. The correlation matrix for the radiative capture cross section is shown in [Fig. 38](#). In the URR, the experimental method was used (Sirakov et al. 2006, ^{232}Th : evaluation of the average resonance parameters and their covariances in the URR from 4 to 100 keV, private communication).

Cross-section covariance data in the fast neutron region were generated by the Monte Carlo technique (Smith, 2004) using the EMPIRE code. In the Monte Carlo approach, a large collection of nuclear parameter sets (normally more than 1,000) is generated by randomly varying these parameters with respect to chosen central values. These parameter sets are then used to calculate a corresponding large collection of nuclear model derived values for selected physical quantities, such as cross sections and angular distributions. These results are subjected to a statistical analysis to generate covariance information. The GANDR code system (Trkov, 2005) updates these nuclear model covariance results by merging them with the uncertainty information for available experimental data using the generalized least-squares technique.

Covariances for $\bar{\nu}$ were obtained from the unpublished evaluation performed by Ignatyuk (Obninsk) for the Russian library BROND-3 (this library has not been released yet). This evaluation was based on the analysis of experimental data.

4.4 Covariance Libraries

Despite the fact that only a limited amount of covariance evaluations have been produced to date (end of 2009), three covariance libraries were created in the USA as briefly described below. It should be understood that each of these libraries represents an approximate solution and has, therefore, inherent limitation. This stems from the fact that the development of quality covariances is a formidable task that requires considerable resources. This challenge should

be addressed by future releases of major evaluated libraries. Accordingly, it is expected that covariances will be part of the next release of the ENDF/B-VII library.

4.4.1 Low-Fidelity Covariance Library

The development of this library was funded by the US Nuclear Criticality Safety Program. The library provides the first complete, yet simple, estimate of neutron covariances for 387 materials listed in ENDF/B-VII.0; for details see Little et al. (2008). Covariances cover main reaction channels, elastic scattering, inelastic scattering, radiative capture, and fission (cross sections and nubar) over the energy range from 10^{-5} eV to 20 MeV. Various approximations were utilized depending on the mass of the target, the neutron energy range, and the neutron reaction. The resulting covariances are not an official part of ENDF/B-VII.0, but they are available for testing in nuclear applications.

In general, at low energies simple estimates were made following the approach proposed by Williams (2004). In the thermal region, defined by the cutoff energy 0.5 eV, experimental uncertainties of thermal cross sections were uniformly adopted. In the epithermal region, from 0.5 eV to 5 keV, the uncertainties of resonance integrals were used and uniformly applied. This led to simple and often reasonable estimates of cross section uncertainties. An example is shown in [Fig. 39](#).

In the fast neutron region, the model-based estimates of covariances were produced for 307 materials from ^{19}F to ^{209}Bi (Pigni et al., 2009). To this end, EMPIRE code was employed

Figure 39

Low-fidelity uncertainties for $^{232}\text{Th}(n, \gamma)$ cross sections, labeled as integral quantities, are compared with ENDF/B-VII.0 values

■ **Table 7**

Sources of covariance data in the SCALE-6 covariance library

Source	Material
ENDF/B-VII.0	$^{152,158,160}\text{Gd}$, ^{232}Th , ^{99}Tc , $^{191,193}\text{Ir}$

Low-fidelity	About 200 materials, mostly fission products and minor actinides

and parametrization from the latest version of the RIPL library (Capote et al., 2009) was adopted along with global estimates of related model parameters. Parameter uncertainties were propagated into cross-section uncertainties.

Light nuclei, $A < 19$, were treated differently. Recent R-matrix evaluations were adopted for three materials; for the remaining materials, simple estimates were supplied by looking into experimental data in the entire energy region.

Actinides in the fast neutron region were again treated differently. Latest full scale evaluations by ORNL-LANL were used for major actinides, while simple model-based estimates using EMPIRE were used for minor actinides.

4.4.2 SCALE-6 Covariance Library

This is the covariance library included in the well-known ORNL reactor licensing code SCALE (2000). The library was produced by selecting covariances from a variety of sources as summarized in [▶ Table 7](#) (Williams and Rearden, 2008).

It should be noted that inherent limitation of selecting covariances from various sources is inconsistency with basic cross sections, which may or may not be negligible.

4.4.3 AFCI Covariance Library

This library was developed for AFCI funded by the US DOE Nuclear Energy. It should be suitable for nuclear data adjustment needed for fast reactor applications, such as advanced burner reactor (ABR). The list of materials contains 110 materials, including

- Twelve light nuclei
- Seventy-eight structural materials and fission products
- Twenty actinides

Covariances are produced by BNL-LANL collaboration (Obložinský et al., 2009a). Major reaction channels are covered and covariance data are supplied in 33-energy group representation.

It is important to note that these covariances are tested by highly experienced reactor users in Argonne and Idaho National Laboratory.

It is expected that a fairly robust version of the AFCI covariance library will be available by the end of 2010. Then, it should serve as the basis for producing ENDF-6 formatted files suitable for inclusion into the next release of ENDF/B-VII. We note that whenever possible, AFCI library adopts new covariance evaluations produced for ENDF/B-VII. As an example, we refer the reader to [► Fig. 37](#) where we have shown covariances for $^{235}\text{U}(n, f)$ in AFCI 33-energy group representation.

5 Validation of Neutron Data

Integral data testing of evaluated cross sections plays an essential role for validation purposes. The importance is twofold: First, since many of the integral experiments are very well understood (especially the critical assembly experiments), they provide a strong test of the accuracy of the underlying nuclear data used to model the assemblies, and can point to deficiencies that need to be resolved. Second, such integral data testing can be viewed as a form of “acceptance testing” prior to these data being used in various applications. Many applications, ranging from reactor technologies to defense applications, have a high standard required of a nuclear database before it is adopted for use. Critical assemblies, while involving many different nuclear reaction processes, can still be thought of as “single-effect” phenomena that probe the neutronics and nuclear data (but not other phenomena), and therefore an important acceptance test is that a sophisticated radiation transport simulation of the assembly should reproduce the measured k_{eff} to a high degree.

Of necessity, the testing of an evaluated data library must be performed after the evaluation process. Ideally though, this testing is not performed as an afterthought, but more as an integral part of the evaluation process. It has been demonstrated many times that a close link between the data evaluators and the data users can provide valuable feedback to the evaluation process – quantifying the sensitivity of performance parameters to specific changes in nuclear data.

We note that ENDF/B-VII.0 benchmarking was largely facilitated by the fact that for the first time benchmark model descriptions were available from the International Criticality Safety Benchmark Evaluation Project (ICSBEP) handbook. This criticality safety handbook contains benchmark descriptions of almost 4,000 critical assembly configurations (compared to the tens of benchmark descriptions contained in the ENDF-202 Benchmark Specifications used previously). Furthermore, this rich collection of benchmark descriptions spans the range of fuel types, compositions, spectra, geometries, etc. However, an additional feature of these benchmarks is the evaluation of the benchmark uncertainties, that is, estimates of the total experimental uncertainties combined with any additional modeling uncertainties (Briggs et al., 2004). As a result, the most diverse and robust aspect of the ENDF/B-VII.0 validation effort was the analysis of hundreds of criticality configurations compared with their benchmark eigenvalues and uncertainties.

5.1 Criticality Testing

In reference to ENDF/B-VII.0, C/E values for k_{eff} (for the sake of clarity we use the term “C/E value for k_{eff} ” rather than the term “normalized eigenvalue;” here, C/E stands for the ratio of

■ Table 8

The number of benchmarks per main International Criticality Safety Benchmark Evaluation Project (ICSBEP) category for compound, metal, and solution systems with thermal, intermediate, fast, and mixed neutron spectrum used in ENDF/B-VII.0 validation (van der Marck, 2006)

	COMP				MET				SOL	
	Ther	Inter	Fast	Mix	Ther	Inter	Fast	Mix	ther	Total
Low-enriched U	257				1				49	307
Intermediate-enriched U	6	4					16			26
High-enriched U		6		1	41	5	66	5	87	211
Mixed	34		1				4		10	49
Low-energy Pu		1				1	7	6	105	120
²³³ U	8						4		5	17
Total	305	11	1	1	42	6	97	11	256	730

calculated to experimental values, and k_{eff} means the effective multiplication factor defined as the ratio of the average number of neutrons produced to the average number of neutrons absorbed per unit time) have been calculated for hundreds of critical benchmarks using continuous energy Monte Carlo programs including MCNP (versions 4c3 or 5), RCP01, RACER, and VIM. These calculations generally use benchmark models derived from the ICSBEP Handbook. Benchmark evaluations in this handbook are revised and extended on an annual basis. Unless otherwise noted, benchmark models derived from the 2004 or 2005 editions of the handbook were used in the calculations described below.

Since the C/E values for k_{eff} have all been obtained using continuous energy Monte Carlo calculations there is a stochastic uncertainty associated with each C/E value for k_{eff} . The magnitude of this uncertainty is very small, typically less than 25 pcm (0.025%, pcm is derived from Italian “per cento mille,” meaning per hundred thousands; it is a unit of reactivity, where 1 pcm = 0.00001 $\Delta k/k$, i.e., 100 pcm is a 0.1% discrepancy).

A paper by van der Marck (2006) presents independent European data testing of ENDF/B-VII.0, using MCNP4c3 with data processed by NJOY, and also shows extensive neutron transmission benchmark comparisons. ▶ Table 8 provides a summary of 730 benchmark criticality experiments that were simulated and compared with measurements.

▶ Table 9 summarizes the average value of C/E-1 (the average deviation of Calculation/Experiment from unity) for these benchmarks. We show for comparison in *italics* the values for the previous ENDF/B-VI.8. While it is important to study the individual benchmark results for a more thorough understanding, it is still very useful to observe the overall averaged behavior shown in ▶ Table 9:

- The low-enriched U (LEU) compound benchmarks are modeled much more accurately (owing to improved ²³⁸U, as well as ¹⁶O and ¹H).
- The intermediate-enriched U (IEU) benchmarks are modeled more accurately.
- The Pu and HEU fast benchmarks are modeled more accurately.

■ Table 9

The average value of C/E –1 in pcm (100 pcm = 0.1%) for ENDF/B-VII.0 per main ICSBEP benchmark category

	COMP				MET				SOL
	Ther	Inter	Fast	Mix	Ther	Inter	Fast	Mix	ther
LEU	17				–41				123
	–452				–270				<i>107</i>
IEU	103	219					182		
	–299	–238					712		
HEU		1,744		104	–51	88	147	812	108
		1,442		–273	–411	–42	186	462	142
MIX	428		110				193		–254
	377		978				69		–257
PU		1,110				4,565	229	936	620
		967				4,654	375	745	531
²³³ U	146						–364 ^a		66
	–380						–338		–292

^aThis becomes –64 pcm versus –254 pcm if we restrict ourselves to the well-understood UMF-001 and UMF-006 assemblies Shown in *italics* are the values for the ENDF/B-VI.8 library

- The ²³³U thermal benchmarks are modeled more accurately. Although the ²³³U fast benchmarks simulations appear to have become worse, this is perhaps more due to deficiencies in modeling of beryllium for two of the assemblies studied – for bare ²³³U (Jezebel-23 and Flattop-23) the new ENDF/B-VII.0 are clearly much better.
- Lower energy Pu (PU) benchmarks were modeled poorly in ENDF/B-VI.8 and continue to be modeled poorly in the new library.

5.2 Fast U and Pu Benchmarks

Fast U and Pu benchmarks were given considerable attention in the validation of the ENDF/B-VII.0 library. Shown below are selected examples for several benchmark categories.

Bare, and ²³⁸U reflected, assemblies: A large number of well-known Los Alamos fast benchmark experiments have been incorporated into the ICSBEP Handbook and are routinely calculated to test new cross-section data. Unmoderated enriched ²³⁵U benchmarks include Godiva (HEU-MET-FAST-001 or HMF1) (“HEU-MET-FAST-001” is the identifier assigned in the ICSBEP Handbook for this assembly. It is comprised of four parts which, respectively, classify the assembly by fissile materials (PU, HEU, LEU), fuel form (METal, SOLution, COMpound), and energy-spectrum (FAST, INTERmediate, THERMal, or MIXED) and benchmark

Figure 40

Los Alamos National Laboratory (LANL) highly enriched uranium (HEU), Pu and ^{233}U unmoderated benchmark C/E values for k_{eff} calculated with ENDF/B-VI.8 and ENDF/B-VII.0 cross-section data

number (-NNN). It is also common to use a shorthand form for this identifier, such as HMF1 for HEU-MET-FAST-001), Flattop-25, and Big-10 assemblies.

Results of MCNP5 k_{eff} calculations with ENDF/B-VI.8 and ENDF/B-VII.0 cross sections for this suite of benchmarks are displayed in [Fig. 40](#). The improved accuracy in calculated k_{eff} for these systems with the new ENDF/B-VII.0 cross sections is readily apparent.

Assemblies with various reflectors: A number of additional HEU benchmarks, either bare or with one of a variety of reflector materials including water, polyethylene, aluminum, steel, lead, and uranium have also been calculated with MCNP5 and both ENDF/B-VI.8 and ENDF/B-VII.0 cross sections. The calculated values for k_{eff} are illustrated in [Fig. 41](#). Once again, significant improvement in the calculated k_{eff} is observed with the ENDF/B-VII.0 cross sections.

Pb-reflected assemblies: Two reflector elements of particular historical interest are lead and beryllium. Often there are multiple evaluations that contain similar materials, in particular the same core with differing reflectors, thereby facilitating testing of cross-section data for individual reflector materials. Such is the situation for lead, displayed in [Fig. 42](#), with calculated k_{eff} for a variety of benchmarks.

The significant improvements in these lead-reflected calculated k_{eff} reflects improvements made in the new ENDF/B-VII.0 ^{208}Pb evaluation, which was based on modern calculational methods together with careful attention to accurately predicting cross-section measurements, and by adopting the JEFF-3.1 evaluations for $^{204,206,207}\text{Pb}$, which (together with the JEFF-3.1 file for ^{208}Pb) have reduced this bias by a similar amount in JEFF-3.1 benchmarking.

The situation is not so clear for thermally moderated systems (LCT) as shown in [Fig. 42](#). This figure also shows the k_{eff} calculations for the HMF57 benchmark, which consists of either a spherical or cylindrical HEU core with a lead reflector. In any event, the C/E values for k_{eff} are significantly different from unity in most cases regardless of cross-section data set.

Bare and lead-reflected C/E values for k_{eff} calculated with ENDF/B-VI.8 and ENDF/B-VII.0 cross-section data for several HMF, PMF, and LCT benchmarks

Figure 43

HEU-MET-FAST-058 benchmark C/E values for k_{eff} with ENDF/B-VI.8 and ENDF/B-VII.0 cross-section data as a function of the beryllium reflector thickness

Be-reflected assemblies: C/E values for k_{eff} of beryllium-reflected benchmarks are shown in ► Figs. 43 and ► 44. These comparisons are useful to assess the changes made in the ^9Be cross sections for ENDF/B-VII.0.

Zero power reactor assemblies: The k_{eff} calculations by the code VIM for a suite of 26 Argonne zero power reactor (ZPR) or zero power physics reactor (ZPPR) benchmarks are presented in ► Fig. 45. These benchmarks come from various areas of the ICSBEP Handbook. These benchmarks exhibit large variation in calculated k_{eff} , with the smallest k_{eff} being biased several tenths of a percent below unity while the maximum positive C/E k_{eff} bias is in excess of 3%. Calculated k_{eff} with ENDF/B-VII.0 cross sections are generally an improvement over those obtained with ENDF/B-VI.8, but significant deviations from unity remain.

5.3 Thermal U and Pu Benchmarks

Thermal benchmarks are of considerable interest to reactor applications. Shown below are selected examples for ^{235}U solution benchmarks, fuel rod U benchmarks, and Pu solution, as well as MOX benchmarks.

5.3.1 ^{235}U Solution Benchmarks

Thermal, highly enriched ^{235}U homogeneous solution benchmarks were used to test the accuracy of low energy ENDF/B cross-section data sets for many years. The new ENDF/B-VII.0 library, like the old ENDF/B-VI.8 library, performs well for these assemblies. C/E values for k_{eff} have been calculated for a suite of critical assemblies from 14 HEU-SOL-THERM (HST)

■ Figure 44

HEU-MET-FAST-066 benchmark C/E values for k_{eff} for ENDF/B-VI.8 and ENDF/B-VII.0 cross-section data as a function of the beryllium reflector thickness. The poorer agreement using ENDF/B-VII.0 appears to be in contradiction to the results shown in [Fig. 43](#)

■ Figure 45

C/E values for k_{eff} for 26 zero power reactor (ZPR) and zero power physics reactor (ZPPR) benchmarks from Argonne. The ENDF/B-VII results are for the beta2 version, but one does not expect significant changes for ENDF/B-VII.0

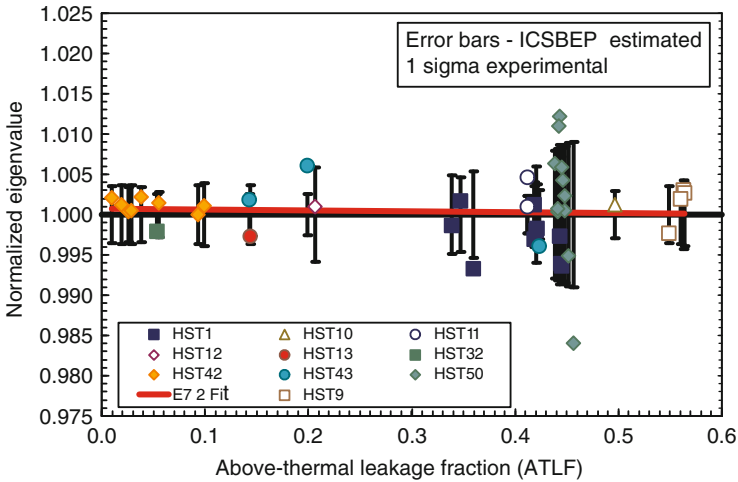

Figure 46

HEU-SOL-THERM (HST) benchmark C/E values for k_{eff} with ENDF/B-VII.0 cross sections

or LEU-SOL-THERM (LST) benchmark evaluations. These benchmarks have most commonly been correlated versus above-thermal leakage fraction (ATLF), for example, $k_{\text{calc}}(\text{ATLF}) = b_0 + b_1 \cdot \text{ATLF}$, where ATLF is the net leakage out of the solution of neutrons whose energies exceed 0.625 eV. Smaller systems with large ATLF test the higher energy cross sections, the ^{235}U fission spectrum, elastic scattering angular distributions, and, for reflected systems, the slowing down and reflection of above-thermal neutrons back into the fissile solution.

An important goal in developing the new ENDF/B-VII.0 library was to improve the data files while at the same time retain the good performance seen with ENDF/B-VI.8 (in the homogeneous solution benchmark category). As shown in Fig. 46, this goal has been attained. This result is nontrivial, since we have made changes in the ENDF/B-VII.0 library for ^{16}O (the n, α cross section was significantly reduced) and for hydrogen (a new standard cross section, as well as an updated scattering kernel).

5.3.2 U Fuel Rod Benchmarks

The ^{238}U cross-section data in ENDF/B-VII.0 have led to major improvements in the ability to accurately calculate thermal LEU benchmark C/E values for k_{eff} . Calculated C/E for k_{eff} for arrays of low-enriched UO_2 fuel rods have historically been biased with previous data libraries including ENDF/B-VI.8, frequently falling 500–1,000 pcm below unity. These C/E values have also varied systematically when correlated against parameters such as rod pitch, average fission energy, unit cell H/U ratio, or ^{238}U absorption fraction. Some of these characteristics are illustrated in Figs. 47 and 48, which illustrate calculated k_{eff} obtained with MCNP5 and either ENDF/B-VI.8 and/or ENDF/B-VII.0 cross sections.

Results using the new ENDF/B-VII.0 cross sections are significantly more accurate as shown in Fig. 48, which illustrates calculated k_{eff} for the LCT7 benchmark with both ENDF/B-VI.8

■ Figure 47

LEU-COMP-THERM benchmark C/E values for k_{eff} with the old ENDF/B-VI.8 cross sections

■ Figure 48

LEU-COMP-THERM-007 benchmark C/E values for k_{eff} for the ENDF/B-VI.8 and ENDF/B-VII.0 cross sections

and ENDF/B-VII.0 cross sections. The ENDF/B-VI.8 C/E for k_{eff} trend and bias have both been eliminated with the ENDF/B-VII.0 cross-section data set.

A summary of all water moderator and reflected LCT k_{eff} reveals that previously identified deficiencies have been largely eliminated. A total of 58 LEU-COMP-THERM benchmarks have

been calculated with the ENDF/B-VII.0 cross-section data set. The average calculated k_{eff} is 1.0000 with a population standard deviation of 0.0025. This standard deviation represents a significant decrease over that obtained with ENDF/B-VI.8 cross sections and is further evidence for the reduction or elimination in C/E k_{eff} trends, such as versus H/U ratio (► Fig. 48), with the ENDF/B-VII.0 cross sections.

The ENDF/B-VII.0 cross section changes that are responsible for the improved C/E k_{eff} are due primarily to (1) ORNL and CEA ^{238}U revisions in the resonance range for ^{238}U , and (2) the new Los Alamos analysis of ^{238}U inelastic scattering in the fast region. The contribution to the increased calculated criticality of these two revisions are of about the same magnitude. Two additional cross section changes also contributed to increase the calculated k_{eff} of these assemblies: the reduced $^{16}\text{O}(n, \alpha)$ cross section, and a revised scattering kernel for hydrogen bound in water.

5.3.3 Pu Solution and MOX Benchmarks

While excellent calculated k_{eff} results continue to be obtained for thermal uranium solution critical assemblies, the same cannot be said for plutonium solution (PU-SOL-THERM, or PST) assemblies. MCNP5 C/E values for k_{eff} , calculated with ENDF/B-VII.0 cross sections are plotted versus ATLF and versus H/Pu ratio in ► Figs. 49 and ► 50, respectively. There are obvious variations in these C/E values for k_{eff} when plotted versus ATLF or H/Pu ratio, but it is not obvious what changes in the plutonium cross-section evaluation that could also be supported by the underlying microscopic experimental cross-section data would mitigate these trends.

The results for a MOX benchmark, six critical configurations from MIX-COMP-THERM-002, show less variation than the solutions, possibly because there are fewer of them. The fuel pins contain 2 wt.% MOX, and the plutonium contains 8% ^{240}Pu . The benchmarks include a

► Figure 49
PU-SOL-THERM (PST) benchmark C/E values for k_{eff} with ENDF/B-VII.0 cross sections as a function of the above-thermal leakage fraction (ATLF)

■ Figure 50

PST benchmark C/E values for k_{eff} with ENDF/B-VII.0 cross sections as a function of the H/Pu ratio

highly (several hundred ppm) borated case and a slightly (a few ppm) borated case for each of the three lattice pitches. The highly borated cases contain many more fuel pins than the slightly borated cases and exhibit a small positive bias, but all three fall within a band of about a quarter of a percent in reactivity.

5.4 Conclusions from Criticality Testing

Hundreds of criticality benchmarks from the ICSBEP Handbook have been calculated to test the accuracy of the ENDF/B-VII.0 cross-section library. Significant improvement in C/E values for k_{eff} has been observed in many cases, including bare and reflected fast uranium and plutonium systems and in particular for arrays of low-enriched fuel rod lattices. The C/E values for k_{eff} for bare HEU and Pu assemblies are larger compared to those obtained with ENDF/B-VI.8 data, and now agree very well with the measurements. The reflector bias for the ^{238}U reflected Flattop assemblies has been largely eliminated.

Furthermore, major improvements have been obtained in the calculations for intermediate energy assemblies such as Big-10 and, to a lesser extent, the Argonne ZPR assemblies. Homogeneous uranium solution systems have been calculated accurately with the last several versions of ENDF/B-VI cross sections, and these accurate results are retained with the ENDF/B-VII.0 cross-section library. Many fast-reflected systems are more accurately calculated with the ENDF/B-VII.0 cross-section library, but disturbing discrepancies remain, particularly in lead- and beryllium-reflected systems (although certain reflector-bias improvements were obtained using the new data for these isotopes).

A significant accomplishment has been excellent C/E for k_{eff} for the LCT assemblies, where the historical underprediction of criticality has been removed. This advance has come from improved ^{238}U evaluation (both in the resonance region and in the fast region), together with

revisions to the $^{16}\text{O}(n, \alpha)$ cross section and the hydrogen bound in water scattering kernel. Plutonium solution systems are not calculated as well as uranium solutions, with C/E values for k_{eff} typically being several tenths of a percent greater than unity. There is a 1.5% spread in these C/E values for k_{eff} , but there does not appear to be a trend as a function of ^{239}Pu abundance. Although advances have been made at Los Alamos to the ^{239}Pu cross sections in the fast region, there has been no recent work on ^{239}Pu at lower energies. Clearly such efforts are needed in the future. The performance of the new ENDF/B-VII.0 evaluations for ^{233}U and ^{232}Th is much improved in both fast and thermal critical assemblies; an analysis of the Np-U composite fast benchmark suggests important improvements have been made in ^{237}Np fission cross-section evaluation.

5.5 Delayed Neutron Testing, β_{eff}

Delayed neutron data can be tested against measurements of the effective delayed neutron fraction β_{eff} in critical configurations. Unlike the situation for k_{eff} , only a handful of measurements of β_{eff} have been reported in the open literature with sufficiently detailed information. In van der Marck (2006), more than twenty measurements are listed, including two thermal spectrum cores and five fast spectrum cores:

TCA: A light water-moderated low-enriched UO_2 core in the Tank-type Critical Assembly (Nakajima, 2001).

IPEN/MB-01: A core consisting of 28×26 UO_2 (4.3% enriched) fuel rods inside a light water-filled tank (dos Santos et al., 2004).

Masurca: Measurements of β_{eff} by several international groups in two unmoderated cores in Masurca (R2 had ~30% enriched uranium, ZONA2 had both plutonium and depleted uranium), surrounded by a 50–50% UO_2 -Na mixture blanket and by steel shielding (Okajima et al., 2002).

FCA: Measurements of β_{eff} in three unmoderated cores in the Fast Critical Assembly (HEU; plutonium and natural uranium; plutonium), surrounded by two blanket regions, one with depleted uranium oxide and sodium, the other with only depleted uranium metal (Okajima et al., 2002).

The calculation of β_{eff} for these systems was done using a version of MCNP-4C3 with an extra option added to it as described in Klein Meulekamp and van der Marck (2006). This method was used earlier to test delayed neutron data from JEFF-3.1 and JENDL-3.3 (van der Marck et al., 2004). The results based on ENDF/B-VII.0 are given in [Table 10](#), as well as the results based on those other libraries. One can see that the calculated β_{eff} now agrees better with experiment as compared to the old ENDF/B-VI.8 (specially for the more thermal systems).

5.6 Reaction Rates in Critical Assemblies

Many different critical assemblies have been developed over the years: Godiva is a bare sphere of HEU; Jezebel is a bare sphere of plutonium; Jezebel 23 is a bare sphere of ^{233}U . The Flattop experiments involved spherical cores of HEU or plutonium surrounded by ^{238}U reflector material to make the composite systems critical. These different systems all produce neutron spectra within them that are “fast,” that is, the neutrons are predominantly of energies in the 100 keV to

■ Table 10

C/E values for β_{eff} of several critical systems, using ENDF/B-VII.0 and other libraries

System	C/E β_{eff}			
	ENDF/B-VII.0	ENDF/B-VI.8	JEFF-3.1	JENDL-3.3
TCA	0.998 ± 0.002	1.053 ± 0.011	1.029 ± 0.002	0.987 ± 0.012
IPEN/MB-01	1.008 ± 0.005	1.054 ± 0.005	1.040 ± 0.005	1.019 ± 0.005
Masurca R2	1.012 ± 0.009	1.035 ± 0.009	1.011 ± 0.009	1.018 ± 0.010
Masurca ZONA2	0.973 ± 0.013	0.983 ± 0.015	1.021 ± 0.013	0.994 ± 0.014
FCA XIX-1	0.987 ± 0.010	1.005 ± 0.011	1.010 ± 0.010	0.985 ± 0.011
FCA XIX-2	1.010 ± 0.013	1.003 ± 0.014	1.054 ± 0.013	1.022 ± 0.013
FCA XIX-3	0.981 ± 0.017	1.016 ± 0.016	0.997 ± 0.016	0.996 ± 0.016

The uncertainties in the C/E values are statistical uncertainties from the calculations only

■ Figure 51

The integral ^{241}Am neutron capture rate (divided by the ^{239}Pu fission rate) as a function of spectral index for different critical assembly locations. In this case, the measurements, which detect the ^{242}Cm , are divided by 0.84 to account for the fraction of ^{242g}Am that beta decays to ^{242}Cm

few MeV region, but the exact spectra vary from system to system. The neutron spectrum gets softer as one moves out from the center of the assembly, thereby giving additional information about the quality of the cross-section data in different energy regimes.

Neutron capture of ^{241}Am is shown in  Fig. 51 for different critical assembly spectra. We see good agreement between the calculations and the measurements, except that for the

hardest-spectrum system (Jezebel) the measurement appears to be underpredicted by up to 6%. This tells us that the ^{241}Am capture cross section to the ground state may be too low in the current evaluation in the $\approx 0.5\text{--}1$ MeV region.

5.7 Shielding and Pulsed-Sphere Testing

In a paper (van der Marck, 2006), Steven van der Marck presents extensive data testing results for neutron transmission (shielding) benchmarks. We show some illustrative examples from that paper, focusing on validation benchmarks that test 14 MeV evaluations that have changed between ENDF/B-VI.8 and ENDF/B-VII.0 (e.g., $^{235,238}\text{U}$, ^{239}Pu , Pb, Li, and Be). These comparisons test the accuracy of the secondary emission spectra of neutrons following nuclear reactions.

► [Figure 52](#) shows an example from the above paper for the fusion neutronics source (FNS) benchmark corresponding to 14 MeV neutrons transmitted through 20 cm lead at an angle of 42.8° . The agreement between simulation and the FNS data is seen to be good, it shows an improvement on the earlier ENDF/B-VI.8 data and provides support for the accuracy of the new ^{208}Pb evaluation.

Numerous high-energy pulsed-sphere experiments (Wong et al., 1972; Webster et al., 1976) have been performed in which small, medium, and large spheres of 32 different materials were pulsed with a burst of high-energy (14 MeV) neutrons at LLNL's insulated core transformer (ICT) accelerator facility. Measured time-dependent neutron fluxes at collimated detectors located at a distance of 7–10 m provide a benchmark by which various neutron transport codes and cross-section libraries may be evaluated.

The results can be seen in ► [Fig. 53](#). The peak on the left-hand side corresponds to the transmission of the 14 MeV source neutrons; the broad peak further right (lower energies) corresponds to the neutrons created through compound nucleus and fission mechanisms.

■ **Figure 52**

Simulation of 14 MeV neutron transmission through 20 cm Pb at 42.8° (van der Marck, 2006)

■ Figure 53

Comparison of the simulated results using ENDF/B-VI.6 and ENDF/B-VII.0 data for the 0.7 mfp ^{235}U sphere. The experiment used a NE-213 detector biased at 1.6 MeV and located 9.455 m along the 26° flightpath. See the footnote for the definition of shake. Note the improved simulation predictions in the minimum region ($E_n \approx 8\text{--}12$ MeV), where preequilibrium and direct inelastic scattering are present

Numerous improvements (Marchetti and Hedstrom, 1998; Frankle, 2004a,b; Bucholz and Frankle, 2002) to the simulations have been made since the early implementations of these benchmarks. Simulations were performed by comparing the measured data with calculated results using ENDF/B-VI.6 or ENDF/B-VII.0 data with MCNP for the smallest spheres of ^{235}U , ^{238}U , and ^{239}Pu . With improvements in the modeling of the pulsed sphere experiments, problems with down-scattering from 14-MeV to the 8–12 MeV energy region had been noted especially for ^{235}U and ^{239}Pu . Recent efforts by LANL to improve the evaluated data for inelastic scattering at these higher incident neutron energies have been incorporated into the ENDF/B-VII.0 evaluations.

As shown in ► Fig. 53, the ENDF/B-VII.0 library improves the treatment of inelastic scattering for ^{235}U and ^{239}Pu showing much better agreement with the measured data. The improvements in modeling these integral transmission data experiments in the minimum region around 20 shakes (a shake is an informal unit of time used in nuclear science, 10^{-8} s; the word comes from the expression “two shakes of a lamb’s tail” to mean a very short time

interval) can be directly related to the cross-section improvements in the fundamental data for an incident energy of 14 and 8–12 MeV emission energies, (see [▶ Fig. 23](#)).

5.8 Testing of Thermal Values and Resonance Integrals

Important quantities at low neutron energies are thermal capture cross sections and capture resonance integrals. These quantities can be extracted from the ENDF/B-VII.0 files and compared with the data in the recently published *Atlas of Neutron Resonances* (Mughabghab, 2006).

Ratios of capture cross sections at thermal energies are shown in [▶ Fig. 54](#). Overall, there is a fairly good agreement between the values in ENDF/B-VII.0 and the Atlas, although in several instances there are notable discrepancies. The thermal region in ^{232}Pa was revised for ENDF/B-VII.0 by Wright (ORNL) leading to the thermal capture nearly 3 times bigger than the one reported in the Atlas. The origin of this discrepancy is not clear and should be addressed in the future.

Ratios for capture resonances integrals can be seen in [▶ Fig. 55](#). Several comments should be made. Resonance integrals for ^{136}Xe , ^{142}Nd , ^{152}Gd , and ^{232}U : these ratios deviate from unity since there are inconsistencies between resonance parameters and resonance integral measurements reported in Mughabghab (2006) and the evaluators adopted resonance parameters rather than the experimental integrals. In the extreme case of ^{166m}Ho , the experiment is deemed doubtful due to the cadmium cutoff because of the low energy resonance at 0.274 eV. In ^{158}Dy , the resolved resonance range is very limited (up to 86 eV) and extrapolation of the URR to such low energies might not be reliable (in particular, the exact position of the lower boundary might play

■ Figure 54

Thermal neutron capture cross sections in ENDF/B-VII.0 compared to the *Atlas of Neutron Resonances* (Mughabghab, 2006)

■ Figure 55

Neutron capture resonance integrals in ENDF/B-VII.0 compared to the *Atlas of Neutron Resonances* (Mughabghab, 2006)

a significant role). The remaining outliers (^{31}P , ^{46}Ca , ^{58}Co , ^{176}Hf , ^{204}Hg , ^{244}Pu) are real discrepancies. These are old evaluations that will have to be updated in future releases of the ENDF/B library.

6 Other Nuclear Data of Interest

Other evaluated nuclear data of interest to nuclear technology applications, primarily to fission reactor applications, are fission yields (also termed FPY), thermal neutron scattering, and radioactive decay data.

6.1 Fission Yields

The fission yields from the 1989 LANL evaluation by England and Rides (1992) were adopted by ENDF/B-VII.0. In this evaluation, fission yield measurements reported in the literature and calculated charge distributions were used to produce a recommended set of yields for the fission products. Independent yields were taken from a calculated charge distribution model. A Gaussian charge distribution was calculated by using the most probable charge and Gaussian width. The weighted average experimental independent yields, the weighted average experimental cumulative yields, the weighted average experimental cumulative yields, and the calculated cumulative yields were combined statistically to form a recommended value.

There are two fission product yield sublibraries in ENDF/B-VII.0. Both of them have been taken over from ENDF/B-VII.8 without any change:

- The neutron-induced fission yields sublibrary contains data for 31 actinides. Incident neutron interacts with the target material that undergoes fission, which gives rise to extensive number of fission products. There are 31 such target materials, from ^{227}Th to ^{255}Fm ; neutron incident energies include the thermal energy of 0.0253 eV, 500 keV, and 14 MeV. While for some materials, such as ^{235}U , fission yields are given for all three energies, for many other materials, yields are given only for one or two energies.
- Spontaneous fission yields sublibrary contains nine materials, ^{238}U , $^{244,246,248}\text{Cm}$, $^{250,252}\text{Cf}$, ^{253}Es , and $^{243,256}\text{Fm}$. Each of these material undergoes spontaneous fission, which again gives rise to an extensive set of fission products.

Fission yields can be conveniently retrieved and plotted by Sigma web interface (Pritychenko and Sonzogni, 2008), which was developed and continues to be maintained by the NNDC, BNL.

6.2 Thermal Neutron Scattering

In ENDF/B-VII.0, this sublibrary contains 20 evaluations. As described below, seven were reevaluated or updated due to the combined efforts of MacFarlane, Los Alamos, and by Mattes and Keinert, IKE Stuttgart (Mattes and Keinert, 2005). The remaining evaluations were taken over from the ENDF/B-VI.8 library.

New thermal neutron scattering evaluations were generated by the LEAPR module of the NJOY code (MacFarlane, 1994). The physical model has been improved over the one used at General Atomics in 1969 to produce the original ENDF/B-III evaluations (Koppel and Houston, 1978). The alpha and beta grids have been extended to allow for larger incident energies and to properly represent the features of $S(\alpha, \beta)$ for the various integrations required. The physical constants have been updated for ENDF/B-VII.0 to match the current hydrogen and oxygen evaluations. The changes include additional alpha and beta points, interpolating the rotational energy distributions and translational energies onto the new temperature grid, and slightly reducing the rotational energies to improve the energy region between 0.01 and 0.1 eV.

6.2.1 H_2O and D_2O

H_2O : This evaluation was generated by Mattes and Keinert (2005). Water is represented by freely moving H_2O molecule clusters with some temperature dependence to the clustering effect. Each molecule can undergo torsional harmonic oscillations (hindered rotations) with a broad spectrum of distributed modes. The excitation spectra were improved over the older ENDF model, and they are given with a temperature variation. In addition, there are two internal modes of vibration at 205 and 436 meV. The stretching mode was reduced from the older ENDF value of 480 meV to account for the liquid state. Scattering by the oxygen atoms is not included in the tabulated scattering law data. It should be taken into account by adding the scattering for free oxygen of mass 16.

We note that the new H_2O thermal scattering kernel in ENDF/B-VII.0 led to a slight increase in calculated criticality of LEU-COMP-THERM critical assemblies.

D₂O: This was based on the IKE-IAEA-JEFF-3.1 evaluation done by Mattes and Keinert (2005). Changes made for ENDF/B-VII include using a more ENDF-like temperature grid and an extension of the α and β grids to improve results for higher incident energies.

6.2.2 O in UO₂ and U in UO₂

Uranium dioxide has a structure similar to fluoride, CaF₂. A lattice dynamical model was developed by Dolling, Cowley, and Woods to fit dispersion curve measurements. In addition to short-range core-core forces, the model includes shell-core, shell-shell, and long-range Coulomb interactions. Weighted frequency distributions were calculated from a dynamical matrix based on this model. The O in UO₂ part is kept separate from the U in O₂ part, and one-fourth of the coherent elastic cross section from the original General Atomics evaluation was included. The various constants were updated to agree with the ENDF/B-VII.0 evaluation of oxygen.

6.2.3 H in ZrH

The lattice dynamics of ZrH were computed from a central force model. The slightly tetragonal lattice of ZrH₂ was approximated by a face-centered cubic lattice. Four force constants (μ , γ , ν , and δ) were introduced describing, respectively, the interaction of a zirconium atom with its nearest neighbors (8 H atoms) and its next nearest neighbors (12 Zr atoms), and the interaction of a hydrogen atom with its next nearest neighbors (6 H atoms) and its third nearest atoms (12 H atoms). Eigenvalues and eigenvectors of the dynamical matrix were calculated and a phonon frequency spectrum was obtained by means of a root sampling technique. Weighted frequency spectra for hydrogen in ZrH were then obtained by appropriate use of the dynamical matrix eigenvectors. The final values of the four force constants were obtained by fitting both specific heat and neutron data. The position of an optical peak observed by neutron scattering techniques to be centered roughly around 0.14 eV determines the constant μ , while the overall width and shape of this peak determine ν and δ , respectively. Existing neutron data are not sufficiently precise to confirm the structure predicted in the optical peak by the central force model. Specific heat data were used to determine the force constant γ , which primarily determines the upper limit on the phonon energies associated with acoustic modes.

6.2.4 Other Modified Materials

Liquid methane at 100 K used the model of Agrawal and Yip as implemented by Picton, modified to include a diffusive component. Solid methane at 22 K used the model of Picton based on the spectrum of Harker and Brugger. Liquid para and ortho hydrogen at 20 K were computed with LEAPR. The scattering law is based on the model of Keinert and Sax (1987), which includes spin correlations from the Young and Koppel (1964) model, diffusion and local hindered motions from an effective translational scattering law based on a frequency distribution, and intermolecular coherence after Vineyard (1957).

Data for aluminum are provided for temperatures of 20, 80, 293.6, 400, 600, and 800 K using frequency distribution of Stedman et al. (1967). ^{56}Fe was modeled using iron frequency distribution of Brockhouse et al. (1967).

6.3 Decay Data

The decay data part of the ENDF/B-VII.0 library was produced by Sonzogni (NNDC, BNL) in 2006. This new sublibrary contains 3,838 materials and is mostly derived from the Evaluated Nuclear Structure Data File (ENSDF, 2006) and the 2005 edition of the *Nuclear Wallet Cards* (Tuli, 2005). Each material corresponds to the ground state or an isomeric level of a given nucleus. The library provides information for stable and unstable nuclei, from the neutron to ^{283}Rg ($Z = 111$).

For sections of the library corresponding to unstable levels, the half-life, decay modes, and energy released during the decay is presented. For stable levels, the only information given is the spin and parity of the level. The energy released can be given with varying degrees of detail. The most basic information includes mean electromagnetic energy (EEM), mean light particle energy (ELP), and mean heavy particle energy (EHP).

For materials whose decay scheme is well known, that is, satisfying that the sum of the average energies for each radiation type is very close to the effective Q -value, the ENSDF database was used and discrete radiation information was provided. In contrast, for materials with unknown or poorly known decay schemes, the Nuclear Wallet Cards database was used. In this case, a simple rule was used to obtain the mean energies. If for instance the level in question undergoes beta decay, it was assumed that EEM and ELP corresponds each to a third of decay Q -value, while the neutrinos take the remaining third. For β -delayed particle emission, it was assumed that the neutrinos carried away a quarter of the available energy and that leptons, baryons, and photons took a quarter each.

The measurement of decay characteristics of fission products becomes increasingly difficult as the fission products are further from the valley of stability. Typically, as the β -decay Q -value increases, more weak gamma rays are produced, which are difficult to place or simply escape detection. To address this issue, a series of measurements using a ^{252}Cf source and a total absorption gamma spectrometer (TAGS) were performed at INL, Idaho (Greenwood et al., 1997). Using these data, EEM and ELP values were obtained for 48 materials, which can improve the decay heat predicting power of the library (Hagura et al., 2006). To obtain the EEM and ELP values from TAGS experiments, the evaluator followed the prescription developed by Hagura et al. (2006), where it is assumed that the decay from excited levels proceeds only by gamma emission, that is, conversion electrons are neglected. As a result, the EEM values is really an upper limit and the ELP a lower one. The effect of electron conversion is expected to be small, less than 10% of EEM. The use of TAGS data in decay data libraries is one of the issues under study by WPEC Subgroup 25 (Yoshida et al., 2006).

Additionally, the following features were included:

- Internal conversion coefficients were calculated for all gamma rays of known multipolarity using the code BRICC (Band et al., 2002).
- For ^{36}Cl , ^{59}Fe , ^{99}Tc , ^{129}I , and ^{137}Cs average β -energies for second forbidden nonunique transitions were calculated using the code SPEBETA (Cassette, 1992).

■ Figure 56

Decay heat per fission for a ^{235}U sample as a function of time. Shown is the total decay heat and its two components (light particles, electromagnetic)

- Theoretical β -decay half-lives and β -delayed neutron emission probabilities (P_n) using the Kratz–Hermann systematics (Pfeiffer et al., 2002) were used for some neutron-rich nuclides that were produced in the fission of ^{235}U and ^{239}Pu with limited experimental $T_{1/2}$ or P_n information.

6.3.1 Decay Heat Calculations

A plot of the decay heat following a fission event of ^{235}U can be seen in [Fig. 56](#). The total decay heat is separated into two components, electromagnetic and light particles. The former includes gamma and X-rays, while the latter includes electrons from β -decay as well conversion and Auger electrons. A heavy particle component, including neutrons and alphas is negligible. The data come from the 1989 compilation of Tobias and Mills (1989, private communication). The effect of the TAGS data is clearly visible. Without including it, many unmeasured weak gamma rays would be missing due to incomplete decay schemes, resulting in artificially high values of electron and neutrino mean energies as well as artificially low values of mean gamma energies.

The JEFF-3.1 decay data library was released in 2005 (correction to TAGS not yet introduced) and shares a similar spirit and scope with the ENDF/B-VII.0 decay data library. One

■ Figure 57

Decay heat per fission for a ^{235}U sample as a function of time using the ENDF/B-VII.0 and the JEFF-3.1 decay data without total absorption gamma spectrometer (TAGS) data

possible way of comparing both libraries would be to plot decay heats without TAGS data for ^{235}U . This is shown in [Fig. 57](#) and, as expected, both libraries give very similar results under this condition.

7 Evaluated Nuclear Data Libraries

There are numerous evaluated nuclear data libraries available from various nuclear data centers. National interests and different applications are the two principal factors causing this variety. Countries with strong nuclear programs, such as the USA, the European Union, Japan, Russia, and China, develop their own general purpose libraries to maintain evaluation expertise and ensure technological independence.

On the other hand, various applications of nuclear technology require special purpose libraries that satisfy particular needs of a given application. These derived libraries add another class to that mentioned above. One should also take into account various versions (releases) of the major libraries. Frequent sharing of evaluations among different libraries, often with some modifications, makes this picture even more complicated.

7.1 Overview of Libraries

A brief overview of evaluated nuclear data libraries should assist users to make the right choice for their application. It should be understood that there is internal dynamics in data development. Therefore, users should always consult webpages of the most prominent data centers to make sure that the library they are interested in is the latest version available.

7.1.1 General Purpose Libraries

General purpose libraries are not limited to any specific application and they are meant to satisfy a broad class of users. In practice, though, they often started as libraries for reactor applications.

Evaluations in a general purpose library are usually most complete in terms of physical quantities and nuclear reactions. They have to be suitable for transport calculations and as such have to fulfill quite strict requirements regarding completeness and consistency. Thus, neutron evaluations have to cover thermal, resolved, and unresolved resonance as well as fast neutron ranges extending at least up to 20 MeV, contain all major reaction channels, provide cross sections and possibly angular distributions, energy-angle correlated cross sections, and photon production data. Internal consistency implies that individual cross sections must sum up to the total cross section and the integrals of emission spectra correspond to the respective reaction cross sections.

Typically, the general purpose libraries are extensively validated against integral measurements. Sometimes, results of these integral measurements are incorporated into a library. This procedure introduces implicit correlations between various reactions and materials causing such a library to become an entity rather than a simple collection of individual evaluations.

Major general purpose libraries are maintained by the following countries:

1. USA – ENDF/B-VII.0, released in 2006; new version is expected in 2011.
2. Europe – JEFF-3.1, released in 2005; new version is expected in 2010.
3. Japan – JENDL-3.3, released in 2002; JENDL-4 is expected in 2010.
4. Russia – BROND-2.2, released in 1992; BROND-3 has not been completed yet, it is partly available in the selected evaluations of ROSFOND, which was released in 2008.
5. China – CENDL-2, released in 1991; CENDL-3 was developed but not internationally released; development of CENDL-4 is underway.

Over the first decade of the twenty-first century three evaluated data libraries (ENDF/B, JEFF, and JENDL) have been continuously updated and improved. These libraries will be briefly summarized later in this section.

7.1.2 Special Purpose Libraries

The special purpose libraries address particular exigencies of certain applications. Typical examples of such libraries are:

- International Reactor Dosimetry File, IRDF (Griffin and Paviotti-Corcuera, [2003](#))
- European Activation File, EAF (Forrest et al., [2007](#))
- Standards neutron cross section library (Carlson et al., [2009](#)), and
- Fusion Evaluated Nuclear Data Library, FENDL (Lopez Aldama and Trkov, [2004](#))

Evaluations in these libraries are not as comprehensive as those in the general purpose libraries but excel in certain features that would be impractical or too costly to be implemented in the general purpose files.

For example, activation library does not have to cover the full energy range, does not require spectra and angular distributions but does need to provide cross sections for the reactions leading to the radioactive products. Often, these are metastable states that are rarely considered in the general purpose libraries. There is no internal consistency requirement, but the amount of materials in the activation library is usually far larger than in the general purpose libraries.

The dosimetry libraries are similar to the activation ones but cover very limited number of well-known reactions that are used for the determination of neutron spectra. Cross-section covariances are critical for spectra deconvolution and are mandatory in dosimetry libraries.

On top of this pyramid are libraries of standards that include cross sections and covariances for an even smaller number of reactions that are known to a very high accuracy. The evaluation of standards is particularly thorough and is predominantly based on a detailed analysis of precise experimental data. Since standards are used as reference in many measurements they are a potential source of correlations among seemingly independent experiments. Therefore, cross-correlations among standards cross sections are required in the standards library. These libraries provide by far most accurate and reliable data but their coverage is very fragmentary.

Another type of special purpose libraries are those that are created as a selection of evaluations from various major libraries to better serve particular application. The prominent example is FENDL (Lopez Aldama and Trkov, 2004), the international library compiled under auspices of the IAEA in support of the fusion program.

Some examples of special purpose libraries are:

- IRDF-2002: The International Reactor Dosimetry File (Griffin and Paviotti-Corcuera, 2003) is a standardized, updated, and benchmarked evaluated cross section library of neutron dosimetry reactions with uncertainty information for use in lifetime management assessments of nuclear power reactors and other neutron metrology applications such as boron neutron capture therapy, therapeutic use of medical isotopes, nuclear physics measurements, and reactor safety applications. It contains damage cross sections, decay data, standard spectra, and dosimetry cross sections in ENDF-6 pointwise and groupwise representation. The development of IRDF-2002 was coordinated by IAEA during 2001–2004.
- INDL/TSL: An improved set of thermal neutron scattering law data prepared for ten elements/compounds in 2004–2006 by Mattes and Keinert under auspices of the IAEA.
- IAEA-Standards, 2006: The most respected international library of neutron cross-section standards (Carlson et al., 2009). It contains data for nine reactions including covariances. The library relies on a very careful evaluation of the selected set of most precise and reliable experiments. ENDF/B-VII.0 adjusted its neutron sublibrary to these cross sections and the whole set is available in its standards sublibrary.
- EAF-2003: The European Activation File (Forrest et al., 2003) is the most extensive library of neutron activation cross sections. It contains 12 617 excitation functions on 774 different targets from ^1H to ^{257}Fm stored in the extended ENDF-6 format (EAF format). The ENDF-6 formatted version is included as JEFF-3.1/A sublibrary in the general purpose library JEFF-3.1.
- EAF-2007: An extension of the European Activation File to proton- and deuteron-induced reactions (Forrest et al., 2007) in addition to the traditional neutron-induced data (Forrest et al., 2003). The deuteron-induced library contains 66,864 reactions, while the proton-induced

library contains 67,925 reactions. The library makes extensive use of model calculations with the TALYS code (Koning et al., 2004).

JENDL/AC-2008: The JENDL Actinoid File 2008 is a consistent set of new evaluations for 79 actinides ($89 \leq Z \leq 100$) released in 2008 with the intention of being included in JENDL-4.

MINSK: The library of original evaluations for 17 actinides developed by Maslov et al. (Minsk, Belarus) between 1995 and 2003. It contains data for isotopes of Th, Pa, U, Np, Pu, Am, and Cm.

MENDL-2: The neutron reaction data library for nuclear activation and transmutation at intermediate energies developed by Shubin et al. (IPPE Obninsk) around 1995–1998. It contains production cross sections for the formation of radioactive product nuclides for incident neutrons with energies up to 100 MeV. The 505 nuclides included cover the range from ^{26}Al to ^{210}Po with half-lives larger than one day.

ENDF/HE-VI: The high-energy library developed by S. Perlstein (BNL) and T. Fukahori (JAERI) in the 1990s containing neutron and proton data for ^{12}C , ^{56}Fe , ^{208}Pb , and ^{209}Bi up to 1,000 MeV.

7.1.3 Derived Libraries

Derived libraries are obtained from the libraries discussed above by processing them with a dedicated computer code such as NJOY (MacFarlane and Muir, 1994). In most cases, this processing is carried out to reconstruct cross sections in the resonance region, perform their Doppler broadening at a given temperature (pointwise representation), and to provide averages over certain energy intervals (groupwise representation). Derived libraries are generally needed for transport calculations (e.g., ACE libraries used in the Monte Carlo MCNP code (X5-MCNP-Team, 2003)).

The derived libraries may also be adjusted to reproduce particular set of integral experiments. In most cases, such adjustment is performed on the groupwise library and targets very well-defined applications such as sodium cooled fast reactors. The performance of the adjusted library is superior when it is used for the intended application but it might be poor for other applications. This is a consequence of the selection of integral experiments and adoption of energy-group structure that are tailored for the intended application.

7.2 ENDF-6 Format

Use of the ENDF-6 format is common for most of the evaluated nuclear data libraries. Only some of the activation and derived libraries deviate from this standard. Otherwise, all major libraries are using ENDF-6 format that has been accepted internationally. This unification had a great impact on the worldwide cooperation, greatly facilitated by exchanging files between the national libraries and easy comparison of the data.

The ENDF format has been developed by the CSEWG and it is maintained by the NNDC. The work started in 1966, the first version was released in 1968, and then in 1970, 1972, 1975, 1979, and 1990 along with the subsequent releases of the US ENDF library. The current

version, ENDF-6 (Herman and Trkov, 2009), has been used for both the ENDF/B-VI and ENDF/B-VII library implying that a new version of the format has not been developed for the ENDF/B-VII. We note that to differentiate it from the library that is denoted with Roman numerals (say, ENDF/B-VI), the ENDF format is always denoted with the Arabic numeral (ENDF-6).

For historic reasons, the ENDF-6 format uses 80-character records conforming to the old-fashioned versions of FORTRAN. It is organized in a strict hierarchical structure. Any library is a collection of material evaluations from a recognized evaluation group. It is divided into sublibraries that distinguish between different incident particles and types of data, namely, neutron induced-reactions, proton-induced reactions, thermal scattering data, fission yields, decay data, etc. The sublibraries contain the data for different materials identified by MAT numbers. Each material evaluation contains data blocks referred to as “Files” and denoted with MF numbers.

File 1: MF=1 is the descriptive part of the numerical file with details of evaluation, it also contains $\bar{\nu}$ values.

File 2: MF=2 contains neutron resonance parameters. Neither thermal constants, nor cross sections in the resonance region are provided, these are reconstructed from resonance parameters by processing codes.

File 3: MF=3 contains cross sections. The minimum required energy range for neutron reactions is from the threshold or from $10^{4.55}$ eV up to 20 MeV, but higher energies are allowed. There is a section for each important reaction or sum of reactions. The reaction MT-numbers for these sections are chosen based on the emitted particles.

Files 4–6: Energy and angle distributions for emitted neutrons and other particles or nuclei. File 4 is used for simple two-body reactions (elastic, discrete inelastic). Files 4 and 5 are used for simple continuum reactions, which are nearly isotropic and emit only one important particle. File 6 is used for more complex reactions that require energy-angle correlation that are important for heating or damage, or that have several important products that must be tallied.

Files 8–10: If any of the reaction products are radioactive, they should be described further in File 8. This file indicates how the production cross section is to be determined (from Files 3, 6, 9, or 10) and gives minimal information on the further decay of the product. Additional decay information can be retrieved from the decay data sublibrary when required. Branching ratios (or relative yields) for the production of different isomeric states of a radionuclide may be given in File 9. Alternatively, radionuclide isomer-production cross sections can be given in File 10.

Files 12–15: For compatibility with earlier versions, photon production and photon distributions can be described using File 12 (photon production yields), File 13 (photon production cross sections), File 14 (photon angular distributions), and File 15 (photon energy distributions). File 12 is preferred over File 13 when strong resonances are present (capture, fission).

Files 30–40: Covariance data are given in Files 30–40, with $\bar{\nu}$ covariances in File 31, resonance parameter covariances in File 32, and cross-section covariances in File 33.

A concise list of basic definitions and constants used in the ENDF-6 format is given in  [Table 11](#). For a detailed description we refer to the extensive manual (Herman and Trkov, 2009).

■ Table 11

ENDF-6 format: Selected definitions and constants. See Herman and Trkov (2009) for more details

File	Section	Quantity
MF=1		General information
MF=1	MT=451	Description of the evaluation
	MT=452	Average number of neutrons per fission, $\bar{\nu}$ ($\bar{\nu} = \bar{\nu}_d + \bar{\nu}_p$)
	MT=455	Average number of delayed neutrons per fission, $\bar{\nu}_d$
	MT=456	Average number of prompt neutrons per fission, $\bar{\nu}_p$
	MT=458	Energy release in fission for incident neutrons
	MT=460	β -Delayed photon spectra
MF=2		Resonance parameters
MF=2	MT=151	Resolved resonance parameters, flag LRU=1
	MT=151	Unresolved resonance parameters, flag LRU=2
MF=3		Reaction cross sections
MF=3	MT=1	Total cross sections
	MT=2	Elastic cross sections
	MT=4	Sum of all inelastic cross sections
	MT=5	Sum of cross sections for all reaction channels not given explicitly under other MT numbers
	MT=16	$(n,2n)$ cross sections
	MT=17	$(n,3n)$ cross sections
	MT=18	(n,xf) total fission cross sections
	MT=19	(n,f) first chance fission cross sections
	MT=20	(n,nf) second chance fission cross sections
	MT=21	$(n,2nf)$ third chance fission cross sections
	MT=22	$(n,n'\alpha)$ cross sections
	MT=28	$(n,n'p)$ cross sections
	MT=51	(n,n') cross sections (inelastic scattering to the 1 st excited level)
	MT=52	(n,n'_2) cross sections (inelastic scattering to the 2 nd excited level)
	MT=91	(n,n'_{cont}) cross sections (inelastic scattering to continuum)
	MT=102	(n,γ) cross sections
	MT=103	(n,p) cross sections
MT=105	(n,t) cross sections	
MT=107	(n,α) cross sections	

Table 11 (continued)

File	Section	Quantity
	MT=601	(n,p_1) cross sections for the (n,p) reaction leaving residual nucleus in the 1 st excited level
	MT=600	(n,p_0) cross sections for the (n,p) reaction leaving residual nucleus in the ground state
	MT=801	(n,α_1) cross sections for the (n,α) reaction leaving residual nucleus in the 1 st excited level
MF=4		Angular distributions of emitted particles expressed as normalized probability distributions
MF=4	MT=2	Angular distributions for elastic scattering
	MT=51	Angular distributions for inelastic scattering to the 1 st excited level
MF=5		Energy distributions (spectra) of emitted particles expressed as normalized probability distributions
MF=5	MT=16	Spectra of emitted neutrons, photons, and recoils for the $(n,2n)$ reaction (neutron spectra contain both cascading neutrons)
MF=6		Energy-angle distributions of emitted particles (for a given reaction should contain subsections for all reaction products including γ 's and recoils)
MF=6	MT=5	Energy-angle distributions of products for all reactions lumped into MT=5 (reactions are identified by the residual nuclei)
	MT=91	Energy-angle distributions of continuum neutrons (only those neutrons that were not followed by any other particle emission are counted)
	MT=28	Energy-angle distributions of neutrons, protons, residual nuclei, and photons emitted in the $(n,n'p)$ reaction
MF=7		Thermal neutron scattering on moderating materials
MF=7	MT=2	Elastic thermal neutron scattering
	MT=4	Inelastic thermal neutron scattering
MF=8		Decay data and fission-product yields
MF=8	MT=454	Independent fission product yields
	MT=459	Cumulative fission product yields
	MT=457	Radioactive decay data
MF=9		Multiplicities for production of radioactive nuclei (activation/isomeric cross sections expressed as a fraction of the respective cross sections in MF=3)

■ Table 11 (continued)

File	Section	Quantity
MF=10		Absolute cross sections for production of radioactive nuclei (similar to MF=9 but without reference to MF=3)
MF=12		Multiplicities for photon production and branching ratios for γ transitions between discrete levels (respective cross sections in MF=3 must be used for absolute values)
MF=13		Absolute photon spectra and photon production cross sections (similar to MF=12 but without reference to MF=3)
MF=14		Angular distributions for discrete and continuum photons
MF=15		Energy spectra for continuum photons (normalized distributions to be multiplied by the respective cross sections in MF=3)
MF=23		Electromagnetic interaction cross sections (such as total, coherent and incoherent (Compton) elastic scattering for photons and elastic scattering, brehm- sstrahlung and ionization for electrons)
MF=23	MT=501	Total cross section for incident photons
	MT=502	Photon coherent scattering cross section
	MT=516	Pair production cross section
	MT=522	Photoelectric absorption cross section
	MT=527	Electro-atomic brehmsstrahlung cross section
MF=26		Spectra and angular distributions of photons and electrons emitted in inter-action of photons or electrons with atoms
MF=27		Atomic form factors or scattering functions for angular distribution of photons
MF=28		Atomic relaxation data (emission of X-rays and electrons from ionized atoms)
MF=31		Covariances for nubar ($\bar{\nu}$)
MF=32		Covariances for resonance parameters
MF=33		Covariances for cross sections
MF=33	MT=1	Covariances for total cross sections
	MT=2	Covariances for elastic cross sections
	MT=851–870	Covariances for cross sections of lumped channels
MF=34		Covariances for angular distributions of emitted particles
MF=35		Covariances for energy spectra of emitted particles
MF=40		Covariances for activation cross sections

$h/2\pi$	Planck's const./ 2π	$6.582 118 89 \times 10^{-16}$ eV s
k	Boltzmann's constant	$8.617 342 \times 10^{-5}$ eV/K
c	Speed of light	299 792 458 m/s
N_A	Avogadro's number	$6.022 141 99 \times 10^{23}$ 1/mol

■ **Table 12**

Major releases of the ENDF/B library of the USA. The library is maintained by the Cross Section Evaluation Working Group (CSEWG), established in 1966

ENDF/B	I	II	III	IV	V	VI	VII
Year	1968	1970	1972	1974	1978	1990	2006

7.3 ENDF/B-VII.0 (USA, 2006)

The ENDF/B-VII.0 library, released by the US CSEWG in December 2006, contains data primarily for reactions with incident neutrons, protons, and photons on almost 400 isotopes, based on experimental data and theory predictions. The new library plays an important role in nuclear technology applications, including transport simulations supporting national security, nonproliferation, advanced reactor and fuel cycle concepts, criticality safety, fusion, medicine, space applications, nuclear astrophysics, and nuclear physics facility design.

Major releases of the US ENDF/B library are summarized in ▶ [Table 12](#). After an initial 2-year release cycle, CSEWG moved to ever longer release cycles. Recent releases occurred at widely spaced intervals: ENDF/B-V was released in 1978, ENDF/B-VI in 1990, followed by this ENDF/B-VII.0 release in 2006. However, interim releases have occurred more frequently and ENDF/B-VI had upgrades embodied in eight releases, the last one occurring in October 2001 and referred to as ENDF/B-VI.8 (CSEWG-Collaboration, [2001](#)).

7.3.1 Overview of the ENDF/B-VII.0 Library

The ENDF/B-VII.0 library contains 14 sublibraries, summarized in ▶ [Table 13](#), according to the identification number NSUB. The number of materials (isotopes or elements) are given for both the new (VII.0) and previous (VI.8) versions of the ENDF/B library. Although the ENDF/B library is widely known for evaluated neutron cross sections, it also contains a considerable amount of non-neutron data.

Out of the total of 14 sublibraries, there are two new sublibraries; seven sublibraries were considerably updated and extended, and the remaining five sublibraries were taken over from ENDF/B-VI.8 without any change:

1. The photonuclear sublibrary is new; it contains evaluated cross sections for 163 materials (all isotopes) mostly up to 140 MeV. The sublibrary has been supplied by LANL and it is largely based on the IAEA-coordinated collaboration completed in 2000 (Chadwick et al., [2000](#)).
2. The photo-atomic sublibrary has been taken over from ENDF/B-VI.8. It contains data for photons from 10 eV up to 100 GeV interacting with atoms for 100 materials (all elements). The sublibrary has been supplied by LLNL.
3. The decay data sublibrary has been completely reevaluated and considerably extended by the NNDC, BNL.
4. The spontaneous fission yields were taken over from ENDF/B-VI.8. The data were supplied by LANL.

■ Table 13

Contents of the ENDF/B-VII.0 library, with ENDF/B-VI.8 shown for comparison

No.	NSUB	Sublibrary name	Short name	ENDF/B- VII.0 materials	ENDF/B-VI.8 materials
1	0	Photonuclear	g	163	–
2	3	Photo-atomic	Photo	100	100
3	4	Radioactive decay	Decay	3,838	979
4	5	Spontaneous fission yields	s/fpy	9	9
5	6	Atomic relaxation	ard	100	100
6	10	Neutron	n	393	328
7	11	Neutron fission yields	n/fpy	31	31
8	12	Thermal scattering	tsl	20	15
9	19	Standards	Std	8	8
10	113	Electro-atomic	e	100	100
11	10010	Proton	p	48	35
12	10020	Deuteron	d	5	2
13	10030	Triton	t	3	1
14	20030	³ He	he3	2	1

NSUB stands for the sublibrary number, given in the last two columns are the number of materials (isotopes or elements)

- The atomic relaxation sublibrary was taken over from ENDF/B-VI.8. It contains data for 100 materials (all elements) supplied by LLNL.
- The neutron reaction sublibrary represents the heart of the ENDF/B-VII.0 library. The sublibrary has been considerably updated and extended; it contains 393 materials, including 390 isotopic evaluations and 3 elemental ones (C, V, and Zn). These evaluations can be considered to be complete (the only exception is ²⁵³Es that contains (*n*, γ) dosimetry cross sections) since they contain data needed in neutronics calculations. Important improvements were made to the actinides by LANL, often in collaboration with ORNL. Evaluations in the fission product range ($Z = 31\text{--}68$) have been entirely changed. Of the 393 materials, about two-thirds of the evaluations are based upon recent important contributions from US evaluators. The remaining evaluations were adopted from other sources (mostly the JENDL-3.3 library). LLNL provided β -delayed γ -ray data for ²³⁵U and ²³⁹Pu for the first time in ENDF/B.
- Neutron fission yields were taken over from ENDF/B-VI.8. The data were supplied by LANL.
- The thermal neutron scattering sublibrary contains thermal scattering-law data, largely supplied by LANL, with several important updates and extensions (Mattes and Keinert, 2005).
- The neutron cross-section standards sublibrary is new. Although standards traditionally constituted part of the ENDF/B library, in the past these data were stored on a tape. As the

concept of tapes has been abandoned in ENDF/B-VII.0, the new sublibrary (short name *std*, sublibrary number NSUB = 19) has been introduced. Out of eight standards materials, six were newly evaluated, while the $^3\text{He}(n,p)$ and $^{nat}\text{C}(n,n)$ standards were taken over from ENDF/B-VI.8. The standard cross sections were adopted by the neutron reaction sublibrary except for the thermal cross section for $^{235}\text{U}(n,f)$ where a slight difference occurs to satisfy thermal data testing. These new evaluations come from the international collaboration coordinated by the IAEA (Carlson et al., 2009).

10. The electro-atomic sublibrary was taken over from ENDF/B-VI.8. It contains data for 100 materials (all elements) supplied by LLNL.
11. The proton-induced reactions were supplied by LANL, the data being mostly up to 150 MeV. There are several updates and several new evaluations.
12. The deuteron-induced reactions were supplied by LANL. This sublibrary contains five evaluations.
13. The triton-induced reactions were supplied by LANL. This sublibrary contains three evaluations.
14. Reactions induced with ^3He were supplied by LANL. This sublibrary contains two evaluations.

7.3.2 Processing and Data Verification

The ENDF/B-VII.0 library was issued in its basic format defined by the ENDF-6 Formats Manual (Herman and Trkov, 2009). For practical applications, the library must be processed so that basic data are converted into formats suitable as input for applied codes such as the Monte Carlo transport code, MCNP, and the reactor licensing code, SCALE (SCALE, 2000). Recommended processing codes:

- Los Alamos code NJOY-99 (MacFarlane and Muir 1994; MacFarlane and Kahler, 2009, “NJOY-99.304”, www.t2.lanl.gov/codes/njoy99/index.html (5 october 2009), to be obtained from RSICC (RSICC, 2009) or NEA Data Bank (2009), with patches available at the LANL T-2 webpage (2009).
- Two codes are available for processing of covariance data, ERRORJ (Kosako, 2001) – since recently a part of the NJOY package, and PUFF (Wiarda and Dunn, 2006) – a module of the Oak Ridge processing code AMPX (Dunn and Greene, 2002).

Data verification was performed by the NNDC, BNL:

- Checking the library by ENDF-6 utility codes (CHECKR, FIZCON, PSYCHE) (Dunford, 2005) for possible formatting problems and inconsistencies in physics.
- Processing of photonuclear, neutron, thermal scattering, and proton sublibraries by NJOY-99 to ensure that a processed library suitable for neutronics calculations can be produced.
- Use of the processed files by the Monte Carlo codes MCNP (X5-MCNP-Team, 2003) and MCNPX (2006) in simple neutronics test to ensure that neutronics calculations can be performed.
- Processing of covariance data to ensure that multigroup data for applied calculations can be produced.

Data validation is a complex process described earlier in this chapter. CSEWG used continuous energy Monte Carlo transport codes and validation focused on the neutron reaction and thermal neutron scattering sublibraries. These are the best validated sublibraries. The neutron standards sublibrary contains a special category of data where the highest quality was achieved. The photonuclear sublibrary was subject to partial validation, and the decay data sublibrary went through some limited testing. The remaining nine sublibraries were not included in the ENDF/B-VII.0 validation process.

7.4 JEFF-3.1 (Europe, 2005)

The JEFF project is a collaborative effort among the European member countries of the NEA Data Bank. The initial objective was to improve performance for existing reactors and fuel cycles. More recently, the goal is to provide users with a more extensive set of data for a wider range of applications, including innovative reactor concept (Gen-IV), transmutation of radioactive waste, fusion, and medical applications. These data include neutron- and proton-induced reactions, radioactive decay, fission yields, thermal scattering law, and photo-atomic interactions.

The JEFF-3.1 version of the library was released in May 2005, for summary description see JEFF Report 19 (JEFF3, 2005). The library combines the efforts of the JEFF and EFF/EAF (European Fusion File/European Activation File) working groups. The neutron general purpose sublibrary contains 381 materials from ^1H to ^{255}Fm . The activation sublibrary is based on the EAF-2003 and contains cross sections for neutron reactions on 774 targets; radioactive decay sublibrary contains three 852 isotopes of which only 226 are stable; proton sublibrary covers 26 materials from ^{40}Ca to ^{209}Bi ; thermal scattering law sublibrary includes nine materials; neutron-induced-fission-yield sublibrary covers 19 isotopes from ^{232}Th to ^{245}Cm , and spontaneous-fission-yield sublibrary contains $^{242,244}\text{Cm}$ and ^{252}Cf .

The JEFF-3.0 library was upgraded mainly because of underprediction of the reactivity for LEU systems relevant to light water reactors. The reactivity issue was linked to the ^{238}U cross sections and the improved evaluation was assembled as a result of the broad international effort. Transport calculations proved that the predictions of this reactivity was appreciably improved.

New evaluations or major revisions were performed for Ti isotopes (IRK Vienna); Ca, Sc, Fe, Ge, Pb, and Bi isotopes (NRG Petten); ^{103}Rh , $^{127,129}\text{I}$, and Hf isotopes; and $^{236,237,238}\text{U}$ and ^{214}Am (CEA). For other isotopes, more recent evaluations from other libraries were adopted. Revised thermal scattering data have been produced for all important moderator and structural materials.

The JEFF project put considerable effort to validation of the library, which was done particularly carefully from the point of view of nuclear reactor applications. The overall performance of the library is excellent.

7.5 JENDL-3.3 (Japan, 2002)

JENDL-3.3 is the Japanese evaluated library that was released in 2002, see the summary paper by Shibata et al. (2002b). The library is largely based on evaluations that originated in Japan, thus representing probably the most extensive source of independent evaluations, just after the US effort.

The objective of the JENDL effort is to supply Japanese evaluated data for fast breeder reactors, thermal reactors, fusion neutronics, and shielding calculations, as well as other applications. The JENDL-3.3 library contains data for 337 materials, from 10^{-5} to 20 MeV. Major issues in the previous version of the library, JENDL-3.2, were addressed: overestimation of criticality values for thermal fission reactors was improved by the modification of fission cross sections and fission neutron spectra for ^{235}U ; incorrect energy distributions of secondary neutrons from important heavy materials were replaced by the statistical model results; inconsistency between elemental and isotopic evaluations were removed for medium-heavy nuclides.

JENDL-3.3 also contains covariances for 20 most important materials. Of them, 16 materials have been originally developed for JENDL-3.2 covariance file, made available in March 2002 (Shibata et al., 2002a), and adopted shortly afterward with minor modifications by JENDL-3.3. Three additional materials were produced for JENDL-3.3, while the dosimetry material ^{55}Mn was taken over. The list of resulting 20 materials includes actinides, structural materials, and light nuclides, which are of interest primarily for fast reactor applications:

- ^1H , $^{10,11}\text{B}$, ^{16}O , ^{23}Na , ^{48}Ti , V, ^{52}Cr , ^{55}Mn , ^{56}Fe , ^{59}Co , $^{58,60}\text{Ni}$, ^{90}Zr , $^{233,235,238}\text{U}$, $^{239,240,241}\text{Pu}$.

A new version of the library, JENDL-4, is under development, with a release expected in 2010.

7.6 Web Access to Nuclear Data

Several major webpages offer evaluated nuclear data. These are regularly maintained by the four well-established data centers:

1. NNDC, USA, www.nndc.bnl.gov
2. IAEA, Nuclear Data Section (IAEA-NDS), Vienna, www.nds.iaea.org
3. Nuclear Energy Agency, Data Bank (NEA-DB), Paris, www.nea.fr/html/dbdata
4. Nuclear Data Center, Japan Atomic Energy Agency (NDC-JAEA), Japan, wwwndc.tokai-sc.jaea.go.jp

The NNDC has probably the largest portfolio of data with web retrieval capabilities, including both nuclear structure (ENSDF, NuDat, Chart of Nuclides) and nuclear reactions (EXFOR, ENDF, Sigma).

For the readers of the present Handbook of most interest would be *Sigma* nuclear reaction retrieval and plotting system, which was developed by the NNDC to satisfy needs of both professional users and those without knowledge of complex ENDF-6 formatting system. Sigma uses the latest web technologies to provide browsing and search tools as well as interactive graphics. It can be easily accessed at www.nndc.bnl.gov/sigma and includes the following capabilities:

1. Retrieval, browsing, search
2. Plotting
 - Cross sections
 - Angular distributions, energy spectra
 - Covariances (MF33)
 - Fission yields
3. Computations (ratios, integrals, weighting)

4. Thermal values and resonance integrals

Sigma offers data from the following nuclear reaction libraries:

- ENDF/B-VII.0 (USA, 2006)
- JEFF-3.1 (Europe, 2005)
- JENDL-3.3 (Japan, 2002)
- ROSFOND (Russia, 2008)
- ENDF/B-VI.8 (USA, 2001)
- ENDF/A (USA, selected files only)
- EXFOR (NRDC network, experimental data, latest version)

The IAEA Nuclear Data Service (Vienna) offers major nuclear reaction data libraries as well as a number of smaller libraries and specialized results of the IAEA-coordinated data projects. Its signature nuclear reaction retrieval system is *ENDF*, which is also offered by the NNDC as an alternative to Sigma.

The NEA Data Bank (Paris) data services are more restricted, focusing on nuclear reaction data and nuclear reaction computer codes. Its signature nuclear reaction data retrieval and plotting system is Java-based *JANIS*.

The Nuclear Data Center of the Japan Atomic Energy Agency (Tokaimura) offers data services with the focus on data included in the Japanese Evaluated Nuclear Data Library, JENDL.

Acknowledgments

It would not have been possible to write this chapter without results produced by the dedicated work of numerous scientists and colleagues over years, both in the USA and abroad. We are particularly grateful to members of CSEWG and many other colleagues who contributed to ENDF/B-VII.0 and other nuclear data libraries. We owe special thanks to the authors of the “Big Paper” on ENDF/B-VII.0 (Chadwick et al., 2006), which supplied most of the figures and served as the basis for preparing this chapter.

Abstract: The theory behind the generation of thermal cross sections is presented, concentrating on the phonon expansion method. Examples are given for graphite, water, heavy water, and zirconium hydride. The graphite example demonstrates incoherent inelastic scattering and coherent elastic scattering for crystalline solids. The water example demonstrates incoherent inelastic scattering for liquids with diffusive translations. Heavy water adds a treatment for intermolecular coherence. Zirconium hydride shows the effects of the “Einstein oscillations” of the hydrogen atoms in a cage of zirconium atoms, and it also demonstrates incoherent elastic scattering. Neutron thermalization is introduced using Monte Carlo simulations of several systems, followed by multigroup discrete-ordinates and collision-probability methods. Size effects in thermalization are demonstrated. Steady-state slowing down is discussed by illustrating typical cross-section data, and showing slowing down by elastic scattering, inelastic scattering, and resonance cross sections in the narrow resonance approximation. Intermediate resonance self-shielding effects are introduced using the NJOY flux calculator and the WIMS implementation. The effects of time and space on slowing down are demonstrated using Monte Carlo simulations, and the theoretical basis is summarized.

1 Thermal Neutron Scattering

1.1 Introduction

At high energies, the wavelengths of neutrons are small, and it is reasonable to treat scattering as classical collisions between particles. At thermal energies, however, the wavelengths of neutrons approach the size of molecules and the spacing of crystalline lattices. Scattering becomes a quantum mechanical problem. The theory for this was worked out in the late 1950s and is described in detail by Williams (1966). This theory was reduced to practice for the US Evaluated Nuclear Data File (ENDF) in the 1960s, mainly by researchers at General Atomic (Koppel and Houston 1978). This theoretical basis remains largely valid today except for the improvements in scope and detail allowed by modern computing machines (MacFarlane 1994; Mattes and Keinert 2005).

In this section, we will summarize the theoretical basis for the thermal scattering evaluations in ENDF/B-VII (Tuli et al. 2006), and show examples for graphite, water, heavy water, and zirconium hydride as they are currently given in ENDF format (Herman 2005).

1.2 Chemical Binding

The simplest system of targets is a free gas of protons moving in thermal equilibrium with a temperature T . From basic statistical mechanics, the energies of these protons will be given by the Maxwell–Boltzmann distribution

$$M(E) = e^{-E/kT} \quad (1)$$

where k is Boltzmann’s constant. These protons are free to recoil, so a neutron can lose energy by colliding with a proton, but because the protons are moving, the neutron can also gain energy in a scattering event. It is assumed that the density of neutrons is small with respect to the density of scatterers; thus, the distribution of neutron energies does not affect the thermal distribution

of the scatterers. In this one case, the thermal scattering can be obtained by both quantum and classical methods.

Now if we bind the protons into a free gas of water molecules, the scattering process gets more interesting. Collisions of a neutron with a water molecule can result in a gain or loss of energy by reducing or increasing the velocity of the molecule (translational modes), and they can interact to make the molecule slow down or speed up its rotations (rotational modes) or vibrations (vibrational modes). The thermal energy kT for the gas of water molecules is divided among the various possible translational, rotational, and vibrational modes according to their characteristic energies by the Maxwell–Boltzmann distribution. The chemical binding of the proton into the water molecule reduces its ability to change the energy of the neutron upon scattering.

Now, to get more realistic, we condense this gas of water molecules into a liquid. The vibrational modes are not changed very much by this condensation. The rotational modes become hindered rotations. You can visualize little V-shaped molecules moving back and forth like torsional oscillators. The translational modes act like the diffusion of clusters of molecules with some internal order moving through a matrix of other clusters. All of these modes are considered to be quantized. The good quantum numbers are energy and momentum, and the energies of the modes are distributed according to the Maxwell–Boltzmann distribution. The good quantum numbers for the incident and scattered neutron are also energy and momentum (or wave vector). When the neutron scatters in the liquid, it changes its energy and momentum. The difference is associated with a change in the energy and momentum of various modes of excitation in the liquid.

In a solid, the possible modes of excitation are various wave-like vibrations of the crystal lattice. In quantum language, these excitations are called “phonons.” Phonons are characterized by particular energies and momenta (or wave vectors). The equilibrium distribution of phonon energies is described by the Maxwell–Boltzmann distribution. When a neutron scatters through a crystalline lattice, it can exchange energy and momentum by creating or annihilating phonons in such a way as to conserve energy and momentum. This can lead to a change of energy and direction (wave vector) for the neutron. There is another thing that can happen. Because the neutron can be characterized as a wave, it can scatter from the lattice in the same way that light scatters from a diffraction grating. This is called “coherent elastic scattering,” and it results in a change of direction for the neutron with no change in energy.

1.3 Coherent and Incoherent Scattering

When the neutron wave impinges on the crystalline lattice, there is a secondary wave produced from each scattering center. If the resulting waves are “coherent,” they can combine constructively and destructively to produce maxima and minima in various directions. This is similar to the behavior of a diffraction grating for light. For a material of randomly ordered crystallites, this would result in rings of neutron intensity in the forward direction. However, the diffraction can also be “incoherent.” A primary example of this is scattering from bound protons. Protons have spin, like the neutron, and the spins can be randomly arranged in a hydrogenous scatter. This randomness breaks the coherence and destroys the diffraction pattern. Inelastic scattering also tends to reduce the coherence in the scattering, and we normally assume that inelastic thermal scattering can be treated as incoherent. In general, hydrogenous materials

scatter incoherently. Nuclei with spin zero (many important materials) scatter coherently for elastic scattering (no energy change), but incoherently for inelastic scattering.

1.4 The Quantum Mechanical Scattering Function

This process has been analyzed in terms of a position and time correlation function. Let $G(\mathbf{r}, t)$ be the probability that a particle will be at the origin at time $t = 0$ and at position \mathbf{r} at time t (s for “self” particle). Using the incoherent approximation and assuming a liquid or a powdered crystalline material, the scattering function can be written as

$$\sigma_{inc}(E \rightarrow E', \mu) = (a_{inc}^2 + a_{coh}^2) \frac{k'}{k} \int d\mathbf{r} \int dt e^{i(\kappa \cdot \mathbf{r} - \varepsilon t/\hbar)} G_s(\mathbf{r}, t), \quad (2)$$

where E and E' are the incident and secondary energies, μ is the cosine of the scattering angle, a_{inc} and a_{coh} are the characteristic scattering lengths for the material, k and k' are the incident and outgoing wave numbers (momenta), κ is the change in wave vector in scattering, and ε is the energy transfer in scattering.

1.5 The Intermediate Scattering Function

This expression is often written in terms of the “intermediate scattering function” χ , or

$$\sigma_{inc}(E \rightarrow E', \mu) = (a_{inc}^2 + a_{coh}^2) \frac{k'}{k} \int dt e^{i\varepsilon t/\hbar} \chi_s(\kappa, t), \quad (3)$$

where the coherent scattering is treated with the incoherent approximation. For most of the cases of interest in thermal scattering, it turns out that χ takes on a Gaussian form in momentum transfer κ

$$\chi(\kappa, t) = e^{-\gamma(t)}, \quad (4)$$

where

$$\gamma(t) = \kappa^2 \int_{-\infty}^{\infty} P(\varepsilon) (1 - e^{-i\varepsilon t/\hbar}) e^{-\varepsilon/2kT} d\varepsilon, \quad (5)$$

and where

$$P(\varepsilon) = \frac{\rho(\varepsilon)}{2\varepsilon \sinh(\varepsilon/2kt)}. \quad (6)$$

The quantity $\rho(\varepsilon)$ is the energy spectrum of excitations in the system. In this context, the Gaussian approximation is basically equivalent to treating the internal excitations of the system as quantized harmonic oscillators. The excitation energy spectrum is often written as $\rho(\omega)$, with $\varepsilon = \hbar\omega$ and called a “frequency distribution.”

1.6 Detailed Balance

The thermal scattering cross section must obey a very important property called the condition of “detailed balance” or “reciprocity.” From very basic principles like time reversal invariance, it can be shown that for thermal equilibrium, the down-scattering must be balanced by the up-scattering. Thus,

$$EM(E, T)\sigma(E \rightarrow E', \mu) = E'M(E', T)\sigma(E' \rightarrow E, \mu). \quad (7)$$

This condition guarantees that the thermal neutron flux spectrum in an infinite non-absorbing medium at temperature T will take on a Maxwell–Boltzmann flux shape appropriate to the temperature T ; that is, the flux shape will be

$$\phi(E) = Ee^{-E/kT}. \quad (8)$$

Absorption and leakage from the medium can modify the spectrum from this ideal shape.

1.7 The Scattering Law

It has proved to be convenient to write the thermal neutron scattering cross section in terms of the “scattering law.” First, the momentum transfer and the energy transfer are written in terms of two new variables

$$\alpha = \frac{\hbar^2 \kappa^2}{kT} = \frac{E' + E - 2\mu\sqrt{E'E}}{AkT}, \quad (9)$$

and

$$\beta = \frac{\varepsilon}{kT} = \frac{E' - E}{kT}, \quad (10)$$

where A is the ratio of the target mass to the neutron mass. Then we write

$$\sigma_{inc}(E \rightarrow E', \mu) = \frac{\sigma_b}{2kT} \sqrt{\frac{E'}{E}} \hat{S}(\alpha, \beta), \quad (11)$$

where $\sigma_b = 4\pi(a_{coh}^2 + a_{inc}^2)$ is the characteristic bound scattering cross section for the material. Note that all the nuclear terms involving the cross section, the incident wave, and the scattered wave have been separated from the chemical-binding effects, all of which have been consolidated in \hat{S} . Specifically, \hat{S} does not depend on incident energy E or the scattered energy E' , but only on the amount of energy transferred between the scattered neutron and the material. This will be true as long as the atomic motions are small enough for the oscillations to remain harmonic. Anharmonicity and actual disruption of molecules or displacements of atoms from their normal lattice positions could eventually cause this theory to break down for large energy transfers at high incident energies.

Using this form of the incoherent scattering cross section and the principle of detail balance, we see that

$$\hat{S}(\alpha, \beta) = e^\beta \hat{S}(\alpha, -\beta). \quad (12)$$

The scattering law must also obey two so-called moments theorems or sum rules: the zeroth moment theorem or sum rule

$$\int \hat{S}(\alpha, \beta) d\beta = 1, \quad (13)$$

and the first moment theorem or sum rule

$$\int \hat{S}(\alpha, \beta) \beta d\beta = -\alpha. \quad (14)$$

The latter guarantees that the thermal cross section will approach the correct limit at high incident energies, namely, the free cross section σ_f , where

$$\sigma_b = \left(\frac{A+1}{A} \right)^2 \sigma_f. \quad (15)$$

In practice, the symmetric form of the scattering law is often used

$$S(\alpha, \beta) = e^{\beta/2} \hat{S}(\alpha, \beta). \quad (16)$$

Then, the detail balance condition becomes

$$S(\alpha, \beta) = S(\alpha, -\beta), \quad (17)$$

and the scattering law is symmetric in β (energy transfer). Thermal neutron scattering laws in ENDF format are normally given in terms of S , but this can lead to numerical difficulties. The asymmetric \hat{S} function can be represented by normal numbers (say 10^{-8} to 1) for all β . But the symmetric S can be smaller than \hat{S} by factors like $e^{-\beta/2} \approx e^{-80} \approx 10^{-35}$. Processing codes have to be careful to allow for this huge range of values. The problem can be even more difficult for cold moderators where numbers ranging from 1 to 10^{-99} can be required in evaluated data files.

As discussed above, the chemical binding for protons in water can be decomposed into translational, rotational, and vibrational modes. More formally, we can write

$$\rho(\varepsilon) = \sum_i w_i \rho_i(\varepsilon), \quad (18)$$

where the following possibilities are allowed

$$\rho_j(\beta) = \delta(\beta_j) \quad \text{discrete oscillator} \quad (19)$$

$$\rho_j(\beta) = \rho_s(\beta) \quad \text{solid-type spectrum} \quad (20)$$

$$\rho_j(\beta) = \rho_t(\beta) \quad \text{translational spectrum} \quad (21)$$

The solid-type spectrum must vary as ε^2 , as ε goes to zero, and it must integrate to w_s , the weight for the solid-type law. The translational spectrum is sometimes represented as a free gas for liquids, but more realistically, it can be represented using a diffusion-type spectrum represented with the approximation of Egelstaff and Schofield that will be discussed later. In either case, the spectrum must integrate to w_t , the translational weight. The sum of all the partial weights must equal 1. This partition of the energy distribution leads to a recursive formula for the scattering law:

$$\hat{S}(\alpha, \beta) = \hat{S}^{(K)}(\alpha, \beta), \quad (22)$$

where

$$\hat{S}^{(J)}(\alpha, \beta) = \int \hat{S}_J(\alpha, \beta') \hat{S}^{(J-1)}(\alpha, \beta - \beta') d\beta'. \quad (23)$$

As an example of the use of this recursive procedure, consider a case where the desired frequency spectrum is a combination of ρ_s and two discrete oscillators. First, calculate $\hat{S}^{(1)} = \hat{S}_1$ using ρ_s . Then calculate \hat{S}_2 using $\rho(\beta_1)$, the distribution for the first discrete oscillator, and convolve \hat{S}_2 with $\hat{S}^{(1)}$ to obtain $\hat{S}^{(2)}$, the composite scattering law for the first two partial distributions. Repeat the process with the second discrete oscillator to obtain $\hat{S}^{(3)}$, which is equal to $\hat{S}(\alpha, \beta)$ for the full distribution.

One simple example of the translational component of the scattering law represents the free gas with a weight of w_t :

$$\hat{S}(\alpha, -\beta) = \frac{1}{\sqrt{4\pi w_t \alpha}} \exp\left[-\frac{(w_t \alpha - \beta)^2}{4w_t \alpha}\right], \quad (24)$$

and

$$\hat{S}_t(\alpha, \beta) = e^{-\beta} \hat{S}_t(\alpha, -\beta), \quad (25)$$

with β positive. Note that for large α and β , the main contribution to this comes from the region $w_t \alpha \approx \beta$. The shape is a Gaussian, and as α and β increase (high incident energies), the Gaussian gradually goes over to a delta function, and we recover the normal classical elastic scattering behavior.

A number of approximate methods and full-up computer methods have been used over the years to compute the scattering law for realistic cases. Notable among these was the GASKET method, (Koppel et al. 1967) which was used by General Atomic to prepare the initial ENDF/B thermal scattering evaluations. Here we will limit our discussion to the phonon expansion method as implemented in the LEAPR module of the NJOY Nuclear Data Processing System (MacFarlane and Muir 1994), which has been used to prepare the more recent thermal scattering evaluations available in modern neutron cross-section compilations. LEAPR is a descendent of the British codes LEAP and ADDELTA (Butland 1973).

1.8 The Phonon Expansion

Consider first $\gamma_s(t)$, the Gaussian function for solid-type excitation spectra. Expanding the time-dependent part of the exponential gives

$$e^{-\gamma_s(t)} = -\alpha \lambda_s \sum_{n=0}^{\infty} \frac{1}{n!} \left[\alpha \int_{-\infty}^{\infty} P_s(\beta) e^{-\beta/2} e^{-i\beta t} d\beta \right]^n, \quad (26)$$

where λ_s is the Debye–Waller coefficient

$$\lambda_s = \int_{-\infty}^{\infty} P_s(\beta) e^{-\beta/2} d\beta. \quad (27)$$

The scattering law becomes

$$\hat{S}_s(\alpha, \beta) = e^{-\alpha\lambda_s} \sum_{n=0}^{\infty} \frac{1}{n!} \alpha^n \times \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{i\beta t} \left[\int_{-\infty}^{\infty} P_s(\beta') e^{-\beta'/2} e^{-i\beta' t} d\beta' \right]^n dt. \quad (28)$$

For convenience, define the quantity in the second line of this equation to be $\lambda_s^n \mathcal{T}_n(\beta)$. Then clearly,

$$\hat{S}_s(\alpha, \beta) = e^{-\alpha\lambda_s} \sum_{n=0}^{\infty} \frac{1}{n!} [\alpha\lambda_s]^n \mathcal{T}_n(\beta), \quad (29)$$

where

$$\mathcal{T}_0(\beta) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{i\beta t} dt = \delta(\beta), \quad (30)$$

and

$$\mathcal{T}_1(\beta) = \int_{-\infty}^{\infty} \frac{P_s(\beta') e^{-\beta'/2}}{\lambda_s} \left\{ \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{i(\beta-\beta')t} dt \right\} d\beta' = \frac{P_s(\beta) e^{-\beta/2}}{\lambda_s}. \quad (31)$$

In general,

$$\mathcal{T}_n(\beta) = \int_{-\infty}^{\infty} \mathcal{T}_1(\beta') \mathcal{T}_{n-1}(\beta-\beta') d\beta'. \quad (32)$$

The \mathcal{T} functions obey the relationship $\mathcal{T}_n(\beta) = e^{-\beta} \mathcal{T}_n(-\beta)$. In addition, each of the \mathcal{T}_n functions obeys the following normalization condition:

$$\int_{-\infty}^{\infty} \mathcal{T}_n(\beta) d\beta = 1. \quad (33)$$

In LEAPR, the \mathcal{T} functions are computed up to some specified maximum value, typically 100, and these results are used to compute $\hat{S}(\alpha, \beta)$. What does the phonon expansion mean physically? Consider a neutron scattering in water. If the energy loss of the neutron is large, there is no way that energy can be absorbed by only kicking the mass 18 molecule into additional motion. That would violate conservation of momentum. But it is possible to transfer part of the energy to translations and the rest to exciting rotations and vibrations. In other words, a multiplicity of phonons is excited. For small energy changes in scattering, only a few phonons may be required, but large transfers may require up to 100. For water in equilibrium at temperature T , intermolecular collisions will excite a spectrum of these 100 different modes in accordance with their characteristic energies following the Maxwell–Boltzmann distribution. This very complicated target motion can then deliver energy and momentum to a slow neutron, thus scattering it up to higher energies. It is assumed that the changes in the occupation of target modes caused by the neutrons are very small when compared to the thermal excitation of the target modes – this linearizes the scattering problem.

1.9 The Short Collision Time Approximation

Very large energy transfers may even require more than 100 phonons to be created or annihilated. In this case, a limiting form of the phonon expansion is available called the short collision time (SCT) approximation, which can be written

$$\hat{S}_s(\alpha, -\beta) = \frac{1}{\sqrt{4\pi w_s \alpha \bar{T}_s / T}} \exp \left[-\frac{(w_s \alpha - \beta)^2}{w_s \alpha \bar{T}_s / T} \right], \quad (34)$$

and

$$\hat{S}_s(\alpha, \beta) = e^{-\beta} \hat{S}_s(\alpha, -\beta), \quad (35)$$

where β is positive and where the effective temperature is given by

$$\bar{T}_s = \frac{T}{2w_s} \int_{-\infty}^{\infty} \beta^2 P_s(\beta) e^{-\beta} d\beta. \quad (36)$$

As above, w_s is the weight for the solid-type spectrum. The effective temperature can be substantially higher than the ambient temperature; for example, the effective temperature is about 1,370 K at room temperature for hydrogen bound in water.

1.10 Diffusive Translations

As discussed above, translational effects in liquids like water are often represented using a diffusion term. The “effective width model” of Egelstaff and Schofield provides a tractable approximation for the diffusive motion:

$$\hat{S}_t(\alpha, \beta) = \frac{2c w_t \alpha}{\pi} e^{2c^2 w_t \alpha - \beta/2} \frac{\sqrt{c^2 + 0.25}}{\sqrt{\beta^2 + 4c^2 w_t^2 \alpha^2}} K_1 \left\{ \sqrt{c^2 + 0.25} \sqrt{\beta^2 + 4c^2 w_t^2 \alpha^2} \right\}, \quad (37)$$

and

$$\rho(\beta) = w_t \frac{4c}{\pi \beta} \sqrt{c^2 + 0.25} \sinh(\beta/2) K_1 \left\{ \sqrt{c^2 + 0.25} \beta \right\}. \quad (38)$$

In these equations, $K_1(x)$ is a modified Bessel function of the second kind, and the translational weight w_t and the diffusion constant c are chosen to try to represent experiment. The scattering law for a combination of solid-type modes and diffusion can be computed as follows:

$$\hat{S}(\alpha, \beta) = \hat{S}_t(\alpha, \beta) e^{-\alpha \lambda_s} + \int_{-\infty}^{\infty} \hat{S}_t(\alpha, \beta') \hat{S}_s(\alpha, \beta - \beta') d\beta'. \quad (39)$$

The first term in this equation comes from the delta function in (37), the “zero phonon” term, which is not included in the normal calculation of \hat{S} . The effective temperature for a combination of solid-type and diffusive modes is given by

$$\bar{T}_s = \frac{w_t T + w_s \bar{T}_s}{w_t + w_s}. \quad (40)$$

The “effective width” refers to the width of the pseudo-elastic peak seen in neutron scattering experiments. Crudely speaking, one can think of clusters of water molecules with some internal order diffusing through a matrix of other clusters. Larger clusters are harder to set into motion

with neutron collisions, and the translational effects on neutron scattering are reduced from the free molecule value. Although this diffusive model helps to achieve better agreement with experiment at modest thermal energies, it leaves something to be desired at very low thermal energies. However, because of the effects of detail balance, the actual value of the cross section at the lowest neutron energies has little effect on the shape of the equilibrium flux, so this failure of the diffusive effect has normally been accepted. Some experiments seem to show that there is a distribution of cluster sizes in real liquids, and taking better account of this distribution might improve the agreement with experiment.

1.11 Discrete Oscillators

Polyatomic molecules normally support a number of vibrational modes that can be represented as discrete oscillators. The distribution function for one oscillator is given by $w_i \delta(\beta_i)$, where w_i is the fractional weight for mode i , and β_i is the energy-transfer parameter computed from the mode's vibrational frequency. The corresponding scattering law is given by

$$\begin{aligned}\hat{S}_i(\alpha, \beta) &= e^{-\alpha\lambda_i} \sum_{n=-\infty}^{\infty} \delta(\beta - n\beta_i) I_n \left[\frac{\alpha w_i}{\beta_i \sinh(\beta_i/2)} \right] e^{-n\beta_i/2} \\ &= \sum_{n=-\infty}^{\infty} A_{in}(\alpha) \delta(\beta - n\beta_i),\end{aligned}\quad (41)$$

where

$$\lambda_i = w_i \frac{\coth(\beta_i/2)}{\beta_i}.$$
 (42)

The combination of a solid-type mode (s) with discrete oscillators (1) and (2) would give

$$\hat{S}^{(0)}(\alpha, \beta) = \hat{S}_s(\alpha, \beta),$$
 (43)

$$\begin{aligned}\hat{S}^{(1)}(\alpha, \beta) &= \int_{-\infty}^{\infty} \hat{S}_1(\alpha, \beta') \hat{S}^{(0)}(\alpha, \beta - \beta') d\beta' \\ &= \sum_{n=-\infty}^{\infty} A_{1n}(\alpha) \hat{S}^{(0)}(\alpha, \beta - n\beta_1),\end{aligned}\quad (44)$$

$$\begin{aligned}\hat{S}^{(2)}(\alpha, \beta) &= \int_{-\infty}^{\infty} \hat{S}_2(\alpha, \beta') \hat{S}^{(1)}(\alpha, \beta - \beta') d\beta' \\ &= \sum_{m=-\infty}^{\infty} A_{2m}(\alpha) \sum_{n=-\infty}^{\infty} A_{1n}(\alpha) \hat{S}^{(0)}(\alpha, \beta - n\beta_1 - m\beta_2).\end{aligned}\quad (45)$$

and so on through $\hat{S}_3(\alpha, \beta)$, $\hat{S}^{(4)}(\alpha, \beta)$, etc., until all the discrete oscillators have been included. The Debye-Waller λ for the combined modes is computed using

$$\lambda = \lambda_s + \sum_{i=1}^N \lambda_i.$$
 (46)

The effective temperature for the combined modes is given by

$$\bar{T}_s = w_t T + w_s \bar{T}_s + \sum_{i=1}^N w_i \frac{\beta_i}{2} \coth\left(\frac{\beta_i}{2}\right) T.$$
 (47)

1.12 Incoherent Elastic Scattering

In hydrogenous solids (such as polyethylene), there is an elastic (no energy loss) component of scattering arising from the zero-phonon term of the phonon expansion. This is called the “incoherent elastic” term. Clearly,

$$S_{\text{iel}}(\alpha, \beta) = e^{-\alpha\lambda} \delta(\beta). \quad (48)$$

The corresponding differential scattering cross section is

$$\sigma(E, \mu) = \frac{\sigma_b}{2} e^{-2WE(1-\mu)}, \quad (49)$$

and the integrated cross section is

$$\sigma(E) = \frac{\sigma_b}{2} \left\{ \frac{1 - e^{-4WE}}{2WE} \right\}. \quad (50)$$

In these equations, the Debye–Waller coefficient is given by

$$W = \frac{\lambda}{AkT}, \quad (51)$$

where λ is computed from the input frequency spectrum as modified by the presence of discrete oscillators (if any) any as shown above.

1.13 Coherent Elastic Scattering

In solids consisting of coherent scatterers (e.g., graphite) the zero-phonon term leads to interference scattering from the various planes of atoms of the crystals making up the solid. Once again, there is no energy loss. The neutrons only change direction. This is called “coherent elastic scattering.” The differential scattering cross section is given by

$$\sigma_{\text{coh}}(E, \mu) = \frac{\sigma_c}{E} \sum_{E_i < E} f_i e^{-4WE_i} \delta(\mu - \mu_i), \quad (52)$$

where

$$\mu_i = 1 - E_i/E, \quad (53)$$

and the integrated cross section is given by

$$\sigma_{\text{coh}} = \frac{\sigma_c}{E} \sum_{E_i < E} f_i e^{-4WE_i}. \quad (54)$$

In these equations, σ_c is the effective bound coherent scattering cross section for the material, W is the effective Debye–Waller coefficient, E_i are the so-called Bragg Edges, and the f_i are related to the crystallographic structure factors.

It can be seen from (52) that the cross section is zero below the first Bragg edge (typically about 2–5 meV). It then jumps sharply to a value determined by f_i and the Debye–Waller term. At higher energies, the cross section drops off as $1/E$ until $E = E_2$. It then takes another jump and continues falling off like $1/E$. The sizes of the jumps gradually become smaller, and at high energies, there is nothing left but an asymptotic $1/E$ decrease (typically above 1–2 eV).

The calculation of the E_i and f_i depends on a knowledge of the crystal structure of the scattering material. The Bragg edges are given by

$$E_i = \frac{\hbar^2 \tau_i^2}{8m}, \quad (55)$$

where τ_i is the length of the vectors of one particular “shell” of the reciprocal lattice, and m is the neutron mass. The f_i factors for a material containing a single atomic species are given by

$$f_i = \frac{2\pi\hbar^2}{4mNV} \sum_{\tau_i} |F(\tau)|^2, \quad (56)$$

where the sum extends over all reciprocal lattice vectors of the given length, and the crystallographic structure factor is given by

$$|F(\tau)|^2 = \left| \sum_{j=1}^N e^{i2\pi\phi_j} \right|^2, \quad (57)$$

where N is the number of atoms in the unit cell, $\phi_j = \vec{\tau} \cdot \vec{\rho}_j$ are the phases for the atoms, and the $\vec{\rho}_j$ are their positions. The situation is a little more difficult for a material with more than one atomic species, such as BeO, and an approximation has to be made for the effective Debye–Waller factor for the cell.

As an example of this process, consider graphite. It has an hexagonal lattice described by the constants a and c . The reciprocal lattice vector lengths are given by

$$\left(\frac{\tau}{2\pi} \right)^2 = \frac{4}{3a^2} (\ell_1^2 + \ell_2^2 + \ell_1\ell_2) + \frac{1}{c^2} \ell_3^2, \quad (58)$$

where ℓ_1, ℓ_2 , and ℓ_3 run over all the positive and negative integers, including zero. The volume of the unit cell is

$$V = \sqrt{3}a_2c/2. \quad (59)$$

For graphite, there are four atoms in the unit cell at positions (Wyckoff 1963)

$$(0, 0, 0), \left(-\frac{1}{3}, \frac{1}{3}, 0 \right), \left(-\frac{2}{3}, -\frac{1}{3}, \frac{1}{2} \right), \left(-\frac{1}{3}, \frac{1}{3}, \frac{1}{2} \right).$$

These positions give the following phases:

$$\phi_1 = 0, \quad (60)$$

$$\phi_2 = (-\ell_1 + \ell_2)/3, \quad (61)$$

$$\phi_3 = -(2/3)\ell_1 - (1/3)\ell_2 + (1/2)\ell_3, \quad (62)$$

$$\phi_4 = -(1/3)\ell_1 + (1/3)\ell_2 + (1/2)\ell_3. \quad (63)$$

■ Figure 1
The phonon frequency spectrum $\rho(\epsilon)$ used for graphite

The form factor for graphite becomes

$$|F|^2 = \begin{cases} 6 + 10 \cos[2\pi(\ell_1 - \ell_2)/3] & \ell_3 \text{ even} \\ 4 \sin^2[\pi(\ell_1 - \ell_2)/3] & \ell_3 \text{ odd} \end{cases} \quad (64)$$

Similar methods can be used to obtain the lattice vectors and structure factors for the HCP structure (beryllium), the FCC structure (aluminum), or the BCC structure (iron). These options are built into the LEAPR module of the NJOY processing system.

1.14 Example of Thermal Scattering in Graphite

As an example of the application of the theory presented above, we consider graphite, the moderator used in the very first critical reactor. To obtain the phonon excitation spectrum, the binding in graphite is modeled using four force constants: a nearest neighbor central force that binds the hexagonal planes together, a bond-bending force in an hexagonal plane, a bond-stretching force between nearest neighbors in the plane, and a restoring force against bending of the hexagonal plane. These force constants are then used to compute the phonon energies in various directions in the crystal, the “phonon dispersion curves.” These results are analyzed to get the phonon density of states; that is, the number of phonons that can exist with energies in a given range. The phonon excitation curve used for the ENDF/B-VII evaluation of thermal scattering in graphite is shown in [Fig. 1](#). Note the ϵ^2 dependence at low energy transfers.

This frequency spectrum can be used with the phonon expansion method to generate the \hat{S} scattering law using NJOY’s LEAPR module. Some results are shown in [Figs. 2](#) and [3](#).

■ **Figure 2**
 $\hat{S}(\alpha, \beta)$ vs. α for several values of β in graphite at 293.6 K

■ **Figure 3**
 $\hat{S}(\alpha, \beta)$ vs. β for several values of α in graphite at 293.6 K. Note how the shape approaches a smooth Gaussian as α increases

Note that as α increases, the curves get smoother and begin to look like Gaussians, as predicted by the SCT extension to the phonon expansion.

In [Fig. 4](#), we show the incoherent part of the inelastic scattering from graphite at two temperatures, and in [Fig. 5](#), we show the coherent elastic contribution to the cross section displaying the low-energy cutoff and the Bragg edges.

■ Figure 4

Incoherent inelastic cross section of graphite at 293.6 K (solid curve) and 1,600 K (dashed curve). Note how the cross section approaches the free-atom value at high incident energies

■ Figure 5

Coherent elastic cross section of graphite at 293.6 K (solid curve) and 1,600 K (dashed curve) showing the Bragg edges and the asymptotic $1/E$ decrease at high energies

There are also thermal effects on the angular distributions for scattering. ➤ [Figure 6](#) shows the average cosine for scattering for both coherent elastic and incoherent inelastic scattering. Note how the scattering cosine for elastic scattering varies from a backward direction at the Bragg edge toward the forward direction as the energy increases above the edge. The inelastic $\bar{\mu}$ is less than the normal high-energy value of 0.05556.

■ **Figure 6**
Average scattering cosine for inelastic (solid curve) and elastic (dashed curve) in graphite at room temperature

In [Fig. 7](#), we show the neutron emission curves for the incoherent inelastic component of the scattering at room temperature (293.6 K) featuring the low-energy range. For the low-energy incident neutrons, these curves show upscatter structure with peaks coming from the excitation peaks in the graphite phonon spectrum that are excited at thermal equilibrium at room temperature. For the higher incident energies, the emission spectra show features in the downscatter resulting from exciting phonons corresponding to the peaks in the phonon spectrum. At the highest incident energy, the scattering begins to look more and more like the rectangle-shaped characteristic of high-energy elastic scattering.

Finally, [Fig. 8](#) gives a perspective view of the energy distribution for inelastic scattering in graphite at room temperature.

1.15 Example of Thermal Scattering in Water

The current ENDF/B-VII evaluation for the thermal scattering law for H bound in H_2O is based on recent work done under IAEA auspices (Mattes and Keinert 2005) with some slight modifications. It is assumed that scattering from the oxygen atom can be treated as a free gas of mass 16. The hydrogen binding has a component describing hindered rotations of the water molecules using the phonon frequency distribution shown in [Fig. 9](#) with a weight of 0.4904. The translational modes are treated as the diffusion of water clusters through the liquid with a weight of 0.0192. Finally, there are two discrete oscillator frequencies with energies of 0.205 and 0.436 eV and weights of 0.16347 and 0.326933, respectively.

The scattering law computed from this model using the LEAPR module of NJOY is shown in the next few figures. In [Fig. 10](#), the peak at low α and β comes from the diffusive translations.

Figure 9
The phonon frequency spectrum $\rho(\epsilon)$ used for H in H_2O

Figure 10
 $\hat{S}(\alpha, -\beta)$ for H in H_2O at room temperature plotted versus β for various values of α

For high α , the curves begin to take on the Gaussian shape predicted by the SCT approximation. In between, the peaks in the curves come from the effects of the discrete oscillators.

As discussed above, there are peaks at the main oscillator energies and at various “harmonics,” that is, sums and differences of multiples of the basic energies. Table 1 shows the oscillator energies possible for $\alpha = 1$.

■ **Figure 11**
 $\hat{S}(\alpha, -\beta)$ vs. α for a number of β values

In **Fig. 11** the high-energy cutoff of the energy distribution for the rotational modes is visible, as well as the effect of the discrete oscillators. Note the singularity at low α and β where the slope changes sign. This is an effect characteristic of the translational modes in liquids.

The neutron emission spectra for incoherent inelastic scattering that results from processing this scattering law is shown in **Fig. 12** for several incident energies. For very low incident energies, the neutron gains energy from the rotational modes excited at thermal equilibrium.

■ **Figure 12**
Incoherent inelastic spectra for several incident energies for H in H₂O

■ **Figure 13**
Detailed view of a neutron emission spectrum for inelastic scattering for H in H₂O

For higher energies, it is more probable that the neutron will lose energy, and the effects of exciting translational, rotational, and vibrational modes are visible. The downscatter behavior is shown in more detail in [▶ Fig. 13](#). The sharp peak at $E' = E$ is the quasi-elastic peak coming from the diffusive translations. The next lower hump is from rotational modes, and the other peaks are from vibrational modes.

The integrated cross section is shown in [▶ Figs. 14](#) and [▶ 15](#) for two temperatures. As the incident energy increases, the cross section begins to approach the free-atom value, as predicted

■ Figure 14
The incoherent inelastic cross section for H in H₂O at two temperatures

■ Figure 15
The incoherent inelastic cross section for H in H₂O for higher incident energies showing the static limit (scattering from atoms at rest) and the free-gas cross section

by the theory. In practice, multigroup codes would normally change from the thermal value to the target-at-rest value at some particular break-point energy chosen so that error caused by the additional discontinuity at that energy group was not too significant. Monte Carlo codes normally change from the thermal cross section to the free-gas cross section at some break-point

■ **Table 2**

400	1,289
450	1,305
500	1,324
550	1,344
600	1,367
800	1,473

■ **Figure 16**

The average scattering cosine for H in H₂O compared to the static value for scattering from atoms at rest. The effect of the binding of H in H₂O is to make the scattering more isotropic at thermal energies

energy. There again, it is hoped that the break-point can be made high enough to minimize the adverse effects of the discontinuity.

Another approach that has been used in practice is to shift from the thermal cross section to an SCT cross section, that is, a free-gas cross section at a higher temperature than the ambient value. ➤ [Table 2](#) shows the effective SCT temperatures for H in H₂O. This approach gives a fairly good integrated cross section versus energy above the thermal cutoff of the scattering law calculation, and it gives a good downscatter spectrum, but the upscatter is too large.

The angular behavior of thermal scattering is also of interest. For H bound in H₂O, the hydrogen atom is not as free to recoil as the free atom. This makes it look like it has a higher effective mass, and it causes the scattering to be more isotropic on the average. See ➤ [Fig. 16](#).

■ Figure 17
A perspective view of an angle-energy distribution for H in H₂O

However, as ► Fig. 17 demonstrates, there are still interesting anisotropies seen, especially near $E' = E$, where translational effects are important. ► Figure 18 shows a perspective view of the thermal scattering for H in H₂O.

As the description of the evaluation for H in H₂O demonstrates, ENDF scattering law data are not obtained directly from experimental measurement. That would require more complete differential data than are currently available. Instead, they are modeled based on various kinds of input data ranging from neutron scattering measurements to optical results. The model results are then compared to the available experimental data to see how good a job was done with the evaluation. Examples of the comparison of the modeled thermal cross section for water with experiment are shown in ► Figs. 19 and ► 20. Additional comparisons with differential data are shown in the report on the IAEA evaluation (Mattes and Keinert 2005). The results are fairly good, except around 300–400 meV and below 1 meV. The problem at the lowest energies comes from the failure of the diffusive model. As discussed above, because of the principle of detailed balance, the value of the cross section in this region does not have much influence on the computed flux in a water-moderated system. Therefore, this discrepancy can be accepted for nuclear engineering calculations.

1.16 Example for Thermal Scattering in Heavy Water

The structure of heavy water is similar to that of water, except that the weights on the ends of the arms of the vee are twice as heavy. This shifts the scale of the rotational and vibrational modes.

Figure 18

A perspective view of the isotropic part of the incoherent inelastic scattering from H in H₂O. The variations in the size of the quasi-elastic peak are artifacts of the plotting program

Figure 19

Comparison of the ENDF/B-VII thermal cross section for water at lower incident energies with experimental results for the CSISRS compilation at the the National Nuclear Data Center of the Brookhaven National Laboratory

Figure 20

Comparison of the ENDF/B-VII thermal cross section for water at higher incident energies with experimental results for the CSISRS compilation at the the National Nuclear Data Center of the Brookhaven National Laboratory

The work of Mattes and Keinert (2005) resulted in the temperature-dependent frequency distribution shown in Fig. 21. The two oscillator frequencies are 0.145 and 0.338 eV (they were 0.205 and 0.48 for water – the scaling is the square root of the mass ratio)).

The new feature illustrated by this example is intermolecular coherence. As discussed above, the random orientation of proton spins in water allows us to use an incoherent approximation for the calculation. But the spin of the deuterons in D_2O is zero and this simplification does not apply. Even though heavy water is a liquid, there is still some persistent structure. There tends to be certain characteristic values of the spacing between the molecules, and this is sufficient to preserve some degree of coherence in the scattering. This effect is made more objective by using a “static structure factor,” such as the ones shown in Fig. 22. These were generated assuming a hard core for small distances and a Lennard-Jones potential for larger distances. The scattering function is then computed using the Skold approximation (Skold 1967):

$$S(\alpha, \beta) = (1 - f) S^{inc}(\alpha, \beta) + f s^{inc}(\alpha', \beta) S(\kappa), \quad (65)$$

where

$$f = \frac{\sigma^{coh}}{\sigma^{inc} + \sigma^{coh}}, \quad (66)$$

and

$$\alpha' = \frac{\alpha}{S(\kappa)}. \quad (67)$$

■ Figure 21

Frequency distribution for D in heavy water. The solid line is for a temperature of 293.6 K, and the dashed line is for a temperature of 600 K

■ Figure 22

Static structure factor for D in heavy water. The solid curve is for a temperature of 293.6 K, and the dashed curve is for a temperature of 600 K

The static structure factor for room temperature shows strong structure, but as the temperature increases, the correlations in spacing get smoothed out and the coherence is suppressed. This is evident in the computed cross sections shown in [Fig. 23](#). The dip below 3 meV in the room temperature curve comes from the coherence – it has basically disappeared at 600 K. The curve at the higher temperature looks more like the water cross section.

■ Figure 23

Incoherent inelastic scattering for D in D_2O . The solid curve is for a temperature of 293.6 K, and the dashed curve is for a temperature of 600 K

➤ [Figure 24](#) compares the calculated cross section with experimental data for heavy water extracted from the CSISRS compilation at the NNDC. The match is not perfect, but it is clear that the new evaluation partially accounts for the dip below 2 meV due to intramolecular coherence.

1.17 Example for Thermal Scattering in Zirconium Hydride

Zirconium hydride, ZrH_x , has variable stoichiometry with x near 2. Therefore, it is necessary to treat it as two separate materials, namely, H bound in ZrH , and Zr bound in ZrH . We will only consider the first of those here. The ENDF/B-VII evaluation follows the GA model (Koppel and Houston 1978) with a few small changes. It used a force-constant model to generate the frequency distribution. Because there are two atoms in the unit cell, there are both low-energy acoustic modes and high-energy optical modes. These two parts of the distribution are shown separately in ➤ [Figs. 25](#) and ➤ [26](#).

The optical modes form an isolated peak near 0.14 eV. This comes about because the hydrogen atoms sit in a cage of surrounding zirconium atoms (the variable stoichiometry results from some of these cages being occupied and some being empty). The cage provides a potential well for the hydrogen atom to vibrate in. In quantum language, this is an “Einstein oscillator,” and the spectrum of evenly spaced states in this well lead to interesting oscillations in $S(\alpha, \beta)$, the integrated cross section (➤ [Fig. 27](#)), and the spectra of emitted neutrons (➤ [Fig. 29](#)). ➤ [Figure 28](#) shows the incoherent elastic cross section.

1.18 Using the ENDF/B Thermal Scattering Evaluations

➤ [Table 3](#) gives a summary of the thermal scattering evaluations available in ENDF/B-VII.

■ Figure 24

Comparison of the calculated cross section for heavy water to experiment. The dip due to coherence below 2 meV is partially accounted for by the evaluation. The experimental data are from the CSISRS compilation maintained by the NNDC at BNL. See the compilation for the references

■ Figure 25

Frequency distribution for H in ZrH for the acoustic modes

Note the “Secondary scatterer” column. For H in H₂O, the evaluation only describes the H scattering. The effect of oxygen is to be added on using free-gas scattering. On the other hand, the benzene evaluation (C₆H₆) includes both C and H scattering. Care must be taken to not add on free C scattering in the thermal range.

■ Figure 26

Frequency distribution for H in ZrH for the optical modes. The function is zero from the top of the acoustic modes to the start of the optical modes

■ Figure 27

Incoherent inelastic scattering cross section for H in ZrH. The solid curve is for a temperature of 293.6 K, and the dashed curve is for a temperature of 600 K

A number of these evaluations were prepared for use at neutron scattering centers where moderators are cooled down to make long wavelength neutrons. They are not needed for reactor calculations.

The ENDF/B thermal scattering evaluations are not ready to be used directly in practical reactor calculations. They have to be converted into cross sections in appropriate formats by a nuclear data processing code such as NJOY (MacFarlane and Muir 1994). In NJOY, this is done using the THERMR module. It reads in an ENDF thermal scattering evaluation and produces cross sections versus energy and scattering distributions giving incident energy, secondary energy, probability, and a set of discrete emission cosines for incoherent inelastic scattering. For crystalline coherent scattering, it just produces a cross section with Bragg edges. The angular distribution can be deduced from that in subsequent codes. For incoherent elastic scattering, it produces a cross section and a set of emission cosines. The output from the THERMR module can be passed to GROUPT to be formatted for multigroup codes or to ACER to be formatted for the MCNP continuous energy Monte Carlo code.

2 Neutron Thermalization

2.1 Introduction

In nuclear reactors, neutrons are born at million electron-volts (MeV) energies, and they slow down (are “moderated”) by elastic and inelastic collisions with the materials in the reactor until they reach the thermal range below a few electron-volts (eV). In this range, in addition to losing energy in collisions, they can also gain energy by collisions with atoms and molecules in thermal motion. After some time, the distribution of the neutrons will come into equilibrium with the thermal motion of the atoms or molecules of the material and show a Maxwellian-like shape. Fission reactions caused by this distribution of neutrons will lead to the production of more neutrons at high energies, continuing the thermalization process. In addition to causing fission, the thermal neutrons can suffer absorption losses, and neutrons can be lost by leaking out of the system. These absorptions and leakages can affect the shape of the equilibrium neutron spectrum.

In this section, we will consider the process of neutron thermalization in the region below a few eV, how to compute the equilibrium neutron spectrum, and the various influences on the shape of the equilibrium spectrum. We will first demonstrate this by direct Monte Carlo simulation of the thermalization process, and then move on to methods based on solving the transport equation for thermal neutrons (the Boltzmann equation) using multigroup techniques.

2.2 Monte Carlo Simulations of Neutron Thermalization

The Monte Carlo method is based on following the histories of many particles using a random selection of the reactions that the neutrons go through between their production in a fission event, and their eventual death by absorption or leakage from the system. There are a number of Monte Carlo codes available that perform well for thermal neutrons. The examples in this section use MCNP (2003).

As a first example, let us consider a cylindrical steel tank partly filled with a solution of highly enriched uranium nitrate in water. This particular case is called HIGH-ENRICHED-SOLUTION-THERMAL-42-5 (or shortly HST42-5) in the International Criticality System Benchmark Experiment Program (ICSBEP) handbook (Briggs et al. 2004). Using cross sections from ENDF/B-VII (Tuli et al. 2006) and running this assembly for 50 million histories gives a predicted multiplication k_{eff} of 1.00019 with an estimated standard deviation of 0.00004 as compared to an experimental prediction of 1.0000 ± 0.0034 .

What this means is that the production rate of neutrons by fission is almost exactly balanced by the loss rate of neutrons to absorption and leakage from the system, or

$$k_{\text{eff}} = \frac{\bar{\nu}\sigma_f\phi}{(\sigma_f + \sigma_{n\gamma})\phi + L}, \quad (68)$$

where these quantities stand for integrals over energy and space, $\bar{\nu}$ is the number of neutrons produced per fission, σ_f is the fission cross section, $\sigma_{n\gamma}$ is the capture cross section, L is the leakage rate from the system, and ϕ is the neutron flux. In practice, this equation is a little too simple. The reactions $(n, 2n)$ and $(n, 3n)$ also produce neutron multiplication, and there are also other less-common reactions that produce neutron multiplication. MCNP and many of

the multigroup transport codes handle this by reducing the absorption to compensate for the increased production

$$k_{\text{eff}} = \frac{\bar{\nu}\sigma_f\phi}{(\sigma_f + \sigma_{n\gamma} - \sigma_{n2n} - 2\sigma_{n3n})\phi + L}. \quad (69)$$

MCNP normalizes itself so that the denominator of this equation is one. Some other transport codes use the full production in the numerator, getting

$$k_{\text{eff}} = \frac{(\bar{\nu} + 2\sigma_{n2n} + 3\sigma_{n3n})\phi}{(\sigma_f + \sigma_{n\gamma} + \sigma_{n2n} + \sigma_{n3n})\phi + L}. \quad (70)$$

These two different definitions are equivalent when k_{eff} is not too far from unity.

The MCNP result for the HST42-5 case gives $L = 0.032446$; therefore, the leakage is fairly small for this case. It is strongly thermalized. **►** *Figure 30* shows the computed flux (solid curve) compared to a Maxwellian at room temperature and the effective contribution due to slowing down from higher energies (dotted curves). The numbers plotted in this figure are the hits in MCNP tally bins defined logarithmically with 50 bins per decade; therefore, they are proportional to “flux per unit lethargy.” The term “lethargy” is often used in reactor physics. It is defined as

$$\text{lethargy} = \exp\left[\frac{10 \text{ MeV}}{E}\right]. \quad (71)$$

It increases as the neutron slows down. The flux per unit lethargy is equivalent to $E * \phi(E)$. Because the epithermal slowing down in a system like this gives a shape close to $1/E$, the flux per unit lethargy plots are approximately flat in the epithermal region.

■ *Figure 30*

Calculated flux for the HST42-5 critical assembly (solid curve). The dotted curves show the theoretical Maxwellian flux and nominal $1/E$ source due to slowing down from higher energies

■ **Figure 31**
 Calculated flux for the LCT6-6 critical assembly. The average over the lattice region is shown

For a more realistic example, we consider the assembly called LCT6-6. This one has a 19×19 square lattice of 2.6%-enriched uranium oxide rods with aluminum cladding placed in a tank of water. The water outside the lattice acts as a reflector. The calculated k_{eff} using ENDF/B-VII cross sections is 1.00047 ± 0.00010 as compared to the evaluated model k_{eff} of 1.0000 ± 0.0020 .

► **Figure 31** shows the flux in the lattice region (not including the water reflector).

The region around each fuel rod can be defined as a “cell,” where each square cell contains a fuel pin, the aluminum cladding, and the associated water. With MCNP, we can calculate (or “tally”) the flux in the fuel pin and the flux in the associated water separately as averages over the entire lattice. The result is shown in ► **Fig. 32**. At high energies, the flux in the pin is higher than the flux in the water because of the fission neutron source there. At the middle energies, we see strong dips in the fuel flux from absorption resonances, but the water flux is smoother. The $1/E$ shape we saw in the previous example is modified somewhat because of the losses to absorption in the fuel. At thermal energies, we see typical Maxwellian flux shapes from thermalization, but the thermal flux in the fuel is depressed because of the absorption by capture and fission.

► **Figure 33** shows an expanded view of the thermal region. The solid line is the water flux, and the dotted lines are the theoretical Maxwellian and slowing-down shapes. It is clear that the water flux matches the expected Maxwellian shape quite well. However, the fuel flux (dashed curve) has been depressed by the absorption from capture and fission, and its shape is been “hardened” somewhat.

► **Figure 34** shows an expanded view of the resonance region. The slowing down in the water shows a slightly harder shape than $1/E$ because of the losses to absorption in the fuel, and also because some effect of the strong absorption resonances in the fuel shows up as dips in the water flux. The absorption dips in the fuel are very large and lead to the “self-shielding” effects that will be discussed below.

In order to get a better idea of the details of thermalization in a lattice like LCT6-6, we consider an infinite lattice of LCT6 pin cells. With MCNP, this is represented as a single pin

■ Figure 32

Calculated flux for the LCT6-6 critical assembly showing water flux (solid) and fuel flux (dashed)

■ Figure 33

Expanded view of the thermal region flux for the LCT6-6 critical assembly showing water flux (solid), fuel flux (dashed), and the theoretical Maxwellian and slowing down shapes (dotted)

of fuel and clad surrounded by water in a square cross section with reflecting surfaces and extended vertically with reflecting ends. Of course, without the leakage, this cell is supercritical with $k_{\infty} = 1.37577$.

➤ *Figure 35* shows the net current out of the pin (actually at the surface of the clad) into the water moderator. Note that the current is positive at high energies where the fission neutron

■ Figure 34

Expanded view of the resonance region flux for the LCT6-6 critical assembly. The solid curve shows the flux in the cell water, and the dashed curve shows the flux in the fuel pin

■ Figure 35

Net current out of pin into water for an infinite lattice of LCT6 pin cells showing fission neutrons entering the water at high energies, slowing down, and reentering the pin at low energies

are born. Many of the fission neutrons are leaking from the fuel pin into the moderator. They then slow down quickly to thermal energies and reenter the fuel pin (negative current) to cause new fissions or to be killed by capture. In the epithermal range, there are occasional negative dips in the current where neutrons are being drawn out of the moderator by strong absorption

■ Figure 36

Flux vs. radius in the fission peak around 2 MeV (solid) and the thermal dip around 0.05 eV (dashed). The vertical dotted lines show the location of the clad

resonances in the fuel (especially around 6.7 eV). At higher energies, you can see the effects of the aluminum and oxygen resonances.

► *Figure 36* shows the radial shape of the flux in the fission peak around 2 MeV and in the thermal dip around 0.05 eV. The fission source is slightly peaked in the center and decreases as you move out into the moderator due to the leakage into the moderator. The thermal shape is depressed in the center of the pin due to absorption from fission and capture. More dramatically, ► *Fig. 37* shows the strong depression in the center of the pin due to absorption in the 6.7 eV capture resonance of U-238. The mean free path of the neutrons near the center of the resonance is very small, and they do not penetrate very far into the pin. Only a small fraction of the U-238 in the pin actually contributes to the absorption, and this is the real source of the dip in the flux seen in ► *Fig. 34*. The U-238 in the center of the pin is “self-shielded” from the neutrons in the moderator. Energy self-shielding and spatial self-shielding are seen to closely related.

This example helps to explain why a heterogeneous arrangement of fuel pins in a moderator is used in thermal reactors. Having the neutrons slow down in a moderator outside the fuel pins allows most of the neutrons to avoid being absorbed in the strong resonances of U-238, thereby allowing them to reach thermal energies where they can continue the fission chain reaction. The HST42 example could reach criticality using a homogeneous arrangement for fuel and moderator because the fuel was highly enriched in U-235, making the U-238 absorptions less of a problem. The LCT6 fuel is a low-enriched material (2.6% U-235) and U-238 absorption must be well managed to design an effective reactor.

2.3 Discrete Ordinates Methods

The examples above used simulations of the real physical process going on during thermalization, following the neutron as it bounced around the assembly losing and gaining energy until

■ Figure 37

Flux vs. radius in the 6.7 eV resonance (solid) and below the resonance at 3 eV (dashed). The vertical dotted lines show the location of the clad

it came into equilibrium and was lost by absorption or escape from the system. An alternate approach is to solve the Boltzmann transport equation, which describes the balance of neutrons in a region of space and energy. There are a number of highly developed computer codes that solve this equation using the multigroup “discrete ordinates,” or S_N , method. An example of this is PARTISN (Alcouffe et al. 2005) from Los Alamos.

2.3.1 S_N Theory

The S_N transport codes solve the equation (Bell and Glasstone 1970)

$$\mu \frac{\partial}{\partial x} \phi_g(\mu, x) + \sigma_g^{S_N}(x) \phi_g(\mu, x) = \sum_{\ell=0}^N P_\ell(\mu) \sum_{g'} \sigma_{\ell g \leftarrow g'}^{S_N}(x) \phi_{lg'} + S_g(\mu, x), \quad (72)$$

where one-dimensional plane geometry has been used for simplicity, μ is the scattering cosine, x is position, $\phi(\mu, x)$ is the angular flux for group g , ϕ_{lg} is the Legendre flux for group g , $P_\ell(\mu)$ is a Legendre polynomial, and $S_g(\mu, x)$ is the external and fission source into group g . The cross sections in (72) must be defined to make ϕ_g as close as possible to the solution of the Boltzmann equation. As shown in the reference, the multigroup Boltzmann equation can be written in the P_N form:

$$\mu \frac{\partial}{\partial x} \psi_g(\mu, x) + \sum_{\ell=0}^N P_\ell(\mu) \sigma_{\ell g}^{P_N}(x) \psi_{\ell g} = \sum_{\ell=0}^N P_\ell(\mu) \sum_{g'} \sigma_{\ell g \leftarrow g'}^{P_N}(x) \psi_{\ell g'} + S_g(\mu, x), \quad (73)$$

where the P_N cross sections are given by the following group averages:

$$\sigma_{\ell t g}^{P_N} = \frac{\int_g \sigma_t(E) W_\ell(E) dE}{\int_g W_\ell(E) dE}, \quad (74)$$

and

$$\sigma_{\ell g \leftarrow g'}^{P_N} = \frac{\int_{g'} dE' \int_g dE \sigma_\ell(E' \rightarrow E) W_\ell(E')}{\int_{g'} dE' W_\ell(E')}. \quad (75)$$

In these formulas, $\sigma_t(E)$ and $\sigma_\ell(E' \rightarrow E)$ are the basic energy-dependent total and scattering cross sections, and $W_\ell(E)$ is a weighting flux that should be chosen to be as similar to ψ as possible.

So “there’s the rub.” To solve for the unknown flux, we have to have a good estimate of the flux to start with! This is not a serious problem for thermalization. As we saw in [Fig. 30](#), the thermalized flux is well represented by a Maxwellian flux shape with a $1/E$ slowing-down contribution. This will almost always be the case for a practical thermal reactor. To keep good neutron economy, it is important not to lose too many neutrons to unproductive leakage or capture, which tends to preserve the well-thermalized flux shape shown in the picture. We can use the Maxwellian flux shape with a slowing-down contribution for the weighting function $W_\ell(E)$. It is still necessary to divide the thermal range into a number of energy groups to account for deviations from the simple Maxwell plus slowing-down shape, such as the hardening seen in [Fig. 33](#), and especially around the break between the two functions or where strong resonances may occur (e.g., the 1 eV resonance of Pu-240). The venerable THERMOS-LASER structure used 35 groups between 0.00253 and 1.855 eV with velocity spacing over most of the range and extra coverage around 1 eV. The widely used WIMS structure uses 42 thermal groups between 10^{-5} and 4 eV. Because of the increased capabilities of modern computers, many newer systems use even more thermal groups.

2.3.2 Transport Corrections

When (73) is compared with (72), it is evident that the S_N equations require

$$\sigma_{\ell g \leftarrow g'}^{S_N} = \sigma_{\ell g \leftarrow g'}^{P_N} \quad \text{for } g' \neq g, \quad (76)$$

and

$$\sigma_{\ell g \leftarrow g}^{S_N} = \sigma_{\ell g \leftarrow g}^{P_N} - \sigma_{\ell t g}^{P_N} + \sigma_g^{S_N}, \quad (77)$$

where $\sigma_g^{S_N}$ is not determined. The choice of $\sigma_g^{S_N}$ gives rise to a “transport approximation” and various recipes are in use. It is convenient to write

$$\sigma_{\ell g \leftarrow g}^{S_N} = \sigma_{\ell g \leftarrow g}^{P_N} - \left(\sigma_{\ell t g}^{P_N} - \sigma_{o t g}^{P_N} \right) - \Delta_g^N, \quad (78)$$

and

$$\sigma_g^{S_N} = \sigma_{o t g}^{P_N} - \Delta_g^N. \quad (79)$$

The term in parentheses corrects for the anisotropy in the total reaction rate term of the Boltzmann equation, and Δ_g^N can be chosen to minimize the effects of truncating the Legendre expansion at $\ell = N$. Some recipes for doing this follow:

Consistent-P approximation:

$$\Delta_g^N = 0, \quad (80)$$

Inconsistent-P approximation:

$$\Delta_g^N = \sigma_{otg}^{P_N} - \sigma_{N+1,tg}^{P_N}, \quad (81)$$

Diagonal transport approximation:

$$\Delta_g^N = \sigma_{otg}^{P_N} - \sigma_{N+1,tg}^{P_N} + \sigma_{N+1,g \leftarrow g}^{P_N}, \quad (82)$$

Bell–Hansen–Sandmeier (BHS) or extended transport approximation:

$$\Delta_g^N = \sigma_{otg}^{P_N} - \sigma_{N+1,tg}^{P_N} + \sum_{g'} \sigma_{N+1,g' \leftarrow g}^{P_N}, \quad (83)$$

and

Inflow transport approximation:

$$\Delta_g^N = \sigma_{otg}^{P_N} - \sigma_{N+1,tg}^{P_N} + \frac{\sum_{g'} \sigma_{N+1,g \leftarrow g'}^{P_N} \phi_{N+1,g'}}{\phi_{N+1,g}}. \quad (84)$$

The first two approximations are most appropriate when the scattering orders above N are small. The inconsistent option removes most of the delta-function of forward scattering introduced by the correction for the anisotropy in the total scattering rate and should normally be more convergent than the consistent option. For libraries produced with an ℓ -independent flux guess and in the absence of self-shielding, the difference between “consistent” and “inconsistent” vanishes.

The diagonal and BHS recipes make an attempt to correct for anisotropy in the scattering matrix and are especially effective for the forward-peaked scattering normally seen for high neutron energies. The BHS form is most often used, but the diagonal option can be substituted when BHS produces negative values, which is often the case in the thermal range.

The inflow recipe makes the $N+1$ term of the P_N expansion vanish, but it requires a good knowledge of the $N+1$ flux moment from some previous calculation. Inflow reduces to BHS for systems in equilibrium by detail balance (i.e., the thermal region). The diffusion approximation obtained using the inflow formula is equivalent to a P_1 transport solution.

These corrections require data from the $(N+1)$ -th Legendre moments of the cross sections to prepare a corrected N -table set.

2.3.3 Fission Source

The source of fission neutrons into a group is given by

$$S_g = \sum_{g'} \sigma_{fg \leftarrow g'} \phi_{0g'}, \quad (85)$$

where $\sigma_{fg \leftarrow g'}$ is the fission matrix computed from the energy-dependent fission spectra given in the ENDF-format evaluation. However, most existing transport codes do not use this matrix form because the upscatter is expensive to handle and a reasonably accurate alternative exists. Except for relatively high neutron energies, the spectrum of fission neutrons is only weakly dependent on initial energy. Therefore, the fission source can be written as

$$S_g = \chi_g \sum_{g'} \bar{v}_{g'} \sigma_{fg'} \phi_{0g'}, \quad (86)$$

where \bar{v}_g is the fission neutron yield, σ_{fg} is the fission cross sections, and χ_g is the average fission spectrum, which can be defined by

$$\chi_g = \frac{\sum_{g'} \sigma_{fg \leftarrow g'} \phi_{0g'}}{\sum_{g'} \bar{v}_{g'} \sigma_{fg'} \phi_{0g'}}, \quad (87)$$

where the fission neutron production rate can also be written as

$$\sum_{g'} \bar{v}_{g'} \sigma_{fg'} \phi_{0g'} = \sum_g \sum_{g'} \sigma_{fg \leftarrow g'} \phi_{0g'}. \quad (88)$$

Clearly, χ_g as given by (87) depends on the flux in the system of interest. The dependence is weak except for high incident energies, and a rough guess for ϕ_{0g} usually gives an accurate spectrum. When this is not the case, a sequence of calculations can be made, using the flux from each step to improve the χ_g for the next step.

The matrix as described above represents the prompt part of fission only. Steady-state (SS) fission is obtained using two auxiliary pieces of data: delayed \bar{v} and delayed χ . Therefore,

$$\bar{v}_{g'}^{SS} \sigma_{fg'} = \sum_g \sigma_{fg \leftarrow g'} + \bar{v}_{g'}^D \sigma_{fg'}, \quad (89)$$

and

$$\chi_g^{SS} = \frac{\sum_{g'} \sigma_{fg \leftarrow g'} \phi_{0g'} + \chi_g^D \sum_{g'} \bar{v}_{g'}^D \sigma_{fg'} \phi_{0g'}}{\sum_g \sum_{g'} \sigma_{fg \leftarrow g'} \phi_{0g'} + \sum_{g'} \bar{v}_{g'}^D \sigma_{fg'} \phi_{0g'}}. \quad (90)$$

2.3.4 The Eigenvalue Iteration

In order to solve (72), it is converted into an eigenvalue problem by multiplying the fission source term by a factor k . Starting with an initial estimate for k (such as $k = 1$), the flux is computed. This is called the “inner iteration.” This flux is then used to compute a new value for k , and a new flux is computed. This is called the “outer iteration.” It is continued until a sufficiently converged value for k is obtained. The outer iteration is needed to adjust the fission source and the thermal upscatter source. Referring back to the discussion of (69) and (70), we see that this method produces the value of k_{eff} defined for fission productions.

2.3.5 S_N Data Requirements

The data required for an S_N flux solution using (72) have been shown to be

$$\sigma_g, \sigma_{\ell g \leftarrow g'}, \bar{v}_g \sigma_{fg}, \text{ and } \chi_g,$$

where the superscript S_N has been omitted for simplicity. The S_N codes also traditionally use a particle-balance cross section (often loosely called “absorption”) defined by

$$\sigma_{ag} = \sigma_g - \sum_{g'} \sigma_{0g' \leftarrow g}. \quad (91)$$

This quantity can also be computed by adding all the absorption reactions [(n, γ), fission, (n, p), (n, α), etc.] and subtracting ($n, 2n$), twice ($n, 3n$), and so on. The two methods are formally equivalent, except that small numerical differences due to cross-section processing lead to unreasonable values for σ_{ag} , as computed from (91), when σ_{ag} is small in relation to σ_g . In such cases, σ_{ag} can be replaced by the value from the direct calculation, and the σ_g position of the transport table is adjusted accordingly. Note that σ_{ag} can be negative if more particles are produced by (n, xn) reactions than are absorbed. Note that σ_a is the quantity that appears in the denominator of the fission-based definition for k_{eff} (see (69)).

When the flux calculation is complete, it is often necessary to compute some response such as heating, radiation damage, gas production, photon production, or dose to tissue. Therefore, S_N codes allow for reading several response-function edit cross sections, σ_{Eg} .

The original S_N codes read χ as a special array, and the cross sections were arranged into “transport tables” by “position” as shown in  Table 4. Note that the positions containing scattering data give all the source groups that scatter into the same final or “sink” group. Even the newer codes retain many features of this structure. We call this “DTF format” in honor of the pioneering discrete ordinates code (Lathrop 1965).

A transport table like this is required for each group, Legendre order, and material. The tables may be “material-ordered” or “group-ordered.” Material ordering is the natural result of preparing a library from evaluated nuclear data. The tables are written onto a library with the outermost loop being material, then Legendre order, and then group as the inner loop. However, group ordering is the way the cross sections are needed in the codes. The S_N equations are solved by sweeping down from group 1 to the lower energy groups, so cross sections for all materials and orders are needed for each group in sequence. The library is ordered with group as the outermost loop, then Legendre order, and then material.

2.3.6 Example for HST42-5

An S_N model for HST42-5 can be constructed using two-dimensional r - z geometry, including the vessel and the solution level inside the vessel. Effective cross sections can be constructed (see below) including the appropriate thermal scattering data for H in H_2O and self-shielded cross sections in the resonance range. When PARTISN is used to run the problem, it finds a k_{eff} value of 0.99979 as compared to 1.00019 from MCNP, which is satisfactory agreement. This calculation was done with 187 groups; P_3 , S_{16} , 55 radial intervals; and 115 axial intervals.

 Figure 38 shows the flux at an energy of 0.05 eV (or $2kT$, the maximum of the flux per

unit lethargy) vs. the radial coordinate r and the axial coordinate z . The cosine shape of the axial distribution is typical; it is called the “fundamental mode” shape. ➤ *Figure 39* shows a view of the HST42-5 flux per unit lethargy vs. energy and radius at the axial midpoint of the solution region. Just as for the MCNP result shown in ➤ *Fig. 31*, we see the fission source at high energies, the $1/E$ slowing down region, and the thermal peak at low energies.

➤ *Table 5* compares the reaction-rate balances for PARTISN and MCNP. At this point, it might be well to remind ourselves that a k calculation does not determine the actual values of the flux or reaction rates; a reactor can be critical at a wide range of operating power values. The normalization in a table like this is arbitrary. The default normalization for both PARTISN and MCNP is to make the effective loss rate (i.e., the denominator of (69)) equal to one. The entry “ (n, xn) ” in the table is the amount subtracted from capture + fission to get the effective absorption. Specifically, it is $(n, 2n) + 2(n, 3n) + \dots$. As a counterexample, the TART Monte Carlo code (Cullen 2005) normalizes itself so that the total production $v\sigma_f + 2(n, 2n) + 3(n, 3n) + \dots$ is one (see the numerator of (70)).

2.3.7 Preparing S_N Cross-Section Data

Normal multigroup cross-section data need some extra processing to be used for a calculation like this HST42-5 example. The microscopic cross sections need to be assembled into macroscopic cross sections that include the shielding effects on the resonance features of the actinides

■ **Table 5**
Reaction balances for HST42-5

Reaction rate	PARTISN	MCNP
$\nu\sigma_f$	0.99979	
Leakage	0.032556	0.032446
Absorption	0.96744	0.96753
Losses	1.00000	0.99998
Fission		0.41039
$(n,\chi n)$		0.00001

in the solution. In addition, the normal low-energy scattering cross section for H-1 has to be modified to include the H in H₂O thermal scattering, and the other materials need to be modified to include thermal free-gas scattering. One way to do this additional processing is with the TRANSX code (MacFarlane 1992). TRANSX works with multigroup libraries produced by NJOY in MATXS format. The libraries provide tables of self-shielded microscopic cross sections vs. background cross section and temperature (more on these kinds of self-shielded cross sections will be found below). TRANSX determines the background cross section using the mixture and geometry information provided by the user and interpolates for the effective cross sections. The libraries contain normal target-at-rest down scatter at low energies, and they also contain tables of the bound and free thermal-scattering cross sections with upscatter. TRANSX will replace the target-at-rest values with the proper thermal data as specified by the user. The code will also prepare the fission source in the χ and $\nu\sigma_f$ representation, using a user-supplied weighting flux to get the good χ vector. This feature can be used to iterate for an improved χ for cases where the library weighting function does not match the computed flux very well. This problem is common for fast critical assemblies. Other features provided by TRANSX include group collapse, cell homogenization, coupled sets, adjoint cross sections, and data for the multigroup mode of MCNP. Output can be prepared in formats adaptable to a number of popular multigroup transport codes.

2.3.8 Example for an Infinite Pin-Cell Lattice

With S_N codes, the normal way to simulate an infinite pin-cell lattice is to convert the square cells with reflective boundaries into cylindrical shells with white boundary conditions. This allows us to use a one-dimensional calculation. That runs very fast with PARTISN, giving $k_\infty = 1.38158$ (as compared to the MCNP value of 1.37577). The result of that calculation is region fluxes for 187 groups in the fuel, clad, and moderator. These fluxes can be used in a second TRANSX run to perform a cell homogenization and group collapse. A simplified result of such a calculation is shown in ► [Table 6](#). These macroscopic effective cross sections can then be used in a large-scale calculation for the entire reactor using transport, diffusion, or collision-probability methods.

The TRANSX self-shielding calculation for the infinite lattice also included a Dancoff correction. When a neutron escapes from the fuel pin in a lattice, there is a possibility that it will reach another fuel pin before scattering from the moderator material. In that case, it would be as

■ **Table 6**
Two-group macroscopic cross sections for a pin cell in an infinite lattice

Reaction	Group 1 3.92 eV–20 MeV $\sigma \text{ cm}^{-1}$	Group 2 1e-5 eV–3.92 eV $\sigma \text{ cm}^{-1}$
nf	1.4509-3	2.1708-2
ng	6.3808-4	1.8059-2
abs	2.2180-3	3.9767-2
nusigf	4.0130-3	5.2894-2
Total	2.1677-1	4.5865-1

if it did not escape from the fuel pin at all. There is a reduction in the effective escape probability. TRANSX handles that effect with several possible Dancoff correction options, for example, pins in a square lattice. Another improvement to this calculation is possible using PARTISN. It is possible to simulate the cosine “fundamental mode” axial shape seen in  Fig. 38 by imposing a “buckling.” This simulates axial leakage from the top and bottom of the lattice of cells, leaving the effective radius or x - y extent of the entire core large (zero leakage).

2.3.9 Monte Carlo vs. Multigroup

From these examples, we can begin to appreciate the different advantages and disadvantages of the Monte Carlo and multigroup methods. The Monte Carlo method uses good physics for slowing down and resonance reactions, and it allows for a very complete geometry representation. However, it is a statistical calculation, and it is not so good for looking at small differences or for getting smooth detailed distributions like those shown in  Fig. 38. The Monte Carlo calculations are also relatively expensive. On the other hand, the multigroup methods are relatively fast, and they are useful for looking for the effects of small differences in materials or geometry. They are good for getting smooth distributions of things like flux or nuclear heating over the geometry. However, they work best for simple geometries (requiring some approximation of the actual arrangements). The self-shielding effects from the resonances are not handled as accurately as with Monte Carlo.

In the end, it has been the speed advantages of the multigroup methods that have kept them prominent in reactor core calculations. This is especially important when time-dependent fuel burnup and fission-product accumulation are considered – in these cases many time steps are required, making the Monte Carlo approach even more expensive.

2.4 Collision Probability Methods

Collision probability methods are based on the integral form of the transport equation. As used above, the transport equation was of integro-differential form. As shown in Bell and Glasstone (1970), standard mathematical methods can be used to convert that form of the equation

into integral form. For our purposes, let us limit ourselves to the time-independent case with isotropic scattering and source. Then

$$\phi(\mathbf{r}, E) = \int \frac{\exp[-\tau(E, \mathbf{r}' \rightarrow \mathbf{r})]}{4\pi|\mathbf{r} - \mathbf{r}'|^2} \times \left[\int \sigma(\mathbf{r}', E \rightarrow E) \phi(\mathbf{r}', E') dE' + Q(\mathbf{r}', E) \right] dV', \quad (92)$$

where $\tau(E, \mathbf{r}' \rightarrow \mathbf{r})$ is the optical path length from \mathbf{r}' to \mathbf{r} (i.e., the number of mean free paths, or the integral of $\sigma(\mathbf{r}, E)$ along the path from \mathbf{r}' to \mathbf{r}). Clearly, the quantity in square brackets is the source into energy E and volume element dV' around \mathbf{r}' due to scattering from other energies and external contributions. The factor in the first line is the attenuation of that while traveling from \mathbf{r}' to \mathbf{r} . In practice, the energy range is divided into a number of energy groups within which the cross section can be taken as constant, and the geometry is divided into a number of subregions in which the flux and source can be taken as constant. The result is

$$\phi_{g,i} = \frac{1}{V_i \sigma_{g,i}} \sum_j V_j P_{g,j \rightarrow i} \left[\sum_{g'} \sigma_{g' \rightarrow g,j} \phi_{g',j} + Q_{g,j} \right], \quad (93)$$

where $P_{g,j \rightarrow i}$ is the probability that a neutron born in group g and subregion j will suffer its next collision in subregion i . This is the collision probability matrix

$$P_{g,j \rightarrow i} = \frac{\sigma_{g,i}}{V_j} \int_{V_i} \int_{V_j} \frac{\exp[-\tau(E_g, \mathbf{r}' \rightarrow \mathbf{r})]}{4\pi|\mathbf{r} - \mathbf{r}'|^2} dV dV'. \quad (94)$$

The limitation to isotropic scattering can be alleviated by using a transport correction similar to the ones described above in connection with the S_N method.

Collision probability methods have been widely used for core physics calculations. An early example was the THERMOS code (Honek 1961), which could compute CP matrices for plate and pin-cell geometries in the thermal region. For a pin cell, the fuel, clad, and moderator regions were subdivided into a number of parts in order to handle the spatial self-shielding well. The resulting flux was then used to homogenize the cell and collapse to a coarser group structure. These numbers could then be used by simpler methods, such as diffusion, to complete the calculation for the whole reactor.

In comparing CP and S_N methods, we see that the CP approach can handle very complex geometries, while the S_N method works best when it can work with simpler geometries, such as slab, sphere, or cylindrical r - z . However, the CP methods couples every cell in the calculation to every other cell. With N subregions and G groups, the problem grows like $N^2 G$. This makes the CP method impractical for representing a reactor in all its awful detail. However, it has been used for quite complex fuel bundles in the past. To handle larger problems, it makes sense to use the CP method on a fuel element or cluster, homogenize, and collapse. Then another CP calculation can be made using the effective fuel element cross sections for the core region and modeling the radial and axial components as a CP matrix.

2.5 Size Effects in Thermalization

Full thermalization requires multiple collisions between the neutrons and the material to bring the neutrons into equilibrium at the temperature of the material. This implies that the system

■ **Table 7**

Mean free paths near 1 meV (10^{-3} eV) for several moderators

Moderator material	Mean free path near 1 meV
Water	0.045 cm
Heavy water	0.5 cm
Graphite	25 cm

■ **Figure 40**

Effect of size on thermalization in graphite. The flux in spheres with radii of 30, 90, 150, and 250 cm are shown (some curves were shifted vertically for clarity)

must be large with respect to the mean free path of the neutrons in the material. ➤ [Table 7](#) shows the mean free paths at energies around 1 meV (10^{-9} MeV) for three common moderators.

➤ [Figure 40](#) shows fluxes computed using MCNP for spheres of graphite of various sizes. At a radius of 250 cm, the flux is nearly thermalized, showing the typical Maxwellian shape. However, for a radius of 30 cm, the flux shows features coming from the cross-section shape. The Bragg edges previously seen in ➤ [Fig. 5](#) are evident.

It is apparent that systems with sizes of ten mean free paths or more will produce a Maxwellian flux shape independent of the details of the shape of the scattering cross section. This is a consequence of the detail balance as discussed in ➤ [Sect. 1.6](#). It is also the reasoning behind the statement at the end of ➤ [Sect. 1.15](#) claiming that the problem that theory has in matching the experimental cross section below 1 meV (see ➤ [Fig. 19](#)) is not too important in practice. The part of any capture or fission reaction rate that comes from the millivolt region will not depend on the detailed shape of the scattering cross section there.

In heavy water, the ENDF/B-VII evaluation shows a dip in the scattering cross section below about 3 meV coming from intermolecular coherence (see ➤ [Fig. 23](#)). This effect was not included in earlier ENDF/B versions. The original GA evaluators (Koppel and Houston 1978)

said, "... integral quantities like the thermal neutron spectra can actually be predicted quite accurately with an incoherent model." This is born out by MCNP calculations of the flux in spheres of heavy water, which show a Maxwellian shape at low energies even at relatively small sizes. The effect of the coherence dip is not visible.

3 Steady-State Slowing Down

3.1 Introduction

If a nuclear assembly is driven by a steady-state source, the neutrons will slow down and become thermalized. In this section, we will summarize the elastic and inelastic cross sections that are responsible for the slowing down, study the spectra of the downscattered neutrons, and discuss how resonance structure affects slowing down.

3.2 Slowing-Down Cross Sections

The important materials for neutron slowing down are the ones that occur in large concentrations in nuclear systems. We will concentrate on H-1, H-2, O-16, C-nat, and U-238 in this section. The simplest materials are H-1 and H-2. They only support elastic scattering and (n, γ) capture.  [Figure 41](#) shows those cross sections as obtained from the tabulated data in the ENDF/B-VII evaluations for the two isotopes. The elastic cross sections for both materials are basically constant over much of their energy range, and the capture cross sections are small with a $1/v$ energy dependence (mostly). This makes materials containing H-1 or H-2 very useful as neutron moderators. The angular distributions in the center-of-mass (CM) system are nearly isotropic for the lower energies, gradually becoming somewhat backwardly peaked at the higher energies. In the ENDF/B-VII file for H-1, the angular distribution in the CM is represented using an expansion in Legendre polynomials

$$f(E, \omega) = \sum_{\ell} \frac{2\ell + 1}{2} a_{\ell}(E) P_{\ell}(\omega), \quad (95)$$

where ω is the scattering cosine in the CM system and ℓ is the Legendre order varying from zero to some stated maximum. The angular distribution for H-2 is given as a set of tabulations of $f(E, \omega)$ vs. ω . The center-of-mass motion causes the angular distributions in the laboratory system to be forward-peaked. At the lower energies, the average cosine for elastic scattering goes like $2/3A$, where A is the ratio of the scatterer mass to the neutron mass. Thus, the nominal $\bar{\mu}$ is 0.667 for H-1 and 0.334 for H-2. Here, we use the symbol μ for the scattering cosine in the laboratory system.

For O-16, the elastic cross section has the additional complication of resonant behavior at the higher energies, as shown in  [Fig. 42](#). The (n, γ) capture cross section for O-16 is extremely small, and it is not plotted in the figure. However, at higher energies, an (n, α) channel opens, and this absorption cross section, although small, does have some effect on criticality in water systems. O-16 also has the additional complication of inelastic scattering, as shown in  [Fig. 43](#). Only the first four inelastic levels are shown. The deep dip in the elastic scattering is a cross-section "window." This kind of feature can lead to additional leakage because the mean free path

■ Figure 41

Elastic and capture cross sections for H-1 (solid) and H-2 (dashed) from ENDF/B-VII

■ Figure 42

Elastic (solid) and (n, α) (dashed) cross sections for O-16 from ENDF/B-VII

is very large in the window. The CM angular distribution for elastic scattering is fairly isotropic up to the 10 keV region. Because of the higher atomic mass, the laboratory scattering angular distribution is fairly isotropic with a $\bar{\mu}$ of 0.042.

The total cross section for U-238 is shown in [Fig. 44](#). For heavy materials like this, the resonance behavior becomes pronounced. The range from 10^{-5} eV to 20 keV is the “resolved resonance region” (RRR), the range from 20 to 149 keV is the “unresolved resonance region” (URR), and the range above 149 keV is the “fast region.”

■ Figure 43

The first four levels of inelastic scattering for O-16 from ENDF/B-VII (in increasing order of excitation energy, solid, dash, chain-dash, dotted)

■ Figure 44

The total cross section of U-238 at room temperature

➤ Figure 45 shows the cross sections for U-238 in the fast range. (The $(n, 3n)$ reaction, which is open above 11.33 MeV, was omitted.) The inelastic reaction includes 40 discrete inelastic channels and a continuum inelastic channel. Note that U-238 is a threshold fissioner – there is only a small amount of subthreshold fission below the effective threshold near 800 keV. Also note that the (n, γ) capture cross section is very small in this range. The angular distributions for elastic scattering are given using the Legendre representation, and they show significant

■ Figure 45

The fast region for U-238 showing elastic (solid), inelastic (dashed), fission (chain-dash), $(n, 2n)$ (chain-dot), and (n, γ) capture (dotted)

structure. This structure has proved to be important for getting the proper leakage out of uranium bodies in critical assembly benchmarks. The angular distributions for the discrete inelastic levels are also given using the Legendre representation and show significant structure. The continuum inelastic and $(n, 2n)$ reactions are represented as coupled energy-angle distributions. An angular distribution specification is given for each $E \rightarrow E'$ scattering. At lower energies, these distributions are fairly isotropic. The excited compound system resulting from the initial collision has had time to come to equilibrium; thus, the emitted neutron has “forgotten” the direction of the incident neutron. At higher energies, we begin to see preequilibrium emissions, and the angular distributions become more and more forward peaked.

In the unresolved resonance region, a tabulated cross section is given to represent the average behavior. However, there are resonance effects there that lead to self-shielding of the cross sections. This will be discussed in more detail below. The resonance effects are described by giving average parameters and distribution rules for the unresolved resonances. The average parameters include spacing and resonance widths. These data can be used to produce self-shielded cross sections for multigroup methods or probability tables for Monte Carlo methods.

The resolved resonance region can be extremely complex. 🔍 Figure 46 shows the elastic and capture cross sections between 1 and 100 eV. The 6.7 eV capture resonance is very important for thermal reactors. We have already seen its effect in 🔍 Fig. 34.

3.3 Spectra for Elastic Downscatter

Because the neutron wavelength is very small at the higher energies, neutron elastic scattering can be treated by classical “billiard ball” kinematics. If ω is the cosine of the scattering angle in

■ Figure 46

The elastic (solid) and capture (dashed) cross sections of U-238 for room temperature at the lower end of the resolved resonance range

the CM system, E is the incident energy, and A is the ratio of the target mass to the neutron mass, the secondary energy E' and laboratory scattering cosine μ are given by

$$E' = \frac{E}{(A+1)^2} (A^2 + 1 + 2A\omega), \quad (96)$$

and

$$\mu = \frac{1 + A\omega}{\sqrt{A^2 + 1 + 2A\omega}}. \quad (97)$$

Clearly, the maximum fractional energy change in elastic scattering (commonly called α) occurs when $\omega = -1$ and is given by

$$\alpha = \left[\frac{A-1}{A+1} \right]^2. \quad (98)$$

For H-1 with $A = 0.9991673$, α is almost zero, and a neutron can lose almost all of its energy in an elastic scattering event. If the CM scattering distribution is isotropic, the energy distribution for elastically scattered neutrons is given by

$$f(E, E') = \frac{1}{(1-\alpha)E}, \quad (99)$$

for E' between αE and E , and zero otherwise. We can simulate the behavior of elastic downscatter by running MCNP on a “broomstick.” We take a very long, very thin cylinder of a material, start neutrons into one end, and look at the spectrum of neutrons escaping from the surface integrated over all angles. Because the cylinder is very thin, these neutrons will have undergone only one scattering event, and the distribution we see will be just $\sigma(E \rightarrow E') = \sigma(E)f(E, E')$.

► Figure 47 shows an example of elastic downscatter spectra for D_2O . At the lowest energy, we see the rectangular shapes predicted by (99) with the effects of both H-2 and O-16 visible. The rectangle for O-16 is narrower than that for H-2 because of its larger mass (larger A). For the higher incident energies, the effects of anisotropy in the scattering cross section show up.

Figure 47
Elastic slowing-down spectra for D_2O at 0.01, 0.10, and 2 MeV

3.4 Spectra for Inelastic Downscatter

At high incident energies, inelastic neutron scattering becomes possible. For the lighter isotopes, the first inelastic threshold is in the million electron volts range, but for heavy isotopes, it can come down to tens of kiloelectron volts or lower. We can extend the kinematics formulas to include inelastic scattering (and even charged-particle emission) as follows:

$$E' = \frac{A'E}{(A+1)^2} (\beta^2 + 1 + 2\beta\omega), \quad (100)$$

and

$$\mu = \frac{1 + \beta\omega}{\sqrt{\beta^2 + 1 + 2\beta\omega}}, \quad (101)$$

where

$$\beta = \left(\frac{A(A+1-A')}{A'} \left[1 + \frac{A+1}{A} \frac{Q}{E} \right] \right)^{1/2}. \quad (102)$$

The quantity A' is the ratio of mass of the emitted particle to the mass of the incident particle; thus it is equal to one for neutron inelastic scattering. The quantity $(A+1)(-Q)/A$ is the threshold energy for the inelastic level with excitation energy Q . The quantity β acts sort of like an effective mass ratio. When E is close to the inelastic threshold, β is small, and a scattered neutron can lose a large part of its energy, just as elastic scattering from a light target can cause the neutron to lose a large part of its energy. ▶ [Figure 48](#) illustrates this for U-238 just above the threshold for the first inelastic level at 45.09 keV.

As the neutron energy increases in the inelastic region, the levels get closer and closer together. At some point, it becomes reasonable to treat them continuously. ◀ [Figure 49](#) shows the continuum inelastic spectra for incident energies near 1.25 and 3 MeV. The dotted line shows

■ Figure 48

Inelastic slowing-down spectra for the first inelastic level for U-238 at incident energies of 0.048, 0.050, 0.052 and 0.054 MeV. The threshold for this level is 0.04509 MeV

■ Figure 49

Inelastic slowing-down spectra for the continuum inelastic reaction for U-238 at incident energies of 1.25 and 3 MeV. The dotted line goes as \sqrt{E}

the expected shape for low energies, namely \sqrt{E} . From theory, we expect that the low-energy shape for the CM distribution will go as $\sqrt{E_{CM}}$. The Jacobian for transforming from the CM to the laboratory frame is $\sqrt{E_{lab}/E_{CM}}$, so both the CM and the lab distributions must take on the \sqrt{E} shape.

Actual ENDF/B evaluations often use fairly coarse histogram representations for curves like this (they come from nuclear model calculations). We have smoothed the low-energy \sqrt{E} shape of these curves for this plot.

3.5 Resonance Cross Sections

In the ENDF format (Herman 2005), resolved resonance range cross sections are represented using resonance parameters based on four different methodologies: Single-Level Breit–Wigner (SLBW), Multi-Level Breit–Wigner (MLBW), Reich–Moore (RM), and Reich–Moore Limited (RML). Additional representations were used in the past, but they are no longer represented in the ENDF/B-VII library (Tuli et al. 2006).

3.5.1 Single-Level Breit–Wigner Representation

The SLBW resonance shapes are given by

$$\sigma_n = \sigma_p + \sum_{\ell} \sum_r \sigma_{mr} \left\{ \left[\cos 2\phi_{\ell} - \left(1 - \frac{\Gamma_{nr}}{\Gamma_r} \right) \right] \psi(\theta, x) + \sin 2\phi_{\ell} \chi(\theta, x) \right\}, \quad (103)$$

$$\sigma_f = \sum_{\ell} \sum_r \sigma_{mr} \frac{\Gamma_{fr}}{\Gamma_r} \psi(\theta, x), \quad (104)$$

$$\sigma_{\gamma} = \sum_{\ell} \sum_r \sigma_{mr} \frac{\Gamma_{\gamma r}}{\Gamma_r} \psi(\theta, x), \quad (105)$$

and

$$\sigma_p = \sum_{\ell} \frac{4\pi}{k^2} (2\ell + 1) \sin^2 \theta_{\ell}, \quad (106)$$

where σ_n , σ_f , σ_{γ} , and σ_p are the neutron (elastic), fission, radiative capture, and potential scattering components of the cross section arising from the given resonances. There can be “background” cross sections given that must be added to these values to account for competitive reactions such as inelastic scattering or to correct for the inadequacies of the single-level representation with regard to multilevel effects or missed resonances. The sums extend over all the ℓ values and all the resolved resonances r with a particular value of ℓ . Each resonance is characterized by its total, neutron, fission, and capture widths (Γ , Γ_n , Γ_f , Γ_{γ}), by its J value (AJ in the file), and by its maximum value σ_{mr}/Γ_r

$$\sigma_{mr} = \frac{4\pi}{k^2} g_J \frac{\Gamma_{nr}}{\Gamma_r}, \quad (107)$$

where g_J is the spin statistical factor

$$g_J = \frac{2J + 1}{4I + 2}, \quad (108)$$

and I is the target spin, and k is the neutron wave number, which depends on incident energy E and the atomic weight ratio to the neutron for the isotope A as follows:

$$k = (2.196771 \times 10^{-3}) \frac{A}{A + 1} \sqrt{E}. \quad (109)$$

There are two different characteristic lengths that appear in the ENDF resonance formulas: first, there is the “scattering radius” \hat{a} , and second, there is the “channel radius” a , which is given by

$$a = 0.123 A^{1/3} + 0.08. \quad (110)$$

In some cases, a is set equal to \hat{a} in calculating penetrabilities and shift factors (see below). The neutron width in the equations for the SLBW cross sections is energy-dependent due to the penetration factors P_ℓ ; that is,

$$\Gamma_{nr}(E) = \frac{P_\ell(E) \Gamma_{nr}}{P_\ell(|E_r|)}, \quad (111)$$

where

$$P_0 = \rho, \quad (112)$$

$$P_1 = \frac{\rho^3}{1 + \rho^2}, \quad (113)$$

$$P_2 = \frac{\rho^5}{9 + 3\rho^2 + \rho^4}, \quad (114)$$

$$P_3 = \frac{\rho^7}{225 + 45\rho^2 + 6\rho^4 + \rho^6}, \quad (115)$$

and

$$P_4 = \frac{\rho^9}{11025 + 1575\rho^2 + 135\rho^4 + 10\rho^6 + \rho^8}, \quad (116)$$

where E_r is the resonance energy and $\rho = ka$ depends on the channel radius or the scattering radius. The phase shifts are given by

$$\phi_0 = \hat{\rho}, \quad (117)$$

$$\phi_1 = \hat{\rho} - \tan^{-1} \hat{\rho}, \quad (118)$$

$$\phi_2 = \hat{\rho} - \tan^{-1} \frac{3\hat{\rho}}{3 - \hat{\rho}^2}, \quad (119)$$

$$\phi_3 = \hat{\rho} - \tan^{-1} \frac{15\hat{\rho} - \hat{\rho}^2}{15 - 6\hat{\rho}^2}, \quad (120)$$

and

$$\phi_4 = \hat{\rho} - \tan^{-1} \frac{105\hat{\rho} - 10\hat{\rho}^3}{105 - 45\hat{\rho}^2 + \hat{\rho}^4}, \quad (121)$$

where $\hat{\rho} = k\hat{a}$ depends on the scattering radius. The final components of the cross section are the actual line shape functions ψ and χ . At zero temperature,

$$\psi = \frac{1}{1 + x^2}, \quad (122)$$

$$\chi = \frac{x}{1 + x^2}, \quad (123)$$

$$x = \frac{2(E - E'_r)}{\Gamma_r}, \quad (124)$$

and

$$E'_r = E_r + \frac{S_\ell(|E_r|) - S_\ell(E)}{2(P_\ell(|E_r|))} \Gamma_{nr}(|E_r|), \quad (125)$$

in terms of the shift factors

$$S_0 = 0, \quad (126)$$

$$S_1 = -\frac{1}{1 + \rho^2}, \quad (127)$$

$$S_2 = -\frac{18 + 3\rho^2}{9 + 3\rho^2 + \rho^4}, \quad (128)$$

$$S_3 = -\frac{675 + 90\rho^2 + 6\rho^4}{225 + 45\rho^2 + 6\rho^4 + \rho^6}, \quad (129)$$

and

$$S_4 = -\frac{44100 + 4725\rho^2 + 270\rho^4 + 10\rho^6}{11025 + 1575\rho^2 + 135\rho^4 + 10\rho^6 + \rho^8}. \quad (130)$$

To go to higher temperatures, define

$$\theta = \frac{\Gamma_r}{\sqrt{\frac{4kTE}{A}}}, \quad (131)$$

where k is the Boltzmann constant and T is the absolute temperature. The line shapes ψ and χ are now given by

$$\psi = \frac{\sqrt{\pi}}{2} \theta \operatorname{Re} W\left(\frac{\theta x}{2}, \frac{\theta}{2}\right), \quad (132)$$

and

$$\chi = \frac{\sqrt{\pi}}{2} \theta \operatorname{Im} W\left(\frac{\theta x}{2}, \frac{\theta}{2}\right), \quad (133)$$

in terms of the complex probability function.

$$W(x, y) = e^{-z^2} \operatorname{erfc}(-iz) = \frac{i}{\pi} \int_{-\infty}^{\infty} \frac{e^{-t^2}}{z - t} dt, \quad (134)$$

where $z = x + iy$. The $\psi\chi$ method is not as accurate as kernel broadening (see below) because the backgrounds (which are sometimes quite complex) are not broadened, and terms important for energies less than about $16kT/A$ are neglected; however, the $\psi\chi$ method is less expensive than kernel broadening.

The SLBW formalism is deprecated for new evaluations, and there are only a few holdovers remaining in ENDF/B-VII. It has the problem of sometimes producing negative cross sections from the χ interference term. However, it is the basis for the unresolved range methodology, and it is still important to understand it.

3.5.2 Multi-Level Breit-Wigner Representation

The MLBW representation is formulated as follows:

$$\sigma_n(E) = \frac{\pi}{k^2} \sum_{\ell} \sum_{s=|I-\frac{1}{2}|}^{I+\frac{1}{2}} \sum_{J=|I-s|}^{I+s} g_J \left| 1 - U_{nn}^{\ell s J}(E) \right|^2, \quad (135)$$

with

$$U_{nn}^{\ell J}(E) = e^{2i\phi_\ell} - \sum_r \frac{i\Gamma_{nr}}{E_r' - E - i\Gamma_r/2}, \quad (136)$$

where the other symbols are the same as those used above. Expanding the complex operations gives

$$\begin{aligned} \sigma_n(E) = \frac{\pi}{k^2} \sum_\ell \sum_{s=|I-\frac{1}{2}|}^{I+\frac{1}{2}} \sum_{J=|I-s|}^{I+s} g_J \left\{ \left(1 - \cos 2\phi_\ell - \sum_r \frac{\Gamma_{nr}}{\Gamma_r} \frac{2}{1+x_r^2} \right)^2 \right. \\ \left. + \left(\sin 2\phi_\ell + \sum_r \frac{\Gamma_{nr}}{\Gamma_r} \frac{2x_r}{1+x_r^2} \right)^2 \right\}, \end{aligned} \quad (137)$$

where the sums over r are limited to resonances in spin sequence ℓ that have the specified value of s and J . Unfortunately, the s dependence of Γ is not known. The file contains only $\Gamma_J = \Gamma_{s_1 J} + \Gamma_{s_2 J}$. It is assumed that the Γ_J can be used for one of the two values of s , and zero is used for the other. Of course, it is important to include both channel-spin terms in the potential scattering. Therefore, the equation is written in the following form:

$$\begin{aligned} \sigma_n(E) = \frac{\pi}{k^2} \sum_\ell \left[\sum_J g_J \left\{ \left(1 - \cos 2\phi_\ell - \sum_r \frac{\Gamma_{nr}}{\Gamma_r} \frac{2}{1+x_r^2} \right)^2 \right. \right. \\ \left. \left. + \left(\sin 2\phi_\ell + \sum_r \frac{\Gamma_{nr}}{\Gamma_r} \frac{2x_r}{1+x_r^2} \right)^2 \right\} + 2D_\ell(1 - \cos 2\phi_\ell) \right], \end{aligned} \quad (138)$$

where the summation over J now runs from

$$\left| |I - \ell| - \frac{1}{2} \right| \rightarrow I + \ell + \frac{1}{2}, \quad (139)$$

and D_ℓ gives the additional contribution to the statistical weight resulting from duplicate J values not included in the new J sum; namely,

$$D_\ell = \sum_{s=|I-\frac{1}{2}|}^{I+\frac{1}{2}} \sum_{J=|I-s|}^{I+s} g_J - \sum_{J=||I-\ell|-\frac{1}{2}|}^{I+\ell+\frac{1}{2}} g_J \quad (140)$$

$$= (2\ell + 1) - \sum_{J=||I-\ell|-\frac{1}{2}|}^{I+\ell+\frac{1}{2}} g_J. \quad (141)$$

A case where this correction would appear is the $\ell = 1$ term for a spin-1 nuclide. There will be $5J$ values: $1/2$, $3/2$, and $5/2$ for channel spin $3/2$; and $1/2$ and $3/2$ for channel spin $1/2$. All five contribute to the potential scattering, but the file will only include resonances for the first three.

The fission and capture cross sections are the same as for the single-level option.

The $\psi\chi$ Doppler-broadening cannot be used with this formulation of the MLBW representation.

However, there is an alternate formulation that can be used with $\psi\chi$ broadening:

$$\begin{aligned} \sigma_n = \sigma_p + \sum_{\ell} \sum_r \sigma_{mr} \left\{ \left[\cos 2\phi_{\ell} - \left(1 - \frac{\Gamma_{nr}}{\Gamma_r} \right) + \frac{G_{r\ell}}{\Gamma_{nr}} \right] \psi(\theta, x) \right. \\ \left. + \left(\sin 2\phi_{\ell} + \frac{H_{r\ell}}{\Gamma_{nr}} \right) \chi(\theta, x) \right\}, \end{aligned} \quad (142)$$

where

$$G_{r\ell} = \frac{1}{2} \sum_{\substack{r' \neq r \\ J_{r'} \neq J_r}} \Gamma_{nr} \Gamma_{nr'} \frac{\Gamma_r + \Gamma_{r'}}{(E_r - E_{r'})^2 + (\Gamma_r + \Gamma_{r'})^2/4}, \quad (143)$$

and

$$H_{r\ell} = \sum_{\substack{r' \neq r \\ J_{r'} \neq J_r}} \Gamma_{nr} \Gamma_{nr'} \frac{E_r - E_{r'}}{(E_r - E_{r'})^2 + (\Gamma_r + \Gamma_{r'})^2/4}. \quad (144)$$

Nominally, this method is slower than the previous one because it contains a double sum over resonances at each energy. However, it turns out that G and H are slowly varying functions of energy, and the calculation can be accelerated by computing them at just a subset of the energies and getting intermediate values by interpolation. It is important to use a large number of r' values on each side of r .

The GH method works well at higher energies when compared to the more accurate kernel broadening method (more on this below). However, in the electron volts range and below, it compares more poorly with kernel broadening. Since the accelerated GH method is only marginally faster than kernel broadening, it probably should not be used at the lower energies for cases where the details of elastic scattering are important. This still leaves it useful for materials like fission products where absorption is the most important factor.

The MLBW representation does not produce the negative cross sections that plague the SLBW method. However, it is more expensive to use. It is used extensively for mid-mass isotopes (such as fission products) in the ENDF/B-VII library.

3.5.3 Reich–Moore Representation

The RM representation is a multilevel formulation with two fission channels; hence, it is useful for both structural and fissionable materials. (The name “Reich” is pronounced like “rich” by the co-originator of this method.) The cross sections are given by

$$\sigma_t = \frac{2\pi}{k^2} \sum_{\ell} \sum_J g_J \left\{ (1 - \text{Re } U_{nm}^{\ell J}) + 2d_{\ell J} [1 - \cos(2\phi_{\ell})] \right\}, \quad (145)$$

$$\sigma_n = \frac{\pi}{k^2} \sum_{\ell} \sum_J g_J \left\{ |1 - U_{nn}^{\ell J}|^2 + 2d_{\ell J} [1 - \cos(2\phi_{\ell})] \right\}, \quad (146)$$

$$\sigma_f = \frac{4\pi}{k^2} \sum_{\ell} \sum_J g_J \sum_c |\mathcal{I}_{nc}^{\ell J}|^2, \quad (147)$$

and

$$\sigma_y = \sigma_t - \sigma_n - \sigma_f, \quad (148)$$

where \mathcal{I}_{nc} is an element of the inverse of the complex R-matrix and

$$U_{nn}^{\ell J} = e^{2i\phi_\ell} [2\mathcal{I}_{nn} - 1]. \quad (149)$$

The elements of the R-matrix are given by

$$R_{nc}^{\ell J} = \delta_{nc} - \frac{i}{2} \sum_r \frac{\Gamma_{nr}^{1/2} \Gamma_{cr}^{1/2}}{E_r - E - \frac{i}{2} \Gamma_{\gamma r}}. \quad (150)$$

In these equations, “c” stands for the fission channel, “r” indexes the resonances belonging to spin sequence (ℓ, J) , and the other symbols have the same meanings as for SLBW or MLBW. Of course, when fission is not present, σ_f can be ignored. The R-matrix reduces to an R-function, and the matrix inversion normally required to get \mathcal{I}_{nn} reduces to a simple inversion of a complex number.

As in the MLBW case, the summation over J runs from

$$\left| |I - \ell| - \frac{1}{2} \right| \rightarrow I + \ell + \frac{1}{2}. \quad (151)$$

The term $d_{\ell J}$ in the expressions for the total and elastic cross sections is used to account for the possibility of an additional contribution to the potential scattering cross section from the second channel spin. There is unity if there is a second J value equal to J , and zero otherwise. This is just a slightly different approach for making the correction discussed in connection with (141). Returning to the $I = 1, \ell = 1$ example given above, d will be one for $J = 1/2$ and $J = 3/2$, and it will be zero for $J = 5/2$.

The RM representation is used for many of the most important isotopes in ENDF/B-VII, because it is very true to the underlying physics, resulting in good fits to experimental data. For fissile materials, its ability to handle two fission channels provides a better representation of the effects of the double-humped fission barriers seen for isotopes like U-235.

3.5.4 Reich–Moore-Limited Representation

The new RML representation is a more general multilevel and multichannel formulation. In addition to the normal elastic, fission, and capture reactions, it allows for inelastic scattering and Coulomb reactions. Furthermore, it allows resonance angular distributions to be calculated. The RML processing in NJOY is based on the SAMMY code (Larson 2008).

The quantities that are conserved during neutron scattering and reactions are the total angular momentum J and its associated parity π , and the RML format lumps all the channels with a given $J\pi$ into a “spin group.” In each spin group, the reaction channels are defined by $c = (\alpha, \ell, s, J)$, where α stands for the particle pair (masses, charges, spins, parities, and Q-value), ℓ is the orbital angular momentum with associated parity $(-1)^\ell$, and s is the channel spin (the vector sum of the spins of the two particles of the pair). The ℓ and s values must vector sum to $J\pi$ for the spin group. The channels are divided into incident channels and exit channels. Here, the important input channel is defined by the particle pair neutron + target. There can be several such incident channels in a given spin group. The exit channel particle pair defines

the reaction taking place. If the exit channel is the same as the incident channel, the reaction is elastic scattering. There can be several exit channels that contribute to a given reaction.

The R-matrix in the RM “eliminated width” approximation for a given spin group is given by

$$R_{cc'} = \sum_{\lambda} \frac{\gamma_{\lambda c} \gamma_{\lambda c'}}{E_{\lambda} - E - i\Gamma_{\lambda\gamma}/2} + R_c^b \delta_{cc'}, \quad (152)$$

where c and c' are incident and exit channel indexes, λ is the resonance index for resonances in this spin group, E_{λ} is a resonance energy, $\gamma_{\lambda c}$ is a resonance amplitude, and $\Gamma_{\lambda\gamma}$ is the “eliminated width,” which normally includes all of the radiation width (capture). The channel indexes run over the “particle channels” only, which does not include capture. The quantity R_c^b is the “background R-matrix.”

In order to calculate the contribution of this spin group to the cross sections, we first compute the following quantity:

$$X_{cc'} = P_c^{1/2} L_c^{-1} \sum_{c''} Y_{cc''}^{-1} R_{c''c'} P_{c'}^{1/2}, \quad (153)$$

where

$$Y_{cc''} = L_c^{-1} \delta_{cc''} - R_{cc''}, \quad (154)$$

and

$$L_c = S_c - B_c + iP_c. \quad (155)$$

Here, the P_c and S_c are penetrability and shift factors, and the B_c are boundary constants. The cross sections can now be written down in terms of the $X_{cc'}$. For elastic scattering

$$\sigma_{\text{elastic}} = \frac{4\pi}{k_{\alpha}^2} \sum_{J\pi} \left[\sin^2 \phi_c (1 - 2X_{cc}^i) - X_{cc}^r \sin(2\phi_c) + \sum_{c'} |X_{cc'}|^2 \right], \quad (156)$$

where $X_{cc'}^r$ is the real part of $X_{cc'}$, $X_{cc'}^i$ is the imaginary part, ϕ_c is the phase shift, the sum over $J\pi$ is a sum over spin groups, the sum over c is limited to incident channels in the spin group with particle pair α equal to neutron + target, and the sum over c' is limited to exit channels in the spin group with particle pair α . Similarly, the capture cross section becomes

$$\sigma_{\text{capture}} = \frac{4\pi}{k_{\alpha}^2} \sum_{J\pi} \sum_c g_{J\alpha} \sum_{c'} \left[X_{cc}^i - \sum_{c'} |X_{cc'}|^2 \right], \quad (157)$$

where the sum over $J\pi$ is a sum over spin groups, the sum over c is a sum over incident channels in the spin group with particle pair α equal to neutron + target, and the sum over c' includes all channels in the spin group. The cross sections for other reactions (if present) are given by

$$\sigma_{\text{reaction}} = \frac{4\pi}{k_{\alpha}^2} \sum_{J\pi} g_{J\alpha} \sum_c \left[X_{cc}^i - \sum_{c'} |X_{cc'}|^2 \right], \quad (158)$$

where the sum over c is limited to channels in the spin group $J\pi$ with particle pair α equal to neutron + target, and the sum over c' is limited to channels in the spin group with particle pair α' . The reaction is defined by $\alpha \rightarrow \alpha'$. This is one of the strengths of the RML representation. The reaction cross sections can include multiple inelastic levels with full resonance behavior. They

can also include cross sections for outgoing charged particles, such as (n, α) cross sections, with full resonance behavior. The total cross section can be computed by summing up its parts.

For non-Coulomb channels, the penetrabilities P , shift factors S , and phase shift ϕ are the same as those given for the SLBW representation. They are a little more complicated for Coulomb channels. See the SAMMY reference for more details.

The RML representation is new to the ENDF format and is not represented by any cases in ENDF/B-VII. There are experimental evaluations for F-19 and Cl-37 available. However, the RML approach provides a very faithful representation of resonance physics, and it should see increasing use in the future. NJOY is currently able to process RML evaluations using coding adapted from SAMMY.

3.5.5 Angular Distributions

One of the physics advances available when using the RML format is the calculation of angular distributions from the resonance parameters. A Legendre representation is used:

$$\frac{d\sigma_{\alpha\alpha'}}{d\Omega_{\text{CM}}} = \sum_L B_{L\alpha\alpha'}(E) P_L(\cos \beta), \quad (159)$$

where the subscript $\alpha\alpha'$ indicates the cross section as defined by the particle pairs, P_L is the Legendre polynomial of order L , and β is the angle of the outgoing particle with respect to the incoming neutron in the CM system. The coefficients $B_{L\alpha\alpha'}(E)$ are given by a complicated six-level summation that we will omit from this text.  [Figure 50](#) shows the first few Legendre coefficients for the elastic scattering cross sections as computed by NJOY from the experimental evaluation for F-19.

 **Figure 50**

Legendre coefficients of the angular distribution for elastic scattering in F-19 using the RML resonance representation (P_1 solid, P_2 dashed, P_3 dotted)

3.5.6 Resonance Reconstruction and Doppler Broadening

In practice, the formulas presented in the preceding paragraphs must be used to generate cross section vs. energy tables – this is called “resonance reconstruction.” There are a number of computer codes available that carry out this reconstruction. The examples in this chapter were generated using the RECONR module of NJOY (MacFarlane and Muir 1994). Another system that provides resonance reconstruction and Doppler broadening is PREPRO (Cullen 2007). Most commonly, the resonances are reconstructed at 0 K, and they are Doppler broadened to the required temperatures. For this chapter, we used the BROADR module of NJOY. The methods for resonance reconstruction and Doppler broadening are described in detail in Volume I,  Chap. 4.

3.5.7 Thermal Constants

In thermal-reactor work, people make very effective use of a few standard thermal constants to characterize nuclear cross sections. These parameters include the cross sections at the standard thermal value of 0.0253 eV (2,200 m/s), the integrals of the cross sections against a Maxwellian distribution for 0.0253 eV, the g-factors (which express the deviation of the cross section from $1/v$; namely, $2/\sqrt{\pi}$ times the ratio of the Maxwellian integral to the corresponding thermal cross section), η , α , and $K1$. Here, η is the Maxwellian-weighted average of $(\bar{v}\sigma_f)/(\sigma_f + \sigma_c)$, α is the average of σ_c/σ_f , and $K1$ is the average of $(\bar{v} - 1)\sigma_f - \sigma_c$. These quantities are routinely calculated by NJOY when it does Doppler broadening to the temperature corresponding to 0.0253 eV (293.6 K).  [Table 8](#) shows values for three important nuclides from ENDF/B-VII.

3.6 Resonance Slowing Down

Continuous-energy Monte Carlo codes like MCNP (2003) simulate the physics of the slowing-down process. The cross-section tables are used to randomly select the reaction channel following a collision. If elastic scattering is selected, the angular distribution is used to randomly select an emission cosine to get a new particle direction, and this cosine is used to compute the energy of the scattered neutron. This process is very faithful to the physics for some materials and energy ranges, but in practice there are two problems. First, at low energies the motion of the target nuclei corresponding to the temperature of the material becomes important. The Doppler broadening method described in Volume I,  Chap. 4 preserves the total reaction rate for the neutron at energy E averaged over all angles, but it does not produce a correct shape for the energy spectrum of the scattered neutrons. Current codes use the Doppler-broadened cross section with the target-at-rest downscatter spectrum given by (99). Second, the detailed variation of the angular distribution as the energy through a resonance is often not available in current data libraries. Average angular distributions over a range of resonances are more commonly provided.

Multigroup methods for calculating neutron slowing down require average cross sections like those defined in (74) and (75). The problem is coming up with good estimates for the neutron flux shape inside the group $W(E)$. One approach to this is based on B_0 theory. Using

■ Table 8

Thermal constants for three important resonance nuclides from ENDF/B-VII

Fission resonance integral	2.6916E+0	2.7596E+2	3.0260E+2

one-dimensional slab geometry for simplicity, the Boltzmann transport equation can be written in the form

$$\mu \frac{\partial}{\partial x} \phi(E, \mu, x) + \Sigma(E, x) \phi(E, \mu, x) = \int_E^\infty \Sigma_s(E' \rightarrow E, \mu' \rightarrow \mu, x) \phi(E', \mu', x) + S(E, \mu, x), \quad (160)$$

where we are now using the symbol Σ for the macroscopic cross sections. Next, we assume that the flux and the source can be separated into spatial- and energy-angle parts

$$\phi(E, \mu, x) = \phi(E, \mu) e^{iBx}, \quad (161)$$

and

$$S(E, \mu, x) = S(E, \mu) e^{iBx}. \quad (162)$$

This assumption certainly is not valid over the entire energy range, but it may be reasonable for the energy range of one group. To get an idea of the physical meaning of this, consider a critical slab. The B parameter is positive, and the real part of the flux has a cosine shape across the slab with its zeros a bit outside of the slab. Here $1/B$ becomes a measure of the thickness of the system. For a slab with a source on one face, B is imaginary, and the flux decreases exponentially as you move through the slab.

After inserting the separated flux and source into the Boltzmann equation, expanding the flux using Legendre polynomials, and assuming that the scattering cross section is isotropic, we

get the B_0 equations:

$$\Sigma(E)\phi_\ell(E) = A_{0\ell} \int_E^\infty \Sigma_s(E' \rightarrow E)\phi_0(E') + S_0(E), \quad (163)$$

where the A coefficients that we need are given by

$$A_{00} = \frac{\tanh^{-1}y}{y}, \quad (164)$$

and

$$A_{01} = \frac{A_{00} - 1}{y}, \quad (165)$$

where

$$y = \frac{iB}{\Sigma(E)}. \quad (166)$$

Note that small y indicates that the system is large with respect to the mean free path of the neutrons. This leads us to our next approximation. If the system is very large, we can take the limit of small y , getting $A_{00} = 1$ and $A_{01} = y/3$. The P_0 and P_1 (current) components of the flux become

$$\phi_0(E) = \frac{1}{\Sigma(E)} \left[\int_E^\infty \Sigma_s(E' \rightarrow E)\phi(E') + S_0(E) \right], \quad (167)$$

and

$$\phi_1(E) = \frac{B}{3\Sigma(E)^2} \left[\int_E^\infty \Sigma_s(E' \rightarrow E)\phi(E') + S_0(E) \right]. \quad (168)$$

We can now make another important approximation, the “narrow resonance approximation” (NR). If the resonances near E are narrow with respect to the downscatter predicted by Σ_s , the contributions to the bracketed term in (167) and (168) will come from energies well above the resonances near E and will not contain any structure correlated with those resonances. Therefore, we can replace the bracketed term with a smooth function $C(E)$, such as $1/E$. Let us assume that the material consists of a resonance isotope mixed with a moderator material that has a constant cross section. Then the weighting function for the group cross sections becomes

$$W_\ell(E) = \frac{C(E)}{[\sigma_0 + \sigma_t(E)]^{\ell+1}}, \quad (169)$$

where σ_t is the microscopic total cross section for the absorber nuclide the “background cross section” σ_0 represents the effect of the other isotopes in the material. As an example, the multigroup total cross section for isotope i and group g becomes

$$\sigma_{tg}^i = \frac{\int_g \frac{\sigma_t^i(E)C(E)}{\sigma_{0g}^i + \sigma_t^i(E)} dE}{\int_g \frac{C(E)}{\sigma_{0g}^i + \sigma_t^i(E)} dE}. \quad (170)$$

Physically, the term $\sigma_t^i(E)$ in the denominators puts a dip in the weighting flux that corresponds to the resonance peak in the cross section in the numerator. The size of this dip is controlled by

σ_{0g}^i . When the background cross section is large with respect to the heights of the resonances, the dips are very small. This is called “infinite dilution,” because it corresponds to the case of a solution of the absorber and the moderator with very small amounts of the absorber. When the background cross section is smaller, there can be a significant dip in the weighting flux. This dip then cancels out a part of the effect of the resonance in the numerator – the resonance is “self-shielded.” This approach is often called the “Bondarenko Method” after the Russian scientist who originally put it into practice (Bondarenko 1964). For a mixture of materials, the background cross section for isotope i is given by

$$\sigma_{0g}^i = \frac{1}{\rho_i} \sum_{j \neq i} \rho_j \sigma_{tg}^j. \quad (171)$$

This formula makes sense for homogeneous systems, but when heterogeneity effects are important, the background cross-section method can be extended as follows. In an infinite system of two regions (fuel and moderator), the neutron balance equations are

$$V_f \sigma_f \phi_f = (1 - P_f) V_f S_f + P_m V_m S_m, \quad (172)$$

and

$$V_m \sigma_m \phi_m = P_f V_f S_f + (1 - P_m) V_m S_m, \quad (173)$$

where V_f and V_m are the region volumes, σ_f and σ_m are the corresponding total macroscopic cross sections, S_f and S_m are the sources per unit volume in each region, P_f is the probability that a neutron born in the fuel will suffer its next collision in the moderator, and P_m is the probability that a neutron born in the moderator will suffer its next collision in the fuel. We then apply the reciprocity theorem,

$$V_f \sigma_f P_f = V_m \sigma_m P_m, \quad (174)$$

and the Wigner rational approximation to the fuel escape probability,

$$P_f = \frac{\sigma_e}{\sigma_e + \sigma_f}, \quad (175)$$

where σ_e is a slowly varying function of energy called the escape cross section, to obtain an equation for the fuel flux in the form

$$(\sigma_f + \sigma_e) \phi_f = \frac{\sigma_e S_m}{\sigma_m} + S_f. \quad (176)$$

In the limit where the resonances are narrow with respect to both fuel and moderator scattering, the source terms S_f and S_m take on their asymptotic forms of σ_p/E and σ_m/E , respectively, and this equation becomes equivalent to the Bondarenko model quoted above with

$$\sigma_0^f = \frac{\sigma_e}{\rho_f}, \quad (177)$$

and

$$C(E) = \frac{\sigma_e + \sigma_p}{\rho_f E}. \quad (178)$$

Note that a large escape cross section (a sample that is small relative to the average distance to collision), corresponds to infinite dilution as discussed above. To illustrate the general case, consider a neutron traveling through a lump of uranium oxide with an energy close to a resonance energy. If the neutron scatters from an oxygen nucleus, it will lose enough energy so that it can no longer react with the uranium resonance. Similarly, if the neutron escapes from the lump, it can no longer react with the uranium resonance. The processes of moderator scattering and escape are equivalent in some way. Comparing (177) with (171) gives an “equivalence principle” that says that a lump of particular dimensions and a mixture of particular composition will have the same self-shielded cross sections when the narrow resonance approximation is valid. The effects of material mixing and escape can simply be added to obtain the effective σ_0 for a lump containing admixed moderator material. Therefore, (171) is extended to read

$$\sigma_{0g}^i = \frac{1}{\rho_i} \left\{ \sigma_e + \sum_{j \neq i} \rho_j \sigma_{i0g}^j (\sigma_{0g}^j, T) \right\}, \quad (179)$$

where the escape cross section for simple convex objects (such as plates, spheres, or cylinders) is given by $(4V/S)^{-1}$, where V and S are the volume and surface area of the object, respectively. The quantity $4V/S$ is often called the “mean chord length” $\bar{\ell}$. For example, the mean chord length for a sphere is equal to the radius, the mean chord length for a cylinder is equal to twice its radius, and the mean chord length for a slab is twice its thickness. Many codes that use the background cross-section method modify the escape cross section as defined above to correct for errors in the Wigner rational approximation (“Bell factor,” “Levine factor”), or to correct for the interaction between different lumps in the moderating region (“Dancoff correction”). These enhancements will not be discussed here. Note that a thin slab is equivalent to a dilute solution – they both will have infinitely dilute cross sections.

3.7 Flux Calculations

This narrow-resonance approach is quite useful for practical fast reactor problems. However, for nuclear systems sensitive to energies from 1 to 500 eV, there are many broad- and intermediate-width resonances that cannot be self-shielded with sufficient accuracy using the Bondarenko approach. The GROUPE module of NJOY contains a flux calculator that can give some insight for such problems.

Consider an infinite homogeneous mixture of two materials and assume isotropic scattering in the center-of-mass system. The integral slowing-down equation becomes

$$\sigma(E) \phi(E) = \int_E^{E/\alpha_1} \frac{\sigma_{s1}(E')}{(1-\alpha_1)E'} \phi(E') dE' + \int_E^{E/\alpha_2} \frac{\sigma_{s2}(E')}{(1-\alpha_2)E'} \phi(E') dE'. \quad (180)$$

Furthermore, assume that material 1 is a pure scatterer with constant cross section and transform to the σ_0 representation. The integral equation becomes

$$[\sigma_0 + \sigma_{t2}(E)] \phi(E) = \int_E^{E/\alpha_1} \frac{\sigma_0}{(1-\alpha_1)E'} \phi(E') dE' + \int_E^{E/\alpha_2} \frac{\sigma_{s2}(E')}{(1-\alpha_2)E'} \phi(E') dE'. \quad (181)$$

Finally, assume that the moderator (material 1) is light enough so that all the resonances of material 2 are narrow with respect to scattering from material 1. This allows the first integral

to be approximated by its asymptotic form $1/E$. More generally, the integral is assumed to be a smooth function of E given by $C(E)$. In this way, material 1 can represent a mixture of other materials just as in the Bondarenko method. Fission source and thermal upscatter effects can also be lumped in $C(E)$. The integral equation has now been reduced to

$$[\sigma_0 + \sigma_t(E)] \phi(E) = C(E) \sigma_0 + \int_E^{E/\alpha} \frac{\sigma_s(E')}{(1-\alpha)E'} \phi(E') dE'. \quad (182)$$

This is the simplest problem that can be solved using the flux calculator. The results still depend on the single parameter σ_0 , and they can be used easily by codes that accept Bondarenko cross sections.

For heterogeneous problems, when the narrow-resonance approximation fails, both S_f and S_m in (176) will show resonance features. To proceed further with the solution of this equation, it is necessary to eliminate the moderator flux that is implicit in S_m . As a sample case, consider a fuel pin immersed in a large region of water. The fission neutrons appear at high energies, escape from the pin, slow down in the moderator (giving a $1/E$ flux), and are absorbed by the resonances in the pin. In this limit, any dips in the moderator flux caused by resonances in the fuel are small. On the other hand, in a closely packed lattice, the flux in the moderator is very similar to the flux in the fuel, and resonance dips in the moderator flux become very evident. Intermediate cases can be approximated (MacFarlane 1980) by assuming

$$\phi_m = (1 - \beta) C(E) + \beta \phi_f, \quad (183)$$

where β is a heterogeneity parameter given by

$$\beta = \frac{V_f \sigma_e}{V_m \sigma_m}, \quad (184)$$

Note that $\beta \rightarrow 0$ gives the isolated rod limit and $\beta \rightarrow 1$ gives the close-packed lattice limit. This substitution reduces the calculation of the fuel flux to

$$(\sigma_f + \sigma_e) \phi_f = (1 - \beta) C(E) \sigma_e + S_\beta, \quad (185)$$

where S_β is the source term corresponding to a homogeneous mixture of the fuel isotopes with the isotopes from the moderator region changed by the factor $\beta \sigma_e / \sigma_m$. If the fuel and moderator each consisted of a single isotope and for isotropic scattering in the center-of-mass system, the integral equation would become

$$\begin{aligned} [\sigma_0 + \sigma_t(E)] \phi_f(E) &= (1 - \beta) C(E) \sigma_0 + \int_E^{E/\alpha_m} \frac{\beta \sigma_0}{(1 - \alpha_m) E'} \phi_f(E') dE' \\ &+ \int_E^{E/\alpha_f} \frac{\sigma_{sf}(E')}{(1 - \alpha_f) E'} \phi_f(E') dE', \end{aligned} \quad (186)$$

where σ_0 is σ_e divided by the fuel density (units are barns/atom), α_m and α_f are the maximum fractional energy change in scattering for the two isotopes, and $\sigma_{sf}(E')$ is the fuel-scattering cross section.

This result has a form parallel to that of (182), but the solution depends on the two parameters β and σ_0 . For any given data set, β must be chosen in advance. This might not be difficult if

the data are to be used for one particular system, such as pressurized water reactors. The routine also has the capability to include one more moderator integral with a different α value and a constant cross section. The full equation is

$$\begin{aligned}
 [\sigma_0 + \sigma_t(E)] \phi_f(E) = & (1 - \beta) C(E) \sigma_0 + \int_E^{E/\alpha_3} \frac{\beta(1 - \gamma)(\sigma_0 - \sigma_{am})}{(1 - \alpha_3)E'} \phi_f(E') dE' \\
 & + \int_E^{E/\alpha_2} \frac{\sigma_{am} + \beta\gamma(\sigma_0 - \sigma_{am})}{(1 - \alpha_2)E'} \phi_f(E') dE' \\
 & + \int_E^{E/\alpha_f} \frac{\sigma_{sf}(E')}{(1 - \alpha_f)E'} \phi_f(E') dE', \quad (187)
 \end{aligned}$$

where σ_{am} is the cross section of the admixed moderator (with energy loss α_2), and γ is the fraction of the admixed moderator that is mixed with the external moderator (which has energy loss α_3). This allows calculations with H₂O as the moderator and an oxide as the fuel. The flux calculator can thus obtain quite realistic flux shapes for a variety of fuel, admixed moderator, and external moderator combinations. An example comparing the Bondarenko flux with a more realistic computed flux is given in [▶ Fig. 51](#).

3.8 Intermediate Resonance Self-Shielding

In this section, we will describe how the reactor-physics code WIMS (Askew et al. 1966) treats the problem of self-shielding for intermediate resonances. First, we refer back to (167). If the

■ Figure 51

A comparison of the Bondarenko flux model (dashed) with a realistic computed flux (solid) for a U-238 oxide pin in water in the region of the 6.7 eV resonance

energy lost by the downscatter represented by the integral is small with respect to the width of a resonance, the integral can be replaced by $\Sigma_s(E)\phi(E)$, and the equation becomes

$$[\Sigma(E) - \Sigma_s(E)]\phi(E) = S_0(E). \quad (188)$$

The weighting flux would become

$$W_0(E) = \frac{C(E)}{\sigma_0 + \sigma_a(E)}, \quad (189)$$

where σ_a is the absorption cross section. This is called the “wide resonance” (WR) or the “narrow resonance infinite mass” (NRIM) approximation. For resonances with widths intermediate to the NR and WR limits, we can change the formulas for the weighting flux and background cross section for for isotope i to

$$W_{0g}^i(E) = \frac{C(E)}{\sigma_{Pg}^i + \sigma_{ag}^i}, \quad (190)$$

and

$$\sigma_{Pg}^i = \frac{1}{\rho_i} \left\{ \sigma_\epsilon + \sum_j \rho_j \lambda_g^j \sigma_{Pg}^j \right\}. \quad (191)$$

Note that the sum is now over all j , and we have used the potential scattering cross section rather than the total cross section (which neglects the effect of scattering resonances on the weighting flux). If $\lambda_g^i = 1$, we get back the narrow resonance result because σ_p^i adds to σ_{ag}^i to return the total cross section (still neglecting resonance scattering). For $\lambda_g^i = 0$, we get the WR result. With intermediate values of λ , we get the “intermediate resonance” (IR) approximation. The equivalence principle is the same as for narrow resonances; namely, all systems with the same value of IR σ_{Pg}^i will have the same self-shielded cross sections for that isotope and group.

WIMS takes the additional step of expressing the self-shielding data in terms of “resonance integrals,” instead of using the self-shielded cross sections produced by GROUPE. That is,

$$\sigma_x(\sigma_0) = \frac{\sigma_p I_x(\sigma_p)}{\sigma_p - I_a(\sigma_p)}, \quad (192)$$

and

$$I_x(\sigma_p) = \frac{\sigma_p \sigma_x(\sigma_0)}{\sigma_p + \sigma_a(\sigma_0)}, \quad (193)$$

where $\sigma_x(\sigma_0)$ is a normal cross section as produced by the GROUPE module of NJOY, and x can stand for capture, fission, or nu-fission.

In order to clarify the meaning of this pair of equations, consider a homogeneous mixture of U-238 and hydrogen with concentrations such that there are 50 barns of hydrogen scattering per atom of uranium. The GROUPE flux calculator can be used to solve for the flux in this mixture, and GROUPE can then calculate the corresponding absorption cross section for U-238. Assuming that $\lambda = 0.1$ and $\sigma_p = 10$ for the uranium, the numbers being appropriate for WIMS group 25, we get $\sigma_p = 51$. This value of σ_p goes into the the WIMS library along with the corresponding I_a .

At some later time, a WIMS user runs a problem for a homogeneous mixture of U-238 and hydrogen that matches these specifications. WIMS will compute a value of σ_p of 51.0, interpolate in the table of resonance integrals, and compute a new absorption cross section that is exactly equal to the accurate computed result from the original GROUPE flux-calculator run.

This argument can be extended to more complex systems. For example, the assembly calculated using the flux calculator could represent an enriched uranium-oxide fuel pin of a size typical of a user's reactor system with a water moderator. The computed absorption cross section is converted to a resonance integral and stored with the computed value of σ_p . In any later calculation that happens to mimic the same composition and geometry, WIMS will return the accurate calculated absorption cross section. Equivalence theory, with all its approximations, is only used to interpolate and extrapolate around these calculated values. This is a powerful approach, because it allows a user to optimize the library in order to obtain very accurate results for a limited range of systems without having to modify the methods used in the lattice-physics code.

Let us call the homogeneous uranium-hydrogen case discussed above "case 0." Now, consider a homogeneous mixture of U-238, oxygen, and hydrogen. Arrange the ratio of the number densities to the uranium density such that there is 1 barn/atom of oxygen scattering and 50 barn/atom of hydrogen scattering. Carry out an accurate flux calculation for the mixture, and call the result "case 1." Also do an accurate flux calculation with only hydrogen, but at a density corresponding to 51 barns/atom. Call this result "case 2." The IR lambda value for oxygen is then given by

$$\lambda = \frac{\sigma_a(1) - \sigma_a(0)}{\sigma_a(2) - \sigma_a(0)}. \quad (194)$$

Note that λ will be 1 if the oxygen and hydrogen have exactly the same effect on the absorption cross section. In practice, $\lambda = 0.91$ for WIMS group 27 (which contains the large 6.7 eV resonance of U-238), and $\lambda = 1$ for all the other resonance groups. That is, all the resonances above the 6.7 eV resonance are effectively narrow with respect to oxygen scattering.

This process can be continued for additional admixed materials from each important range of atomic mass. The result is the table of λ_{gi} values needed as WIMSR input.

What are the implications of this discussion? The foremost is the observation that the lambda values for the isotopes are a function of the composition of the mixture that was used for the base calculation. To make the effect of this clear, let us consider two different types of cells:

1. A homogeneous mixture of U-238 and hydrogen
2. A homogeneous mixture of U-235 and hydrogen

A look at the pointwise cross sections in group 27 shows very different pictures for the two uranium isotopes. The U-238 cross section has one large, fairly wide resonance at 6.7 eV, and the U-235 cross section has several narrower resonances scattered across the group. If the lambda values are computed for these two different situations, the results in [Table 9](#) are obtained.

It is clear that the energy dependence of the two lambda sets is quite different. This is because of the difference in the resonance structure between U-238 and U-235. Clearly, the one resonance in group 27 in U-238 is effectively wider than the group of resonances in group 27 for U-235. Group 26 has essentially no resonance character for U-238, which reverses the sense of the difference. In groups 24 and 25, the U-238 resonances become more narrow, while the U-238 resonances stay fairly wide. Finally, in group 23, the U-238 resonances begin to get narrower.

These results imply that completely different sets of λ values should be used for different fuel/moderator systems, such as U-238/water, U-235/water, or U-238/graphite. In practice, this is rarely done.

■ Table 9

IR λ values for several resonance groups and two different reactor systems

3.9 Unresolved Resonance Range Methods

In the unresolved resonance range, there are still significant fluctuations in the cross sections, but we do not know exactly where they are. However, it is possible to evaluate the average properties of the unresolved resonances. The ENDF format provides the average spacing \bar{D} and the average widths for the elastic, capture, fission, and competitive reactions ($\bar{\Gamma}_n$, $\bar{\Gamma}_\gamma$, $\bar{\Gamma}_f$, and $\bar{\Gamma}_x$). All of these can depend on E , J , and ℓ . The resonance spacing is normally assumed to be distributed with the Wigner distribution, and the resonance widths are distributed with chi-square distributions with degrees of freedom μ_n , μ_γ , μ_f , and μ_x , for the elastic, capture, fission, and competitive widths, respectively. These quantities are also functions of E , J , and ℓ .

The infinitely dilute cross sections in the unresolved resonance region can be computed using these parameters in the SLBW method.

$$\sigma_n(E) = \sigma_p + \frac{2\pi^2}{k^2} \sum_{\ell, J} \frac{g_J}{D} \left[\bar{\Gamma}_n^2 R_n - 2\bar{\Gamma}_n \sin^2 \phi_\ell \right], \quad (195)$$

$$\sigma_x(E) = \frac{2\pi^2}{k^2} \sum_{\ell, J} \frac{g_J}{D} \bar{\Gamma}_n \bar{\Gamma}_x R_x \quad (196)$$

and

$$\sigma_p = \frac{4\pi}{k^2} \sum_{\ell} (2\ell + 1) \sin^2 \phi_\ell, \quad (197)$$

where σ_p is the potential scattering cross section, the \sin^2 term is the interference correction, x stands for either fission or capture, $\bar{\Gamma}_i$ and \bar{D} are the appropriate average widths and spacing for the ℓ, J spin sequence, and R_i is the fluctuation integral for the reaction and sequence. These integrals are simply the averages taken over the chi-square distributions specified in the file; for example,

$$\bar{\Gamma}_n \bar{\Gamma}_f R_i = \left\langle \frac{\Gamma_n \Gamma_f}{\Gamma} \right\rangle$$

$$\begin{aligned}
&= \int dx_n P_\mu(x_n) \int dx_f P_\nu(x_f) \int dx_c P_\lambda(x_c) \\
&\quad \times \frac{\Gamma_n(x_n) \Gamma_f(x_f)}{\Gamma_n(x_n) + \Gamma_f(x_f) + \Gamma_\gamma + \Gamma_c(x_c)}, \tag{198}
\end{aligned}$$

where $P_\mu(x)$ is the chi-square distribution for μ degrees of freedom. The integrals are evaluated with the quadrature scheme developed by R. Hwang for the MC²-2 code (Henryson et al. 1976) giving

$$R_f = \sum_i W_i^\mu \sum_j W_j^\nu \sum_k W_k^\lambda \frac{Q_i^\mu Q_j^\nu}{\bar{\Gamma}_n Q_i^\mu + \bar{\Gamma}_f Q_j^\nu + \Gamma_\gamma + \bar{\Gamma}_c Q_k^\lambda}. \tag{199}$$

The W_i^μ and Q_i^μ are the appropriate quadrature weights and values for μ degrees of freedom, and Γ_γ is assumed to be constant (many degrees of freedom). The competitive width $\bar{\Gamma}_c$ is assumed to affect the fluctuations, but a corresponding cross section is not computed (we will discuss this in more detail below).

It should be noted that the reduced average neutron width Γ_n^0 is given in the evaluations, and

$$\bar{\Gamma}_n = \Gamma_n^0 \sqrt{E} V_\ell(E), \tag{200}$$

where the penetrabilities for the unresolved region are defined as

$$V_0 = 1, \tag{201}$$

$$V_1 = \frac{\rho^2}{1 + \rho^2}, \tag{202}$$

and

$$V_2 = \frac{\rho^4}{\rho + 3\rho^2 + \rho^4}. \tag{203}$$

Other parameters are defined as for SLBW.

In practice, this simple unresolved resonance representation can not always fit the experimental data with sufficient accuracy. For actinide fission, the double-humped fission barriers seen there lead to “secondary structure” in the cross sections that are not included in the simple theory. In addition, if the break from the resolved range to the unresolved range is not high enough, there can be semi-resolved resonances or clusters of resonances underlying the resonances that do not act like the simple theory predicts. Because of this, the ENDF format has an option to provide evaluated experimental values directly for the infinitely dilute unresolved resonance range cross sections (examples are U-235 and U-238). In these cases, the simple unresolved resonance theory is only used to calculate self-shielding (see below). In other cases, the parameters of the theory are adjusted to try to give reasonable agreement to experiment, even for the features that are not consistent with the simple theory (e.g., Pu-239). Both the infinitely dilute cross section and the self-shielding are computed using the simple theory. Both of these procedures leave much to be desired. However, the self-shielding effects of the unresolved energy range are quite small for thermal reactor systems and modest for fast reactor system; therefore, fairly large uncertainties can be accepted in the unresolved resonance range without serious impact on normal calculations. Work is underway in the nuclear-data community to improve this situation.

There are two methods in common use for calculating self-shielding effects in the unresolved resonance range. For multigroup codes, tables of self-shielded cross sections using the Bondarenko method are normally provided. For continuous-energy Monte Carlo codes like MCNP, probability tables are normally used. The PURR module of NJOY can be used to generate both types of data. This method is based on generating “ladders” of resonances using the statistical properties of the unresolved range. One ladder can be generated appropriate for an energy E by randomly selecting a starting resonance energy for one ℓ, J sequence, and also randomly selecting a set of widths for that resonance using the appropriate average widths and chi-square distribution functions. We can then select the next higher resonance energy by sampling from the Wigner distribution for resonance spacings, and we can choose a new set of widths for that resonance. The process is continued until we have a long ladder of resonances for that ℓ, J . We then repeat the process for the other ℓ, J sequences, each such sequence being uncorrelated in positions from the others. With this ladder of resonance parameters in place, PURR randomly samples energy values and computes the cross sections at those energy using the SLBW method. This random sampling is consistent with the narrow resonance approximation in which neutrons arrive without a knowledge of the local resonance structure. These cross sections can be used in formulas like (170) to obtain statistical estimates for the self-shielded cross sections to be used in multigroup codes. They can also be used to obtain a probability distribution function for the total cross section. This is done by accumulating the “hits” in a set of predefined total cross-section bins. This can be used to determine the probability that the total cross section will present a value in that bin’s range and the average total cross section for that range. At the same time, conditional averages can be accumulated for the elastic, capture, and fission reactions. A conditional average is the average value for the reaction over a bin when the associated total cross also falls in that bin. Once all the cross section samples have been processed for the ladder, a new ladder is constructed, and the entire process is repeated. A typical calculation uses 20 bins and 32 ladders. The structure of a probability table for one energy is shown in ► [Table 10](#). In MCNP, a random number is used with the cumulative probability to select a bin, and the resulting cross sections are returned to characterize the collision. Intermediate incident energies are obtained by interpolation.

Figure 52

The probability distribution for the total cross section at 20 keV (solid) and 140 keV (dashed) in the unresolved resonance range of U-238

The probability table can be used to generate a picture of the probability distribution for the total cross section as shown in [Fig. 52](#). This example is for U-238. It demonstrates how the fluctuations get smaller as energy increases, which means that the self-shielding effect also gets smaller. The probability table can also be used to generate Bondarenko self-shielded cross sections as follows:

$$\sigma_x(E) = \frac{\sum_i \frac{P_i(E)\sigma_{xi}(E)}{\sigma_0 + \sigma_{ti}(E)}}{\sum_i \frac{P_i(E)}{\sigma_0 + \sigma_{ti}}}, \quad (204)$$

where x is t , n , f , or γ . An example of the self-shielded total cross section for the unresolved resonance range of U-238 is shown in [Fig. 53](#). In practice, a σ_0 value of about 30 is characteristic of an oxide reactor pin, and one of 1 is appropriate for a very fast system with large amounts of U-238.

In U-238, the threshold for the (n, n_1) inelastic level is 45.09125 keV, well within the unresolved resonance range. The threshold for (n, n_2) is 149.0288 keV, which is the upper limit of the unresolved resonance range. In this energy range, inelastic scattering competes with elastic scattering and capture – this is the origin of the “competitive width” mentioned above. In the current ENDF procedures, we are instructed to use the unshielded value of the inelastic cross section as given in the evaluation when constructing the cross section libraries. However, theory predicts that the inelastic cross section should have resonance fluctuations in this energy range just as the other channels do. Adding this self-shielding effect would affect the inelastic slowing down, and the nuclear data community is working to understand the effects of this. One processing system currently attempts to include this inelastic self-shielding effect (Sublet et al. 2006).

4 Time and Space in Slowing Down

4.1 Introduction

For most reactor-physics applications, the equilibrium slowing down and thermalization discussed above is sufficient. However, to get a more complete understanding of the process, it is useful to consider time dependence. The MCNP Monte Carlo code can be used to do time-dependent simulations; for example, what is the behavior of a pulse of neutrons introduced at time zero and position zero as time increases and the neutron flux spreads out from the origin. This is a problem that was analyzed in the past using eigenvalue–eigenfunction theory or age theory.

4.2 Time Dependence of the Energy Spectrum

In this section, we introduce a pulse of neutrons at some initial energy at the center of a large sphere of a material and watch the evolution of the energy spectrum averaged over the entire assembly as a function of time. The first example is for graphite. The initial energy is taken to be 4 MeV to avoid the inelastic levels. The time-dependent flux contours are shown in [Fig. 54](#). At early times, there are complex transients resulting from the delta-function source interacting with the discontinuous slowing-down kernel. But as time increases, the flux peaks smooth out into Gaussian shapes that slow down with time with little change in shape. Note that the natural time unit for MCNP is the shake (10^{-8} s).

If we do the same thing for heavy water, we get similar results (see [▶ Fig. 55](#)). Note that the slowing down is faster for heavy water than it was for carbon, and the pulses shapes are slightly broader.

This behavior of neutron pulses in large systems is the basis for the experimental technique called the “lead slowing-down spectrometer.” Theory says that for large A , the width of the pulse (the dispersion) should vary as $1/\sqrt{A}$. [▶ Figure 56](#) shows the slowing-down behavior in a very

■ Figure 54

Neutron spectra for slowing down in carbon. The curves are for 10% time bins around times of 1, 2, 5, 10, 20, 50, 100, 200, and 500 shakes (one shake is 10^{-8} s)

■ Figure 55

Neutron spectra for slowing down in heavy water. The curves are for 10% time bins around times of 1, 2, 5, 10, 20, 50, 100, 200, and 500 shakes (one shake is 10^{-8} s)

■ **Figure 56**

Neutron spectra for slowing down from a point source at 14 MeV in a large lead sphere. The curves correspond to 10% time bins around times of 50, 100, 200, 500, 1,000, 2,000, 5,000, 10,000, and 20,000 shakes (one shake is 10^{-8} s)

large sphere of lead. Note that the pulses are narrower than they were for the lighter materials and that the slowing down is much slower. If you put a sample inside the block of lead, you can observe its response to different energies by observing it at different times. Theory says that the time for a given energy should vary like $1/v$. ➤ [Figure 57](#) shows that the calculation shown in ➤ [Fig. 56](#) obeys this prediction.

A classical experiment is the measurement of “slowing down time.” A pulse is introduced at high energies, and the time required to excite a known resonance in a sample is measured. We can simulate that using MCNP. The definition of “high energy” is ambiguous, but neutrons slow down very quickly near the source energy from inelastic scattering, so the effect of using different starting energies is not too serious. Looking at ➤ [Fig. 57](#), we can pick off the time associated with an energy of 1 eV and call that the slowing-down time. ➤ [Table 11](#) shows results for several materials from ENDF/B-VII.

4.3 Time Dependence of the Spatial Distribution

To look at the spatial distribution of slowing down, we start a pulse of 1 MeV neutrons in the center of a large sphere of graphite and watch how the integrated flux spreads out with time. See ➤ [Fig. 58](#). This was an MCNP calculation using five million source particles. At early times, the distribution is still close to the origin, but as time increases it gradually gets broader. The neutrons act like they are diffusing outward. The outward diffusive current is strong at early times because of the large gradient in the flux. As the central flux is depleted, it gets smaller and flatter, and the outward current gets smaller. As a result, the central flux does not decrease as fast as time increases.

■ Figure 57

Time vs. peak energy for slowing down in lead (points). The solid curve is the theoretical $1/v$ dependence

■ Table 11

Slowing down time for several materials from ENDF/B-VII

Material	Slowing-down time (μs)
Heavy water	11.5
Carbon	24.0
Sodium	200
Lead	425

At long times, the flux shape will approach the “fundamental mode” shape. For a spherical geometry, the shape would be

$$\frac{1}{r} \sin\left(\frac{\pi r}{\hat{R}}\right), \quad (205)$$

where \hat{R} is the extrapolated endpoint radius just outside of the real radius R . For spheres that are large with respect to the mean free path, \hat{R} will be close to R . What does “long times” mean?

➤ Figure 59 shows the final stages of the thermalization of the neutron pulse. The dotted line is the theoretical Maxwellian shape for an infinite medium with no absorption. It is clear that the computed flux in this graphite sphere is approaching the theoretical limit after about 1,000 μs . As we saw in ➤ Table 11, the slowing down time to 1 eV for carbon is about 24 μs . The thermalization time is seen to be much larger than that. This is a consequence of the chemical binding of the carbon atoms in the graphite and the presence of upscatter. After about 1,000 μs ,

■ Figure 58

Spatial dependence of slowing down in carbon. The curves are for 10% time bins around times of 1, 2, 5, 10, 100, and 1,000 shakes (one shake is 10^{-8} s)

■ Figure 59

Final thermalization of a pulse in a graphite sphere. The solid curves are for 10% time bins around times of 5,000, 10,000, 20,000, 50,000, and 100,000 shakes (one shake is 10^{-8} s). The dotted curve is a Maxwellian thermal spectrum

the spatial flux shape in the graphite sphere should have reached the fundamental mode shape shown in the equation above.

4.4 Eigenvalues and Eigenfunctions

One theoretical approach to time-dependent slowing down and thermalization makes use of eigenvalues and eigenfunctions. In the diffusion approximation, the transport equation for a homogeneous medium with an isotropic source at energy E_0 and time $t = 0$ can be written as

$$\begin{aligned} \frac{1}{v} \frac{\partial \phi(E, \mathbf{r}, t)}{\partial t} + \Sigma_a(E) \phi(E, \mathbf{r}, t) - D(E) \nabla^2 \phi(E, \mathbf{r}, t) \\ = \mathbf{S}_0 \phi(E, \mathbf{r}, t) + \delta(E - E_0) \delta(t) Q(\mathbf{r}), \end{aligned} \quad (206)$$

where $Q(\mathbf{r})$ is the shape of the source, $D(E)$ is the diffusion coefficient, Σ_a is the macroscopic absorption cross section, and the scattering operator is given by

$$\mathbf{S}_0 \phi(E) = \int_0^\infty \Sigma(E' \rightarrow E) \phi(E') dE' - \Sigma_s(E) \phi(E), \quad (207)$$

where $\Sigma(E' \rightarrow E)$ is the differential scattering cross section, and $\Sigma_s(E)$ is the integrated scattering cross section. Following the scheme described in (Williams 1966). We first separate out the spatial part by writing

$$\phi(E, \mathbf{r}, t) = \sum_n \phi_n(E, t) F_n(\mathbf{r}). \quad (208)$$

The F_n are given by a Helmholtz equation

$$\nabla^2 F_n(\mathbf{r}) + B_n^2 F_n(\mathbf{r}) = 0. \quad (209)$$

subject to appropriate boundary conditions at the edge of the system. The B_n^2 are spatial eigenvalues with associated spatial eigenfunctions F_n . We will give an example below. The ϕ_n are solutions of

$$\begin{aligned} \frac{1}{v} \frac{\partial \phi_n(E, t)}{\partial t} + \Sigma_a(E) \phi_n(E, t) - D(E) B_n^2 \phi_n(E, t) \\ = \mathbf{S}_0 \phi_n(E, t) + \delta(E - E_0) \delta(t) Q_n, \end{aligned} \quad (210)$$

where

$$Q_n = \int d\mathbf{r} Q(\mathbf{r}) F_n(\mathbf{r}). \quad (211)$$

We next assume that the flux can be divided into energy and time factors as follows:

$$\phi_n(E, t) = \phi_n(E) e^{-\lambda_n t}. \quad (212)$$

The equation for the ϕ_n becomes

$$\left[-\frac{\lambda_n}{v} + D(E) B_n^2 \right] \phi_n(E) = \mathbf{S}_0 \phi_n(E) + \delta(E - E_0) \delta(t) Q_n. \quad (213)$$

The homogeneous part of this provides another eigenvalue problem

$$\mathbf{S}_0 \phi_n(E) = \left[-\frac{\lambda_n}{v} + D(E)B_n^2 \right] \phi_n(E). \quad (214)$$

The eigenvalues of this equation (square brackets) correlate the spatial eigenvalues B_n^2 with the time-decay eigenvalues λ_n .

In principle, this eigenvalue problem can be attacked by expanding ϕ_n and Q_n using an appropriate set of orthonormal basis functions and solving for the eigenvalues and expansion coefficients. In practice, this is rather difficult in general. As we saw from  Fig. 59, the temporal eigenfunction corresponding to λ_0 would have to be similar to the Maxwellian distribution $M(E)$, and higher eigenfunctions would have to represent the faster decaying Gaussian peaks from the slowing-down process. Similarly, the spatial eigenfunction corresponding to B_0^2 would be the fundamental mode shape, and the higher modes would correspond to higher values of λ_n and would decay away faster. The eigenvalue–eigenfunction approach is useful in understanding how the temporal and spatial modes behave, but Monte Carlo and multigroup methods are much more useful in practice.

As an example of the spatial eigenfunctions, consider the simple slab reactor of thickness T . A good set of basis functions is

$$\psi_n(x) = \begin{cases} \cos \frac{n\pi x}{\hat{T}}, & n = 1, 3, 5, \dots \\ \sin \frac{n\pi x}{\hat{T}}, & n = 2, 4, 6, \dots, \end{cases} \quad (215)$$

and the corresponding eigenvalues are

$$B_n^2 = \left(\frac{n\pi}{\hat{T}} \right)^2, \quad n = 1, 2, 3, \dots \quad (216)$$

All these eigenfunctions are zero at the extrapolated half widths of the slab $-\hat{T}/2$ and $+\hat{T}/2$. The ψ_1 function is the fundamental mode, and it is nonzero over the entire slab. The ψ_2 function is asymmetric with a zero at the midpoint of the slab. The ψ_3 function is symmetric with two zeros. If one imagines starting with an initial source that is off center, the flux soon after the initial pulse would also be off center and would be represented by a Fourier series containing sine terms that reflects that. But these higher modes will have larger λ values and decay away faster than the lower modes. The spatial flux will gradually become smoother, and by the time that full thermalization is obtained, only the fundamental mode will remain.

4.5 Analytic Age Theory

To understand age theory and other “continuous slowing down” methods, it is useful to write the P_1 approximation to the transport equation in terms of the lethargy

$$\frac{\partial \phi_1(x, u)}{\partial x} + \Sigma_t(x, u) \phi_0(x, u) = \int \Sigma_s(x, u' \rightarrow u) \phi_0(x, u') du' + Q_0(x, u) \quad (217)$$

$$\frac{\partial \phi_0(x, u)}{\partial x} + \Sigma_t(x, u) \phi_1(x, u) = 3 \int \Sigma_s(x, u' \rightarrow u) \phi_1(x, u') du' + 3Q_1(x, u). \quad (218)$$

If A is not too small, in the energy range where elastic scattering dominates, and if the absorption is not too large, the collision density $\Sigma_s \phi_0$ tends to be slowly varying. It is reasonable to make Taylor expansions of the P_0 and P_1 collision densities, keeping two terms for the first and one for the second. Making the following definitions

$$\int \Sigma_s(x, u' \rightarrow u) du' = \Sigma_s(x, u), \quad (219)$$

$$\int (u - u') \Sigma_s(x, u' \rightarrow u) du' = \xi(u) \Sigma_s(x, u), \quad (220)$$

and

$$\int \Sigma_1(x, u' \rightarrow u) du' = \bar{\mu}(u) \Sigma_s(x, u), \quad (221)$$

the P_1 equations become

$$\frac{\partial \phi_1}{\partial x} + (\Sigma_t - \Sigma_s) \phi_0 = \frac{\partial}{\partial u} (\xi \Sigma_s \phi_0) + Q_0 \quad (222)$$

$$\frac{\partial \phi_0}{\partial x} + 3(\Sigma_t - \bar{\mu} \Sigma_s) \phi_1 = 3Q_1. \quad (223)$$

Taking $Q_1 = 0$, the second equation gives “Fick’s Law,”

$$\psi_1 = -\frac{1}{3(\Sigma_t - \bar{\mu} \Sigma_s)} \frac{\partial \phi_0}{\partial x} = -D \frac{\partial \phi_0}{\partial x}, \quad (224)$$

where D is the diffusion coefficient. Putting this into the first of the P_1 equations gives the “age-diffusion equation”

$$-\frac{\partial}{\partial x} \left(D \frac{\partial \phi_0}{\partial x} \right) + (\Sigma_t - \Sigma_s) \phi_0 = \frac{\partial}{\partial u} (\xi \Sigma_s \phi_0) + Q_0. \quad (225)$$

The quantity ξ is the average increase in lethargy for a neutron–nucleus collision, and $\bar{\mu}$ is the average cosine for scattering. For isotropic CM scattering in a single material, these two quantities take on the simple values

$$\xi = 1 + \frac{\alpha \ln \alpha}{1 - \alpha} \quad (226)$$

$$\bar{\mu} = \frac{2}{3A}. \quad (227)$$

The quantity $\xi \Sigma_s \phi_0$ is called the “slowing-down density” and is usually denoted by $q(x, u)$. If $Q_0 = 0$ and there is no absorption ($\Sigma_t = \Sigma_s$), the age-diffusion equation is reduced to

$$\frac{\partial^2 q(x, u)}{\partial x^2} = \frac{\partial q}{\partial \tau}, \quad (228)$$

where τ is called the Fermi age,

$$\tau(u) = \int_0^u \frac{D}{\xi \Sigma_s} du'. \quad (229)$$

This is the “Fermi age equation” in plane geometry. Note that τ has the dimensions of square centimeters, strange for an “age.” It is really something like the square of the mean distance to a collision.

An interesting variation on age theory comes about if we write the time-dependent and space-independent version for a pulsed source in the form

$$\frac{1}{v} \frac{\partial \phi(u, t)}{\partial t} = -\frac{\partial}{\partial u} [\xi \Sigma_s \phi(u, t)] + \delta(u) \delta(t). \quad (230)$$

This equation can be solved using a Laplace transform, giving

$$\xi \Sigma_s(u) \phi(u, t) = \delta \left(t - \int_0^u \frac{1}{v' \xi \Sigma_s(u')} du' \right), \quad (231)$$

that is, the pulse retains its original shape and slows down with time. We saw this behavior in [▶ Fig. 56](#).

Age theory is mostly of historical significance in these days of fast computers. It does not work for hydrogen, and it is weak for other light moderators, like heavy water and beryllium. There are other slightly more complicated continuous slowing-down models, such as the Selengut–Goertzel and Greuling–Goertzel methods, that have found some usefulness in fast-reactor analysis.

5 Concluding Remarks and Outlook

This chapter opened with a discussion on how to generate scattering cross sections in the thermal range with the $S(\alpha, \beta, T)$ representation. Experience has shown that this approach works well for calculating water–uranium critical systems (Tuli et al. 2006). However, [▶ Figs. 19](#) and [▶ Figure 20](#) suggest that further improvements for H in H_2O are possible, especially for the diffusive representation at low neutron energies. The region from 0.2 to 0.5 eV is also of concern. Some correspondents have been concerned about the effects of the break between the $S(\alpha, \beta, T)$ representation at low energies and the epithermal treatment above. The discontinuity at the breakpoint looks nonphysical. Current methods use breakpoints all the way from 0.625 to 10 eV. It is not clear whether the $S(\alpha, \beta, T)$ representation works for energies as high as 10 eV. At some point, anharmonic effects should begin to show up. At higher energies, bond breaking and atomic displacements could even occur. The current experimental data are not good enough to resolve these questions. Additional high-accuracy differential and integrated experimental data could drive improvements for the water scattering data.

[▶ Figure 24](#) showed some improvement in matching experimental data for heavy water coming from the treatment of intermolecular interference, but there are still problems around 1 meV and in the region from 0.01 to 0.05 eV that suggest that further physics improvements are needed. There may also be problems with the temperature dependence of the interference effect coming from the static structure factor ([▶ Fig. 22](#)). There are only a few good heavy-water critical assemblies available for test calculations, so the confidence we have for water–uranium systems is not available for heavy-water systems.

A shortage of reliable critical experiments also exists for other moderator materials, including beryllium and graphite.

A key problem with the $S(\alpha, \beta, T)$ approach is that it only works for materials for which the free-scattering cross section is constant. This condition is well satisfied for the light materials like water, heavy water, and graphite. However, it certainly breaks down for uranium oxide. New methods would be required to extend the thermal-scattering treatment for U-238 to 10 eV, spanning the important 6.7 eV resonance. Some work has been done on this in recent years, but it has not been reduced to common practice as yet.

Finally, from time to time, people have expressed the desire for $S(\alpha, \beta, T)$ data for additional materials. These evaluations are fairly difficult, and there are few people with experience in the field. Progress is slow.

The second section discussed thermalization. There are several computer code systems available that treat this well, as demonstrated by the good results obtained for many thermal critical assemblies during ENDF/B-VII data testing (Tuli et al. 2006). The Monte Carlo approach works best here because of its good treatments of the complex geometry features of many of the critical experiments.

The third section discussed steady-state slowing down. At higher energies and for lighter isotopes, both Monte Carlo and S_N methods are capable of calculating slowing down well. The limitations come from the nuclear data. As we saw from  Fig. 47, the slowing-down spectra are sensitive to the angular distributions. These are not always as good as we would like for current evaluations. During the development of the ENDF/B-VII data for U-238, good improvement in matching critical-experiment data for both lattice experiments and fast-reflected criticals was obtained, and part of this improvement came from using the best current nuclear models for the elastic angular distributions. The agreement between calculation and experiment is not that good for fast-reflected critical assemblies with other reflectors (lead, iron, nickel, and copper). This suggests that the angular distributions for scattering could be improved for other materials, resulting in better slowing-down calculations. If there are resonances in the higher energy part of the slowing-down range, a more complete representation of the change in the angular distributions across the resonances, such as the variations shown in  Fig. 50, could be helpful. This would require more extensive use of the RML resonance representation and enhancements in data-processing and transport codes to make use of these data.

Another data issue for slowing down comes from the representation of continuum scattering reactions, such as (n, n'_c) and $(n, 2n)$. These data are often obtained from nuclear model calculations, which normally produce histogram representations of the scattering. In current evaluations, these histogram representations are often fairly coarse and do not do a good job of simulating the \sqrt{E} dependence of these distributions at low energies. See  Fig. 49. This histogram issue also comes up for low-energy delayed-neutron spectra.

For the heavier isotopes, the slowing down eventually passes into the unresolved resonance range where reactions are treated statistically. Here, the cross sections are treated to include the temperature, but the downscatter shapes are not. Some correspondents have questioned the reliance on the Single-Level Breit-Wigner representation currently used. A multilevel treatment of scattering might be needed. A more complicated resonance representation might be necessary to handle the secondary structure coming from the double-humped fission barriers. In most current methods, self-shielding effects are omitted for the slowing down from inelastic scattering in the unresolved range.

In the resolved resonance range for the heavier isotopes, Doppler broadening of the resonances becomes important. We currently handle that well for the integrated cross sections, but the downscatter shapes are taken from the target-at-rest representation. In addition, we do not normally treat the angular distributions for resonance scattering in detail. The technical

problems with properly Doppler-broadening scattering distributions and angular distribution are very difficult. The current methods work reasonably well for most reactor problems. Resolved resonance self-shielding is handled in good detail by the continuous-energy Monte Carlo codes, but with less accuracy by codes that depend on multigroup self-shielding factors.

The discussion of time-dependent slowing down concentrated on providing some understanding of the effects using Monte Carlo examples. The theoretical methods presented help to provide some of this understanding, but they are of mostly historical interest. They are not really used for modern reactor calculations.

In summary, the data and methods used to describe neutron slowing down and thermalization are in fairly good shape for reactor calculations, but there are improvements that we can look forward to in future years.

Abstract: Today, new evaluated data are almost always prepared in the now universally accepted ENDF/B format. Between the originally evaluated data as coded in the ENDF/B format and our particle transport codes, which actually use the evaluated data, are the often overlooked data-processing codes. These data-processing codes translate and manipulate the data from the single universal ENDF/B format to a variety of formats used by our individual particle transport codes, that is, in contrast to our universally accepted evaluated data format, ENDF/B, as yet there is no universally accepted format used by all of our application codes.

This chapter covers in detail the work done by our data-processing codes to prepare the evaluated data for use in our applications: this includes reconstructing energy-dependent cross sections from resonance parameters, Doppler broadening to a variety of temperatures encountered in real systems, defining data for use in both continuous energy Monte Carlo codes, as well as multigroup Monte Carlo and deterministic methods codes.

In this chapter, both WHAT needs to be done by our data-processing codes and WHY have been defined; also, the overall perspective of a general plan, “The Big Picture,” for the historical and current development of the methods used over the last half century as well as today, has been given.

The importance that processing code verification projects have played over the past decades as well as today has been stressed here. It should be remembered that computer codes have always been very complicated, and it is almost impossible to verify the results calculated by any one code without any comparison with one or more other independently developed codes. A classic mistake is to assume that checking the results will impede progress, whereas in fact experience has shown that taking the time to verify results can actually in the long run lead to savings in time and major improvements in the reliability of our codes.

1 Overview

1.1 Introduction

The chapter on Nuclear Data Preparation for the CRC Handbook of Nuclear Reactors Calculations (Cullen 1986) was written by me in 1986; the present chapter is an update of this earlier work. When this earlier work was reread now, what was surprising is that even after 20 years only a very little has changed. Most of the methods described here are the same that we used back then. The big differences between the Nuclear Data Preparation then and now are mostly due to the enormous advances that have occurred in computer size and power since then. This now allows us to routinely do things in a few minutes that 20 years ago took us days or weeks or was simply not feasible at all. Closely related are the advances in nuclear model codes, which have resulted in current nuclear data that are much more detailed, and advances in particle transport codes that are capable of using this much more detailed data. Standing as an interface between the evaluators and their evaluations, on the one hand, and the transport codes, on the other hand, are our nuclear data-processing codes; these data-processing codes have also made great strides to take advantage of the enormous increase in computer size and power, and to accommodate changes in modern evaluations and their use in our transport codes. In order to document the historical development of the methods that we use today, references to the methods as they were originally developed have been retained;

these are references: Weinberg and Wigner (1958), Glasstone and Edlund (1962), Kinsey (1970), Howerton et al. (1975, 1978), Igarasi et al. (1969), Pope (1973), Goel and Krieg (1975), Kolesave and Nikolaev (1977), Garber and Brewster (1975), Plechaty et al. (1978a,b), Alder et al. (1963), Cashwell et al. (1972), Lichtenstein et al. (1979), Plechaty and Kimlinger (1971), Emmett (1975), Engle (1967), Mynatt et al. (1973), Lathrop and Brinkley (1970), Hardie and Little (1969), Fowler et al. (1971), Cullen (1974, 1976, 1977a,b, 1978a,b, 1979a–c, 1980a–c), Cashwell and Everett (1959), Seamon (1981), Cullen et al. (in press), Greene et al. (1976), Lamb (1939), Wigner and Wilkins (1944), Meghreblian and Holmes (1960), Friedman (1961), Breit and Wigner (1936), Gregson and James (1965), Hutchins et al. (1973), Green and Pitterle (1968), Patrick (1982), Mughabghab et al. (1981), Gyulassy et al. (1972), Jeans (1948), Toppel (1971), Joanou et al. (1961), Goldstein and Cohen (1962), Goldstein (1972, 1975), Abramowitz and Stegun (1965), Doyas et al. (1971), Lathrop (1965), Bondarenko et al. (1964), Shakespeare (1982), Weisbin and LaBauve (1973), Zijp et al. (1981), Konshin (1981), Ganesan (1981), Ganesan et al. (1982), Perez et al. (1981), Buchholz (1980), Westfall (1978), MacFarlane and Boicourt (1975), Perkins (1982), Greene (1973), Hong and Shultis (1982), Nikolaev and Phillipov (1963), Stewart (1964), Levitt (1972), Cullen and Pomraning (1980), Plechaty and Kimlinger (in press), Graves-Morris (1973), Askew et al. (1966), Bremblett and Czirr (1969), Czirr and Bramblett (1967), Lewis and Soran (1978), Plechaty (1977), and updated references starting with Cullen (1986) have also been added by me. It is hoped that this allows us to preserve the historical record, and much of this chapter presents details of methods used in today's data-processing codes, ll in particular the ENDF/B preprocessing codes – PREPRO (Cullen 2007a–c) and NJOY (MacFarlane and Muir 1994), as they exist today. (Note that the SIGMA1 convention of extending cross sections outside of their tabulated range as $1/V$ differs from the original convention of extending them as constant. The $1/V$ convention is an improvement based upon accumulated years of experience using the SIGMA1 method; This result indicates that to minimize the error in the contribution from any given energy, such as a resonance peak energy, E_R , the Doppler width should be defined at $\sqrt{E_0} = 1/2 (\sqrt{E_R} + \sqrt{E})$, not simply ER ; The Joint Evaluated File (JEF), to be distributed by the NEA-Data Bank, Saclay, on behalf of the contributing OECD countries.)

This *Handbook of Nuclear Energy* will present a variety of methods that are currently used to solve nuclear fission-related problems, with emphasis on reactor core problems. The solution of these problems involves describing the transport of neutrons, photons, and charged particles through matter and the interaction of these “particles” with matter. Throughout the following discussion, for simplicity, neutrons, photons, and charged particles will collectively be referred to as particles.

In this handbook, there will be a great deal of discussion concerning solution of the linearized Boltzmann equation in order to determine the distribution of particles or flux in space, direction, energy, and time. For time-dependent problems, we may also have to solve a related system of equations to describe the change in composition of the medium, due to burn-up and radioactive decay. Throughout this discussion, it is important to remember that generally the determination of the distribution of particles or flux is a means to an end, rather than an end itself. That is to say, generally, what we are interested in describing is some effect caused by the interaction of the particles with the medium through which they are transported. For example, in reactor core calculations, we are interested in determining the reaction rates for

individual reactions and leakage from the core. These may in turn be used to determine a variety of quantities or properties, including

1. The *static and dynamic multiplication factor* of the system, which will allow us to determine whether or not the system is statically stable (i.e., is critical) and whether or not the system is dynamically stable (e.g., has a negative Doppler coefficient).
2. The *energy deposition rate*, which will allow us to determine the amount of power generated and the temperature distribution throughout the system. This information can be used to determine how much power a reactor can safely generate and temperature-dependent effects within the reactor.
3. The *rate of disappearance or build-up of materials* within the reactor, which will allow us to determine the time-dependent composition of the system. This information can be used to establish a fuel management program and will allow us to determine the radiation damage to the reactor, e.g., gas production, atom displacement, etc.

Any number of examples of such kind may be given. The important point to understand is that none of these quantities can be defined directly in terms of the distribution of particles, such as the neutron flux; so it is not sufficient to merely solve the linearized Boltzmann equation to define the flux. Again, let us stress that knowing the flux distribution is merely a means to an end. All the effects we are really interested in depend on nuclear data. Even if one could somehow exactly calculate the distribution of particles or flux, without any adequate nuclear data, it would still not be possible to determine the effects that we are really interested in. The second point is that in discussing the nuclear data we must consider not only the data that are used directly to determine the distribution of particles, but also the data that are then subsequently used in conjunction with the determined distribution of particles or flux to define the quantities that we are really interested in, e.g., energy deposition, gas production, and many other quantities as explained later in this chapter. The third point is that throughout this book many methods and approximations will be introduced; and in all cases, these methods and approximations will attempt to conserve some basic properties of the Boltzmann equation. However, since we are interested in effects, as opposed to determining the particle distributions alone, we will attempt to conserve reactions, rather than flux or cross section. In principle, reactions are a physical observable that we can directly relate to what is happening in any system.

1.2 The ENDF/B Format

As of the mid-1960s there were many nuclear data libraries; basically, each laboratory had its own data library, in its own format, for its own computer codes. Each library was designed to get the “best” answers using the laboratories’ own computer codes, for the specific applications that each laboratory was interested in. This often required nonphysical “fixes” or fits to force agreement between computer code results and the laboratory’s finished applications.

By the mid-1960s an effort had begun to establish a nuclear data library, containing evaluated data based solely on the “best” available differential measurements and nuclear model calculations. It was hoped that one common library of data could be universally adopted for use throughout the world. Unfortunately, this goal has not been achieved yet. Even today we have a variety of nuclear data libraries, to name a few: ENDF/B-VII in the United States, JEF in the European Community, JENDL in Japan, CENDL in China, and BROND in Russia.

Even over 40 years after the start of the ENDF/B project we still have significant differences between the important evaluations in these various data libraries; these differences are often based on valid, scientifically based judgments that one set of measured data or one nuclear model calculation is better than another; unfortunately, the differences can also be based on national “pride and prejudice”; simply, the human nature that we cannot seem to avoid.

Even though the ENDF/B effort has not led to a common set of evaluated nuclear data, it has led to a common universally accepted format for the data; e.g., all the nuclear data libraries mentioned earlier: ENDF/B-VII, JEF, JENDL, CENDL, and BROAD have all adopted the ENDF/B format, which is now in its sixth version and is named ENDF/B-6 (Kinsey 1970; Rose and Dunford 1990). This common format is a great step forward, because it allows us to more easily compare data from the various libraries, and has also greatly reduced the effort on the nuclear data-processing codes. Compared to the earlier situation wherein each laboratory had to develop its own codes to process its own nuclear data, in its own computer-based format, today there are only a few nuclear data-processing code systems that service the needs of the entire international nuclear community.

As today the ENDF/B-6 format is universally used, it simplifies the writing of this chapter; because the focus can be on this single format and the few nuclear data-processing code systems that are used today are being focused. The latest ENDF/B-VII.0 data (Oblozinsky et al. 2006), which are now freely available online (Cullen 2007a–c), are also scrutinized.

1.2.1 ENDF/B Tables and Interpolation

Most of the nuclear data contained in the ENDF/B system are in the form of tabulated values with an interpolation law defining how to interpolate between the tabulated values. Since we are interested in the integral results, these interpolation laws are very important in order to uniquely define our nuclear data at all energies; and not just the energies at which the data are tabulated. The interpolation laws allowed in ENDF/B include histogram, linear or log in the x and y dimensions (five basic interpolation laws), and additional laws for special cases such as charged-particle thresholds.

These interpolation laws are very useful during the evaluation process; e.g., low-energy capture and fission cross sections tend to vary as $1/V$, which can be exactly defined using log–log interpolation. Similarly, spectra often have analytical forms such as \sqrt{E} at low energy and exponential at high energy, which can be defined exactly using nonlinear interpolation laws. For these reasons, we would like to maintain these quite general interpolation laws for use during evaluation and presentation of original evaluations in the ENDF/B format.

But these interpolation laws present problems when we want to use the evaluated data in the ENDF/B format. The most obvious problem is that the sum (redundant) cross sections, such as the total, cannot be exactly defined using any of the ENDF/B interpolation laws, except linear–linear. Less obvious is that although the nonlinear interpolation laws can be used to analytically define integrals of the data, these integrals are often numerically unstable in ways that are difficult to detect, and can cause errors in our calculated results.

Soon after my work got started at Brookhaven National Laboratory in 1967, over 40 years ago, it was realized that the interpolation laws defined for use with ENDF/B were a great advantage to allow evaluators to use analytical shapes for cross sections and secondary-particle

distributions. For example, at low energies both capture and fission cross sections are $1/V$ in shape, which can be exactly defined using log-log interpolation; similarly, at low energy many secondary-neutron distributions tend to vary as \sqrt{E} , which can also be defined using log-log interpolation.

However, at the same time, the flexibility of these interpolation laws has a disadvantage when these evaluations are used in applications. The most obvious disadvantage being that it can cause inconsistency in the cross sections. Subsequently, we will see an example wherein the tabulated total cross section is not the sum of its parts, solely because of the use, or in this case, misuse, of nonlinear interpolation.

To allow for both the advantages to evaluators and avoid problems during the use of the evaluations, it was realized that the solution was to provide computer codes to allow the evaluated data in the ENDF/B format to be converted from their original nonlinear-tabulated form to linearly interpolable tabulated form, to within any accuracy needed for use in applications; these codes could be used by evaluators to insure that their evaluations are consistent, and also by evaluated data users to insure that whether or not the original evaluator data are consistent, what they use in their applications are consistent.

To meet this need, a series of codes were worked out and they are all included in the ENDF/B Pre-processing codes: PREPRO (Cullen 1980a–c, 2007a–c): (1) LINEAR, to convert tabulated data to linearly interpolable form, (2) RECENT, to reconstruct linearly interpolable cross sections from resonance parameters, (3) SIGMA1, the sigma1 method to Doppler-broaden linearly interpolable cross sections was invented by me, (4) FIXUP, to define the redundant cross sections, such as total, by summation. These codes were required to make linearly interpolable cross sections available to ENDF/B-formatted evaluations. To complete the definition of cross sections, the multiband method was developed by me to handle the unresolved-resonance region. Finally to handle secondary distributions, (5) LEGEND, to linearize angular distributions, and (6) SPECTRA, to linearize energy distributions were added. As these codes were made available they were adopted by MINX (Weisbin et al. 1976), and then inherited by MINX's successor NJOY (MacFarlane et al. 1982; MacFarlane and Muir 1994); thus we now have several code systems that use this linearized data concept.

Initially, there was a great deal of resistance to the idea of replacing an “exact” cross section, such as $1/V$ at low energy by a linearized “approximation.” But eventually, data users accepted the idea as they realized that it was needed for them to be able to have consistent data for use in their applications. Today, nobody seems to question this approach, and it is widely used in our nuclear data-processing codes and our neutron transport codes. This linearizing is now such an integral part of our codes that much of this chapter is devoted to how it is used to reconstruct cross sections from resonance parameters, to Doppler-broaden cross sections, and to calculate multigroup constants.

Development of these codes has taken many years to complete; but today, we have complete systems that are freely available to data users, which include the PREPRO (Cullen 2007a–c) and NJOY (MacFarlane and Muir 1994). Much of this chapter is designed to document what these codes do, and of at least equal importance, why they do it. As successful as these efforts have been we must accept the fact that it is time to pass the torch to the next generation of nuclear data-processing code designers, wherein we will change from our traditional FORTRAN codes to a new generation of C and other language computer codes. Hopefully, this chapter will help make this transition a smooth one by allowing the new generation to understand not only what we did, but also why.

1.3 The Importance of Nuclear Data-Processing Codes

It is now common practice for transport code users to define the transport codes and nuclear data they are using, as when we say we used MCNP (Cashwell et al. 1972; X-5 Monte Carlo Team 2003) and the ENDF/B-VII.0 nuclear data (Oblozinsky et al. 2006; Cullen 2007a–c). This ignores a very important step, namely the nuclear data-processing code; this is what we call the overlooked, but often limiting factor. For example, in addition to telling users that we used MCNP and ENDF/B-VII.0, it is important for users to know that we used the NJOY data-processing system (MacFarlane and Muir 1994), and also know what versions of MCNP and NJOY were used. Only then would we be able to describe how our calculations were done.

Our recent studies (Cullen et al. 2006, 2007a–c) demonstrate that our transport codes are now very accurate, and many of the remaining limitations in the accuracy of our solutions can be traced not to transport, or even the nuclear data, but rather to approximations introduced by our data-processing codes. This suggests that rather than being the overlooked factor, more emphasis should be placed on improving the accuracy and reliability of our nuclear data-processing codes. In this chapter, we will attempt to clearly define the approximations that are being introduced by our data-processing codes.

1.4 First-Order Approximations: Space, Energy, and Time

Even today, with all the available computer size and speed it is still not possible for us to exactly solve the linearized Boltzmann equation. Today's methods still include approximations needed to allow us to solve our problems within sufficient accuracy and in a timely manner to meet our programmatic needs. The most obvious, first-order approximations, is that we do not attempt to define solutions on a continuous spatial and energy basis. Instead, we try to accurately define “average” values; averaged over spatial zones, over-energy groups, and sometimes over time intervals. In terms of our applications wherein we are interested in physical observables, if we can accurately define averages these are usually good enough to meet our programmatic needs. Beyond these first-order approximations, there are other approximations that are related to the accuracy of our nuclear data, and how accurately our nuclear data can be processed into a form that it can be used by our transport codes; this includes multigroup cross sections and group-to-group transfer matrices, which are also averaged over energy ranges and spatial zones and time intervals.

1.5 Basic Equations

In this handbook, we will be discussing how to solve the linearized Boltzmann equation, which in its energy- and time-dependent form can be written as (1),

$$\begin{aligned} \frac{1}{v} \frac{\partial}{\partial t} N(r, \Omega, E, t) + \vec{\Omega} \cdot \vec{\nabla} N(r, \Omega, E, t) + \Sigma_t(r, E, t) N(r, \Omega, E, t) \\ = \frac{1}{4\pi} \int_0^\infty dE' \int_{\Omega'} d\Omega' \Sigma(r, E' \rightarrow E, \Omega' \rightarrow \Omega) N(r, \Omega', E', t) + S(r, \Omega, E, t), \end{aligned} \quad (1)$$

where

$N(r, \Omega, E, t)$ neutron flux per unit volume, energy, and solid angle at time t .

v is the neutron speed (not, velocity).

$\Sigma_t(r, E, t)$ total macroscopic cross section at location r and time t for a particle of energy E .

Generally, the macroscopic cross sections will be spatially dependent since different materials will be used at different positions (e.g., core vs. shield) and time dependent because of burn-up.

$\Sigma(r, E' \rightarrow E, \Omega' \rightarrow \Omega)$ differential cross section, describing the transfer of particles with initial coordinates E', Ω' before the interaction to E, Ω after the interaction. Written in this form, it includes the effect of all possible processes, e.g., scatter, fission, ($n, 2n$), etc.

$S(r, \Omega, E, t)$ flux-independent neutron source.

The differential cross section can be written in terms of the contributions from the individual reactions in the form

$$\Sigma(r, E' \rightarrow E, \Omega' \rightarrow \Omega) = \sum_k M_k(E') \Sigma_k(r, E') P_k(E' \rightarrow E, \Omega' \rightarrow \Omega), \quad (2)$$

where the summation is over reactions k , e.g., $k =$ elastic, fission, etc., and

$M_k(E')$ Multiplicity or average number of secondary neutrons, e.g., 1 for elastic, 2 for ($n, 2n$), and $\nu(E')$ for fission.

$\Sigma_k(r, E')$ Reaction cross section for process k .

$P_k(E' \rightarrow E, \Omega' \rightarrow \Omega)$ Probability distribution for process k , describing the transfer of particles with initial coordinates E', Ω' before the interaction to E, Ω after the interaction. This is a normalized distribution which is equal to unity when integrated over all final E, Ω .

For the linearized Boltzmann as written previously, everything is assumed to happen instantaneously at time t , at a given spatial location r . If we consider delayed neutrons, the equation is further complicated by an additional integral over all earlier times t' ; for simplicity, this complication will not be included in the following equations.

If we are to consider the changes in composition due to burn-up and/or radioactive decay, we must consider the coupled set of equations describing the changes in the composition for each constituent material $N_j(r, t)$ as a function of position and time.

$$\frac{dA_j(r, t)}{dt} = -[R_j(r, t) + \lambda_j]A_j(r, t) + \sum_{j'} [R_{j'}(r, t)\alpha(j' \rightarrow j) + \beta(j' \rightarrow j)]A_{j'}(r, t)$$

and

$$R_j(r, t) = \int_0^{\infty} dE \sigma_j(E) N_0(r, E, t), \quad (3)$$

where

$A_j(r, t)$ Atoms of nuclide j

λ_j Decay constant of nuclide j

$\sigma_j(E)$ Microscopic cross section of nuclide j

$\alpha(j' \rightarrow j)$ Probability that an interaction with a nuclide j' atom will create a nuclide j atom

- $\beta(j' \rightarrow j)$ Probability that a decay of a nuclide j' atom will create a nuclide j atom
 $N_0(r, E, t)$ Scalar neutron flux (integrated over direction Ω)
 $R_j(r, t)$ Reaction rate of nuclide j at (r, t)

1.6 Species of Particles

Within a fission reactor, each fission event results in the release of approximately 190–200 MeV of energy. This energy is distributed approximately as follows (2),

Kinetic energy of fission production	162 MeV
Beta decay energy	5
Gamma decay energy	5
Neutrino energy	11
Fission neutron energy	6
Instantaneous gamma ray energy	6
Total	195 MeV

In addition to the energy released in fission, energy is also released because of exoergic reactions, such as (n, p) . Finally, the energy of the neutron as it slows down is distributed to other species of particles because of photon production from inelastic scatter and nuclear recoil due to scatter.

Since energy within the reactor core is distributed between neutrons, photons, and charged particles, in principle, there will be similar equations for each species and these equations will be coupled, since one species of particles can produce particles of a different species, e.g., photon production due to neutron capture, and photonuclear neutrons due to photon interactions. However, as applied to nuclear-fission reactor cores, the only transport calculations that will be considered here will be transport of neutrons and photons.

The mean-free path of fission products and charged particles is short enough that they may be considered to come to rest and deposit their energy at the point at which they are “created” or emitted by a nucleus, and their transport need not be considered at all. Although the transport of charged particles be ignored, the production of charged particles will be considered, as it is important to consider the production of hydrogen and helium gas due to proton, deuteron, triton, He₃, and alpha emission. The production of such gases can be determined directly from a known (previously calculated) distribution of neutrons, since evaluated data libraries now contain hydrogen- and helium-production cross sections (Kinsey 1970; Rose and Dunford 1990). Similarly, effects such as heat production (KERMA) and displacement production (DPA) can be calculated. From a known neutron distribution and production cross section, the production of gas of type x can be simply calculated from

$$\frac{dG_x(r, t)}{dt} = \int_0^\infty dE \Sigma_x(r, E, t) N_0(r, E, t), \quad (4)$$

where

- $\frac{dG_x(r, t)}{dt}$ Production rate of gas of type x
 $\Sigma_x(r, E, t)$ Macroscopic production cross section of gas x
 $N_0(r, E, t)$ Scalar flux (integrated over direction Ω)

The transport of photons is important in reactor core calculations. Since photons tend to transport longer distances than neutrons, the photons tend to have a smoothing influence on energy deposition, by depositing their energy over a wider spatial region. In principle, neutron production due to photon interaction (photonuclear reactions) should also be considered; there are a number of situations wherein such production is important, e.g., systems containing appreciable quantities of beryllium. However, coupling of the neutron and photon transport equations in this way complicates the solution of the equations and for reactor core calculations, it is generally judged as “not to be worth the effort.” Therefore, the only coupling that we will consider may be photon production due to neutron interactions. With this assumption, the neutron transport equation may be solved independently; the then known neutron distribution may be used to define a neutron-induced photon source, and the photon transport equation may then in turn be solved. Therefore, the cross sections that we must consider include the following five categories:

1. Neutron interaction
2. Neutron-induced photon production
3. Photon interaction
4. Gas (charged particle) production due to neutron interaction
5. “Effect” production, such as heat (MERMA) and displacement (DPA)

Of these five categories, gas and “effect” production can be calculated using a known (previously calculated) neutron distribution and production cross sections, as in (4). Since it is completely analogous to our treatment of multigroup cross sections presented later in this chapter, it will not be explicitly considered further in this chapter. Another type of data that must be considered is thermal-scattering law data; this data is briefly discussed here and more extensively in  Chap. 3 on slowing down and thermalization.

Of the remaining three categories, since the emphasis of this handbook is on nuclear power and fission reactor core calculations, major emphasis will be placed on the treatment of neutron interactions. Much of the treatment of photon interaction and production is very similar to the treatment of neutron interactions and secondary-neutron energy distributions. Therefore, photon interaction and production will only be mentioned when its treatment differs from that required for neutron interactions.

1.7 Evaluated Data

In order to solve (1), obviously we need to know the total cross section and the cross section, and multiplicity and secondary energy–angle distributions for each reaction. In order to solve (3), we need to know the cross sections for individual reactions, half-lives, and probability of production of nuclides due to interaction or absorption of other nuclides. Of the data required to solve (3), only the cross sections need to be processed prior to use; half-lives and production probabilities are basic nuclear data that may be used directly in applications. The treatment of cross sections for use in (3) is completely analogous to the treatment of cross sections for use in (1); and as such, (3) will not be explicitly considered further in this chapter.

At the present time, there is no single unified theory of nuclear cross sections that will allow us to predict all nuclear cross sections. Therefore, the presently available cross sections are obtained by combining the results of differential and integral experimental measurements with the results of nuclear model calculations, to define the evaluated cross sections that are

used in reactor calculations. The presently available, evaluated nuclear data libraries contain almost all the data that we require, and in the following sections, we will briefly review the representations that are used in these data libraries. Examples of data that may not be explicitly present in the evaluated libraries and may require the use of additional models is the calculation of KERMA and DPA; these additional models will be covered elsewhere in this handbook.

1.7.1 Neutron-Interaction Data

Cross Sections

Evaluations represent the total, elastic, capture, and fission cross sections in the form of resonance parameters plus a tabulated-background cross section (Kinsey 1970; Rose and Dunford 1990). The most general representation at successively higher energies is

1. Tabulated cross sections at low energy.
2. Resolved-resonance parameters plus a tabulated background cross section.
3. Unresolved-resonance parameters plus a tabulated background cross section.
4. Tabulated cross sections at higher energies.

The cross sections for all other reactions are represented in tabular form, e.g., inelastic, ($n, 2n$), etc. Since in order to use cross sections they must be defined at all energies, all tabulated cross sections also have an interpolation law associated with them, in order to uniquely define the cross sections at all energies between the energies at which the cross sections are tabulated.

The major difficulty in processing the neutron-interaction data for later use in applications is that modern evaluations contain a great deal of resonance structure, which makes it very difficult to accurately define the combination of resonances and background cross sections. For example,  [Fig. 1](#) illustrates the ENDF/B-VII.0 (Cullen 2007a–c), U238 elastic cross section, at 0 and 300 K, which has been reconstructed from resonance and background combinations; and in the case of 300 K data, Doppler broadened, in order to obtain the energy-dependent cross section in tabulated form (Cullen 2007a–c). Here, just this one elastic cross section requires between 250,000 energy points (at 0 K) and 50,000 (at 300 K). The sheer size of these data tables can cause a problem during not only during data processing, but also during subsequent use in applications.

 [Figure 1](#) shows some interesting details that we should mention. First at the top of the figure, we can see that the resolved-resonance region extends from 10^{-5} eV up to 20 keV, and above this the unresolved-resonance region extends from 20 keV up to 149 keV. Note the resonance structure in the resolved-resonance region that abruptly changes to the smooth cross section in the unresolved-resonance region; this is because for this figure in the unresolved-resonance region we only plot the infinitely dilute cross section (explained later). Note also the effect of temperature, with the 300 K temperature cross section being much smoother than the 0 K data, in the resolved-resonance region.  [Figure 2](#) for the 1–2 keV energy range, shows the effect of Doppler broadening in better details. Finally, note the range of the cross section that extends over many orders of magnitude, in very narrow energy ranges; this makes the sampling of this data with accuracy, very difficult. For example, if we randomly sample an energy in the energy range of  [Fig. 2](#), we can see that in most cases we will completely miss the resonances and select the smooth potential cross section between resonances.

Figure 1
U238 elastic cross section, entire energy range

Secondary-Neutron Distributions

The secondary-neutron distributions are represented in one of several available forms depending on whether the secondary energy and scattering angle are considered to be correlated or uncorrelated. For two body reactions, such as elastic and inelastic scattering, the scattering angle and secondary energy are exactly correlated. In order to describe such reactions, the angular distribution is specified and the corresponding secondary energy can be uniquely calculated by considering conservation of energy and momentum. In this case, the angular distribution may be given in either tabulated or Legendre coefficient form and is given in the center-of-mass system. Figure 3 illustrates elastic angular distributions for ENDF/B-VII.0 (Oblozinsky et al. 2006; Cullen 2007a–c), which were reconstructed from Legendre coefficients using the LEGEND code (Cullen 2007a–c).

For uncorrelated reactions, both angular and energy distributions of secondary neutrons are specified and the final distribution is the product of these two distributions. In this case, the angular distribution must be given in the laboratory system. The most common representation for such reactions in current evaluations is to specify the angular distribution as isotropic.

Figure 4 illustrates some fission spectra for ENDF/B-VII.0 (Oblozinsky et al. 2006; Cullen 2007a–c), which are given as uncorrelated data, with tabulated energy spectra and isotopic angular distributions. From this figure, we can see that the fission spectra between 0 and 5 MeV incident neutron energy are very smoothly varying with incident neutron energy.

Figure 2
U238 elastic cross section, 1–2 keV energy range

Finally we have correlated energy–angle distributions, which are correlated, but not exactly correlated. In this case, we have distributions that are defined as functions of both secondary energy and direction; defined by specifying either the energy spectra at a given set of directions, or the angular distributions at a given set of secondary energies. Recent evaluations are using correlated energy–angle distributions more and more, indicating the improved ability of our nuclear model codes to accurately calculate such distributions. Figure 5 illustrates some (n, n') continuum spectra for ENDF/B-VII.0 (Oblozinsky et al. 2006; Cullen 2007a–c) that are given as correlated energy–angle distributions, which were reconstructed as energy spectra for viewing using the SIXPAK code (Cullen 2007a–c). These correlated energy–angle distributions were created using a nuclear model code that outputs results as histograms, rather than as continuous in energy. These histogram steps are typically keV wide and at high energy; these are more than adequate, but we can see that at low energy these histograms result in unrealistic “steps” in the distributions; our transport codes are already dealing with this problem (Cullen et al. 2007a–c).

1.7.2 Neutron-Induced Photon Production

Photon production is complicated because in general it will be composed of both discrete and continuum photons; and in addition, there may also be a time-dependent component wherein

Figure 3
U238 elastic angular distributions, 1–3.5 MeV energy range

some photons are not produced instantaneously at the time of the neutron collision. Discrete photons may be represented in a number of different forms (Kinsey 1970; Rose and Dunford 1990). In one form, the cross section for a given reaction and the resulting transition probability array, between levels, are given. In a second form, one may specify the multiplicity (average number of photons) and cross section for the production of each discrete photon. Both these representations require knowledge of the neutron cross section that induced the reaction. Alternatively, one may simply specify a photon-production cross section for each discrete photon and the continuum.

The distribution of neutron-induced photon production is represented in a form similar to the distribution of secondary neutrons. For discrete photons, energy and angle are exactly correlated and only the angular distribution of photons is specified. For continuum photons, both angular- and energy distribution of photons must be specified. In most current evaluations, the angular distribution of photon production is isotropic, which greatly simplifies the calculation and use of photon-production data (► Fig. 6).

Nuclear data users should be warned that many current evaluations do not include neutron-induced photon-production data. For example, the ENDF/B-VII.0 library (Oblozinsky et al. 2006; Cullen 2007a–c) contains 393 evaluations (isotopes and elemental) and only about half of these include neutron-induced photon production; the fraction is even lower in older data libraries. Almost none of the current evaluations include capture-gamma ray lines, which are

■ **Figure 4**
U238 elastic fission spectra, 0–5 MeV energy range

unique to each isotope. A second warning is that when the neutron-induced photon production is included, energy conservation can be a problem; this can be so severe that photons carry off more energy than is available in a reaction.

1.7.3 Photon Interaction Data

The ENDF/B-VII.0 photon-interaction data is based entirely on the Livermore Evaluated Photon Data Library (EPDL) (Cullen et al. 1997). For those interested in fluorescence and/or electron transport, there are also two other libraries included in ENDF/B-VII.0: The Evaluated Atomic Data Library (EADL) (Cullen et al. 1991a,b) and the Evaluated Electron Data Library (EEDL) (Cullen et al. 1991a,b); these libraries are of little interest for reactor core calculations and as such will not be discussed further in this chapter. The EPDL library included elemental data for all $Z = 1-100$. Photon-interaction cross sections are given in a tabulated form with an interpolation law specified between tabulated points. Compared to neutron cross sections, photon-interaction cross sections are relatively smooth and do not create any special processing problems. For uranium, photon-interaction cross sections are shown in [Fig. 7](#).

■ **Figure 5**
 U238 (n, n') continuum spectra, 8.5–16 MeV energy range

In principle, the angular distribution of secondary photons could be specified in the same form as is used for neutrons. However, in the case of photons, a more natural representation is to use a combination of analytical forms and a correction factor: for coherent scattering, this correction factor is named the form factor; and for incoherent scattering, it is named the scattering function. At high energies, the Klein–Nishina formula is an excellent means of describing incoherent scattering; and at low energies, the coherent distribution assumes the simple form $(1 + \mu^2)$, where μ is the scattering cosine. At other energies, these analytical forms are modified by the form factor (coherent scatter) and scattering function (incoherent scatter), as shown in [Fig. 8](#).

Generally, when compared with neutrons, the processing of photon cross sections are rather straightforward and present little or no difficulty. However, processing the angular distributions of secondary photons can be difficult for two reasons. First, although analytical forms and correction factors are a convenient means to represent angular distributions, Legendre coefficients or tabulated angular distributions are more convenient for use in many applications. Second, the angular distributions can be very anisotropic and difficult to adequately represent in transport calculations, e.g., in S_n calculations, many Legendre coefficients are required to accurately represent the angular distributions. An alternative method of using these correction factors is defined in (Cullen 1995).

Figure 6
U238 (n, n') nonelastic photon emission spectra

1.8 Approximate Methods

Unfortunately, an exact solution to Boltzmann equation (1) is still beyond our capabilities, even with the most modern and powerful computers that we have today, and we must introduce certain simplifying assumptions before attempting a solution. Once we consider introducing simplifying assumptions, we find that there are a variety of them that can be used, each of which leads to a different method of solving the pertinent equations. For example, several well-known methods include Monte Carlo, discrete ordinates (S_n), and diffusion. Even within each of these methods there are still further subdivisions, such as continuous energy or multigroup Monte Carlo. Unfortunately, the data requirements and methods of cross-section preparation depend on the method that will subsequently be used to solve the Boltzmann equation or an approximation to it.

1.8.1 Monte Carlo Versus Deterministic Codes

There are two basic approaches to using cross sections: continuous energy and multigroup. Generally, continuous energy particles and cross sections are used in Monte Carlo calculations as eight (8) codes, such as the code used in a recent code comparison (Cullen et al. 2007a-c), in the

Figure 7
Uranium photon-interaction cross sections

following alphabetical order: COG, CE-KENO, MCNP, MERCURY, MONK, TRIPOLI, TART, and VIM. However, there are also Monte Carlo codes such as TART (Cullen 2005), which uses continuous energy particles and can use either continuous energy or multigroup cross sections, and even Monte Carlo codes such as MORSE (Emmett 1975) which uses multigroup particles and cross sections. Multigroup particles and cross sections are used in discrete ordinates codes, such as ANISN (Engle 1967), DOT (Mynatt et al. 1973), TWOTRAN (Lathrop and Brinkley 1970), and PARTISN (Ray et al. 2005) and diffusion codes such as 1DX (Hardie and Little 1969) and CITATION (Fowler et al. 1971). We will consider each of these approaches in turn.

1.8.2 Continuous Energy

Cross Sections

In this section, we will discuss continuous-energy cross sections and secondary-neutron distributions as used in Monte Carlo codes. The main difficulties in processing cross sections for use in these codes are reconstruction of energy-dependent cross sections and Doppler broadening, in order to account for temperature dependent effects. Each of these topics requires extensive discussion and is covered in detail in the later sections of this chapter.

■ **Figure 8**
Uranium form factor and scattering function

Another problem is how to define the cross sections in the unresolved-resonance energy region. In the unresolved-resonance region, modern evaluations do not uniquely define energy-dependent cross sections; they only define the distribution of resonance widths and spacing (Kinsey 1970; Rose and Dunford 1990), from which it is possible to uniquely define average properties. One of three approaches may be used in the unresolved-resonance region:

1. *Use group-average cross sections* processing of data into this form is discussed later in this chapter under self-shielding.
2. *Statistically select a ladder of resonances* from the distribution of resonance widths and spacings. The ladder of resonances can be either used to calculate energy-dependent cross sections, for direct use in transport codes or can be processed further into the form of cross-section probability tables (Levitt 1972), for later use in Monte Carlo calculations. This approach essentially eliminates the unresolved region or at least allows it to be treated in a manner similar to the resolved-resonance region, as will be discussed later in this chapter under reconstruction and Doppler broadening.
3. *Statistically include the distribution of cross sections* by attempting to simultaneously reproduce both shielded and unshielded conditions. This approach will be described later in this chapter under the multiband method (Cullen 1972, 1974, 1977a,b, 1978a,b).

Angular Distributions

In order to describe the angular distribution of secondary neutrons, the normalized angular distributions are converted into the form of either a continuous integral distribution or equally probable angular bins. For example, given a tabulated, linearly interpolable angular distribution for one reaction,

$$1 = \int_{-1}^{+1} p(E, \mu') d\mu', \quad (5)$$

where μ' is the cosine of the scattering angle.

We can define a continuous cumulative angular distribution

$$P(E, \mu) = \int_{-1}^{\mu} p(E, \mu') d\mu'.$$

Starting from a given tabulated, linearly interpolable angular distribution, the continuous cumulative angular distribution will be quadratically interpolable; and in order to reproduce the differential distribution $p(E, \mu)$, it is very important that quadratic interpolation be used, e.g., assuming the cumulative distribution as linearly interpolable is equivalent to assuming the differential distribution as a constant between tabulated values, similar to the equally probable bins described later. Following this procedure makes sampling very accurate, but it can be expensive too.

An alternative is N equally probable angular bins, where one solves for cosines μ_k such that

$$\frac{k}{N} = \int_{-1}^{\mu_k} p(E, \mu') d\mu', \quad k = 1, 2, \dots, N. \quad (6)$$

Within each bin, the distribution is then assumed to be constant. Following this procedure makes sampling very fast.

Within a Monte Carlo code, either of these representations can be randomly sampled. Each of these representations has its advantages and disadvantages. The continuous cumulative angular distribution has the advantage of being very accurate, but it has the disadvantage that it can be time consuming to sample. The equally probable angular bins have the advantage of being very fast to sample, but it has the disadvantage of being less accurate, and details of the angular distribution may be lost. When many equally probable bins are used, we expect the results using either approximation to yield similar results.

In the evaluated data, angular distributions are given at a set of incident neutron energies; again, we show an example of U238 elastic angular distributions.

One problem that either method has is how to accurately interpolate in incident energy between incident neutron energies at which angular distributions are tabulated. For example, from the previous figures we can see how the interference minima and maxima shift with incident neutron energy. Obviously, to interpolate between say 3 and 3.5 MeV incident neutron energy, we would introduce an error if we interpolate the earlier-shown differential angular distributions orthogonally, along lines of constant cosine; and yet, many codes do exactly this, and this is what ENDF-102 specifies for the evaluated data (Kinsey 1970; Rose and Dunford 1990). It is much more accurate to interpolate the cumulative angular distribution; the shifting minima and maxima are better modeled as continuously shifting with the cumulative integrals.

Energy Distributions

For uncorrelated distributions, the secondary-energy distribution must also be sampled. This can be done directly using the functional forms available in evaluations, such as Maxwellian, exponential, etc. Alternatively, this can be done using a technique that is completely analogous to the treatment of angular distributions described earlier.

If this is done, using the cumulative distribution can be very expensive, as it may require many tabulated secondary-energy points to represent each tabulated spectrum. When using equally probable bins, extreme care must be taken in order to avoid distorting the secondary-energy distributions, as illustrated in [Fig. 9](#).

Unlike the angular distributions that extend over the cosine interval $(-1, +1)$ alone, the secondary-energy distributions in principle can extend over the entire range of possible secondary energies, up to $(0, \infty)$, and over many decades in value. The histogram representation of secondary-energy distributions can result in very wide energy bins in low-probability energy ranges. This is particularly a problem if it occurs at the low- and high-energy limit of the distributions. For example, starting from a Maxwellian or Watt distribution (Kinsey 1970; Rose and Dunford 1990) to represent the spectrum of fission neutrons, using 32 equally probable bins, can result in the highest energy bin extending from only several MeV to the upper-energy limit of the evaluation, e.g., 20 MeV. Using more bins cannot solve this problem because in this case even using 1024 bins can result in the highest energy bin extending from near 9 to 10 MeV,

Figure 9
U238 fission spectrum compared to bins and fit

up to 20 MeV, as shown in  Fig. 9. This uniform distribution over this energy range may be compared to the exponential decrease with energy predicted by the Maxwellian or Watt distribution to realize how much this representation can distort the actual distribution; e.g., in  Fig. 9 the last bin from about 9–20 MeV overestimates the extreme high-energy spectrum by a factor of over 60 (6,000%). An alternative treatment of energy distributions is to sample an analytical expression in low-probability energy ranges. For example, at low energy most energy distributions will vary as \sqrt{E} in E , and at high energy as $\text{Exp}[-A \cdot E]$ or $E \cdot \text{Exp}[-A \cdot E]$. This figure illustrates the results for a U238 fission spectrum, where we have shown 1,024 equally probable bins, as well as a low-energy \sqrt{E} fit and a high energy $E \cdot \text{Exp}[-A \cdot E]$ fit. Note how poorly the equally probable bins agree with the fission spectrum in the low-probability energy ranges at low and high energy. In contrast, the analytical extensions show an excellent agreement with the fission spectrum. This illustrates that equally probable bins, for speed of sampling, can be combined with analytical extension to produce accurate results over the entire secondary-energy range of spectra.

As in the case of angular distributions, one also has the problem of how to accurately interpolate in incident energy, between the energies at which the energy spectra are tabulated. Here, it is also much more accurate to interpolate the cumulative energy distribution; the shifting minima and maxima are better modeled as continuously shifting with the cumulative integrals.

1.8.3 Multigroup

By examining  Fig. 1 it is easy to see that modern evaluations require an enormous number of data points to represent cross sections in energy-dependent form. This makes it very difficult and expensive to use cross sections in continuous energy form. An alternative is to average (1) over adjacent energy intervals to obtain the equation

$$\begin{aligned} & \frac{1}{v} \frac{\partial}{\partial t} N_g(r, \Omega, t) + \vec{\Omega} \cdot \vec{\nabla} N_g(r, \Omega, t) + \Sigma_t g(r, t) N_g(r, \Omega, t) \\ & = \frac{1}{4\pi} \sum_{g'} \int_{\Omega'} d\Omega T(g', g' - > g; \Omega' - > \Omega) N_{g'}(r, \Omega', t) + S_g(r, \Omega, t), \end{aligned} \quad (7)$$

where

$$\begin{aligned} N_g(r, \Omega, t) &= \int_{E'_g}^{E'_{g+1}} N(r, \Omega, E', t) dE', \\ \Sigma_t g(r, t) N_g(r, \Omega, t) &= \int_{E'_g}^{E'_{g+1}} \Sigma_t(r, E', t) N(r, \Omega, E', t) dE', \\ T(g', g' - > g; \Omega' - > \Omega) N_{g'}(r, \Omega', t) \\ &= \int_{E_g}^{E_{g+1}} dE \int_{E_{g'}}^{E'_{g+1}} dE' \Sigma(r, E' - > E, \Omega' - > \Omega) N(r, \Omega', E', t). \end{aligned} \quad (8)$$

Since in general we are really interested in effects caused by the distribution of neutrons and these effects depend on integral or average values of the distributions alone, if we can accurately solve these equations, then the solution is usually adequate to meet our needs, that is,

it is not necessary to determine the continuous energy-dependent distribution of neutrons. The processing of cross sections for use in these equations requires a discussion of the subject of self-shielding. In addition, the group-to-group transfer matrix must also be defined. Finally, the concept of group collapse is important. All these points are addressed in the following sections of this chapter.

The multigroup approach has a number of basic drawbacks that are difficult to eliminate by using more groups. An alternative approach to improve the multigroup approach is presented later in this chapter under the multiband method.

1.9 Summary

The preceding sections have described what nuclear data are required to be processed before they can be used in transport calculations. The following sections will describe how the data are actually processed, which include (1) reconstruction of energy-dependent cross sections from resonance parameters and (2) Doppler broadening. These two sections are required in order to obtain energy-dependent cross sections for use in Monte Carlo neutron transport codes; they also serve as a source of data in order to obtain cross sections for use in multigroup codes. In order to meet the needs of multigroup codes, we will consider (3) self-shielding, (4) the group-to-group transfer matrix, and (5) group collapse. Finally, because of the limitations of the multigroup method we will consider improvements under (6) the multiband method. By the conclusion of this chapter, we will be ready to proceed to the following chapters of this handbook, which will consider actual applications.

2 Reconstruction of Energy-Dependent Cross Sections

2.1 Introduction

Modern evaluated libraries may be divided into two separate classes depending on how cross sections are represented. One class of libraries represents cross sections using resonance parameters directly in the evaluated files, which includes ENDF/B, JEF, JENDL, CENDL, and BROND. The other class of libraries represents cross sections in tabulated form with a defined interpolation law between tabulated points, which include KEDAK, UKNDL, and ENDL. Even though the latter class of libraries does not use resonance parameters directly in the evaluated files, it does use resonance parameters in order to derive its tabulated cross sections. Therefore, by the time cross sections are ready to be used in any given application, virtually all modern evaluations have the problem of reconstructing or at least defining the resonance contribution to the cross section. In a later section on self-shielding, the problem of defining the resonance contribution in an integral sense will be addressed. Here we will address the problem of calculating energy-dependent cross sections alone.

2.2 Representation of Cross Sections

Current evaluations represent cross sections as a combination of tabulated cross sections and resonance parameters. The most general representation is

1. Tabulated cross sections at low (thermal) energy.
2. At higher energies, resolved-resonance parameters plus possibly a background section in the “the resolved-resonance region.”
3. Above the resolved-resonance region, unresolved-resonance parameters plus a background cross section in “the unresolved-resonance region.”
4. At still higher energies, tabulated cross sections extending up to the upper-energy limit of the evaluation.

We must consider how to combine these tabulated cross sections and resonance parameters in order to obtain energy-dependent cross sections spanning the entire energy range of interest. In order to do this in the following sections, we will first address the problem of how to simplify the representation of tabulated cross sections and then how to treat the resonance contribution.

2.3 Tabulated Cross Sections

In order to be used in transport calculations, cross sections must be uniquely defined at all energies. In tabular form, this is accomplished by representing the cross section as a series of (energy, cross section) tabulated points and an interpolation law between tabulated points. It is important to understand that since we are interested in integral effects we must define our data at ALL energies, not just at the energies where they are tabulated.

Some libraries use only one interpolation law to define cross sections, e.g., ENDL and SOKRATOR always assume that between tabulated points the cross section may be defined by linear interpolation in energy and cross section, whereas KEDAK and UKNDL assume logarithmic interpolation. The ENDF/B, JEF, and JENDL libraries use the ENDF/B format, which allows cross sections to be represented over different energy ranges by up to five different types of interpolation laws, such as

1. Constant cross section between tabulated energies (constant or histogram).
2. Linear variation in cross section and energy (linear-linear).
3. Linear variation in cross section, log variation in energy (linear-log).
4. Log variation in cross section, linear variation in energy (log-linear).
5. Log variation in cross section and energy (log-log).

In addition, there are interpolation laws to handle special situations, such as charged particle thresholds.

Some of these interpolation laws are extremely useful during the evaluation process as they lend themselves to accurately and simply represent some cross-section shapes, e.g., a $1/V$ cross section can be exactly represented using log-log interpolation. Even though these interpolation laws are convenient to use, care must be exercised as they can introduce inconsistencies during the evaluation process and can result in a nonunique representation of the cross section during later use in applications.

As long as the cross sections for each reaction are represented separately and there are no redundant cross sections (i.e., no sums of reactions), these five interpolation laws described earlier may be used in any combination to represent the cross sections for each reaction. However, formats such as ENDF/B do normally include redundant cross sections, e.g., the total cross section, total inelastic cross section, etc. This presents a problem, since if two different reactions are evaluated using different interpolation laws over the same energy range, generally the sum

of these reactions cannot be exactly represented by any of the five interpolation laws, with the following exceptions,

1. Constant + constant can be represented as constant.
2. Constant + linear can be represented as linear.
3. Linear + linear can be represented as linear.

There are no other legal combinations of interpolation laws. In particular, if one reaction uses any of the log-interpolation laws, it cannot be added together with any other reaction to yield a sum which can be exactly represented by any of the five interpolation laws. For example, at low energy the elastic cross section may be constant and the capture cross section may be $1/V$. If we use the constant interpolation law to represent the elastic and log-log to represent the capture, we may be able to represent each of these two reactions by tabulated points at 10^{-2} and 100 eV and their interpolation laws between these two tabulated points. However, the total cross section, which is the sum of the elastic and capture, cannot be represented by tabulated points at 10^{-2} and 100 eV and any of the allowable five interpolation laws.

How much difference does it make if in the previous example we use one interpolation law or the other to represent the total cross section? More generally, is it important to worry about interpolation laws at all? Obviously, at the tabulated energies we obtain the same cross section regardless of how we interpolate between values. What are the consequences if we simply ignore the interpolation law specified by the evaluator and assume linear-linear variation between tabulated points?

◆ *Figure 10* presents a comparison between a $1/V$ cross section and linear-linear variation for a cross section tabulated at 10^{-2} and 100 eV, as in the case of the capture cross section in the above example. From this example, it is easy to see that the difference between interpolated values using different interpolation laws can be enormous. In this case, the energy-dependent values differ by up to almost a factor of 40 (4,000%), and the average value of the cross section using linear-linear interpolation over this energy range is over five times higher than the average obtained assuming $1/V$ (log-log) variation. We can agree that such large errors are not acceptable in our applications; we need a unique interpretation of our nuclear data to avoid such errors.

This is by no means merely a theoretical example; with currently available libraries, such as ENDF/B-VII (Oblozinsky et al. 2006; Cullen 2007a-c), when one calculates even broadly energy-dependent quantities, such as resonance integrals, it is found that for many evaluations the total resonance integral is not equal to the sum of the parts. By examining the evaluations it can be seen that these differences are due to the inconsistencies in the cross sections due to the use of log interpolation.

From the preceding discussion, it may be seen that the availability of a variety of interpolation laws to represent cross sections is very convenient during the evaluation process; however, interpolation laws may introduce inconsistencies into the final evaluation. In addition, when the cross sections are actually used in applications, log interpolation laws can cause difficulties because

1. In order to make cross sections consistent, it may be necessary to ignore one or more cross sections. For example, one may ignore the tabulated total cross section and always define the total cross section as the sum of all other reactions. Alternatively, based on our experimental knowledge of cross sections, one could claim that the total is better known than the elastic, and one could also define the elastic as the total minus of all other reactions. The fact that

■ Figure 10

Example of interpolation error

there is more than one possible way to interpret an evaluation, in order to make an evaluation that uses log interpolation consistent, means that the results obtained using the evaluation may not be unique.

2. Failure to recognize the inconsistency due to interpolation laws may result in inconsistencies during a transport calculation. For example, if the total cross section is more than the sum of its parts, the difference between the total and sum of its parts can be mathematically equivalent to additional neutron disappearance. Alternatively, if the total is less than the sum of its parts, the difference can be equivalent to additional neutron multiplication. In a Monte Carlo calculation, such inconsistencies can cause a computer code to simply get confused, resulting in unreliable answers.
3. Even though it is possible to express the group integrals of cross sections using log interpolation in an analytical form, the resulting expressions when applied to use on a computer can be extremely numerically unstable, in very subtle ways that are difficult to analyze.

2.3.1 Linearized Cross Sections

For all the reasons mentioned, here we will introduce an algorithm that allows one to start from an evaluation in which any combination of the five interpolation laws described earlier are used

and reduce all cross sections to linearly interpolable form. The first question to ask is whether or not it is always possible to reduce cross sections which use any one of the five interpolation laws, between two tabulated points, to linearly interpolable form.

The constant interpolation (law 1) represents the cross section as constant (histogram), equal to the tabulated value of the cross section at one energy, for all energies between the tabulated energy and the next higher tabulated energy. This constant interpolation law can be exactly reduced to linearly interpolable form by replacing each original (energy, cross section) pair by two final (energy, cross section) pairs, one at the lower and another at the upper limit of the energy interval, with the cross section for both final pairs equal to the cross section of the original pair. For example, starting from tabulated cross sections with constant (histogram) interpolation,

$E1$ A
 $E2$ B
 $E3$ C, etc.

This table can be exactly reduced to the linearly interpolable form,

$E1$ A
 $E2$ A
 $E2$ B
 $E3$ B
 $E3$ C, etc.

Tables using law 2 are already linearly interpolable and need not be considered.

Tables obeying interpolation laws 3, 4, or 5 can be reduced to linearly interpolable form by using an interval-halving technique. Each interval is divided in half, until the value at the middle of each interval can be approximated to within some acceptable accuracy by linear interpolation between the ends of the interval. In this process, the midpoint of an interval is defined in a linear sense $(E_K + E_{K+1})/2$ for interpolation law 4 (linear E) and in a logarithmic sense $(E_K E_{K+1})^{1/2}$ for interpolation laws 3 or 5 (log E).

The convergence of the interval-halving technique can be demonstrated for these three cases by considering the difference between values obtained using linear interpolation and the exact values obtained using the given interpolation law. In terms of the interval endpoints (X_K, Y_K) and (X_{K+1}, Y_{K+1}) , the interpolation laws are

$$\begin{aligned} Y(2) &= Y_K + A_K(X - X_K); & A_K &= (Y_{K+1} - Y_K)/(X_{K+1} - X_K), \\ Y(3) &= Y_K + B_K \log(X/X_K); & B_K &= (Y_{K+1} - Y_K)/\log(X_{K+1}/X_K), \\ \log Y(4) &= \log Y_K + C_K(X - X_K); & C_K &= \log(Y_{K+1}/Y_K)/(X_{K+1} - X_K), \\ \log Y(5) &= \log Y_K + D_K \log(X/X_K); & D_K &= \log(Y_{K+1}/Y_K)/\log(X_{K+1}/X_K). \end{aligned} \quad (9)$$

Here (2), (3), (4), and (5) refer to the interpolation laws 2 through 5.

The differences between each interpolation law and linear interpolation are

$$\begin{aligned} \delta 3 &= Y(2) - Y(3) = A_K(X - X_K) - B_K \log(X/X_K), \\ \delta 4 &= Y(2) - Y(4) = A_K(X - X_K) + Y_K[1 - \exp(C_K(X - X_K))], \\ \delta 5 &= Y(2) - Y(5) = A_K(X - X_K) + Y_K \left[1 - \left(\frac{X}{X_K} \right)^{D_K} \right] \end{aligned} \quad (10)$$

We differentiate with respect to X to define

$$\begin{aligned}\frac{d\delta 3}{dX} &= A_K - \frac{Bk}{X}, \\ \frac{d\delta 4}{dX} &= A_K - C_K Y_K \exp [C_K (X - X_K)], \\ \frac{d\delta 5}{dX} &= A_K - \frac{Dk Y_K}{Xk} \left(\frac{X}{Xk} \right)^{Dk-1}.\end{aligned}\quad (11)$$

The points of maximum difference are found by setting these expressions equal to zero, as

$$\begin{aligned}X(3)_{\max} &= \frac{Bk}{A_K}, \\ X(4)_{\max} &= X_K + \frac{1}{C_K} \log \left(\frac{A_K}{Xk Y_K} \right), \\ X(5)_{\max} &= X_K \left(\frac{A_K Xk}{Dk Y_K} \right)^{1/[Dk-1]}.\end{aligned}\quad (12)$$

An important point to note is that in each case there is only one point of maximum difference. This means that during interval halving a straight line drawn between the ends of the interval will always lie either above or below the exact curve, thus preventing false convergence (see false convergence later in this chapter). This property is a result of the variation in X and Y , being either linear or log in each dimension; this is not true for other interpolation laws, such as quadratic or spline; in these cases, convergence cannot be proven.

The maximum differences are

$$\begin{aligned}\delta 3 &= B_K - A_K X_K - B_K \log \left(\frac{Bk}{A_K Xk} \right), \\ \delta 4 &= Y_K \left[1 - \frac{A_K}{C_K Y_K} \right] + \frac{A_K}{C_K} \log \left(\frac{A_K}{C_K Y_K} \right), \\ \delta 5 &= Y_K \left[1 - \left(\frac{1}{Xk} \right)^{Dk} \left(\frac{A_K Xk}{Dk Y_K} \right)^{Dk/(Dk-1)} \right] + A_K X_K \left[\left(\frac{A_K Xk}{Dk Y_K} \right)^{1/(Dk-1)} - 1 \right].\end{aligned}\quad (13)$$

By expanding these expressions and studying their convergence as the length of the interval decreases (i.e., $E_K \geq E_{K+1}$), it can be shown that all the above maximum differences approach zero as fast as $(E_{K+1} - E_K)$, except for three trivial cases. Thus, any algorithm for subdividing intervals will yield data points between which linear interpolation is satisfactory. The three cases in which the maximum error does not approach zero as fast as $(E_{K+1} - E_K)$ are the following:

1. $E_{K+1} = E_K$, $Y_{K+1} \neq Y_K$, a cross-section discontinuity that can be treated as a histogram.
2. $Y_{K+1} = Y_K$, a constant cross section that is already linear interpolable.
3. $D_K = 0$ or 1 , the cross section is already constant ($D_K = 0$) or linear ($D_K = 1$).

The subdivision at points given by (12) could be used instead of interval halving; both algorithms yield roughly the same number of final energy points. However, comparison of the two algorithms indicates that interval halving is simpler and faster.

More General Interpolation Laws

It is important to understand that although the interval-halving technique converges and allows all cross sections which initially use any of the ENDF/B interpolation laws to be reduced to

linearly interpolable form, it is not a general method of reducing an arbitrary function $f(X)$ to linearly interpolable form. An example of a case that does not converge is $f(X) = X^2$, for X between 0 and 1.

Over the decades since the start of the ENDF/B effort, other more general interpolation laws have been proposed, but they have been rejected, because they do not lend themselves to controlled convergence. An example is a cubic spline, which today is widely used in many scientific applications, but it is difficult to control. In the case of ALL, the current ENDF/B interpolation laws – the tabulated data points at the two ends of each interval (X_K , Y_K) and (X_{K+1} , Y_{K+1}) are the extrema of $Y(X)$, that is, for all values of X between X_K and X_{K+1} , the function $Y(X)$ is bound between Y_K and Y_{K+1} . This is an important point because it allows us to use the mean value theorem to bound integrals, to within any accuracy that we require. This may not be true for other interpolation laws; and in particular, it is certainly not true for cubic splines. This is an important point to understand as it affects our ability to accurately define the integral quantities that we are interested in.

Effect in Integral Quantities

If we start from any exactly known cross section subject to any of the five ENDF/B interpolation laws, we can construct an approximate cross section that can be linearly interpolated. In addition, we can guarantee that the approximate cross section is within some acceptable error of the exact cross section at ALL energies, that is,

$$(1 - \varepsilon) \sigma_{\text{exact}}(E) \leq \sigma_{\text{approx}}(E) \leq (1 + \varepsilon) \sigma_{\text{exact}}(E) \quad (14)$$

for all E .

When we multiply by some weighting spectrum and integrate, we find

$$(1 - \varepsilon) \int_{E_1}^{E_2} \sigma_{\text{exact}}(E) \Phi(E) dE \leq \int_{E_1}^{E_2} \sigma_{\text{approx}}(E) \Phi(E) dE \leq (1 + \varepsilon) \int_{E_1}^{E_2} \sigma_{\text{exact}}(E) \Phi(E) dE. \quad (15)$$

Similarly, if we integrate a weighted reciprocal cross section we find

$$\frac{1}{(1 - \varepsilon)} \int_{E_1}^{E_2} \frac{\Phi(E)}{\sigma_{\text{exact}}(E)} dE \leq \int_{E_1}^{E_2} \frac{\Phi(E)}{\sigma_{\text{approx}}(E)} dE \leq \frac{1}{(1 + \varepsilon)} \int_{E_1}^{E_2} \frac{\Phi(E)}{\sigma_{\text{exact}}(E)} dE. \quad (16)$$

Therefore, the integral quantities of the earlier mentioned form using linearly interpolable cross sections are always guaranteed to be within ε of the exact integrals (because of cross cancellation of errors during integration the results are generally much closer than ε).

Summary of Linearizing

In the preceding section, an algorithm that allows cross sections to be reduced to linearly interpolable form has been presented. This algorithm is only of practical use if the number of data points in the resulting linearized evaluation is comparable to the number of points in the original (nonlinear) evaluation. Application of this algorithm to entire ENDF/B libraries (IV, V, VI, and VII), by linearizing each library to within 0.1% accuracy, demonstrates that in some

evaluations the resulting number of points can be slightly less or more than the original evaluation, but for each library taken as a whole, the total number of data points in the linearized library is actually slightly less than in the original library. Therefore, linearizing all cross sections is practical in the sense that it significantly increases neither the size of the resulting library nor the number of data points that must be used in the later calculations.

As mentioned earlier, this process of linearizing data can be used by evaluators to guarantee the consistency of their cross sections by performing their evaluations using the convenience of the ENDF/B interpolation laws (i.e., exact $1/V$ capture and fission at low energy). After the evaluation is complete, but before distribution, it is recommended that evaluators always convert all cross sections to linearly interpolable form and define all sum cross sections (such as total) consistently by performing the additions in the linearly interpolable form. Finally, the evaluator can present the final evaluation in a linearly interpolable form for use in applications. Program LINEAR (Cullen 2007a–c) is freely available online to linearize cross sections in the ENDF/B format.

Unfortunately, evaluators do not always understand the importance of doing this. Let us take a simple example of a current evaluation to illustrate the effect that this can have on the consistency of an evaluation; consider an actual current evaluation, 1-H-1 from ENDF/B-VII.0 (Oblozinsky et al. 2006; Cullen 2007a–c). At low energy, the only possible reactions are elastic scatter, which is almost constant and uses interpolation law 2 (lin–lin), and capture, which is $1/V$ and uses interpolation law 5 (log–log). Both are good logical choices for these individual reactions. But evaluators introduced an error by assuming that the total cross section, which is the sum of elastic and capture, can be “accurately” defined using interpolation law 5 (log–log); unfortunately, there is no ENDF/B interpolation law that can exactly represent the sum of a constant and $1/V$ cross section; indeed, the only interpolation law that can be used to represent redundant cross sections, such as total, is law 2, linear (lin–lin) interpolation. What this means is that the total defined by the evaluator is not actually equal to the sum of its parts over the entire energy range. ➤ *Figure 11* illustrates that this seemingly trivial oversight introduces an inconsistency in the 1-H-1 ENDF/B-VII.0 data of over 0.5% in the total cross section. In this figure, we see “loops” showing that at the energy points where the cross sections are tabulated, the given total is equal to the sum of its parts; but between these energies, the inconsistent interpolation laws introduce an error. Note that the error is always on only one side of the original data, so that any errors in integrals based on this data will be maximized; this can be seen if one calculated the resonance integrals from the originally evaluated data, not only in this case but also for many current evaluations.

Most evaluated data users would be shocked if told that such a trivial oversight could have such a relatively large effect on one of the best-known cross sections (1-H-1), but unfortunately that is the reality of the currently available evaluator data. This is but one trivial example of how misuse of ENDF/B interpolation laws can introduce inconsistencies in the evaluated data that can lead to a nonunique interpretation of the data. For example, in this case, when people actually use this data, they will either end up with inconsistent results (the total is not the sum of its parts) or have to make a decision as to how to make them consistent, such as ignoring the given total, linearizing all cross sections, and then adding them up to define a consistent total (what we recommended), or use some other procedure, such as assuming that the elastic is least well known and define it as the difference between the total and capture (sounds reasonable, but leads to strange results).

This confusion could have been easily avoided if the evaluator had understood the importance and limitations of ENDF/B cross-section representation, and made the cross consistent by

Figure 11
Example of interpolation error in 1-H-1 data

linearizing them, and then consistently defining the total by summing the linearized elastic and capture. Only after this has been done should the evaluation be considered finished and ready for distribution. Program FIXUP (Cullen 2007a–c) is freely available online to make consistent cross sections in the ENDF/B format.

As this example illustrates, evaluations do not always contain consistent data, so users are forced to make the data consistent before using it. This process of linearizing data can be used by data users to simplify their processing codes by linearizing all cross sections and defining redundant cross sections (such as total) by summation, as a first step in their data processing. Then all subsequent codes for resonance reconstruction, Doppler broadening, and group averaging can be greatly simplified and made more numerically stable by assuming that all cross sections are in a linearly interpolable form. This is the approach built into a number of currently available nuclear data-processing codes (Cullen 2007a–c; MacFarlane and Muir 1994).

The bottom line is that we strongly recommend that the distributed evaluated data NEVER use nonlinear ENDF/B interpolation laws, because this always leads to inconsistencies in the cross sections. Evaluators are certainly free to take advantage of nonlinear interpolation (e.g., $1/V$ capture and fission at low energy), during the evaluation process. But before distributing any evaluation, ALL cross sections should be linearizing, and redundant cross sections (such as total) be defining by summation. This is the only way that evaluators can be sure that their data

are uniquely defined and interpreted for use in applications. Any evaluation in which the cross sections are not linearly interpolable should come with the warning: CAVEAT EMPTOR!!!!

2.4 Reconstructing the Contribution of Resonances

There are now a number of programs available to reconstruct energy-dependent cross sections from a combination of resonance parameters and tabulated cross sections. In principle, the procedures used by all these codes are equivalent and yield equivalent results. In practice, in a comparison of the cross sections generated by these programs, large differences were found (Cullen et al. 1985, 1988). Here we will concentrate on pointing out those areas that require care if accurate cross sections are to be obtained.

In the resolved-resonance region, the ENDF/B format allows the following types of parameters:

1. Breit–Wigner single-level parameters
2. Breit–Wigner multilevel parameters
3. Reich–Moore parameters
4. Adler–Adler parameters
5. General R-matrix parameters
6. Hybrid R-function parameters

In the unresolved region, the ENDF/B format allows the following types of parameters:

1. Constant, or energy-independent, parameters
2. Energy-dependent fission width, all other widths constant
3. All widths energy dependent

All the pertinent equations for these resolved and unresolved representations are presented in ENDF-102, the formats and convention manual (Kinsey 1970; Rose and Dunford 1990), and will not be reproduced here. The important point that we will focus on here is not the exact equations, but rather the procedures that are used to accurately calculate energy-dependent cross sections from these parameters. Since these are different in the resolved and unresolved energy ranges, we will consider each region separately.

2.4.1 The Resolved-Resonance Region

In principle, the approach for reconstructing energy-dependent cross sections is quite straightforward. There are three basic approaches that are used. In one approach, starting from the peak of a resonance, the total width of the resonance is used to define a grid of energy points located as multiples of the total width on either side of the peak of the resonance. In the second approach, starting from the peaks of two adjacent resonances, the intervening energy interval is subdivided, using the interval-halving technique, described in the preceding section, until the cross section is linearly interpolable over each of the resulting energy intervals. The third approach combines the first two approaches. In the third approach, the total width of two adjacent resonances is first used to subdivide the intervening energy between the two resonances into a number of subintervals; the length of each subinterval is determined by the total width of

the nearest resonance. Each subinterval is then subdivided using the interval-halving technique, until the cross section is linearly interpolable over each resulting energy interval.

In principle, if performed to high precision using many data points all three approaches will yield identical results. Each approach offers advantages and disadvantages. The first approach is the most economical since it does not involve any iteration; however, this approach does not attempt to guarantee the accuracy of the resulting cross section to within any given criteria. The second approach is mechanically the simplest since it only involves selecting two resonance peak energies and applying the interval-halving technique; however, this approach can lead to false convergence (as described later) and for widely spaced and narrow resonances, the convergence between resonances can be quite slow. The third approach, while more complicated than the second, can actually be much more economical to use. The reason for this is that the third approach uses the fact that in any iterative procedure convergence can be accelerated by starting as close to the solution as possible. By defining subintervals, as multiples of the total width around each resonance, the third approach does not begin iterating until it has already roughly defined the shape of each resonance. In contrast, the second method does not use any initial information concerning the shape of the two adjacent resonances, and as such can iterate for a considerable period of time before achieving convergence.

The third approach, being the most general, will be described in detail in the following section. Reference will be made to the other two approaches for comparison purposes when appropriate to illustrate where care must be exercised in order to insure their accuracy.

Subdivision into Intervals

In the ENDF/B format within each evaluation, resolved-resonance parameters are given for each isotope that contributes to the evaluation; each evaluation can be for a single isotope or for an elemental mixture of isotopes. For each isotope, resolved parameters are given for each L state (i.e., s, p, d wave). First, the resolved resonance for all isotopes and L states are sorted into ascending energy order, and each interval is defined as extending from the peak of one resonance to the peak of the next resonance. Up to this point, the approach is similar to the second method, the difference being that at this point the second method begins iterating. The third method subdivides intervals into subintervals.

Subdivision into Subintervals

Starting at each end of an interval and using the total width of the resonance at that end, subinterval boundaries are placed as multiples of the total width from the peak of the resonance, e.g., 1, 2, 4, 6, 10, 20, 40, 60, and 100 half-widths from the end or until the midway point between two resonances is reached. “Midway” is here defined as equidistant from the ends of the interval measured in half-widths of the resonance at each end of the interval. ➤ [Figure 12](#) illustrates this process.

With this algorithm, the interval between two narrow, widely spaced resonances is divided into many subintervals, while the interval between two wide, closely spaced resonances is divided into only a few subintervals. From ➤ [Fig. 12](#), the starting point for iteration using the third method can be visualized as the shape obtained by drawing a straight line between the dots (ends of subintervals). This may be compared with the starting point using the second method, which is a straight line between the peaks of the two resonances. From this comparison, it is easy to see why the third method generally converges much faster than the second. The shape

■ **Figure 12**
Subdivision of a resonance region into intervals and subintervals

obtained by drawing a straight line between the dots may be visualized as the shape obtained using the first method, since in the first method there is no subsequent iteration or subdivision.

Subinterval Halving

Each subinterval is further subdivided using the iterative interval-halving technique, until the cross section can be approximated by linear interpolation between successive energy points. Because of the similarity between the calculations for total, elastic, capture, and fission, the most economical approach is to calculate all four simultaneously, using the same energy grid and continue to subdivide until all four have converged.

The interval-halving technique begins at the lower end of the energy range of interest and proceeds as follows (see the ► [Fig. 13](#)). Consider the two successive energy points, $E1$ and $E2$. Tentatively define the energy point $E3$, halfway between $E1$ and $E2$, and calculate the total, elastic, capture, and fission cross sections at each of these three points. The point at $E3$ need not be kept and the interval between $E1$ and $E2$ need not be further subdivided if any of the following criteria are met:

1. All four cross sections can be approximated at the midpoint $E3$ by linear interpolation from the ends of the interval to within an allowable fractional uncertainty ϵ_{\max} . Calculate the exact cross section $\sigma_k(E1)$, $\sigma_k(E2)$, and $\sigma_k(E3)$, for $k = 1, 2, 3$, and 4 (where the indices refer to the four reactions) and the approximate cross section at the midpoint by linear interpolation

$$\sigma_k^*(E3) = \frac{1}{2} [\sigma_k(E2) + \sigma_k(E1)]. \quad (17)$$

The convergence criterion is met if for all reactions, k ,

$$|\sigma_k(E3) - \sigma_k^*(E3)| \leq \epsilon_{\max} |\sigma_k(E3)|. \quad (18)$$

■ **Figure 13**
Iteration to convergence

2. The absolute value of all four cross sections at both ends of the interval is less than some minimum cross section of interest, e.g., less than 10^{-10} barns. The cross section may be positive or negative, but convergence is assumed if the cross section at both ends of the interval is closer to zero than the minimum cross section. This prevents needlessly homing in on the energy at which the cross section goes from positive to negative; cross sections are probabilities, so physically they cannot be really negative, but unfortunately negative values occasionally arise for elastic-scattering cross sections that have been reconstructed from single-level Breit–Wigner parameters.
3. The reconstructed cross sections are to be the output in the ENDF/B format, and $E3$ is closer to $E1$ than the energy resolution of the format. For example, if an interval extends from 123.456813 to 123.457294, both energies would be equal to 1.23457E+2 in the six-digit format and are thus indistinguishable. Today, modern codes such as RECENT (Cullen 2007a–c) minimize this problem by outputting energies to 9-digit accuracy, e.g., if output is in F rather than E format, we can distinguish between 123.456813 and 123.457294, in the ENDF/B format, and this would not be considered as convergence.

If one or more of these criteria are met, the point $E3$ is dropped, and the next higher subinterval ($E2$ – $E7$ in  Fig. 13) is subdivided. If not the point $E3$ is included, and the convergence tests are applied again to the point $E4$, the midway between $E1$ and $E3$. This procedure is continued until the entire energy range of interest has been treated.

False Convergence

False convergence of the interval-halving method may be most easily explained by an example. If we attempt to calculate $\sin(x)$ from 0 to 2π by starting at the end points 0 and 2π , we will find that as soon as we subdivide, the first time our iteration will converge since $\sin(x)$ is exactly zero at $x = 0, \pi,$ and 2π , and we would reach the ridiculous conclusion that $\sin(x)$ is everywhere exactly zero. In order to insure that the interval-halving technique converges to the correct answer, it is important to first divide the interval of interest into subintervals in each of which the function is either concave or convex. For example, in the $\sin(x)$ example, it is sufficient to start with the subintervals $x = 0$ to π and $x = \pi$ to 2π in order to obtain convergence; however, convergence can be accelerated by starting with smaller subintervals that better approximate the shape of $\sin(x)$ before beginning interval halving.

For a single isolated resonance, the cross section within one half-width of the peak of the resonance is convex, and it is concave for all energies further from the peak of the resonance. Therefore, a straight line (as used in linear interpolation) drawn from the peak of the resonance to points more than one half-width from the peak may pass through the exact shape of the resonance at some point. This may cause false convergence of the interval-halving technique, as the value calculated by linear interpolation to the midpoint of the interval may be quite close to the exact value calculated at the midpoint of the interval. For example, linear interpolation from the peak of the resonance to a point two half-widths from the resonance may indicate that the shape of the resonance can be accurately approximated by the straight line between the two points. If this result is believed, the integral contribution of the resonance (i.e., the area under the curve) will be drastically underestimated. The third method described above prevents this problem, since the iteration is only performed within subintervals, and subintervals have been defined to isolate the convex and concave energy ranges of each resonance in different subintervals. Therefore, during iteration a straight line drawn between the ends of any subinterval will always lie either above or below the exact value and cannot lead to false convergence.

Resonance Energies

In all the aforementioned methods, we have merely used the term “resonance energy.” In order to insure the accuracy of the methods described here, it is important that the “resonance energy” be defined as the observed peak energy of the resonance, so that the division starts from the actual peak of the resonance and does not miss a peak. For the data in the ENDF/B format, the convention (see ENDF-102, appendix D) is that all resonance energies are observed peak energies, and there is no problem with the methods described here. In some other neutron-data libraries, the resonance energies are eigenvalues of the nucleus. For s-wave resonances, the two correspond, but for p, d, etc., wave resonances, the two differ by the shift factor (again see ENDF-102, appendix D). Since these resonances can be quite narrow, failure to use the observed peaks to define the ends of intervals for subdivision can cause narrow p- and d-wave resonances which would otherwise be missed.

2.4.2 Unresolved-Resonance Region

In the unresolved-resonance region, the unresolved-resonance parameters do not uniquely define the energy-dependent cross section; they only define the probability distribution of the cross sections at each energy region, from which only averaged cross sections can be

derived. Therefore, in principle, the discussion of the unresolved-resonance region should be covered later in this chapter, under self-shielding. However, for convenience during reconstruction of the energy-dependent cross section, many codes will also calculate the infinitely dilute cross section in the unresolved-resonance region. Generally, this is a simpler calculation than that involved in calculating the cross sections in the resolved-resonance-energy region; the cross sections are generally smooth and have simple variations between the tabulated values.

The main source of differences in calculating the cross sections in the unresolved-resonance region is due to interpolation. The ENDF/B convention (ENDF-102, page 2.20) is that cross sections should be calculated at the energy points at which unresolved parameters are given, and in order to define the cross section at other energies the cross section, not the parameters, should be interpolated. Although ENDF-102 asks evaluators to use a “dense enough” energy grid to insure that either interpolation of parameters or cross sections yield essentially identical answers, evaluators often do not follow these guidelines, e.g., comparisons for some ENDF/B-V-evaluated data show 18% differences between the cross sections obtained by interpolating parameters versus cross sections. These differences are not due to errors in individual processing codes, but are rather due to the ambiguity in the ENDF/B conventions, because “dense enough” is not quantitatively defined for either evaluators or processing-code designers. If a code designer assumes that an evaluator knows best and has provided parameters on a “dense enough” energy grid, the results will be quite different from those obtained by assuming that the parameters are not given on a “dense enough” energy grid and that they must first be interpolated to a “dense enough” grid using parameter interpolation. Although these two approaches lead to quite different answers, both seem to be justified under ENDF/B conventions as long as “dense enough” is not uniquely defined. This is but one example of where ENDF/B conventions can lead to ambiguity in interpreting the data.

2.4.3 Adding Resonance and Background Cross Sections

Once the resonance contribution has been calculated, it must be added to the background cross section to define the actual energy-dependent cross section; background or correction cross sections are used most often with single-level, Breit–Wigner resonance parameters, to correct for limitations in the single-level resonance model. Since the resonance contribution has been calculated to be linearly interpolable, if the background cross section is also linearly interpolable, as pointed out earlier, the two can be added together to obtain a linearly interpolable cross section. An additional consideration is that the ENDF/B formats and convention (Kinsey 1970; Rose and Dunford 1990) define how to reconstruct 0 K cross sections; so that once reconstructed these can only be added to a 0 K background cross section. Therefore, the necessary constraints on the background cross section to allow it to be added to the resonance contribution are that it has to be defined at 0 K temperature and be linearly interpolable.

However, if the background cross section is not linearly interpolable, the two cannot be added together to obtain a cross section that can be represented by any of the ENDF/B interpolation laws. Failure to recognize this fact can lead to large errors in the cross section. For example, if the resonance contribution and background are added together and given as an output using the interpolation law of the background, in many cases, ENDF/B evaluations define the background to be zero over the entire resolved-resonance region and represented by the constant

interpolation law. In this case, even though the background makes zero contribution, the combined cross section will be described as constant (a series of histograms) between tabulated values, instead of the original linearly interpolable form in which the resonance contribution was calculated. Therefore, before reconstructing the resonance contribution, all background cross sections should be converted to linearly interpolable form. Note that this is in agreement with my earlier recommendation that ALL ENDF/B-formatted cross sections be linearized before distribution.

All the ENDF/B-resonance equations define the cross sections at 0 K temperature. Therefore, another case in which the resonance contribution and background cannot be immediately added together is if the background cross section is not defined at 0 K temperature. In this case, the resonance contribution can be Doppler broadened to the temperature of the background, and the two can then be added together. Program LINEAR (Cullen 2007a–c) is designed to allow cross sections to be converted to linearly interpolable form; program RECENT (Cullen 2007a–c) can then be used to reconstruct the resonance contribution and added to the background cross section to define the complete cross sections; if necessary, program SIGMA1 (Cullen 2007a–c) can be used to Doppler-broaden cross sections to any required temperature(s).

2.4.4 Output Format

If after reconstruction the cross sections are stored in a binary form, the full accuracy of the reconstructed cross sections will be preserved. However, if they are written in character form, significant errors can be introduced if care is not taken. For example, if the cross sections are written in the ENDF/B character format, limiting floating point numbers to 11 columns, the number of digits normally used to represent energies is not sufficient to accurately represent the shape of narrow resonances, particularly for heavy even–even isotopes such as Th232, U238, and Pu240. Truncation of energies can cause narrow resonances to either disappear or appear to be much wider than they really are.

As part of a cross-section processing-code verification study (Cullen et al. 1985, 1988), the ENDF/B-VI dosimetry library was used to calculate energy-dependent cross sections to within 0.1% accuracy, and three different forms were used as output in the ENDF/B format representing the energies to 5 – (1.2345E + 3), 6 – (1.23456 + 3), and 9 – (1234.56789) digit accuracy. The results showed that the cross sections with energies to five-digit accuracy differed from the nine-digit output by up to 72%. The six-digit results differed from the nine-digit results by up to 6%. Therefore, even integral results are affected unless care is used to accurately represent the data, particularly the energies associated with cross sections reconstructed from narrow resonances. It is important to understand that since in the above example within the computer memory the cross sections in all three cases are calculated to exactly the same 0.1% accuracy and were identical, the above-quoted differences are due solely to truncation of the energy during output to the 11-column ENDF/B, floating-point number format.

At present, two different approaches have been introduced to prevent this truncation problem. In one approach by recognizing that the exponent associated with the energy is always one digit, the ENDF/B E11.4 format or energies can be extended to present energies to seven digits, e.g., 1234.56789 can be made output as 1.234568 + 3. In the second approach, it is recognized that for energies between 10^{-3} eV and 100 MeV, the energy can be written to more than six digits of accuracy, simply to writing the energy in F, rather than E format, e.g., 1234.56789 can be made

output as 1234.56789. For energies below 10^{-3} eV and above 100 MeV, the normal six-digit output is used; since there are no narrow resonances in these energy ranges, this does not present any serious limitation to the algorithm.

A word of WARNING: output such as 1.234568 + 3, used by some codes to add an additional digit of accuracy to the output by dropping the “E” or “D” preceding the exponent, is compatible and can be read by FORTRAN codes, but it is not compatible for use with C codes; indeed, C codes will read this without indicating any error, and incorrectly interpret the data, in ways that differ from one computer to another. For this reason, this output form without the “E” or “D” is no longer used as the PREPRO codes (Cullen 2007a–c), and all PREPRO output is now C compatible, such as all the ENDF/B-VII.0 data is now available online (Cullen 2007a–c).

3 Doppler Broadening

3.1 Introduction

In the following section, the concept of Doppler broadening is introduced. The physical phenomenon that causes Doppler broadening is described with emphasis on the effect that we expect broadening to have a variety of commonly encountered cross-section shapes. Next, the methods commonly used to calculate Doppler-broadened cross sections are presented, including an explicit description of the approximations introduced by each method and how these approximations limit the range of applicability of each method. Throughout this section, numerous references are made to computer codes that actually use these methods. Hopefully, by the end of this section, users will be able to decide which of the available methods is most applicable to their applications and will be aware of which computer codes are available for use.

The following discussion will be limited to the effect of Doppler broadening due to the so-called free atoms. We will not discuss thermal-scattering law data, which includes binding effects such as vibration and rotation of crystals; this topic will be covered in another chapter of this handbook.

Since the primary intent of this handbook is for use in fission-reactor core calculations, emphasis will be placed on the role that Doppler broadening plays for broadening of neutron-induced cross sections at fission-reactor temperatures, particularly in the resonance region. However, for generality, reference will also be made to fusion and astrophysics applications, involving neutron- and charged particle-induced cross sections.

3.1.1 What Causes Doppler Broadening?

Let me first cover the most important point to understand: free-atom cross sections are not temperature dependent. That is, the cross sections for the same relative speed between a projectile (neutron) and a target atom are independent of temperature. Note that this is not true for thermal-scattering law data, wherein temperature will affect binding; that is one reason that thermal-scattering law data are not covered here.

Although the cross section in the relative frame of reference is not temperature dependent, the Boltzmann equation that we solve using our transport codes is expressed in the laboratory frame of reference, rather than in the relative frame between the neutron and target nuclei. It is because we want to perform our calculations in the laboratory frame of reference that requires us to define our cross sections in this frame of reference, and it is solely due to our necessity to transform data from the relative to laboratory frame of reference that forces us to include Doppler broadening of cross sections.

The cross section or probability of a neutron interacting with any given nucleus depends on the relative speed between the neutron and the nucleus. In neutron transport, usually neutron energy rather than speed is used, and evaluated data libraries present cross sections and resonance parameter as a function of neutron energy, wherein the neutron energy is measured relative to stationary target nuclei. However, the transport equation describes neutrons in the laboratory frame of reference, and, therefore, in order to solve this equation, we must define cross sections in the same frame of reference. If all the nuclei in a medium were stationary (the so-called “cold” medium), then the energy of the neutron in the laboratory system would be exactly equal to the energy measured, relative to the nuclei in the medium, that is, in this case, the relative and lab frames of references coincide. In this case, the evaluated data as presented in evaluated libraries are exactly what we need for use in the transport equation. However, in any real case, the nuclei in a medium will have a distribution of kinetic energies and will be moving about in a random manner. In this case, for any given neutron energy in the laboratory system, there will not be one unique neutron energy, measured relative to the distribution of randomly moving nuclei, rather there will be an entire spectrum of relative energies.

Visualize a neutron with laboratory energy corresponding to the peak energy of a resonance, incident upon a medium in which the nuclei are moving about due to thermal agitation. Since the nuclei are moving about, there is a probability that the nucleus that the neutron actually interacts with is moving either toward or away from the neutron before the collision; this would cause the relative energy of the neutron to either increase or decrease, respectively. Since we assumed that the neutron was incident with a laboratory energy corresponding to the peak of the resonance, if the relative energy is lower or higher than this value, the cross section that the neutron actually encounters will be lower than the peak value. Of course, there is also a probability that the neutron will interact with a nuclei such that its relative energy is identical to the peak of the resonance. We must consider not only a single neutron interacting with one nuclei, but rather the average due to an ensemble of neutrons interacting with the ensemble of nuclei within the medium. It is easy to see that in the case of this example if we consider neutrons incident with a laboratory energy corresponding to the peak of a resonance, the average cross section that they encounter will actually be less than the cross section corresponding to the peak of the resonance. Therefore, when the nuclei are moving about due to thermal agitation, the cross section that a neutron of a given laboratory energy encounters will be different from the cold (0 K) cross sections.

To further complicate the situation, when the bulk temperature of the medium changes, the kinetic energy of the nuclei in the medium changes, which changes the distribution of relative speeds, or energy, between a neutron of a given laboratory energy and the nuclei in the medium. Therefore, we should expect the effects that we see to depend upon the temperature of the medium. If we are to solve our transport equation in the laboratory system, we must somehow reduce this complicated situation to define a single “equivalent” laboratory frame-of-reference cross section.

In what sense should our cross section in the laboratory frame-of-reference be “equivalent” to what is happening in the relative frame-of-reference? What we are interested in conserving is what we can observe in either frame of reference. We cannot observe neutrons, flux, or barns directly. We can only observe when neutrons interact with the medium; in other words, we can only observe reactions. Therefore, we will define our laboratory frame-of-reference cross sections in order to assure that the number of reactions per unit time will be the same in either system. In the following discussion, this laboratory frame-of-reference cross section will simply be referred to as the Doppler-broadened cross section.

3.2 The Doppler-Broadening Equation

► **Figure 14** illustrates the physical significance of the following terms.

m	Projectile mass (e.g., neutron, proton, alpha)
\bar{V}	Projectile velocity
V	$ \bar{V} $ = Projectile speed
E	$1/2mV^2$ = Projectile energy
M	Target nuclei mass
\bar{V}_T	Target velocity
V_T	$ \bar{V}_T $ = Target speed
E_T	$1/2MV_T^2$ = Target energy
A	M/m = Atomic weight ration (target mass/projectile mass)
\bar{V}_r	$\bar{V} - \bar{V}_T$ = Relative velocity
V_r	$ \bar{V}_r $ = Relative speed
E_r	$1/2mV_r^2$ = Relative energy of the projectile
$\sigma(V, 0)$	Cold (0 K) cross section
$\sigma(V, T)$	Doppler-broadened cross section at temperature T
$R(V, T)$	$V\sigma(V, T)$ = Reaction rate (per unit time and particle)
$P(\bar{V}_T)d\bar{V}_T$	Normalized target-nuclei velocity distribution

► **Figure 14**
Coordinates for interaction of neutron and nucleus

Although the following derivation is expressed in terms of neutrons, it is equally applicable to any particle incident with nonrelativistic energy.

As mentioned above, we will define our Doppler-broadened cross section in order to conserve the reaction rate observed in either system. In a medium in which the nuclei are stationary (0 K temperature), the relative speed (V_R) between a monoenergetic beam of neutrons and the target nuclei is merely the speed of the neutrons (V). In such a medium in order to conserve reactions, the cross section is simply defined as the ratio of reactions to flux, or per incident neutron,

$$\begin{aligned} \text{Lab reactions} &= \text{Relative reactions} \\ V\sigma(V, 0) &= V_r\sigma(V_r, 0) = R(V, 0). \end{aligned}$$

Since in this case the speed of the neutron is equal to the relative speed, we obtain a simple identity. In terms of conserving reaction rate, we need not be concerned with the point $V = V_r = 0$, since it does not contribute to the reaction rate.

In any real medium at a temperature above absolute zero, the target nuclei are in thermal agitation and possess a distribution of velocities. Here, the relative speed (V_R) between a monoenergetic beam of neutrons incident upon the medium and the nuclei within the medium will also be distributed. In such a medium, we must still define our laboratory cross section to agree with the observed reaction rate. However, because the cross section is determined by the relative speed, as opposed to the laboratory speed of the neutron, the Doppler-broadened cross section will not generally be the same as the cold cross section. The observed reaction rate per unit neutron will be

$$\begin{aligned} \text{Lab reactions} &= \text{Relative reactions} \\ R(V, T) = V\sigma(V, T) &= \int_{[V_r:V_r>0]} R(V_r, 0) p(\bar{V}_T) d\bar{V}_T \\ &= \int_{[V_r:V_r>0]} V_r\sigma(V_r, 0) p(\bar{V}_T) d\bar{V}_T. \end{aligned} \quad (19)$$

Since $p(\bar{V}_T) d\bar{V}_T$ is a normalized distribution, it is obvious from this equation that if the reaction rate $V_r\sigma(V_r, 0)$ is constant, the broadened cross section $V\sigma(V, T)$ will also be constant, independent of temperature, regardless of the model, $p(\bar{V}_T) d\bar{V}_T$, used to describe the thermal motion of the target nuclei. That is, to say, a $1/V$ cross section will be independent of temperature. It has been demonstrated elsewhere that a $1/V$ cross section is the only cross-section shape that is independent of temperature. Therefore, in all other cases, we must consider Doppler broadening, as we expect the laboratory cross section to be temperature dependent.

From our earlier discussion of physically what causes Doppler broadening, it is easy to understand why a $1/V$ cross section is independent of temperature. In this case, if we have a neutron with speed V that interacts with a nucleus such that the relative speed is V_r , the reaction rate observed will be exactly the same regardless of the value of V_r ; the reaction rate will be exactly the same as if the interaction had occurred with a relative speed V , independent of the velocity distribution of the target nuclei. This is not true even for simple cross-section shapes, such as a constant cross section; since in this case, if the relative speed V_r is larger than V , the observed reaction rate will be larger, and it will conversely be lower if V_r is smaller than V .

It will be shown later in this work that these two effects of larger and smaller values of V_r do not quite balance out, and a cold constant cross section is temperature dependent.

In order to derive the Doppler-broadening equation, it will be assumed that the velocity distribution of the target nuclei is isotropic, when

$$p(\bar{V}_T) d\bar{V}_T = \frac{1}{4\pi} P(V_T) dV_T d\mu d\phi, \quad (20)$$

where $\mu = \cos(\theta)$ and the form of $P(V_T)$ depends on the specific model of the thermal distribution of nuclei. Upon integrating over $d\phi$, (19) becomes

$$V\sigma(V, T) = \frac{1}{2} \int_{-1}^{+1} d\mu \int_{[V_i; V_r > 0]} V_r \sigma(V_r, 0) p(V_T) dV_T. \quad (21)$$

From the  Fig. 14, we have

$$\frac{1}{2} m V_r^2 = \frac{1}{2} m [V^2 - 2\mu V_T V + V_T^2]. \quad (22)$$

The Jacobian transformation is

$$d\mu = \frac{V_r dV_r}{V V_t}, \quad (23)$$

and the Doppler-broadening equation for a general isotropic thermal distribution of target nuclei is

$$V\sigma(V, T) = \frac{1}{2V} \int_0^\infty [V_r \sigma(V_r, 0)] V_r dV_r \int_{|V-V_r|}^{|V+V_r|} P(V_t) \frac{dV_t}{V_t}. \quad (24)$$

The limits of integration are illustrated in  Fig. 15, which shows the area of integration in the (V_r, V_t) plane. For any given thermal distribution $P(V_t)$, the inner integral may be evaluated to define the Doppler-broadened cross section in terms of a singly dimensioned integral over the relative speed V_r .

Usually, the Maxwell gas model is used to represent the thermal distribution of nuclei in the medium. Although this model is not exact, Lamb (Lamb 1939) has demonstrated that many materials of interest in reactor calculations can be treated as an ideal monatomic gas at an effective temperature. This model improves with increasing temperature where crystalline effects become progressively less important.

For the Maxwell gas model, the distribution of nuclei speed is assumed to be

$$P(V_t) dV_t = \frac{4}{\sqrt{\pi}} \beta^{3/2} V_t^2 \exp[-\beta V_t^2] dV_t : \beta = \frac{m}{2KT}, \quad (25)$$

Figure 15
Region of Integration

where K is Boltzmann's constant. By assuming this form for $P(V_t)$ in (24), after evaluating the inner integral, the well-known Doppler-broadening equation is obtained, in terms of speed, as

$$\begin{aligned}
 V\sigma(V, T) = & \frac{1}{V} \left(\frac{\beta}{\pi} \right)^{1/2} \int_0^{\infty} [V_r \sigma(V_r, 0)] V_r dV_r \\
 & \times \{ \text{Exp}[-\beta(V - V_r)^2] - \text{Exp}[-\beta(V + V_r)^2] \}
 \end{aligned} \quad (26)$$

or in terms of energy, as

$$\begin{aligned} \sqrt{E}\sigma(E, T) &= \frac{1}{2} \left(\frac{\alpha}{\pi E} \right)^{1/2} \int_0^{\infty} [\sqrt{E_r}\sigma(E_r, 0)] dE_r \\ &\times \left\{ \text{Exp} \left[-\alpha(\sqrt{E} + \sqrt{E_r})^2 \right] - \text{Exp} \left[-\alpha(\sqrt{E} - \sqrt{E_r})^2 \right] \right\}, \end{aligned} \quad (27)$$

where

$$\alpha = \frac{2\beta}{m} = \frac{A}{KT} : A = \frac{M}{m}.$$

This Doppler-broadening equation can be generalized by recognizing that not only can it be used to broaden cross sections from 0 K to a higher temperature, but it can also be used to broaden cross sections from any temperature T_1 to any higher temperature T_2 (Meghreblian and Holmes 1960). For example, it is possible to start from experimentally measured data at room temperature (293.6 K) and Doppler broaden it to 600 K to obtain cross sections, which in turn can be used to broaden from 600 to 1,000 K. The generalized equation are identical to the above equations with the temperatures 0 and T replaced by T_1 and T_2 , as

$$\begin{aligned} V\sigma(V, T_2) &= \frac{1}{V} \left(\frac{\beta}{\pi} \right)^{1/2} \int_0^{\infty} [V_r\sigma(V_r, T_1)] V_r dV_r \\ &\times \left\{ \text{Exp} \left[-\beta(V - V_r)^2 \right] - \text{Exp} \left[-\beta(V + V_r)^2 \right] \right\}, \end{aligned} \quad (28)$$

where

$$\begin{aligned} \beta &= \frac{m}{2K(T_2 - T_1)}, \\ \sqrt{E}\sigma(E, T_2) &= \frac{1}{2} \left(\frac{\alpha}{\pi E} \right)^{1/2} \int_0^{\infty} [\sqrt{E_r}\sigma(E_r, T_1)] dE_r \\ &\times \left\{ \text{Exp} \left[-\alpha(\sqrt{E} + \sqrt{E_r})^2 \right] - \text{Exp} \left[-\alpha(\sqrt{E} - \sqrt{E_r})^2 \right] \right\}, \end{aligned} \quad (29)$$

where

$$\alpha = \frac{A}{K(T_2 - T_1)}.$$

It is important to recognize that in these equations the V_r and E_r associated with the T_1 cross sections $\sigma(V_r, T_1)$ is merely the laboratory speed or energy of the neutron and not the relative or center of mass energy of the neutron. Therefore, starting from cross sections at 0 K, where the relative energy E is identical to the laboratory energy of the neutron, the Doppler-broadened equation can be used to calculate Doppler-broadened cross section versus the laboratory energy of the neutron for a temperature T_1 . This data are then exactly in the form that can be used in turn to broaden the data from T_1 to any higher temperature T_2 . This is a well-known property of the Doppler-broadening equation that allows cross sections to be bootstrapped from one temperature to the next higher temperature; this can result in a major decrease in the computer time required, comparing to always starting at 0 K to create cross sections at a series of higher temperatures.

3.2.1 Mathematical Interpretation

In terms of reaction rate, (28) can be written in the form

$$VR(V, T2) = \left[\frac{1}{4\pi\tau} \right]^{1/2} \int_0^\infty V_r R(V_r, T1) dV_r \times \{ \text{Exp}[-(V - V_r)^2/4\tau] - \text{Exp}[-(V + V_r)^2/4\tau] \},$$

where

$$\tau = \frac{k(T2 - T1)}{2M}, \quad (30)$$

which by differentiating can be shown to be mathematically analogous to the diffusion equation (age diffusion for neutrons or heat conduction) equation in an infinite, homogenous, spherically symmetric system. In this analogy, the normal independent variables of space and time in the neutron or heat-diffusion equation are equivalent in the Doppler-broadening equation to the independent variables, neutron speed, and temperature of the medium. Similarly, the normal-dependent variable neutron flux or temperature is analogous to the dependent-variable reaction rate in the Doppler-broadening equation. The differential form of the Doppler-broadening equation is

$$\nabla^2 R(V, \tau) = \frac{\partial}{\partial \tau} R(V, \tau), \quad (31)$$

where ∇^2 is the Lapacian operator in spherical coordinates

$$\nabla^2 = \frac{1}{V} \frac{\partial}{\partial V^2} [VR(V, \tau)],$$

and the “initial” condition is that $R(V, \tau_1)$ is known for some initial value of $\tau = \tau_1$.

The main reason for demonstrating at this point that the Doppler-broadening equation is simply the diffusion equation is not because this is a simple or convenient starting point to solve the Doppler-broadening equation; indeed, trying to solve the differential form of this equation can lead to many numerical difficulties when applied to neutron cross sections. The main reason is to improve our understanding of the Doppler-broadening process and to be able to simply predict what will happen to a cross section under Doppler broadening to successively higher temperatures by analogy to what happens to a temperature distribution at successively later times when we solve the diffusion equation.

Two well-known properties of the diffusion equation are its smoothing and conservation properties. As is well known, in the diffusion equation, the effect of increasing the independent variable τ (e.g., time in the heat-conduction equation, temperature in the Doppler-broadening equation) is to “smooth” the dependent variable (e.g., temperature in the heat-conduction equation, reaction rate in the Doppler-broadening equation). Therefore, starting from any initial reaction-rate distribution $R(V, 0)$, as the temperature is increased, the reaction rate $R(V, \tau)$ will become smoother, and will asymptotically approach a constant or uniform distribution throughout all V space. The second important property of the diffusion equation is that if the initial condition $R(V, 0)$ can be integrated over all V space, the quantity $R(V, \tau)$ integrated over all space will be conserved, independent of τ .

For an infinite, spherical symmetric system, these two properties of the diffusion equation may be written in the following form:

1. *Asymptotic value*

$$\text{Lim} \overline{R(\tau)} = \text{Lim} \frac{4\pi \int_0^{V_{\max}} V^2 R(V, 0) dV}{4\pi \int_0^{V_{\max}} V^2 dV}, \quad (32)$$

where $\tau \rightarrow \infty$, $V_{\max} \rightarrow \infty$, independent of V .

2. *Conserved integral*

$$I = \text{Lim} 4\pi \int_0^{V_{\max}} V^2 R(V, 0) dV, \quad (33)$$

where $V_{\max} \rightarrow \infty$, independent of τ .

By comparing (32) and (33), we can see that if the integral, I , is finite, the reaction rate $R(V, \tau)$ will asymptotically approach zero for increasing τ . That is to say, starting from a reaction rate whose integral over all velocity space, (33), is finite, the integral will be conserved for all τ ; when, due to Doppler broadening the finite integral I is uniformly distributed over the infinite velocity space, (32), the average value of the reaction rate will obviously be zero.

From the differential form of the Doppler-broadening equation, (31), the natural dependent variable is the reaction rate $R(V, \tau)$, and it is this variable which becomes smooth and is conserved. It is important to note that without introducing additional approximations, it is not possible to derive a diffusion equation involving the cross section, rather than the reaction rate. Similarly, there is no conservation law which involves the cross section. In particular, the so-called “area under the curve” of the cross section is not conserved, and variations of this area as a function of temperature can be quite large. It is a common error in many textbooks to state that the “area under the curve” is conserved; it is not stressed enough in these textbooks that this is in general not true, and only becomes true after a variety of approximations are introduced in the Doppler-broadening model.

A corollary to the smoothing property of the diffusion equation in a spherically symmetric system is that the reaction rate must be constant at the origin, as

$$\text{Lim} \frac{\partial}{\partial V} [R(V, \tau)] = 0; \text{ all } \tau > 0 \quad (34)$$

where $V \rightarrow 0$, or equivalently, $\text{Lim} R(V, \tau) = \text{constant}$, where $V \rightarrow 0$.

Therefore, for all temperatures greater than 0 K, since the low-energy limit of the reaction rate must be constant, the low-energy limit of all cross sections must be $1/V$. At exactly 0 K, the initial condition $R(V, 0)$ can contradict this condition.

With this as background, we can now use these smoothing and conservation properties to simply predict the effect of Doppler broadening. We will consider the following four cases:

1. $R(V, 0) = C$ ($1/V$ cross section): Since the reaction rate is already smooth, Doppler broadening will not have any effect, that is, a $1/V$ cross section is independent of temperature. Since

this is the only case in which the reaction rate is constant, it is easy to understand why this is the only case where the cross section is independent of temperature. This is an important actual case, since most low-energy capture and fission cross sections tend to be $1/V$ in shape.

2. $R(V, 0) = CV$ (*constant cross section*): Since the reaction rate is initially minimum at the origin ($V = 0$), as the temperature increases the reaction rate will attempt to become uniform by increasing to higher and higher values in the vicinity of the origin (● Fig. 16).

Since the integral of the reaction rate is highly divergent (see (23)), the reaction rate will continue to rise toward infinity. In terms of cross section, since the low-energy limit must be $1/V$, at successively higher temperature, this $1/V$ behavior will extend to higher and higher neutron energies as illustrated in the above figure. The fact that a constant cross section is temperature dependent is often overlooked and yet the change due to broadening can be

■ Figure 16

Doppler broadening of initially constant cross section

quite large. For example, by Doppler broadening the hydrogen elastic cross section, which at 0 K is constant at low energy, we find that even at room temperature the cross section at thermal energy (0.0253 eV) is 30 barns as opposed to the cold 0 K value of 20 barns (a difference of 50%). This is an important actual case, as most low-energy elastic cross sections tend to be constant in shape.

3. $R(V, 0) = C \delta(V - V_0)$ – a Dirac delta function: For a Dirac delta function the reaction rate will be

$$VR(V, \tau) = C \left(\frac{1}{4\pi} \right)^{1/2} V_0 \{ \text{Exp} [-(V - V_0)^2 / 4\tau] - \text{Exp} [-(V + V_0)^2 / 4\tau] \}. \quad (35)$$

By examining the low- V limit, it can be demonstrated that the constant low-energy reaction rate ($1/V$ cross section) is still obtained. Since the integral of the reaction rate over all velocity space is finite (see (32)), the reaction rate will asymptotically approach zero for increasing τ . This case is of interest because it approximates the behavior of any resonance that is very narrow when compared with the width of the Gaussian shape of the kernel in the Doppler-broadening equation (see (30)). This case illustrates that such resonances when Doppler broadened, regardless of the details of their shape, will assume a Gaussian shape characteristic, solely of the temperature of medium, and have a magnitude consistent with the conservation of the reaction rate.

4. *A simple Briet–Wigner line shape:*

(a) *Capture and fission resonance*

$$\sigma(E, 0) = \left(\frac{E_0}{E} \right)^{1/2} (\Gamma/2) A / [(\Gamma/2)^2 + (E - E_0)^2]$$

and

$$R(V, 0) = V_0 (\Gamma'/2) A / [(\Gamma'/2)^2 + (V^2 - V_0^2)^2]. \quad (36)$$

(b) *Elastic resonance*

$$\sigma(E, 0) = (\Gamma/2) A / [(\Gamma/2)^2 + (E - E_0)^2]$$

and

$$R(V, 0) = V (\Gamma'/2) A / [(\Gamma'/2)^2 + (V^2 - V_0^2)^2].$$

(c) *Elastic interference*

$$\begin{aligned} \sigma(E, 0) &= B(E - E_0) / [(\Gamma/2)^2 + (E - E_0)^2] \\ R(V, 0) &= VB'(V^2 - V_0^2) / [(\Gamma'/2)^2 + (V^2 - V_0^2)^2]. \end{aligned}$$

By examining the integral of these reaction rates over all velocity space (33), it can be demonstrated that in all cases the average value (32) will asymptotically approach zero for increasing τ .

However, of the three, only the capture and fission resonance has a finite integral over all velocity space, while the other two have $\log(V)$ and V^2 divergence, respectively. The relative strength of these three forms indicates that the capture and fission will dissipate the fastest, and the elastic interference will be the most persistent. This is in marked contrast to the prediction of ψ - χ (Greene et al. 1976; Hutchins et al. 1973; Green and Pitterle 1968), and other approximate Doppler-broadening methods, in which the elastic interference rapidly dissipates because of its asymmetric form.

3.3 Methods of Solution

With the preceding sections as background on Doppler broadening and the effect that it has on different cross-section shapes, we will now proceed to examine the various methods that are used to actually solve the Doppler-broadening equation. Today, there are basically two approaches to solving the Doppler-broadening equation. One approach starts from tabulated cross sections or reaction rates as a function of energy and solves the equation directly; this approach is referred to as a kernel broadening and is typified by SIGMA1 (Cullen 1979a-c), TEMPO (Gregson and James 1965), and SIGAR (Pope et al. in press). The second approach starts from resonance parameters and by introducing certain approximations, obtains an expression for the broadened cross section in terms of easily tabulated and calculated functions; this is the so-called ψ - χ (Greene et al. 1976; Hutchins et al. 1973; Green and Pitterle 1968) method. Each of these methods has its own advantages and disadvantages.

The advantage of the kernel-broadening approach is that it can be applied to any cross sections that are either initially in tabulated form or can be reduced to tabulated form (see Reconstruction of Energy-Dependent Cross Sections), and it can be used to accurately calculate broadened cross sections at any energy and temperature. Since all modern evaluations can be reduced to tabulated form, the kernel approach is a general approach that can be applied to any cross section. The major disadvantage of the kernel-broadening approach is that relative to the ψ - χ method it can be quite expensive in terms of computer time.

The advantage of the ψ - χ method is that it is relatively inexpensive and for many reactor applications, it is sufficiently accurate of calculating broadened cross sections. The major disadvantage of the ψ - χ method is that it can only be applied to evaluations in which the cross sections are represented by single-level, Breit-Wigner resonances or Adler-Adler parameters. There are other restrictions on the ψ - χ method regarding the energy range and resonance spacing wherein the method may be applied accurately, which will be discussed later in this chapter.

Both these approaches have their place in reactor calculations and are somewhat complementary in the sense that there are a variety of applications where one approach is more applicable than the other. For example, in the situation in which an evaluated library will be processed to a few standard temperatures (Cullen 2007a-c) and then used for a large number of subsequent reactor calculations, it may be worth the initial investment of computer time to use the kernel method in order to guarantee the general utility and accuracy of the broadened cross sections. However, survey calculations involving a large number of temperatures and calculations that must be performed quickly and cheaply can best be done using the ψ - χ method. In order to assist the reader in deciding which of these methods is most appropriate for any application, each method will be examined.

3.3.1 Kernel Broadening

The SIGMA1 (Cullen 1973, 1979a–c) method that has been invented by me assumes that the cross section is given as a table of cross sections versus incident neutron energy, with linear interpolation in cross section and energy between tabulated values; this form was assumed for compatibility with the representation of cross sections in the ENDF/B format. The SIGAR (Pope et al. in press) method is similar except that it assumes that the reaction rate, rather than the cross section, is tabulated and linearly interpolable. With either of these assumptions, the Doppler-broadening equation can be solved exactly without any further approximations. Therefore, these two methods are quite general and do not include any energy or temperature restrictions and are equally applicable to neutron or charged-particle cross sections.

Returning to the well-known Doppler-broadening equations (28) and (29), and substituting

$$Y^2 = \alpha E = \beta V^2$$

and

$$X^2 = \alpha E_r = \beta V_r^2,$$

the Doppler-broadening equation assumes the form

$$\sigma(Y, T2) = \frac{1}{Y^2} \left(\frac{1}{\pi} \right)^{1/2} \int_0^{\infty} X^2 \sigma(X, T1) dX \{ \text{Exp}[-(X-Y)^2] - \text{Exp}[-(X+Y)^2] \}. \quad (37)$$

The following development can be simplified by defining

$$\sigma * (Y, T2) = \frac{1}{Y^2} \left(\frac{1}{\pi} \right)^{1/2} \int_0^{\infty} X^2 \sigma(X, T1) \text{Exp}[-(X-Y)^2] dX, \quad (38)$$

and noting that the Doppler-broadened cross section is

$$\sigma(Y, T2) = \sigma * (Y, T2) - \sigma * (-Y, T2). \quad (39)$$

The SIGMA1 method assumes that the cross section is given as a table of cross sections versus energy and linear interpolation between tabulated values

$$\begin{aligned} \sigma(E, T1) &= \left[\frac{E - E_k}{E_{k+1} - E_k} \right] \sigma_{k+1} + \left[\frac{E_{k+1} - E}{E_{k+1} - E_k} \right] \sigma_k \\ &= A_k + B_k E; \quad E \in (E_k, E_{k+1}), \end{aligned} \quad (40)$$

which is equivalent to

$$\sigma(X, T1) = A_k + C_k X^2; \quad X \in (X_k, X_{k+1}). \quad (41)$$

Since tabulated cross sections only span a finite-energy range (e.g., 10^{-5} eV to 20 MeV), the cross section is extended outside of their tabulated energy range as $1/V$ (e.g., a constant reaction rate). With this assumed form for the cross section, (38) becomes

$$\sigma * (Y, T2) = \frac{1}{Y^2} \left(\frac{1}{\pi} \right)^{1/2} \sum_k \int_0^{\infty} X^2 [A_k + C_k X^2] \text{Exp}[-(X-Y)^2] dX. \quad (42)$$

Changing variables, let $Z = X - Y$ and collecting terms in powers of Z ,

$$\sigma * (Y, T2) = \frac{1}{Y^2} \left(\frac{1}{\pi} \right)^{1/2} \sum_k \int_0^\infty F_k(Z) \text{Exp}[-Z^2] dZ$$

and

$$F_k(Z) = C_k Z^4 + 4C_k Y Z^3 + (A_k + 6C_k Y^2) Z^2 + (2A_k Y + 4C_k Y^3) Z + (A_k Y^2 + C_k Y^4). \quad (43)$$

Similarly, the SIGAR method assumes that the reaction rate is tabulated and linearly interpolable between tabulated values

$$X\sigma(X, T1) = D_k + F_k X^2; \quad X \in (X_k, X_{k+1}). \quad (44)$$

Substituting this expression into (38), changing variables to $Z = X - Y$, and collecting terms in powers of Z , we obtain

$$\sigma * (Y, T2) = \frac{1}{Y^2} \left(\frac{1}{\pi} \right)^{1/2} \sum_k \int_0^\infty G_k(Z) \text{Exp}[-Z^2] dZ$$

and

$$G_k(Z) = F_k Z^3 + 2F_k Y Z^2 + (D_k + 2F_k Y^2) Z + (D_k Y + F_k Y^3). \quad (45)$$

Either the SIGMA1 (43) or the SIGAR (45) can be defined exactly in terms of the family of function,

$$H^n(a, b) = F^n(a) - F^n(b); \quad n = 0, 1, 2, 3, 4$$

and

$$F^n(a) = 2 \left(\frac{1}{\pi} \right)^{1/2} \int_0^a Z^n \text{Exp}[-Z^2] dZ. \quad (46)$$

These functions can easily be shown to satisfy the recursion relationship

$$F^n(a) = \frac{n-1}{2} F^{n-2}(a) - \left(\frac{1}{\pi} \right)^{1/2} a^{n-1} \text{Exp}[-a^2] + \left(\frac{1}{\pi} \right)^{1/2} \delta_{n,1}. \quad (47)$$

By explicitly evaluating (46) for $n = 0$ and 1 and then applying the recursion relationship, the required functions are

$$\begin{aligned} F0(a) &= \text{ERF}(a), \\ F1(a) &= \left(\frac{1}{\pi} \right)^{1/2} [1 - \text{Exp}(-a^2)], \\ F2(a) &= \frac{1}{2} \text{ERF}(a) - a \left(\frac{1}{\pi} \right)^{1/2} \text{Exp}(-a^2), \\ F3(a) &= \left(\frac{1}{\pi} \right)^{1/2} [1 - (1 + a^2) \text{Exp}(-a^2)], \\ F4(a) &= \frac{3}{4} \text{ERF}(a) - \left(\frac{1}{\pi} \right)^{1/2} \left[\frac{3a}{2} + a^3 \right] \text{Exp}(-a^2). \end{aligned} \quad (48)$$

With the definition of these functions, the algorithm describing the SIGMA1 and SIGAR methods to calculate Doppler-broadened cross sections at any arbitrary energy is complete. For additional considerations regarding how to optimize and stabilize this algorithm as actually implemented in computer codes (Cullen 1973) and (Cullen 2007a–c), see the documentation for these codes.

3.3.2 Tabulated Broadened Cross Sections

The preceding algorithms describe how to calculate the broadened cross section at any given energy, but they do not specify how to choose the energies at which to calculate the broadened cross sections. In order to address this question, the SIGMA1 and SIGAR methods use different approaches.

The SIGMA1 program is one of a series of computer programs that are intended to insure that their calculated output cross sections are in a tabulated form with linear interpolation between tabulated values. This convention was adopted because of the existence of a variety of programs that produce multigroup data or use continuous-energy cross sections in applications (e.g., Monte Carlo), starting from tabulated, linearly interpolable cross sections. Therefore, with this convention, output from each of the series of codes, of which SIGMA1 is one, can be used directly as input to many other codes.

Although the SIGMA1 Doppler-broadening algorithm described above allows the cross section to be calculated at any given energy, it does not guarantee that the broadened cross section is linearly interpolable between any two given energies. Even though the cross sections that SIGMA1 uses as input are linearly interpolable, the same energy grid cannot be used for the broadened cross section. The reason is that from the preceding discussion we know that the reaction rate, not the cross section, will become smoother under Doppler broadening. However, “smoothing” occurs on an average basis, and not necessarily at all energies. For example, visualize a series of narrow, widely spaced resonances. At low temperature, much of the energy between resonances will be smooth or even constant and does not require many energy points to describe the energy dependence. But with increasing temperature, the resonance will “smooth,” becoming broader, and the wings of the resonances will extend into the formally constant cross-section energy range between resonances, requiring more points to describe the energy dependence.

At higher energies where the dominant structure in the cross section is due to resonances, the distinction between the reaction rate and cross section is not that important. However, at lower energies, where the cold cross section may be smooth, the distinction is extremely important. For example, the “cold” (0 K) hydrogen-elastic cross section is approximately 20 barns from 10^{-5} eV up to 1 keV; see (Cullen 2007a–c). Although two tabulated energy points (at 10^{-5} eV and 1 keV) and linear interpolation between these points can be used to represent the 0 K elastic cross sections over this energy range and to calculate the broadened cross section at 10^{-5} eV and 1 keV, the broadened cross section is certainly not linearly interpolable between these two energy points. Enormous errors would result if subsequent processing or application programs used such data and assumed linear dependence. For example, in the case of hydrogen at room temperature, the actual broadened cross section at thermal energy, 0.0253 eV, is roughly 30 barns. The room-temperature cross section at 10^{-5} eV is roughly 1140 barns, and the cross section at 1 keV is about 20 barns. Linearly interpolating between the two

values at 10^{-5} eV and 1 keV predicts a thermal cross section of essentially 1140 barns, when compared with the actual broadened value of 30 barns. Therefore, in this simple example, the error introduced by using the input-energy grid structure for the output cross sections and assuming linear interpolation leads to an error of a factor of almost 40 (4,000%) in the hydrogen-thermal cross section.

The SIGMA1 method uses the smoothing properties of the Doppler-broadening process and the fact that the cold cross section that it uses are linearly interpolable in order to define an energy grid for the broadened cross section. Doppler broadening is a “smoothing” process, but it is the reaction rate and not the cross section, which is smoothed. Therefore, if the energy grid that is used to represent the unbroadened (cold) reaction is sufficiently dense, as a starting point, the smoother Doppler-broadened reaction rate can be adequately represented using the same energy grid. At higher energies ($AE \gg KT$), this smoothing process applies equally well to the cross section. However, at lower energies, although the reaction rate is becoming smoother, the same may not be true of the cross section because the two differ by a factor of $1/V$ [$R(V, T) = V\sigma(V, T)$]. To insure that this low-energy $1/V$ tail does not prevent the cross section from being linearly interpolable, it is sufficient to choose an energy grid for the broadened data that is merely the energy grid for the unbroadened data supplemented by an additional set of energy points. These additional points are selected such that between any two energy points of the broadened energy grid the difference between linear interpolation and $1/V$ variation in the section is always lesser than some allowable error, e.g., 0.1%. Once this starting energy grid is defined, the SIGMA1 method then uses the interval-halving technique described earlier to iterate to convergence to within any user-defined accuracy.

This can be done easily as it is very simple to replace a $1/V$ cross section by a linearly interpolable table of cross sections, where linearly interpolable cross sections are everywhere within any given allowable uncertainty of the $1/V$ cross section. For example, consider two possible representations of a cross section: $1/V$ and tabulated, linearly interpolable, with the additional condition that the tabulated cross sections agree exactly with the $1/V$ at the energies at which it is tabulated and also that successive energies are multiples of one another, as

$$\sigma(V) = \frac{1}{V}, V \in (V_1, V_2)$$

and

$$\sigma(V) = \frac{1}{V_1} - \frac{(V^2 - V_1^2)}{V_1^3 S(S+1)}, V_2 = SV_1. \quad (49)$$

The fractional difference between these two representations and the variation at this point are

$$V_{\max} = V_1 \left[\frac{1}{3} (1+S+S^2) \right]^{1/2}$$

and

$$\varepsilon(V_{\max}) = 1 - \left(\frac{2}{3} \right) \left(\frac{2}{3} \right)^{1/2} \frac{(1+S+S^2)^{1/2}}{S(S+1)}.$$

Note that $\epsilon(V_{\max})$ is independent of V , and depends only on the spacing, S , between points. This demonstrates that it is possible to represent $1/V$ variation by linear variation in energy to within any allowable error ϵ , simply by ensuring that the energies for successive tabulated values are within S^2E of one another, independent of E .

➤ *Table 1* illustrates the typical factor S required for any allowable tolerance ϵ , for ϵ in the range from 0.1 to 1.0%. This table also shows the number of energy points that would be required to space points S^2E apart between 10^{-5} eV and 20 MeV. For example, an allowable uncertainty of 0.5% would require only 124 energy points or roughly 10 per energy decade.

Therefore, in order to insure that the Doppler-broadened cross sections are linearly interpolable in cross section and energy, it is sufficient to start from the same energy points that are used to represent the cold (0 K) cross sections; and to supplement this grid in any interval where the points are more widely spaced than S^2E , where S depends on the allowable uncertainty (➤ *Table 1*). Relative to the number of points normally encountered in current evaluations (Oblozinsky et al. 2006; Cullen 2007a–c), this procedure introduces only a modest increase in the total number of points, and, as such, this procedure is an economically practical method of ensuring that the broadened cross sections are linearly interpolable over their entire energy range. Once this starting energy grid is defined, the SIGMA1 method then uses the interval-halving technique described earlier to iterate to convergence to within any user-defined accuracy. The SIGMA1 method of generating linearly interpolable Doppler-broadened cross sections has now been completely described.

The SIGAR (Pope et al. in press) method uses a different approach to selection of the energy grid. Unlike SIGMA1 which starts from linearly interpolable cross sections, SIGAR starts from resonance parameters and defines two separate energy grids: the first grid for the cold (0 K) cross sections, based on the natural width of each resonance, and the second grid for the broadened cross sections, based on the broadened width of each resonance. Rather than attempting to insure that the reaction rate in either of these grids is linearly interpolable the SIGAR method simply selects energy points which are a multiple of widths on either side of each resonance. Preliminary comparisons of SIGMA1 and SIGAR results indicate that they yield results which closely agree.

■ **Table 1**

Linear approximation to $1/V$

0.010	1.1772	88

3.3.3 TEMPO and Psi-Chi Methods

The Doppler-broadening equation (30) is the starting point for many approximate methods of calculating Doppler-broadened cross sections. Among these methods is the TEMPO method (Gregson and James 1965) that calculates Doppler-broadened cross sections starting from tabulated linearly interpolable reaction rates (similar to SIGAR) and the psi-chi method (Greene et al. 1976; Hutchins et al. 1973; Green and Pitterle 1968), which calculated broadened cross sections directly from resonance parameters.

Both the TEMPO and psi-chi methods introduce certain approximations before proceeding to solve the Doppler-broadening equation (30). The validity of these approximations is based on the strongly convergent properties of the exponentials in the Doppler-broadening kernel. The Gaussian character of these exponentials indicates that in order for the cross section at an energy E_R to make a nontrivial contribution to the integral, it must be close to E .

To better understand the validity of the approximations introduced by these approximate methods, we should briefly examine the Doppler-broadening equation (19), in this case, explicitly including the normalization of the distribution of target nuclei, $p(\bar{V}_T) d\bar{V}_T$, as

Lab reactions = Relative reactions, that is

$$R(V, T) = V\sigma(V, T) = \frac{\int_{[V_i; V_r > 0]} V_r \sigma(V_r, 0) p(\bar{V}_T) d\bar{V}_T}{\int_{[V_i; V_r > 0]} p(\bar{V}_T) d\bar{V}_T}.$$

The denominator in this equation defining the normalization of $p(\bar{V}_T) d\bar{V}_T$ is only implicit in the form of the Doppler-broadening equation that is normally used. We will see that following approximations take the liberty of “changing,” $p(\bar{V}_T) d\bar{V}_T$, without considering that this is a normalized distribution.

The approximations introduced are as follows:

In the Doppler-broadening kernel, the second exponential can be ignored when compared with the first as

$$\begin{aligned} & \text{Exp} \left[-\alpha \left(\sqrt{E_R} - \sqrt{E} \right)^2 \right] - \text{Exp} \left[-\alpha \left(\sqrt{E_R} + \sqrt{E} \right)^2 \right] \\ &= \text{Exp} \left[-\alpha \left(\sqrt{E_R} - \sqrt{E} \right)^2 \right] \left[1 - \text{Exp} \left(-4\alpha \sqrt{EE_R} \right) \right] \\ &\approx \text{Exp} \left[-\alpha \left(\sqrt{E_R} - \sqrt{E} \right)^2 \right]. \end{aligned} \quad (50)$$

In this form, it may be seen that this approximation is valid for large $\alpha\sqrt{EE_R}$ ($\sim AE/KT$). If applied at lower energies, ignoring the second exponential will overestimate the broadened kernel (it ignores a negative term), and will result in larger Doppler-broadened reaction rates (and therefore, cross sections) than would be obtained using the exact kernel.

The major contribution to the remaining integral comes from a narrow range of E_R either close to E or close to some other energy E_0 (usually the peak of a resonance). This assumption allows $\sqrt{E_R}$ to be expanded in a Taylor series of about E or E_0 . An equivalent form that better lends itself to analysis can be obtained simply by adding and subtracting terms to find

$$\alpha \left(\sqrt{E_R} - \sqrt{E} \right)^2 = \frac{\alpha}{4E} (E_R - E)^2 - \frac{\alpha}{4E} \left(\sqrt{E_R} - \sqrt{E} \right)^2 \left[\left(\sqrt{E_R} - \sqrt{E} \right) \left(\sqrt{E_R} - 3\sqrt{E} \right) \right] \quad (51)$$

or

$$\alpha \left(\sqrt{E_R} - \sqrt{E} \right)^2 = \frac{\alpha}{4E} (E_R - E)^2 - \frac{\alpha}{4E} \left(\sqrt{E_R} - \sqrt{E} \right)^2 \times \left[\left(\sqrt{E_R} - \sqrt{E} \right) \left(\sqrt{E_R} + 3\sqrt{E} \right) + 4(E - E_0) \right]. \quad (52)$$

Defining the Doppler width, evaluated at any arbitrary energy E_A (either E_R or E_0),

$$\Delta_A = 2 \left(\frac{E_A}{\alpha} \right)^{1/2} = \left(\frac{4KTE_A}{A} \right)^{1/2}, \quad T = T_2 - T_1. \quad (53)$$

And ignoring higher-order terms, it is found that

$$\alpha \left(\sqrt{E_R} - \sqrt{E} \right)^2 \approx \left[\frac{E_R - E}{\Delta_A} \right]^2. \quad (54)$$

By examining (55) and (58), we can see that in both cases the magnitude of the error introduced by this assumption increases with decreasing energy. The error in both equations is asymmetric about the point $\sqrt{E_R} = \sqrt{E}$ or $\sqrt{E_R} = 2\sqrt{E_0} - \sqrt{E}$, respectively. Relative to this point of asymmetry, for fixed E and E_0 , the variation in the error as a function of E_R is identical in both cases.

For various values of αE , **Table 2** illustrates the error introduced into the Doppler-broadening kernel by this approximation. For $\alpha E = 10^6$ and higher energies, the error introduced by this assumption is less than 1% over the entire range of the table. For example, since αE is simply AE/KT , for U238 at room temperature ($KT = 0.0253$ eV), $AE/KT = 10^6$ corresponds to roughly 100 eV. Since $\alpha E_R = \alpha E = 1$, the second exponential in the Doppler-broadening equation (30) is about 0.01 and less for higher energies; it is obvious that of the two approximations introduced so far, the second is the more restrictive in terms of limiting the validity of the approximation to higher energies. From **Table 2**, we can see that the error introduced by this approximation is asymmetric. Therefore, for fairly symmetric reaction rates, such as constant or near the peak of a resonance, this asymmetry of the error causes first-order cancellations of the errors and helps to provide better results than one would expect from **Table 2**. However, for asymmetric reaction rates, such as on the sides of resonances, or near as minimum elastic interference, the errors reinforce and cause worse results.

The psi-chi method introduces a third approximation by extending the lower limit of the integration from 0 to $-\infty$, assuming that the contribution to the integral from the interval $(-\infty, 0)$ is negligible. Generally, this assumption is less restrictive than the second assumption, and as such is consistent with the second assumption introduced above.

Introducing these approximations allows the Doppler-broadening equation (30) to be reduced to the form

$$\sqrt{E}\sigma(E, T_2) = \frac{1}{\Delta\sqrt{\pi}} \int_a^{\infty} \sqrt{E_R}\sigma(E_R, T_1) \text{Exp} \left\{ - \left[\frac{(E_R - E)}{\Delta} \right]^2 \right\} dE_R, \quad (55)$$

where

$$\begin{aligned} a &= 0 - \text{TEMPO} \\ &= -\infty - \text{psi-chi.} \end{aligned}$$

Table 2
Error Introduced by Doppler width

$\frac{\alpha}{4E} (E - E_r)^2$	$\alpha E = 10^2$			$\alpha E = 10^3$			$\alpha E = 10^4$			$\alpha E = 10^5$

Note: Error = 100% × (exact-approximate)/exact

$$\text{Exact} = \exp \left[-\alpha \left(\sqrt{E} - \sqrt{E_r} \right)^2 \right]$$

$$\text{Approximate} = \exp \left[-\frac{\alpha}{4E} (E - E_r)^2 \right]$$

Note that the approximations introduced result in the “weighting function” (the equivalent of $p(\bar{V}_T)d\bar{V}_T$) that is unnormalized.

At this point, the TEMPO and psi-chi method separate by assuming different forms for the reaction rate (or cross section). The psi-chi method assumes that the 0 K cross sections are composed of a series of single-level, Breit–Wigner resonances, each of the form,

Capture and fission

$$\sigma(E_R, 0) = \left(\frac{E_0}{E_R}\right)^{1/2} \frac{(\Gamma/2)A}{(\Gamma/2)^2 + (E_R - E_0)^2}.$$

Elastic

$$\sigma(E_R, 0) = \frac{(\Gamma/2)B}{(\Gamma/2)^2 + (E_R - E_0)^2} \frac{C(E_R - E_0)}{(\Gamma/2)^2 + (E_R - E_0)^2}, \quad (56)$$

where E = Laboratory energy, E_R = relative energy, E_0 = resonance energy, and Γ = resonance total width. By evaluating the Doppler width at the resonance energy $\Delta = (4KTE_0/A)^{1/2}$ and assuming $(E_0/E_R)^{1/2} \approx 1$ and by changing variables

$$\begin{aligned} \xi_R &= \frac{\Gamma}{\Delta} = \Gamma \left(\frac{A}{4KTE_0}\right)^{1/2}, \\ X &= 2(E_0 - E_R)/\Gamma, \\ Y &= 2(E - E_R)/\Gamma, \end{aligned} \quad (57)$$

the Doppler-broadening equation can be written in the form

Capture and fission $\sigma(E, T) = \left(\frac{2}{\Gamma}\right) \left(\frac{E_R}{E}\right)^{1/2} A \Psi(X, \xi_R)$.

$$\text{Elastic } \sigma(E, T) = \left(\frac{2}{\Gamma}\right) [B\Psi(X, \xi_R) + C\chi(X, \xi_R)], \quad (58)$$

where the psi Ψ and chi χ functions are defined by

$$\Psi(X, \xi_R) = \left(\frac{\xi_R}{2}\right) \left(\frac{1}{\pi}\right)^{1/2} \int_{-\infty}^{+\infty} \text{Exp} \left\{ - \left[\frac{(X - Y)}{2} \xi_R \right]^2 \right\} \frac{dY}{Y^2 + 1}$$

and

$$\chi(X, \xi_R) = \left(\frac{\xi_R}{2}\right) \left(\frac{1}{\pi}\right)^{1/2} \int_{-\infty}^{+\infty} \text{Exp} \left\{ - \left[\frac{(X - Y)}{2} \xi_R \right]^2 \right\} \frac{YdY}{Y^2 + 1}. \quad (59)$$

In addition to the approximations explicitly introduced to accomplish the transition from (59)–(63), there is an additional assumption concerning the energy dependence of Γ , A , B , and C . Although these are fairly complicated functions of incident neutron energy, they are usually slowly varying functions of energy. The psi-chi method only broadens the simple Breit–Wigner line shape and maintains the energy dependence of Γ , A , B , and C by writing the final equations in the form,

$$\sigma(E, T) = \left(\frac{2}{\Gamma(E)}\right) \left(\frac{E_R}{E}\right)^{1/2} A(E) \Psi(X, \xi_R)$$

and

$$\sigma(E, T) = \left(\frac{2}{\Gamma(E)} \right) [B(E) \Psi(X, \xi_R) + C(E) \chi(X, \xi_R)]. \quad (60)$$

Historically, the psi-chi method has been the most heavily used for Doppler calculations as the method is both relatively inexpensive to use and fairly accurate for many reactor calculations. However, more and more evaluations are representing cross sections in terms of not just single-level parameters, but rather in terms of either single-level parameters plus a background cross section (which includes resonant structure), other resonance formalisms, or directly in terms of tabulated cross sections. For these evaluations, the user is forced to either use other methods (e.g., SIGMA1, SIGAR, or TEMPO) or introduce additional approximations in order to justify using the psi-chi method.

The TEMPO method proceeds from (59) by assuming that the cold (0 K) reaction rate $\sqrt{E_R} \sigma(E_R, T1)$ is a tabulated function with linear variation in energy between tabulated values. By introducing this assumption, the approximate Doppler-broadening equation (59) can be written as

$$R(E, T2) = \sqrt{E} \sigma(E, T2) = \frac{1}{\Delta \sqrt{\pi}} \sum_k \int_{E_k}^{E_{k+1}} [P_k + Q_k E_R] \text{Exp} \left\{ - \left[(E_R - E) / \Delta \right]^2 \right\} dE_R. \quad (61)$$

By changing variables to $x = (E_R - E) / \Delta$, (65) can immediately be analytically integrated to yield

$$R(E, T2) = \sqrt{E} \sigma(E, T2) = \frac{1}{2} \sum_k \left\{ [P_k + Q_k E] [\text{ERF}(x_{k+1}) - \text{ERF}(x_k)] + \Delta \left(\frac{1}{\pi} \right)^{1/2} [\text{Exp}(-x_k^2) - \text{Exp}(-x_{k+1}^2)] \right\}. \quad (62)$$

The TEMPO method has the same limitations as the psi-chi method, in that it can only be applied to those energy ranges where αE is large when compared with unity. However, compared with the psi-chi method, the TEMPO method has the advantage that by reconstructing the 0 K reaction rate in a linearly interpolable form (e.g., from resonance parameters plus background cross sections) it can be used to Doppler broaden virtually any currently available evaluation of cross sections. However, the TEMPO method does not have any significant advantage when compared with the more accurate and less-restrictive SIGMA1 and SIGAR methods.

3.3.4 Mathematical Comparisons

The derivation of the various methods that are commonly used to Doppler broaden is now complete. However, it is interesting to proceed further to compare the results that the various approximations used to derive each method have on the resulting equations. The intent here is to improve the reader's understanding of the Doppler-broadening process and the effect of the various approximations, as opposed to proposing an alternative method to solving the Doppler-broadening equation.

It has already been demonstrated in this work that the Doppler-broadening equation, (29) and (30), is equivalent to solving the diffusion equation in an infinite spherically symmetric

velocity space. It is interesting to note that the approximate equation used by the psi-chi and the TEMPO method is also a diffusion equation. In fact, all the Doppler-broadening methods discussed in this work can be shown to satisfy the integral equation

$$F(X, \tau) = \left(\frac{1}{4\pi\tau} \right)^{1/2} \int_{-\infty}^{+\infty} F(X', 0) \text{Exp} \left[-(X - X')^2 / 4\tau \right] dX', \quad (63)$$

or the equivalent differential equation and initial condition,

$$\begin{aligned} \frac{\partial^2 F}{\partial X^2}(X, \tau) &= \frac{\partial F}{\partial \tau}(X, \tau), \\ F(X, 0) &= q(X); \quad q(X) \text{ given.} \end{aligned} \quad (64)$$

The only difference between the various methods is the physical interpretation of $F(X, \tau)$, X , τ , and the initial condition. **► Table 3** summarizes the interpretation of these parameters for each of the methods discussed in this work.

As pointed out earlier, the differential form of the Doppler-broadening equation as applied to neutron cross sections is difficult to solve numerically, but it is of great use in examining the effect of each approximation introduced to derive the psi-chi and TEMPO methods. Specifically, starting from the exact differential equation (32) and changing variables to those used in the other methods, e.g., change from speed to energy and from $VR(V, \tau)$ to $R(E, \tau)$ or $\sigma(E, \tau)$, leads to the equations

TEMPO or psi-chi capture/fission:

$$\frac{A}{KE} \frac{\partial}{\partial t} R(E, t) \frac{\partial^2}{\partial E^2} R(E, t) \frac{3}{2E} \frac{\partial}{\partial E} R(E, t) \quad (65)$$

► **Table 3**

Interpretation of diffusion equation parameters

Method	x	t	$f(x, t)$	Initial conditions		Conservation
Exact	V	$\frac{kT}{2M}$	$VR(V, t)$	$(-\infty, \infty)$	$VR(V , 0)$	$4\pi \int_0^{+\infty} R(V, t) V^2 dV$
TEMPO	E	$\frac{kTE_0}{A}$	$R(E, t)$	$(0, \infty)$	$R(E, 0)$	None (see applications)
				$(-\infty, 0)$	0	
Psi-chi capture or fission	E	$\frac{kTE_0}{A}$	$R(E, t)$	$(0, \infty)$	$R(E, 0)$	$\int_{-\infty}^{+\infty} R(E, t) dE$
				$(-\infty, 0)$ extend	$R(E, 0)$	
Psi-chi elastic	E	$\frac{kTE_0}{A}$	$\sigma(E, t)$	$(0, \infty)$	$\sigma(E, 0)$	$\int_{-\infty}^{+\infty} \sigma(E, t) dE$
				$(-\infty, 0)$ extend	$\sigma(E, 0)$	

and

$$\text{Psi-chi elastic : } \frac{A}{KE} \frac{\partial}{\partial t} \sigma(E, t) = \frac{\partial^2}{\partial E^2} \sigma(E, t) + \frac{5}{2E} \frac{\partial}{\partial E} \sigma(E, t) + \frac{1}{2E^2} \sigma(E, t). \quad (66)$$

These two equations are exactly equivalent to the Doppler-broadening equations (29) and (30). Besides the initial conditions, the only difference between the SIGMA1 and SIGAR and the approximate psi-chi and TEMPO methods is that the approximate methods only include the first term on the right-hand side of equations (69) and (70). As such, the approximate equations are only valid wherein the other trailing terms are small when compared with the first term.

How were these terms eliminated during the derivation of the psi-chi and TEMPO methods? The first derivative term was eliminated by expansion of the exponential argument; and in the case of elastic scatter, the cross-section term was eliminated by assuming $(E_0/E_R) \approx 1$. Ignoring the second exponential and extending the lower limit of integration change the initial conditions, but not the differential equation.

The net effect of ignoring these trailing terms is to convert from the exact diffusion equation using speed in a spherical system, to using energy in a planar system, in which either the reaction rate or cross section will become “smoother” under Doppler broadening. Earlier, it was pointed out that the approximations introduced in order to derive the psi-chi and TEMPO methods limit then to “large” E . From the mathematical comparisons, here we see that this is equivalent to saying that far from the origin (i.e., at large E), a spherical system may be approximated as linear. For example, on the surface of the earth many physical problems may be accurately approximated by assuming that we live on a plane surface. Similarly, the approximate methods introduced here can be quite accurate when restricted to their ranges of applicability.

The introduction of the approximations that allow us to convert from speed to energy space is also the genesis of the conservation of the “area under the curve.” To reiterate, this is NOT a property of the exact Doppler-broadening equation, but rather a consequence of the approximations introduced to obtain the approximate broadening equation. Therefore, the concept of conservation of “area under the curve” must be restricted to those energy ranges where the approximations are valid. In particular, it must not be extended to low energies, e.g., CAVEAT EMPYTOR in resonance-integral calculations.

The only cases where it is exactly valid to ignore the trailing terms on (65) and (66) are

1. In (65) for a constant reaction rate ($1/V$ cross section) and
2. In (66) for a cross section of the highly unlikely form $(E/E_0)^{-1/5}$.

In other cases, the $1/E$ and $1/E^2$ dependence of the trailing terms are used as justification to apply the approximate methods at higher energies. However, from (65) and (66), it can be seen that even at high energy the values and the first derivatives should also be considered. As e.g.,  Table 4 lists the 0 K values and derivatives for a simple Breit–Wigner resonance of the terms that appear in (66). In addition, the value of these terms at the peak inflection point, $E_R = E_0 \pm (\Gamma/2)$, where the second derivative is zero and the distant energy $E_R \gg E_0$, are also listed. From this table, three points that are obvious are as follows:

1. Close to the peak of the resonance, the trailing terms can be ignored if the half-width is much smaller than the energy, that is, $(\Gamma/2) \ll E$.
2. By definition, at the inflection point, where the second derivative is zero, the trailing terms cannot be ignored.

■ **Table 4**
Breit–Wigner resonances and parameters

		Peak	Inflection	Distant
$\frac{1}{2E} \sigma(E, 0)$	$\frac{1}{2E^2} \frac{(\Gamma/2)^2}{(\Gamma/2)^2 + (E - E_R)^2}$	$\frac{1}{2E^2}$	$\frac{1}{2E_1^2(4/3)}$	$\frac{(\Gamma/2)^2}{2E^4}$
$\frac{1}{2E} \frac{\partial \sigma}{\partial E}(E, 0)$	$-\frac{(E - E_R)/(\Gamma/2)^2}{E[(\Gamma/2)^2 + (E - E_R)^2]^2}$	0	$\pm \frac{(1/3)^{1/2}}{E_1(4/3)^2}$	$\pm \frac{(\Gamma/2)^2}{E^4}$
$\frac{\partial^2}{\partial E^2} \sigma(E, 0)$	$\frac{(\Gamma/2)^2 [6(E - E_R)^2 - 2(\Gamma/2)^2]}{[(\Gamma/2)^2 + (E - E_R)^2]^3}$	$-\frac{1}{(\Gamma/2)^2}$	0	$\frac{6(\Gamma/2)^2}{E^4}$

3. At distant energies, the contribution from all three terms is comparable magnitude and the trailing terms cannot be ignored.

These results may be summarized by stating that the psi–chi and TEMPO methods applied at a single-level Breit–Wigner resonance at higher energy (e.g., $AE \gg KT$) will yield accurate results close to the peak of the resonance. However, caution is advised in applying these methods to calculate the broadened cross sections far from the peak of the resonance, e.g., heavy even–even nuclei, such as Th232, U238, and Pu240, in which the ratio of the mean-level spacing to total width is very large (~ 500).

3.4 Numerical Results

In the preceding sections, the approximations introduced to obtain the approximate Doppler-broadening equation (55) were quantitatively explained to restrict the range of applicability of the psi–chi and TEMPO methods to the energy range where $AE/KT \gg 1$. In this section, we will first quantitatively examine the effect of these approximations when applied to low energy. Next, examples will be presented in order to illustrate the effect of Doppler broadening at higher energies in the resonance region. Finally, an example will be presented to illustrate the effect that the very high temperatures, such as those occur in fusion plasmas, have on cross sections.

3.4.1 Low Energies

It can be seen that for light isotopes the low-energy limit of the various reactions at 0 K is either constant or $1/V$. Usually, such behavior extends into the keV energy range so that the following analysis is valid even for CTR core temperatures. Since the low-energy limit of a single-level Breit–Wigner resonance is also either constant (elastic) or $1/V$ (capture and fission), in principle the following also applies to the low-energy tails of such resonances. However, in practice only materials with a large atomic weight (i.e., large A) have resonances at lower energies, and in such materials, the effects that are described as follows occur only at extremely low energies.

In order to examine the effect of Doppler broadening at lower energies and the approximations introduced in the psi-chi and TEMPO methods, we will define two functions:

$$F(\pm X) = \frac{1}{X^2} \left(\frac{1}{\pi}\right)^{1/2} \int_0^{\infty} Y^2 \sigma(Y, T) \text{Exp}[-(Y \mp X)^2] dY$$

and

$$G(\pm X) = \frac{1}{X^2} \left(\frac{1}{\pi}\right)^{1/2} \int_0^{\infty} Y^2 \sigma(Y, T) \text{Exp}\left[-\left(\frac{Y^2 \mp X^2}{2X}\right)^2\right] dY.$$

In terms of these two functions, the various methods described here correspond to

$F(X) - F(-X)$ Exact SIGMA1 and SIGAR,

$F(X)$ Ignore second exponential,

$F(X) + F(-X)$ Ignore second exponential and extend integral from ∞ to $-\infty$,

$G(X) - G(-X)$ Expand argument of exponential,

$G(X)$ Expand argument and ignore second exponential (TEMPO),

$G(X) + G(-X)$ Expand argument, ignore second exponential, and extend integral from ∞ to $-\infty$.

For a cross section that, at 0 K, is either constant or $1/V$ cross section, these functions can be easily evaluated analytically. For comparison purposes,  Fig. 17 presents graphical results and  Tables 5 and  6 tabular results.

The $1/V$ results illustrate that of the six possible combinations examined here, only the exact and psi-chi methods reproduce a $1/V$ -cross section independent of temperature. Since a $1/V$ cross section is a constant reaction rate integrated over the target nuclei velocity

distribution (19), this illustrates that the other combinations are not properly normalized. It should always be remembered that implied in the Doppler-broadening equations is a normalizing target nuclei velocity distribution as a denominator to the equations

$$R(x,t) = \frac{\int R(x',0) M(V) dV}{\int M(V) dV},$$

such that when $R(x',0) = C$ (a 1/cross section), this reduced to an identity

$$R(x,t) = C = C \frac{\int M(V) dV}{\int M(V) dV}.$$

So that in this case, $R(x,t)$ is independent of temperature.

Any approximation introduced into the numerator of the equation should also be introduced into the implied denominator. In the case of the psi-chi method, the combination of approximations does conserve this normalization, whereas in the TEMPO equations it does not; and the lower energy TEMPO results converge to only one-half of the exact value. If the TEMPO method is renormalized by $[1 + \text{ERF}(X)]/2$, it will yield the correct $1/V$ behavior and will also agree well with the psi-chi results for a constant cross section (described later). As actually implemented in computer codes, in contrast to the equations presented in the TEMPO report (Gregson and James 1965), this normalization problem has been eliminated by renormalizing as described here.

The results for the constant cross section case illustrates that for a reaction rate that is increasing with energy, that is $R(V,0) = V$, the approximations introduced cause the psi-chi and TEMPO methods to underestimate the low-energy cross sections. This result is expected from (65) and (66), since in this case in (37) the derivative of the reaction rate is a positive constant; and in (66), although the derivative of the cross section is zero the value of the cross section is positive and ignoring these terms underestimate the then effect of broadening.

From \blacktriangleright Fig. 17 we can see that expanding the exponential is the most restrictive of the approximations since $G(x)$ deviates from the exact solution at a higher energy than $F(x)$. From \blacktriangleright Tables 5 and \blacktriangleright 6, it can be seen that expanding the argument of the first exponential and keeping the correct second exponential $G(x) - F(-x)$, can lead to negative cross sections.

From \blacktriangleright Fig. 17, we can see that for the two cases considered here the results presented by the various methods are virtually indistinguishable from one another for $AE/KT > 100$. For example, at room temperature (i.e., $KT = 0.0253$ eV) for hydrogen ($A = 1$), the approximate methods should only be applied for $E > 2.5$ eV.

3.4.2 Resonance Region

At higher energies, in the resonance region, the psi-chi method can be an accurate and economical means of defining broadened cross sections, particularly close to the peak of a resonance. In order to illustrate the effect of broadening in the resonance region, \blacktriangleright Figs. 18 and \blacktriangleright 19 illustrate the psi and chi functions, respectively. The psi and chi functions, (59), are particularly convenient and economical to use as they are only a function of two variables

1. The distance from the peak of the resonance, measured in half-widths

$$X = 2(E - E_0)/\Gamma \quad \text{and}$$

2. The ratio of the total width to Doppler widths

$$\Delta_A = \Gamma (A/4KTE_A)^{1/2}.$$

\blacksquare Figure 18
Psi and chi functions

Figure 19
U235 Total, 0 to 10,000 K temperature

Figure 18 illustrates the psi and chi functions for a range of $\xi = \infty, 4, 2, 1, 1/2 \dots 1/64$. For successively smaller ξ (higher T), the resonance broadens (psi) and the interference dissipates (chi).

Figure 19 illustrates the effect of Doppler broadening the U235 total cross section for temperatures between 0 and 10,000 K. In the resolved-resonance region, the difference between the broadened cross sections obtained by each of the methods described here can differ for two reasons: (1) the approximations introduced to obtain the approximate Doppler-broadening equation (55) and (2) the cross section may not be described by a series of single-level, Breit–Wigner resonances.

The approximations introduced will limit the accuracy of the psi–chi and TEMPO methods to high energies, as described in the preceding sections, but also limits these methods to calculate cross sections close to the peak of resonances. For example, for isotopes with wide overlapping resonances, such as U235- and Pu239 s-wave resonances, we expect the psi–chi and TEMPO methods to be accurate methods of calculating cross sections both near the peaks of resonances and at energies between the resonances. This is because the cross section between resonances will be dominated by the contributions from neighboring resonances, which are never more than a few half-widths distant. Although the contribution of distant resonances may not be calculated accurately, their actual contribution to the cross section will be so small as to not affect the accuracy of the overall result.

In contrast for heavy even–even nuclei with narrow, widely spaced resonances, such as Th232, U238, and Pu240, on average resonances are about 500 half-widths apart. In this case, the cross section between resonances can be dominated by a single nearest resonance, in which mid-way between resonances is 250 half-widths away; on average, the next nearest resonance will be 750 half-widths away. For the elastic cross section, this presents no calculational problems, since far from the nearest resonance the resonance contribution will become small when compared with the potential scattering and the broadened cross section will simply reduce to the potential-scattering cross section. However, the Doppler-broadened capture and fission cross sections between resonances will be defined solely in terms of the contribution from the nearest resonance, or resonances, which can be many half-widths distant. In this case, the approximations introduced by the psi–chi and TEMPO methods can introduce large errors.

3.4.3 High Energies

At energies higher than the resolved-resonance region, in the unresolved-resonance region, it is still important to consider Doppler broadening. However, in this energy range evaluations do not uniquely define a set of resonance energies and widths; rather, the evaluations define distributions of resonance spacings and widths. Therefore, it is not possible to discuss calculating energy-dependent cross sections directly from the data given in evaluations. In this energy range, two approaches are possible to define Doppler-broadened cross sections: (1) the distribution of resonance widths and spacings may be sampled to obtain a ladder of resonances. Once a ladder is chosen, any of the methods described here may be used to broaden the cross sections and (2) the distribution of resonance widths and spacings is used directly to define temperature-dependent, self-shielded, group-averaged cross sections; this approach will be described later in this chapter under self-shielding.

At still higher energies above the unresolved-resonance region, usually the resonance structure overlaps, the cold (0 K) cross section becomes smooth, and Doppler broadening has little or no effect on neutron-induced cross sections. Therefore, generally for fission-reactor core application, Doppler broadening need not be considered in this energy range. However, for completeness in this section on Doppler broadening, it will be mentioned and illustrated that for fusion plasma and astrophysics, temperature effects on cross sections can be important even at high energies. The reason is the enormously high temperatures that are encountered in plasmas and astrophysics. For example, in a plasma temperature is usually described in energy units, using KT ($T = 293.6$ is equivalent to $KT = 0.0253$ eV), and temperatures in the keV range are required for plasma ignition, to cause any significant fusion. The enormity of these temperatures

■ **Figure 20**
U235 total, 0–10,000 eV temperature

can be appreciated by first examining ► *Fig. 19* which illustrates broadening with temperatures up to 10,000 K, which is roughly an order of magnitude higher than what would be encountered in a fission reactor, and then realize that in forms of temperatures expressed in energy 12,000 K is approximately only 1 eV. For comparison, ► *Fig. 20* illustrates the effect of broadening to plasma-like temperatures; note the eventual $1/V$ shape of the cross section at very high energy, corresponding to smoothing of the reaction rate.

■ Figure 21
 (D, D) cross section 0–100 keV temperature

One important effect on the equivalent laboratory frame of reference cross section that must be considered at plasma-like temperatures is that for threshold reactions even projectiles with laboratory energies below the threshold may interact with a target nuclei whose motion may combine with that of the projectile to produce a relative energy above the threshold and make the reaction energetically possible. The result of this phenomenon is to make the effective-laboratory threshold energy for any reaction decrease to a lower energy as the temperature of the medium is increased. As the temperature of the medium approaches the energy of the threshold, there is essentially no longer a laboratory frame of reference threshold, since in this case there is an appreciable cross section or probability of a thermal projectile resulting in a relative energy that lies above the reaction threshold. 📌 Figure 21 illustrates the effect of temperature on the (D, D) fusion cross section for temperatures between 0 and 100 keV. In principle, a similar phenomenon occurs to threshold reactions in fission-reactor cores. However, in practice, the temperatures encountered in fission systems are so low when compared with the threshold energies that the effect is negligible and can be ignored, e.g., for fission reactors we need not consider Doppler broadening of inelastic cross sections.

4 Self-Shielding

4.1 Introduction

Since the neutron flux at any energy E is merely the total distance traveled per unit time by all neutrons of energy E , it is not surprising that increasing the cross section, which decreases the average distance that neutrons travel between collisions, lead to a decrease in the neutron flux. This phenomenon is referred to as self-shielding, since in terms of resonances it is the increase in cross section itself that depresses, or shields the resonance, from the flux.

By considering certain limiting cases, it is easy to see the effect that self-shielding has on the neutron flux. First, consider a uniform source in a totally absorbing infinite medium. In this case, the Boltzmann equation reduces to

$$\Sigma_T(E) \Phi_0(E) = S_0(E). \quad (67)$$

Obviously by dividing both sides of this equation by the total cross section, we find that the scalar flux will vary inversely to the total cross section.

Next consider a monoenergetic source in a totally scattering infinite medium. In this case, the Boltzmann equation at energies below the source energy reduces to

$$\Sigma_T(E) \Phi_0(E) = \frac{1}{1-\alpha} \int_E^{E/\alpha} \Sigma_T(E') \Phi_0(E') \frac{dE'}{E'}. \quad (68)$$

It is easy to demonstrate by substitution that the solution to this equation is simply

$$\Phi_0(E) = \frac{C}{E \Sigma_T(E)}, \quad (69)$$

where the constant C only depends upon the source strength. Therefore, we again see that the flux varies inversely to the total cross section.

Since both the extremes of total absorption and total scattering lead to the same simple inverse relationship between flux and total cross section, it is tempting to consider the possibility that this relationship always exists between flux and cross section. Unfortunately, such is not the case and the effects of self-shielding are much more complicated than this.

In order to illustrate the complexity of self-shielding, consider a slab of material with a source of neutrons incident upon it, from the left, as shown in  Fig. 22.

At the left-hand-side boundary of this slab for directions oriented into the slab, the flux is simply equal to the source, and as such the flux is not self-shielded; in terms of cause and effect, since the source has not yet “seen” or interacted with the material in the slab, it could not possibly be self-shielded. However, if we look at the neutrons which are transmitted through the slab, we will see depressions in the flux corresponding to peaks in the total cross section. If we change the thickness of the slab, the magnitude of the flux depressions will also change. This illustrates that self-shielding is a spatially dependent phenomena (since it is different at the left- and right-hand sides of the slab), which also depends on geometry (since varying the slab thickness will vary the amount of flux depression or self-shielding). This spatial dependence is widely known, but what is often overlooked is that self-shielding is also a direction-dependent phenomena. For example, the albedo from the left-hand side of the slab in our example will also show depressions at energies corresponding to peaks in the total cross section. The incident flux at the left-hand boundary is merely equal to the incident source and is not self-shielded, but the albedo is, obviously the amount of self-shielding, depending on direction. This would imply, e.g., that S_n programs (Engle 1967; Mynatt et al. 1973; Lathrop and Brinkley 1970), should use different self-shielded cross sections along each ray; to my knowledge, this is never done.

■ **Figure 22**
Finite thickness slab geometry

Somehow we must try to combine all these effects in order to obtain an adequate description of the self-shielded flux, or usually the Legendre moments of the flux, in order to use it as a weighting function to obtain the required group-averaged data for use in the multigroup equations. For example, in the case of our slab, at the left-hand boundary, in order to define the self-shielding of the scalar flux, we must somehow combine the unshielded incident source with the self-shielded albedo to define an equivalent average, self-shielding factor. However, this average will also depend upon the source, since if in our slab problem there was also a source incident on the right boundary of the slab it would change the balance between the incident source and the leakage at the left boundary, thereby changing the average self-shielding of the flux.

This may seem to be an impossible task to define a self-shielding factor that is a function of geometry, space, direction, source, energy, and possibly time (the latter of which we have not even discussed). However, what is actually done in reactor calculations is to use the results of certain limiting cases (such as the absorption and scattering problems that we discussed earlier) and various approximations so that in each spatial region it is possible to define one single self-shielding factor for the scalar flux, and possibly scalar current, which can be applied as an average for the entire region, e.g., one form within a fuel rod and another within the surrounding moderator.

4.2 Narrow, Intermediate, and Wide Resonances

In this chapter, we only describe self-shielding alone as it effects the generation of application-independent, multigroup libraries. Other chapters of this handbook will consider more details as they relate to specific applications and classes of calculations, in particular the energy ranges in which these models are valid.

Since the most pronounced effects of self-shielding occur when the neutron cross section rapidly changes as a function of energy, it is natural to examine the effect that resonances have on the neutron flux. Therefore, we will consider the case of neutrons produced by fission, slowing down in a mixture of a heavy resonant material (such as a fuel), and a light material (such as a moderator). For simplicity, in the following discussion, these two materials will be referred to as the absorber and the moderator. In an infinite medium, we can write the Boltzmann equation in the following form

$$[\Sigma_T(E) + \Sigma_0(E)] \Phi_0(E) = R_0(E),$$

where

$$R_0(E) = \frac{1}{1 - \alpha} \int_E^{E/\alpha} \Sigma_s(E') \Phi_0(E') \frac{dE'}{E'} + \frac{1}{1 - \alpha_m} \int_E^{E/\alpha_m} \Sigma_m(E') \Phi_0(E') \frac{dE'}{E'}, \quad (70)$$

in which,

- $\Phi_0(E)$ Scalar flux,
- $R_0(E)$ Secondary distribution of elastically scattered neutrons,
- $\Sigma_T(E)$ Total cross section of the absorber,
- $\Sigma_0(E)$ Total cross section of the moderator,
- $\Sigma_s(E)$ Scattering cross section of the absorber, and
- $\Sigma_m(E)$ Scattering cross section of the moderator.

To the first order, spatially dependent effects may be included in the equations by adding a buckling factor, as in the B_n method (Joanou et al. 1961). Inclusion of a buckling term will merely have the effect of adding a term $DB^2 \Phi_0(E)$ to the left-hand side of (70). Therefore, the following discussion may be generalized to consider the first-order spatial corrections by considering $\Sigma_0(E)$ as the sum of the moderator total cross section plus the buckling term DB^2 to account for spatially dependent leakage.

Each of the methods used to obtain an approximate solution to this equation proceeds by assuming a different form for the secondary distribution of neutrons. In all approximations that will be discussed later, the range of secondary energies to which neutrons can scatter from the moderator atom will be considered to be large when compared with the width of the resonance. In this case, the effect of scattering from the wide range of initial energies E' will be to produce a smooth distribution of scattered neutron at E , that is,

$$\frac{1}{1 - \alpha_m} \int_E^{E/\alpha_m} \Sigma_m(E') \Phi_0(E') \frac{dE'}{E'} \approx \frac{1}{E} \langle \Sigma_m \Phi_0 \rangle. \quad (71)$$

In particular, there will be no correlation between the value of the absorber cross section at E and the arrival of scattered neutrons from higher energies E' .

4.2.1 Narrow Resonances

In the narrow-resonance (NR) approximation, it is assumed that the resonances are also narrow when compared with the range of secondary energies to which neutrons can scatter from an absorber atom, in which case (70) reduces to

$$[\Sigma_T(E) + \Sigma_0(E)] \Phi_0(E) \approx \frac{1}{E} [\langle \Sigma_s \Phi_0 \rangle + \langle \Sigma_m \Phi_0 \rangle]. \quad (72)$$

This relationship simply predicts that the flux will vary inversely as the total cross section of the mixture. Since generally the total cross section of a moderator is much smoother than that of heavy absorber materials, over-energy ranges comparable to the width of an energy group, it may be considered to be independent of energy, $\Sigma_0(E) \approx \Sigma_0$, and in the NR approximation, the predicted form of the flux is

$$\Phi_0(E) \propto \frac{1}{E [\Sigma_T(E) + \Sigma_0]}. \quad (73)$$

Different mixtures of fuel (absorber) and moderator may be considered simply by different values of Σ_0 . First-order geometric corrections may also be included by the addition of DB^2 to Σ_0 .

The ratio of moderator to fuel cross sections may be anywhere between zero (pure fuel, no moderator) to infinity (pure moderator, infinitely dilute fuel). Therefore, the NR predicts a flux that will be maximally self-shielded for pure fuel; in which case, the flux will vary inversely to the total cross section of the fuel and the energy as

$$\Phi_0(E) \propto \frac{1}{E \Sigma_T(E)} : \Sigma_0 = 0. \quad (74)$$

Conversely for the case wherein the fuel is infinitely dilute, the flux will not be self-shielded as

$$\Phi_0(E) \propto \frac{1}{E} : \Sigma_0 \gg \Sigma_T(E), \Sigma_0 \text{ constant}. \quad (75)$$

Since the NR approximation depends only on the details of the absorber cross section, it leads itself to development of application-independent, multigroup libraries (MacFarlane et al. 1982; MacFarlane and Muir 1994).

4.2.2 Wide Resonances

In the wide-resonance (WR) or wide-resonance, infinite absorber (WRIA) approximation, the resonance is assumed to be wide when compared with the range of secondary energies that can be reached by scattering from the absorber atom. In this case, the absorber is treated as infinitely heavy (not as the name WRIA seems to imply, infinitely absorbing), and neutron slowing down occurs only because of scattering from moderator atoms. In this case, the scatter from an absorber atom merely leads to the emission of a scattered neutron at the incident

energy, that is,

$$\frac{1}{1-\alpha} \int_E^{E/\alpha} \Sigma_S(E') \Phi_0(E') \frac{dE'}{E'} \approx \Sigma_S(E) \Phi_0(E). \quad (76)$$

In this case, (70) becomes

$$[\Sigma_T(E) + \Sigma_0(E)] \Phi_0(E) = \Sigma_S(E) \Phi_0(E) + \frac{1}{E} \langle \Sigma_m \Phi_0 \rangle, \quad (77)$$

or upon subtracting the absorber elastic scattering from both sides of this equation,

$$\begin{aligned} [\Sigma_A(E) + \Sigma_0(E)] \Phi_0(E) &= \frac{1}{E} \langle \Sigma_m \Phi_0 \rangle \\ \Sigma_A(E) &\text{ - absorber absorption cross section.} \end{aligned} \quad (78)$$

Again recognizing that over-energy ranges comparable to the width of an energy group, the moderator cross section, will be much smoother than the absorber cross section, and that as such they may be treated as a constant, the wide resonance infinite absorber (WRIA) approximation predicts a flux of the form as

$$\Phi_0(E) \propto \frac{1}{E [\Sigma_A(E) + \Sigma_0]}. \quad (79)$$

As in the case of the NR approximation, the ratio of cross sections may be anywhere from zero to infinity, and the WR approximation predicts a maximum self-shielding for a pure fuel (absorber) and no self-shielding for an infinitely dilute fuel.

4.2.3 Intermediate Resonances

When we compare the maximum energy loss in the elastic scattering for a variety of materials to the widths of resonances in these materials, it is obvious that all resonances do not neatly fall into any one of these two categories of NRs or WRs. In reality, resonances span the entire range of widths from narrow to intermediate to wide (Mughabghab et al. 1981; Gyulassy et al. 1972).

The intermediate-resonance (IR) approximation (Goldstein and Cohen 1962; Goldstein 1972, 1975), was developed in order to treat the entire range of resonances. Since the original development of this method, it has been greatly extended to handle complex geometric situations. In this chapter, only the basic IR approximation will be presented. In the basic IR approximation, the secondary-energy distribution of neutrons elastically scattered by an absorber atom is assumed to be described by a linear combination of the distributions obtained from the NR and WR approximations as

$$\frac{1}{1-\alpha} \int_E^{E/\alpha} \Sigma_S(E') \Phi_0(E') \frac{dE'}{E'} \approx \left\{ \lambda \frac{\langle \Sigma_S \Phi_0 \rangle}{E} + (1-\lambda) \Sigma_S(E) \Phi_0(E) \right\}. \quad (80)$$

Substituting this expression into (70) for the absorber scattering, using (71) to describe the moderating scattering and solving for the scalar flux, it is found that

$$\Phi_0(E) \propto \frac{1}{E} \left\{ \frac{\langle \Sigma_m \Phi_0 \rangle + \lambda \langle \Sigma_s \Phi_0 \rangle}{\Sigma_A(E) + \lambda \Sigma_s(E) + \Sigma_0} \right\}. \quad (81)$$

The NR and WR approximations may be easily recognized to correspond to the limits of λ equal to unity (narrow) or zero (wide), respectively; in most cases, λ is different for each resonance and lies in the range, zero to unity.

In the chapter on unit-cell calculations, these three models of NR, IRs, and WRs will be discussed in more detail. Here, the important point to be observed is that each of these three models leads to a scalar flux which can be expressed as the product of two terms: an energy-dependent spectrum $M(E)$ (in this case $1/E$) and a self-shielding factor $W_0(\Sigma)$ that explicitly depends on the cross sections alone. It should be noted that this result is not restricted to resonances alone, as we obtained similar results for pure absorption, (67) and pure scattering, and (69) cases considered earlier. Therefore, in the following sections, to describe the scalar flux we will use a model that is a product of two independent terms.

4.3 Cross-Section Dependence of Flux

We now have a model that can be used to describe the scalar flux. However, generally we need to describe the Legendre moments of the angular flux, e.g., scalar flux, scalar current, etc. Here, we will examine a simple model to predict the cross-section dependence of any Legendre moment of the flux.

In the resonance region, the neutron energy is low enough that we may consider scattering to be isotropic. In plane geometry, we may write the Boltzmann equation in the form

$$\mu \frac{\partial \Phi}{\partial z}(z, \mu, E) + \Sigma_T(E) \Phi(z, \mu, E) = \frac{1}{4\pi} R_0(z, E). \quad (82)$$

Introducing the assumption

$$\Phi(z, \mu, E) = \Phi_v(\mu, E) \text{Exp}[-z/\nu]$$

and

$$R_0(z, E) = R_{0v}(E) \text{Exp}[-z/\nu] \quad (83)$$

leads to the equation

$$[\nu \Sigma_T(E) - \mu] \Phi_v(\mu, E) = \frac{\nu}{4\pi} R_{0v}(E). \quad (84)$$

Any Legendre moment of the flux may be determined by dividing by $[\nu \Sigma_T(E) - \mu]$, multiplying by $P_n(\mu)$, and integrating over the angular range $\bar{\Omega}$, to find

$$\Phi_{vn}(E) = \nu Q_n(\nu \Sigma_T(E)) R_{0v}(E), \quad (85)$$

where Q_n is merely the Legendre function of the second kind (Abramowitz and Stegun 1965) as

$$Q_n(X) = \frac{1}{2} \int_{-1}^{+1} \frac{P_n(\mu) d\mu}{X - \mu}. \quad (86)$$

From the discussion in the preceding section, the NR approximation predicts that the energy of $R_0(z, E)$ will simply be proportional to $1/E$. Therefore, (85) again gives us a result wherein any Legendre moment of the flux may be expressed as the product of two terms: one that explicitly depends on energy alone and the other that explicitly depends on cross section alone.

In order to determine the cross-section dependence of each Legendre moment, we need to look only at the definition of the Legendre functions of the second kind (Abramowitz and Stegun 1965) as

$$Q_n(X) = \frac{1}{2} \left(\frac{1}{X}\right)^{n+1} \sum_{m=0}^{\infty} \left(\frac{1}{X}\right)^{2m} \frac{(n+2m)!(n+m)!}{m!(2n+2m+1)!}. \quad (87)$$

Therefore, any Legendre moment of the flux can be written in the form

$$\Phi_{vn}(E) \propto \frac{\nu}{E [\nu \Sigma_T(E)]^{n+1}} \left\{ 1 + C_{2n} \left(\frac{1}{\nu \Sigma_T(E)}\right)^2 + C_{4n} \left(\frac{1}{\nu \Sigma_T(E)}\right)^4 \right\} + \dots \quad (88)$$

In particular, as we approach the infinite medium case ν approaches infinity (no spatial dependence), and the Legendre moments approach

$$\Phi_{vn}(E) \rightarrow \frac{1}{E [\Sigma_T(E)]^{n+1}}. \quad (89)$$

This limit agrees with the NR approximation result that we obtained earlier for the scalar flux ($n = 0$) where we found a $1/\Sigma_T(E)$ dependence. However, this result can now be used to define other moments of the flux, such as the current ($n = 1$) which is predicted to be self-shielded by $1/\Sigma_T^2(E)$. From (88), we also obtain the result that for finite media the self-shielding will also depend on higher moments of the cross sections.

4.4 Computation of Multigroup Cross Sections

Now that we have a model to describe the energy and cross-section dependence of the moments of the flux, we can return to evaluation of the multigroup cross sections. The general definition of the multigroup cross section, weighted by moments of the flux, is,

$$\langle \Sigma_{Rn} \rangle_g = \frac{\int_{E_g}^{E_{g+1}} \Sigma_R(E) \Phi_n(E) dE}{\int_{E_g}^{E_{g+1}} \Phi_n(E) dE}, \quad (90)$$

where $\Sigma_R(E)$ is the cross section for any reaction R , e.g., $R =$ total, elastic, capture, etc., and $\Phi_n(E)$ is the n th Legendre moment of the flux, e.g., $0 =$ scalar flux and $1 =$ scalar current. In our

model, each component of the flux will be defined as the product of two independent terms: the energy-dependent weighting spectrum $M_n(E)$ and the cross-section-dependent, self-shielding factor $W_n(\Sigma_T)$.

In principle, the spectrum is different for each Legendre moment of the flux, and some computer codes are capable of using different spectrum for each component (Weisbin et al. 1976; Doyas et al. 1971). However, in practice most codes use only a single weighting function (MacFarlane et al. 1982; MacFarlane and Muir 1994; Weisbin et al. 1976; Rieffe et al. 1981; Panini 1973; Vertes 1981), and (Pope et al. in press). In such codes, the effect of different spectrum may be examined by making a series of computer runs, one for each spectrum. In the following development, we will discuss the use of an energy-dependent spectrum, which the reader may interpret to be the same for all moments or different for each moment of the flux.

The result of the NR, IR, and WR approximations is that the self-shielding factor for the scalar flux will vary inversely with cross sections, either the total cross of the mixture, the sum of the absorber absorption and moderator total cross section, or a linear combination of the two. Then we saw that, in general, the NR approximation for the higher Legendre moments of the flux will depend on higher reciprocal powers of the total cross section of the mixture. In the following section, we will use the results of the NR approximation to illustrate how to compute self-shielded cross sections. This approach will highlight the computational problems involved and can easily be extended to include IR and WR effects. Therefore, we will assume a weighting function of the form

$$\frac{M(E)}{[\Sigma_T(E) + \Sigma_0]^k} : k = 0, 1, 2, \dots, \quad (91)$$

where

$M(E)$ Energy-dependent spectrum, e.g., Maxwellian, $1/E$, fission, and fusion spectrum at progressively higher energy.

$\Sigma_T(E)$ Total cross section of the material of interest

Σ_0 Total cross section of all other constituents of the mixture (possibly including DB^2 or equivalent to escape cross section for spatial effects).

k Integer for different Legendre moments

0 = no self-shielding

1 = self-shielded scalar flux

2 = self-shielded scalar current

In order to consider different atom ratios of absorber and moderator, all values of Σ_0 between zero (no moderator, pure absorber) and infinity (infinitely dilute absorber) will be considered. Note that the limit as Σ_0 approaching infinity corresponds to the no self-shielding, or $k = 0$, for each moment of the flux.

This model corresponds to the Bondarenko model of self-shielding (Bondarenko et al. 1964), and is widely used in a number of cross-section-processing codes. The most commonly used procedure is to create application-independent libraries of self-shielded cross sections for a variety of values of Σ_0 , usually powers of 10, e.g., 0, 10, 100, 1,000, etc. (Bondarenko et al. 1964). Once calculated at fixed values of Σ_0 , the tables of self-shielded cross sections are interpolated to define the self-shielded cross section at any other value of Σ_0 .

For any reaction R and group g , we must calculate the self-shielded, group-averaged cross section as

$$\langle \Sigma_{Rk}(\Sigma_0) \rangle_g = \frac{\int_{E_g}^{E_{g+1}} \frac{\Sigma_R(E) M(E) dE}{[\Sigma_T(E) + \Sigma_0]^k}}{\int_{E_g}^{E_{g+1}} \frac{M(E) dE}{[\Sigma_T(E) + \Sigma_0]^k}}. \quad (92)$$

Before considering how to perform this calculation, the first question to be asked is – Is all of this complexity necessary, or is this merely a “much ado about nothing”? (Shakespeare 1982). How much does self-shielding actually affect cross sections? In order to answer this question,  Fig. 23 illustrates the Th232-unshielded, 175 group ENDL cross sections (Plechaty et al. 1978a,b), and  Fig. 24 illustrates the Th232 self-shielding factors, which are merely the ratio of the shielded to unshielded cross section. If self-shielding has little or no effect, we would expect the ratio of shielded to unshielded cross sections to be close to unity. However, from  Fig. 24 in the resonance region, the ratio is drastically different from unity and, in the worst case, has a value of only 0.02. This corresponds to a change between unshielded and shielded cross sections of a factor of 50 (5,000%) in the Th232 capture cross section. By examining results for a variety of materials (Plechaty et al. 1978a,b), we can see that the effect of self-shielding is very important for virtually any material that has a resonant structure (Howerton et al. 1978; Garber and Brewster 1975; Cullen et al. 1976).

4.4.1 Tabulated Cross Sections

In order to calculate self-shielded cross sections, we will first consider the case in which the required cross sections $\Sigma_R(E)$ and $\Sigma_T(E)$ are each given in a tabulated form with an interpolation law between tabulated values. In this case, the methods used in the preceding section on Doppler broadening may be used to prepare tabulated cross sections at one or more temperatures; and in this section, we need not explicitly consider Doppler broadening, that is, the cross sections that we discuss later may be at any temperature.

The energy-dependent weighting spectrum $M(E)$ is chosen to agree with some system of interest: a common choice is a combination of Maxwellian, $1/E$, fission, and fusion spectra at successively higher energies (Cullen 1980a–c). If a large number of groups is used, the resulting group averages become insensitive to the selection of the energy-dependent weighting spectrum, and it is acceptable to use a constant or flat-weighting spectrum within each group to create a truly application-independent library (Plechaty et al. 1978a,b; Weisbin and LaBauve 1973). Such a library can be used as an economical starting point to group collapse, using a specific weighting spectrum in order to obtain a library that is tailored to a specific application (Cullen 1979a–c).

4.4.2 Linearly Interpolable Data

In principle, it is possible to use any one of a number of analytical forms for the weighting spectrum $M(E)$ (e.g., Maxwellian, $1/E$, fission, and fusion spectra at successively higher energies)

■ **Figure 23**
Th232, 175-group unshielded cross sections

and tabulated cross sections, using any combination of linear or log interpolation in energy or cross section, to define the required group-averaged cross sections in terms of analytical integrals. However, in practice, as applied to use on a digital computer, this general approach is extremely error prone, because the resulting equations can be extremely numerically unstable and can lead to large errors in extremely subtle ways that are difficult to detect.

Therefore, in this section, an approach that is completely numerically stable, yields answers that are always within any allowable uncertainty ε of the exact answer, and requires the fewest possible integrals and stability conditions to analyze and program will be presented. The approach is quite simple: prepare the energy-dependent spectrum and all cross sections in a tabular form with linear interpolation in energy and cross section between tabulated values. In the preceding section on reconstruction of cross sections, it was pointed out that it is possible

■ **Figure 24**
Th232-, 175-group totally shielded f -factors

to economically replace all the cross sections in a library, such as ENDF/B (Cullen 2007a–c), which can use any combination of log and linear interpolation in energy and cross section, by a table of cross sections with linear interpolation in energy and cross section between tabulated values, such that the resulting linearly interpolable cross sections are everywhere within some allowed uncertainty ε of the original cross section. That is to say, if the original cross sections are $\Sigma_n(E)$ and the linearized cross sections are $\bar{\Sigma}(E)$, we have the relationship

$$(1 - \varepsilon)\Sigma_n(E) \leq \bar{\Sigma}(E) \leq (1 + \varepsilon)\Sigma_n(E), \quad (93)$$

not just at the energy points where these cross sections are tabulated alone, but at all energies itself.

Since the energy-dependent weighting spectrum is inherently positive, the preceding section on the reconstruction of cross sections applies equally well to converting the weighting

spectrum from its functional form $M(E)$ (e.g., Maxwellian, $1/E$, fission, and fusion spectra at successively higher energies) to a tabulated linearly interpolable form, such that if $M(E)$ is the original weighting spectrum and $\bar{M}(E)$ the tabulated approximation, at all energies E , then

$$(1 - \varepsilon)M(E) \leq \bar{M}(E) \leq (1 + \varepsilon)M(E). \quad (94)$$

Generally, the size of the resulting linearized spectrum tabulations, when compared with the size of the tabulations of modern evaluations, is very small; and as such, this approach is an economical and practical means of treating the weighting spectrum.

The important point to realize is that once we have all the required data in a linearly interpolable form, we will be able to express our group averages in terms of only one function (the natural logo and we can use the error bounds on our linear data to guarantee the accuracy of our resulting integrals. As long as our spectrum and cross sections are not negative (they are be zero or positive), we have bounds that the approximate integral using the linearized data

$$\bar{F} = \int_{E_g}^{E_{g+1}} \frac{\bar{\Sigma}_R(E) \bar{M}(E) dE}{[\bar{\Sigma}_T(E) + \Sigma_0]^k} \quad (95)$$

and the exact integral using the original data

$$F = \int_{E_g}^{E_{g+1}} \frac{\Sigma_R(E) M(E) dE}{[\Sigma_T(E) + \Sigma_0]^k} \quad (96)$$

are related through

$$\frac{(1 - \varepsilon_R)(1 - \varepsilon_M)}{(1 + \varepsilon_T)^k} F \leq \bar{F} \leq \frac{(1 + \varepsilon_R)(1 + \varepsilon_M)}{(1 - \varepsilon_T)^k} F, \quad (97)$$

and therefore, we can guarantee the accuracy of the resulting integrals. For example, if all data are reconstructed to within an accuracy of 0.1%, all of the resulting, scale flux ($k = 1$)-weighted integrals are guaranteed to be accurate to within 0.3% (approximately $\varepsilon_R + \varepsilon_M + \varepsilon_T$). Furthermore, since the uncertainty in the spectrum and the total cross section appear in both numerator and denominator of the definition of the group-averaged cross section, (92), when we use the ratio to define the actual group-averaged cross section, there is a strong tendency for cancellation of errors and to obtain results that are accurate to well within the accuracy to which the cross section $\Sigma_R(E)$ was linearized.

4.4.3 Solution

Once the spectrum and cross sections are represented in a linearly interpolable form, the integrals required to define the group-averaged cross sections for any group g can be expressed in terms of a sum of integrals; each integral over an energy interval that lies within the group and within which all of the tabulated data are linearly interpolable. For example, if we wish to integrate from 5 to 35 eV and the cross sections are tabulated at 5, 15, 25, and 35 eV, and the

spectrum is tabulated at 0, 10, 20, 30, and 40 eV, the required integral can be expressed in terms of the sum of integrals over the energy ranges 5–10, 10–15, 15–20, 20–25, 25–30, and 30–35; note that within each of these six energy intervals, the spectrum and cross sections are both linearly interpolable. Therefore, we can write the required integral in the form

$$\int_{E_g}^{E_{g+1}} \frac{\Sigma_R(E) M(E) dE}{[\Sigma_T(E) + \Sigma_0]^k} = \sum_j \int_{E_j}^{E_{j+1}} \frac{\Sigma_R(E) M(E) dE}{[\Sigma_T(E) + \Sigma_0]^k}, \quad (98)$$

where within each energy interval, E_j to E_{j+1} , each of the three functions, $\Sigma_R(E)$, $M(E)$, $\Sigma_T(E)$ is linearly interpolable, and as such can be written in the form

$$F(E) = \frac{(E - E_j)}{(E_{j+1} - E_j)} F_{j+1} + \frac{(E_{j+1} - E)}{(E_{j+1} - E_j)} F_j, \quad (99)$$

where F_j and F_{j+1} are the tabulated values of $F(E)$ at the energies E_j and E_{j+1} , respectively.

This form can be inserted for $\Sigma_R(E)$, $M(E)$, $\Sigma_T(E)$ and the resulting equation evaluated in terms of energy. However, even this seemingly simple equation involving linear interpolable functions can lead to numerical instability, particularly for cross sections in the resonance region, unless extreme care is used to evaluate this equation.

It is better to transform the integral over the energy range E_j to E_{j+1} into an integral in the “normal form” over the interval -1 to $+1$, by changing variables to

$$Z = 2 \left[\frac{E - (E_j + E_{j+1})/2}{(E_{j+1} - E_j)} \right]$$

and

$$dZ = \frac{2dE}{(E_{j+1} - E_j)}. \quad (100)$$

In terms of this new variable, each of the three functions can be written in the form

$$\begin{aligned} F(Z) &= \left(\frac{1}{2}\right) (1 + Z) F_{j+1} + \left(\frac{1}{2}\right) (1 - Z) F_j \\ &= \left(\frac{1}{2}\right) (F_{j+1} + F_j) + \left(\frac{1}{2}\right) (F_{j+1} - F_j) Z. \end{aligned} \quad (101)$$

If we define the average value over the interval E_j to E_{j+1} , then

$$\langle F \rangle_j = \left(\frac{1}{2}\right) (F_{j+1} + F_j). \quad (102)$$

And the relative change in the function

$$\Delta_j = \frac{(F_{j+1} - F_j)}{(F_{j+1} + F_j)}. \quad (103)$$

Each function can be written in the form

$$F(Z) = \langle F \rangle_j [1 + \Delta_j Z]. \quad (104)$$

And the integral becomes

$$\sum_j \frac{(E_{j+1} - E_j)}{2} \frac{\langle \Sigma_R \rangle_j \langle M \rangle}{\langle \Sigma_T^* \rangle_j^k} \int_{-1}^{+1} \frac{[1 + \Delta_R Z][1 + \Delta_M Z]}{[1 + \Delta_T^* Z]^k}, \quad (105)$$

where Σ_T^* is merely the total cross section of the mixture, that is, $\Sigma_T(E) + \Sigma_0$; and Δ_T^* is the corresponding relative change in the total mixture.

In this normal form, the integral has the following important properties:

1. Energy has been completely removed from the integral; it only spears as $(E_{j+1} - E_j)$ outside the integral. Therefore, points of discontinuity (i.e., points where $E_j = E_{j+1}$, but $F_j \neq F_{j+1}$) do not lead to numerical instability because of the infinite derivatives in the cross section. In particular, energy intervals of zero length, $E_j = E_{j+1}$, will automatically make zero contribution to the integral.
2. The only variable terms that appear in the integral are tabulated values of Σ_R , M , Σ_M . Therefore, as long as the tabulated values are finite and the total cross section is positive, the value obtained for the integral will be numerically stable and well defined.
3. If any function is constant over an interval (i.e., $F_j = F_{j+1}$), its contribution to the integral automatically reduces to its average value, (102), without any further differences or cross cancellation in the definition of the integral; this further improves numerical stability.
4. For any positive function F , the average value $(F_{j+1} + F_j)/2$ will always be greater than the change $(F_{j+1} - F_j)/2$. Therefore, the effect of the constant term in the definition of each function in the normal form, (104), will be dominant, further improving the numerical stability.

The required integrals can be written as

$$\sum_j \frac{(E_{j+1} - E_j)}{2} \frac{\langle \Sigma_R \rangle_j \langle M \rangle}{\langle \Sigma_T^* \rangle_j^k} [F_k^0(\Delta_T) + (\Delta_R + \Delta_M) F_k^1(\Delta_T) + \Delta_R \Delta_M F_k^2(\Delta_T)], \quad (106)$$

where

$$F_k^L(\Delta_T) = \int_{-1}^{+1} \frac{Z^L dZ}{[1 + \Delta_T Z]^k}. \quad (107)$$

This family of functions, $F_k^L(\Delta_T)$, can be shown to satisfy recursion relations that allow functions of higher values of L and k to be expressed in terms of functions with lower values of L and k . These functions are particularly easy to accurately compute since for fixed L and k they are only a function of a single variable Δ_T and they can be expressed in terms of functions that are no more complicated than a natural log. \blacktriangleright [Table 7](#) presents expressions for a number of functions $F_k^L(\Delta_T) : L = 0, 1, 2, k = 0, 1, 2, 3$.

Even to evaluate these relatively simple functions $F_k^L(\Delta_T)$ requires care if we are to obtain numerically stable results. By inspection of (105) and (107) when $\Delta_T = 0$, we obtain a particularly simple result which is independent of k . Since $\Delta_T = 0$ corresponds to a constant total cross section over the energy interval E_j to E_{j+1} , this is what we would expect, namely, the integral reduces to the averaging of the product of the cross section Σ_R and the spectrum M to obtain,

$$\frac{\langle \Sigma_R \rangle_j \langle M \rangle}{\langle \Sigma_T^* \rangle_j^k} \left[1 + \frac{1}{3} \Delta_R \Delta_M \right]. \quad (108)$$

In order to obtain this result and have a numerically stable algorithm, care must be exercised as Δ_T approaches zero. For example, from \blacklozenge Table 7 we can see that

$$F_1^0(\Delta) = \frac{1}{\Delta} \text{Log} \left[\frac{1+\Delta}{1-\Delta} \right]. \quad (109)$$

\blacksquare Table 7

Function form for $F_k^L(\Delta_T)$

2	2	$\frac{2}{\delta^2} \left[\frac{2-\delta^2}{1-\delta^2} - \frac{1}{\delta} \ln \left(\frac{1+\delta}{1-\delta} \right) \right]$	$\frac{2}{1-\delta^2} \left(\frac{1}{3} + \frac{4}{15} \delta^2 + \frac{4}{35} \delta^4 + \frac{4}{63} \delta^6 \right)$
2	3	$\frac{1}{\delta^2} \left[\frac{1}{\delta} \ln \left(\frac{1+\delta}{1-\delta} \right) - \frac{2-4\delta^2}{(1-\delta^2)^2} \right]$	$\frac{2}{(1-\delta^2)^2} \left(\frac{1}{3} + \frac{8}{35} \delta^2 + \frac{8}{105} \delta^4 + \frac{8}{315} \delta^6 \right)$

However, as Δ approaches zero, this assumes the indeterminate form of zero divided by zero. This is nonsense since the zero- Δ limit of $F_1^0(\Delta)$, (107), merely corresponds to uniformly integrating from -1 to $+1$, to obtain a result of 2. This indeterminate form can be avoided by expanding the natural log in the definition of this family of functions, (see [Table 7](#)) and examining the small- Δ limit. For example, in the case of $F_1^0(\Delta)$, following this procedure, we find the completely stable for small Δ as

$$F_1^0(\Delta) = 2 \left[1 + \frac{1}{3}\Delta^2 + \frac{1}{5}\Delta^4 + \frac{1}{7}\Delta^6 + \frac{1}{9}\Delta^8 \right] + \dots \quad (110)$$

For all those functions that involve natural logarithms, [Table 7](#) also presents numerically stable forms for small Δ . In each of these expressions, the first term is of order unity and the expansion is truncated at order Δ^8 . Therefore for $|\Delta| \leq 10^{-2}$, these expressions will be accurate to approximately 16 digits; and for larger values of Δ , the analytical expressions in terms of natural logarithms can be used without encountering any numerical instability. The combination of the analytical expressions plus the expansion for small Δ can therefore be used in a combination to define all of the required functions in a completely stable manner to the maximum accuracy available on today's computers. Since the required function $F_k^L(\Delta_T)$ is a function of a continuous variable Δ , no other limiting cases need to be considered. In [Table 7e](#), for convenience, the notation, $\Delta = \delta$, has been used.

The definition of the group-averaged cross section, (25), actually involves the ratio of two integrals, and so far, we have only discussed how to evaluate the numerator. However, evaluation of the denominator is completely analogous to the evaluation of the numerator by simply setting $\Sigma_R(E)$ as equal to unity.

One last word of caution concerning evaluation of the self-shielded total cross section. If we use the notation,

$$\left\langle \frac{\Sigma_T}{(\Sigma_T + \Sigma_0)^k} \right\rangle = \int_{E_g}^{E_{g+1}} \frac{\Sigma_R(E) M(E) dE}{[\Sigma_T(E) + \Sigma_0]^k} \quad (111)$$

It is tempting to rewrite this equation in the form,

$$\begin{aligned} \left\langle \frac{\Sigma_T}{(\Sigma_T + \Sigma_0)^k} \right\rangle &= \left\langle \frac{(\Sigma_T + \Sigma_0)}{(\Sigma_T + \Sigma_0)^k} \right\rangle - \left\langle \frac{\Sigma_0}{(\Sigma_T + \Sigma_0)^k} \right\rangle \\ &= \left\langle \frac{1}{(\Sigma_T + \Sigma_0)^{k-1}} \right\rangle - \Sigma_0 \left\langle \frac{1}{(\Sigma_T + \Sigma_0)^k} \right\rangle. \end{aligned} \quad (112)$$

Since these two integrals correspond to the denominators required to define the averages of other reactions $\Sigma_R(E)$, this would appear to be an efficient approach to follow; if the average of any other reaction is evaluated, the average of the total can be evaluated without computing any additional integrals. Here, for large values of Σ_0 , this is an unstable approach to calculating the average total cross section, as it will be defined by a small difference between two large numbers.

The above mentioned algorithms that have been described for the Bondarenko (Bondarenko et al. 1964) or NR approximation are easily extended to handle the IR approximation,

simply by using a differently tabulated, linearly interpolable cross section in the denominator of the self-shielding factor. Those algorithms have been implemented for use with ENDF/B-formatted cross sections (MacFarlane et al. 1982; MacFarlane and Muir 1994; Weisbin et al. 1976; Cullen 1980a–c).

The amount of detail required to insure the numerical stability of even this simple approach to calculating average cross sections, using only linearly interpolable data, may seem extensive, but it is minor when compared with what would have to be done in order to obtain numerical stability if one attempts to use analytical spectra and cross sections that may be log or linearly interpolable in either cross section or energy. The number of special limiting cases that must be considered using the latter approach is enormous and many of these limiting cases occur in extremely subtle situations that are difficult to detect and analyze. Therefore, the latter approach is not recommended. Indeed, in closing this section, it is fair to say that the simplicity and stability of the methods we use to define self-shielded multigroup cross sections by first LINEARIZING EVERYTHING, is an excellent example of why in this chapter so much emphasis is placed on linearizing nuclear data; the payback comes when we use the simplified data in our applications.

4.4.4 Direct Integration

So far we have discussed calculating group-averaged cross sections starting from tabulated energy-dependent cross sections. There are a number of other approaches that either start from resonance parameters in the resolved-resonance region or distributions of resonance parameters in the unresolved-resonance region, and calculate group averages directly without an intermediate step of creating energy-dependent, tabulated cross section data files.

One class of computer programs will start from resonance parameters and use the psi-chi method (Greene et al. 1976) to define broadened cross sections in the resolved-resonance region. Beyond this point, there are two approaches to defining averages. In one approach, the psi-chi representation of the cross section is used to calculate cross sections at specific energy points, and an iterative procedure is used to subdivide the energy intervals and calculate average values until convergence is achieved in the integrals (Rieffe et al. 1981). Although physically this approach differs from that described earlier, logically it reduces to the same algorithms, the major difference being the use of psi-chi rather than the more accurate SIGMA1 of broadening. At the end, the averages are calculated by integrating between energy points at which the cross sections are calculated; the cross sections are simply not tabulated in advance. In a comparison of cold (0 K), unshielded fine-group constants calculated directly from resonance parameters (Rieffe et al. 1981), to those calculated from tabulated cross sections (Cullen 1980a–c), the results were found to be in good agreement (Cullen et al. 1985, 1988); we would expect this result since the psi-chi method is fairly accurate to define cross sections near the peaks of resonances. But large differences are found when self-shielded cross sections were compared.

In a second approach, the psi-chi representation in the resolved-resonance region is used to calculate integrals directly, without recourse to first-defining energy-dependent cross sections. If we examine our definition of average cross section, (92), and consider the cold (0 K) cross section for some reaction R , $\Sigma_R(E)$, and the total cross section, $\Sigma_T(E)$, each to be composed of

a series of single-level resonances, then the Doppler-broadened cross section will be composed of a series of psi and chi functions as

$$\Sigma_R(E) = \sum_j A_{Rj}(E) \Psi(\xi_j, X_j)$$

and

$$\Sigma_T(E) = \Sigma_p(E) + \sum_j \{A_{Tj}(E) \Psi(\xi_j, X_j) + B_{Tj}(E) \chi(\xi_j, X_j)\}, \quad (113)$$

where $\Sigma_p(E)$ is the potential-scattering cross section, and the summation is over all resonances. For simplicity, in the following, the chi function will not be written explicitly; this is merely for simplicity, but it is consistent with the treatment used by many codes, which ignores the effect of elastic interference on the total cross section when describing the self-shielding factor.

Using this representation for the cross section, the group-averaged cross section can be defined as

$$\frac{\sum_j A_{Rj}(E) \int_{E_g}^{E_{g+1}} \frac{\Psi(\xi_j, X_j) dE}{\left[\sum_{j'} A_{Tj'}(E) \Psi(\xi_{j'}, X_{j'}) + \Sigma_p + \Sigma_0 \right]^k}}{\int_{E_g}^{E_{g+1}} \frac{dE}{\left[\sum_{j'} A_{Tj'}(E) \Psi(\xi_{j'}, X_{j'}) + \Sigma_p + \Sigma_0 \right]^k}}. \quad (114)$$

Usually, this expression is only calculated for $k = 1$ (scalar flux weighting) and only this case will be described below. The main difficulty that is encountered when one tries to define these integrals is due to the summation of resonances in the denominator, used to define the total cross section. If the resonances are well separated, then in the neighborhood of any single resonance, the total cross section may be considered to be given by the contribution from that one resonance, plus a smooth contribution from distant resonances,

$$\sum_{j'} A_{Tj'}(E) \Psi(\xi_{j'}, X_{j'}) + \Sigma_p + \Sigma_0 \approx A_{Tm}(E) \Psi(\xi_m, X_m) + \Sigma_p^* + \Sigma_0, \quad (115)$$

where E is close to the peak of the m th resonance, and Σ_p^* is the contribution of the potential-scattering cross section plus a smooth contribution from distant resonances.

In this approximation, the average cross section can be written in the form of the contribution from each resonance as,

$$\sum_j A_{Rj}(E) \frac{\int_{E_g}^{E_{g+1}} \frac{\Psi(\xi_j, X_j) dE}{\Psi(\xi_j, X_j) + \beta_j}}{\int_{E_g}^{E_{g+1}} \frac{dE}{\Psi(\xi_j, X_j) + \beta_j}}, \quad (116)$$

where

$$\beta_j = \frac{\Sigma_p^* + \Sigma_0}{A_{Tj}}. \quad (117)$$

If the resonance is narrow when compared with the width of the group, it may be considered to lie totally within the group. When we change variables from E to X ,

$$X = 2(E - E_j) / \Gamma_{Tj}, \quad (118)$$

where E_j and Γ_{Tj} are the energy and total width of the j th resonance, the resulting integrals will extend for $(-\infty, +\infty)$. However, since the psi function is a symmetric function of X and appears in both numerator and denominator, we can define the functions as

$$J(\beta, \xi) = \int_0^{\infty} \frac{\Psi(\xi, X) dX}{\Psi(\xi, X) + \beta}$$

and

$$K(\beta, \xi) = \int_0^{\infty} \frac{dX}{\Psi(\xi, X) + \beta}. \quad (119)$$

And our group-averaged cross section can be written in the form

$$\sum_j A_{Rj}(E) \frac{J(\beta_j, \xi_j)}{K(\beta_j, \xi_j)}. \quad (120)$$

We have arrived at a definition of the group-averaged cross section, but there are a number of approximations that have been introduced to reach this point. Let us briefly review these approximations and examine how appropriate they are

1. The psi-chi method is used to describe the Doppler-broadened cross sections. The range of applicability of this method has been discussed in the section under Doppler broadening and will not be discussed further here.
2. We ignore the elastic interference in describing the self-shielding function. This is usually valid since the resonances are either widely spaced and the interference minima occur in an energy range where resonance-reaction cross sections are low and will not make an appreciable contribution to the group integral, or the resonances overlap in energy and the interference minima will not have a noted effect on the total cross section.
3. We assume that the resonances are isolated (widely spaced) and the local cross section can be approximated as the contribution from a single local resonance plus a smooth contribution from other resonances. At first glance, this might appear to be an extremely restrictive assumption. However, in practice, it works surprisingly well if implemented properly. Even when resonances are partially or extremely overlapped allowing for different sequences of resonances, some narrow and some wide, the local flux will be dominated by each resonance in turn; and this approximation works quite well if the contribution of all resonances other

than the local resonance are properly included. If we define the average contribution to the total cross section of all resonances except the local resonance, then

$$\langle \Sigma \rangle_j = \sum_{j' \neq j} A_{Tj'}(E) \frac{J(\beta_j, \xi_j)}{K(\beta_j, \xi_j)}. \quad (121)$$

This can be added to the potential cross section Σ_p in order to define the contribution of all other resonances to define Σ_p^* , for use in the definition of the group average. This is an iterative procedure as when we begin to solve these equations we would not know what the contribution of all other resonances would be and we would have to use some initial guess for each $\langle \Sigma \rangle_j$, solve our equations to obtain an improved approximation for $\langle \Sigma \rangle_j$, and then repeat the calculations until we obtain convergence. With this approach, the method works quite well to describe the relative self-shielding in the vicinity of each resonance.

4. We assume that resonances are locally totally within the group, i.e., many half-widths from either group boundary. This would appear to be a very restrictive assumption. However, it should be remembered that in developing this model of self-shielding we are using the NR approximation.

For the important wide resonances, such as that occur at low energies in U235 and Pu239, this approximation is quite poor. However, these resonances are not NRs, and this self-shielding model is inappropriate. The self-shielding of such resonances can best be treated by solving the actual slowing-down (58) in the neighborhood of these resonances, to determine a good approximation to the flux, and to then use this flux as a weighting function to calculate the self-shielded group-averaged cross sections.

The last case to consider is calculation of self-shielded, group-averaged cross sections in the unresolved-resonance region. In the unresolved-resonance-region evaluated data (Kinsey 1970; Rose and Dunford 1990), a unique sequence of resonances need not be defined, as only the average level widths and spacings are only given. Associated with this data are models that represent the level widths as distributed according to a chi-squared distribution with a given number of degrees of freedom (Konshin 1981), and the level spacings as distributed according to a Wigner distribution (Konshin 1981).

In this case, if we again use the psi-chi method to represent the Doppler-broadened cross section and ignore the elastic interference, we arrive at an equation similar to (114). However, instead of a summation over a sequence of discrete resonances, as in (114), our summation will be replaced by a weighted (according to their distribution) integral over the distribution of resonance widths and spacings. In order to evaluate these expressions, the integrals will be replaced by quadratures to obtain a weighted sum over contributions from resonances of different widths and spacings. Once this approximation has been introduced, we obtain an expression that is completely analogous to (114), for the series of resonances in the resolved-resonance region; the only difference is that here our sum is not over true resonances, but merely a contribution from each portion of our distribution of widths and spacings.

If we now introduce the assumptions that we introduced earlier in order to solve (114) in the resolved-resonance region, we obtain a completely analogous solution to that obtained in the resolved-resonance region (120). However, in introducing these assumptions it is found that the summations are simplified because when we introduce the “local”-resonance assumption, we find that the quadrature over resonance spacing merely reduces to multiplying the contribution of each resonance sequence (Mughabghab et al. 1981; Gyulassy et al. 1972), by the

reciprocal of the level spacing for that sequence. Physically, this makes sense as it merely states that for isolated resonances if the spacing between resonances decreases by a factor of two, in any given energy interval, we will then have twice as many resonances, each will be shielded independently (as isolated), and the group-averaged cross section over this energy interval will be as twice as large. As actually applied with all the assumptions introduced to obtain and solve (120), the level spacing will affect the calculation of the nonlocal resonances, $\langle \Sigma \rangle_j$, (121), and the iterative procedure used to determine the final, group-averaged, self-shielded cross section in the unresolved-resonance region.

The above discussion presents an overview of procedures used to define self-shielded cross sections. Considerations concerning resonance overlap (overlap for resonances for the same isotope, sequence of resonances: same isotope, sequence–sequence; isotope–isotope), and ranges of applicability for specific applications will be presented elsewhere in this handbook.

4.5 Comparison of Results

There are many more sophisticated methods of calculating self-shielded cross sections for specific applications of transport models (Vertes 1981; Green and Pitterle 1968; Toppel 1971); however, at this point, we will digress in order to examine how accurate our methods are. In order to do this, we will compare the cross sections calculated by the various methods presented in this section. Presumably, consistent with our model of self-shielding, we should obtain the most accurate results by calculating self-shielded cross sections directly from tabulated results data, as this approach uses the fewest approximations. We will consider two cases, the resolved and the unresolved-resonance regions. Ganesan reported (Ganesan 1982), that starting from ENDF/B data, by comparing the results obtained by preparing linearly interpolable data and group averaging it (Cullen 1980a–c), to his results obtained by direct integration in the resolved-resonance region (Ganesan et al. 1981), he obtained differences of up to a factor of two, that is, 100% differences.

In order to define unresolved parameters, the usual methods used (Mughabghab et al. 1981; Gyulassy et al. 1972), involve extrapolation of the observed, average-resonance widths and spacing from the resolved energy range into the unresolved energy range. When this is done, we would expect the group-averaged cross sections calculated from resolved-resonance parameters near the upper-energy limit of the resolved-resonance region to be similar to the group-averaged cross sections calculated from unresolved-resonance parameters near the lower-energy limit of the unresolved-resonance region. Perez (Perez et al. 1981) used resolved-resonance parameters to calculate tabulated cross sections and then group averaged this data to define averages in the resolved-resonance region. Next he used unresolved-resonance parameters to calculate group averages in the unresolved-resonance region. For two groups, one on either side of the resolved–unresolved-resonance-region boundary, he found differences in excess of 30%.

These results indicate that there is an inconsistency in the models that are used to calculate self-shielded cross sections; as yet, the source of this inconsistency is not yet fully understood. Until it is understood, we must assume that the errors introduced by these self-shielding models are of the order of those quoted above, based on the results of Ganesan and Perez.

Naturally, the differences reported by Ganesan and Perez may not lead to differences of the same magnitude in specific macroscopic calculated quantities (e.g., K-eff), when these cross

sections are used in transport calculations of any specific application. This is particularly true of quantities, such as K -eff, that are more sensitive to ratios than to absolute cross sections. However, it should be realized that quantities, such as reaction rates, can be directly affected by uncertainties in cross sections.

5 Transfer Matrix

5.1 Introduction

Consider the definition of the group-to-group transfer

$$\int_{E'_g}^{E'_{g+1}} dE' \int_{\Omega'} d\Omega' \Phi(\Omega', E') \int_{E_g}^{E_{g+1}} dE \Sigma(\Omega' \rightarrow \Omega, E' \rightarrow E). \quad (122)$$

One of the difficulties associated with this definition is that we must define the probability of scattering from an initial direction Ω' and energy E' to the final direction Ω and energy E . However, the evaluated data are presented not in terms of fixed spatial directions, but rather in terms of the scattering angle, or, cosine. This is because we assume that a medium is homogeneous and isotropic, so that the scattering can only be a function of the angle between the initial and final directions, Ω' and Ω . The cosine of this scattering angle, μ_s , in terms of the initial and final directions can be written in the form (Meghreblian and Holmes 1960)

$$\mu_s = \Omega' \cdot \Omega = \mu' \mu + \sqrt{1 - \mu'^2} \sqrt{1 - \mu^2} \cos(\psi' - \psi), \quad (123)$$

and in general,

$$\Sigma(\Omega' \rightarrow \Omega, E' \rightarrow E) = \Sigma(\mu_s, E' \rightarrow E). \quad (124)$$

In order to convert this into a function of initial and final directions, we will expand the distribution in a series of Legendre polynomials

$$\Sigma(\mu_s, E' \rightarrow E) = \sum_{n=0}^{\infty} \frac{2n+1}{2} \Sigma_n(E' \rightarrow E) P_n(\mu_s), \quad (125)$$

where

$$\Sigma_n(E' \rightarrow E) = \int_{-1}^{+1} d\mu_s P_n(\mu) \Sigma(\mu_s, E' \rightarrow E), \quad (126)$$

and use the relationship,

$$P_n(\mu_s) = \sum_{m=-n}^n Y_n^m(\Omega') Y_n^m(\Omega). \quad (127)$$

Substituting this expression into (122), we obtain

$$\sum_{n=0}^{\infty} \frac{2n+1}{2} \sum_{m=-n}^n Y_n^m(\Omega) \int_{E'_g}^{E'_{g+1}} dE' \int_{\Omega'} d\Omega' Y_n^m(\Omega') \Phi(\Omega', E') \int_{E_g}^{E_{g+1}} dE \Sigma_s(E' \rightarrow E). \quad (128)$$

Upon defining the spherical harmonic moment of the flux, as

$$\Phi_n^m(E') = \int_{\Omega'} Y_n^m(\Omega') \Phi(\Omega', E') d\Omega', \quad (129)$$

we obtain the expression

$$\sum_{n=0}^{\infty} \frac{2n+1}{2} \sum_{m=-n}^n Y_n^m(\Omega) \int_{E'_g}^{E'_{g+1}} dE' \Phi_n^m(E') \int_{E_g}^{E_{g+1}} dE \Sigma_s(E' \rightarrow E) \quad (130)$$

which expresses the transfer to the final direction Ω , in terms of the spherical harmonics moments of the flux.

In the azimuthally symmetric system, (130) can be simplified by integrating over the azimuthal angle; in this case, all the terms will be zero except those with $m = 0$, and we find

$$\sum_{n=0}^{\infty} \frac{2n+1}{2} P_n(\mu) \int_{E'_g}^{E'_{g+1}} dE' \Phi_n(E') \int_{E_g}^{E_{g+1}} dE \Sigma_s(E' \rightarrow E), \quad (131)$$

where

$$\Phi_n(E') = \int_{-1}^{+1} P_n(\mu) \Phi(\mu, E') d\mu \quad (132)$$

is a Legendre moment of the flux. From either of these equations, we can define the Legendre moment of the transfer

$$\sum_{n=0}^{\infty} \frac{2n+1}{2} \sum_{m=-n}^n Y_n^m(\Omega') \Phi_{ng'}^m \Sigma_{g' \rightarrow g}^n, \quad (133)$$

where

$$\Phi_{ng'}^m \Sigma_{g' \rightarrow g}^n = \int_{E'_g}^{E'_{g+1}} dE' \Phi_n^m(E') \int_{E_g}^{E_{g+1}} dE \Sigma_n(E \rightarrow E'). \quad (134)$$

In the absence of additional information, it will be assumed that the energy dependence will be the same for all spherical harmonic moments of the flux with the same n , but any m . With this assumption, we can generate geometry-independent moments of the transfer matrix. In any given application, these moments can be used to reconstruct the transfer in one dimension

(Engle 1967), as in (131); or in two or three dimensions (Mynatt et al. 1973; Lathrop and Brinkley 1970; Ray et al. 2005), as in (130). In the S_n method, a quadrature is used to reconstruct the required Legendre or spherical harmonic moments of the flux.

In order to understand the implications of (130), we will consider two cases: uncorrelated and correlated. For uncorrelated distributions, the distribution will be expressed as the product of an angular distribution in the laboratory system and an energy distribution, as

$$\Sigma(\mu_s, E' \rightarrow E) = \Sigma(E', \mu_s) g(E' \rightarrow E), \quad (135)$$

and generally, the angular distribution is either isotropic or can be expressed by a low-order Legendre expansion, as

$$\Sigma(E', \mu_s) = \sum_{l=0}^L \frac{2l+1}{2} \Sigma_l(E') P_l(\mu_s). \quad (136)$$

In this case, from (136), we find

$$\begin{aligned} \Sigma_n(E' \rightarrow E) &= \Sigma_n(E') g(E' \rightarrow E) : n \leq L \\ &= 0 : n > L \end{aligned} \quad (137)$$

and the infinite series implied by (130) and (131) is truncated at the same order as the order of the Legendre expansion of the uncorrelated angle distribution.

For the correlated distribution, the distribution will be expressed as the product of an angular distribution, in the laboratory or center of mass, and a Dirac delta function that expresses the exact correlation between scattering angle and initial and final energies, as

$$\Sigma(\mu_s, E' \rightarrow E) = \Sigma(E', \mu_s) \delta[\mu_s - \mu(E, E')]. \quad (138)$$

In this case, from (126) we find,

$$\Sigma(\mu_s, E' \rightarrow E) = \Sigma[E', \mu(E, E')] P_n[\mu(E, E')]. \quad (139)$$

Therefore, the infinite series in (130) and (131) is not truncated, since all the Legendre coefficients will be nonzero. That is to say, even a correlated distribution that is isotropic in the laboratory system will lead to an infinite number of terms in the transfer matrix. This is an important effect that is sometimes overlooked; even at low energies in heavy materials where the scattering is essentially isotropic, the transfer matrix will contain nonisotropic terms due to the correlation between scattering cosine and initial and final energies. The importance, or magnitude, of these terms depends on the material involved and the group structure used. For groups that are wide (few groups) when compared with the maximum energy loss in elastic scattering, these non-isotropic terms tend to be very small. However, for very narrow groups (many groups), which tend to accentuate the transfer between specific initial and final directions, these terms can be large and important.

5.2 Solution

The n th moment of the flux may be written as in (134)

$$\int_{E'_g}^{E'_{g+1}} dE' \Phi_n(E') \int_{E_g}^{E_{g+1}} dE \Sigma_n(E \rightarrow E), \quad (140)$$

or by using (126) to define the n th Legendre moment of the distribution

$$\int_{E'_g}^{E'_{g+1}} dE' \Phi_n(E') \int_{E_g}^{E_{g+1}} dE \int_{-1}^{+1} d\mu_s P_n(\mu) \Sigma(\mu_s, E' \rightarrow E). \quad (141)$$

The latter form is how it is normally expressed as the starting point in order to evaluate these terms.

Since cross section is a probability and therefore inherently positive, all the integrals that we have considered in the preceding sections have been expressed as the sum of positive terms, and, if properly written and evaluated, led to numerically stable algorithms. Physically, all the terms in the above equation should be positive, except for the Legendre polynomials, $P_n(\mu_s)$. The presence of this polynomial makes the accurate evaluation of this equation very difficult, as we expect cross cancellation between negative and positive contributions to the integral. Therefore, extreme care must be exercised in order to express this integral in a form that is numerically stable.

Before proceeding to solve this equation, we will first express the secondary-energy-angle distribution in the form that it is represented in evaluated libraries (Kinsey 1970; Rose and Dunford 1990), where each reaction is represented in the form

$$\Sigma(\mu_s, E' \rightarrow E) = m(E') \Sigma_s(E') p(E', \mu_s) g(\mu_s, E' \rightarrow E), \quad (142)$$

where

$m(E')$ Multiplicity for the reaction, e.g., 1 for elastic, inelastic; 2 for $(n, 2n)$; $\nu(E')$ for fission.

In evaluated libraries, this is either given explicitly as in the case of $\nu(E')$, or implied by the reaction (elastic).

$\Sigma(E')$ Cross section for the reaction.

$p(E', \mu_s)$ Angular distribution, which is a function of the incident energy. For correlated distributions, it is usually given in the center-of-mass system. Uncorrelated distributions are given in the laboratory system. Either may be given in terms of Legendre coefficients or tabulated values.

$g(\mu_s, E' \rightarrow E)$ Energy distribution: For correlated distributions, this is an implied Dirac delta function, which expresses the exact correlation between scattering cosine and initial and final energies. For uncorrelated distributions, it is the actual secondary-energy distribution, independent of μ_s .

Uncorrelated and correlated distributions will each be discussed as follows.

5.2.1 Uncorrelated Distributions

Let us consider the uncorrelated case first. In this case the secondary distribution is expressed as the product of two independent distributions, one in angle and another in energy, and each is normalized to unity when integrated over secondary-angle or -energy, respectively,

$$p(\mu_s, E' \rightarrow E) = p(E', \mu_s) g(E' \rightarrow E). \quad (143)$$

5.2.2 Angular Distributions

The angular distribution will be given in the laboratory system in terms of Legendre coefficients or tabulated values. In either case, we may immediately perform the integral over angle in (141), as

$$\int_{-1}^{+1} d\mu_s P_n(\mu_s) p(E', \mu_s). \quad (144)$$

For the angular distribution given in terms of Legendre coefficients,

$$p(E', \mu_s) = \sum_{l=0}^{\infty} \frac{2l+1}{2} p_l(E') P_l(\mu_s). \quad (145)$$

The integral in (144) immediately reduces to the n th laboratory Legendre coefficient of the angular distribution as

$$p_n(E') = \int_{-1}^{+1} d\mu_s P_n(\mu_s) p(E', \mu_s). \quad (146)$$

For the angular distribution given in tabular form, we can reduce it to be linearly interpolable by LEGEND (Cullen 2007a-c), as

$$p(E', \mu_s) = \frac{(\mu - \mu_k) p_{k+1}(E') + (\mu_{k+1} - \mu) p_k(E')}{\mu_{k+1} - \mu_k} : \mu \in (\mu_k, \mu_{k+1}), \quad (147)$$

where $p_k(E')$ and $p_{k+1}(E')$ are the values of the angular distribution tabulated at μ_k and μ_{k+1} , respectively. In this case, the integral becomes

$$\sum_k \int_{\mu_k}^{\mu_{k+1}} d\mu_s P_n(\mu_s) \left\{ \frac{(\mu - \mu_k) p_{k+1}(E') + (\mu_{k+1} - \mu) p_k(E')}{\mu_{k+1} - \mu_k} \right\}. \quad (148)$$

Once this expression is evaluated, we will obtain the equivalent of the n th laboratory Legendre coefficient $p_n(E')$ of the tabulated distribution. Since the Legendre polynomial $P_n(\mu_s)$ is merely an n th-order polynomial, we could write this expression as a sum of powers of μ_s and then integrate. However, the resulting expression can be numerically unstable. In order to

obtain a numerically stable expression, we will introduce a change of variable to convert the above expression into an integral in a formal form over the interval $(-1, +1)$, as

$$\begin{aligned}
 Z &= \frac{2\mu - (\mu_{k+1} + \mu_k)}{\mu_{k+1} - \mu_k}, \\
 \mu &= \langle \mu \rangle_k [1 + \Delta_k Z], \\
 \langle \mu \rangle_k &= \frac{1}{2} (\mu_{k+1} + \mu_k), \\
 \Delta_k &= \frac{1}{2} \left(\frac{\mu_{k+1} - \mu_k}{\mu_{k+1} + \mu_k} \right), \\
 d\mu &= \langle \mu \rangle_k \Delta_k dZ = \frac{1}{2} (\mu_{k+1} - \mu_k) dZ;
 \end{aligned} \tag{149}$$

the tabulated angular distribution takes the form

$$\begin{aligned}
 f(Z) &= \langle f \rangle_k [1 + \delta_k Z], \\
 \langle f \rangle_k &= \frac{1}{2} (f_{k+1} + f_k), \\
 \delta_k &= \frac{1}{2} \left(\frac{f_{k+1} - f_k}{f_{k+1} + f_k} \right);
 \end{aligned} \tag{150}$$

and the integral becomes

$$\frac{1}{2} \sum_k (\mu_{k+1} - \mu_k) \langle f \rangle_k \int_{k-1}^{+1} dZ P_n [\langle \mu \rangle_k (1 + \Delta_k Z)] [1 + \delta_k Z]. \tag{151}$$

In most transport calculations, this expression is normally only evaluated for a small number of n values, typically three for P_3 scattering. Therefore, the evaluation of this expression will be presented here for the first four terms (P_0 through P_3) for illustrative purposes; this procedure can easily be extended to any required order of n . From the definition of the Legendre polynomials, we get

$$\begin{aligned}
 P_0 &= 1, \\
 P_1 &= \langle \mu \rangle_k [1 + \Delta_k Z], \\
 P_2 &= \frac{3}{2} \langle \mu \rangle_k^2 [1 + \Delta_k Z]^2 - \frac{1}{2}, \\
 P_3 &= \frac{5}{2} \langle \mu \rangle_k^3 [1 + \Delta_k Z]^3 - \frac{3}{2} \langle \mu \rangle_k [1 + \Delta_k Z].
 \end{aligned} \tag{152}$$

We obtain an expression for the integral in terms of a sum of powers of Z , but since the integral is over the normal interval $(-1, +1)$ we will only obtain nonzero contributions from the even

powers of Z . Using our expression for the Legendre polynomials, we can easily evaluate

$$\begin{aligned} & \frac{1}{2} \int_{-1}^{+1} dZ P_n[< \mu >_k (1 + \Delta_k Z)] [1 + \delta_k Z], & (153) \\ n = 0 : 1, \\ n = 1 : & < \mu >_k \left[1 + \frac{1}{3} \Delta_k \delta_k \right], \\ n = 2 : & \frac{3}{2} < \mu >_k^2 \left[1 + \frac{1}{3} (\Delta_k^2 + 2\Delta_k \delta_k) - \frac{1}{2} \right], \\ n = 3 : & \frac{5}{2} < \mu >_k^3 \left[1 + (\Delta_k^2 + \Delta_k \delta_k) + \frac{1}{5} \Delta_k^3 \delta_k \right] - \frac{3}{2} < \mu >_k \left[1 + \frac{1}{3} \Delta_k \delta_k \right]. & (154) \end{aligned}$$

Expressed in this form, we can see that for any angular distribution that is tabulated on a very fine cosine grid (i.e., very small Δ_k), the integral reduces to a sum of terms, each of which is just the width of the cosine interval times, the average value of the tabulated angular distribution times, the Legendre polynomial evaluated at the middle of the cosine interval,

$$\sum_k (\mu_{k+1} - \mu_k) < f >_k P_n[< \mu >_k]. \quad (155)$$

This form is much more numerically stable than the integrating (148) in terms of powers of the cosine, but it is still not an optimum algorithm as generally there will still be a cross section of positive and negative terms, since the Legendre polynomial will be positive and negative over different cosines ranges.

Stability can be further enhanced by using the parity property of the Legendre polynomials, as

$$P_n(-\mu) = (-1)^n P_n(\mu), \quad (156)$$

and rewriting the expression for the n th Legendre coefficient, (144), in the form

$$\int_0^{+1} d\mu_s P_n(\mu_s) [p(E', \mu_s) + (-1)^n p(E', -\mu_s)], \quad (157)$$

and tabulating

$$p * (E', \mu_s) = p(E', \mu_s) + (-1)^n p(E', -\mu_s) : \mu_s \in (0, 1). \quad (158)$$

One can use the procedures presented above to evaluate this integral. Note that in this form for any symmetric angular distribution, all the odd Legendre coefficients automatically reduce to zero without taking any differences other than those explicitly already included in (158).

5.2.3 Energy Distributions

Having calculated the n th Legendre coefficient of the angular distribution, the group-to-group transfer matrix can be written in the form

$$\Phi_{ng'} \Sigma_{g' \rightarrow g}^n = \int_{E_{g'}}^{E_{g'+1}} dE' m(E') \Sigma(E') p_n(E') \Phi_n(E') \int_{E_g}^{E_{g+1}} dE g(E' \rightarrow E). \quad (159)$$

We note that the integral over the secondary-energy distribution is independent of n ; this is a consequence of our assumption that the angular and energy distributions are uncorrelated.

In order to proceed further, we must examine the representations of the secondary-energy distribution that are used in the evaluated data libraries (Kinsey 1970; Rose and Dunford 1990). These include

1. *An arbitrary tabulated function* – for a series of incident energies, E' , the secondary distribution is tabulated as a function of the secondary energy, E .
2. *General evaporation spectrum (Maxwellian)*

$$g(E' \rightarrow E) = g(E/\theta(E')), \quad (160)$$

where $\theta(E')$ is tabulated as a function of the incident energy E' , and $g(X)$ is tabulated as a function of $X : X = E/\theta(E')$.

3. *Simple fission spectrum (Maxwellian)*

$$\begin{aligned} g(E' \rightarrow E) &= \frac{\sqrt{E}}{I} \text{Exp}[-E/\theta(E')], \\ I &= \theta^{3/2} \left[\frac{\sqrt{\pi}}{2} \text{ERF}(\sqrt{X}) - \sqrt{X} \text{Exp}(-X) \right], \\ X &= (E' - U)/\theta. \end{aligned} \quad (161)$$

While θ is tabulated as a function of the incident energy E' , U is a constant introduced to define the upper limit of the secondary-energy distribution: $0 \leq E \leq E' - U$.

4. *Evaporation spectrum*

$$\begin{aligned} g(E' \rightarrow E) &= \frac{E}{I} \text{Exp}[-E/\theta(E')], \\ I &= \theta^2 [1 - (1 + X) \text{Exp}(-X)], \\ X &= (E' - U)/\theta. \end{aligned} \quad (162)$$

θ is tabulated as a function of the incident energy E' . U is a constant introduced to define the upper limit of the secondary-energy distribution: $0 \leq E \leq E' - U$.

5. Energy-dependent Watt spectrum

$$\begin{aligned}
 g(E' \rightarrow E) &= \frac{1}{I} \text{Exp}[-E/a] \sinh[\sqrt{bE}], \\
 I &= \frac{1}{2} \sqrt{\frac{\pi a^2 b}{4}} \text{Exp}\left[\frac{ab}{4}\right] \left[\text{ERF}(\sqrt{X} - \sqrt{C}) + \text{ERF}(\sqrt{X} + \sqrt{C}) \right] - a \text{Exp}[-X \sinh(D)], \\
 X &= (E' - U)/\theta, \\
 C &= ab/4, \\
 D &= \sqrt{b(E' - U)}.
 \end{aligned} \tag{163}$$

While a and b are tabulated as a function of incident energy E' , U is a constant introduced to define the upper limit of the secondary-energy distribution:

$$0 \leq E \leq E' - U.$$

Any of these representations may be integrated over the secondary energy, E , in order to reduce (141) to a singly dimensioned integral over the initial energy distribution

$$\Phi_{ng'} \Sigma_{g' \rightarrow g}^n = \int_{E_{g'}}^{E_{g'+1}} dE' m(E') \Sigma(E') p_n(E') \Phi_n(E') g(E' \rightarrow g), \tag{164}$$

where

$$g(E' \rightarrow g) = \int_{E_g}^{E_{g+1}} dE g(E' \rightarrow E). \tag{165}$$

For the tabulated forms of $g(E' \rightarrow E)$ described above, the transformation to the normal interval $(-1, +1)$ should be used to improve numerical stability of the resulting integrals. The analytical expressions for the integral of $g(E' \rightarrow E)$ in (165) will be similar in form to the “ I ” in (161) through (163), only evaluated at E_g and E_{g+1} . In order to insure numerical stability, care must be exercised in evaluating these analytical expressions, particularly for small-energy intervals (fine-energy groups) wherein round-off problems may error.

The major difficulty in evaluating (164) is the dependence of $g(E' \rightarrow g)$ on the initial energy E' ; all the other terms can be reduced to linearly interpolable form and integrated using the procedures described earlier under self-shielding. Fortunately, even though in principle any of the forms described above for $g(E' \rightarrow E)$ can be used, in practice usually the secondary-energy distribution is either independent of initial energy, or at least has coefficients that vary slowly with energy. When the secondary-energy distribution is independent of initial energy, (159) and (164) just become the product of an integral over initial energy, which can be solved in a manner analogous to the procedures introduced earlier under self-shielding, and the integral of $g(E' \rightarrow E)$ over secondary-energy equation (165). When the secondary-energy distribution is dependent on the initial energy, the slow variation of its coefficients may be used to divide the integral into a series of integrals in each of which $g(E' \rightarrow E)$ may be considered to be linearly variable, or even constant. Therefore, here we will only illustrate the result that is obtained

using an arbitrary tabulated, energy distribution. We assume that for each initial energy E' , the angular distribution is given in linearly interpolable form by LEGEND (Cullen 2007a–c), as a function of secondary energy; using our normalized coordinates, this can be written in the form

$$\begin{aligned} g(E' \rightarrow E) &= \langle g(E') \rangle_k [1 + \delta_k Z] : E \in (E_k, E_{k+1}), \\ Z &= \frac{2E - (E_k + E_{k+1})}{E_{k+1} - E_k}, \\ \langle g(E') \rangle_k &= \frac{1}{2} [g_{k+1}(E') + g_k(E')], \\ \delta_k(E') &= \frac{1}{2} \left[\frac{g_{k+1}(E') - g_k(E')}{g_{k+1}(E') + g_k(E')} \right]. \end{aligned} \quad (166)$$

If we further assume that the energy distribution is also a linearly interpolable function of the incident energy, E' , we obtain an analogous expression for

$$\langle g(E') \rangle_k = g_{k'k} [1 + \delta_{k'k} Z'] : E' \in (E'_k, E'_{k+1}). \quad (167)$$

Integrating (166) over those energy integrals that lie within the energy range (E_g, E_{g+1}) yields

$$g(E' \rightarrow g) = \int_{E_g}^{E_{g+1}} dE g(E' \rightarrow E) = \sum_k (E_{k+1} - E_k) \langle g(E') \rangle_k, \quad (168)$$

which states that since $g(E' \rightarrow E)$ depends on the secondary energy, integrating this distribution over each secondary-energy interval that lies in the range (E_g, E_{g+1}) , simply contributes the width of each energy interval times the average value of g within the energy interval; it does not depend on the detailed-energy dependence within each secondary-energy interval.

From (167) and (168), we now have an expression for $g(E' \rightarrow E)$ as a linearly interpolable function of E' . All the terms in (161) can be reduced to a similar form, and the procedure described under self-shielding can be used to evaluate the resulting expression. Of the terms in (161), all are inherently positive except the Legendre coefficient $p_n(E')$. If $p_n(E')$ does not change sign within the energy interval (E'_g, E'_{g+1}) , the resulting integral will be numerically stable; if it does change sign, cross cancellation may introduce round-off problems.

5.2.4 Correlated Distributions

In the case of correlated distributions, the secondary distribution is expressed as the product of the angular distribution and a Dirac delta function expressing the exact correlation between scattering angle and initial and final energies, as

$$p(\mu_s, E' \rightarrow E) = p(E', \mu_s) \delta[\mu_s - S(E, E')]. \quad (169)$$

For example, for neutron inelastic scattering,

$$\mu_s = S(E, E') = \frac{1}{2} \left(\frac{E'}{E} \right)^{1/2} \left[(A+1) \left(\frac{E}{E'} \right) - (A-1) + \frac{AQ}{E} \right],$$

and for photon Compton scattering,

$$\mu_s = S(E, E') = 1 - \frac{\beta}{E} + \frac{\beta}{E'},$$

where β is the energy equivalent of the electron rest mass, m_0c^2 (roughly 0.51 MeV). For correlated distributions, the angular distribution may be given in Legendre coefficient or tabulated form and is usually in the center of mass system.

Since correlated distributions occur in two-body interactions alone with defined Q-values (e.g., elastic and discrete, inelastic neutron scattering, or Compton photon scattering), it may be assumed that the multiplicity in (142) is always unity for such interactions and need not be explicitly written in the following equations.

The presence of the Dirac delta function reduces the number of the dimensions of the integral in (141) from three to two. At present, there are a variety of methods in use to solve this equation, and they are worth reviewing.

Most of the methods presently in use write (141) in the form

$$\int_{E_{g'}}^{E_{g'+1}} dE' \Sigma(E') \Phi_n(E') F_n(E'), \quad (170)$$

where

$$F_n(E') = \int_{-1}^{+1} \mu_s P_n(\mu_s) \int_{E_g}^{E_{g+1}} dE p(E', \mu_s) \delta[\mu - S(E, E')]. \quad (171)$$

This may be written in terms of a singly dimensioned integral over the cosine in either of the laboratory system

$$F_n(E') = \int_{\mu_{\min}}^{\mu_{\max}} p(E', \mu_s) P_n(\mu_s) d\mu_s, \quad (172)$$

or the center-of-mass system,

$$F_n(E') = \int_{\eta_{\min}}^{\eta_{\max}} p(E', \eta_s) P_n(\mu_s) d\eta_s, \quad (173)$$

or a mix of the above two systems,

$$F_n(E') = \int_{\mu_{\min}}^{\mu_{\max}} p(E', \eta_s) P_n(\mu_s) \left| \frac{d\eta_s}{d\mu_s} \right| d\mu_s. \quad (174)$$

In these equations, the cosine limits are a function of the incident energy E' and correspond to the minimum and maximum scattering cosines that will permit a particle with an initial energy E' to end up with a secondary energy between E_g and E_{g+1} .

By assuming that the angular distribution is given in terms of a Legendre expansion in the laboratory system,

$$p(E', \mu_s) = \sum_{l=0}^L \frac{2l+1}{2} P_l(E') P_l(\mu_s). \quad (175)$$

Equation (172) can be written in the form

$$F_n(E') = \sum_{l=0}^L \frac{2l+1}{2} P_l(E') Y_l^n(E'), \quad (176)$$

where

$$Y_l^n(E') = \int_{\mu_{\min}}^{\mu_{\max}} P_l(\mu_s) P_n(\mu_s) d\mu_s. \quad (177)$$

This is the approach developed by Weisbin et al. (1974), and used in the MINX code (Weisbin et al. 1976).

By assuming that the angular distribution is given in terms of a Legendre expansion in the center-of-mass system

$$p(E', \eta_s) = \sum_{l=0}^L \frac{2l+1}{2} \tilde{p}(E') P_l(\eta_s), \quad (178)$$

One obtains a similar expression with

$$\tilde{Y}_l^n(E') = \int_{\mu_{\min}}^{\mu_{\max}} P_l(\eta_s) P_n(\mu_s) \left| \frac{d\eta_s}{d\mu_s} \right| d\mu_s \quad (179)$$

and

$$F_n(E') = \sum_{l=0}^L \frac{2l+1}{2} \tilde{p}_l(E') \tilde{Y}_l^n(E'). \quad (180)$$

This is the approach developed by Buchholz (1980), and used in the ROLAIDS code (Westfall 1978).

If the integration in (177) is performed over the center-of-mass cosine, rather than the laboratory cosine, then

$$\tilde{Y}_l^n(E') = \int_{\eta_{\min}}^{\eta_{\max}} P_l(\eta_s) P_n(\mu_s) d\eta_s. \quad (181)$$

Then, $F_n(E')$ corresponds to the “feed function” introduced by MacFarlane and Boicourt (MacFarlane and Boicourt 1975), and used in the NJOY code (MacFarlane et al. 1982; MacFarlane and Muir 1994).

Starting from a tabulated, linearly interpolable distribution in the center-of-mass system, this feed function can be written in the form

$$F_n(E') = \sum_k \int_{\eta_{k \min}}^{\eta_{k \max}} f_k(\eta_s) P_n(\mu_s) d\eta_s, \quad (182)$$

$$F_n(E') = \sum_k \int_{\mu_{k \min}}^{\mu_{k \max}} f_k(\eta_s) P_n(\mu_s) \left| \frac{d\eta_{ss}}{d\mu_s} \right| d\mu_s, \quad (183)$$

where $f_k(\eta_s)$ is the tabulated angular distribution that is linearly interpolable in η between η_k and η_{k+1} , and the cosine limits correspond to those portions of the cosine intervals that lie within the contribution cosine range as η_{\min} and η_{\max} or μ_{\min} and μ_{\max} , respectively. Equation (183) corresponds to the approach developed by Perkins and Giles (Graves-Morris 1973) and used in the CLYDE code (Doyas et al. 1971).

All the above approaches save the integration over the initial energy for last. In some of the above approaches, the so-called “feed function” can be defined in an analytical form, notably the Bucholz formulation for the Legendre coefficient representation in the center-of-mass system and the Perkins–Giles formulation for the tabulated representation in the center-of-mass system. Since the angular distributions are smoother in the center-of-mass system, the use of this system is the most appropriate in which to represent the data and the Bucholz’s and Perkins–Giles’s analytical results are the most important to consider.

An alternative approach to all the methods considered above is to save the integration over cosine for last and to write (141) in the form

$$\int_{-1}^{+1} d\mu_s P(\mu_s) \Sigma_{g' \rightarrow g}^n(\mu_s), \quad (184)$$

where

$$\begin{aligned} \Sigma_{g' \rightarrow g}^n(\mu_s) &= \int_{E_{g'}}^{E_{g'+1}} dE' \Sigma(E') \Phi_n(E') \int_{E_g}^{E_{g+1}} dE p(\mu_s, E' \rightarrow E) \\ &= \int_{E_{g'}}^{E_{g'+1}} dE' \Sigma(E') \Phi_n(E') p(E' \eta_s) \left| \frac{d\eta_s}{d\mu_s} \right|. \end{aligned} \quad (185)$$

This is the approach developed by Greene (1973), and used in the AMPX code (Greene et al. 1976). After solving for the group-to-group transfer due to scatter through a given cosine, AMPX uses a Gaussian quadrature to solve (184). Hong and Shultis (Hong and Shultis 1982), have shown that this approach can be greatly improved in terms of efficiency and accuracy by dividing the range of the final integral into a number of subranges, such that $\Sigma_{g' \rightarrow g}(\mu_s)$ is smooth within each subrange.

It is impossible to thoroughly cover all these methods in this chapter. However, because of the analytical results obtained by Bucholz and Perkins–Giles, their methods will be presented for illustration purposes. Once the definition of the transfer matrix is reduced to a singly dimensioned integral, the methods introduced earlier under self-shielding can be used to evaluate it. Therefore, here we need to consider only the inner integral.

5.2.5 Solution of the Inner Integral

Both Bucholz and Perkins–Giles recognized the advantage of expressing the inner integral in terms of an angular distribution in the center-of-mass system, but performing the integration over the laboratory cosine. In this form, the inner integral can be written as

$$F_n(E') = \int_{\mu_{\min}}^{\mu_{\max}} p(E', \eta) P_n(\mu) \left| \frac{d\eta}{d\mu} \right| d\mu. \quad (186)$$

For neutrons elastically scattering from a nucleus of weight A times the neutron mass, the relationship between the center-of-mass and laboratory cosine is

$$\eta = \frac{1}{A} [\mu^2 - 1 + \mu r] : r = (a^2 + \mu^2)^{1/2} : a = A^2 - 1. \quad (187)$$

By differentiating, we find

$$\frac{d\eta}{d\mu} = \frac{1}{A} \left[2\mu + r + \frac{\mu^2}{r} \right]. \quad (188)$$

Therefore, (186) can be written in a form that involves μ alone,

$$F_n(E') = \frac{1}{A} \int_{\mu_{\min}}^{\mu_{\max}} p \left[E', \frac{1}{A} (\mu^2 - 1 + \mu r) \right] P_n(\mu) \left[2\mu + r + \frac{\mu^2}{r} \right] d\mu. \quad (189)$$

At this point, Bucholz assumes that the angular distribution can be written in terms of a Legendre expansion in the center-of-mass cosine, and Perkins–Giles assume that it can be written in terms of a tabulated distribution that is linearly interpolable in cosine. The result of either of these assumptions is that since the Legendre polynomials can be written in terms of powers of μ , the resulting integral can be defined exactly in terms of the family of functions,

$$\begin{aligned} f_n(X) &= \int X^n dX, \\ g_n(X) &= \int X^n r dX, \\ h_n(X) &= \int \frac{X^n}{r} dX. \end{aligned} \quad (190)$$

These functions satisfy a number of convenient recursion relationships and can be defined in terms of analytical functions (Perkins 1982). Perkins–Giles (Perkins 1982) present results for a general two-body problem, and their results can be used to extend the results presented by Bucholz (1980), for elastic scattering, to handle inelastic scattering. After solving this inner integral, the solution of the final singly dimensioned integral is rather straightforward and as mentioned earlier, it can be evaluated using the techniques described earlier under self-shielding.

5.2.6 Thermal-Scattering Law Data: $S(\alpha, \beta)$

The thermal-scattering law data $S(\alpha, \beta)$ is covered in  Chap. 3 on slowing down and thermalization.

6 Group Collapse

6.1 Introduction

The preceding sections describe how to calculate multigroup sections and transfer matrices. An efficient approach to utilizing multigroup cross sections is to generate fine-group, multigroup data directly from the evaluated data in an application-independent form and to group collapse the fine-group data for use in any specific application (MacFarlane et al. 1982, Weisbin et al. 1976; Cullen 1979a–c; MacFarlane and Muir 1994).

The selection of both fine and collapsed group boundaries should consider “important” threshold regions and prominent WRs. Since what is “important” depends on the specific application, guidelines will not be provided in this chapter; this point is only mentioned here to impress on the reader the importance of selecting an appropriate set of groups to meet the needs of individual applications.

Recalling the definition of the multigroup cross section and transfer matrix,

$$\langle \Sigma_R \rangle_g = \frac{\int_{E_g}^{E_{g+1}} \Sigma_R(E) \Phi(E) dE}{\int_{E_g}^{E_{g+1}} \Phi(E) dE}, \quad (191)$$

$$T_{Rg' \rightarrow g} = \frac{\int_{E_g}^{E_{g+1}} dE \int_{E_{g'}}^{E_{g'+1}} dE' T_R(E' \rightarrow E) \Phi(E')}{\int_{E_{g'}}^{E_{g'+1}} \Phi(E') dE'}, \quad (192)$$

where,

$\Sigma_R(E)$ Cross section for any reaction R (R = total, elastic, capture, etc.),

$\Phi(E)$ Energy-dependent weighting spectrum, e.g., scalar flux,

$T_R(E' \rightarrow E)$ Reaction R , transfer function from source energy E' to sink energy E ,

g', g Source- and sink-group indices, respectively,

$(E_g, E_{g'+1})$ Energy range of source group,

(E_g, E_{g+1}) Energy range of sink group,

$\langle \Sigma_R \rangle_g$ Group-averaged cross section for reaction R in group g ,

$T_{Rg' \rightarrow g}$ Group-averaged transfer matrix for reaction R describing the transfer from source group g' to sink group g ,

In group collapsing, instead of performing the integrals in (191) and (192), we would like to define our group averages for one group structure in terms of known-group averages for

another, more detailed or finer, group structure. In order to accomplish this, we may partition the ranges of the integrals in (191) and (192) into a collection of subintervals as follows:

$$\langle \Sigma_R \rangle_g = \frac{\sum_j \int_{E_j^*}^{E_{j+1}^*} \Sigma_R(E) \Phi(E) dE}{\sum_j \int_{E_j^*}^{E_{j+1}^*} \Phi(E) dE}, \quad (193)$$

$$T_{Rg' \rightarrow g} = \frac{\sum_j \sum_{j'} \int_{E_j^*}^{E_{j+1}^*} dE \int_{E_{j'}^*}^{E_{j'+1}^*} dE' T_R(E' \rightarrow E) \Phi(E')}{\sum_{j'} \int_{E_{j'}^*}^{E_{j'+1}^*} \Phi(E') dE'}. \quad (194)$$

j', j Source- and sink-group indices for our fine-group structure.

$(E_{j'}^*, E_{j'+1}^*)$ That portion of the energy range of the source-fine group that lies within the energy range of the source-coarse group.

(E_j^*, E_{j+1}^*) That portion of the energy range of the sink-fine group that lies within the energy range of the sink-coarse group.

The summation over j and j' extends over those fine groups which either partially or totally overlap the energy range of the coarse groups g' and g . The energy range of fine group j will overlap the energy range of coarse group g if $E_{j+1} \geq E_g$ and $E_j \leq E_{g+1}$. That is to say, the energy ranges will overlap if the upper-energy limit of the fine group is greater than the lower limit of the coarse group and the lower limit of the fine group is less than the upper-energy limit of the coarse group. Given that fine group j does overlap coarse group g , the range and fraction of overlap are given by

$$E_j^* = \max(E_j, E_g),$$

$$E_{j+1}^* = \min(E_{j+1}, E_{g+1}), \quad (195)$$

$$P_j = \frac{E_{j+1}^* - E_j^*}{E_{j+1} - E_j}. \quad (196)$$

If we treat the fine-group data as exact histograms in source- and sink energy, we may rewrite the group-collapse equations in the forms

$$\langle \Sigma_R \rangle_g = \frac{\sum_j P_j < \Sigma_R >_j I_j(\Phi)}{\sum_j P_j I_j(\Phi)}, \quad (197)$$

$$T_{Rg' \rightarrow g} = \frac{\sum_j \sum_{j'} P_j P_{j'} T_{Rj' \rightarrow j} I_{j'}(\Phi)}{\sum_{j'} P_{j'} I_{j'}(\Phi)}, \quad (198)$$

5.2.6 Thermal-Scattering Law Data: $S(\alpha, \beta)$

The thermal-scattering law data $S(\alpha, \beta)$ is covered in  Chap. 3 on slowing down and thermalization.

6 Group Collapse

6.1 Introduction

The preceding sections describe how to calculate multigroup sections and transfer matrices. An efficient approach to utilizing multigroup cross sections is to generate fine-group, multigroup data directly from the evaluated data in an application-independent form and to group collapse the fine-group data for use in any specific application (MacFarlane et al. 1982, Weisbin et al. 1976; Cullen 1979a–c; MacFarlane and Muir 1994).

The selection of both fine and collapsed group boundaries should consider “important” threshold regions and prominent WRs. Since what is “important” depends on the specific application, guidelines will not be provided in this chapter; this point is only mentioned here to impress on the reader the importance of selecting an appropriate set of groups to meet the needs of individual applications.

Recalling the definition of the multigroup cross section and transfer matrix,

$$\langle \Sigma_R \rangle_g = \frac{\int_{E_g}^{E_{g+1}} \Sigma_R(E) \Phi(E) dE}{\int_{E_g}^{E_{g+1}} \Phi(E) dE}, \quad (191)$$

$$T_{Rg' \rightarrow g} = \frac{\int_{E_g}^{E_{g+1}} dE \int_{E_{g'}}^{E_{g'+1}} dE' T_R(E' \rightarrow E) \Phi(E')}{\int_{E_{g'}}^{E_{g'+1}} \Phi(E') dE'}, \quad (192)$$

where,

$\Sigma_R(E)$ Cross section for any reaction R (R = total, elastic, capture, etc.),

$\Phi(E)$ Energy-dependent weighting spectrum, e.g., scalar flux,

$T_R(E' \rightarrow E)$ Reaction R , transfer function from source energy E' to sink energy E ,

g', g Source- and sink-group indices, respectively,

$(E_g, E_{g'+1})$ Energy range of source group,

(E_g, E_{g+1}) Energy range of sink group,

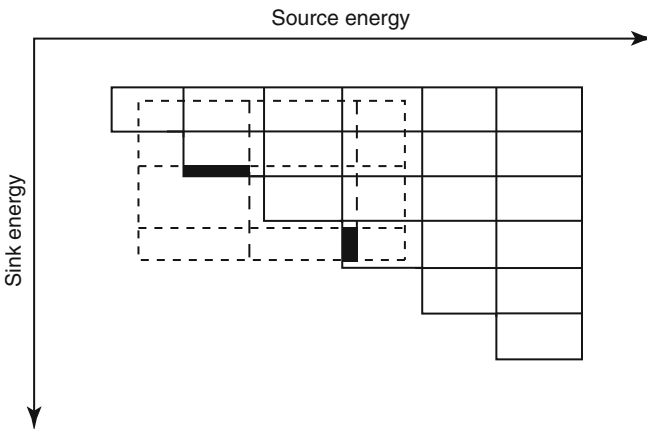

$\langle \Sigma_R \rangle_g$ Group-averaged cross section for reaction R in group g ,

$T_{Rg' \rightarrow g}$ Group-averaged transfer matrix for reaction R describing the transfer from source group g' to sink group g ,

In group collapsing, instead of performing the integrals in (191) and (192), we would like to define our group averages for one group structure in terms of known-group averages for

■ Figure 25
Comparison of exact- and six-group transfer

■ Figure 26
Comparison of six- and three-group transfer

Off-diagonal initial elements represent a rectangular area in (source, sink) energy space given by

$$(E_{j+1} - E_j)(E_{j'+1} - E_{j'}). \quad (200)$$

On diagonal initial elements represent a triangular area in (source, sink) energy space given by

$$\frac{1}{2}(E_{j+1} - E_j)^2. \quad (201)$$

■ Figure 27

Comparison of six- and three-group downscattering transfer

The contribution of an off-diagonal initial element to any final element is a rectangular area in (source, sink) energy space given by

$$(E_{j+1}^* - E_j^*)(E_{j'+1}^* - E_{j'}^*). \quad (202)$$

See ► Fig. 27 and (195) for a definition of E_j^* , etc.

Therefore, assuming the initial element to be uniformly distributed over its rectangular area $(E_{j+1} - E_j)(E_{j'+1} - E_{j'})$, its contribution to the final group will be the magnitude of the initial element times the ratio of the overlap area to the total area of the initial element,

$$P_j P_{j'} T_{j' \rightarrow j} = \frac{(E_{j+1}^* - E_j^*)(E_{j'+1}^* - E_{j'}^*)}{(E_{j+1} - E_j)(E_{j'+1} - E_{j'})} T_{j' \rightarrow j}, \quad (203)$$

which is identical to the contribution for a general transfer matrix.

The contribution of an on-diagonal initial element to an off-diagonal final element is a triangular area in (source, sink) energy space given by

$$\frac{1}{2} (E_{j+1}^* - E_j^*)^2. \quad (204)$$

See ► Fig. 25, area B, and (195) for a definition of E_j^* , etc.

Again assuming that the initial element to be uniformly distributed over its triangular area $1/2(E_{j+1} - E_j)^2$, its contribution to the final group will be the magnitude of the initial element

times the ratio of overlap area to the total area of the initial element,

$$P_j P_j T_{j \rightarrow j} = \frac{\frac{1}{2} (E_{j+1}^* - E_j^*)^2}{\frac{1}{2} (E_{j+1} - E_j)^2}. \quad (205)$$

The factors of 1/2 cancel, and we again obtain an expression which is identical to that obtained for a general transfer matrix.

The contribution of an on-diagonal initial element to an off-diagonal final element is a rectangular area in (source, sink) energy space given by

$$(E_{j+1}^* - E_j^*) (E_{j'+1}^* - E_{j'}^*). \quad (206)$$

See  [Fig. 25](#), area C, and (195) for a definition of E_j^* , etc. Again assuming that the initial element to be uniformly distributed over its triangular area $1/2(E_{j+1} - E_j)^2$, its contribution to the final group will be the magnitude of the initial element times the ratio of the square overlap area to the triangular total area of the initial element,

$$2P_j P_j T_{j \rightarrow j} = \frac{(E_{j+1}^* - E_j^*)^2}{\frac{1}{2} (E_{j+1} - E_j)^2}, \quad (207)$$

which is twice the contribution for a general transfer matrix.

This doubling of weight may be understood by examining  [Fig. 25](#). If we assume that the initial transfer element $T_{2 \rightarrow 2}$ is uniformly distributed over the upper triangular area $1/2(E_3 - E_2)^2$ alone, then the fraction of the area occupied by area C will be twice as large as if we had assumed a uniform distribution over the square area $(E_3 - E_2)^2$. Therefore, the fraction of the initial transfer element $T_{2 \rightarrow 2}$ contributing to the final element will be twice as large in this case.

From the above discussion, it may be seen that interpreting a transfer matrix as the only downscattering will eliminate upscattering, and otherwise, only effect the contribution of any diagonal elements to off-diagonal elements. To reiterate, group collapse is not recommended unless the coarse-group boundaries are a subset of the fine-group boundaries. However, if this condition is not met, the above procedures will at least prevent misinterpreting downscattering transfer matrices.

7 The Multiband Method

7.1 Introduction

From the preceding section on self-shielding, it can be seen that self-shielding is a fairly complicated process that involves a large number of approximations before one can obtain self-shielded cross sections for use in multigroup calculations. One particularly restrictive approximation is the use of a single set of self-shielded cross sections for the entire volumes of a problem; since from our earlier discussions, we know that the self-shielded cross section can actually be a continuous varying function of space and direction. For example, if we consider a piece of

Th232, which will be used to breed U233, at the surface for neutrons incident upon Th232, we would expect the cross section to be the unshielded values, see ref. (Plechaty et al. 1978a,b) and [Fig. 23](#). Deep inside the Th232, we would expect the cross sections to be heavily self-shielded. From our earlier discussion, we know that the self-shielded Th232-capture cross section would be much smaller than its unshielded value, with up to a factor of 50 (5,000%) difference between the two ([Fig. 24](#)). Therefore, in this case, even if we can somehow define a single, spatially averaged, self-shielded cross section which will allow us to correctly calculate the spatial dependence of the flux within the Th232, if we then use the correctly calculated flux and the spatially averaged self-shielded cross section, we will underestimate the capture near the surface and overestimate it deep within the Th232. An example of the magnitude of the resulting differences will be given later in this section.

There is an alternative approach that can be used to avoid the problems encountered when one tried to calculate self-shielded cross sections. In the preceding section on self-shielding, we found that in numerous limiting situations the self-shielded flux can be approximated by the product of an energy-dependent term (the energy-dependent spectrum) times a cross-section-dependent term (the self-shielding factor). We found this result for a purely absorbing or scattering medium as well as in the case of NRs, IRs, and WRs. The main difficulty in applying this knowledge is that the self-shielding factor can be strongly spatially and directionally dependent and must be approximated or guessed in advance, in order to calculate self-shielded cross sections for use in the actual multigroup transport calculation. From our earlier discussion we can see that a poor guess can lead to totally incorrect self-shielded cross sections and even if we do manage to obtain a good “average” cross section for a zone, it can lead to large errors if it is used to calculate reaction rates at specific space points within the zone. This latter point can effect burn-up, isotope production, energy deposition and therefore temperature, etc.

There are two approaches than can be used to avoid the problem of self-shielding. Since the self-shielding factors that we have found depend on the variation of the total cross section within the group, one approach is to use enough groups such that the variation in the total cross section within any group is small. This approach is not really very practical, since for modern evaluations (Garber and Brewster 1975; Cullen et al. 1976), an enormous number of groups would be required; essentially each group would have to be narrow when compared with the width of any resonance. Therefore, this approach is similar to and has no advantage over using continuous energy-dependent rather than multigroup cross sections. In addition, this approach is not practical in the unresolved-resonance region, since in this region evaluations do not provide enough information to allow the energy to be finely subdivided enough to ever uniquely define the resonance structure in the cross section.

The second approach recognizes that the objective of finely dividing the energy range into more groups is merely to arrive at the point where the variation in the cross section in each group is small, that is, to reduce the range of the total cross section within each group. If this is the objective and it cannot be attained by dividing the energy range into more energy groups, why not at some point stop the division and address the problem directly by dividing each energy group into a number of total cross section ranges. Since our discussion on self-shielding points out that the self-shielded flux depends strongly on the total cross section, it makes sense to group together those neutrons that interact with similar total cross sections.

In multigroup transport or diffusion, Nikolaev and Phillipov (1963) for neutrons, and Stewart (1964) for photons, originated the idea of characterizing the neutrons or photons within each group by the value of the total cross section with which they interact. The underlying idea of their approaches is to make full use of the predictions of various limiting transport problems,

some of which have been discussed earlier in this work. Levitt (1972) independently developed his probability table method, which is equivalent to Nikolaev's subgroup method (Nikolaev and Phillipov 1963), when applied to Monte Carlo in the unresolved-resonance region. I have combined the aspects of Nikolaev's, Stewart's, and Levitt's work with Goldstein's work on IRs (Goldstein 1962, 1972, 1975), in order to develop the multiband method (Cullen 1974, 1977a,b; Cullen and Pomraning 1980), which can be applied to neutrons or photons, in any energy range, using Monte Carlo (Plechaty and Kimlinger 1971; Cullen 2005), deterministic transport, S_n , and diffusion.

In the normal multigroup method, one can attempt to improve the transport model by using more energy groups. This is accomplished by further subdividing each energy group. Within each energy group, all neutrons interact with the same cross section. In the multiband method, each group is further subdivided, not into smaller energy intervals, but rather into total cross section ranges. The resulting equations allow the neutrons within each group to interact with more than one total cross section. More importantly, instead of the multigroup approach where one has to approximate or guess how the flux varies as a function of cross section, in the multiband method the cross section dependent on the flux is actually calculated, and even starting from spatially and directionally independent multiband cross sections, the equivalent multigroup cross section can be spatially and directionally continuously variable.

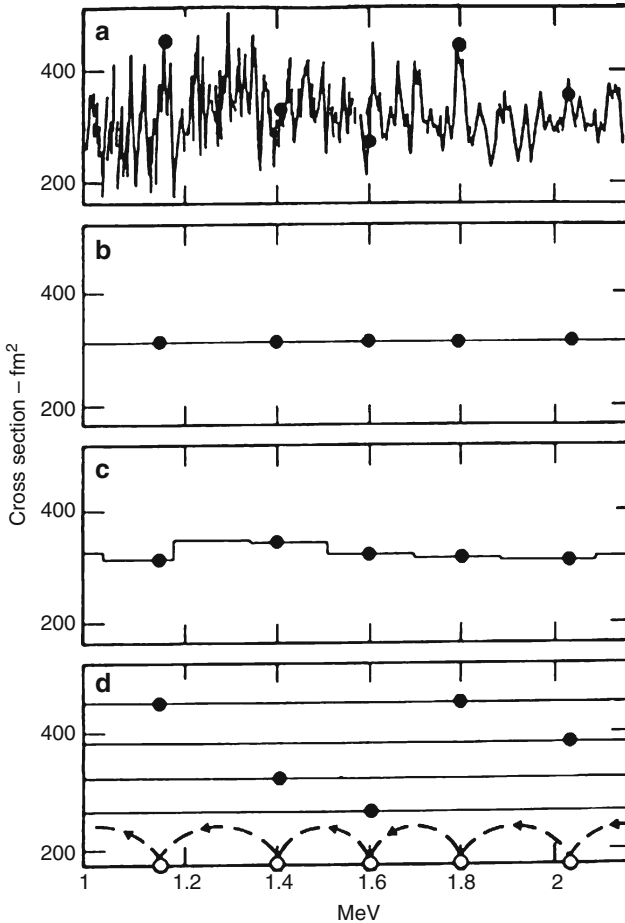

To illustrate how the multiband method differs from other methods consider the schematic of neutron transport shown in  Fig. 28. Here, we are interested in calculating the neutron flux, which at each energy is equal to the path length per unit volume and time traveled by the neutrons at that energy.  Figure 28 illustrates a neutron slowing down due to elastic scattering in the 2.2–1.0 MeV neutron energy range. The neutron loses energy in a series of collisions indicated by dots and connected by the looping dashed line at the bottom of the figure. In the time between collisions the neutron moves in space and thereby, contributes to the flux.

 Figure 28a shows the detailed total cross section variation over this energy range of nickel (Howerton 1978) that exhibits a rapidly varying cross section. The cross sections are quite different following each collision, and therefore on the average the contribution of neutrons to the flux (the distance traveled by the neutrons) varies for different energies.

 Figure 28b shows how a 26-group cross section (Bondarenko et al. 1964), continuous energy calculation handles this situation. Since in this group structure the energy range from 1.0 to 2.2 MeV all lies within the same group, a single multigroup cross section applies to all energies within the group, and therefore on the average the contribution of a neutron to the flux tends to be the same at all energies within this group.

The conventional approach to improving this multigroup approximation is to divide the energy range into narrower segments so that the average cross section more closely approximates the true cross section.  Figure 28c illustrates the effect of using 176 groups (Plechaty et al. 1978a,b), instead of 26 groups. Because of the narrow peaks and valleys in the cross section in this case, each of the new groups in this energy range has about the same average cross section as the single group in the 26-group case. As a result the flux calculated in this energy interval with the 175-group calculation is hardly any improvement over that calculated using 26 groups. This illustrates that increasing the number of groups does not necessarily improve the results of a multigroup calculation.

 Fig. 28d, the total cross section is divided into four total cross

■ **Figure 28**
Schematic comparison of methods

section ranges, or bands, and an average total in each band cross section range is defined in each band. Following each collision, neutrons are allowed to interact not with only one cross section, as in the multigroup method, but rather they may statistically interact with any one of the four cross sections. If the statistical probabilities of interacting with each of these four cross section bands are properly defined, this model can simulate the variations in the cross section and flux, as illustrated in [Fig. 28d](#).

The multigroup approach may have limitations due to self-shielding, but it has the advantage that it has been widely investigated and used, and at present there are a large number of computer codes that may be used to solve the multigroup equations. Realizing this, the multiband method was designed to utilize these available multigroup codes and to introduce the multiband method only by modifying the input “multigroup” data and by making minor internal modifications to the multigroup code itself.

7.2 Multiband Equations

Starting from the time-independent linearized neutron, Boltzmann equation

$$\begin{aligned} \Omega * \nabla N(r, \Omega, E) + \Sigma_t(r, E)N(r, \Omega, E) &= R(r, \Omega, E), \\ R(r, \Omega, E) &= \frac{1}{4\pi} \int_0^\infty dE' \int_{\Omega'} d\Omega' \Sigma(r, E' \rightarrow E, \Omega' \rightarrow \Omega) N(r, \Omega', E'). \end{aligned} \quad (208)$$

The multigroup equations are obtained from (208) by integrating over adjacent energy intervals extending from E_g to E_{g+1} (Weinberg and Wigner 1958; Glasstone and Edlund 1962). This yields the coupled set of equations

$$\Omega * \nabla N_g(r, \Omega) + \Sigma_{tg}(r)N_g(r, \Omega) = R_g(r, \Omega), \quad (209)$$

where N_g , $\Sigma_{tg}N_g$, and R_g are defined by integration over energy, e.g.,

$$N_g(r, \Omega) = \int_{E_g}^{E_{g+1}} N(r, \Omega, E) dE. \quad (210)$$

And R_g describes the contribution of all other groups and directions to group g and direction Ω ,

$$R_g(r, \Omega) = \frac{1}{4\pi} \sum_{g'} \int_0^\infty dE' \int_{\Omega'} d\Omega' \Sigma(r, g' \rightarrow g, \Omega' \rightarrow \Omega) N_g(r, \Omega'). \quad (211)$$

The multiband equations are obtained in a similar manner, however, in order to select specific total cross section ranges, (208) is first multiplied by the weighting function,

$$\delta[\Sigma_t(E) - \Sigma_t^*]. \quad (212)$$

And then integrated over both an energy group and a total cross section range, with respect to Σ_t . The result is a coupled set of equations

$$\Omega * \nabla N_{gB}(r, \Omega) + \Sigma_{tgB}(r)N_{gB}(r, \Omega) = R_{gB}(r, \Omega), \quad (213)$$

where N_{gB} , $\Sigma_{tgB}N_{gB}$, and R_{gB} are defined by integration over energy and total cross section range, e.g.,

$$N_{gB}(r, \Omega) = \int_{\Sigma_{tgB}}^{\Sigma_{tgB+1}} d\Sigma_t^* \int_{E_g}^{E_{g+1}} N(r, \Omega, E) \delta[\Sigma_t(E) - \Sigma_t^*] dE. \quad (214)$$

Physically, the effect of the delta function is to only select those energy intervals in the group where the total cross section is between Σ_{tgB} and Σ_{tgB+1} . ► Figures 29 and ► 30 illustrate the procedure involved in dividing an energy range (E_g, E_{g+1}) into four total cross section bands. In

Figure 29
Total cross section showing four cross sections bands

Figure 30
Total cross section contribution of third band

► Fig. 29 the total cross section is divided into four cross section ranges (bands). ► Figure 30 illustrates the effect of multiplying (208) by the Dirac delta function in total cross section, (212) and integrating over the energy range of the group and the third cross section band. Only those energy ranges in which the total cross section is between Σ_{T3} and Σ_{T4} contribute to the integral.

It is important to note that the multiband equations (213) and the multigroup equations (209) are identical in form and differ only in the magnitude of the cross sections, Σ_{igB} and Σ_{ig} , and the transfer into the group, band (R_{gB}) or group (R_g). Therefore, in principle once

these parameters are defined, the multiband equations can be solved by an existing multigroup computer code, such as MBANISN (MultiBand ANISN), a variant of ANISN (Engle 1967).

If the multigroup and multiband equations are so similar, why is there an advantage to the multiband equations? In either approach, we must approximate or guess the energy and cross section dependence of the flux in order to calculate the group or group, band parameters before performing the transport calculation. However, just as in the multiband method where we only need to specify the form of the flux within each group, (210), in the multiband method we only need to specify the form of the flux within each group, band (214). Since each group, band spans only a portion of the total cross section range, its variation within each group, band is smaller than within each group and our results are less sensitive to the approximation used to represent the self-shielding within each group, band. Indeed viewed in combination the set of group, band fluxes N_{gB} for the bands within each energy group defines the spatially and directionally dependent self-shielding factor. Therefore, the solution of the multiband equations allows for spatially and directionally dependent group self-shielding, even if the group, band cross sections are spatially independent.

Once the multiband equations have been solved to define the neutron flux and reaction rates in each group, band of a group, from definitions, (210) and (214), the equivalent multigroup quantities can be defined simply by summing over the bands in each group; e.g., the group flux is

$$N_g(r, \Omega) = \sum_B N_{gB}(r, \Omega). \quad (215a)$$

One important characteristic of the multiband method is that by defining the equivalent multigroup cross section in the normal way, as the ratio of reactions to flux, we find

$$\Sigma_{tg}(r, \Omega) = \frac{\sum_B \Sigma_{tgB} N_{gB}(r, \Omega)}{\sum_B N_{gB}(r, \Omega)}. \quad (215b)$$

We can see that even starting from spatially and directionally independent, multiband cross section Σ_{tgB} , the equivalent multiband cross sections defined by (215b) may be spatially and directionally dependent due to the variation of the neutron flux within each cross section band; i.e., we obtain spatially and directionally dependent self-shielding.

7.3 Multiband Parameters

The practicality of using the multiband method depends on the number of cross section bands required within each group. For example, if a large number of bands are required in each group, the method may not be a practical alternative to merely subdividing the energy range into many more energy groups. Fortunately, such is not the case and in all cases only a few bands per group are required; usually, only two and never more than four; this is shown next.

The direct use of (214) to define multigroup, band parameters would be complicated and expensive. However, there is a simple procedure that may be used to derive the required multiband parameters from the existing group's self-shielded data libraries (MacFarlane et al. 1982; MacFarlane and Muir 1994; Weisbin et al. 1976; Greene et al. 1976; Cullen 1980a–c). In order to illustrate this, first it is shown that the normal definition of multigroup cross sections in

terms of integrals over energy can be exactly transformed into an integral over total cross section. This point is not surprising, since it merely shows that one can either integrate over the energy interval in the Riemann sense or over the total cross section range in the Lebesgue sense. This exercise is important because it introduces the concept of a band weight or cross section probability.

Considering the normal definition of a multigroup cross section for reaction R (R = total, elastic, capture, etc.) in group g .

$$\Sigma_{Rg} = \frac{\int_{E_g}^{E_{g+1}} \Sigma_R(E) \Phi(E) dE}{\int_E^{E_{g+1}} \Phi(E) dE}. \quad (216)$$

If we introduce the approximate form for the flux that we calculated earlier, namely the product of an energy-dependent spectrum times a cross-section-dependent self-shielding factor, we can rewrite the definition of our multigroup cross section in the form,

$$\Sigma_{Rg} = \frac{\int_{E_g}^{E_{g+1}} \Sigma_R(E) M(E) W[\Sigma_T(E)] dE}{\int_E^{E_{g+1}} M(E) W_T[\Sigma(E)] dE} \quad (217)$$

or equivalently,

$$\Sigma_{Rg} = \frac{\int_{E_g}^{E_{g+1}} dE \int_{\Sigma_T^*} d\Sigma_T^* \delta[\Sigma_T^* - \Sigma_T(E)] \Sigma_R(E) M(E) W(\Sigma_T^*)}{\int_{E_g}^{E_{g+1}} dE \int_{\Sigma_T^*} d\Sigma_T^* \delta[\Sigma_T^* - \Sigma_T(E)] M(E) W(\Sigma_T^*)}. \quad (218)$$

Equations (217) and (218) are equivalent in the sense that if the integration over Σ_T^* in (218) is performed first, we merely obtain (217). However, if the integration over E is performed first, we obtain the equivalent equation

$$\Sigma_{Rg} = \frac{\int d\Sigma_T^* \Sigma_R(\Sigma_T^*) W(\Sigma_T^*) P(\Sigma_T^*)}{\int d\Sigma_T^* W(\Sigma_T^*) P(\Sigma_T^*)}, \quad (219)$$

where we have defined

$$P(\Sigma_T^*) = \frac{\int_{E_g}^{E_{g+1}} dE \delta[\Sigma_T^* - \Sigma_T(E)] M(E)}{\int_{E_g}^{E_{g+1}} dEM(E)}, \quad (220)$$

$$\Sigma_R(\Sigma_T^*) P(\Sigma_T^*) = \int_{E_g}^{E_{g+1}} dE \delta[\Sigma_T^* - \Sigma_T(E)] \Sigma_R(E) M(E). \quad (221)$$

Equations (220) and (221) define the total cross section probability density $P(\Sigma_T^*)$ and the cross section for reaction R as a function of the total cross section $\Sigma_R(\Sigma_T^*)$. $P(\Sigma_T^*) d\Sigma_T^*$ is merely the normalized probability of the total cross section within $d\Sigma_T^*$ of Σ_T^* within the energy interval (E_g, E_{g+1}) .

The transformation from the normal definition of multigroup cross sections, (216) as an integral over energy to (219) in terms of an integral over cross section does not really require the assumption of a separable flux; this assumption has been introduced here merely to simplify the definitions in (220) and (221) and the two forms (energy or cross section integral) are exactly equivalent.

If one uses a self-shielding model that characterizes the flux as only depending on the total cross section within each group (e.g., NR or Bondarenko model), there are obvious advantages of using the cross-section-dependent form to define group-averaged cross sections. This may be illustrated by considering the relative difficulty of evaluating the same integral in the energy

$$\int_{E_g}^{E_{g+1}} \frac{dE}{E[\Sigma_T(E) + \Sigma_0]} \quad (222)$$

or in terms of the cross section

$$\int_{\Sigma_{T \min}}^{\Sigma_{T \max}} \frac{d\Sigma_T^* P(\Sigma_T^*)}{[\Sigma_T^* + \Sigma_0]} = \int_0^1 \frac{dP}{[\Sigma_T^*(P) + \Sigma_0]}, \quad (223)$$

where in this example $P(\Sigma_T^*)$ is given by (220) with $M(E)$ equal to $1/E$.  Figures 31 and  32 illustrate the Pu239 total cross section between 40 and 300 eV in the energy and cross section probability planes, respectively. From  Fig. 31 it is obvious that for fixed Σ_0 in the energy plane, $\Sigma_T(E) + \Sigma_0$ is a rapidly varying function of energy, which in this case is represented by thousands of tabulated data points. In contrast to  Fig. 32, for fixed Σ_0 in the

 **Figure 31**
Pu239 Neutron-Interaction cross section versus energy

Figure 32
Pu239 Neutron-Interaction cross section versus probability

cross section probability plane $\Sigma_T(P) + \Sigma_0$ is a simple monotonically increasing function of P . Therefore, once the total cross section probability density is known, integrals in the cross section versus probability plane may be performed very efficiently for a variety of self-shielding factors $W(\Sigma_T^*)$ in (219). Another advantage of using the cross section versus probability is the increased insight that is obtained by allowing one to examine the importance of certain cross section ranges as shown in [Fig. 32](#), instead of having to deal with hundreds of minima and maxima, as shown in [Fig. 31](#).

In order to define the multiband parameters, the exact definition of the multigroup section, (219), as an integral over the total cross section, is replaced by a quadrature

$$\Sigma_{Rg} = \frac{\int d\Sigma_T^* \Sigma_R(\Sigma_T^*) W(\Sigma_T^*) P(\Sigma_T^*)}{\int d\Sigma_T^* W(\Sigma_T^*) P(\Sigma_T^*)} = \frac{\sum_B \Sigma_{RB} W(\Sigma_{TB}) P_B}{\sum_B W(\Sigma_{TB}) P_B}. \quad (224)$$

This is obviously equivalent to assuming that the cross section probability density $P(\Sigma_T^*)$ is given by a series of Dirac delta functions

$$P(\Sigma_T^*) = \sum_B P_B \delta[\Sigma_T^* - \Sigma_{TB}]. \quad (225)$$

Once the band weights P_B and cross sections Σ_{RB} are known, (224) may be used to define the multigroup, self-shielded cross section Σ_{Rg} , using any self-shielding model $W(\Sigma_{TB})$.

However, we use the reverse procedure. If we know a set of group-averaged cross sections, obtained using a variety of different weighting functions, $W(\Sigma_{TB})$, (224) may be solved to determine the required weights P_B and cross sections Σ_{RB} .

7.4 Solution for Band Parameters

Since we know the forms that we expect the self-shielded moments of the flux to assume in a number of widely applicable cases, we define our quadrature to insure that in these cases,

we obtain exactly the correct self-shielded cross sections. For example, if we have a standard, self-shielded multigroup library for each group, material, and reaction, we will have a variety of self-shielded cross sections, each corresponding to using a different self-shielding factor in the form,

$$W(\Sigma_T) = \frac{1}{[\Sigma_T + \Sigma_0]^k}; \quad \text{for various } k \text{ and } \Sigma_0 \quad (226)$$

as described in the preceding section on self-shielding. Since from this library we know the self-shielded cross sections (the equivalent of Σ_{Rg} in (224) corresponding to each self-shielding factor (the equivalent of $W(\Sigma_{TB})$ in (224)) as defined by (226), we can use this information to solve the system of equations (224) to define our multiband weights, P_B , and cross sections, Σ_{RB} , for each band.

7.4.1 Analytical Solution for Two Bands

In order to illustrate this procedure, consider the simplest possible case of using two bands; in this case we have four unknowns, the two-band weights P_1 and P_2 , and the two-band cross sections Σ_{R1} and Σ_{R2} , for each reaction R . Assume that from a normal, multigroup-processing code calculation we have calculated the unshielded cross section ($W(\Sigma_T) = 1$), the totally shielded flux weighted cross section ($W(\Sigma_T) = 1/\Sigma_T$) and the totally shielded current weighted cross section ($W(\Sigma_T) = 1/\Sigma_T^2$), which we donate by $\langle \Sigma_0 \rangle$, $\langle \Sigma_1 \rangle$, $\langle \Sigma_2 \rangle$, respectively. Then for the total cross section ($\Sigma_R = \Sigma_T$), the four equations sufficient to uniquely calculate our two-band parameters are obtained by realizing that our quadrature must be normalized

$$P_1 + P_2 = 1 \quad (227)$$

and by inserting each of the three weighting functions into (224) and equating the resulting equations to three known, precalculated self-shielded cross sections

$$\begin{aligned} \langle \Sigma_0 \rangle &= \frac{\Sigma_{T1}P_1 + \Sigma_{T2}P_2}{P_1 + P_2}; & (W(\Sigma_T) = 1), \\ \langle \Sigma_1 \rangle &= \frac{P_1 + P_2}{\frac{P_1}{\Sigma_{T1}} + \frac{P_2}{\Sigma_{T2}}}; & (W(\Sigma_T) = 1/\Sigma_T), \\ \langle \Sigma_2 \rangle &= \frac{\frac{P_1}{\Sigma_{T1}} + \frac{P_2}{\Sigma_{T2}}}{\frac{P_1}{\Sigma_{T1}^2} + \frac{P_2}{\Sigma_{T2}^2}}; & (W(\Sigma_T) = 1/\Sigma_T^2). \end{aligned} \quad (228)$$

We obtain a set of four nonlinear equations in four unknowns. Unfortunately, the solution to this set of equations is not unique. For example, the two bands are indistinguishable, so that if we obtain one solution for this system of equations, we can obtain a second solution merely by exchanging the weights and cross sections for the two bands. The solution does not become unique until we introduce an ordering into the parameters, such that $\Sigma_{T1} \leq \Sigma_{T2}$. This leads us to believe that the two-band parameters are related to the roots of a quadratic equation, which

are also not unique without an ordering. Therefore, we make the standard change of variables used to solve a quadratic equation,

$$\begin{aligned} P_1 &= \frac{1}{2} + \delta; & \Sigma_{T1} &= \frac{1}{X_1} = \frac{1}{A+B}, \\ P_2 &= \frac{1}{2} - \delta; & \Sigma_{T2} &= \frac{1}{X_2} = \frac{1}{A-B}. \end{aligned} \quad (229)$$

This change of variables immediately satisfies (227) and the remaining three equations are easily solved to find

$$\begin{aligned} \delta &= \frac{1 - A < \Sigma_1 >}{2B < \Sigma_1 >}, \\ A &= \frac{1}{2 < \Sigma_2 >} \left[\frac{< \Sigma_0 > - < \Sigma_2 >}{< \Sigma_0 > - < \Sigma_1 >} \right], \\ B^2 &= \frac{1}{< \Sigma_0 >} [1 - 2A + < \Sigma_0 > A^2]. \end{aligned} \quad (230)$$

As expected there are two possible equations for B , corresponding to the positive and negative roots of B^2 (230). This is the result of the nonuniqueness of the solution without an ordering. From the definitions of Σ_{T1} , Σ_{T2} and δ in terms of A and B (229), we can see that choosing the positive or negative root of B^2 merely corresponds to the same solution with the two bands interchanged. In order to obtain a unique solution we always define B to be positive, which from (229) corresponds to introducing the ordering $\Sigma_{T1} \leq \Sigma_{T2}$.

The above algorithm always produces physically acceptable parameters (positive band weights and cross sections) as long as $< \Sigma_0 > \geq < \Sigma_1 > \geq < \Sigma_2 >$. It can be demonstrated (Cullen et al. 1978) that the only time when the three of these are equal is when the total cross section is independent of energy across the group (i.e., the total is constant); in all other cases this inequality is true. When the total cross section is constant, the two bands become indistinguishable and only one band is required in the group (i.e., the normal multigroup equation).

Once the two-band parameters for the total cross section are known, from (229) and (230), for each other reaction R (R = elastic, capture), we may return to (224). For this two-band example for each reaction there are two unknowns, the two-band cross sections Σ_{R1} and Σ_{R2} . If from the normal multigroup library for each reaction we know the unshielded cross section ($W(\Sigma_T) = 1$), and the totally shielded flux weighted cross section ($W(\Sigma_T) = 1/\Sigma_T$) then we can use (224) to obtain two equations for each reaction R

$$\begin{aligned} < \Sigma_0 >_R &= \frac{\Sigma_{R1}P_1 + \Sigma_{R2}P_2}{P_1 + P_2}; & (W(\Sigma_T) = 1), \\ < \Sigma_1 >_R &= \frac{\Sigma_{R1}P_1 + \Sigma_{R2}P_2}{\frac{\Sigma_{T1}}{P_1} + \frac{\Sigma_{T2}}{P_2}}; & (W(\Sigma_T) = 1/\Sigma_T). \end{aligned} \quad (231)$$

Since from the total cross section definitions, (229) and (230), we know P_1 , P_2 , Σ_{T1} and Σ_{T2} , we may solve these two linear equations to define the unknowns Σ_{R1} and Σ_{R2} . In order to solve

these two equations, it is convenient to introduce the change of variables,

$$\begin{aligned}\Sigma_{R1} &= \langle \Sigma_0 \rangle_R - \frac{C}{P_1}, \\ \Sigma_{R2} &= \langle \Sigma_0 \rangle_R + \frac{C}{P_2}.\end{aligned}\quad (232)$$

This change of variables immediately satisfies the first equation, and the second can be solved to find

$$C = [\langle \Sigma_0 \rangle_R - \langle \Sigma_1 \rangle_R] \left[\frac{\frac{P_1}{\Sigma_{T1}} + \frac{P_2}{\Sigma_{T2}}}{1 - \frac{1}{\Sigma_{T1}} - \frac{1}{\Sigma_{T2}}} \right] = [\langle \Sigma_0 \rangle_R - \langle \Sigma_1 \rangle_R] \frac{1}{2B}.\quad (233)$$

Again, the only case when this equation cannot be used is identical to the case mentioned earlier for the total cross section, namely when the total cross section is constant across the entire group. In this case only one band is used in each group and the definition of the cross section for each reaction R reduces to its normal multigroup unshielded average $\langle \Sigma_0 \rangle_R$.

From (232) and (233) we can see that for any reaction where the unshielded and shielded cross sections $\langle \Sigma_0 \rangle_R$ and $\langle \Sigma_1 \rangle_R$ are equal, we find $C = 0$, and the two-band cross sections are the same in both bands and equal to their normal unshielded multigroup average. This will be the case for reactions that do not include resonant structure. Therefore, normally in using the multiband method (Plechaty and Kimlinger 1971; Cullen 1977a,b, 1980a–c, 2005; Otter et al. 1972), is to calculate multiband parameters for total, elastic, capture, and fission, and to use the normal, multigroup-unshielded, cross section for all other reactions. Although other reactions do have variations (Howerton et al. 1978; Garber and Brewster 1975), for the number of groups regularly used in multiband calculations (Plechaty and Kimlinger 1971; Cullen 2005), their self-shielding is negligible and can be ignored.

Once these two-band parameters have been defined, they may be used in transport calculations and they correctly reproduce the limiting cases of unshielded and totally shielded flux. For example, again consider a piece of Th232 in which we use two-band spatially and directionally independent parameters. In this case the combination of the two bands at the boundary for directions oriented into the Th232 produces the correct equivalent of the unshielded-group-averaged cross section. However, deep within the Th232 the flux in the band with a larger cross section is suppressed, relative to the other band, and the equivalent, group-averaged cross sections approach their self-shielded value, that is, we are reproducing continuously varying spatially dependent self-shielding. If we consider the albedo from the surface the flux in the larger cross section band will be suppressed, relative to the other band, which will result in self-shielding, that is, we are reproducing directionally dependent self-shielding, with the flux incident on the slab unshielded, and at exactly the same spatial point, the albedo from the slab is self-shielded.

7.4.2 Generalization to N Bands

The procedures introduced earlier to define two-band parameters may be generalized to define the band parameters for any number of bands per group. In general, (224) is a system of coupled,

nonlinear algebraic equations. Given a set of self-shielded cross sections, this system must be solved for the band cross sections Σ_{RB} and Σ_{TB} and band weights P_B .

This is a classic moments problem: for $\Sigma_0 = 0$ and various values of N , it is the Hausdorff moments problem (Graves-Morris 1973), while for $N = 1$ and various values of Σ_0 it is the Stieltjes–Hilbert moments problem (Graves-Morris 1973). Both of these problems have been widely studied, and only pertinent results are given here.

First take $R = \text{total}$. In this case, for N bands we have $2N$ unknowns: they are P_B and Σ_{TB} , for $B = 1, 2, \dots, N$. Given $2N$ values of the self-shielded total cross sections (defined for $2N$ different combinations of Σ_0 and N), the system of equations (224) can be solved uniquely for P_B and Σ_{TB} . Given more than $2N$ values of the self-shielded cross section, the system can be solved in some “best fit” sense (e.g., least squares or min-max),

Once the P_B and Σ_{TB} are known, the system of equations (224) is linear in the N unknowns Σ_{RB} for $R = \text{elastic, capture, fission}$; given N or more values of the self-shielded cross section for reaction R , the system is easy to solve uniquely or in some “best fit” sense.

7.4.3 How Many Bands are Required?

If the multiband approach is to be a practical alternative to the multigroup method in all energy ranges, it must be demonstrated that only a few bands are needed to correctly reproduce the self-shielding effects that we expect to encounter in a wide variety of applications; clearly if several hundred bands were required in each energy group, the method would not be economically feasible. In a wide variety of applications, we have seen that the neutron scalar flux is of the form

$$\frac{1}{[\Sigma_T(E) + \Sigma_0]^N} \text{ with } \Sigma_0 \geq 0 \text{ and } N = 1.$$

If we allow for all transport situations, so that Σ_0 can have any value between 0 and ∞ , how many bands are required to reproduce the entire self-shielding curve within some acceptable uncertainty? In order to answer this question, program GROUPIE (Cullen 1980a–c, 2007a–c), calculates the self-shielded cross section in each group for a large number of values of Σ_0 between 0 and ∞ (the ∞ limit corresponds to calculating the unshielded $N = 0$ value). Using 23 values of Σ_0 (0 and ∞ and multiples of the unshielded cross section between 2^{-10} and 2^{+10} , a range of over 1 million variation in Σ_0) GROUPIE finds the minimum number of bands such that for all 23 values of Σ_0 ,

$$\left| \langle \Sigma_T(\Sigma_0, N) \rangle - \frac{\sum_B \frac{\Sigma_{TB} P_B}{\Sigma_{TB} + \Sigma_0}}{\sum_B \frac{P_B}{\Sigma_{TB} + \Sigma_0}} \right| \leq \epsilon_{\max} \langle \Sigma_T(\Sigma_0, N) \rangle. \quad (234)$$

► **Table 8** presents the results for the entire ENDL library (Howerton et al. 1978) using the TART-175-group structure (Plechaty et al. 1978a,b). This table shows that the entire curve of self-shielded total cross sections can be reproduced within 0.1% accuracy for every material in the library with two or three (or occasionally four) bands. These results indicate that the multiband method can be used in all energy groups and will be both accurate and economical to use.

^a1 band = unshielded multigroup cross sections.

7.5 Transfer Matrix

So far we have only discussed how to calculate multiband cross sections. However, in order to actually complete the analogy to the multigroup equations and to be able to perform multiband calculations, we must also define the transfer matrix between one (group, band) and another (group, band). In the subgroup method (Nikolaev and Phillipov 1963), and probability table method (Levitt 1972), the NR approximation is used to define the transfer matrix. Specifically, if a neutron scatters at some initial energy E' to some final energy E , the probability of the final energy E lying in any given energy interval (E_G, E_{G+1}) is independent of the cross section at both the initial energy E' and the final energy E . Therefore, we expect the probability of scattering from a band in any initial group to any final group to be the same for all bands in the initial group. The NR approximation is used only to describe the distribution of scattered neutrons between the bands in the final group. Specifically, the NR approximation is that the energy range over which neutrons scatter is wide when compared with the WR and as such the probability of scattering to any final band is independent of the initial band and only depends upon the probability of the final cross-section band, that is, it only depends on the weight of the final band.

Starting from the normal elastic multigroup transfer matrix in the form

$$T_{G' \rightarrow G} = \langle \Sigma_{\text{elastic}} \rangle_{G'} P_{G' \rightarrow G}. \quad (235)$$

Since the probability of scattering to any final group is independent of the initial- and final-group sections, we expect the transfer from any initial (group, band) to any final group to merely depend on the initial (group, band) elastic cross section and exactly the same group-to-group

transfer probability as occurs in the normal, multigroup transfer matrix,

$$T_{B'G' \rightarrow G} = \langle \Sigma_{\text{elastic}} \rangle_{B'G'} P_{G' \rightarrow G}. \quad (236)$$

This is a general result for any scattering model.

The NR model, used by the subgroup (Nikolaev and Phillipov 1963), and probability table methods (Levitt 1972), is equivalent to distributing all the neutrons scattered into group G among the bands in group G only according to the weight of each band in group G

$$T_{B'G' \rightarrow BG} = P_B \langle \Sigma_{\text{elastic}} \rangle_{B'G'} P_{G' \rightarrow G}. \quad (237)$$

Comparison of this multigroup, band-transfer matrix to the normal, multigroup transfer matrix, (235), illustrates that the former can be derived from the latter as

$$T_{B'G' \rightarrow BG} = P_B \frac{\langle \Sigma_{\text{elastic}} \rangle_{B'G'}}{\langle \Sigma_{\text{elastic}} \rangle_{G'}} T_{G' \rightarrow G}. \quad (238)$$

The multiband method extends the range of validity of this approximation by using the IR approximation (Cullen 1977). The basic IR approximation, described earlier in this chapter, is a linear combination of the NR and WR approximations. As pointed out earlier, the NR approximation is equivalent to assuming no correlation between the initial and final cross sections. Since the WR approximation assuming no slowing down due to the absorber, scattered neutrons will have a secondary energy equal to their initial energy and as such there will be an exact correlation between the initial and final cross sections. That is to say in the WR approximation elastic scatter from the absorber may change the direction of the neutron, but it will stay in the same group, that is, for a WR scattering from the absorber leads to

$$T_{B'G' \rightarrow BG} = \langle \Sigma_{\text{elastic}} \rangle_{B'G'} \delta_{B'B} \delta_{G'G}. \quad (239)$$

The IR approximation is equivalent to using the NR approximation to describe the scatter from one initial group to any other final group (use (237) and (238)). However, for the in-group scatter, the transfer matrix will be

$$T_{B'G' \rightarrow BG} = [\lambda P_B + (1 - \lambda) \delta_{B'B}] \langle \Sigma_{\text{elastic}} \rangle_{B'G'} P_{G' \rightarrow G}. \quad (240)$$

This equation states that elastic scatter happens in (group, band) $B'G'$ with cross section $\langle \Sigma_{\text{elastic}} \rangle_{B'G'}$ and of those that collide, a fraction $P_{G' \rightarrow G}$ remains within the energy range of the group G' . Of this fraction that stays in group G' , λ are randomly distributed among the bands in the group (NR approximation), according to the weight of each band P_B , and the remaining $(1 - \lambda)$ remain in the same band they were in prior to the collision (WR approximation).

The only new parameter introduced here is λ , which is slightly different from Goldstein's IR treatment, wherein each resonance has a λ associated with it. Here, we use λ in the sense of a group-averaged value. However, even these group-averaged λ are available in multigroup libraries (MacFarlane et al. 1982; Askew et al. 1966). Therefore, as in the case of multiband weights and cross sections, we can use an existing multigroup library containing

group-to-group transfer matrices in order to derive the multi (group, band) transfer matrix. Therefore, all the required multiband parameters can be derived from existing self-shielded multigroup data libraries.

7.6 Boundary Condition

As in the case of multigroup transport, the multiband method must guarantee continuity of the group-averaged angular flux across all boundaries, indeed in the absence of concentrated sources it must guarantee continuity at all points. In addition, the multiband method must exactly correlate cross sections for the same material encountered in two different spatial zones. Continuity of the group angular flux is guaranteed in the multiband method if the sum of group, band fluxes (i.e., the group flux) is the same on both sides of each boundary surface, e.g.,

$$\sum_B \Phi_{BG}(-\vec{s}, \Omega) = \sum_B \Phi_{BG}(+\vec{s}, \Omega), \quad (241)$$

where $\Phi_{BG}(-\vec{s}, \Omega)$ and $\Phi_{BG}(+\vec{s}, \Omega)$ are the (group, band) fluxes on either side of the boundary surface \vec{s} .

In Monte Carlo calculations (Plechaty and Kimlinger 1971; Cullen 2005), the fact that the cross section in each material is uncorrelated means that following a scatter, multiband parameters may be selected independently for each material in the zone, and if the neutron then transports without collision to another zone, if any new materials are encountered, multiband parameters may be selected independently for each of them. The fact that cross sections for the same material in two different zones are exactly correlated means that once a material has been encountered in any other zone, the multiband parameters selected when the material was first encountered MUST be used to describe the material in the new zone. In Monte Carlo, this is easily achieved (Plechaty and Kimlinger 1971; Cullen 2005) by keeping a list of materials encountered by the neutron between collisions, and multiband parameters are selected only once for each material; the list is re-initialized when a collision occurs.

In deterministic methods, it is possible to maintain this exact boundary condition as in Nikolaev's so-called "all the way" method (Nikolaev and Phillipov 1963) where each material is treated as having N -bands independent from other materials. However, for any realistic problem, this can lead to an enormous number of bands per group, negating the advantage of the multiband method. For example, for a problem involving 10 materials each with two bands per group, there will be $2^{10} = 1,024$ bands per group of the transport problem.

An alternative approach is to use an approximate boundary condition which works quite well for many problems. The correct condition of continuity of the group, band flux within each material zone will be used. The approximate condition is used at the boundary between zones containing different materials. At this boundary the correct condition will be continuity of the group flux and the cross sections on the two sides of the boundary will be uncorrelated.

The fact that the cross section in any two materials is uncorrelated means that the group flux crossing a material boundary should be distributed into the bands in the next region according to the probability of each band. That is, if we define the group flux for all directions $\vec{\Omega}$ oriented from the region on the $-\vec{s}$ side of the boundary to the region on the $+\vec{s}$ side of a boundary surface \vec{s} ,

$$\Phi_G(-\vec{s}, \vec{\Omega}) = \sum_B \Phi_{BG}(-\vec{s}, \vec{\Omega}) \quad (242)$$

this flux should be distributed across the boundary into the bands in the $+\vec{s}$ region according to the weight of each band in the $+\vec{s}$ region

$$\Phi_{BG}(+\vec{s}, \vec{\Omega}) = P_{BG}^+ \Phi_G(-\vec{s}, \vec{\Omega}), \quad (243)$$

where P_{BG}^+ is the weight of each band on the $+\vec{s}$ side of the boundary.

This boundary condition is approximate because it ignores the correlation that exists between the cross sections for the same material in adjacent or nearby zones. For instance, if there is U238 in zone A and the neutron transports without collision from zone A, through adjacent zone B, and into another zone C which also contains U238, this boundary condition ignores the correlation between the U238 cross sections in zones A and C. However, in many practical cases in which there is an intervening zone, if it is optically thick (over a few mean-free paths), the probability of transiting the intervening zone without collision is small and the correlation can be ignored. An example of this situation is a collection of fuel pins, each surrounded by moderator.

7.7 Example Results

7.7.1 Theoretical Cases

In order to illustrate the effect of the multiband method, let us first consider two theoretical problems: first a totally absorbing medium and next a totally scattering medium. First consider a totally absorbing planar half space with a source incident from the left, so that our flux at $x = 0$ is given by

$$\Phi(0, E, \mu) = S(E, \mu). \quad (244)$$

The exact solution to this problem is exponential attenuation independently at each energy. For our example we consider $S(E, \mu)$ to be independent of energy, incident perpendicular to the surface, and normalized to one “particle” incident per unit time and area, as shown in  Fig. 33.

$$\Phi(0, E, \mu) = S(E, \mu) = \delta(\mu - 1)$$

For this source the contribution of any energy to the flux at any point x depends only on the total cross section $\Sigma_T(E)$. This cross section is assumed to have a simple linear variation across the energy range of interest, with,

$$\Sigma_T(E_G) = 10; \quad \Sigma_T(E_{G+1}) = 0.1 \quad (245)$$

It should be emphasized that the group-averaged flux over this energy interval will be the same for any cross section which has the same cross section probability density as that corresponding to (245). For example, the solution for each of the total cross section variations shown in  Fig. 34 will be identical.

 Figure 35 illustrates the results of an exact calculation compared to using unshielded, totally shielded, and two-band cross sections for the flux

$$\Phi_0(x) = \int_{E_G}^{E_{G+1}} \text{Exp}[-\Sigma_T(E)x] dE. \quad (246)$$

■ Figure 33
Absorbing half-space geometry

And the absorption rate

$$R_0(x) = \int_{E_G}^{E_{G=1}} \Sigma_T(E) \text{Exp}[-\Sigma_T(E)x] dE. \quad (247)$$

From ► Fig. 35 we can see that using unshielded cross sections causes the flux to rapidly deviate from the exact solution. The solution obtained using shielded cross sections stays closer to the exact solution flux deeper into the medium, but eventually it too deviates from the exact solution. By comparison, the two-band solution approximates the exact solution quite well over the entire range of x shown in ► Fig. 35.

From ► Fig. 35 we can see one of the problems associated with using normal-group, self-shielded cross sections. At $x = 0$ by taking the ratio of (247) and (246) we can see that the exact group-averaged cross section is the unshielded average. The use of self-shielded cross sections allows the flux to penetrate further into the slab, as shown in ► Fig. 35, by reducing the cross section and therefore the reaction rate. In the case presented here, the effect of using self-shielded cross sections is to lower the absorption rate by a factor of 2 at the point of highest reaction rate, $x = 0$.

In this example we are being somewhat unfair by comparing the multiband method to using unshielded or totally shielded cross sections, since in this example the multiband method was

Figure 34
Cross sections that ALL yield the same answer

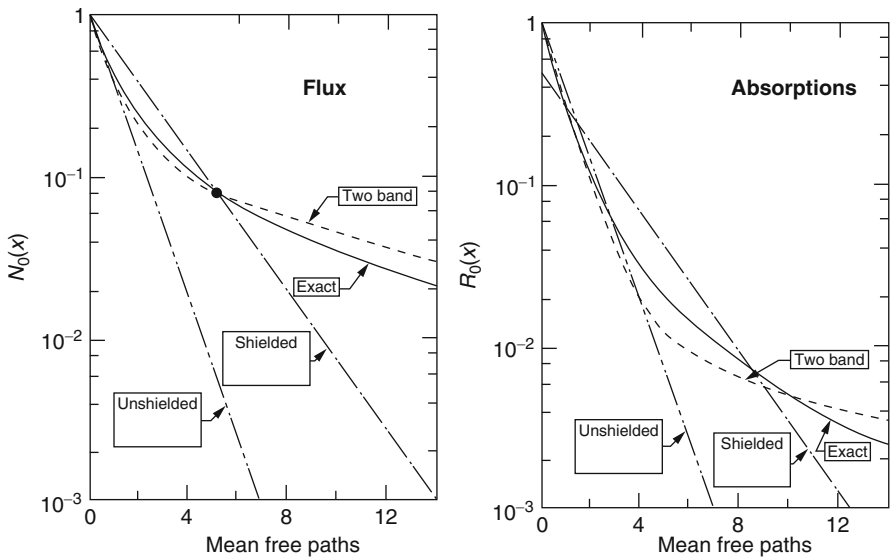

Figure 35
Scalar flux and absorptions for totally absorbing half-space

illustrated using two bands, which involved solving two equations, while using unshielded or shielded cross sections only involved solving one equation. Furthermore, none of the methods exactly reproduce the exact answer. It is reasonable to inquire as to what happens if we subdivide the energy interval E_G to E_{G+1} into successively more groups. For a fair comparison, we compare a 10-group, 2-band solution to 20-group multigroup solutions. **►** *Figure 36* illustrates the results obtained for each method by using progressively more groups. In this figure, for each method, the ratio of the approximate method to the exact solution at $x = 10$ is plotted versus the number of equations used. From **►** *Fig. 36* we can see that in order to obtain a solution using group unshielded or shielded cross sections to the same accuracy as a two-band solution, one needs an order of magnitude more equations. In particular, the dotted line in this figure shows that a two-group, two-band solution is comparable in accuracy to 25 groups with shielded cross sections or 40 groups with unshielded cross sections. This is a characteristic that the two-band solution exhibits in many applications: the two-band method can be very accurate using only a few groups.

In the opposite extreme to the case just considered, we may investigate what happens in a purely scattering medium. In this case, we consider a steady-state problem with an isotropic source incident upon a slab of isotropically scattering material of thickness X , as shown schematically in **►** *Fig. 37*. Since there is no absorption, the incident radiation will either be reflected or transmitted. **►** *Figure 38* presents results obtained for the transmission and albedo as the slab thickness is varied between 0.01 and 1,000 shielded mean-free paths. For this example the shielded total cross section is assumed to be 0.1 times the unshielded total cross section. What we expect is that for optically thin slabs the solution will be that corresponding to the use of unshielded cross sections, and for thick slabs it will be that corresponding to the use of shielded cross sections. **►** *Figure 38* clearly illustrates an important characteristic of the multiband method; it smoothly varies between the correct unshielded and shielded limiting cases.

■ *Figure 36*

Comparison of multiband and multigroup number versus equations

■ **Figure 37**
Scattering finite slab geometry

That is to say one spatially independent set of multiband parameters, in this case only two bands, may be used to reproduce geometrically dependent results, such as that occur when exactly the same material is used in small or large volumes.

The above examples illustrate some of the properties of the multiband method when applied to theoretical problems. Let us now see how well the multiband method performs when used in actual transport calculations. In the following examples only two bands per group were used. Even so the improvement over normal multigroup calculations is striking.

7.7.2 Bramblett–Czirr Plate Measurements

In the Bramblett–Czirr plate measurements (Bramblett and Czirr 1968; Czirr and Bramblett 1967), the fission rate was measured in fission chambers behind the plates of various thicknesses of U235 or Pu239, because of a $1/E$ spectrum incident on the plate. Because of a combination of geometry and timing, this measurement is equivalent to measuring the fission rate due to the uncollided flux.

Because of the many maxima and minima in the U235 and Pu239 cross sections (Howerton et al. 1978; Garber and Brewster 1975), this measurement has always been difficult to reproduce in a transport calculation without an extremely detailed representation of energy dependence of the cross section. In particular, multigroup calculations, even with a very large number of groups, fail to reproduce the measured results.

■ **Figure 38**
Scattering slab results

When one uses a given transport method to simulate this experiment, uncertainties in the results are introduced due to both uncertainties in the evaluated data (Howerton et al. 1975), as well as the uncertainty introduced due to the transport model used. In order to determine the uncertainty introduced by the transport model, we compare (Cullen 1978a,b),

1. An analytical calculation of the fission rate due to the uncollided (i.e., exponentially attenuated) flux using the energy-dependent ENDL cross sections (Howerton et al. 1975).
2. A 175-group, two-band calculation (Plechaty and Kimlinger 1971; Cullen 2005).
3. A 175-group calculation (Plechaty and Kimlinger 1971; Cullen 2005).
4. A 2020-group calculation (Plechaty and Kimlinger 1971; Cullen 2005).

The result of this calculation (Cullen 1978a,b) clearly illustrates that the two-band calculation accurately reproduces the analytical calculation. The 175-group calculation, on the other hand, differs from the analytical results in some energy ranges by over 40%. The 2020-group calculation is a definite improvement compared to the 175-group calculation, but it is not as accurate as the two-band, 175-group calculation. These results indicate that if the multiband method is used to analyze these measurements, any differences between the calculated results and the measurement will be only due to the uncertainties in the evaluated data and the experiment itself. Therefore, the multiband calculated results may be used to validate evaluated data. The multi-group approach, however, introduces significant calculational errors, which make its results difficult to rely on.

7.7.3 Criticality Calculations

Results have been reported (Lewis and Soran 1978), comparing the critical radius of a sphere of uranium hydride (UH₃) as a function of enrichment in U235, using four different transport

models. All four models used continuous energy Monte Carlo to describe the neutrons and they differ only in the treatment of the cross sections. The four models were

1. Continuous energy-dependent cross sections: MCNP (Cashwell et al. 1972; X-5 Monte Carlo Team 2003).
2. Two band, 175-group cross sections: TART (Plechaty and Kimlinger 1971; Cullen 2005).
3. 175-group cross sections: TART (Plechaty and Kimlinger 1971; Cullen 2005).
4. 2020-group cross sections: TART (Plechaty and Kimlinger 1971; Cullen 2005).

► *Figure 39* presents the results obtained for the first three of these models. The results illustrate that the multiband method results agree with the continuous energy cross section results over the entire range of U235 enrichment. By contrast, the 175-group results significantly overpredict the critical radius of the sphere. The 2020-group results are an improvement compared to the 175-group results, but they do not agree with the continuous energy cross section results as the multiband results do.

Similar results have been obtained for homogenous mixtures of enriched uranium and water (Lewis and Soran 1978), as a function of the hydrogen to uranium atom fraction. ► *Table 9* presents the results obtained using three methods: (1) 2 band, 175 group, (2) 175 groups, and (3) 2020 groups. The reactivity (K-eff) results indicate that, as in the previous problem, the 175 group calculation underpredicts the reactivity. Using 2020 groups improves results, but even 2020 groups are insufficient to represent the NRs in U238.

► *Table 9* also presents the median energy of neutrons that induce fission as calculated by each of the three methods; this helps to explain the differences that we see in reactivity. Since the uranium cross sections have a more resonant structure, whereas the hydrogen cross sections

■ **Figure 39**
Critical radius of sphere of uranium hydride versus enrichment

■ **Table 9**

Reactivity (K-eff) and median fission energy for uranium/water sphere

Method	Hydrogen/ ²³⁸ U ratio		
	3/1	10/1	30/1
Calculated reactivity ^a			
175 groups	0.901	0.859	0.866
2020 groups	0.950	0.978	0.993
175 groups, 2 bands	0.957	0.989	0.996
Calculated median energy of neutrons inducing fission, eV			
175 groups	12,600	113.2	0.364
2020 groups	7,700	56.6	0.244
175 groups, 2 bands	7,250	54.3	0.244

^aAll reactivity values are ± 0.003 .

are relatively smooth, self-shielding will reduce the effective, group-averaged cross sections, but not the hydrogen cross section. The net effect is to make the hydrogen more effective in slowing down neutrons, thereby shifting the neutron spectrum to lower energies where the fission cross section is higher, resulting in an increase in reactivity.

The preceding two problems illustrate the importance of self-shielding in the eV to low keV neutron energy range, i.e., the resonance region. Self-shielding is also important at higher energies, up into the MeV energy range. We illustrate this by considering the reactivity of a fast nickel reflected critical assembly, where experimentally K-eff = 1.0. TART-175 group calculations (Plechaty and Kimlinger 1971; Cullen 2005) have always overpredicted the reactivity of this type of system; for a typical system the TART calculated K-eff = 1.018. A multiband calculation (Cullen 1978a,b) of the same system yields a lower and more acceptable answer of K-eff = 1.004. This decrease may be understood by examining the nickel cross sections. Nickel has a resonance structure well into the MeV energy range. Self-shielding of these resonances lowers the effective nickel cross section and increases the depth that neutrons will penetrate into the nickel reflector, which thereby reduces the reflectivity of the nickel reflector back into the core. The net effect is a decrease in the reactivity of the system.

7.7.4 Shielding Calculations

As an illustration of a shielding problem a number of computer codes were used to calculate the uncollided transmission through an iron slab 30.4 cm (1 foot) thick due to an incident spectrum of neutrons from $1/E$ sources, 10 eV to 20 MeV. ➤ *Figure 40* illustrates the natural iron total cross sections. ➤ *Figure 40* illustrates the uncollided flux transmitted through the first 10m cm of iron. The many minima and maxima in the transmission indicate how difficult it would be to calculate this experiment using the multigroup method. ➤ *Table 10* compares the results obtained using various computational models. The analytical solution is simply the

■ Figure 40

(a) Energy-dependent total cross section for natural Fe. (b) Energy spectrum of uncollided flux transmitted through 10 cm of iron

■ **Table 10**

Uncollided transmission of neutrons through 30.4 cm (1 foot) of iron

Method	Transmission (%)	Ratio to analytic
Analytic	0.486	1.0
MCNP	0.478	1.02
TART, 2 bands, 175 groups	0.463	1.05
TART, 175 groups	0.065	7.48
TART, 2020 groups	0.430	1.13

uncollided, exponentially attenuated flux at each energy, and is obtained using all the details of the energy-dependent cross section. The MCNP Monte Carlo code (Cashwell et al. 1972; X-5 Monte Carlo Team 2003) is in excellent agreement with the analytical solution, as is the multi-band solution (2 band, 175 groups) (Plechaty and Kimlinger 1971; Cullen 2005). By contrast, the 175-group solution is a factor of 7 lower than the analytical solution. Even when we increase the number of groups to 2020 the agreement is still not as good as with the 2-band, 175-group method.

7.7.5 Fusion Reactor Blanket

➤ *Figure 41* illustrates a geometrically complicated fusion reactor blanket. The multiband and multigroup methods were used to calculate the fission rate observed at three fission detector positions, per 14.12 MeV source neutron, at the center of the assembly. For detectors located successively further from the source the multigroup results deviate more from the multiband results, up to a difference of 43% at the detector position labeled C in ➤ *Fig. 41*.

In this case the self-shielding has two important effects: it increases both the neutron's penetration depth and the moderation due to the light materials. The net result is more fission at greater distances from the source, than that predicted by the multigroup method.

7.8 Conclusions

Comparison of the calculational results obtained using a variety of cross section treatments (i.e., continuous energy, multiband, and multigroup) and a variety of problems indicate that the multiband results agree well with the results obtained using continuous energy cross sections. In particular, it should be noted that the multiband results were in better agreement with the continuous energy results, than were the results obtained using over an order of

■ **Figure 41**
Geometrically complex fusion source system

magnitude more energy groups (i.e., 2 band, 175 groups, versus 2020 groups). All these results were obtained using a simple two-band per-group calculation and spatially independent, unshielded multiband parameters. Further improvements in the multiband method are easy to achieve using more bands per group (Cullen 1980a–c). However, agreement with the Bondarenko self-shielding model (Bondarenko et al. 1964) can be obtained usually with two or three and in no case more than four bands per group (🔗 [Table 8](#)).

Acknowledgments

The author thanks Robert E. MacFarlane (LANL) for the cooperation he has shared for decades in comparing nuclear data processing (NJOY versus PREPRO) and use of nuclear data in applications (MCNP versus TART). The author thanks Andrej Trkov (Jozef Stefan Institute, Ljubljana, Slovenia), S. Ganesan (BARC, India), and Ivan Sirakov (Geel, Belgium), who have significantly contributed to improving the PREPRO nuclear data processing codes. The author also thanks Ernest F. Plechaty, the original author of TART, who retired many years ago, but who has nonetheless unselfishly continued to contribute ideas and constructive criticism of TART and its use. Last, but certainly not the least, the author thanks Prof. Herbert Goldstein (Columbia University), who taught him everything he knows about this subject.

Abstract: This chapter describes the basic theory underlying the neutron transport equation and the principal approximations used in this equation's applications to reactor physics. In addition to presenting detailed classical derivations of various forms of the transport equation, we discuss several important topics in a more rigorous manner than is found in typical derivations. For instance, we include (i) a discussion of the lack of smoothness of the angular flux in multi-dimensional geometries (this has a negative impact on numerical simulations); (ii) derivations of the transport equation in specialized 1-D, 2-D, and 3-D geometries; (iii) a derivation of the time-dependent integral transport equation; (iv) an asymptotic derivation of the point kinetic equation; and (v) an asymptotic derivation of the multigroup P_1 and diffusion equations. The basic approach taken by the authors in this chapter is theoretical, in the hope that this will complement more intuitive presentations of related topics found in other chapters of this handbook.

1 Introduction

A central problem in the design and analysis of nuclear reactors is the accurate and detailed prediction of the space, angle, energy, and time-dependence of neutron and photon distributions in all components of the reactor. Neutrons are responsible for propagating the chain reaction and releasing energy through fission, but neutrons and photons, through fission, capture, scattering, and excitation/ionization interactions, also induce a thermal-mechanical response in the reactor core and, moreover, cause degradation of structural components, fuel rods, and the control system, through radiation damage, depletion, and fission product poison buildup. These consequences, in turn, affect the distribution of the radiation field itself through several feedback mechanisms. A synergistic description of all nuclear and nonnuclear processes is therefore essential for the economic development and safe operation of nuclear power plants, and driving much of this challenge is the need to have an appropriate mathematical and computational framework for adequately characterizing the neutron and photon distributions.

The transport of neutral radiation, including but not restricted to neutrons and photons, through matter is extremely well described by the transport equation, a linear version of Boltzmann's celebrated equation originally developed within the framework of the kinetic theory of gases (for this reason, the transport equation is sometimes also referred to as the linear Boltzmann equation). This equation is an integrodifferential equation having (generally) seven independent variables, whose solution is not smooth, and which can only be solved exactly for the simplest of problems. Essentially, all neutron transport problems of practical interest must be solved either approximately or numerically.

In this chapter, we present the basic theory underlying the neutron transport equation, and we describe some of this equation's principal approximations. In [▶ Sect. 2](#), we derive the transport equation and discuss some of its general properties. In [▶ Sect. 3](#), we discuss problems with special spatial symmetries, which enable the transport equation to be formulated using fewer independent variables; these formulations are at the heart of all practical 1-D and 2-D computer simulations of neutron transport. In [▶ Sect. 4](#), we discuss the integral form of the transport equation, which, under certain conditions, is advantageous for computer simulations. In [▶ Sect. 5](#), we describe the adjoint transport equation and some of its applications. [▶ Sect. 6](#) describes the standard multigroup approximation to the energy variable, along with the one-speed transport equation. [▶ Sect. 7](#) develops the Age and Wigner approximations, which enable certain neutron slowing-down problems to be solved analytically. [▶ Sect. 8](#) is

devoted to the diffusion approximation, the most important approximate form of the transport equation for nuclear reactor core problems. ➤ Sect. 9 describes the point kinetics approximation, which is used for time-dependent simulations of nuclear reactors. ➤ Sect. 10 provides a brief discussion of numerical methods for simulating neutron and photon transport problems, and we close ➤ Chap. 5 with some concluding remarks in ➤ Sect. 11.

We have consciously adopted a somewhat theoretical approach to this chapter of the handbook, but we have strived for an exposition that presents advanced material in a pedagogical manner that will hopefully appeal both to the novice and to the expert in the field of neutron transport. We include detailed, self-contained presentations of classical material, such as the derivation of the forward and adjoint integrodifferential equations and the forward integral equation, but also, in several of the sections in this chapter, we present material that is either not commonly found in standard texts, or represents a different and more rigorous theoretical approach than standard approaches to the topics under discussion. For instance, ➤ Sect. 2 includes a discussion of the (lack of) smoothness of the angular flux in multidimensional problems; this negatively affects the accuracy of numerical solutions of multidimensional transport problems. Also, ➤ Sect. 3 on the different forms of the Boltzmann equation for 1-D, 2-D, and 3-D geometries is exceptionally important in practice, but this material is not found in standard texts. ➤ Sect. 9 presents a new asymptotic derivation of the point kinetics equation; formerly, this equation has been derived by ad hoc, or at best by variational approaches. Also, ➤ Sect. 7 derives the standard Age and Wigner approximations without introducing the lethargy variable, and ➤ Sect. 8 on the diffusion approximation attempts to put some rigor into the standard P_1 approximation that leads to the multigroup form of this approximation.

Overall, we have attempted to cover significant material in a way that makes use of theoretical approaches that have been developed in recent years, but that has not found its way yet into standard texts. We hope that this will make the chapter more interesting, and that it will provide a more fundamental approach to basic material that may be presented more intuitively in other chapters of this handbook.

2 Derivation of the Neutron Transport (Linear Boltzmann) Equation

Neutron transport is the process in which neutrons propagate through the atoms in a physical system. This includes the *streaming* of neutrons from one collision site (an atomic nucleus) to the next, the *scattering* of neutrons off nuclei, the *capture* of neutrons by nuclei, and the initiation by neutrons of *fission events*, in which a nucleus splits and two or more neutrons are emitted. In this chapter, we develop the mathematical equations that describe the neutron transport process. We begin by defining the necessary independent variables. Then we (i) outline the relevant physics, (ii) define the relevant unknowns (angular flux, precursor densities – for problems with delayed neutrons), and (iii) derive the appropriate mathematical equations for these unknowns. (Our derivation is patterned closely on previous derivations in classic texts [Bell and Glasstone 1970; Case and Zweifel 1967; Henry 1975; Weinberg and Wigner 1958].) Finally, we discuss conditions under which the transport equation is valid and some properties of its solution.

Figure 1

The spatial (x), direction-of-flight or angular (Ω), and energy (E) variables

2.1 Independent Variables

To characterize a general 3-D neutron transport process, *seven* independent variables are required: three components of the position vector \mathbf{x} , two angles to specify the unit vector Ω denoting the direction of flight, the kinetic energy E , and time t . These variables enable one to specify the population of neutrons (i) at an arbitrary point \mathbf{x} in the system, (ii) traveling in an arbitrary direction of flight Ω , (iii) with any energy E , and (iv) at any time t (Fig. 1).

In steady-state problems, the time variable is extraneous, and in problems with spatial symmetries (discussed in Sect. 3), fewer spatial and/or angular variables are required.

To derive the 3-D transport equation, it is convenient to use the familiar Cartesian coordinates, defined in the usual manner by:

$$\mathbf{x} = x\mathbf{i} + y\mathbf{j} + z\mathbf{k}, \quad (1)$$

where \mathbf{i} , \mathbf{j} , and \mathbf{k} are mutually orthogonal unit vectors.

The direction-of-flight vector Ω , a unit vector ($|\Omega| = 1$), is specified using a *polar angle* θ , defined relative to the z -axis, and an *azimuthal angle* ω , defined relative to the x -axis (Fig. 2). In terms of the *direction cosines* projected onto the three Cartesian axes, we have:

$$\Omega = \Omega_x\mathbf{i} + \Omega_y\mathbf{j} + \Omega_z\mathbf{k}, \quad (2a)$$

where:

$$\Omega_x = l_3 = \sqrt{1 - \mu^2} \cos \omega, \quad (2b)$$

$$\Omega_y = l_4 = \sqrt{1 - \mu^2} \sin \omega, \quad (2c)$$

$$\Omega_z = l_1 = \mu. \quad (2d)$$

Figure 2
The polar angle θ and azimuthal angle ω

Figure 3
Incremental volume dV

If we independently displace the spatial variables x , y , and z by incremental (very small) amounts dx , dy , and dz , the spatial variable \mathbf{x} will sweep out an incremental hexahedral volume $dV = dx dy dz$ about \mathbf{x} (see \blacktriangleright Fig. 3).

Similarly, if we independently displace the angular variables μ and ω by incremental amounts $d\mu$ and $d\omega$, then the unit vector Ω will sweep out an incremental, rectangular, dimensionless *element of area* or *solid angle* $d\Omega = ds dl$ on the unit sphere (see \blacktriangleright Fig. 4).

\blacktriangleright Figure 4 shows that $ds = d\omega \sqrt{1 - \mu^2}$, and \blacktriangleright Fig. 5, drawn in the plane generated by Ω and \mathbf{k} , shows that $dl = d\mu / \sqrt{1 - \mu^2}$. Thus, $d\Omega$ is given by:

$$d\Omega = ds dl = \left(d\omega \sqrt{1 - \mu^2} \right) \left(\frac{d\mu}{\sqrt{1 - \mu^2}} \right) = d\mu d\omega. \tag{3}$$

For example, the surface area of the entire unit sphere is then:

$$\text{Area} = \int_{4\pi} d\Omega = \int_0^{2\pi} \int_{-1}^1 d\mu d\omega = 4\pi,$$

Figure 4
Solid angle $d\Omega$

Figure 5
Relationship between $d\mu$ and $d\ell$

where integration over the unit sphere is denoted by:

$$\int_{4\pi} f(\Omega) d\Omega = \int_0^{2\pi} \int_{-1}^1 f(\Omega) d\mu d\omega = \int_0^{2\pi} \int_{-1}^1 f(\mu, \omega) d\mu d\omega.$$

2.2 The Basic Physics of Neutron Transport

Let us consider a neutron, streaming with direction Ω and energy E inside a material with known physical properties. As the neutron travels an incremental distance ds , there is an incremental probability dp that the neutron will interact with a nucleus. To determine the

relationship between dp and ds , let us consider the neutron to be normally incident, at an arbitrary point, on a target of area A and incremental thickness ds (see [Fig. 6](#)).

We assume that the *microscopic cross-sectional area of a target nucleus* $\sigma(E)$ (cm^2) and the *number density of target nuclei* N (cm^{-3}) are known. The *neutron's-eye-view* of the target is depicted in [Fig. 7](#).

If the target is sufficiently thin that one target nucleus does not shield another, then the probability of a collision is:

$$\begin{aligned} dp &= \frac{\text{total area of nuclei}}{\text{area of target}} \\ &= \frac{n\sigma}{A}, \end{aligned} \quad (4)$$

where $n = NdV = N(Ads)$ = the number of nuclei in the target. [Equation \(4\)](#) gives:

$$dp = \frac{N(Ads)\sigma}{A} = (N\sigma)ds.$$

Therefore, dp is proportional to ds :

Figure 6
Incrementally thin neutron target

Figure 7
Neutron's-eye-view of the target

$$dp = \Sigma_t(E) ds, \quad (5a)$$

where the “constant” of proportionality is:

$$\Sigma_t(E) = N\sigma(E) = \text{total macroscopic cross section} \quad (\text{cm}^{-1}). \quad (5b)$$

When a neutron collides with a nucleus, it is captured with probability $p_\gamma(E)$, scatters with probability $p_s(E)$, or initiates a fission event with probability $p_f(E)$. (We ignore other possible, but generally rare, events such as (n, α) , (n, p) , and $(n, 2n)$.) Then:

$$p_\gamma(E) + p_s(E) + p_f(E) = 1. \quad (6)$$

With $r = (\gamma, s, f)$, the probabilities also define the *macroscopic cross sections* $\Sigma_r(E)$, such that:

$$\Sigma_r(E) ds = \Sigma_t(E) ds p_r(E) \quad (7)$$

is the probability that a neutron with energy E , while traveling a distance ds , will experience a collision of type r . The total macroscopic cross section then satisfies:

$$\Sigma_t(E) = \Sigma_\gamma(E) + \Sigma_s(E) + \Sigma_f(E). \quad (8)$$

If the neutron is captured, it is considered to be removed from the system. If the neutron (with direction Ω and energy E) scatters, it emerges from the scattering event with a new direction Ω' and energy E' . We assume that the distribution of post-collision directions Ω' and energies E' is known and can be expressed as:

$$p(\Omega \cdot \Omega', E \rightarrow E') d\Omega' dE' = \text{probability that the scattered neutron} \\ \text{has direction in } d\Omega' \text{ about } \Omega' \text{ and} \\ \text{energy in } dE' \text{ about } E'. \quad (9)$$

In writing p as $p(\Omega \cdot \Omega', E \rightarrow E')$, we indicate that scattering in media with randomly distributed scattering centers (nuclei) is *rotationally invariant*. That is, the probability that a neutron will scatter from direction Ω to direction Ω' depends only on the *scattering angle* θ_0 between Ω and Ω' (or, on the cosine of this angle, $\mu_0 = \cos \theta_0 = \Omega \cdot \Omega'$). Thus, all scattered directions of flight Ω' on the cone of equal scattering angle are equally probable (► Fig. 8).

The distribution function for elastic s -wave neutron scattering, which is isotropic in the center-of-mass frame, can be shown from kinematics (Duderstadt and Hamilton 1976) to be given by:

$$p(\Omega \cdot \Omega', E \rightarrow E') = p_0(E \rightarrow E') \frac{\delta[\Omega \cdot \Omega' - \mu_0(E \rightarrow E')]}{2\pi}. \quad (10a)$$

Here, $p_0(E \rightarrow E')$ is a histogram distribution function for outgoing energies E' :

$$p_0(E \rightarrow E') = \begin{cases} \frac{1}{(1-\alpha)E} & \text{if } \alpha E < E' < E, \\ 0 & \text{otherwise,} \end{cases} \quad (10b)$$

where:

$$\alpha = \left(\frac{A-1}{A+1} \right)^2, \tag{10c}$$

and A is the nucleus-to-neutron mass ratio ($A \geq 1$). Also, δ is the familiar delta-function, and $\mu_0(E \rightarrow E')$ is the scattering cosine for a neutron, initially with energy E , that elastically scatters into energy E' :

$$\mu_0(E \rightarrow E') = \left(\frac{A+1}{2} \right) \sqrt{\frac{E'}{E}} - \left(\frac{A-1}{2} \right) \sqrt{\frac{E}{E'}}. \tag{10d}$$

Thus, the outgoing neutron energy E' is random and *uniformly distributed* between αE and E . Once E' is known, the scattering cosine $\mu_s(E \rightarrow E')$ is uniquely specified by (10d), but the scattering azimuthal angle ω' is random and uniformly distributed on $0 \leq \omega' < 2\pi$. As depicted in **Fig. 9**, the minimum neutron energy loss is associated with the minimal change in direction of the neutron (“forward” scattering, $\mu_s = +1$), while the maximum neutron energy loss is associated with the maximum change in direction of the neutron (“backward” scattering, $\mu_s = -1$).

We now define the *macroscopic differential scattering cross section* as:

$$\Sigma_s(\Omega \cdot \Omega', E \rightarrow E') = \Sigma_s(E) p(\Omega \cdot \Omega', E \rightarrow E'), \tag{11}$$

Figure 8
Scattering angle θ_0

Figure 9
Scattering cosine as a function of the outgoing energy E'

which has dimension $\text{cm}^{-1} \text{MeV}^{-1}$. Then:

$$\Sigma_s(\mathbf{\Omega} \cdot \mathbf{\Omega}', E \rightarrow E') ds d\Omega' dE' = \text{probability that a neutron, with direction } \mathbf{\Omega} \text{ and energy } E \text{ and traveling a distance } ds, \text{ will scatter into } d\Omega' \text{ about } \mathbf{\Omega}' \text{ and } dE' \text{ about } E'. \quad (12)$$

Equations (9)–11 imply:

$$\int_0^\infty \int_{4\pi} p(\mathbf{\Omega} \cdot \mathbf{\Omega}', E \rightarrow E') d\Omega' dE' = 1, \quad (13a)$$

$$\int_0^\infty \int_{4\pi} \Sigma_s(\mathbf{\Omega} \cdot \mathbf{\Omega}', E \rightarrow E') d\Omega' dE' = \Sigma_s(E). \quad (13b)$$

If a neutron with energy E initiates a fission event, the target nucleus splits into two smaller *daughter nuclei*, and on the average, $\nu(E)$ neutrons are released. Of this number, $\nu(E)[1 - \beta(E)]$ are *prompt* (emitted within 10^{-15} s of the fission event) and $\nu(E)\beta(E)$ are *delayed* (emitted roughly 0.1–60 s after the fission event). Thus, the *delayed neutron fraction* $\beta(E)$ is the probability that a fission neutron, created by a neutron with energy E , is delayed ($\beta \approx 0.01$). Delayed fission neutrons are created from the radioactive decay of unstable daughter nuclei, which can be produced during fission events.

Prompt fission neutrons are born at the location of the fission event, their initial direction of flight is *isotropic* (uniformly distributed on the unit sphere), and their initial energy is consistent with the *prompt fission spectrum* $\chi_p(E')$, defined by:

$$\chi_p(E') dE' = \text{the probability that a prompt fission neutron has energy in } dE' \text{ about } E'. \quad (14a)$$

This definition implies:

$$\int_0^\infty \chi_p(E) dE = 1. \quad (14b)$$

The unstable daughter nuclei are often grouped into six *precursor groups*, each with its own *radioactive decay constant* λ_j , *delayed fraction* $\beta_j(E)$, and *delayed neutron fission spectrum* $\chi_j(E)$, where $1 \leq j \leq 6$. The functions $\beta_j(E)$ satisfy:

$$\sum_{j=1}^6 \beta_j(E) = \beta(E). \quad (15)$$

To conclude this discussion, we introduce the notion of the neutron *mean free path*. Let us consider a large number (N_0) of neutrons, all emitted in the same direction of flight, with the same energy E , and from the same spatial point within a large homogeneous region. Each neutron travels along the same flight path within the system and eventually undergoes a collision with a nucleus. Let $N(s, E)$ be the number of neutrons that penetrate to depth s without experiencing a collision. Clearly, $N(s, E)$ is a decreasing function of s , starting with the initial value

$N(0, E) = N_0$. For $s > 0$ and an incremental distance $ds > 0$, the number of neutron–nucleus collisions between s and $s + ds$ is given by:

$$\begin{aligned} N(s, E) - N(s + ds, E) &\approx N(s, E) - \left(N(s, E) + ds \frac{\partial N}{\partial s}(s, E) \right) \\ &= - ds \frac{\partial N}{\partial s}(s, E). \end{aligned} \quad (16)$$

Dividing by $N(s, E)$ and noting that the left side becomes the probability that a neutron will have a collision while traveling a distance ds , we have from (5a):

$$\frac{1}{N(s, E)} \left(- \frac{\partial N}{\partial s}(s, E) ds \right) = \Sigma_t(E) ds.$$

This relationship can be rearranged to yield the differential equation:

$$\frac{\partial N}{\partial s}(s, E) + \Sigma_t(E)N(s, E) = 0, \quad N(0, E) = N_0,$$

which has the solution:

$$N(s, E) = N_0 e^{-\Sigma_t(E)s}. \quad (17)$$

Next, defining $P(s, E)ds$ as the probability that an uncollided neutron will collide with a nucleus between s and $s + ds$, we have:

$$\begin{aligned} P(s, E)ds &= \frac{\text{the number of collisions between } s \text{ and } s + ds}{\text{the initial number of neutrons (at } s = 0)} \\ &= \frac{1}{N_0} \left(- \frac{\partial N}{\partial s}(s, E) ds \right) \quad (\text{by [16]}) \\ &= \Sigma_t(E) e^{-\Sigma_t(E)s} ds \quad (\text{by [17]}). \end{aligned}$$

Thus,

$$P(s, E) = \Sigma_t(E) e^{-\Sigma_t(E)s}. \quad (18a)$$

We note that P satisfies the normalization $\int_0^\infty P(s, E)ds = \int_0^\infty \Sigma_t(E) e^{-\Sigma_t(E)s} ds = 1$, which simply states that in an infinite medium, a neutron must collide somewhere.

The probability density $P(s, E)$ can be used to obtain the mean distance-to-collision, or the *mean free path*:

$$\lambda(E) = \int_0^\infty s P(s, E) ds = \frac{1}{\Sigma_t(E)}. \quad (18b)$$

Thus, the mean free path of a neutron with energy E is equal to the inverse of the macroscopic total cross section at that energy.

Figure 10
 dV about \mathbf{x} , $d\Omega$ about Ω , and dE about E

2.3 The Angular Neutron Density and Angular Flux

We now define the physical quantities needed to describe the neutron population. We consider all neutrons that, at time t , (i) are geometrically located in a volume increment dV about a point \mathbf{x} , (ii) travel within a solid angle $d\Omega$ about the direction Ω , and (iii) have energies between E and $E + dE$ (see Fig. 10). The *angular neutron density* $N(\mathbf{x}, \Omega, E, t)$, a function of (generally) seven independent variables, is defined by:

$$N(\mathbf{x}, \Omega, E, t) dV d\Omega dE = \text{the number of neutrons in } dV d\Omega dE \\ \text{about } (\mathbf{x}, \Omega, E) \text{ at time } t. \quad (19)$$

This definition implies that the value of N is independent of the increments dV , $d\Omega$, and dE . Also, N is a *phase space density*; it has the dimensions $\text{cm}^{-3} \text{MeV}^{-1}$.

Knowledge of $N(\mathbf{x}, \Omega, E, t)$ enables one to calculate the number of neutrons that exist in any “volume” of 6-D phase space (\mathbf{x}, Ω, E) at any time t . For example, for any $E_1 < E_2$ and any subregion R of the physical system V , we have:

$$\int_{E_1}^{E_2} \int_{4\pi} \int_R N(\mathbf{x}, \Omega, E, t) dV d\Omega dE = n(t) = \text{the number of neutrons in } R, \\ \text{with energies between } E_1 \text{ and } E_2, \text{ at time } t.$$

Next, let us consider a planar surface area element dS , located at any point \mathbf{x} in V , with a unit normal vector \mathbf{n} (Fig. 11). We consider neutrons located near \mathbf{x} , traveling in directions in $d\Omega$ about Ω , with energies in dE about E , at time t . What is the *rate* (number per second) at which these neutrons flow through dS at time t ?

In the plane generated by Ω and \mathbf{n} , and with $v =$ neutron speed $= \sqrt{2E/m}$, we consider a volume dV obtained by sweeping dS a distance $ds = vdt$ along the direction of flight Ω (Fig. 12):

Figure 11
Neutron flow through dS

Figure 12
Volume increment dV

In time increment dt , neutrons travel the distance $ds = vdt$. Thus, in time dt , among all neutrons traveling in $d\Omega$ about Ω and dE about E , only those physically located in the incremental volume dV will flow through dS .

The volume of dV is:

$$dV = (dS)(d\ell) = dS(vdt)(\Omega \cdot \mathbf{n}).$$

Thus, the number of neutrons located within $dVd\Omega dE$ about (\mathbf{x}, Ω, E) is:

$$NdVd\Omega dE = NdS(vdt)(\Omega \cdot \mathbf{n})d\Omega dE = [(\Omega \cdot \mathbf{n})vN]dSd\Omega dE dt,$$

and this is the number of neutrons traveling in $d\Omega dE$ about (Ω, E) that pass through dS during time dt about t . Dividing by dt , we obtain:

$$(\Omega \cdot \mathbf{n})vN(\mathbf{x}, \Omega, E, t)dSd\Omega dE = \text{the rate (number per second) at which neutrons, traveling in } d\Omega dE \text{ about } (\Omega, E), \text{ flow through } dS \text{ at time } t. \tag{20}$$

Each incremental surface dS has two normal vectors, \mathbf{n} and $-\mathbf{n}$. The choice of \mathbf{n} determines “positive” and “negative” directions of flow through dS . A positive (negative) rate indicates flow through dS in the hemisphere of directions $\Omega \cdot \mathbf{n} > 0$ ($\Omega \cdot \mathbf{n} < 0$). (see Fig. 13).

Figure 13

“Positive” and “negative” directions of neutron flow through dS

The *angular flux* (or *fluence rate*) $\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ is defined by:

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) = vN(\mathbf{x}, \boldsymbol{\Omega}, E, t), \quad (21)$$

where $v = \sqrt{2E/m}$ is the neutron speed. The dimensions of ψ are $\text{cm}^{-2} \text{MeV}^{-1} \text{s}^{-1}$. A physical interpretation for ψ is obtained by considering neutrons in $dVd\boldsymbol{\Omega}dE$ about $(\mathbf{x}, \boldsymbol{\Omega}, E)$ at time t . During a time increment dt about t ,

$$\begin{aligned} \psi dVd\boldsymbol{\Omega}dEdt &= v(NdVd\boldsymbol{\Omega}dE)dt \\ &= (vdt)(NdVd\boldsymbol{\Omega}dE) \\ &= [\text{distance (path length) traveled by one neutron in time } dt] \\ &\quad \times [\text{number of neutrons in } dVd\boldsymbol{\Omega}dE \text{ about } (\mathbf{x}, \boldsymbol{\Omega}, E)] \\ &= \text{total path length traveled by neutrons, in } dVd\boldsymbol{\Omega}dE \\ &\quad \text{about } (\mathbf{x}, \boldsymbol{\Omega}, E), \text{ during time increment } dt \text{ about } t. \end{aligned}$$

Dividing by dt , we obtain the following *volume-based interpretation* for ψ :

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)dVd\boldsymbol{\Omega}dE = \text{rate at which path length is generated by neutrons in } dVd\boldsymbol{\Omega}dE \text{ about } (\mathbf{x}, \boldsymbol{\Omega}, E) \text{ at time } t. \quad (22)$$

(Hence, ψ is sometimes called the *path length density*.) Also, (20) implies the following *surface-based interpretation* for ψ :

$$|\boldsymbol{\Omega} \cdot \mathbf{n}|\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)dSd\boldsymbol{\Omega}dE = \text{the absolute rate at which neutrons, traveling in } d\boldsymbol{\Omega}dE \text{ about } (\boldsymbol{\Omega}, E), \text{ flow through } dS \text{ at time } t. \quad (23)$$

If the surface increment dS is perpendicular to the direction of neutron travel (i.e., if $\mathbf{n} = \boldsymbol{\Omega}$) (Fig. 14), then (23) reduces to:

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)dSd\boldsymbol{\Omega}dE = \text{the absolute rate at which neutrons, traveling in } d\boldsymbol{\Omega}dE \text{ about } (\boldsymbol{\Omega}, E), \text{ flow through a surface increment } dS \text{ perpendicular to } \boldsymbol{\Omega} \text{ at time } t. \quad (24)$$

Figure 14

Neutron flow through dS in the direction $\Omega = n$

Equation (22) defines ψ in terms of a volume element dV , while (23) and (24) define ψ in terms of a surface element dS . Both interpretations are useful.

For example, if R is a subregion of V and \mathbf{n} is the unit outer normal vector on ∂R , then (23) implies:

$$\begin{aligned} J_R^+(t) &\equiv \int_0^\infty \int_{\partial R} \int_{\Omega \cdot \mathbf{n} > 0} \Omega \cdot \mathbf{n} \psi(\mathbf{x}, \Omega, E, t) d\Omega dS dE \\ &= \text{the rate at which neutrons flow (leak) out of } R \text{ at time } t, \end{aligned} \quad (25a)$$

$$\begin{aligned} J_R^-(t) &\equiv \int_0^\infty \int_{\partial R} \int_{\Omega \cdot \mathbf{n} < 0} |\Omega \cdot \mathbf{n}| \psi(\mathbf{x}, \Omega, E, t) d\Omega dS dE \\ &= \text{the rate at which neutrons flow into } R \text{ at time } t. \end{aligned} \quad (25b)$$

Therefore,

$$\begin{aligned} J_R(t) &\equiv J_R^+(t) - J_R^-(t) \\ &= \int_0^\infty \int_{\partial R} \int_{4\pi} (\Omega \cdot \mathbf{n}) \psi(\mathbf{x}, \Omega, E, t) d\Omega dS dE \\ &= \text{the net rate at which neutrons flow (leak) out of } R \text{ at time } t. \end{aligned} \quad (26)$$

Using the *divergence theorem*,

$$\int_{\partial R} \mathbf{n} f(\mathbf{x}) dS = \int_R \nabla f(\mathbf{x}) dV, \quad (27)$$

we obtain from (26) the equivalent result:

$$\begin{aligned} J_R(t) &= J_R^+(t) - J_R^-(t) \\ &= \int_0^\infty \int_R \int_{4\pi} (\Omega \cdot \nabla) \psi(\mathbf{x}, \Omega, E, t) d\Omega dV dE \\ &= \text{the net rate at which neutrons flow (leak) out of } R \text{ at time } t. \end{aligned} \quad (28)$$

Thus, the “surface” definition (23) of ψ can be used to determine the rates at which neutrons flow across surfaces. (Equations (25) also hold for surfaces that are not closed, i.e., that do not enclose a volume.)

The “volume” definition (22) of ψ is useful because the number of collisions with nuclei that neutrons experience in an incremental time interval is proportional to the incremental distance that the neutrons travel during that time interval. Thus, *the rate at which neutrons interact with nuclei in a volume is proportional to the rate at which the neutrons generate path length in the volume*. The constants of proportionality are the macroscopic cross sections.

In addition to the neutron angular flux $\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)$, the *precursor densities* $C_j(\mathbf{x}, t)$ for the six delayed neutron precursor groups are also required. For $1 \leq j \leq 6$ and for an incremental volume dV about \mathbf{x} , these are defined by:

$$C_j(\mathbf{x}, t)dV = \begin{array}{l} \text{the number of group-}j \text{ precursor nuclei} \\ \text{in } dV \text{ about } \mathbf{x} \text{ at time } t. \end{array} \quad (29)$$

Each precursor nucleus will eventually decay and emit one delayed neutron. Thus, the rate at which group- j precursor nuclei experience radioactive decay equals the rate at which delayed neutrons are emitted by these nuclei.

2.4 Internal and Boundary Sources

In addition to the physical data described above, neutron sources must be prescribed. These exist in two categories: *internal sources* and *boundary sources*.

An internal neutron source $Q(\mathbf{x}, E, t)$, generally produced by radioactive decay, is located inside the physical system V and is usually *isotropic* (in radioactive decay, neutrons are emitted in all directions $\boldsymbol{\Omega}$ with equal probability). Q is defined by:

$$\frac{Q(\mathbf{x}, E, t)}{4\pi}dVd\boldsymbol{\Omega}dE = \begin{array}{l} \text{the incremental rate at which neutrons} \\ \text{are produced in } dVd\boldsymbol{\Omega}dE \text{ about } (\mathbf{x}, \boldsymbol{\Omega}, E) \\ \text{from an internal source, at time } t. \end{array} \quad (30a)$$

This definition implies that the numerical value of Q is independent of dV , $d\boldsymbol{\Omega}$, and dE . The factor 4π is included so that integration of (30a) over the unit sphere gives the following equivalent (for an isotropic source) definition:

$$Q(\mathbf{x}, E, t)dVdE = \begin{array}{l} \text{the incremental rate at which neutrons are} \\ \text{isotropically introduced into } dVdE \text{ about } (\mathbf{x}, E) \\ \text{from an internal source, at time } t. \end{array} \quad (30b)$$

$Q(\mathbf{x}, E, t)$ must be specified for all points \mathbf{x} in V , all energies E , and all times after the initial time.

Boundary sources are specified neutron fluxes that enter the physical system V through its outer boundary ∂V . V is usually assumed to be convex; then neutrons leaking out of V cannot reenter through ∂V . The boundary angular flux $\psi^b(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ is an external source, independent of the flux within the system, which must be specified for: (i) all points on the outer boundary of the system ($\mathbf{x} \in \partial V$), (ii) all directions of flight pointing into the system ($\boldsymbol{\Omega} \cdot \mathbf{n} < 0$, where \mathbf{n} is the unit outer normal vector at $\mathbf{x} \in \partial V$), (iii) all energies, and (iv) all times after the initial time. The angular flux is required to satisfy:

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) = \psi^b(\mathbf{x}, \boldsymbol{\Omega}, E, t), \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \quad 0 < E < \infty, \quad 0 < t. \quad (31)$$

If $\psi^b = 0$, ∂V is called a *vacuum boundary* (► Fig. 15).

Figure 15
Incident directions of flight on ∂V

The internal and boundary neutron sources are specified and independent of the neutron distribution within V . Generally, neutron transport problems are *driven* by these known sources, which generate the “original” neutrons in the problem. After neutrons are introduced into V by the internal or boundary sources, they “transport” within V according to the physical processes of streaming, absorption, scattering, and fission, discussed above.

In nuclear reactor problems, the term *fission source* describes the neutrons that are produced by fission events in V . This “source” directly depends on ψ and must be calculated. Likewise, the *scattering source* of neutrons emitted from scattering events also directly depends on ψ and must be calculated. (Thus, the term “source” sometimes describes a quantity that depends on ψ .) However, to repeat, the *internal* and *boundary* sources are independent of ψ and must be specified.

2.5 The Time-Dependent Equations of Neutron Transport

Next, we derive seven mathematical equations that determine the neutron angular flux $\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ and the six neutron precursor densities $C_j(\mathbf{x}, t)$. Each of these seven equations is a *conservation equation* – each is based on the simple physical concept that the rate of change (of neutrons and precursor densities within increments of phase space) equals the rate of gain minus the rate of loss.

We first consider the incremental population of neutrons within $dVd\Omega dE$ about $(\mathbf{x}, \boldsymbol{\Omega}, E)$ at time t . By (19), the number of these neutrons is:

$$dN = N(\mathbf{x}, \boldsymbol{\Omega}, E, t) dVd\Omega dE = \frac{1}{v} \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) dVd\Omega dE.$$

Thus, the time rate of change of dN is:

$$\begin{aligned} \frac{\partial N}{\partial t} &= \frac{1}{v} \frac{\partial \psi}{\partial t}(\mathbf{x}, \boldsymbol{\Omega}, E, t) dVd\Omega dE \\ &= (\text{rate of gain}) - (\text{rate of loss}). \end{aligned} \tag{32a}$$

From our discussion of neutron physics, we have:

$$\begin{aligned} \text{Rate of loss} &= (\text{collision rate} + \text{net leakage rate}) \\ &\text{in } dVd\Omega dE \text{ about } (\mathbf{x}, \boldsymbol{\Omega}, E) \text{ at time } t, \end{aligned} \quad (32b)$$

and:

$$\begin{aligned} \text{Rate of gain} &= (\text{in-scattering rate} + \text{prompt fission rate} + \text{delayed fission rate} \\ &+ \text{source rate}) \text{ in } dVd\Omega dE \text{ about } (\mathbf{x}, \boldsymbol{\Omega}, E) \text{ at time } t. \end{aligned} \quad (32c)$$

First, we consider the “loss” terms in (32a) and (32b). From (5a) and (19) we have, using $v = ds/dt$, for neutrons in $dVd\Omega dE$ about $(\mathbf{x}, \boldsymbol{\Omega}, E)$:

$$\begin{aligned} \Sigma_t(E)\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)dVd\Omega dE &= \Sigma_t(E) \frac{ds}{dt} N(\mathbf{x}, \boldsymbol{\Omega}, E, t) dVd\Omega dE \\ &= \frac{1}{dt} [\Sigma_t(E) ds] [N(\mathbf{x}, \boldsymbol{\Omega}, E, t) dVd\Omega dE] \\ &= \frac{1}{dt} \left[\begin{array}{l} \text{the probability that a (single) neutron with energy } E \\ \text{will undergo a collision in time interval } dt \end{array} \right] \\ &\quad \times \left[\begin{array}{l} \text{the number of neutrons in } dVd\Omega dE \text{ about} \\ (\mathbf{x}, \boldsymbol{\Omega}, E, t) \text{ at time } t \end{array} \right] \\ &= \frac{1}{dt} \left[\begin{array}{l} \text{the number of collisions in } dVd\Omega dE \text{ about } (\mathbf{x}, \boldsymbol{\Omega}, E) \\ \text{in time interval } dt \text{ about } t \end{array} \right] \\ &= \text{Collision rate (in [32b])}. \end{aligned} \quad (33a)$$

Also, in (28), we let R shrink to an incremental volume dV and directly get:

$$\boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) dVd\Omega dE = \text{Net leakage rate (in [32b])}. \quad (33b)$$

Introducing (33) into (32b), we obtain:

$$\text{Rate of loss} = [\Sigma_t(E)\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)] dVd\Omega dE. \quad (34)$$

The derivation of (33b) relies on the use of the divergence theorem (27) to convert a surface integral into a volume integral. A more physically intuitive understanding of (33b) can be obtained by considering dV to be a special cylindrical volume. Specifically, let us consider neutrons in $dVd\Omega dE$ about $(\mathbf{x}, \boldsymbol{\Omega}, E)$, where dV is an incremental cylindrical volume of length ds and cross-sectional area dA , centered at \mathbf{x} and oriented in the direction $\boldsymbol{\Omega}$, as depicted in

► Fig. 16.

Figure 16
 Cylindrical incremental volume dV

Then $dV = dsdA$, and neutrons in $d\Omega dE$ about (Ω, E) flow into dV through the surface dA at $\mathbf{x} - (ds/2)\Omega$, and flow out of dV through the surface dA at $\mathbf{x} + (ds/2)\Omega$. Hence, by (24), we have:

$$\begin{aligned}
 & \text{Net rate at which neutrons in } d\Omega dE \text{ about } (\Omega, E) \text{ leak out of } dV \\
 &= \left[\psi \left(\mathbf{x} + \frac{ds}{2} \Omega, E \right) - \psi \left(\mathbf{x} - \frac{ds}{2} \Omega, E \right) \right] dA d\Omega dE \\
 &= \left[\frac{\psi \left(\mathbf{x} + \frac{ds}{2} \Omega, E \right) - \psi \left(\mathbf{x} - \frac{ds}{2} \Omega, E \right)}{ds} \right] dV d\Omega dE \\
 &= [\Omega \cdot \nabla \psi(\mathbf{x}, \Omega, E)] dV d\Omega dE. \tag{35}
 \end{aligned}$$

Next, we consider the “gain” terms in (32a) and (32c). From (12) and (19), we have for neutrons in $dV d\Omega' dE'$ about $(\mathbf{x}, \Omega', E')$:

$$\begin{aligned}
 & \Sigma_s(\Omega' \cdot \Omega, E' \rightarrow E) \psi(\mathbf{x}, \Omega', E', t) dV d\Omega' dE' d\Omega dE \\
 &= \Sigma_s(\Omega' \cdot \Omega, E' \rightarrow E) \frac{ds}{dt} N(\mathbf{x}, \Omega', E', t) dV d\Omega' dE' d\Omega dE \\
 &= \frac{1}{dt} [N(\mathbf{x}, \Omega', E', t) dV d\Omega' dE'] [\Sigma_s(\Omega' \cdot \Omega, E' \rightarrow E) ds d\Omega dE] \\
 &= \frac{1}{dt} \left[\text{the number of neutrons in } dV d\Omega' dE' \text{ about } (\mathbf{x}, \Omega', E') \text{ at time } t \right] \\
 &\quad \times \left[\text{the probability that one of these neutrons will scatter into} \right. \\
 &\quad \left. d\Omega dE \text{ about } (\Omega, E) \text{ during time interval } dt \right] \\
 &= \frac{1}{dt} \left[\text{the number of neutrons in } dV \text{ about } \mathbf{x} \text{ that scatter from} \right. \\
 &\quad \left. d\Omega' dE' \text{ about } (\Omega', E') \text{ into } d\Omega dE \text{ about } (\Omega, E) \right. \\
 &\quad \left. \text{during time interval } dt \text{ about } t \right]
 \end{aligned}$$

= the rate at which neutrons in dV about \mathbf{x} scatter from $d\Omega'dE'$
 = the rate at which neutrons in dV about \mathbf{x} scatter from $d\Omega'dE'$
 about (Ω', E') into $d\Omega dE$ about (Ω, E) at time t .

Integrating this expression over all initial directions Ω' and energies E' , we obtain:

$$\left[\int_0^\infty \int_{4\pi} \Sigma_s(\Omega' \cdot \Omega, E' \rightarrow E) \psi(\mathbf{x}, \Omega', E', t) d\Omega' dE' \right] dV d\Omega dE$$

= the rate at which neutrons in dV about \mathbf{x} scatter
 into $d\Omega dE$ about (Ω, E) at time t
 = In-scattering rate (in [32c]).

(36a)

Similarly, the rate at which prompt fission neutrons are produced in $dV d\Omega' dE'$ about $(\mathbf{x}, \Omega', E')$ is given by:

$$[1 - \beta(E')] v(E') \Sigma_f(E') \psi(\mathbf{x}, \Omega', E', t) dV d\Omega' dE'.$$

Integrating this expression over all initial directions Ω' and energies E' , and multiplying by $[\chi_p(E)/4\pi] d\Omega dE$, we obtain:

$$\left[\frac{\chi_p(E)}{4\pi} \int_0^\infty \int_{4\pi} [1 - \beta(E')] v(E') \Sigma_f(E') \psi(\mathbf{x}, \Omega', E', t) d\Omega' dE' \right] dV d\Omega dE$$

= the rate at which prompt fission neutrons are
 produced in $dV d\Omega dE$ about (\mathbf{x}, Ω, E) at time t .

(36b)

Also,

$$\sum_{j=1}^6 \frac{\chi_j(E)}{4\pi} \lambda_j C_j(\mathbf{x}, t) dV d\Omega dE = \text{the rate at which delayed neutrons}$$

are emitted into $dV d\Omega dE$
 about (\mathbf{x}, Ω, E) at time t .

(36c)

Finally, by (30a), we have:

$$\frac{Q(\mathbf{x}, E, t)}{4\pi} dV d\Omega dE = \text{source rate (in [32c])}.$$
(37)

Introducing (36) and (37) into (32c), we obtain:

$$\begin{aligned} \text{Rate of gain} = & \left[\int_0^\infty \int_{4\pi} \Sigma_s(\Omega' \cdot \Omega, E' \rightarrow E) \psi(\mathbf{x}, \Omega', E', t) d\Omega' dE' \right. \\ & + \frac{\chi_p(E)}{4\pi} \int_0^\infty \int_{4\pi} [1 - \beta(E')] v \Sigma_f(E') \psi(\mathbf{x}, \Omega', E', t) d\Omega' dE' \\ & \left. + \frac{1}{4\pi} \sum_{j=1}^6 \chi_j(E) \lambda_j C_j(\mathbf{x}, t) + \frac{1}{4\pi} Q(\mathbf{x}, E, t) \right] dV d\Omega dE. \end{aligned}$$
(38)

Introducing the rate of loss terms (34) and the rate of gain terms (38) into the general conservation equation (32a), we get:

$$\begin{aligned} \frac{1}{v} \frac{\partial \psi}{\partial t} dV d\Omega dE = & \left[\int_0^\infty \int_{4\pi} \Sigma_s \psi d\Omega' dE' + \frac{\chi_p}{4\pi} \int_0^\infty \int_{4\pi} [1 - \beta] v \Sigma_f \psi d\Omega' dE' \right. \\ & \left. + \frac{1}{4\pi} \sum_{j=1}^6 \chi_j \lambda_j C_j + \frac{1}{4\pi} Q \right] dV d\Omega dE - \left[\Sigma_t \psi + \boldsymbol{\Omega} \cdot \nabla \psi \right] dV d\Omega dE. \end{aligned}$$

Dividing by $dV d\Omega dE$ and rearranging, we obtain the following first-order *integro-differential* equation:

$$\begin{aligned} \frac{1}{v} \frac{\partial \psi}{\partial t}(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \Sigma_t(E) \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \\ = \int_0^\infty \int_{4\pi} \Sigma_s(\boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}, E' \rightarrow E) \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\Omega' dE' \\ + \frac{\chi_p(E)}{4\pi} \int_0^\infty \int_{4\pi} [1 - \beta(E')] v \Sigma_f(E') \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\Omega' dE' \\ + \frac{1}{4\pi} \sum_{j=1}^6 \chi_j(E) \lambda_j C_j(\mathbf{x}, t) + \frac{1}{4\pi} Q(\mathbf{x}, E, t). \end{aligned} \quad (39)$$

This is the *time-dependent neutron transport equation (with delayed neutron precursors)*, also called the *linear Boltzmann equation*. The derivation of this equation shows that each of its terms describes a specific physical process that causes a gain or loss of neutrons in each increment of phase space.

We must also derive an equation for each precursor density. The time rate of change of the species- j precursor density may be expressed as:

$$\begin{aligned} \frac{\partial C_j}{\partial t}(\mathbf{x}, t) dV = & \text{the rate of change of the number of group-}j \\ & \text{precursor nuclei in } dV \text{ about } \mathbf{x} \text{ at time } t \\ = & (\text{Rate of gain}) - (\text{rate of loss}). \end{aligned} \quad (40)$$

The rate of loss (due to decay) of these precursors is given by:

$$\begin{aligned} \lambda_j C_j(\mathbf{x}, t) dV = & \text{the rate at which group-}j \text{ precursor nuclei undergo} \\ & \text{radioactive decay in } dV \text{ about } \mathbf{x} \text{ at time } t. \end{aligned} \quad (41)$$

On the other hand,

$$\begin{aligned} \beta_j(E') v \Sigma_f(E') \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) dV d\Omega' dE' \\ = & \text{the rate at which group-}j \text{ precursor nuclei are produced} \\ & \text{by neutrons in } dV d\Omega' dE' \text{ about } (\mathbf{x}, \boldsymbol{\Omega}', E') \text{ at time } t. \end{aligned}$$

Integrating over Ω' and E' , we get the total rate of gain of the group- j precursor nuclei:

$$\left[\int_0^\infty \int_{4\pi} \beta_j(E') v \Sigma_f(E') \psi(\mathbf{x}, \Omega', E', t) d\Omega' dE' \right] dV$$

= the rate at which group- j precursor nuclei
are produced in dV about \mathbf{x} at time t .

(42)

After some rearrangement, (40–42) give for $1 \leq j \leq 6$ the following equations for the precursor densities:

$$\frac{\partial C_j}{\partial t}(\mathbf{x}, t) + \lambda_j C_j(\mathbf{x}, t) = \int_0^\infty \int_{4\pi} \beta_j(E') v \Sigma_f(E') \psi(\mathbf{x}, \Omega', E', t) d\Omega' dE'. \quad (43)$$

As with the transport equation, each term in these equations describes a physical process that causes a gain or loss of group- j neutron precursor nuclei.

Equation (43) must be solved jointly with the neutron transport equation (39). In addition, ψ must satisfy the boundary condition:

$$\psi(\mathbf{x}, \Omega, E, t) = \psi^b(\mathbf{x}, \Omega, E, t), \quad \mathbf{x} \in \partial V, \quad \Omega \cdot \mathbf{n} < 0, \quad 0 < E < \infty, \quad 0 < t, \quad (44)$$

and ψ and C_j must satisfy the initial conditions:

$$\psi(\mathbf{x}, \Omega, E, 0) = \psi^i(\mathbf{x}, \Omega, E), \quad \mathbf{x} \in V, \quad \Omega \in 4\pi, \quad 0 < E < \infty, \quad (45a)$$

$$C_j(\mathbf{x}, 0) = C_j^i(\mathbf{x}), \quad \mathbf{x} \in V, \quad (45b)$$

where ψ^b , ψ^i , and C_j^i are specified.

In full generality, the neutron angular flux $\psi(\mathbf{x}, \Omega, E, t)$ and the precursor densities $C_j(\mathbf{x}, t)$ are obtained by solving (39) and (43), subject to the boundary condition stated in (44) and the initial conditions stated in (45). The subject of *nuclear reactor kinetics* is based on this system of equations.

2.6 Time-Dependent Neutron Transport Without Delayed Neutrons

In some time-dependent problems, the relatively small value of β (≈ 0.01) justifies the neglect of the delayed neutron terms. In such problems one can set $\beta_j = C_j = 0$ in (39). The resulting single transport equation for ψ :

$$\begin{aligned} & \frac{1}{v} \frac{\partial \psi}{\partial t}(\mathbf{x}, \Omega, E, t) + \Omega \cdot \nabla \psi(\mathbf{x}, \Omega, E, t) + \Sigma_t(E) \psi(\mathbf{x}, \Omega, E, t) \\ &= \int_0^\infty \int_{4\pi} \Sigma_s(\Omega' \cdot \Omega, E' \rightarrow E) \psi(\mathbf{x}, \Omega', E', t) d\Omega' dE' \\ &+ \frac{\chi_p(E)}{4\pi} \int_0^\infty \int_{4\pi} v \Sigma_f(E') \psi(\mathbf{x}, \Omega', E', t) d\Omega' dE' + \frac{1}{4\pi} Q(\mathbf{x}, E, t), \end{aligned} \quad (46a)$$

is solved subject to the boundary condition (44) and initial condition (45a):

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) = \psi^b(\mathbf{x}, \boldsymbol{\Omega}, E, t), \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \quad 0 < E < \infty, \quad 0 < t, \quad (46b)$$

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E, 0) = \psi^i(\mathbf{x}, \boldsymbol{\Omega}, E), \quad \mathbf{x} \in V, \quad \boldsymbol{\Omega} \in 4\pi, \quad 0 < E < \infty. \quad (46c)$$

2.7 The Steady-State Neutron Transport Equation

In steady-state problems, the precursor densities can be eliminated to obtain a single equation for ψ . Setting $\partial C_j / \partial t = 0$, in (43), we get:

$$\lambda_j C_j(\mathbf{x}) = \int_0^\infty \int_{4\pi} \beta_j(E') \nu \Sigma_f(E') \psi(\mathbf{x}, \boldsymbol{\Omega}', E') d\Omega' dE',$$

and introducing these expressions into the steady-state equation (39), we obtain:

$$\begin{aligned} & \boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}, E) + \Sigma_t(E) \psi(\mathbf{x}, \boldsymbol{\Omega}, E) \\ &= \int_0^\infty \int_{4\pi} \Sigma_s(\boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}, E' \rightarrow E) \psi(\mathbf{x}, \boldsymbol{\Omega}', E') d\Omega' dE' \\ &+ \frac{\chi_p(E)}{4\pi} \int_0^\infty \int_{4\pi} [1 - \beta(E')] \nu \Sigma_f(E') \psi(\mathbf{x}, \boldsymbol{\Omega}', E') d\Omega' dE' \\ &+ \frac{1}{4\pi} \sum_{j=1}^6 \chi_j(E) \int_0^\infty \int_{4\pi} \beta_j(E') \nu \Sigma_f(E') \psi(\mathbf{x}, \boldsymbol{\Omega}', E') d\Omega' dE' + \frac{1}{4\pi} Q(\mathbf{x}, E). \end{aligned} \quad (47)$$

Since $\beta = \sum \beta_j \approx 0.01$, it is often acceptable to set $\beta_j = 0$. In this case, (47) simplifies to:

$$\begin{aligned} & \boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}, E) + \Sigma_t(E) \psi(\mathbf{x}, \boldsymbol{\Omega}, E) \\ &= \int_0^\infty \int_{4\pi} \Sigma_s(\boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}, E' \rightarrow E) \psi(\mathbf{x}, \boldsymbol{\Omega}', E') d\Omega' dE' \\ &+ \frac{\chi_p(E)}{4\pi} \int_0^\infty \int_{4\pi} \nu \Sigma_f(E') \psi(\mathbf{x}, \boldsymbol{\Omega}', E') d\Omega' dE' \\ &+ \frac{1}{4\pi} Q(\mathbf{x}, E), \quad \mathbf{x} \in V, \quad \boldsymbol{\Omega} \in 4\pi, \quad 0 < E < \infty. \end{aligned} \quad (48a)$$

The first term on the right side of this equation is often called the *scattering source*. The second term is the *fission source*; this is isotropic and *separable* in space and energy – it is the product of a (known) function of energy and an (unknown) function only of space. (This separable form of the fission source is useful in developing strategies to solve [48a].) The third term is the specified *internal source*.

Equation (48a) must be solved subject to the steady-state boundary condition:

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E) = \psi^b(\mathbf{x}, \boldsymbol{\Omega}, E), \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \quad 0 < E < \infty, \quad (48b)$$

which is obtained from (44). As before, if the specified incident boundary flux $\psi^b = 0$, then ∂V is called a *vacuum boundary*.

2.8 k -Eigenvalue Problems

In steady-state reactor calculations, one often sees the following version of (48) in which the inhomogeneous source Q and the boundary source ψ^b are set to zero, and the fission source is modified by a constant factor $1/k$:

$$\begin{aligned} \Omega \cdot \nabla \psi(\mathbf{x}, \Omega, E) + \Sigma_t(E)\psi(\mathbf{x}, \Omega, E) &= \int_0^\infty \int_{4\pi} \Sigma_s(\Omega' \cdot \Omega, E' \rightarrow E)\psi(\mathbf{x}, \Omega', E') d\Omega' dE' \\ &+ \frac{\chi_p(E)}{4\pi k} \int_0^\infty \int_{4\pi} \nu \Sigma_f(E')\psi(\mathbf{x}, \Omega', E') d\Omega' dE', \\ \mathbf{x} \in V, \quad \Omega \in 4\pi, \quad 0 < E < \infty, & \quad (49a) \\ \psi(\mathbf{x}, \Omega, E) = 0, \quad \mathbf{x} \in \partial V, \quad \Omega \cdot \mathbf{n} < 0, \quad 0 < E < \infty. & \quad (49b) \end{aligned}$$

These equations always have the zero solution: $\psi = 0$. The goal is to find the *largest* value of k such that a nonzero solution ψ exists. This k is called the *criticality* (or *criticality eigenvalue*) of the system V ; the corresponding ψ is called the *eigenfunction* or *fundamental mode*.

If a system V has a fissile region, then it can be shown that the criticality eigenvalue k always exists, and the corresponding eigenfunction ψ is unique (up to a multiplicative constant) and positive. (If V has no fissile region, then we adopt the convention that $k = 0$.)

The motivation for defining k in the above manner is as follows. In any system V with fission, neutrons are lost due to capture and leakage, and are produced by fission. If the production of neutrons due to fission exactly balances the loss of neutrons due to capture and leakage, then a nonzero, steady-state neutron flux is possible. (This concept underlies a steady-state power reactor.) By adjusting the magnitude of the fission source through the eigenvalue k , one can make this exact balance occur. If $k < 1$, the fission source must be increased for a steady-state solution to exist; this implies that capture and leakage dominate fission, and the reactor is *subcritical*. If $k > 1$, the fission source must be decreased for a steady-state solution to exist; this implies that fission dominates capture and leakage, and the reactor is *supercritical*. If $k = 1$, capture and leakage exactly balance fission, and the reactor is *critical*. The calculation of k for differing reactor configurations is one of the most important and ubiquitous calculations in the design and operation of nuclear reactors.

In some problems (in particular, the field of reactor kinetics), the criticality k is replaced by the *reactivity* ρ , defined by

$$\frac{1}{k} = 1 - \rho. \quad (50)$$

A reactor is subcritical if $\rho < 0$, critical if $\rho = 0$, and supercritical if $\rho > 0$.

2.9 The Monoenergetic Neutron Transport Equation

A common simplifying assumption is to ignore energy dependence altogether, giving the so-called *one-speed* or *monoenergetic* form of the transport equation. Despite an apparently drastic approximation of the physics, this equation has been, and continues to be, the subject of much investigation, for several reasons. Under certain circumstances, the absence of the energy variable promotes a rigorous mathematical analysis of the transport equation, in

particular the establishment of existence, uniqueness, and completeness theorems for elementary solutions of the transport equation. Also, in special geometries, it is sometimes possible to construct analytic solutions to the one-speed transport equation. These solutions serve as benchmarks against which approximation methods and numerical solution techniques can be evaluated, and they provide insight into the nature of the transport process. In addition, in the widely used *multigroup* treatment of the energy variable in numerical work, the group-wise equations for the group-averaged angular fluxes are of one-speed form. Neutron transfers into a given energy group from all other groups appear only as sources in that group. Thus, methods developed for the solution of the one-speed transport equation can be applicable even when the energy variable is retained.

The monoenergetic transport equation can be derived from first principles, as we did above for the energy-dependent case, but with the one-speed assumption introduced at the outset. Alternatively, the energy-dependent transport equation (48a), in the steady-state case, can be manipulated to obtain the same result. We do this next.

The restriction of (48a) to single-energy neutrons requires the following assumptions:

1. The angular deflection of neutrons during scattering occurs without energy loss. In this case the differential cross section given in (11) can be expressed as:

$$\Sigma_s(\boldsymbol{\Omega} \cdot \boldsymbol{\Omega}', E \rightarrow E') = \Sigma_s(E', \boldsymbol{\Omega} \cdot \boldsymbol{\Omega}') \delta(E' - E). \quad (51a)$$

2. The internal and boundary sources are monoenergetic at some characteristic energy E_0 :

$$Q(\mathbf{x}, E) = Q(\mathbf{x}) \delta(E - E_0), \quad (51b)$$

$$\psi^b(\mathbf{x}, \boldsymbol{\Omega}, E) = \psi^b(\mathbf{x}, \boldsymbol{\Omega}) \delta(E - E_0). \quad (51c)$$

3. All fission neutrons are born at the characteristic energy E_0 :

$$\chi_p(E) = \delta(E - E_0). \quad (51d)$$

Then, since all neutrons are “born” with energy E_0 and cannot change their energy through scattering, the angular flux must contain only neutrons with energy E_0 :

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E) = \psi(\mathbf{x}, \boldsymbol{\Omega}) \delta(E - E_0). \quad (52)$$

Introducing (51–52) into (48a), we find that $\psi(\mathbf{x}, \boldsymbol{\Omega})$ satisfies the following energy-independent equation:

$$\begin{aligned} \boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}) + \Sigma_t(E_0) \psi(\mathbf{x}, \boldsymbol{\Omega}) &= \int_{4\pi} \Sigma_s(E_0, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) \psi(\mathbf{x}, \boldsymbol{\Omega}') d\Omega' \\ &+ \frac{\nu \Sigma_f(E_0)}{4\pi} \int_{4\pi} \psi(\mathbf{x}, \boldsymbol{\Omega}') d\Omega' + \frac{Q(\mathbf{x})}{4\pi}, \quad \mathbf{x} \in V, \quad \boldsymbol{\Omega} \in 4\pi, \end{aligned} \quad (53)$$

with boundary condition:

$$\psi(\mathbf{x}, \boldsymbol{\Omega}) = \psi^b(\mathbf{x}, \boldsymbol{\Omega}), \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0. \quad (54)$$

The energy variable appears here only as a parameter, serving to fix the numerical values of the scattering, fission, and total cross section.

Further simplification ensues when scattering is isotropic in the laboratory frame, for then the differential cross section in (53) can be written as:

$$\Sigma_s(E_0, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) \equiv \Sigma_s(E_0) p(E_0, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) = \frac{\Sigma_s(E_0)}{4\pi}, \quad (55)$$

and (53) becomes:

$$\boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}) + \Sigma_t \psi(\mathbf{x}, \boldsymbol{\Omega}) = \frac{(\Sigma_s + \nu \Sigma_f)}{4\pi} \int_{4\pi} \psi(\mathbf{x}, \boldsymbol{\Omega}') d\Omega' + \frac{Q(\mathbf{x})}{4\pi}. \quad (56)$$

Finally, when the system is *homogeneous* (the cross sections are independent of \mathbf{x}) and the dimensionless *optical depth* variable is introduced:

$$\boldsymbol{\tau} = \mathbf{x} \Sigma_t, \quad (57)$$

then distance becomes measured in units of mean free paths and (56) assumes the following simpler form:

$$\boldsymbol{\Omega} \cdot \nabla \psi(\boldsymbol{\tau}, \boldsymbol{\Omega}) + \psi(\boldsymbol{\tau}, \boldsymbol{\Omega}) = \frac{c}{4\pi} \int_{4\pi} \psi(\boldsymbol{\tau}, \boldsymbol{\Omega}') d\Omega' + \frac{Q_0(\boldsymbol{\tau})}{4\pi}. \quad (58)$$

Here, $Q_0 = Q/\Sigma_t$ and c is the *mean number of secondary neutrons produced per collision*:

$$c = \frac{(\Sigma_s + \nu \Sigma_f)}{\Sigma_t}. \quad (59)$$

If $\nu \sigma_f = 0$, then $c = \Sigma_s/\Sigma_t$ is also called the *scattering ratio*.

Monoenergetic eigenvalue problems can be formulated by setting $\psi^b = 0$ in (54), $Q = 0$ in (56), and letting c be the eigenvalue. The k -eigenvalue is then given in terms of this eigenvalue, or *critical value of c* , by:

$$k = \frac{\nu \Sigma_f}{c \Sigma_t - \Sigma_s}.$$

2.10 Mathematical Issues

Next, we briefly discuss some fundamental (mathematical) questions. Specifically:

1. Do solutions $\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ and $C_j(\mathbf{x}, \boldsymbol{\Omega}, t)$ of the neutron transport equations exist?
2. Are the solutions unique?
3. Are the solutions nonnegative (as they should be, physically)?
4. What can be said about the *smoothness* of these solutions?

In our discussion of these questions, we make a few basic and practically relevant assumptions: the physical system V is specified and finite and has at most a finite number of subregions, each having its own material cross sections. (The cross sections are histogram functions of \mathbf{x} .) The prescribed internal source, the prescribed incident boundary fluxes, and the prescribed

neutron flux and precursor densities at the initial time ($t = 0$) are all specified and nonnegative. The eigenvalue k of V has been calculated (see ● sect. 2.5.4), and V is either subcritical ($0 \leq k < 1$), critical ($k = 1$), or supercritical ($k > 1$). In the following, we attempt to state the basic results with a minimum of mathematical detail.

2.10.1 Existence, Uniqueness, and Nonnegativity of Transport Solutions

Briefly, each time-dependent neutron transport problem, with or without precursor densities, *always* has a unique nonnegative solution. Steady-state neutron transport problems (in which precursor densities are neglected) do not always have a unique nonnegative solution, but when they do not, there is a physical explanation. (A classic theoretical discussion of the existence of solutions of time-dependent transport problems is given in Case and Zweifel (1967).)

To discuss the connection between solutions of time-dependent and steady-state neutron transport problems, we consider time-dependent and steady-state problems without precursor densities in which the internal source and the prescribed incident boundary fluxes are nonnegative and independent of t . We then have:

1. If V is subcritical ($k < 1$), the time-dependent neutron flux limits as $t \rightarrow \infty$ to a steady-state neutron flux, which is the (unique, nonnegative) solution of the steady-state neutron transport problem.
2. If V is critical ($k = 1$) and the internal source and prescribed incident boundary fluxes are *nonzero*, the time-dependent neutron flux grows linearly in t as $t \rightarrow \infty$. In this situation, no limiting ($t \rightarrow \infty$) steady-state solution of the time-dependent problem exists, and no solution of the corresponding steady-state neutron transport problem exists.

However, if the internal source and prescribed incident boundary fluxes are *zero*, then the time-dependent neutron flux limits as $t \rightarrow \infty$ to a steady-state neutron flux of the form:

$$\psi(\mathbf{x}, \Omega, E, t) \approx C\Psi(\mathbf{x}, \Omega, E) \quad \text{for } t \approx \infty, \quad (60)$$

where Ψ is the k -eigenfunction for the critical system and C is a constant that depends on the initial condition ψ^i of the time-dependent problem. In this situation, the steady-state neutron transport problem has an infinite number of solutions, all given by (60), with the constant C arbitrary.

3. If V is supercritical ($k > 1$), the time-dependent neutron flux grows exponentially in t as $t \rightarrow \infty$. If the internal source and prescribed incident boundary fluxes are nonzero, the corresponding steady-state neutron transport problem either has a unique nonpositive solution, or no solution exists.

If the internal source and prescribed incident boundary fluxes are *zero*, then the steady-state neutron transport problem will either have the solution $\psi = 0$, or an infinite number of solutions of the form of (60), where Ψ is now some other (than the $k = 1$) eigenfunction of the system; this eigenfunction is nonpositive (nonphysical).

In all cases, a unique, positive solution of the time-dependent neutron transport problem exists. Also, a positive solution of the steady-state neutron transport problem exists if and only if the solution of a corresponding time-dependent problem has a steady-state limit as $t \rightarrow \infty$; and if the steady-state limit of the time-dependent problem does exist, it *is* a solution of the steady-state problem. Some of these issues are discussed in Case and Zweifel (1967).

2.10.2 The n th Collided Fluxes

The solution of source-driven neutron transport problems can be written in an advantageous way. To illustrate, let us consider the following monoenergetic steady-state problem with isotropic scattering:

$$\boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}) + \Sigma_t(\mathbf{x})\psi(\mathbf{x}, \boldsymbol{\Omega}) = \frac{\Sigma_s(\mathbf{x})}{4\pi} \int_{4\pi} \psi(\mathbf{x}, \boldsymbol{\Omega}') d\boldsymbol{\Omega}' + \frac{Q(\mathbf{x})}{4\pi}, \quad \mathbf{x} \in V, \quad |\boldsymbol{\Omega}| = 1, \quad (61a)$$

$$\psi(\mathbf{x}, \boldsymbol{\Omega}) = \psi^b(\mathbf{x}, \boldsymbol{\Omega}), \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0. \quad (61b)$$

If we define the following problem for $\psi_0(\mathbf{x}, \boldsymbol{\Omega})$:

$$\boldsymbol{\Omega} \cdot \nabla \psi_0(\mathbf{x}, \boldsymbol{\Omega}) + \Sigma_t(\mathbf{x})\psi_0(\mathbf{x}, \boldsymbol{\Omega}) = \frac{Q(\mathbf{x})}{4\pi}, \quad \mathbf{x} \in V, \quad |\boldsymbol{\Omega}| = 1, \quad (62a)$$

$$\psi_0(\mathbf{x}, \boldsymbol{\Omega}) = \psi^b(\mathbf{x}, \boldsymbol{\Omega}), \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \quad (62b)$$

and for $1 \leq n < \infty$ the following problems for $\psi_n(\mathbf{x}, \boldsymbol{\Omega})$:

$$\boldsymbol{\Omega} \cdot \nabla \psi_n(\mathbf{x}, \boldsymbol{\Omega}) + \Sigma_t(\mathbf{x})\psi_n(\mathbf{x}, \boldsymbol{\Omega}) = \frac{\Sigma_s(\mathbf{x})}{4\pi} \int_{4\pi} \psi_{n-1}(\mathbf{x}, \boldsymbol{\Omega}') d\boldsymbol{\Omega}', \quad \mathbf{x} \in V, \quad |\boldsymbol{\Omega}| = 1, \quad (63a)$$

$$\psi_n(\mathbf{x}, \boldsymbol{\Omega}) = 0, \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \quad (63b)$$

then it is possible to interpret each ψ_n as a particular “component” of ψ .

First, in (62) for ψ_0 , neutrons are *created* by the same internal and boundary sources and have the same mean free path as in (61); but when the neutrons in (62) experience a collision, they *die*. Thus, $\psi_0(\mathbf{x}, \boldsymbol{\Omega})$ describes the *uncollided* neutrons in problem (61) – the neutrons in V that have just been born and have yet to experience a collision in V or leak out of V .

Equation (63) for $n = 1$ have as their sole source the uncollided neutrons that scatter; when these (once-scattered) neutrons experience a collision, they die. Thus, $\psi_1(\mathbf{x}, \boldsymbol{\Omega})$ describes the *once-collided* neutron flux in problem (61) – the flux due to neutrons in V that have experienced exactly one scattering event and have yet to experience a second collision in V or leak out of V .

By continuing in this manner, we have for all $n \geq 0$,

$$\begin{aligned} \psi_n(\mathbf{x}, \boldsymbol{\Omega}) &= \text{the } n\text{th collided neutron flux} \\ &= \text{the flux due to neutrons in } V \text{ that have experienced} \\ &\quad \text{exactly } n \text{ scattering events in } V. \end{aligned} \quad (64)$$

Also, if (62) and (63) are summed over $0 \leq n < \infty$, it is easily seen that $\sum \psi_n$ satisfies (61) for ψ . Thus, the solution ψ of (61) can be written:

$$\psi(\mathbf{x}, \boldsymbol{\Omega}) = \sum_{n=0}^{\infty} \psi_n(\mathbf{x}, \boldsymbol{\Omega}). \quad (65)$$

Therefore: at any instant in time, the neutron population consists of “newly born” neutrons, which have experienced only a few collisions (and have scattered in each), with “older” neutrons,

which have experienced many collisions (and have also scattered in each). Moreover, (62) and (63) show how to explicitly calculate, for each n , the flux of neutrons that have experienced exactly n collisions.

This view of neutron transport problems has practical benefits. For example, numerical methods for solving (61) are usually based on the *source iteration* algorithm, in which, effectively, (62) and (63) are solved recursively and the results added, as in (65). Source iteration converges rapidly for small, leaky systems, or systems with significant capture cross sections; here neutrons are unlikely to have long lives, so $\psi_n \rightarrow 0$ quickly. However, source iteration converges slowly for “diffusive” problems, which are many mean free paths in width (having small leakage rates) and scattering-dominated (having small neutron capture rates). For diffusive problems, neutrons can have long lives, so $\psi_n \rightarrow 0$ slowly.

A second benefit of (61–65) occurs in solving problems with localized or point sources. Here, $\psi_0(\mathbf{x}, \Omega)$ [and to a lesser extent $\psi_1(\mathbf{x}, \Omega)$] are strongly varying functions of \mathbf{x} and Ω and are difficult to model numerically. A common strategy is to calculate the uncollided flux ψ_0 analytically and then calculate the collided fluxes ψ_n for $n \geq 1$ numerically. (In recent work, both ψ_0 and ψ_1 have been calculated analytically and the remaining ψ_n are calculated numerically.) This approach makes use of the fact that for point source problems, ψ_0 (and ψ_1) do not have to be treated by numerical methods that are likely to cause large errors.

A third practical benefit of (61–65) occurs in assessing the smoothness of solutions of (61). We briefly discuss this next and refer to Kellog (1974) for a more complete discussion.

2.10.3 Smoothness of the Angular Flux

This often poorly understood topic, dealing with the continuity and differentiability properties of the angular flux, has major implications in the accuracy of approximation schemes and numerical methods for simulating transport problems. It is not possible to discuss this subject fully here; instead we give some illustrative examples. (See Kellog (1974) for a more thorough discussion.) The basic facts are as follows:

1. Solutions of planar-geometry transport problems with vacuum boundaries and finite isotropic internal sources are *smooth* (continuous with continuous first derivatives) functions of x and μ , except at outer boundaries and material interfaces between regions with different cross sections and internal sources. At such interfaces, ψ is (i) continuous in x with a discontinuous first derivative, and (ii) discontinuous in μ at $\mu = 0$. This *boundary-layer* behavior occurs only at the interface between different material regions, and at the outer boundary of the system.
2. Angular flux solutions of multidimensional transport problems with vacuum boundaries exhibit the same boundary-layer behavior as described above at material interfaces and the outer boundary of the system. However, because of geometrical effects, multidimensional angular fluxes also lack smoothness away from boundary layers. Generally, multidimensional transport solutions are continuous functions of \mathbf{x} and Ω but have discontinuous first derivatives. Occasionally, these solutions can even be discontinuous. Thus, multidimensional transport solutions are inherently not “smooth”; they lack even one continuous derivative in \mathbf{x} and Ω . The lack of smoothness of the transport solution is an impediment to the calculation of accurate numerical solutions of multidimensional neutron transport problems.

3. Solutions of problems with nonzero but smooth prescribed incident boundary fluxes have the same smoothness properties as described above. However, if the incident boundary fluxes are not smooth, then the uncollided flux component of ψ can be nonsmooth throughout V . For example, an incident monodirectional (delta function) beam of neutrons on ∂V creates a delta function component of ψ that propagates entirely through V .

To illustrate the lack of smoothness for multidimensional problems (item 2 above), let us consider an infinite ($-\infty < x, y, z < \infty$) purely absorbing ($\Sigma_s = 0$) system with constant total cross section $\Sigma_t = \Sigma_\gamma$, driven by an isotropic, spatially histogram internal source:

$$Q(x, y) = \begin{cases} Q_0, & |x| < X, \quad |y| < Y, \\ 0, & \text{otherwise.} \end{cases} \quad (66)$$

Because of the lack of z -dependence in the geometry and sources, the angular flux ψ is independent of z . The neutron transport equation (see [56] and [2]) is:

$$\sqrt{1-\mu^2} \left(\cos \omega \frac{\partial \psi}{\partial x} + \sin \omega \frac{\partial \psi}{\partial y} \right) + \Sigma_t \psi(x, y, \mu, \omega) = \frac{Q(x, y)}{4\pi}. \quad (67)$$

Also, $\psi \rightarrow 0$ as $|x| \rightarrow \infty$ and $|y| \rightarrow \infty$.

The analytic solution, obtained by integrating (67) along the characteristic curve (the *flight path* of neutrons) $x(s) = x - s \cos \omega$, $y(s) = y - s \sin \omega$ for $0 < s < \infty$, can be written:

$$\psi(x, y, \mu, \omega) = \frac{1}{4\pi\sqrt{1-\mu^2}} \int_0^\infty Q(x - s \cos \omega, y - s \sin \omega) e^{-(\Sigma_t s / \sqrt{1-\mu^2})} ds. \quad (68)$$

If the point (x, y) is outside the source region (which we henceforth assume) and the flight path does not intersect the source region, then $\psi = 0$.

If the flight path intersects the boundary of the source region, it does so for two values of s : $s_0(x, y, \omega) \leq s_1(x, y, \omega)$, as shown in  Fig. 17. In this situation, we obtain explicitly from (68) and (66):

$$\begin{aligned} \psi(x, y, \mu, \omega) &= \frac{1}{\sqrt{1-\mu^2}} \int_{s_0}^{s_1} \frac{Q_0}{4\pi} e^{-(\Sigma_t s / \sqrt{1-\mu^2})} ds \\ &= \frac{Q_0}{4\pi\Sigma_t} \left(e^{-(\Sigma_t s_0(x, y, \omega) / \sqrt{1-\mu^2})} - e^{-(\Sigma_t s_1(x, y, \omega) / \sqrt{1-\mu^2})} \right). \end{aligned} \quad (69)$$

This result can be extended to all points (x, y) outside the source region and all ω by simply defining $s_0 = s_1$ when the flight path does not intersect the source region.

For fixed x, y , and ω , it is evident that $\psi(x, y, \mu, \omega)$ is continuous and infinitely differentiable in the variable μ , with $\psi \rightarrow 0$ as $\mu \rightarrow \pm 1$.

Also, s_0 and s_1 are continuous and infinitely differentiable for most values of x, y , and ω . However, for each spatial point (x, y) , there are generally four azimuthal angles ω for which the flight path passes through a corner of the source region (see  Fig. 18). At one or two of these phase space points, $s_1(x, y, \omega)$ is a continuous function of x, y , and ω , but it has discontinuous first derivatives with respect to all three of these variables! Likewise, at zero or one of these phase space points, $s_0(x, y, \omega)$ is a continuous function of x, y , and ω , but it has discontinuous first derivatives with respect to all three of these variables. At all four of these phase space points,

Figure 17
 $s_0(x, y, \omega)$ and $s_1(x, y, \omega)$

Figure 18
 $s_1(x, y, \omega)$ is not smooth at the indicated values of ω

$\psi(x, y, \mu, \omega)$ is a continuous function of x , y , and ω , but it has discontinuous first derivatives with respect to all three of these variables.

A more extreme situation occurs when the point (x, y) lies on a plane generated by an outer edge of the source region, and when the flight path traces along this outer edge of the source region. For example, from (68) we get for $x > X$, $y = Y$, $\omega = 0$, and any $\epsilon > 0$ (see Fig. 18):

$$\psi(x, Y + \epsilon, \mu, 0) = 0, \tag{70a}$$

$$\psi(x, Y - \epsilon, \mu, 0) = \frac{Q_0}{4\pi\Sigma_t} \left(e^{-\Sigma_t(x-X)/\sqrt{1-\mu^2}} - e^{-\Sigma_t(x+X)/\sqrt{1-\mu^2}} \right). \tag{70b}$$

This implies that at the phase space point $(x, y, \mu, \omega) = (x, Y, \mu, 0)$, ψ is a discontinuous function of y . (And, a discontinuous function of ω .)

This simple problem applies to the uncollided angular flux in any source-driven problem. In general, when the flight path $\mathbf{x} - s\boldsymbol{\Omega}$ passes through a “corner” of a source region, $\psi(\mathbf{x}, \boldsymbol{\Omega}, E)$ is continuous with a discontinuous derivative (with respect to x , y , or ω). When the flight path passes through a corner of a material region that does not contain a source, ψ has a weaker singularity (a continuous first derivative but a discontinuous second derivative). And, as we showed above, when the flight path traces along the planar edge of a source region, ψ is discontinuous. For problems with scattering, the statements in this paragraph hold for each n th collided flux ψ_n , and for ψ itself. For problems driven by boundary sources, similar results also follow.

In general, for multidimensional, multiregion problems, ψ is generally a function with weak smoothness properties (Kellogg 1974). This basic fact has not stopped practitioners from employing numerical methods that require the exact solution to be smoother than it actually is to achieve the theoretically optimal accuracy. However, the lack of smoothness of ψ negatively affects the accuracy and convergence rates of the resulting numerical solutions. For example, methods that would be second-order accurate if the solution is unrealistically smooth exhibit convergence rates that are less than second order when applied to realistic problems (Duo and Azmy 2007; Larsen 1982). (However, numerical experiments also show that certain integrals of the flux actually do converge with second-order accuracy (Larsen 1982).) The topic of the lack of smoothness of the angular flux and how this affects multidimensional numerical simulations is only qualitatively understood.

2.11 Generalizations of the Neutron Transport Equation

For simplicity, the transport equations and boundary conditions discussed above have not been written in the most general possible form. Here, we briefly describe some common generalizations.

2.11.1 Reflecting Boundaries

For physical systems V that possess a planar *symmetry boundary*, an equivalent transport problem can be formulated on a subregion of V using *symmetry* or *reflecting* boundary conditions. For example, the planar-geometry system $-Z \leq z \leq Z$ has a symmetry boundary at $z = 0$ if (i) the cross sections and internal source are even functions of z , e.g., $\Sigma_t(z, E) = \Sigma(-z, E)$, and (ii) the prescribed incident fluxes at $z = -Z$ and Z satisfy $\psi^b(-Z, \mu, E) = \psi^b(Z, -\mu, E)$ for $0 \leq \mu \leq 1$. In this case, symmetry considerations show that the angular flux must satisfy:

$$\psi(z, \mu, E) = \psi(-z, -\mu, E), \quad -Z < z < Z, \quad -1 \leq \mu \leq 1, \quad 0 < E < \infty. \quad (71a)$$

Here, one can formulate an equivalent planar-geometry transport problem on the half-system $0 \leq z \leq Z$. The transport equation on this half-system and the boundary condition at $z = Z$ are the same as before. The new *symmetry* or *reflecting* boundary condition at $z = 0$, obtained by setting $z = 0$ in (71a), is:

$$\psi(0, \mu, E) = \psi(0, -\mu, E), \quad 0 \leq \mu \leq 1, \quad 0 < E < \infty. \quad (71b)$$

If the transport problem on the half-system is solved, then the angular flux over the full system is obtained from (71a).

This strategy enables computer simulations to be performed more efficiently. In 1-D problems with a symmetry boundary, the savings is a factor of 2; in 2-D problems with two symmetry boundaries, the savings is a factor of 4; and in 3-D problems with three symmetry boundaries, the savings is a factor of 8.

2.11.2 Periodic Boundaries

Similarly, if a physical system is infinite with a *periodic* or *lattice* structure, and the angular flux itself is spatially periodic, then for obvious reasons it becomes imperative to formulate an equivalent problem on a single cell of the lattice. For example, if an infinite 1-D planar system $-\infty < z < \infty$ has spatially periodic cross sections and internal sources, e.g., $\Sigma_t(z) = \Sigma_t(z + Z)$, and if there are no sources at $z = \pm\infty$, then the angular flux is spatially periodic:

$$\psi(z, \mu, E) = \psi(z + Z, \mu, E). \quad (72a)$$

In this case, an equivalent transport problem can be formulated on a single cell $0 \leq z \leq Z$ with *periodic* boundary conditions obtained from (72a):

$$\psi(0, \mu, E) = \psi(Z, \mu, E), \quad -1 \leq \mu \leq 1, \quad 0 < E < \infty. \quad (72b)$$

If the transport problem on the single cell is solved, then the angular flux over the full system can be obtained from (72a).

2.11.3 Anisotropic Sources

Physically, internal neutron sources due to radioactive decay or spontaneous fission are isotropic – all directions of flight are equally probable. However, it is sometimes necessary to consider anisotropic internal sources $Q(\mathbf{x}, \boldsymbol{\Omega}, E)$ – for example, in calculating certain Green's functions, or in multigroup calculations, when including the source of neutrons that anisotropically scatter into a given energy group with the internal source for that group. (This latter topic will be discussed in detail in  sect. 6.3). Overall, there is no mathematical reason why the internal neutron sources must be assumed to be isotropic; if appropriate, these sources can be taken to be anisotropic.

2.11.4 Coupled Neutron/Photon Transport

In reactor core calculations, the calculation of reaction rates relies on the determination of the neutron fluxes. However, in reactor shielding calculations, the calculation of dose rates relies on both the neutron fluxes and gamma-ray (photon) fluxes. The photons, which are produced by neutron absorption and inelastic neutron scattering, are more deeply penetrating than neutrons; the dose to humans on the far side of a reactor shield is due mostly to the transmitted

photons. To account for the photon transport in the shield, two coupled transport equations are formulated: one for the neutrons and one for the photons. When these are approximated using the multigroup approximation (discussed in [sect. 6](#)), the resulting two sets of multigroup equations can be merged into a single system of multigroup equations, with some groups describing neutrons and other groups describing photons.

2.11.5 Temperature-Dependent Cross Sections

Our derivation of the neutron transport equation ignores changes that occur in the macroscopic cross sections when temperature changes in the core occur due to an increase or decrease in the neutron flux (with a corresponding increase or decrease in reactor power). This approximation is generally valid when the reactor operates near a steady-state mode, but not when the reactor experiences significant transients in the neutron fluxes. To account for this, (i) an additional equation must be formulated yielding the temperature within the reactor $T(\mathbf{x}, t)$ as a function of space and time, with a source that depends on the reactor power, and (ii) the macroscopic cross sections in the reactor must be expressed as functions of $T(\mathbf{x}, t)$. The resulting equations are *nonlinear*: the neutron flux affects the temperature, which affects the macroscopic cross sections, which affects the flux. This is an extremely important topic in the fields of reactor kinetics and reactor safety.

2.11.6 Advection and Diffusion of Fission Products

Our derivation of the transport equation also ignores the spatial diffusion of fission products; delayed neutrons are assumed to be emitted at the site of the primary fission event. This is an excellent approximation for solid fuel reactors, but not when significant fuel motion is possible, as occurs, for instance, in liquid fuel reactors. The spatial motion of fission products can be accommodated by adding suitable advection or diffusion terms in the equations for the precursor densities. Then, in addition to the delayed emission in time, the delayed neutrons are emitted nonlocally in space.

2.12 Limitations of the Neutron Transport Equation

The neutron transport equation provides an extremely accurate description of the phase space neutron density in a nuclear reactor. In conjunction with appropriately formatted neutron–nucleus interaction data, this equation underlies the methods and codes used in the design of all existing nuclear reactors. However, the derivation of the transport equation has inherent approximations that limit the validity of the equation. Some of these approximations can be relaxed without significantly altering the mathematical structure of the equation. Other approximations are more fundamental and can only be relaxed at the expense of a much more complicated mathematical description. Some of the significant assumptions underlying the neutron transport equation are delineated below.

1. *The neutron is a point, structureless particle whose free motion between interactions can be described by classical mechanics.* Neutron properties requiring a quantum mechanical

description, such as spin and polarization, are assumed to influence only the interaction cross sections which, for the purpose of transport theory, are regarded as given. While the neutron phase space can be expanded to include internal states like spin and polarization, such effects are unimportant in most applications of neutron transport, but especially in reactor physics.

2. *The interaction centers, where neutrons collide with nuclei, are assumed to be randomly located with a Poisson distribution in the host medium, and collisions between neutrons and nuclei are well-defined isolated two-body interactions. Moreover, the probability of interaction with the target nuclei is assumed to depend only on the instantaneous state of the neutron and not on its prior interaction history.* In other words, the transport process is assumed to be *Markovian*, a statement that is encapsulated in the expression for the collision probability:

$$p(s)ds = \Sigma_t(\vec{x}, E, t)ds.$$

That is, the probability of an interaction in an incremental distance ds is proportional to ds and depends only on the neutron's current position and energy at the time of collision. The rate constant for the transition of state is just the macroscopic cross section. Also, the probability that the neutron can suffer more than one collision in ds is $o(ds)$, i.e., is negligible compared to ds . Corrections for non-Markovian effects have not been found necessary in the numerous applications of neutron transport theory. However, this may not be true in applications involving other types of particles. An example is low energy (\sim keV or less) atomic collision phenomena in solids, where isolated two-body collisions cannot be defined.

3. *The neutron transport equation, as derived in this section, describes the "expected" or "mean" neutron population in a medium.* Because of the statistical nature of neutron interactions and of the number of neutrons released per fission, the actual neutron number fluctuates about this mean value. However, the magnitude of the fluctuations depends on the population size. In power reactors, where the neutron number may be $\sim 10^{15}$, the deviation of the neutron population from the mean is small and the neutron transport equation for the expected density provides an accurate description of the transport process. However, for small neutron populations, such as encountered at start up in the presence of a weak source, the instantaneous neutron density will differ significantly and randomly from the mean density. This is because fission chains from a weak source are well separated, and some fission chains die prematurely, while others propagate for unusually long times. Therefore, a sufficiently strong overlap of chains does not occur for fluctuations to cancel out and a mean density to become established. Thus, although the neutron transport equation yields the correct mean neutron density, this is an incomplete characterization of the actual neutron population. Under these circumstances, a fully stochastic description of the neutron population is necessary. A generalization of the theory to explicitly account for stochastic effects in neutron transport is beyond the scope of this chapter but has been presented by Bell (1965).
4. *The neutron transport equation is a linear equation in which the macroscopic cross sections do not directly depend on the neutron density.* Two assumptions are necessary to ensure this independence:
 - (a) *Neutron-neutron collisions are negligible.* In nuclear reactor applications, this is an excellent approximation because the density of target nuclei (10^{22} nuclei per cm^3) greatly exceeds the neutron density ($<10^{15}$ neutrons per cm^3). In applications where interactions between moving particles is important, such as in the kinetic theory of gases, the collision operator becomes nonlinear and the appropriate transport equation becomes

the original (nonlinear) Boltzmann equation, which includes binary collisions between the particles.

- (b) *The neutron reaction rate density is sufficiently small so as to not appreciably modify the isotopic makeup of the host medium, except during very long timescales.* This is also an excellent approximation in nuclear reactor applications. Since changes in material properties due to fuel burnup (density, thermal conductivity, poison accumulation, etc.) occur over much longer timescales than the timescale over which the neutron distribution relaxes, these effects can be treated by performing static transport calculations over various snapshots of the medium.

2.13 Discussion

We have (i) described the basic physical processes that underlie neutron transport, (ii) derived the mathematical equations that describe this process for time-dependent and steady-state nuclear reactor calculations, (iii) discussed some basic properties of the solutions of these equations, and (iv) discussed the conditions of validity of the equation. The neutron transport and precursor density equations form the basis for practical neutron (and photon) transport calculations in nuclear reactors and shields.

3 The Transport Equation in Special Geometries

Phase space for general neutron transport problems is 7-D: there are three spatial dimensions, two angular (*direction-of-flight*) dimensions, one energy dimension, and one temporal dimension. This is problematic for calculating deterministic numerical solutions of realistic problems; if each of the seven independent variables is discretized on a grid with a modest 10^2 cells, the resulting discrete problem will have 10^{14} unknowns! Problems of this magnitude will be beyond the capacity of the world's largest and fastest supercomputers for many years to come.

To formulate practical methods for solving realistic neutron transport problems, the size of phase space must be reduced as much as possible. For 3-D problems that have special space-angle symmetries, this can be done by reducing the number of spatial (and possibly angular) independent variables. In particular, one can formulate and solve a mathematically equivalent neutron transport equation with fewer than three independent spatial variables and possibly one rather than two angular variables. These special geometries are extremely important; for many years it was only possible to obtain practical numerical solutions of spatially 1-D and 2-D transport problems. In recent years, 3-D codes for practical problems have become available, but they are so costly to run that the great majority of neutron transport simulations remain 1-D and 2-D.

In the remainder of this chapter, we discuss the most important special geometries for which the transport equation can be formulated using one or two independent spatial variables. In each situation, we describe the geometry and derive the appropriate form of the transport equation.

To begin, we define a general 3-D problem for steady-state, monoenergetic, anisotropically scattering neutron transport in a prescribed convex spatial region V . This problem is driven by an internal isotropic source $Q(\mathbf{x})$, which is prescribed for all points \mathbf{x} in V , and an incident

flux $\psi^b(\mathbf{x}, \boldsymbol{\Omega})$, which is prescribed for all points \mathbf{x} on the outer boundary ∂V of V and for all incident directions of flight $\boldsymbol{\Omega}$ at \mathbf{x} . The three restrictions of this problem: (i) steady-state, (ii) no fission, and (iii) monoenergetic transport, are made for simplicity only and can easily be relaxed. The problem is:

$$\boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}) + \Sigma_t(\mathbf{x})\psi(\mathbf{x}, \boldsymbol{\Omega}) = \int_{4\pi} \Sigma_s(\mathbf{x}, \boldsymbol{\Omega} \cdot \boldsymbol{\Omega}')\psi(\mathbf{x}, \boldsymbol{\Omega}')d\Omega' + \frac{Q(\mathbf{x})}{4\pi}, \quad \mathbf{x} \in V, \quad \boldsymbol{\Omega} \in 4\pi, \quad (73a)$$

$$\psi(\mathbf{x}, \boldsymbol{\Omega}) = \psi^b(\mathbf{x}, \boldsymbol{\Omega}), \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0. \quad (73b)$$

In the various geometries considered below, two terms in (73a) will change form: the *leakage* term $\boldsymbol{\Omega} \cdot \nabla \psi$ on the left side, and the *scattering integral* $\int \Sigma_s \psi d\Omega'$ on the right side.

To begin, we formulate the above problem using standard 3-D Cartesian spatial variables and spherical harmonic functions to expand the scattering integral. Then, we describe the problem for two simpler Cartesian geometries: (1-D) planar geometry and (2-D) x, y -geometry. After this, we formulate the transport problem in the following *curvilinear* geometries: 1-D spherical geometry, 3-D (r, ϑ, z) -geometry, 2-D (r, z) -geometry, and 1-D cylindrical geometry. The 2-D (r, z) - and 1-D cylindrical-geometry transport equations are special cases of the 3-D (r, ϑ, z) -geometry equation. The most widely used geometries in practical 2-D applications are (x, y) and (r, z) .

3.1 3-D Cartesian Geometry

For a standard 3-D Cartesian (x, y, z) -coordinate system (► Fig. 19) with $\theta =$ polar angle, $\omega =$ azimuthal angle, and $\mu = \cos \theta =$ polar cosine, we have:

$$\mathbf{x} = x\mathbf{i} + y\mathbf{j} + z\mathbf{k}, \quad (74a)$$

$$\begin{aligned} \boldsymbol{\Omega} &= \Omega_x\mathbf{i} + \Omega_y\mathbf{j} + \Omega_z\mathbf{k} \\ &= \sqrt{1 - \mu^2} (\cos \omega \mathbf{i} + \sin \omega \mathbf{j}) + \mu\mathbf{k}, \end{aligned} \quad (74b)$$

$$\mu = \cos \theta, \quad (74c)$$

$$d\boldsymbol{\Omega} = d\mu d\omega. \quad (74d)$$

In this geometry,

$$\psi(\mathbf{x}, \boldsymbol{\Omega}) = \Psi(x, y, z, \mu, \omega), \quad (75)$$

and the leakage term in the transport equation can be written:

$$\begin{aligned} \boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}) &= \left(\Omega_x \frac{\partial}{\partial x} + \Omega_y \frac{\partial}{\partial y} + \Omega_z \frac{\partial}{\partial z} \right) \Psi(x, y, z, \mu, \omega) \\ &= \left[\sqrt{1 - \mu^2} \left(\cos \omega \frac{\partial}{\partial x} + \sin \omega \frac{\partial}{\partial y} \right) + \mu \frac{\partial}{\partial z} \right] \Psi(x, y, z, \mu, \omega). \end{aligned} \quad (76)$$

■ Figure 19
3-D Cartesian geometry

Thus, the leakage operator depends explicitly on all the spatial and angular variables. (*Note:* In this discussion, ψ denotes the angular flux as a *general* function of space \mathbf{x} and direction Ω ; Ψ denotes the angular flux as a function of angular and direction variables that correspond to *specific* coordinate systems.)

To express the scattering integral, we use the fact that scattering is rotationally invariant. Thus, the differential scattering cross section is a function of the scattering cosine $\mu_0 = \Omega \cdot \Omega'$ and can be written as a Legendre polynomial expansion:

$$\Sigma_s(\mathbf{x}, \Omega \cdot \Omega') = \sum_{n=0}^N \frac{2n+1}{4\pi} \Sigma_{s,n}(\mathbf{x}) P_n(\Omega \cdot \Omega'), \quad (77)$$

where $P_n(\mu_0)$ is the n th Legendre polynomial (Duderstadt and Hamilton 1976). The order N of this expansion is generally infinite, but in applications the series is truncated and N is taken to be finite. If $N = 0$ (or 1), scattering is said to be *isotropic* (or *linearly anisotropic*).

The Legendre polynomials satisfy the *addition theorem*:

$$P_n(\Omega \cdot \Omega') = \frac{4\pi}{2n+1} \sum_{m=-n}^n Y_{n,m}(\Omega) Y_{n,m}^*(\Omega'), \quad (78)$$

where for $0 \leq |m| \leq n < \infty$, $Y_{n,m}(\Omega)$ is a *spherical harmonic* function:

$$Y_{n,m}(\Omega) = Y_{n,m}(\mu, \omega) = a_{n,m} P_n^{(|m|)}(\mu) e^{im\omega}, \quad (79a)$$

$$P_n^{l|m|}(\mu) = (1 - \mu^2)^{|m|/2} \left(\frac{d}{d\mu} \right)^{|m|} P_n(\mu)$$

= Associated Legendre function, (79b)

$$a_{n,m} = (-1)^{(m+|m|)/2} \left[\frac{2n+1}{4\pi} \frac{(n-|m|)!}{(n+|m|)!} \right]^{1/2}. \quad (79c)$$

Here * denotes complex conjugate, and $0! = 1$.

Introducing (78) into (77), we obtain:

$$\Sigma_s(\mathbf{x}, \boldsymbol{\Omega} \cdot \boldsymbol{\Omega}') = \sum_{n=0}^N \sum_{m=-n}^n \Sigma_{s,n}(\mathbf{x}) Y_{n,m}(\boldsymbol{\Omega}) Y_{n,m}^*(\boldsymbol{\Omega}'). \quad (80)$$

Thus, the scattering integral in (73a) can be written:

$$\int_{4\pi} \Sigma_s(\mathbf{x}, \boldsymbol{\Omega} \cdot \boldsymbol{\Omega}') \psi(\mathbf{x}, \boldsymbol{\Omega}') d\boldsymbol{\Omega}'$$

$$= \sum_{n=0}^N \sum_{m=-n}^n \Sigma_{s,n}(\mathbf{x}) Y_{n,m}(\mu, \omega) \int_{-1}^1 \int_0^{2\pi} Y_{n,m}^*(\mu', \omega') \Psi(x, y, z, \mu', \omega') d\omega' d\mu'. \quad (81)$$

Introducing (76) and (81) into (73a), we obtain the following 3-D Cartesian-geometry transport equation:

$$\left[\sqrt{1 - \mu^2} \left(\cos \omega \frac{\partial}{\partial x} + \sin \omega \frac{\partial}{\partial y} \right) + \mu \frac{\partial}{\partial z} \right] \psi(\mathbf{x}, \boldsymbol{\Omega}) + \Sigma_t(\mathbf{x}) \psi(\mathbf{x}, \boldsymbol{\Omega})$$

$$= \sum_{n=0}^N \sum_{m=-n}^n \Sigma_{s,n}(\mathbf{x}) Y_{n,m}(\boldsymbol{\Omega}) \int_{4\pi} Y_{n,m}^*(\boldsymbol{\Omega}') \psi(\mathbf{x}, \boldsymbol{\Omega}') d\boldsymbol{\Omega}' + \frac{Q(\mathbf{x})}{4\pi}. \quad (82)$$

In (82), the shorthand notations of (75) and (79a) have been used. Equation (82) holds for all spatial points $\mathbf{x} \in V$ and all unit vectors $\boldsymbol{\Omega}$ ($-1 \leq \mu \leq 1$ and $0 \leq \omega < 2\pi$). To determine ψ , (82) must be solved subject to the boundary condition expressed in (73b).

3.2 1-D Planar Geometry

In problems with 1-D planar symmetry,

1. The physical system is a planar “slab” consisting of spatial points (x, y, z) with $-\infty < x, y < \infty$ and $0 < z < Z$. Thus, the system is infinite in the (*transverse*) x - and y -directions and finite or possibly infinite in the (*depth*) z -direction.
2. The cross sections, isotropic internal source, and prescribed incident boundary fluxes are independent of the transverse variables x and y .

Because the problem geometry and neutron sources are independent of x and y , the angular flux itself is independent of x and y :

$$\psi(\mathbf{x}, \boldsymbol{\Omega}) = \Psi(z, \boldsymbol{\Omega}) = \Psi(z, \mu, \omega). \quad (83a)$$

In these circumstances, (82) immediately reduces to:

$$\mu \frac{\partial \Psi}{\partial z}(z, \Omega) + \Sigma_t(z) \Psi(z, \Omega) = \sum_{n=0}^N \sum_{m=-n}^n \Sigma_{s,n}(z) Y_{n,m}(\Omega) \int_{4\pi} Y_{n,m}^*(\Omega') \Psi(z, \Omega') d\Omega' + \frac{Q(z)}{4\pi}, \quad 0 < z < Z, \quad \Omega \in 4\pi. \quad (83b)$$

The boundary conditions prescribe the incident angular fluxes on the left and right edges of the slab:

$$\Psi(0, \mu, \omega) = \psi^b(\mu, \omega), \quad 0 < \mu \leq 1, \quad 0 \leq \omega < 2\pi, \quad (83c)$$

$$\Psi(Z, \mu, \omega) = \psi^b(\mu, \omega), \quad -1 \leq \mu < 0, \quad 0 \leq \omega < 2\pi. \quad (83d)$$

Equations (83) describe planar-geometry neutron transport *without azimuthal symmetry*.

The azimuthal angle can be eliminated by integrating the equations over $0 \leq \omega < 2\pi$. If we define the *azimuthally integrated angular flux*:

$$\Psi(z, \mu) = \int_0^{2\pi} \Psi(z, \mu, \omega) d\omega, \quad (84)$$

then upon integration over ω , (83b) yields:

$$\begin{aligned} \mu \frac{\partial \Psi}{\partial z}(z, \mu) + \Sigma_t(z) \Psi(z, \mu) &= \sum_{n=0}^N \sum_{m=-n}^n \Sigma_{s,n}(z) \left(\int_0^{2\pi} Y_{n,m}(\Omega) d\omega \right) \int_{4\pi} Y_{n,m}^*(\Omega') \Psi(z, \Omega') d\Omega' \\ &+ \frac{Q(z)}{2}, \quad 0 < z < Z, \quad -1 \leq \mu \leq 1. \end{aligned} \quad (85a)$$

However, (79) imply:

$$\int_0^{2\pi} Y_{n,m}(\Omega) d\omega = 2\pi \delta_{m,0} \left(\frac{2n+1}{4\pi} \right)^{1/2} P_n(\mu), \quad (85b)$$

and:

$$\begin{aligned} \int_{4\pi} Y_{n,0}^*(\Omega') \Psi(z, \Omega') d\Omega' &= \int_{-1}^1 \int_0^{2\pi} \left(\frac{2n+1}{4\pi} \right)^{1/2} P_n(\mu') \Psi(z, \mu', \omega') d\omega' d\mu' \\ &= \left(\frac{2n+1}{4\pi} \right)^{1/2} \int_{-1}^1 P_n(\mu') \Psi(z, \mu') d\mu'. \end{aligned} \quad (85c)$$

Introducing these results into (85a), we obtain the following simpler equation for $\Psi(z, \mu)$:

$$\begin{aligned} \mu \frac{\partial \Psi}{\partial z}(z, \mu) + \Sigma_t(z) \Psi(z, \mu) &= \sum_{n=0}^N \left(\frac{2n+1}{2} \right) \Sigma_{s,n}(z) P_n(\mu) \int_{-1}^1 P_n(\mu') \Psi(z, \mu') d\mu' \\ &+ \frac{Q(z)}{2}, \quad 0 < z < Z, \quad -1 \leq \mu \leq 1. \end{aligned} \quad (86a)$$

Also, integrating the boundary conditions (83c) and (83d) over ω , we obtain:

$$\Psi(0, \mu) = \psi^b(\mu) = \int_0^{2\pi} \psi^b(\mu, \omega) d\omega, \quad 0 < \mu \leq 1, \tag{86b}$$

$$\Psi(Z, \mu) = \psi^b(\mu) = \int_0^{2\pi} \psi^b(\mu, \omega) d\omega, \quad -1 \leq \mu < 0. \tag{86c}$$

Equation (86a) describe azimuthally integrated planar-geometry neutron transport.

To determine $\Psi(z, \mu)$, (86) must be solved. By (84), this solution is the azimuthally integrated angular flux of the original problem.

3.3 2-D (X,Y)-Geometry

In problems with 2-D (x, y) -symmetry (🔗 Fig. 20),

1. The physical system is an infinite “cylinder,” consisting of spatial points (x, y, z) with $(x, y) \in D$ (a convex region in the (x, y) -plane) and $-\infty < z < \infty$.
2. The cross sections, isotropic internal source, and prescribed incident boundary fluxes are independent of z .
3. The prescribed incident boundary fluxes are even functions of $\mu = \boldsymbol{\Omega} \cdot \mathbf{k}$:

$$\psi^b(x, y, \boldsymbol{\Omega}) = \psi^b(x, y, \boldsymbol{\Omega}_r), \quad (x, y) \in \partial D, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \tag{87a}$$

where:

$$\begin{aligned} \boldsymbol{\Omega} &= \sqrt{1 - \mu^2} \cos \omega \mathbf{i} + \sqrt{1 - \mu^2} \sin \omega \mathbf{j} + \mu \mathbf{k} \\ &= \eta \mathbf{i} + \xi \mathbf{j} + \mu \mathbf{k}, \end{aligned} \tag{87b}$$

$$\begin{aligned} \boldsymbol{\Omega}_r &= \eta \mathbf{i} + \xi \mathbf{j} - \mu \mathbf{k}, \\ &= \text{Reflection of } \boldsymbol{\Omega} \text{ across the } (x, y)\text{-plane.} \end{aligned} \tag{87c}$$

Figure 20
2-D (x, y) -geometry

Figure 21
 $d\eta d\xi$ and $d\Omega$

Because the problem geometry is independent of z and the neutron sources are even functions of μ , the neutron angular is also independent of z and an even function of μ : $\psi(\mathbf{x}, \Omega) = \Psi(x, y, \mu, \omega) = \Psi(x, y, -\mu, \omega)$.

If we define:

$$\eta = \Omega_x = \sqrt{1 - \mu^2} \cos \omega, \quad (88a)$$

$$\xi = \Omega_y = \sqrt{1 - \mu^2} \sin \omega, \quad (88b)$$

then $|\Omega| = 1$ implies that for each value of η and ξ , there are two values of μ : $\mu^\pm = \pm\sqrt{1 - \eta^2 - \xi^2}$. Thus, if a function $f(\Omega)$ is an even function of μ , i.e., if for each η and ξ it has the same value at μ^+ and μ^- , then we can write:

$$f(\Omega) = g(\eta, \xi), \quad \eta^2 + \xi^2 \leq 1. \quad (89)$$

Also, from Fig. 21, we have:

$$d\Omega = \left(\frac{d\Omega}{d\eta d\xi} \right) d\eta d\xi = \frac{1}{|\mathbf{n} \cdot \mathbf{k}|} d\eta d\xi = \frac{d\eta d\xi}{|\mu|} = \frac{d\eta d\xi}{\sqrt{1 - \eta^2 - \xi^2}},$$

which implies:

$$\int_{4\pi} f(\Omega) d\Omega = 2 \int_{\eta^2 + \xi^2 \leq 1} \frac{g(\eta, \xi)}{\sqrt{1 - \eta^2 - \xi^2}} d\eta d\xi. \quad (90)$$

(The factor 2 occurs because the integral over $\eta^2 + \xi^2 \leq 1$ accounts for integration over only one hemisphere.)

From the above considerations, we can write:

$$\psi(\mathbf{x}, \boldsymbol{\Omega}) = \frac{1}{2} \Psi(x, y, \eta, \xi). \quad (91)$$

Using (91) and (88) in (76), we immediately get:

$$\boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}) = \frac{1}{2} \left(\eta \frac{\partial}{\partial x} + \xi \frac{\partial}{\partial y} \right) \Psi(x, y, \eta, \xi). \quad (92)$$

Also, the spherical harmonic functions $Y_{n,m}(\boldsymbol{\Omega}) = Y_{n,m}(\mu, \omega)$ are even functions of μ for $n + m = \text{even}$, and odd functions of μ for $n + m = \text{odd}$ (see [79]). Therefore,

$$\begin{aligned} \int_{4\pi} Y_{n,m}^*(\boldsymbol{\Omega}') \psi(\mathbf{x}, \boldsymbol{\Omega}') d\Omega' &= \frac{1 + (-1)^{n+m}}{2} \int_{4\pi} Y_{n,m}^*(\boldsymbol{\Omega}') \psi(\mathbf{x}, \boldsymbol{\Omega}') d\Omega' \\ &= \frac{1 + (-1)^{n+m}}{2} \int_{(\eta')^2 + (\xi')^2 \leq 1} \frac{Y_{n,m}^*(\eta', \xi') \Psi(x, y, \eta', \xi')}{\sqrt{1 - (\eta')^2 - (\xi')^2}} d\eta' d\xi'. \end{aligned} \quad (93)$$

Introducing (92) and (93) into (82), we obtain the following (x, y) -geometry neutron transport equation:

$$\begin{aligned} \left(\eta \frac{\partial}{\partial x} + \xi \frac{\partial}{\partial y} \right) \Psi(x, y, \eta, \xi) + \Sigma_t(x, y) \Psi(x, y, \eta, \xi) \\ = \sum_{n=0}^{\infty} \sum_{m=-n}^n [1 + (-1)^{n+m}] \Sigma_{s,n}(x, y) Y_{n,m}(\eta, \xi) \\ \times \int_{(\eta')^2 + (\xi')^2 \leq 1} \frac{Y_{n,m}^*(\eta', \xi') \Psi(x, y, \eta', \xi')}{\sqrt{1 - (\eta')^2 - (\xi')^2}} d\eta' d\xi' \\ + \frac{Q(x, y)}{2\pi}, \quad (x, y) \in D, \quad \eta^2 + \xi^2 \leq 1. \end{aligned} \quad (94)$$

The (x, y) -geometry boundary condition prescribes the incident neutron flux for spatial points $(x, y) \in \partial D$ and for inward-pointing directions of flight $\boldsymbol{\Omega}$:

$$\begin{aligned} \Psi(x, y, \eta, \xi) = \Psi^b(x, y, \eta, \xi) = 2\Psi^b(x, y, \eta, \xi, \mu^+), \\ (x, y) \in \partial D, \quad (\eta \mathbf{i} + \xi \mathbf{j}) \cdot \mathbf{n} < 0. \end{aligned} \quad (95)$$

To determine $\Psi(x, y, \eta, \xi)$, (94) must be solved subject to the boundary conditions equation (95). The angular flux is then given by (91).

3.4 1-D Spherical Geometry

In problems with 1-D spherical symmetry (► Fig. 22),

The physical system is a sphere of radius R . (In the following, we take the center of the sphere to be the origin of the Cartesian coordinate system.)

■ Figure 22

1-D spherical symmetry. The angular flux is constant for: (i) spatial points \mathbf{x} equally distant from the center of the sphere and (ii) directions of flight Ω that make an equal angle with $\mathbf{e} = \mathbf{x}/r$

The cross sections and internal source are functions only of the radial variable

$$r = (x^2 + y^2 + z^2)^{1/2}. \quad (96)$$

For spatial points on the surface of the sphere ($|\mathbf{x}| = r = R$) and for inward-pointing directions of flight ($\Omega \cdot \mathbf{x} < 0$), the incident boundary fluxes are functions only of:

$$\begin{aligned} \mu &= \Omega \cdot (\mathbf{x}/r) \\ &= \text{Cosine of the angle between the direction of flight } \Omega \\ &\quad \text{and the radially outward direction } \mathbf{e} = \mathbf{x}/r. \end{aligned} \quad (97)$$

In these circumstances, the angular flux should be a function only of r and μ :

$$\psi(\mathbf{x}, \Omega) = \frac{1}{2\pi} \Psi(r, \mu). \quad (98)$$

[The factor 2π is included so that, as in planar geometry,

$$\int_{4\pi} \psi(\mathbf{x}, \Omega) d\Omega = \int_{-1}^1 \Psi(r, \mu) d\mu.] \quad (99)$$

Equation (98) implies:

$$\Omega \cdot \nabla \psi(\mathbf{x}, \Omega) = \frac{1}{2\pi} \left(\frac{\partial \Psi}{\partial r} \Omega \cdot \nabla r + \frac{\partial \Psi}{\partial \mu} \Omega \cdot \nabla \mu \right),$$

where, using (96) and (97), we have:

$$\begin{aligned}\boldsymbol{\Omega} \cdot \nabla r &= \left(\Omega_x \frac{\partial}{\partial x} + \Omega_y \frac{\partial}{\partial y} + \Omega_z \frac{\partial}{\partial z} \right) r = \Omega_x \frac{x}{r} + \Omega_y \frac{y}{r} + \Omega_z \frac{z}{r} = \mu, \\ \boldsymbol{\Omega} \cdot \nabla \mu &= \left(\Omega_x \frac{\partial}{\partial x} + \Omega_y \frac{\partial}{\partial y} + \Omega_z \frac{\partial}{\partial z} \right) \left(\frac{\Omega_x x + \Omega_y y + \Omega_z z}{r} \right) = \dots = \frac{1 - \mu^2}{r}.\end{aligned}$$

Therefore,

$$\boldsymbol{\Omega} \cdot \nabla \Psi(\mathbf{x}, \boldsymbol{\Omega}) = \frac{1}{2\pi} \left(\mu \frac{\partial}{\partial r} + \frac{1 - \mu^2}{r} \frac{\partial}{\partial \mu} \right) \Psi(r, \mu). \quad (100)$$

Also, defining the polar cosine μ locally (at each point) by (97) and letting ω be any consistently defined azimuthal angle, it is evident that Ψ is independent of ω . Thus, (85b) and (85c) hold, with $\Sigma_{s,n}(z)$ and $\Psi(z, \mu)$ replaced by $\Sigma_{s,n}(r)$ and $\Psi(r, \mu)$. Using this and (100) in (83b), we obtain the following 1-D spherical-geometry transport equation:

$$\begin{aligned}& \left(\mu \frac{\partial}{\partial r} + \frac{1 - \mu^2}{r} \frac{\partial}{\partial \mu} \right) \Psi(r, \mu) + \Sigma_t(r) \Psi(r, \mu) \\ &= \sum_{n=0}^{\infty} \left(\frac{2n+1}{2} \right) \Sigma_{s,n}(r) P_n(\mu) \int_{-1}^1 P_n(\mu') \Psi(r, \mu') d\mu' + \frac{Q(r)}{2}, \\ & 0 \leq r \leq R, \quad -1 \leq \mu \leq 1.\end{aligned} \quad (101)$$

The spherical-geometry boundary condition prescribes the incident fluxes on the outer boundary of the sphere:

$$\Psi(R, \mu) = \Psi^b(\mu) = 2\pi \psi^b(R, \mu), \quad -1 \leq \mu < 0. \quad (102)$$

To determine $\Psi(r, \mu)$, (101) must be solved subject to the boundary condition (102). The angular flux is then given by (98).

3.5 3-D (r, ϑ, z) -Geometry

To derive the 2-D (r, z) and the 1-D cylindrical transport equations, we first derive the 3-D transport equation expressed in terms of cylindrical variables: the *radial spatial variable* $r = \sqrt{x^2 + y^2}$ and the *azimuthal spatial angle* $\vartheta = \tan^{-1}(y/x)$. We also replace the azimuthal directional angle ω by the angular deflection γ from the spatial azimuthal angle ϑ . γ ranges over $-\pi \leq \gamma \leq \pi$. Directions satisfying $|\gamma| < \pi/2$ are *outgoing* and describe flow away from $r = 0$. Directions satisfying $|\gamma| > \pi/2$ are *incoming* and describe flow toward $r = 0$. The spatial variable z and the polar cosine μ retain their Cartesian geometry interpretations (see  Fig. 23).

■ **Figure 23**
3-D (r, ϑ, z) variables

The Cartesian spatial variables x and y , and the azimuthal angular variable ω are expressed in terms of the *curvilinear* variables r and ϑ , and the azimuthal angular variable γ by:

$$x = r \cos \vartheta, \quad (103a)$$

$$y = r \sin \vartheta, \quad (103b)$$

$$\omega = \vartheta + \gamma. \quad (103c)$$

Then, defining the unit vectors (see [Fig. 23](#)):

$$\mathbf{e} = \frac{x}{r} \mathbf{i} + \frac{y}{r} \mathbf{j} = \cos \vartheta \mathbf{i} + \sin \vartheta \mathbf{j}, \quad (104a)$$

$$\mathbf{t} = -\frac{y}{r} \mathbf{i} + \frac{x}{r} \mathbf{j} = -\sin \vartheta \mathbf{i} + \cos \vartheta \mathbf{j}, \quad (104b)$$

we have:

$$\tilde{\mathbf{x}} = r\mathbf{e} + z\mathbf{k}, \quad (105a)$$

$$\tilde{\Omega} = \sqrt{1 - \mu^2} (\cos \gamma \mathbf{e} + \sin \gamma \mathbf{t}) + \mu \mathbf{k}, \quad (105b)$$

$$d\tilde{\Omega} = d\mu d\gamma = d\mu d\omega = d\Omega. \quad (105c)$$

(A tilde signifies that $\tilde{\mathbf{x}}$ is expressed in terms of r , ϑ , and z rather than x , y , and z , and that $\tilde{\mathbf{\Omega}}$ is expressed in terms of γ and μ rather than ω and μ . We note that $\tilde{\mathbf{x}} = \mathbf{x}$ and $\tilde{\mathbf{\Omega}} = \mathbf{\Omega}$.) The angular flux is now expressed in terms of the new variables:

$$\begin{aligned}\psi(\mathbf{x}, \mathbf{\Omega}) &= \psi(x, y, z, \mu, \omega) = \psi(r \cos \vartheta, r \sin \vartheta, z, \mu, \vartheta + \gamma) \\ &\equiv \Psi(r, \vartheta, z, \mu, \gamma) = \Psi(\tilde{\mathbf{x}}, \tilde{\mathbf{\Omega}}).\end{aligned}\quad (106)$$

The following identities can easily be shown:

$$\mathbf{\Omega} \cdot \nabla r = \cos \gamma \sqrt{1 - \mu^2}, \quad (107a)$$

$$\mathbf{\Omega} \cdot \nabla \vartheta = \frac{\sin \gamma}{r} \sqrt{1 - \mu^2}, \quad (107b)$$

$$\mathbf{\Omega} \cdot \nabla z = \mu, \quad (107c)$$

$$\mathbf{\Omega} \cdot \nabla \mu = 0, \quad (107d)$$

$$\mathbf{\Omega} \cdot \nabla \gamma = -\frac{\sin \gamma}{r} \sqrt{1 - \mu^2}. \quad (107e)$$

Equations (106) and (107) then give:

$$\mathbf{\Omega} \cdot \nabla \psi = \mu \frac{\partial \Psi}{\partial z} + \cos \gamma \sqrt{1 - \mu^2} \frac{\partial \Psi}{\partial r} + \frac{\sin \gamma}{r} \sqrt{1 - \mu^2} \left(\frac{\partial \Psi}{\partial \vartheta} - \frac{\partial \Psi}{\partial \gamma} \right). \quad (108)$$

We also have the identity:

$$\begin{aligned}\mu_0 &= \mathbf{\Omega} \cdot \mathbf{\Omega}' = \sqrt{1 - \mu^2} \sqrt{1 - (\mu')^2} (\cos \omega \cos \omega' + \sin \omega \sin \omega') + \mu \mu' \\ &= \sqrt{1 - \mu^2} \sqrt{1 - (\mu')^2} \cos(\omega - \omega') + \mu \mu' \\ &= \sqrt{1 - \mu^2} \sqrt{1 - (\mu')^2} \cos(\gamma - \gamma') + \mu \mu' \\ &= \sqrt{1 - \mu^2} \sqrt{1 - (\mu')^2} (\cos \gamma \cos \gamma' + \sin \gamma \sin \gamma') + \mu \mu' \\ &= \tilde{\mathbf{\Omega}} \cdot \tilde{\mathbf{\Omega}}' = \tilde{\mu}_0.\end{aligned}\quad (109)$$

We may define:

$$\begin{aligned}\Sigma_t(\mathbf{x}) &= \Sigma_t(x, y, z) = \Sigma_t(r \cos \vartheta, r \sin \vartheta, z) \\ &\equiv \tilde{\Sigma}_t(r, \vartheta, z) = \tilde{\Sigma}_t(\tilde{\mathbf{x}}),\end{aligned}\quad (110a)$$

$$\begin{aligned}\Sigma_s(\mathbf{x}, \mu_0) &= \Sigma_s(x, y, z, \mu_0) = \Sigma_s(r \cos \vartheta, r \sin \vartheta, z, \mu_0) \\ &\equiv \tilde{\Sigma}_s(r, \vartheta, z, \tilde{\mu}_0) = \tilde{\Sigma}_s(\tilde{\mathbf{x}}, \tilde{\mu}_0),\end{aligned}\quad (110b)$$

$$\begin{aligned}Q(\mathbf{x}) &= Q(x, y, z) = Q(r \cos \vartheta, r \sin \vartheta, z) \\ &\equiv \tilde{Q}(r, \vartheta, z) = \tilde{Q}(\tilde{\mathbf{x}}).\end{aligned}\quad (110c)$$

From (81), the scattering integral becomes:

$$\begin{aligned}&\int_{4\pi} \Sigma_s(\mathbf{x}, \mathbf{\Omega} \cdot \mathbf{\Omega}') \psi(\mathbf{x}, \mathbf{\Omega}') d\Omega' \\ &= \sum_{n=0}^N \sum_{m=-n}^n \tilde{\Sigma}_{s,n}(\tilde{\mathbf{x}}) Y_{n,m}(\mu, \gamma) \int_{-1}^1 \int_{-\pi}^{\pi} Y_{n,m}^*(\mu', \gamma') \Psi(r, \vartheta, z, \mu', \gamma') d\gamma' d\mu'.\end{aligned}\quad (111)$$

Using (109) and (111) in (73a), we obtain the following (r, ϑ, z) -geometry transport equation:

$$\begin{aligned} & \sqrt{1-\mu^2} \left[\cos \gamma \frac{\partial \Psi}{\partial r}(\tilde{\mathbf{x}}, \tilde{\Omega}) + \frac{\sin \gamma}{r} \left(\frac{\partial \Psi}{\partial \vartheta}(\tilde{\mathbf{x}}, \tilde{\Omega}) - \frac{\partial \Psi}{\partial \gamma}(\tilde{\mathbf{x}}, \tilde{\Omega}) \right) \right] + \mu \frac{\partial \Psi}{\partial z}(\tilde{\mathbf{x}}, \tilde{\Omega}) + \tilde{\Sigma}_t(\tilde{\mathbf{x}}) \Psi(\tilde{\mathbf{x}}, \tilde{\Omega}) \\ & = \sum_{n=0}^N \sum_{m=-n}^n \tilde{\Sigma}_{s,n}(\tilde{\mathbf{x}}) Y_{n,m}(\tilde{\Omega}) \int_{4\pi} Y_{n,m}^*(\tilde{\Omega}') \Psi(r, \vartheta, z, \tilde{\Omega}') d\tilde{\Omega}' + \frac{\tilde{Q}(\tilde{\mathbf{x}})}{4\pi}. \end{aligned} \quad (112a)$$

This equation describes 3-D neutron transport in, e.g., a finite cylindrical system of radius R and length Z . The spatial and angular variables then vary over:

$$0 < r \leq R, \quad -\pi \leq \vartheta \leq \pi, \quad 0 \leq z \leq Z, \quad -1 \leq \mu \leq 1, \quad -\pi \leq \gamma \leq \pi. \quad (112b)$$

In addition to (112), we must prescribe the incident angular flux on the outer boundary of the cylinder. First, on the outer “cylindrical” surface, we have:

$$\Psi(R, \vartheta, z, \mu, \gamma) = \Psi^b(\vartheta, z, \mu, \gamma), \quad 0 \leq z \leq Z, \quad -\pi \leq \vartheta \leq \pi, \quad -1 \leq \mu \leq 1, \quad |\gamma| > \frac{\pi}{2}. \quad (113a)$$

At the circular “cap” at $z = 0$, we have:

$$\Psi(r, \vartheta, 0, \mu, \gamma) = \Psi^b(r, \vartheta, \mu, \gamma), \quad 0 < r \leq R, \quad -\pi \leq \vartheta \leq \pi, \quad 0 < \mu \leq 1, \quad -\pi \leq \gamma \leq \pi. \quad (113b)$$

At the other circular “cap” at $z = Z$, we have:

$$\Psi(r, \vartheta, Z, \mu, \gamma) = \Psi^b(r, \vartheta, \mu, \gamma), \quad 0 < r \leq R, \quad -\pi \leq \vartheta \leq \pi, \quad -1 \leq \mu < 0, \quad -\pi \leq \gamma \leq \pi. \quad (113c)$$

Equations (112) and (113) describe 3-D neutron transport in the finite cylindrical system depicted in  Fig. 24.

 **Figure 24**
Finite cylindrical system

3.6 2-D (r, z)-Geometry

In problems with 2-D (r, z)-symmetry,

1. The physical system is typically a finite cylinder consisting of spatial points (r, ϑ, z) with $0 \leq r \leq R$, $-\pi \leq \vartheta \leq \pi$, and $0 \leq z \leq Z$ (see  Fig. 24).
2. The cross sections, internal isotropic source, and prescribed boundary conditions are independent of ϑ .
3. The prescribed incident boundary conditions are arbitrary functions of z, μ , and γ .

Thus, the system is symmetric through rotations of the spatial azimuthal angle ϑ (about the z -axis). The neutron angular flux will also have this symmetry, i.e., will be independent of ϑ :

$$\psi(\mathbf{x}, \boldsymbol{\Omega}) = \Psi(r, z, \mu, \gamma). \quad (114)$$

The (r, z)-geometry transport equation (and boundary conditions) can be obtained as a special case of the (r, ϑ, z)-geometry transport equations in which all quantities are independent of ϑ . Equations (112) and (113) yield:

$$\begin{aligned} \mu \frac{\partial \Psi}{\partial z}(r, z, \tilde{\boldsymbol{\Omega}}) + \sqrt{1 - \mu^2} \left(\cos \gamma \frac{\partial \Psi}{\partial r}(r, z, \tilde{\boldsymbol{\Omega}}) - \frac{\sin \gamma}{r} \frac{\partial \Psi}{\partial \gamma}(r, z, \tilde{\boldsymbol{\Omega}}) \right) + \tilde{\Sigma}_t(r, z) \Psi(r, z, \tilde{\boldsymbol{\Omega}}) \\ = \int_{4\pi} \tilde{\Sigma}_s(r, z, \tilde{\boldsymbol{\Omega}} \cdot \tilde{\boldsymbol{\Omega}}') \Psi(r, z, \tilde{\boldsymbol{\Omega}}') d\tilde{\boldsymbol{\Omega}}' + \frac{\tilde{Q}(r, z)}{4\pi}, \quad 0 < r \leq R, \quad 0 \leq z \leq Z, \\ -1 \leq \mu \leq 1, \quad -\pi \leq \gamma \leq \pi, \end{aligned} \quad (115)$$

and:

$$\Psi(R, z, \mu, \gamma) = \Psi^b(z, \mu, \gamma), \quad 0 \leq z \leq Z, \quad -1 \leq \mu \leq 1, \quad |\gamma| > \frac{\pi}{2}, \quad (116a)$$

$$\Psi(r, 0, \mu, \gamma) = \Psi^b(r, \mu, \gamma), \quad 0 < r \leq R, \quad 0 < \mu \leq 1, \quad -\pi \leq \gamma \leq \pi, \quad (116b)$$

$$\Psi(r, Z, \mu, \gamma) = \Psi^b(r, \mu, \gamma), \quad 0 < r \leq R, \quad -1 \leq \mu < 0, \quad -\pi \leq \gamma \leq \pi. \quad (116c)$$

The scattering integral in (115) can be written as in (111) or (112).

Equations (115) and (116) describe neutron transport in a finite cylindrical system with rotational symmetry.

3.7 1-D Cylindrical Geometry

In problems with 1-D cylindrical symmetry,

1. The physical system is an infinite cylinder consisting of spatial points (r, ϑ, z) with $0 \leq r \leq R$, $-\pi \leq \vartheta \leq \pi$, and $-\infty < z < \infty$.
2. The cross sections, internal isotropic source, and prescribed boundary conditions are independent of ϑ and z .
3. The prescribed incident boundary conditions are arbitrary functions of μ and γ .

Because the system is independent of ϑ and z , the neutron flux will also be independent of these variables:

$$\psi(\mathbf{x}, \boldsymbol{\Omega}) = \Psi(r, \mu, \gamma) = \Psi(r, \tilde{\boldsymbol{\Omega}}). \quad (117)$$

The 1-D cylindrical-geometry transport equation (and boundary conditions) is a special case of the (r, z) -geometry transport equations in which all quantities are independent of z . Equations (115) and (116) yield:

$$\begin{aligned} & \sqrt{1 - \mu^2} \left(\cos \gamma \frac{\partial \Psi}{\partial r}(r, \tilde{\boldsymbol{\Omega}}) - \frac{\sin \gamma}{r} \frac{\partial \Psi}{\partial \gamma}(r, \tilde{\boldsymbol{\Omega}}) \right) + \tilde{\Sigma}_t(r) \Psi(r, \tilde{\boldsymbol{\Omega}}) \\ &= \int_{4\pi} \tilde{\Sigma}_s(r, \tilde{\boldsymbol{\Omega}} \cdot \tilde{\boldsymbol{\Omega}}') \Psi(r, \tilde{\boldsymbol{\Omega}}') d\tilde{\boldsymbol{\Omega}}' + \frac{\tilde{Q}(r)}{4\pi}, \quad 0 < r \leq R, \quad -1 \leq \mu \leq 1, \quad -\pi \leq \gamma \leq \pi, \end{aligned} \quad (118)$$

and:

$$\Psi(R, \mu, \gamma) = \Psi^b(\mu, \gamma), \quad -1 \leq \mu \leq 1, \quad |\gamma| > \frac{\pi}{2}. \quad (119)$$

The scattering integral in (118) can be written as in (111) or (112).

Equations (118) and (119) describe neutron transport in an infinite cylindrical system with rotational symmetry and no axial (z -) dependence. The equations have one spatial variable (r) and two angular variables (μ and γ). In contrast, the 1-D planar and 1-D spherical-geometry transport equations have one spatial variable and only one angular variable.

3.8 Discussion

We have derived several forms of the neutron transport equation for 3-D problems in which geometric symmetries cause the angular flux to depend on fewer than three independent spatial variables. This has been done only for the most widely used 2-D geometries: (x, y) and (r, z) . Less important 2-D geometries, which are not treated here, are the two 2-D spherical geometries, cylindrical (ϑ, z) -geometry, and 2-D *helical* geometry (Larsen 2007). Also, we have not treated 3-D spherical geometry.

In the preceding derivations, we assumed for simplicity monoenergetic transport, no time-dependence, and no fission. However, it is straightforward to include these extra features.

We also assumed that in each geometry, the prescribed internal source Q is isotropic. This can immediately be relaxed to allow an internal anisotropic source whose spatial and angular dependences are the same as those allowed for the angular flux. For instance, in 1-D spherical geometry the angular flux is a function of r and μ , and one can include an internal anisotropic source, which is also a function of r and μ . Such sources arise naturally in multigroup problems, in which all the group angular fluxes have the same space-angle symmetry, and thus the source of neutrons that scatter into each group also share this symmetry.

In our derivations, we have not always stated the most general possible allowed geometric form of the spatial region V . For example, in 1-D spherical geometry, the physical system V was assumed to be the interior of a sphere of radius R . However, R could also be the *exterior* of a sphere of radius R , or, more generally, a *shell* consisting of points (r, ϑ, z) satisfying $R_0 \leq r \leq R_1$.

In these new cases, boundary conditions that prescribe the incident flux must be imposed on *all* physical boundaries.

Also, *reflecting* boundary conditions can be used along planes of geometric symmetry, and *periodic* boundary conditions are used to model one cell of an infinite periodic lattice. These and other types of boundary conditions are often employed in applications.

In all curvilinear geometries, the angular variables are expressed locally in space and change their value continuously as neutrons stream along flight paths. This gives rise to *angular derivative* terms in the neutron transport equation that significantly complicate the derivation of accurate numerical solutions (Lewis and Miller 1984). For example, the 1-D spherical-geometry transport equation (101) contains partial derivatives with respect to both r and μ . Mathematically, this leakage operator is a 2-D partial differential operator. Nonetheless, the historical tradition in the nuclear engineering community is to count only the spatial variables when describing a transport operator as 1-D, 2-D, or 3-D. Thus, the spherical-geometry transport equation is *called* a 1-D transport equation, even though it has partial derivatives with respect to two independent variables.

4 Integral Equation for Neutron Transport

In this section, we derive the integral form of the transport equation (Bell and Glasstone 1970; Case and Zweifel 1967; Williams 1971), an alternate but equivalent description of the transport process embodied in the integrodifferential form that we have been discussing thus far. The integral transport equation can be derived using first flight kernels to relate the angular flux in an element of phase space to the neutron emission rate due to fixed, scattering, and fission sources everywhere in the medium, and to sources on the boundary. Here, though, we proceed directly from the differential part of the integrodifferential transport equation by noting that it is formally a linear first-order partial differential operator that can be inverted using standard techniques. The result is not an explicit solution for the angular flux, because the right side of the equation contains the scattering and fission sources, but is an alternate form of the Boltzmann equation, which has the form of an integral equation.

4.1 Integral Equation for the Angular Flux

We begin by compactly expressing the time- and energy-dependent general-geometry transport equation (46a) as:

$$\frac{1}{v} \frac{\partial \psi}{\partial t}(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \Sigma_t(\mathbf{x}, E, t) \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) = Q(\mathbf{x}, \boldsymbol{\Omega}, E, t), \quad \mathbf{x} \in V, \quad (120a)$$

with the boundary condition (44) and initial condition (45a):

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) = \psi^b(\mathbf{x}, \boldsymbol{\Omega}, E, t), \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \quad 0 < E < \infty, \quad 0 < t, \quad (120b)$$

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E, 0) = \psi^i(\mathbf{x}, \boldsymbol{\Omega}, E), \quad \mathbf{x} \in V, \quad \boldsymbol{\Omega} \in 4\pi, \quad 0 < E < \infty. \quad (120c)$$

The source Q in (120a), now including neutrons arising from inscatter and fission, is given by:

$$Q(\mathbf{x}, \boldsymbol{\Omega}, E, t) = \int_0^\infty \int_{4\pi} \Sigma_s(\boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}, E' \rightarrow E) \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\Omega' dE' \\ + \frac{\chi_p(E)}{4\pi} \int_0^\infty \int_{4\pi} \nu \Sigma_f(E') \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\Omega' dE' + \frac{1}{4\pi} Q(\mathbf{x}, E, t). \quad (121)$$

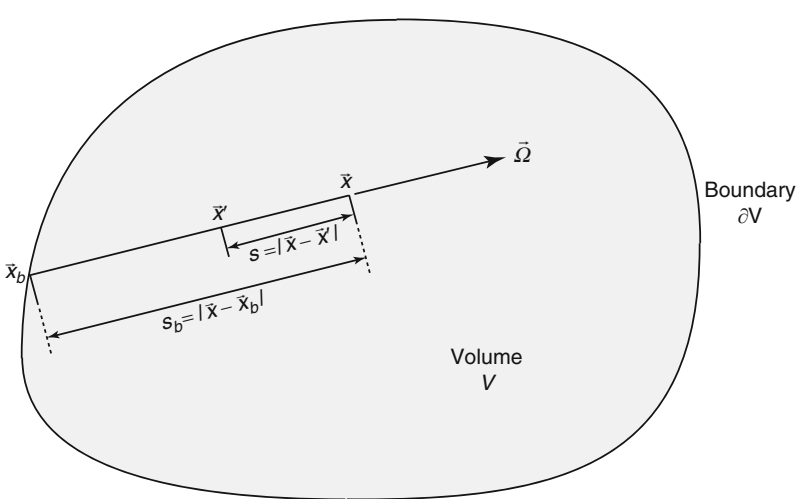

We ignore for the moment the fact that this source depends on the unknown angular flux and view (120) as a transport equation in a purely absorbing medium with a distributed source, and we seek an exact solution for the angular flux. To proceed in the general case, it is convenient to incorporate the initial condition as a source in the transport equation. Equation (120a) then reads:

$$\frac{1}{v} \frac{\partial \psi}{\partial t}(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \Sigma_t(\mathbf{x}, E, t) \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) = \widehat{Q}(\mathbf{x}, \boldsymbol{\Omega}, E, t), \quad \mathbf{x} \in V, \quad (122)$$

where:

$$\widehat{Q}(\mathbf{x}, \boldsymbol{\Omega}, E, t) = Q(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \frac{1}{v} \delta(t) \psi^i(\mathbf{x}, \boldsymbol{\Omega}, E), \quad (123)$$

where $\widehat{Q}(\mathbf{x}, E, \boldsymbol{\Omega}, t) = \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) = 0$ for $t < 0$. The boundary condition remains as given by (120b).

We consider a point $\mathbf{x}' \in V$ that lies a distance s from $\mathbf{x} \in V$ along the direction $-\boldsymbol{\Omega}$, which intersects the boundary ∂V at a point \mathbf{x}_b , as shown in  Fig. 25:

 Figure 25

Coordinates for the integral transport equation

Straightforward vector addition gives:

$$\mathbf{x}' = \mathbf{x} - s\boldsymbol{\Omega}, \quad (124a)$$

$$\mathbf{x}_b = \mathbf{x} - s_b\boldsymbol{\Omega}, \quad (124b)$$

where s_b is the distance from \mathbf{x} to the boundary along the direction $-\boldsymbol{\Omega}$. Similarly, if t is the time at which the neutron traveling along $\boldsymbol{\Omega}$ is found at position \mathbf{x} , then the neutron passed through position \mathbf{x}' at the earlier time t' given by:

$$t' = t - \frac{s}{v}. \quad (125)$$

We now write (122) with respect to the independent variables $(\mathbf{x}', \boldsymbol{\Omega}, E, t')$:

$$\frac{1}{v} \frac{\partial \psi}{\partial t'}(\mathbf{x}', \boldsymbol{\Omega}, E, t') + \boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}', \boldsymbol{\Omega}, E, t') + \Sigma_t(\mathbf{x}', E, t') \psi(\mathbf{x}', \boldsymbol{\Omega}, E, t') = \widehat{Q}(\mathbf{x}', \boldsymbol{\Omega}, E, t'), \quad \mathbf{x}' \in V, \quad (126)$$

where ∇ now operates on \mathbf{x}' , and we consider the derivative of the angular flux with respect to s :

$$\begin{aligned} -\frac{d}{ds} \psi(\mathbf{x}', \boldsymbol{\Omega}, E, t') &= -\frac{d}{ds} \psi\left(\mathbf{x} - s\boldsymbol{\Omega}, \boldsymbol{\Omega}, E, t - \frac{s}{v}\right) \\ &= -\left[\frac{\partial t'}{\partial s} \frac{\partial \psi}{\partial t'} + \frac{\partial \mathbf{x}'}{\partial s} \cdot \nabla \psi \right] \\ &= -\left[\frac{\partial \left(t - \frac{s}{v}\right)}{\partial s} \frac{\partial \psi}{\partial t'} + \frac{\partial (\mathbf{x} - s\boldsymbol{\Omega})}{\partial s} \cdot \nabla \psi \right] \\ &= \frac{1}{v} \frac{\partial \psi}{\partial t'} + \boldsymbol{\Omega} \cdot \nabla \psi. \end{aligned} \quad (127)$$

Thus, the streaming operator in (126) is the total derivative or directional derivative along the path of the neutron. We can then rewrite (126) as:

$$\begin{aligned} -\frac{d\psi}{ds}\left(\mathbf{x} - s\boldsymbol{\Omega}, \boldsymbol{\Omega}, E, t - \frac{s}{v}\right) + \Sigma_t\left(\mathbf{x} - s\boldsymbol{\Omega}, E, t - \frac{s}{v}\right) \psi\left(\mathbf{x} - s\boldsymbol{\Omega}, \boldsymbol{\Omega}, E, t - \frac{s}{v}\right) \\ = \widehat{Q}\left(\mathbf{x} - s\boldsymbol{\Omega}, \boldsymbol{\Omega}, E, t - \frac{s}{v}\right), \quad 0 \leq s \leq s_b, \end{aligned} \quad (128)$$

where:

$$\widehat{Q}\left(\mathbf{x} - s\boldsymbol{\Omega}, \boldsymbol{\Omega}, E, t - \frac{s}{v}\right) = Q\left(\mathbf{x} - s\boldsymbol{\Omega}, \boldsymbol{\Omega}, E, t - \frac{s}{v}\right) + \frac{1}{v} \delta\left(t - \frac{s}{v}\right) \psi^i(\mathbf{x} - s\boldsymbol{\Omega}, \boldsymbol{\Omega}, E). \quad (129)$$

Equation (128) is a first-order ordinary differential equation in s , which can be solved using the integrating factor method. Multiplying (128) by the integrating factor:

$$\exp\left[-\int_0^s \Sigma_t\left(\mathbf{x} - s''\boldsymbol{\Omega}, E, t - \frac{s''}{v}\right) ds''\right]$$

and manipulating the resulting equation in the usual way gives:

$$\begin{aligned} & \frac{d}{ds} \left[\exp \left(- \int_0^s \Sigma_t \left(\mathbf{x} - s'' \boldsymbol{\Omega}, E, t - \frac{s''}{v} \right) ds'' \right) \psi \left(\mathbf{x} - s \boldsymbol{\Omega}, \boldsymbol{\Omega}, E, t - \frac{s}{v} \right) \right] \\ & = -\widehat{Q} \left(\mathbf{x} - s \boldsymbol{\Omega}, \boldsymbol{\Omega}, E, t - \frac{s}{v} \right) \exp \left[- \int_0^s \Sigma_t \left(\mathbf{x} - s'' \boldsymbol{\Omega}, E, t - \frac{s''}{v} \right) ds'' \right]. \end{aligned} \quad (130)$$

Integrating (130) between 0 and s and reorganizing terms yields, after a bit of algebra:

$$\begin{aligned} \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) &= \exp \left(- \int_0^s \Sigma_t \left(\mathbf{x} - s'' \boldsymbol{\Omega}, E, t - \frac{s''}{v} \right) ds'' \right) \psi \left(\mathbf{x} - s \boldsymbol{\Omega}, \boldsymbol{\Omega}, E, t - \frac{s}{v} \right) \\ &+ \int_0^s \widehat{Q} \left(\mathbf{x} - s' \boldsymbol{\Omega}, \boldsymbol{\Omega}, E, t - \frac{s'}{v} \right) \exp \left[- \int_0^{s'} \Sigma_t \left(\mathbf{x} - s'' \boldsymbol{\Omega}, E, t - \frac{s''}{v} \right) ds'' \right] ds'. \end{aligned} \quad (131)$$

Evaluating (131) at the boundary point $s = s_b$ and noting that:

$$\begin{aligned} \psi \left(\mathbf{x} - s_b \boldsymbol{\Omega}, \boldsymbol{\Omega}, E, t - \frac{s_b}{v} \right) &= \psi \left(\mathbf{x}_b, \boldsymbol{\Omega}, E, t - \frac{s_b}{v} \right), \\ &= \psi^b \left(\mathbf{x}_b, \boldsymbol{\Omega}, E, t - \frac{s_b}{v} \right) U(\nu t - s_b), \end{aligned} \quad (132)$$

where $U(\cdot)$ is the Heaviside unit step function, we obtain:

$$\begin{aligned} \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) &= \exp \left(- \int_0^{s_b} \Sigma_t \left(\mathbf{x} - s'' \boldsymbol{\Omega}, E, t - \frac{s''}{v} \right) ds'' \right) \psi^b \left(\mathbf{x}_b, \boldsymbol{\Omega}, E, t - \frac{s_b}{v} \right) U(\nu t - s_b) \\ &+ \int_0^{s_b} \widehat{Q} \left(\mathbf{x} - s' \boldsymbol{\Omega}, \boldsymbol{\Omega}, E, t - \frac{s'}{v} \right) \exp \left[- \int_0^{s'} \Sigma_t \left(\mathbf{x} - s'' \boldsymbol{\Omega}, E, t - \frac{s''}{v} \right) ds'' \right] ds'. \end{aligned} \quad (133)$$

The Heaviside function $U(\nu t - s_b)$ in (133) accounts for the finite neutron speed; a source neutron originating at the boundary and traveling at speed ν cannot stream a distance s_b to arrive at position \mathbf{x} at time t if $\nu t < s_b$.

Next, we note that the integral over s' in (133) for the initial condition part of the source \widehat{Q} can be explicitly carried out to give:

$$\begin{aligned} & \int_0^{s_b} \frac{1}{v} \delta \left(t - \frac{s'}{v} \right) \psi^i(\mathbf{x} - s' \boldsymbol{\Omega}, \boldsymbol{\Omega}, E) \exp \left[- \int_0^{s'} \Sigma_t \left(\mathbf{x} - s'' \boldsymbol{\Omega}, E, t - \frac{s''}{v} \right) ds'' \right] ds' \\ &= \psi^i(\mathbf{x} - \nu t \boldsymbol{\Omega}, \boldsymbol{\Omega}, E) \exp \left[- \int_0^{\nu t} \Sigma_t \left(\mathbf{x} - s'' \boldsymbol{\Omega}, E, t - \frac{s''}{v} \right) ds'' \right] U(s_b - \nu t), \end{aligned} \quad (134)$$

where well-known properties of the delta function have been used. Isolating this term in (133) and noting from (124a) and (124b) that:

$$s_b = |\mathbf{x} - \mathbf{x}_b|, \quad (135)$$

we obtain:

$$\begin{aligned}
 \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) &= \psi^b\left(\mathbf{x}_b, \boldsymbol{\Omega}, E, t - \frac{|\mathbf{x} - \mathbf{x}_b|}{v}\right) \exp\left(-\int_0^{|\mathbf{x} - \mathbf{x}_b|} \Sigma_t\left(\mathbf{x} - s''\boldsymbol{\Omega}, E, t - \frac{s''}{v}\right) ds''\right) \\
 &\times U(vt - |\mathbf{x} - \mathbf{x}_b|) + \psi^i(\mathbf{x} - vt\boldsymbol{\Omega}, \boldsymbol{\Omega}, E) \exp\left(-\int_0^{vt} \Sigma_t\left(\mathbf{x} - s''\boldsymbol{\Omega}, E, t - \frac{s''}{v}\right) ds''\right) \\
 &\times U(|\mathbf{x} - \mathbf{x}_b| - vt) + \int_0^{|\mathbf{x} - \mathbf{x}_b|} Q\left(\mathbf{x} - s'\boldsymbol{\Omega}, \boldsymbol{\Omega}, E, t - \frac{s'}{v}\right) \\
 &\times \exp\left(-\int_0^{s'} \Sigma_t\left(\mathbf{x} - s''\boldsymbol{\Omega}, E, t - \frac{s''}{v}\right) ds''\right) ds'. \tag{136}
 \end{aligned}$$

To obtain the final result, we transform the line integral in the last term in (136) to a volume integral. To effect this transformation, we first introduce an angular direction variable $\boldsymbol{\Omega}'$ and express this term as:

$$\begin{aligned}
 &\int_{4\pi} \int_0^{|\mathbf{x} - \mathbf{x}_b|} \delta(\boldsymbol{\Omega} - \boldsymbol{\Omega}') Q\left(\mathbf{x} - s'\boldsymbol{\Omega}', \boldsymbol{\Omega}', E, t - \frac{s'}{v}\right) \\
 &\times \exp\left(-\int_0^{s'} \Sigma_t\left(\mathbf{x} - s''\boldsymbol{\Omega}', E, t - \frac{s''}{v}\right) ds''\right) ds' d\boldsymbol{\Omega}'. \tag{137}
 \end{aligned}$$

Defining the intermediate position vector:

$$\mathbf{x}' = \mathbf{x} - s'\boldsymbol{\Omega}', \tag{138}$$

we note that an elementary volume about \mathbf{x}' can be written as:

$$dV' = (s' d\theta')(s' \sin \theta' d\phi') ds' = s'^2 ds' \sin \theta' d\theta' d\phi' = s'^2 ds' d\boldsymbol{\Omega}'. \tag{139}$$

Further, noting from (138) that $s' = |\mathbf{x} - \mathbf{x}'|$, (139) yields:

$$ds' d\boldsymbol{\Omega}' = \frac{dV'}{s'^2} = \frac{dV'}{|\mathbf{x} - \mathbf{x}'|^2}. \tag{140}$$

Introducing these results into (136), we obtain:

$$\begin{aligned}
 \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) &= \psi^b\left(\mathbf{x}_b, \boldsymbol{\Omega}, E, t - \frac{|\mathbf{x} - \mathbf{x}_b|}{v}\right) \exp\left(-\int_0^{|\mathbf{x} - \mathbf{x}_b|} \Sigma_t\left(\mathbf{x} - s''\boldsymbol{\Omega}, E, t - \frac{s''}{v}\right) ds''\right) \\
 &\times U(vt - |\mathbf{x} - \mathbf{x}_b|) + \psi^i(\mathbf{x} - vt\boldsymbol{\Omega}, \boldsymbol{\Omega}, E) \exp\left(-\int_0^{vt} \Sigma_t\left(\mathbf{x} - s''\boldsymbol{\Omega}, E, t - \frac{s''}{v}\right) ds''\right) \\
 &\times U(|\mathbf{x} - \mathbf{x}_b| - vt) + \int_V Q\left(\mathbf{x}', \boldsymbol{\Omega}', E, t - \frac{|\mathbf{x} - \mathbf{x}'|}{v}\right) \\
 &\times \frac{\exp\left[-\int_0^{|\mathbf{x} - \mathbf{x}'|} \Sigma_t\left(\mathbf{x} - s''\boldsymbol{\Omega}', E, t - \frac{s''}{v}\right) ds''\right]}{|\mathbf{x} - \mathbf{x}'|^2} \delta(\boldsymbol{\Omega} - \boldsymbol{\Omega}') dV', \tag{141}
 \end{aligned}$$

where we have noted that the integration domain $[0, s_b] \times [0, \pi] \times [0, 2\pi]$ is just the volume V of the medium.

Equation (141), with the source given by (121), represents the most general form of the integral transport equation for the angular flux. It is valid for an arbitrary boundary source, initial condition, and fixed source. Although complicated in appearance, the terms in this equation each have a simple physical interpretation. To see this, we first note that the integral:

$$\tau(\mathbf{x}, \mathbf{x}', \boldsymbol{\Omega}, E, t) = \int_0^{|\mathbf{x}-\mathbf{x}'|} \Sigma_t \left(\mathbf{x} - s''\boldsymbol{\Omega}, E, t - \frac{s''}{v} \right) ds'', \quad (142)$$

is the *optical distance* (the number of mean free paths) that a neutron with energy E experiences while traveling from \mathbf{x}' (at time $t' = t - |\mathbf{x} - \mathbf{x}'|/v$) to \mathbf{x} (at time t) in the direction of flight $\boldsymbol{\Omega} = (\mathbf{x} - \mathbf{x}')/|\mathbf{x} - \mathbf{x}'|$. The exponential factor $\exp[-\tau(\dots)]$ appearing in (141) is the probability that a neutron will not suffer a collision over this distance, while $\exp[-\tau(\dots)]/|\mathbf{x} - \mathbf{x}'|^2$ is the free flight kernel that additionally accounts for geometric spreading of a point source of neutrons. Thus, the first term in (141) describes the contribution to the angular flux at $(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ from neutrons that originated at the boundary \mathbf{x}_b with energy E and direction $\boldsymbol{\Omega}$ at an earlier time $|\mathbf{x} - \mathbf{x}_b|/v$ and arrive at \mathbf{x} without suffering any collisions. The second term describes neutrons from the initial distribution with energy E and direction $\boldsymbol{\Omega}$ that are initially located at $\mathbf{x} - v t \boldsymbol{\Omega}$ and experience no collisions during the subsequent time interval t while streaming to \mathbf{x} . The third term accounts for source neutrons, as well as neutrons born in scattering and fission collisions with energy E and direction $\boldsymbol{\Omega}$ over the entire medium at an earlier time $|\mathbf{x} - \mathbf{x}_b|/v$ that subsequently arrive at \mathbf{x} unattenuated.

4.2 The Integral Equation for the Scalar Flux

The complexity of the integral equation is greatly reduced, and its utility greatly enhanced, when scattering is isotropic and a steady state is assumed. Under these conditions, (141) can be reduced without approximation to an integral equation for the scalar flux. To show this, we observe that the source Q given by (121) becomes independent of $\boldsymbol{\Omega}$ and simplifies to:

$$\begin{aligned} Q(\mathbf{x}, \boldsymbol{\Omega}, E) &= \frac{1}{4\pi} \int_0^\infty \Sigma_s(E' \rightarrow E) \phi(\mathbf{x}, E') dE' \\ &+ \frac{\chi_p(E)}{4\pi} \int_0^\infty v \Sigma_f(E') \phi(\mathbf{x}, E') dE' + \frac{1}{4\pi} Q(\mathbf{x}, E). \end{aligned} \quad (143)$$

Further, assuming a free surface condition, i.e., $\psi^b = 0$ and a homogeneous medium, the integral equation (141) becomes:

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E) = \int_V \frac{\exp(-\Sigma_t(E)|\mathbf{x} - \mathbf{x}'|)}{|\mathbf{x} - \mathbf{x}'|^2} Q(\mathbf{x}', E) \delta(\boldsymbol{\Omega} - \boldsymbol{\Omega}') dV'. \quad (144)$$

Integrating (144) over $\boldsymbol{\Omega}$ and substituting (143) into (144), we obtain the final result:

$$\begin{aligned} \phi(\mathbf{x}, E) &= \int_V \frac{\exp(-\Sigma_t(E)|\mathbf{x} - \mathbf{x}'|)}{4\pi|\mathbf{x} - \mathbf{x}'|^2} \int_0^\infty dE' [\Sigma_s(E' \rightarrow E) + \chi_p(E)v\Sigma_f(E')] \\ &\times \phi(\mathbf{x}', E') dV' + \int_V \frac{\exp(-\Sigma_t(E)|\mathbf{x} - \mathbf{x}'|)}{4\pi|\mathbf{x} - \mathbf{x}'|^2} Q(\mathbf{x}', E) dV'. \end{aligned} \quad (145)$$

This form of the integral equation, which has the scalar flux as the unknown, is known as *Peierls' equation*. Although stated above for a homogeneous medium with a free surface, it is apparent from the foregoing that Peierls' equation can be modified to account for boundary sources and material inhomogeneities.

4.3 Discussion

Peierls' equation is used in reactor physics for computing collision and escape probabilities in the context of fuel assembly homogenization. *Peierls' equation* has the advantage that the angular part of the flux is exactly treated, so that quadrature approximations of angular integrals are not necessary in numerical work. Moreover, boundary conditions are explicitly incorporated into the equation and therefore are not affected by numerical schemes devised to approximate the integral operator. However, unlike the integrodifferential transport equation, the integral equation is spatially nonlocal, which makes it less efficient for numerical solution.

At a more mathematical level, the integral equation is used in establishing the existence and uniqueness of solutions to the integrodifferential equation and, when expressed in terms of the collision density, in establishing rigorous results for convergence of the Monte Carlo method. Finally, we note that (145) can be reduced to the familiar forms of Peierls' equation appropriate in slab, spherically symmetric, and cylindrically symmetric geometries by suitable reductions of the free flight kernel.

5 The Adjoint Neutron Transport Equation

The transport operator is *non-self-adjoint*, and in many circumstances it is useful to formulate and solve the *adjoint transport equation*. This “dual” description is a powerful and enriching feature of the theory of linear operators and has been effectively exploited in reactor physics and neutron transport theory (Bell and Glasstone 1970; Case and Zweifel 1967; Henry 1975; Weinberg and Wigner 1958). Moreover, although the adjoint flux is a mathematical artifice, it can be interpreted physically as an “importance function” that quantifies the relative contribution of neutrons to a desired physical quantity (Lewins 1965). Adjoint formulations underlie the development of perturbation theory and variational methods (Bell and Glasstone 1970; Lewins 1968; Pomraning 1967a,b; Stacey 1974), sensitivity and uncertainty analysis (Cacuci 2003), and play a prominent role in the construction of a priori error estimates in the deterministic numerical solution of the transport equation. Also, neutron importance maps generated from the adjoint flux can be used to develop efficient variance reduction techniques that can result in dramatic improvements in the efficiency of Monte Carlo simulation methods (Van Ripper et al. 1997). Finally, in criticality problems, the adjoint fundamental eigenfunction is pivotal in developing a rigorous basis for reduced-order models, such as the point kinetics equations.

In this section, we derive the equation that is the mathematical adjoint of the general integrodifferential transport equation given by (46). For reasons that will become apparent below, we refer to the latter as the *forward transport equation*. We show how adjoint boundary and initial conditions can be assigned that are consistent with the importance interpretation of the adjoint angular flux, and we close with a presentation on forward and adjoint Green's functions.

A rigorous development of the theory of adjoint operators would rely heavily on techniques from functional analysis, a level of abstraction that is beyond the scope of this book. Instead, we adopt a more pedestrian approach that relies on explicit construction and emphasizes physical interpretation over mathematical rigor.

5.1 Definitions

We begin by defining the inner product, also known as the scalar product, of two real functions u and w of the phase space and time coordinates (\vec{x}, Ω, E, t) as:

$$\langle u, w \rangle = \int_0^T \int_0^\infty \int_R \int_{4\pi} u(\vec{x}, \Omega, E, t) w(\vec{x}, \Omega, E, t) d\Omega dV dE dt. \quad (146)$$

The integration domain is the phase space covering the volume of the body, the surface of the unit sphere, an allowable range of energies, and a time span which in principle can be infinite. The restriction to real functions is not unreasonable, since the functions encountered in neutronics applications, such as cross sections, sources, neutron number, angular flux, neutron importance, etc., are real and have well-defined physical interpretations. Moreover, the operators that act on these functions are also real. Smoothness and continuity of all functions and sufficient orders of their derivatives is tacitly assumed, and all mathematical operations employed are assumed to be valid. Useful properties of the inner product that follow, and which will be applied repeatedly in the ensuing, include symmetry, linearity, and homogeneity. These properties are encapsulated in the following statements:

$$\langle u, w \rangle = \langle w, u \rangle, \quad (147)$$

$$\langle \alpha_1 u_1 + \alpha_2 u_2, \alpha_3 w \rangle = \alpha_1 \alpha_3 \langle u_1, w \rangle + \alpha_2 \alpha_3 \langle u_2, w \rangle, \quad (148)$$

where α_1 , α_2 , and α_3 are real scalars. These properties of the inner product must be modified if the functions of interest are not real.

Given a linear operator \mathcal{L} , which may be differential, integral, or integro-differential, two real functions u and w , and an inner product, the *adjoint* of this operator, denoted by \mathcal{L}^\dagger , is defined by the inner-product identity:

$$\langle w, \mathcal{L}u \rangle = \langle u, \mathcal{L}^\dagger w \rangle. \quad (149)$$

Besides serving as a formal definition of an adjoint operator, this identity also defines an algorithm for the explicit construction of \mathcal{L}^\dagger . In this context, it is understood that all necessary elementary operations from calculus (differentiation rules, integration by parts, switching orders of integration, manipulating dummy variables) are applied until the function u stands freely under the inner product while w is acted upon by an operator. The latter operator is the adjoint operator. If \mathcal{L} is either entirely or partially differential in form, boundary terms will arise during this process, and these must be dealt with to complete the adjoint formulation. Strictly

speaking, \mathcal{L}^\dagger without regard to the boundary terms is referred to as the *formal adjoint* of \mathcal{L} , and the identity equation (149) is more precisely expressed as:

$$\langle w, \mathcal{L}u \rangle = P[u, w] + \langle u, \mathcal{L}^\dagger w \rangle, \quad (150)$$

where P denotes a boundary functional, also known as the bilinear concomitant. When $\mathcal{L}^\dagger = \mathcal{L}$, we say that the operator \mathcal{L} is *formally self-adjoint*. As we shall be treating all boundary terms explicitly, we drop the qualifying “formal” and, in what follows, simply refer to \mathcal{L}^\dagger as the adjoint operator.

5.2 Illustrative Example

Before proceeding with the derivation of the adjoint of the transport operator, it is instructive to apply the process to a 1-D second-order differential operator. Although this is done here for illustrative purposes, it is worth pointing out that the diffusion approximation to the transport equation and heavy gas models in neutron thermalization are described by second-order differential operators in spatial and energy variables, respectively. Thus, let us consider \mathcal{L} to be defined by:

$$\mathcal{L}u = a_2(x) \frac{d^2 u(x)}{dx^2} + a_1(x) \frac{du(x)}{dx} + a_0(x)u(x); \quad x \in [a, b], \quad (151)$$

with the inner product:

$$\langle u, w \rangle = \int_a^b u(x)w(x)dx. \quad (152)$$

Suitable boundary conditions on $u(x)$ are presumed prescribed at $x = a$ and $x = b$, and the coefficients a_0 , a_1 , and a_2 are specified functions of x . Proceeding, we multiply (151) by another function $w(x)$ and integrate over the domain of x . Noting the linearity of the inner product, the resulting expression may be written as a sum of inner products of w with the individual components of \mathcal{L} :

$$\begin{aligned} \langle w, \mathcal{L}u \rangle &= \langle w, \mathcal{L}_2 u \rangle + \langle w, \mathcal{L}_1 u \rangle + \langle w, \mathcal{L}_0 u \rangle \\ &= \int_a^b w(x) a_2(x) \frac{d^2 u(x)}{dx^2} dx + \int_a^b w(x) a_1(x) \frac{du(x)}{dx} dx \\ &\quad + \int_a^b w(x) a_0(x) u(x) dx. \end{aligned} \quad (153)$$

We consider each term independently and manipulate the integrands such that $u(x)$ is free-standing. Beginning with the last term on the right, we note that since multiplication is a commutative operation, we can write simply:

$$\begin{aligned} \langle w, \mathcal{L}_0 u \rangle &= \int_a^b w(x) a_0(x) u(x) dx \\ &= \int_a^b u(x) a_0(x) w(x) dx \\ &= \langle u, \mathcal{L}_0^\dagger w \rangle \equiv \langle u, \mathcal{L}_0 w \rangle. \end{aligned} \quad (154a)$$

This shows that the operation of multiplication is self-adjoint. Next, we consider the term involving the first derivative of u and integrate by parts:

$$\begin{aligned}
 \langle w, \mathcal{L}_1 u \rangle &= \int_a^b w(x) a_1(x) \frac{du(x)}{dx} dx \\
 &= \left[w(x) a_1(x) u(x) \right]_a^b - \int_a^b u(x) \frac{d}{dx} [a_1(x) w(x)] dx \\
 &= \left[w(x) a_1(x) u(x) \right]_a^b + \int_a^b u(x) \left\{ -\frac{d}{dx} [a_1(x) w(x)] \right\} dx \\
 &= \left[w(x) a_1(x) u(x) \right]_a^b + \langle u, \mathcal{L}_1^\dagger w \rangle.
 \end{aligned} \tag{154b}$$

This shows that a first-order differential operator is non-self-adjoint. However, when $a_1 = \text{constant}$, i.e., when \mathcal{L}_1 is a pure first derivative, we have the simple relationship $\mathcal{L}_1^\dagger = -\mathcal{L}_1$. We consider finally the term involving the second derivative of u and integrate by parts twice:

$$\begin{aligned}
 \langle w, \mathcal{L}_2 u \rangle &= \int_a^b w(x) a_2(x) \frac{d^2 u(x)}{dx^2} dx \\
 &= \left[w(x) a_2(x) \frac{du(x)}{dx} \right]_a^b - \int_a^b \frac{du(x)}{dx} \frac{d}{dx} [a_2(x) w(x)] dx \\
 &= \left[w(x) a_2(x) \frac{du(x)}{dx} - u(x) \frac{d}{dx} [a_2(x) w(x)] \right]_a^b + \int_a^b u(x) \frac{d^2}{dx^2} [a_2(x) w(x)] dx \\
 &= \left[w(x) a_2(x) \frac{du(x)}{dx} - u(x) \frac{d}{dx} [a_2(x) w(x)] \right]_a^b + \langle u, \mathcal{L}_2^\dagger w \rangle.
 \end{aligned} \tag{154c}$$

This shows that, in general, a second-order differential operator is non-self-adjoint. However, there are two circumstances under which \mathcal{L}_2 is self-adjoint: (i) when $a_2 = \text{constant}$, i.e., when \mathcal{L}_2 is a pure second derivative, and (ii) when the second-order differential operator appears in the symmetric form:

$$\mathcal{L}_2 u = \frac{d}{dx} \left[a_2(x) \frac{du(x)}{dx} \right]. \tag{155}$$

Combining (154) and inserting them into (153), we obtain for the adjoint of a general second-order ordinary differential operator:

$$\mathcal{L}^\dagger w = \frac{d^2}{dx^2} [a_2(x) w(x)] - \frac{d}{dx} [a_1(x) w(x)] + a_0(x) w(x); \quad x \in [a, b]. \tag{156}$$

We remark that although the operator defined by (151) is non-self-adjoint, it is well known and readily verified that any second-order differential operator can be converted into the self-adjoint form:

$$\mathcal{L} u = \frac{d}{dx} \left[p(x) \frac{du(x)}{dx} \right] + r(x) u(x), \tag{157}$$

by a suitable transformation of the coefficients. To complete this illustration, it is necessary to comment on the boundary functional associated with \mathcal{L} , which is given by:

$$P[u, w] = \left[w(x) a_2(x) \frac{du(x)}{dx} - u(x) \left(\frac{d}{dx} [a_2(x)w(x)] - a_1(x)w(x) \right) \right]_a^b. \quad (158)$$

Since u represents a physical quantity (such as the neutron scalar flux, chemical concentration, or temperature) that satisfies a well-posed mathematical model, a sufficient number of boundary conditions are presumably available. In the above example, these may take the form of u and/or its first derivative being specified at one or the other boundary $x = a$ and $x = b$. However, the adjoint function w is an arbitrary function (assumed sufficiently smooth) with no apparent physical attribute on which to base the assignment of boundary conditions. It will be shown below that a consistent set of boundary conditions can be obtained by requiring the boundary functional $P[u, w]$ to vanish. Thus, in the above example, if u satisfies:

$$u(a) = 0, \quad (159a)$$

$$u(b) = 0, \quad (159b)$$

then, $P[u, w]$ will vanish if:

$$w(a) = 0, \quad (160a)$$

$$w(b) = 0. \quad (160b)$$

On the other hand, if u satisfies:

$$\left. \frac{du}{dx} \right|_a = 0, \quad (161a)$$

$$\left. \frac{du}{dx} \right|_b = 0, \quad (161b)$$

then for $P[u, w]$ to vanish, w must satisfy the mixed boundary conditions:

$$\left. \frac{d}{dx} [a_2(x)w(x)] \right|_a - a_1(a)w(a) = 0, \quad (162a)$$

$$\left. \frac{d}{dx} [a_2(x)w(x)] \right|_b - a_1(b)w(b) = 0. \quad (162b)$$

Similarly, mixed boundary conditions on u , i.e., a linear combination of (159a, 159b) and (161a, 161b), yield mixed boundary conditions on w . Inhomogeneous boundary conditions and inhomogeneous terms (sources) can also be accommodated, as is demonstrated below for the adjoint neutron transport equation. Finally, if the operator is self-adjoint and the boundary conditions for u and w are identical, the problem is said to be self-adjoint, otherwise it is non-self-adjoint.

We close by remarking that the adjoints of 2-D and 3-D second-order differential operators can be similarly derived, employing Green's identities in lieu of integration by parts.

5.3 The Adjoint Transport Equation

We now apply the procedure developed above to derive the adjoint of the time-dependent forward transport equation, which we recall from (46) is:

$$\begin{aligned} & \frac{1}{v} \frac{\partial \psi}{\partial t}(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \Sigma_t(E) \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \\ &= \int_0^\infty \int_{4\pi} \Sigma_s(\boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}, E' \rightarrow E) \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\boldsymbol{\Omega}' dE' \\ &+ \frac{\chi_p(E)}{4\pi} \int_0^\infty \int_{4\pi} v \Sigma_f(E') \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\boldsymbol{\Omega}' dE' + \frac{1}{4\pi} Q(\mathbf{x}, E, t), \end{aligned} \quad (163a)$$

subject to the boundary condition and initial conditions:

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) = \psi^b(\mathbf{x}, \boldsymbol{\Omega}, E, t), \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \quad 0 < E < \infty, \quad 0 < t < T, \quad (163b)$$

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E, 0) = \psi^i(\mathbf{x}, \boldsymbol{\Omega}, E), \quad \mathbf{x} \in V, \quad \boldsymbol{\Omega} \in 4\pi, \quad 0 < E < \infty. \quad (163c)$$

It is convenient to express (163a) in the compact form:

$$\mathcal{L}\psi = \mathcal{L}_t\psi + \mathcal{L}_l\psi + \mathcal{L}_r\psi - \mathcal{L}_s\psi - \mathcal{L}_f\psi = Q, \quad (164)$$

where components of \mathcal{L} symbolically describe time evolution, free streaming or leakage, removal (outscatter and absorption), inscatter, and fission operators, respectively, and Q is the fixed source. Proceeding as outlined earlier, we take the inner product of an auxiliary function $\psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ with $\mathcal{L}\psi$ and define the adjoint operator \mathcal{L}^\dagger through the inner-product identity:

$$\langle \psi^\dagger, \mathcal{L}\psi \rangle = P[\psi, \psi^\dagger] + \langle \psi, \mathcal{L}^\dagger \psi^\dagger \rangle, \quad (165)$$

where we have explicitly noted that boundary terms arise from the differential components of the transport operator. Inserting (164) into (165) and noting the linearity of \mathcal{L} , we can write:

$$\langle \psi^\dagger, \mathcal{L}\psi \rangle = \langle \psi, \mathcal{L}_t^\dagger \psi^\dagger \rangle + \langle \psi, \mathcal{L}_l^\dagger \psi^\dagger \rangle + \langle \psi, \mathcal{L}_r^\dagger \psi^\dagger \rangle - \langle \psi, \mathcal{L}_s^\dagger \psi^\dagger \rangle - \langle \psi, \mathcal{L}_f^\dagger \psi^\dagger \rangle. \quad (166)$$

We begin our treatment with the simplest term, namely, the removal term:

$$\begin{aligned} \langle \psi^\dagger, \mathcal{L}_r\psi \rangle &= \int_0^T dt \int_0^\infty dE \int_{4\pi} d\boldsymbol{\Omega} \int_V dV \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \Sigma_t(E) \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \\ &= \int_0^T dt \int_0^\infty dE \int_{4\pi} d\boldsymbol{\Omega} \int_V dV \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \Sigma_t(E) \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \\ &= \langle \psi, \mathcal{L}_r^\dagger \psi^\dagger \rangle = \langle \psi, \mathcal{L}_r \psi^\dagger \rangle. \end{aligned} \quad (167a)$$

Thus, the removal term is trivially self-adjoint. Next, we consider the time evolution term and integrate by parts:

$$\begin{aligned}
 \langle \psi^\dagger, \mathcal{L}_t \psi \rangle &= \int_0^\infty dE \int_{4\pi} d\Omega \int_V dV \int_0^T dt \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \frac{1}{v} \frac{\partial \psi}{\partial t}(\mathbf{x}, \boldsymbol{\Omega}, E, t) \\
 &= \int_0^\infty dE \int_{4\pi} d\Omega \int_V dV \left[\frac{1}{v} \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \right]_0^T \\
 &\quad + \int_0^T dt \int_0^\infty dE \int_{4\pi} d\Omega \int_V dV \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \left[-\frac{1}{v} \frac{\partial \psi^\dagger}{\partial t}(\mathbf{x}, \boldsymbol{\Omega}, E, t) \right] \\
 &= P_t[\psi, \psi^\dagger] + \langle \psi, \mathcal{L}_t^\dagger \psi^\dagger \rangle. \tag{167b}
 \end{aligned}$$

The boundary functional P_t denotes a restricted inner product, wherein the time variable is constrained to take its initial and final values only. Being a first-order differential operator, the time evolution operator is non-self-adjoint. Proceeding likewise for the streaming operator, we first note the vector identity:

$$\psi^\dagger \mathcal{L}_l \psi = \psi^\dagger \boldsymbol{\Omega} \cdot \nabla \psi = \nabla \cdot (\boldsymbol{\Omega} \psi \psi^\dagger) - \psi \boldsymbol{\Omega} \cdot \nabla \psi^\dagger$$

and apply the divergence theorem to get:

$$\begin{aligned}
 \langle \psi^\dagger, \mathcal{L}_l \psi \rangle &= \int_0^T dt \int_0^\infty dE \int_{4\pi} d\Omega \int_V dV \left[\nabla \cdot (\boldsymbol{\Omega} \psi \psi^\dagger) - \psi \boldsymbol{\Omega} \cdot \nabla \psi^\dagger \right] \\
 &= \int_0^T dt \int_0^\infty dE \int_{4\pi} d\Omega \int_{\partial V} dA \mathbf{n} \cdot \boldsymbol{\Omega} \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \\
 &\quad + \int_0^T dt \int_0^\infty dE \int_{4\pi} d\Omega \int_V dV \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \left[-\boldsymbol{\Omega} \cdot \nabla \psi^\dagger \right] \\
 &= P_l[\psi, \psi^\dagger] + \langle \psi, \mathcal{L}_l^\dagger \psi^\dagger \rangle. \tag{167c}
 \end{aligned}$$

The boundary functional P_l denotes a restricted inner product, wherein the spatial variable is constrained to lie on the surface of the body. We observe that the streaming operator is also non-self-adjoint.

We consider now the adjoint of the inscatter operator, which is an integral operator. The significance of this is that boundary terms will not arise. Thus:

$$\begin{aligned}
 \langle \psi^\dagger, \mathcal{L}_s \psi \rangle &= \int_0^T dt \int_V dV \int_0^\infty dE \int_{4\pi} d\Omega \\
 &\quad \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \int_0^\infty dE' \int_{4\pi} d\Omega' \Sigma_s(\boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}, E' \rightarrow E) \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) \\
 &= \int_0^T dt \int_V dV \int_0^\infty dE' \int_{4\pi} d\Omega' \\
 &\quad \int_0^\infty dE \int_{4\pi} d\Omega \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \Sigma_s(\boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}, E' \rightarrow E) \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t)
 \end{aligned}$$

$$\begin{aligned}
&= \int_0^T dt \int_V dV \int_0^\infty dE \int_{4\pi} d\Omega \\
&\quad \int_0^\infty dE' \int_{4\pi} d\Omega' \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \Sigma_s(\boldsymbol{\Omega} \cdot \boldsymbol{\Omega}', E \rightarrow E') \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}', E', t) \\
&= \int_0^T dt \int_V dV \int_0^\infty dE \int_{4\pi} d\Omega \\
&\quad \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \int_0^\infty dE' \int_{4\pi} d\Omega' \Sigma_s(\boldsymbol{\Omega} \cdot \boldsymbol{\Omega}', E \rightarrow E') \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}', E', t) \\
&= \langle \psi, \mathcal{L}_s^\dagger \psi^\dagger \rangle, \tag{167d}
\end{aligned}$$

where in the first step, the orders of integration for the pre- and post-collision energies were switched, as were the corresponding directions, and in the second step, the dummy variables for pre- and post-collision energies were interchanged, as were those of the corresponding directions. We notice that the adjoint of the inscatter operator is obtained simply by reversing the orders of the pre- and post-collision arguments in the scattering kernel. Since scattering is rotationally symmetric, this affects only the energy loss part of the kernel. In other words, the scattering operator for coherent scattering (i.e., scattering without energy loss) is self-adjoint.

Manipulating the fission operator in the same manner as the scattering operator, we get:

$$\begin{aligned}
\langle \psi^\dagger, \mathcal{L}_f \psi \rangle &= \int_0^T dt \int_V dV \int_0^\infty dE \int_{4\pi} d\Omega \\
&\quad \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \frac{\chi_p(E)}{4\pi} \int_0^\infty dE' \int_{4\pi} d\Omega' \nu \Sigma_f(E') \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) \\
&= \int_0^T dt \int_V dV \int_0^\infty dE' \int_{4\pi} d\Omega' \\
&\quad \int_0^\infty dE \int_{4\pi} d\Omega \frac{\chi_p(E)}{4\pi} \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \nu \Sigma_f(E') \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) \\
&= \int_0^T dt \int_V dV \int_0^\infty dE \int_{4\pi} d\Omega \\
&\quad \int_0^\infty dE' \int_{4\pi} d\Omega' \frac{\chi_p(E')}{4\pi} \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \nu \Sigma_f(E) \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}', E', t) \\
&= \int_0^T dt \int_V dV \int_0^\infty dE \int_{4\pi} d\Omega \\
&\quad \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \nu \Sigma_f(E) \int_0^\infty dE' \int_{4\pi} d\Omega' \frac{\chi_p(E')}{4\pi} \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}', E', t) \\
&= \langle \psi, \mathcal{L}_f^\dagger \psi^\dagger \rangle. \tag{167e}
\end{aligned}$$

The fission operator is non-self-adjoint with respect to the energy variable, the angular distribution being isotropic. It becomes self-adjoint when the fission cross section is energy independent and all fission neutrons are born with the same energy, i.e., in the one-speed approximation.

Finally, substituting (167a–167e) into (166) yields:

$$\langle \psi^\dagger, \mathcal{L} \psi \rangle = P_t [\psi, \psi^\dagger] + P_l [\psi, \psi^\dagger] + \langle \psi, \mathcal{L}^\dagger \psi^\dagger \rangle, \tag{168}$$

and thus for the adjoint transport operator:

$$\begin{aligned} \mathcal{L}^\dagger \psi^\dagger = & -\frac{1}{v} \frac{\partial \psi^\dagger}{\partial t}(\mathbf{x}, \boldsymbol{\Omega}, E, t) - \boldsymbol{\Omega} \cdot \nabla \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \Sigma_t(E) \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \\ & - \int_0^\infty \int_{4\pi} \Sigma_s(\boldsymbol{\Omega} \cdot \boldsymbol{\Omega}', E \rightarrow E') \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\Omega' dE' \\ & - v \Sigma_f(E) \int_0^\infty \int_{4\pi} \frac{\chi_p(E')}{4\pi} \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\Omega' dE'. \end{aligned} \quad (169)$$

Although $\psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ is referred to as the *adjoint angular flux*, the physical interpretation of this quantity (hence its units) can only be established when it is related to some functional of the forward angular flux $\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)$, which, moreover, will dictate the choice of the adjoint source and adjoint boundary-initial conditions. This will be demonstrated shortly below, but first we make some general observations on the adjoint transport process.

An adjoint problem is defined such that the adjoint angular flux $\psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ is a solution of the following adjoint transport equation:

$$\begin{aligned} & -\frac{1}{v} \frac{\partial \psi^\dagger}{\partial t}(\mathbf{x}, \boldsymbol{\Omega}, E, t) - \boldsymbol{\Omega} \cdot \nabla \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \Sigma_t(E) \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \\ & = \int_0^\infty \int_{4\pi} \Sigma_s(\boldsymbol{\Omega} \cdot \boldsymbol{\Omega}', E \rightarrow E') \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\Omega' dE' \\ & \quad + v \Sigma_f(E) \int_0^\infty \int_{4\pi} \frac{\chi_p(E')}{4\pi} \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\Omega' dE' + Q^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t), \end{aligned} \quad (170)$$

for a given source adjoint Q^\dagger and given adjoint boundary and initial conditions. The adjoint flux represents the flow of pseudo-particles, or adjoint particles (sometimes also referred to as “adjunctons”), which, like neutrons, are created, destroyed, and redistributed in phase space. However, the adjoint transport process is fundamentally different. Adjoint particles:

- Are born in the medium distributed in phase space according to the adjoint source, but beginning at some *final* or *terminal* time
- Stream in *reverse* time to earlier times and travel in *reverse* directions
- *Gain* energy in scattering collisions, but the inscattering and outscattering terms do not balance when integrated over all energies and directions, i.e., the energy-dependent adjoint scattering operator is *nonconservative*
- Are isotropically emitted in fission reactions, but the energy-dependence of the adjoint fission cross section is proportional to the neutron fission spectrum while the energy spectrum of the resulting adjoint fission particles is proportional to the neutron fission cross section.

In other words, the adjoint equation is a *backward* transport equation, the adjoint angular flux satisfying a final or terminal condition in time instead of an initial condition, and a boundary condition which is specified for outgoing directions instead of incoming directions. To emphasize this distinction between the two approaches, the neutron transport equation is referred to as a *forward* transport equation.

Like the forward transport equation, the adjoint transport equation has a unique solution for subcritical systems with fixed sources, while adjoint k -eigenvalue and adjoint α -eigenvalue problems can be defined for multiplying systems. For both types of eigenvalue problems, it can

be shown that the adjoint fundamental mode is positive and the dominant adjoint eigenvalue is identical to the dominant eigenvalue of the forward problem.

5.4 Adjoint Flux as an Importance Function

Adjoint transport problems lead to a natural physical interpretation of the adjoint flux and, under certain circumstances, an adjoint formulation results in a more efficient solution to a physical problem than the traditional forward approach. We demonstrate this next.

Expressing the forward and adjoint problems in condensed notation as:

$$\mathcal{L}\psi = Q, \quad (171)$$

$$\mathcal{L}^\dagger \psi^\dagger = Q^\dagger, \quad (172)$$

and then subtracting the inner product of ψ with (172) from the inner-product of ψ^\dagger with (171), we obtain:

$$\langle \psi^\dagger, \mathcal{L}\psi \rangle - \langle \psi, \mathcal{L}^\dagger \psi^\dagger \rangle = \langle \psi^\dagger, Q \rangle - \langle \psi, Q^\dagger \rangle. \quad (173)$$

Noting the definition of the adjoint operator as expressed by the inner product identity equation (168), the left-hand side of (173) can be simplified to obtain:

$$P_t [\psi, \psi^\dagger] + P_l [\psi, \psi^\dagger] = \langle \psi^\dagger, Q \rangle - \langle \psi, Q^\dagger \rangle, \quad (174)$$

where P_t is given by:

$$\begin{aligned} P_t [\psi, \psi^\dagger] &= \int_0^\infty dE \int_{4\pi} d\Omega \int_V dV \frac{1}{v} \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, T) \psi(\mathbf{x}, \boldsymbol{\Omega}, E, T) \\ &\quad - \int_0^\infty dE \int_{4\pi} d\Omega \int_V dV \frac{1}{v} \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, 0) \psi(\mathbf{x}, \boldsymbol{\Omega}, E, 0), \end{aligned} \quad (175)$$

and P_l by:

$$\begin{aligned} P_l [\psi, \psi^\dagger] &= \int_0^T dt \int_0^\infty dE \int_{4\pi} d\Omega \int_{\partial V} dA \mathbf{n} \cdot \boldsymbol{\Omega} \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \\ &= \int_0^T dt \int_0^\infty dE \int_{\mathbf{n} \cdot \boldsymbol{\Omega} > 0} d\Omega \int_{\partial V} dA \mathbf{n} \cdot \boldsymbol{\Omega} \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \\ &\quad - \int_0^T dt \int_0^\infty dE \int_{\mathbf{n} \cdot \boldsymbol{\Omega} < 0} d\Omega \int_{\partial V} dA |\mathbf{n} \cdot \boldsymbol{\Omega}| \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t). \end{aligned} \quad (176)$$

The identity expressed by (174) is a key result in the adjoint-space formulation of transport problems. It relates functionals of the forward and adjoint angular fluxes at initial and final times and along incoming and outgoing directions at the surface of the body to the functionals of these fluxes in the interior of the body with fixed sources. This *generalized reciprocity relationship* enables transport problems to be posed using either forward or adjoint descriptions, provides a physical interpretation of the adjoint flux, and imposes consistent adjoint boundary and terminal conditions. While the class of such problems is wide, we highlight here so-called source-detector problems for subcritical systems at steady state, for which the adjoint formulation is extensively employed.

5.4.1 Source-Detector Problems

A classic forward problem is to determine a desired linear functional of the steady-state flux for a given interior source distribution and a free surface boundary condition. That is, we are interested in the solution of the forward transport equation:

$$\mathcal{L}\psi = Q, \quad (177a)$$

$$\psi = 0, \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \quad 0 < E < \infty, \quad (177b)$$

which is used to compute the functional:

$$\langle f, \psi \rangle = \int_0^\infty dE \int_{4\pi} d\Omega \int_R dV f(\mathbf{x}, \boldsymbol{\Omega}, E) \psi(\mathbf{x}, \boldsymbol{\Omega}, E), \quad (178)$$

where R is a subregion in the body and $f(\mathbf{x}, \boldsymbol{\Omega}, E)$ is a real function that makes the above functional a useful physical quantity. For instance, if it is desired to know the response of a detector to the local neutron flux, then f would be equated with the detector cross section $\Sigma_d(E)$, and subregion R would be the detector volume. If the detector is localized at some point \mathbf{x}_0 so that:

$$f(\mathbf{x}, \boldsymbol{\Omega}, E) = \Sigma_d(E) \delta(\mathbf{x} - \mathbf{x}_0), \quad (179)$$

then the desired functional gives the reaction rate at this point:

$$\begin{aligned} \langle f, \psi \rangle &= \int_0^\infty dE \int_{4\pi} d\Omega \Sigma_d(E) \psi(\mathbf{x}_0, \boldsymbol{\Omega}, E) \\ &= \int_0^\infty dE \Sigma_d(E) \phi(\mathbf{x}_0, E), \end{aligned} \quad (180)$$

where ϕ is the scalar flux at the detector. By choosing f appropriately, the functional can be generalized to yield energy and/or angle-dependent responses.

Since we are dealing with time-independent situations, the reciprocity condition, (174), reduces, upon substituting the vacuum boundary condition (177b), to:

$$\langle \psi^\dagger, Q \rangle - \langle \psi, Q^\dagger \rangle = \int_0^\infty dE \int_{n \cdot \boldsymbol{\Omega} > 0} d\Omega \int_{\partial V} dA \mathbf{n} \cdot \boldsymbol{\Omega} \psi(\mathbf{x}, \boldsymbol{\Omega}, E) \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E), \quad (181)$$

where the right-hand side contains the outward-directed forward and adjoint angular fluxes at the boundary. If now Q^\dagger is identified with f , a permissible operation because of the arbitrariness of the adjoint source, and moreover if we require the outward-directed adjoint flux at the boundary to vanish, (181) reduces to the particularly simple form:

$$\langle f, \psi \rangle = \langle \psi^\dagger, Q \rangle. \quad (182)$$

This result states that the desired functional of the forward flux can alternatively be obtained as the inner product of the adjoint flux with the physical source, where the adjoint flux now solves the *specific* adjoint transport problem:

$$\mathcal{L}^\dagger \psi^\dagger = f, \quad (183a)$$

$$\psi^\dagger = 0, \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} > 0, \quad 0 < E < \infty. \quad (183b)$$

The significance of this adjoint formulation of a detector response is twofold. First, it will be observed that the adjoint problem given by (183a,b) is independent of the source Q in the forward problem. Thus, if a detector response is desired for multiple different sources, an adjoint computation would be more efficient than a forward computation. The latter would require multiple solutions of the forward transport equation, one for each source, followed by evaluation of the inner product $\langle f, \psi \rangle$ for each such solution. The adjoint approach, on the other hand, necessitates obtaining a single solution to the adjoint transport equation, followed by evaluation of the inner product $\langle \psi^\dagger, Q \rangle$ for each source. This is computationally far less laborious than solving the forward problem for each different source. If multiple generalized responses are of interest for the same forward source, the forward computation is preferred for precisely the same reasons.

Second, let us assume that the forward source corresponds to one particle injected into the system locally in phase space, at a specified point \mathbf{x}_0 , direction of flight $\boldsymbol{\Omega}_0$, and energy E_0 :

$$Q(\mathbf{x}, \boldsymbol{\Omega}, E) = \delta(\mathbf{x} - \mathbf{x}_0) \delta(\boldsymbol{\Omega} - \boldsymbol{\Omega}_0) \delta(E - E_0). \quad (184)$$

Then, from (182), the resulting detector response is given by:

$$\langle f, \psi \rangle = \psi^\dagger(\mathbf{x}_0, \boldsymbol{\Omega}_0, E_0). \quad (185)$$

This result indicates that the detector response is equal to the adjoint flux at the point of injection of the neutron. Thus, the adjoint flux is a direct measure of the *importance* of a locally injected neutron to the response of a detector. For this reason, the adjoint flux is commonly referred to as the *importance function*. Moreover, the boundary (and terminal) conditions assigned to the adjoint flux become physically reasonable and consistent with this notion of importance. For instance, in the above problem, a neutron leaving the body at the boundary cannot contribute to the detector response, and hence its importance is *zero*.

For external detector locations, measuring the importance of outgoing neutrons, the adjoint boundary conditions require modification. In this case, we take $Q^\dagger = 0$ and by way of illustration, consider a monodirectional and monoenergetic incident beam condition for the forward problem:

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E) = \delta(\mathbf{x} - \mathbf{x}_b) \delta(\boldsymbol{\Omega} - \boldsymbol{\Omega}_b) \delta(E - E_b), \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \quad 0 < E < \infty, \quad (186)$$

where \mathbf{x}_b is the point on the boundary at which the beam of neutrons of energy E_b is incident along direction $\boldsymbol{\Omega}_b$. Note that since \mathbf{x} is restricted to lie on the boundary, the delta function

$\delta(\mathbf{x} - \mathbf{x}_b)$ is 2-D. This then gives a source normalization of one incident particle per second. The reciprocity relationship equation (174) reduces in this case to:

$$\begin{aligned} \int_0^\infty dE \int_{\mathbf{n} \cdot \boldsymbol{\Omega} > 0} d\Omega \int_{\partial V} dA \mathbf{n} \cdot \boldsymbol{\Omega} \psi(\mathbf{x}, \boldsymbol{\Omega}, E) \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E) \\ = |\mathbf{n} \cdot \boldsymbol{\Omega}_b| \psi^\dagger(\mathbf{x}_b, \boldsymbol{\Omega}_b, E_b), \quad \boldsymbol{\Omega}_b \cdot \mathbf{n} < 0. \end{aligned} \quad (187)$$

If the desired quantity is the total leakage from the body, we may assign:

$$\psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E) = 1, \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} > 0, \quad 0 < E < \infty, \quad (188)$$

and (187) then becomes:

$$\begin{aligned} J^+ &= \int_0^\infty dE \int_{\mathbf{n} \cdot \boldsymbol{\Omega} > 0} d\Omega \int_{\partial V} dA \mathbf{n} \cdot \boldsymbol{\Omega} \psi(\mathbf{x}, \boldsymbol{\Omega}, E) \\ &= |\mathbf{n} \cdot \boldsymbol{\Omega}_b| \psi^\dagger(\mathbf{x}_b, \boldsymbol{\Omega}_b, E_b), \quad \boldsymbol{\Omega}_b \cdot \mathbf{n} < 0. \end{aligned} \quad (189)$$

Thus, the total leakage from a body, given a monodirectional and monoenergetic incident beam, can be obtained by solving the homogeneous adjoint transport equation with unit outgoing adjoint flux at the boundary. In this case, the importance to the detector of neutrons *exiting* the medium will be the highest of any other group of neutrons. Since the forward problem involves singular functions at the boundary while the adjoint problem does not, numerical solution of the adjoint transport equation will be more efficient. With an appropriate choice of adjoint boundary condition in (187), it is evident that adjoint space formulation of surface energy spectra and/or angular distributions can be realized, with and without interior sources. This analysis can be further extended to show that the adjoint flux in a critical system measures the importance of a neutron injected at a particular phase space location in sustaining the fundamental mode.

From the considerations of this section, we observe that the adjoint problem cannot be considered independently of the forward problem. The identification of the adjoint source and assignment of adjoint boundary (and terminal) conditions makes the adjoint formulation (forward-) problem dependent. However, regardless of the application, the adjoint flux can always be imbued with an “importance” attribute, thereby rendering it a physically meaningful quantity.

5.5 Green's Functions

Finally, we consider a particularly interesting special case of the generalized reciprocity relationship given by (174). Let the forward and adjoint sources be completely localized in phase space and in time:

$$Q(\mathbf{x}, \boldsymbol{\Omega}, E, t) = \delta(\mathbf{x} - \mathbf{x}_0) \delta(\boldsymbol{\Omega} - \boldsymbol{\Omega}_0) \delta(E - E_0) \delta(t - t_0), \quad (190a)$$

$$Q^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) = \delta(\mathbf{x} - \mathbf{x}_1) \delta(\boldsymbol{\Omega} - \boldsymbol{\Omega}_1) \delta(E - E_1) \delta(t - t_1). \quad (190b)$$

The resulting solutions of the forward and adjoint transport equations with homogeneous boundary and initial/terminal conditions are the forward and adjoint volume Green's functions and are denoted by:

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \equiv G(\mathbf{x}, \boldsymbol{\Omega}, E, t; \mathbf{x}_0, \boldsymbol{\Omega}_0, E_0, t_0), \quad (191a)$$

$$\psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) \equiv G^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t; \mathbf{x}_b, \boldsymbol{\Omega}_b, E_b, t_b). \quad (191b)$$

For these sources, the reciprocity condition equation (174) reduces to:

$$\langle G^\dagger, Q \rangle = \langle G, Q^\dagger \rangle, \quad (192)$$

which, upon inserting (190a) and (190b) then yields the result:

$$G^\dagger(\mathbf{x}_0, \boldsymbol{\Omega}_0, E_0, t_0; \mathbf{x}_1, \boldsymbol{\Omega}_1, E_1, t_1) = G(\mathbf{x}_1, \boldsymbol{\Omega}_1, E_1, t_1; \mathbf{x}_0, \boldsymbol{\Omega}_0, E_0, t_0), \quad (193)$$

where from causality we require that $t_1 > t_0$. The right-hand side of the above equation is the neutron angular flux at the phase space point $(\mathbf{x}_1, \boldsymbol{\Omega}_1, E_1)$ at time t_1 , known as the field variables, resulting from the injection of a neutron at another phase space point $(\mathbf{x}_0, \boldsymbol{\Omega}_0, E_0)$ at an earlier time t_0 , known as the source variables. Equation (193) shows that this is identical to the angular flux for the adjoint problem but with the source and field variables reversed. A similar relationship involving surface Green's functions may be derived by imposing an incident beam on the boundary:

$$\begin{aligned} \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) &= \delta(\mathbf{x} - \mathbf{x}_0) \delta(\boldsymbol{\Omega} - \boldsymbol{\Omega}_0) \delta(E - E_0) \delta(t - t_0), \\ &\mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \quad 0 < E < \infty, \end{aligned} \quad (194a)$$

$$\begin{aligned} \psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) &= \delta(\mathbf{x} - \mathbf{x}_1) \delta(\boldsymbol{\Omega} - \boldsymbol{\Omega}_1) \delta(E - E_1) \delta(t - t_1), \\ &\mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} > 0, \quad 0 < E < \infty, \end{aligned} \quad (194b)$$

where \mathbf{x}_0 and \mathbf{x}_1 are two arbitrary points on boundary, and the source normalization is one particle (neutron and adjunction) per second. Substituting these into (174) we obtain:

$$|\mathbf{n} \cdot \boldsymbol{\Omega}_0| G^\dagger(\mathbf{x}_0, \boldsymbol{\Omega}_0, E_0, t_0; \mathbf{x}_1, \boldsymbol{\Omega}_1, E_1, t_1) = |\mathbf{n} \cdot \boldsymbol{\Omega}_1| G(\mathbf{x}_1, \boldsymbol{\Omega}_1, E_1, t_1; \mathbf{x}_0, \boldsymbol{\Omega}_0, E_0, t_0), \quad (195)$$

subject to the causality constraint $t_1 > t_0$ and where again homogeneous initial and terminal conditions have been assumed.

These reciprocity relationships can be used to construct the angular flux for a distributed source from the corresponding Green's function. Let us consider a localized adjoint interior source, for which the adjoint angular flux is just the adjoint Green's function G^\dagger , and a distributed forward source, for which the solution is the forward angular flux ψ . The reciprocity condition for this problem reads:

$$\langle G^\dagger, Q \rangle = \langle \psi, Q^\dagger \rangle, \quad (196)$$

or, more explicitly:

$$\begin{aligned} \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) &= \int_0^t dt' \int_V dV' \int_0^\infty dE' \int_{4\pi} d\Omega' Q(\mathbf{x}', \boldsymbol{\Omega}', E', t') G^\dagger(\mathbf{x}', \boldsymbol{\Omega}', E', t'; \mathbf{x}, \boldsymbol{\Omega}, E, t). \end{aligned} \quad (197)$$

Recalling (193), the adjoint Green's function in (197) can be replaced by the forward Green's function but with field and source variables reversed, to finally obtain:

$$\begin{aligned} \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) &= \int_0^t dt' \int_V dV' \int_0^\infty dE' \int_{4\pi} d\Omega' Q(\mathbf{x}', \boldsymbol{\Omega}', E', t') G(\mathbf{x}, \boldsymbol{\Omega}, E, t; \mathbf{x}', \boldsymbol{\Omega}', E', t'). \end{aligned} \quad (198)$$

This result is a statement of the *superposition principle* for linear systems: the angular flux corresponding to a distributed source can be obtained by a superposition of angular fluxes for elementary sources. It is a direct consequence of the linearity of the transport operator.

5.6 Discussion

We have seen that neutron transport problems can be mathematically modeled using either a forward or an adjoint formulation. The adjoint operator is commonly derived using an inner-product identity, and the adjoint formulation always inherits physical relevance that is unique to the forward problem. The interpretation of the adjoint flux as an importance function makes it possible to derive the adjoint transport equation from first principles, using balance arguments akin to those employed in the derivation of the forward equation (Bell and Glasstone 1970; Henry 1975; Lewins 1965). For certain applications, adjoint formulations have clear computational advantages over forward formulations, while for other applications the reverse is true. Forward and adjoint functions taken collectively provide a means of generating highly accurate approximate solutions at reduced cost, as exemplified by their use in variational methods, perturbation theory, and Monte Carlo simulations.

The derivations and results of this section simplify considerably for neutron transport in the one-speed approximation. Under these conditions, the scattering and fission operators become self-adjoint, leaving only the time evolution and streaming operators as non-self-adjoint. However, upon reflecting the direction and time variables, i.e., setting $\boldsymbol{\Omega} \rightarrow -\boldsymbol{\Omega}$ and $t \rightarrow -t$, the one-speed adjoint transport equation becomes identical to the forward transport equation. The distinction between the two formulations then stems purely from the respective sources and boundary and initial/terminal conditions, but for criticality problems in particular, this consequence obviates the need to independently solve the adjoint transport equation – the adjoint angular flux is obtained by simply reflecting the direction variable in the forward angular flux. Moreover, in a critical system, where sources are absent and homogeneous boundary conditions are imposed, the adjoint scalar flux is identical to the forward scalar flux.

Finally, we remark that under certain restrictive conditions, a hybrid forward–backward formulation can be developed to describe linear transport processes. Although this approach has not found utility in reactor physics or neutron transport applications, it is nevertheless widely used in the theory of radiation damage and atomic sputtering (Prinja 1989; Sigmund 1969; Williams 1979).

6 The Multigroup and One-Speed Neutron Transport Equations

The *multigroup* approximation to the neutron transport equation is almost universally used to discretize the continuous-energy variable E (Duderstadt and Hamilton 1976; Henry 1975; Lewis and Miller 1993). The structure of the resulting multigroup transport equations is closely related to that of the original transport equation, the difference being that the energy variable is discrete rather than continuous. (Thus, integrals over E are replaced by sums over *energy groups*.) Several important identities of the original continuous-energy scattering operator are preserved in the multigroup approximation. Here, we derive the multigroup transport equations and discuss some of their properties.

6.1 The Continuous-Energy Problem

We consider a general, steady-state, 3-D neutron transport equation:

$$\begin{aligned} & \Omega \cdot \nabla \psi(\mathbf{x}, \Omega, E) + \Sigma_t(\mathbf{x}, E) \psi(\mathbf{x}, \Omega, E) \\ &= \int_0^\infty \int_{4\pi} \Sigma_s(\mathbf{x}, \Omega' \cdot \Omega, E' \rightarrow E) \psi(\mathbf{x}, \Omega', E') d\Omega' dE' \\ &+ \frac{\chi(\mathbf{x}, E)}{4\pi} \int_0^\infty \int_{4\pi} \nu \Sigma_f(\mathbf{x}, E') \psi(\mathbf{x}, \Omega', E') d\Omega' dE' \\ &+ \frac{1}{4\pi} Q(\mathbf{x}, E), \quad \mathbf{x} \in V, \quad \Omega \in 4\pi, \quad 0 < E < \infty, \end{aligned} \quad (199a)$$

with the boundary condition:

$$\psi(\mathbf{x}, \Omega, E) = \psi^b(\mathbf{x}, \Omega, E), \quad \mathbf{x} \in \partial V, \quad \Omega \cdot \mathbf{n} < 0, \quad 0 < E < \infty. \quad (199b)$$

The cross sections and fission spectrum in these equations satisfy the usual identities (see [8], [13b], [14b], and [77]):

$$\Sigma_t(E) = \Sigma_s(E) + \Sigma_y(E) + \Sigma_f(E), \quad (200a)$$

$$\Sigma_s(E) = \int_0^\infty \int_{4\pi} \Sigma_s(\Omega \cdot \Omega', E \rightarrow E') d\Omega' dE' \quad (200b)$$

$$\int_0^\infty \chi(E) dE = 1, \quad (200c)$$

$$\Sigma_s(\Omega' \cdot \Omega, E' \rightarrow E) = \sum_{n=0}^N \frac{2n+1}{4\pi} \Sigma_{s,n}(E' \rightarrow E) P_n(\Omega' \cdot \Omega). \quad (200d)$$

6.2 The Multigroup Transport Equations

The multigroup approximation requires that a finite number G of energy bins or *groups* be chosen:

$$E_{min} = E_G < E_{G-1} < \cdots < E_g < E_{g-1} < \cdots < E_2 < E_1 = E_{max},$$

with E_{min} sufficiently small that neutrons with energies less than E_{min} are negligible, and with E_{max} sufficiently large that neutrons with energies greater than E_{max} are negligible. The energy range $E_g \leq E < E_{g-1}$ is the g th *energy group*. It is customary to order the energy groups with

the group index g increasing as the energies decrease. Then the slowing down of fast fission neutrons occurs through energy groups with increasing indices.

For each $1 \leq g \leq G$, we define:

$$\begin{aligned}\psi_g(\mathbf{x}, \boldsymbol{\Omega}) &= \int_{E_g}^{E_{g-1}} \psi(\mathbf{x}, \boldsymbol{\Omega}, E) dE \\ &= \text{Angular flux for group } g,\end{aligned}\quad (201a)$$

$$\begin{aligned}\chi_g(\mathbf{x}) &= \int_{E_g}^{E_{g-1}} \chi(\mathbf{x}, E) dE \\ &= \text{Multigroup fission spectrum for group } g,\end{aligned}\quad (201b)$$

$$\begin{aligned}Q_g(\mathbf{x}) &= \int_{E_g}^{E_{g-1}} Q(\mathbf{x}, E) dE \\ &= \text{Internal multigroup source to group } g.\end{aligned}\quad (201c)$$

Because these quantities are integrals over energy groups, the group fluxes have dimensions $\text{cm}^{-2} \text{s}^{-1}$, the multigroup fission spectrum is dimensionless, and the multigroup sources have dimensions $\text{cm}^{-3} \text{s}^{-1}$. Also, by the preceding definitions and (200c), the multigroup fission spectrum automatically satisfies:

$$\sum_{g=1}^G \chi_g(\mathbf{x}) = \sum_{g=1}^G \int_{E_g}^{E_{g-1}} \chi(\mathbf{x}, E) dE = \int_{E_{min}}^{E_{max}} \chi(\mathbf{x}, E) dE = 1. \quad (202)$$

To proceed, we integrate (199a) over the g th energy group, obtaining:

$$\begin{aligned}\boldsymbol{\Omega} \cdot \nabla \psi_g(\mathbf{x}, \boldsymbol{\Omega}) + \int_{E_g}^{E_{g-1}} \Sigma_t(\mathbf{x}, E) \psi(\mathbf{x}, \boldsymbol{\Omega}, E) dE \\ = \sum_{g'=1}^G \int_{E_g}^{E_{g-1}} \int_{E_{g'}}^{E_{g'-1}} \int_{4\pi} \Sigma_s(\mathbf{x}, E' \rightarrow E, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) \psi(\mathbf{x}, \boldsymbol{\Omega}', E') d\Omega' dE' dE \\ + \frac{\chi_g(\mathbf{x})}{4\pi} \sum_{g'=1}^G \int_{E_{g'}}^{E_{g'-1}} \int_{4\pi} \nu \Sigma_f(\mathbf{x}, E') \psi(\mathbf{x}, \boldsymbol{\Omega}', E') d\Omega' dE' + \frac{Q_g(\mathbf{x})}{4\pi}.\end{aligned}\quad (203)$$

Equivalently,

$$\begin{aligned}\boldsymbol{\Omega} \cdot \nabla \psi_g(\mathbf{x}, \boldsymbol{\Omega}) + \left[\frac{\int_{E_g}^{E_{g-1}} \Sigma_t(\mathbf{x}, E) \psi(\mathbf{x}, \boldsymbol{\Omega}, E) dE}{\int_{E_g}^{E_{g-1}} \psi(\mathbf{x}, \boldsymbol{\Omega}, E) dE} \right] \psi_g(\mathbf{x}, \boldsymbol{\Omega}) \\ = \sum_{g'=1}^G \int_{4\pi} \left[\frac{\int_{E_g}^{E_{g-1}} \int_{E_{g'}}^{E_{g'-1}} \Sigma_s(\mathbf{x}, E' \rightarrow E, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) \psi(\mathbf{x}, \boldsymbol{\Omega}', E') dE' dE}{\int_{E_{g'}}^{E_{g'-1}} \psi(\mathbf{x}, \boldsymbol{\Omega}', E') dE'} \right] \psi_{g'}(\mathbf{x}, \boldsymbol{\Omega}') d\Omega' \\ + \frac{\chi_g(\mathbf{x})}{4\pi} \sum_{g'=1}^G \int_{4\pi} \left[\frac{\int_{E_{g'}}^{E_{g'-1}} \nu \Sigma_f(\mathbf{x}, E') \psi(\mathbf{x}, \boldsymbol{\Omega}', E') dE'}{\int_{E_{g'}}^{E_{g'-1}} \psi(\mathbf{x}, \boldsymbol{\Omega}', E') dE'} \right] \psi_{g'}(\mathbf{x}, \boldsymbol{\Omega}') d\Omega' \\ + \frac{Q_g(\mathbf{x})}{4\pi},\end{aligned}\quad (204)$$

or:

$$\begin{aligned} \boldsymbol{\Omega} \cdot \nabla \psi_g(\mathbf{x}, \boldsymbol{\Omega}) + \hat{\Sigma}_{t,g}(\mathbf{x}, \boldsymbol{\Omega}) \psi_g(\mathbf{x}, \boldsymbol{\Omega}) &= \sum_{g'=1}^G \int_{4\pi} \hat{\Sigma}_{s,g' \rightarrow g}(\mathbf{x}, \boldsymbol{\Omega}', \boldsymbol{\Omega}) \psi_{g'}(\mathbf{x}, \boldsymbol{\Omega}') d\Omega' \\ &+ \frac{\chi_g(\mathbf{x})}{4\pi} \sum_{g'=1}^G \int_{4\pi} \hat{\nu} \hat{\Sigma}_{f,g}(\mathbf{x}, \boldsymbol{\Omega}') \psi_{g'}(\mathbf{x}, \boldsymbol{\Omega}') d\Omega' + \frac{Q_g(\mathbf{x})}{4\pi}, \end{aligned} \quad (205)$$

where:

$$\hat{\Sigma}_{t,g}(\mathbf{x}, \boldsymbol{\Omega}) = \left[\frac{\int_{E_g}^{E_{g-1}} \Sigma_t(\mathbf{x}, E) \psi(\mathbf{x}, \boldsymbol{\Omega}, E) dE}{\int_{E_g}^{E_{g-1}} \psi(\mathbf{x}, \boldsymbol{\Omega}, E) dE} \right], \quad (206a)$$

$$\hat{\Sigma}_{s,g' \rightarrow g}(\mathbf{x}, \boldsymbol{\Omega}', \boldsymbol{\Omega}) = \left[\frac{\int_{E_g}^{E_{g-1}} \int_{E_{g'}}^{E_{g'-1}} \Sigma_s(\mathbf{x}, E' \rightarrow E, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) \psi(\mathbf{x}, \boldsymbol{\Omega}', E') dE' dE}{\int_{E_{g'}}^{E_{g'-1}} \psi(\mathbf{x}, \boldsymbol{\Omega}', E') dE'} \right], \quad (206b)$$

$$\hat{\nu} \hat{\Sigma}_{f,g}(\mathbf{x}, \boldsymbol{\Omega}') = \left[\frac{\int_{E_{g'}}^{E_{g'-1}} \nu \Sigma_f(\mathbf{x}, E') \psi(\mathbf{x}, \boldsymbol{\Omega}', E') dE'}{\int_{E_{g'}}^{E_{g'-1}} \psi(\mathbf{x}, \boldsymbol{\Omega}', E') dE'} \right]. \quad (206c)$$

Exact boundary conditions can be obtained by integrating (199b) over the energy groups:

$$\psi_g(\mathbf{x}, \boldsymbol{\Omega}) = \psi_g^b(\mathbf{x}, \boldsymbol{\Omega}) = \int_{E_g}^{E_{g-1}} \psi^b(\mathbf{x}, \boldsymbol{\Omega}, E) dE, \quad \mathbf{x} \in V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0. \quad (207)$$

Equations (205–207) are an exact system of equations for the group fluxes. If the hatted coefficients in (205) were known, then (205) and (207) would, in the absence of spatial and angular discretizations, yield the exact group fluxes. However, by (206), the hatted coefficients depend on the solution of the continuous-energy problem and are not known.

In the multigroup approximation, an approximation for ψ is specified and introduced into the right sides of (206). The resulting approximate *multigroup cross sections* are then used in (205).

Specifically, in each of the bracketed terms in (206), we introduce the approximation:

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E) \approx \Psi(\mathbf{x}, E) f(\mathbf{x}, \boldsymbol{\Omega}), \quad (208)$$

where $\Psi(\mathbf{x}, E)$ is a specified *neutron spectrum*. The function $f(\mathbf{x}, \boldsymbol{\Omega})$ cancels out of each numerator and denominator, and (206) yield the *multigroup cross sections*:

$$\Sigma_{t,g}(\mathbf{x}) = \left[\frac{\int_{E_g}^{E_{g-1}} \Sigma_t(\mathbf{x}, E) \Psi(\mathbf{x}, E) dE}{\int_{E_g}^{E_{g-1}} \Psi(\mathbf{x}, E) dE} \right], \quad (209a)$$

$$\Sigma_{s,g' \rightarrow g}(\mathbf{x}, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) = \left[\frac{\int_{E_g}^{E_{g-1}} \int_{E_{g'}}^{E_{g'-1}} \Sigma_s(\mathbf{x}, E' \rightarrow E, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) \Psi(\mathbf{x}, E') dE' dE}{\int_{E_{g'}}^{E_{g'-1}} \Psi(\mathbf{x}, E') dE'} \right], \quad (209b)$$

$$v\Sigma_{f,g}(\mathbf{x}) = \left[\frac{\int_{E_{g'}}^{E_{g'-1}} v\Sigma_f(\mathbf{x}, E')\Psi(\mathbf{x}, E')dE'}{\int_{E_{g'}}^{E_{g'-1}} \Psi(\mathbf{x}, E)dE'} \right]. \quad (209c)$$

Introducing these expressions into (205), we obtain the *multigroup transport equations* (Duderstadt and Hamilton 1976; Henry 1975; Lewis and Miller 1993):

$$\begin{aligned} \boldsymbol{\Omega} \cdot \nabla \psi_g(\mathbf{x}, \boldsymbol{\Omega}) + \Sigma_{t,g}(\mathbf{x})\psi_g(\mathbf{x}, \boldsymbol{\Omega}) &= \sum_{g'=1}^G \int_{4\pi} \Sigma_{s,g' \rightarrow g}(\mathbf{x}, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega})\psi_{g'}(\mathbf{x}, \boldsymbol{\Omega}')d\Omega' \\ &+ \frac{\chi_g(\mathbf{x})}{4\pi} \sum_{g'=1}^G \int_{4\pi} v\hat{\Sigma}_{f,g}(\mathbf{x})\psi_{g'}(\mathbf{x}, \boldsymbol{\Omega}')d\Omega' + \frac{Q_g(\mathbf{x})}{4\pi}, \quad \mathbf{x} \in V, \quad \boldsymbol{\Omega} \in 4\pi, \quad 1 \leq g \leq G. \end{aligned} \quad (210)$$

The multigroup fluxes $\psi_g(\mathbf{x}, \boldsymbol{\Omega})$ are obtained by solving these equations with the *multigroup boundary conditions* (207).

To complete the multigroup approximation, the multigroup capture, fission, and scattering cross sections are defined analogous to (209):

$$\Sigma_{\gamma,g}(\mathbf{x}) = \left[\frac{\int_{E_g}^{E_{g-1}} \Sigma_{\gamma}(\mathbf{x}, E)\Psi(\mathbf{x}, E)dE}{\int_{E_g}^{E_{g-1}} \Psi(\mathbf{x}, E)dE} \right], \quad (211a)$$

$$\Sigma_{f,g}(\mathbf{x}) = \left[\frac{\int_{E_g}^{E_{g-1}} \Sigma_f(\mathbf{x}, E)\Psi(\mathbf{x}, E)dE}{\int_{E_g}^{E_{g-1}} \Psi(\mathbf{x}, E)dE} \right], \quad (211b)$$

$$\Sigma_{s,n,g' \rightarrow g}(\mathbf{x}) = \left[\frac{\int_{E_g}^{E_{g-1}} \int_{E_{g'}}^{E_{g'-1}} \Sigma_{s,n}(\mathbf{x}, E' \rightarrow E)\Psi(\mathbf{x}, E')dE'dE}{\int_{E_{g'}}^{E_{g'-1}} \Psi(\mathbf{x}, E')dE'} \right]. \quad (211c)$$

Then by (209), (211), and (200a), the following identities hold for all g and g' :

$$\begin{aligned} \Sigma_{t,g}(\mathbf{x}) &= \frac{\int_{E_g}^{E_{g-1}} [\Sigma_s(\mathbf{x}, E) + \Sigma_{\gamma}(\mathbf{x}, E) + \Sigma_f(\mathbf{x}, E)]\Psi(\mathbf{x}, E)dE}{\int_{E_g}^{E_{g-1}} \Psi(\mathbf{x}, E)dE} \\ &= \Sigma_{s,g}(\mathbf{x}) + \Sigma_{\gamma,g}(\mathbf{x}) + \Sigma_{f,g}(\mathbf{x}), \end{aligned} \quad (212a)$$

$$\begin{aligned} \Sigma_{s,g' \rightarrow g}(\mathbf{x}, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) &= \frac{\int_{E_g}^{E_{g-1}} \int_{E_{g'}}^{E_{g'-1}} \left[\sum_{n=0}^N \frac{2n+1}{4\pi} \Sigma_{s,n}(E' \rightarrow E) P_n(\boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) \right] \Psi(\mathbf{x}, E')dE'dE}{\int_{E_{g'}}^{E_{g'-1}} \Psi(\mathbf{x}, E')dE'} \\ &= \sum_{n=0}^N \frac{2n+1}{4\pi} \Sigma_{s,n,g' \rightarrow g} P_n(\boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}), \end{aligned} \quad (212b)$$

and:

$$\begin{aligned}
 \sum_{g'=1}^G \int_{4\pi} \Sigma_{s,g \rightarrow g'}(\mathbf{x}, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) d\boldsymbol{\Omega}' &= \sum_{g'=1}^G \int_{4\pi} \left[\sum_{n=0}^N \frac{2n+1}{4\pi} \Sigma_{s,n,g \rightarrow g'}(\mathbf{x}) P_n(\boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) \right] d\boldsymbol{\Omega}' \\
 &= \sum_{g'=1}^G \left[\sum_{n=0}^N \frac{2n+1}{4\pi} \Sigma_{s,n,g \rightarrow g'}(\mathbf{x}) \int_{4\pi} P_n(\boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) d\boldsymbol{\Omega}' \right] \\
 &= \sum_{g'=1}^G \left[\sum_{n=0}^N \frac{2n+1}{4\pi} \Sigma_{s,n,g \rightarrow g'}(\mathbf{x}) 4\pi \delta_{n,0} \right] \\
 &= \sum_{g'=1}^G \Sigma_{s,0,g \rightarrow g'}(\mathbf{x}) \\
 &= \sum_{g'=1}^G \left[\frac{\int_{E_g^{g'-1}}^{E_g} \int_{E_g}^{E_{g-1}} \Sigma_{s,0}(\mathbf{x}, E' \rightarrow E) \Psi(\mathbf{x}, E') dE' dE}{\int_{E_g}^{E_{g-1}} \Psi(\mathbf{x}, E') dE'} \right] \\
 &= \frac{\int_{E_{min}}^{E_{max}} \left[\int_{E_g}^{E_{g-1}} \Sigma_{s,0}(\mathbf{x}, E' \rightarrow E) \Psi(\mathbf{x}, E') dE' \right] dE}{\int_{E_g}^{E_{g-1}} \Psi(\mathbf{x}, E') dE'} \\
 &= \frac{\int_{E_g}^{E_{g-1}} \Sigma_s(\mathbf{x}, E') \Psi(\mathbf{x}, E') dE'}{\int_{E_g}^{E_{g-1}} \Psi(\mathbf{x}, E') dE'} \\
 &= \Sigma_{s,g}(\mathbf{x}). \tag{212c}
 \end{aligned}$$

Equations (202) and (212) hold for any choice of $\Psi(\mathbf{x}, E)$; they are the multigroup analog of the continuous-energy identities (200). These identities have the following significance: (i) Equations (200a) and (212a) guarantee that the multigroup transport equations describe the same types of physical reactions between neutrons and nuclei as the continuous-energy transport equations. (ii) Equations (200b) and (212c) guarantee that the continuous-energy and multigroup scattering operators are *conservative* – they neither create nor destroy neutrons. (These operators only rearrange neutrons in $(\boldsymbol{\Omega}, E)$ -space.) (iii) Equations (200c) and (201b) guarantee that the continuous-energy and multigroup fission spectra satisfy the same normalization. (iv) Equations (200d) and (212b) guarantee that the continuous-energy and multigroup differential scattering cross sections satisfy the same type of Legendre polynomial expansions.

We have noted that the structure of the multigroup transport equations is similar to that of the continuous-energy transport equation, the difference being that in the multigroup equations, the energy variable is discrete rather than continuous. From the above derivation, the only error in the multigroup equations occurs in replacing the “exact” multigroup cross sections (206) by the approximate multigroup cross sections (209). This replacement is exact in three hypothetical situations:

1. *The continuous-energy angular flux $\psi(\mathbf{x}, \boldsymbol{\Omega}, E)$ has the form of (208) and Ψ is known.* Unfortunately, (208) requires the angular flux to have the same energy spectrum for each direction of flight and the same direction-dependence for each energy. This occurs for an infinite homogeneous spatial medium where ψ is isotropic, but it does not generally occur otherwise.
2. *The continuous-energy cross sections are histograms in E and E' on the specified energy grid.* In this situation, the multigroup cross sections are independent of Ψ and equal to the

Figure 26
Continuous-energy histogram cross sections

continuous-energy cross sections within each group (see [Fig. 26](#)). Unfortunately, physical cross sections lack this simple histogram energy-dependence.

3. *The number of energy groups G becomes very large and the group widths $\Delta E_g = E_{g-1} - E_g$ become small.* In this limiting case, the multigroup cross sections become independent of Ψ and equal to the continuous-energy cross section evaluated at E_g (and $E_{g'}$).

Thus, the multigroup neutron transport equations are rarely exact for realistic neutron transport problems.

Nonetheless, item 2 in the preceding list suggests a useful way to interpret the multigroup transport equations: *they exactly represent a continuous-energy transport problem with cross sections that are histograms in energy.* If a multigroup approximation for a continuous-energy transport problem is developed, then the multigroup approximation yields the exact group fluxes for the continuous-energy transport problem whose (continuous-energy) cross sections $\Sigma^{hist}(E)$ are equal to the multigroup cross sections on each energy group:

$$\Sigma^{hist}(E) = \Sigma_g, \quad E_g \leq E < E_{g-1}, \quad 1 \leq g \leq G.$$

Effectively, then, the multigroup approximation is an approximation to the continuous-energy cross sections. If the physical continuous-energy cross sections are approximated by histograms in energy, then the multigroup approximation will yield the exact group fluxes for the approximate problem with histogram cross sections.

This discussion makes it plausible that as the number of energy groups increases and the energy group widths decrease, the error in the multigroup approximation should decrease. In fact, this is seen in practice.

6.3 The Within-Group and One-Group Transport Equations

For each g , (210) can be written:

$$\begin{aligned} \Omega \cdot \nabla \psi_g(\mathbf{x}, \Omega) + \Sigma_{t,g}(\mathbf{x}) \psi_g(\mathbf{x}, \Omega) &= \int_{4\pi} \Sigma_{s,g \rightarrow g}(\mathbf{x}, \Omega' \cdot \Omega) \psi_g(\mathbf{x}, \Omega') d\Omega' \\ &+ \frac{\chi_g(\mathbf{x})}{4\pi} \int_{4\pi} \nu \hat{\Sigma}_{f,g}(\mathbf{x}) \psi_g(\mathbf{x}, \Omega') d\Omega' + S_g(\mathbf{x}, \Omega), \end{aligned} \quad (213a)$$

where:

$$S_g(\mathbf{x}, \boldsymbol{\Omega}) = \frac{Q_g(\mathbf{x})}{4\pi} + \sum_{g' \neq g} \int_{4\pi} \Sigma_{s, g' \rightarrow g}(\mathbf{x}, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}) \psi_{g'}(\mathbf{x}, \boldsymbol{\Omega}') d\Omega' + \frac{\lambda_g(\mathbf{x})}{4\pi} \sum_{g' \neq g} \int_{4\pi} v \hat{\Sigma}_{f, g}(\mathbf{x}) \psi_{g'}(\mathbf{x}, \boldsymbol{\Omega}') d\Omega'. \quad (213b)$$

Equation (213a) is the *within-group* transport equation; it has the form of a monoenergetic transport equation, with an anisotropic *group-to-group source* S_g representing (i) the internal neutron source, (ii) the scattering source from groups g' to g , and (iii) the fission source from groups g' to g .

Equations (213) suggest an iterative strategy for solving multigroup transport problems. Specifically, estimates of $\psi_{g'}$ could be introduced into (213b) to obtain estimates of S_g . Then (213a) could be solved to obtain new estimates of ψ_g , and the process could be repeated. Variations on this idea are used in practical simulations (Lewis and Miller 1993).

6.4 Discussion

For obvious reasons, a practical goal is to make the number of energy groups G as small as possible and yet achieve sufficient accuracy. For this reason, great care is often taken in the derivation of the neutron spectrum $\Psi(\mathbf{x}, E)$ used to calculate multigroup cross sections. We cannot discuss here the various procedures used to calculate Ψ . However, we do note that different physical circumstances can lead to very different values of G .

For example, in light water reactor cores, where (208) is often a valid approximation, satisfactory numerical results can often be achieved with only $G = 2$ energy groups, group 1 representing the fast neutrons and group 2 representing the thermal neutrons. However, in shielding problems, where the neutron spectrum changes radically (and continuously) from one side of the shield to the other, often $G > 100$ energy groups are required to achieve accurate results.

A fundamental limitation with the conventional multigroup approximation presented here is the assumption (208) that at each spatial point, the energy spectrum is independent of direction $\boldsymbol{\Omega}$. This assumption is not valid at material interfaces between two materials with different capture cross sections. (If the material to the left of an interface has absorption resonances at different energies than the material to the right of the interface, then near the resonance, the neutrons traveling to the right will have an energy spectrum associated with the material on the left of the interface, and the neutrons traveling to the left will have a different energy spectrum associated with the material on the right of the interface.) At present, if highly accurate results are desired near material interfaces, the only option is to use a large number of energy groups G .

Another issue is that because neutron cross sections $\Sigma(E)$ can be extraordinarily complicated functions of E , the angular flux $\psi(\mathbf{x}, \boldsymbol{\Omega}, E)$ will also be a complicated function of E . In such cases, it is, as a practical matter, impossible to choose an energy group structure fine enough to “resolve” all the energy-dependent peaks and valleys of Σ and ψ . Hence, the calculation of suitable multigroup cross sections (i.e., the calculation of suitable neutron spectra to be used in [209] and [211]) becomes a problem-dependent, time-consuming, and yet essential

task. Because of this, the multigroup approximation is, although relatively simple to formulate, difficult to implement in detail for practical problems.

7 The Age and Wigner Approximations

In the classic Age and Wigner approximations to the neutron transport equation, the neutron scattering operator is approximated either directly (in the Age approximation) or indirectly (in the Wigner approximation) by a first-order differential operator (Larsen and Ahrens 2001; Weinberg and Wigner 1958). The resulting approximate equations are easier to solve numerically, and in certain problems, they can be solved analytically.

Conventional derivations of the Age and Wigner approximations from the infinite-medium neutron spectrum equation make use of a transformation of the equation from the energy variable E to the *lethargy* variable $u = \ln(E_0/E)$, where $E_0 \geq$ maximum neutron energy. After this transformation is made, the Age and Wigner approximations are derived, and then the results are converted back to E . (These derivations do not explain why the transformation from E to u is made to facilitate the approximations.) Here, the Age and Wigner approximations are derived directly from the scattering operator expressed in terms of E ; we do not first transform the infinite-medium neutron spectrum equation from E to u . Thus, the derivations given here have a certain pedagogical advantage: they do not involve the lethargy variable.

However, after deriving the Age and Wigner approximations, we briefly discuss why the use of the lethargy variable has a certain practical advantage in the calculation of multigroup cross sections.

7.1 The Infinite-Medium Neutron Spectrum Equation

We consider the eigenvalue problem defined by (49), with the elastic differential scattering cross section defined by (10) and (11). (Equations (10) are valid for *epithermal* energies $E \gg kT =$ the mean thermal energy of the nuclei.) Integrating (49a) over Ω and defining

$$\phi(\mathbf{x}, E) = \int_{4\pi} \psi(\mathbf{x}, \Omega, E) d\Omega = \text{scalar flux}, \quad (214a)$$

$$\mathbf{J}(\mathbf{x}, E) = \int_{4\pi} \Omega \psi(\mathbf{x}, \Omega, E) d\Omega = \text{neutron current}, \quad (214b)$$

we obtain:

$$\nabla \cdot \mathbf{J}(\mathbf{x}, E) + \Sigma_t(E)\phi(\mathbf{x}, E) = \int_E^{E/\alpha} \frac{\Sigma_s(E')\phi(\mathbf{x}, E')}{(1-\alpha)E'} dE' + \frac{\chi_p(E)}{k} \int_0^\infty \nu \Sigma_f(E')\phi(\mathbf{x}, E') dE',$$

where:

$$\alpha = \left(\frac{A-1}{A+1} \right)^2.$$

For an infinite homogeneous medium, ϕ and \mathbf{J} are independent of \mathbf{x} , and the previous equation can be written:

$$\Sigma_t(E)\phi(E) = \int_E^{E/\alpha} \frac{\Sigma_s(E')\phi(E')}{(1-\alpha)E'} dE' + Q(E), \quad (215a)$$

or:

$$\Sigma_a(E)\phi(E) = \mathcal{L}\phi(E) + Q(E), \quad (215b)$$

where $Q(E)$ is the fission source and \mathcal{L} is the *elastic neutron scattering operator*:

$$Q(E) = \frac{\chi_p(E)}{k} \int_0^\infty v\Sigma_f(E')\phi(E')dE', \quad (215c)$$

$$\mathcal{L}\phi(E) = \int_E^{E/\alpha} \frac{\Sigma_s(E')\phi(E')}{(1-\alpha)E'}dE' - \Sigma_s(E)\phi(E). \quad (215d)$$

In the following, we assume that $Q(E) = C\chi_p(E)$, where the constant C is given.

For $A = 1$ (epithermal elastic neutron scattering off hydrogen nuclei), $\alpha = 0$ and (215) become:

$$\Sigma_t(E)\phi(E) = \int_E^\infty \frac{\Sigma_s(E')\phi(E')}{E'}dE' + Q(E). \quad (216)$$

This equation can be solved analytically. Differentiating it with respect to E , we get:

$$\frac{d}{dE} [\Sigma_t(E)\phi(E) - Q(E)] = -\frac{\Sigma_t(E)\phi(E)}{E}, \quad (217)$$

which is an easily solved first-order ordinary differential equation. Assuming $Q(E) = \phi(E) = 0$ for $E \geq E_0$, we obtain the analytic solution:

$$\phi(E) = \frac{1}{\Sigma_t(E)} \left[Q(E) + \int_E^{E_0} Q(E') \frac{\Sigma_s(E')}{\Sigma_t(E')E'} e^{\int_E^{E'} \frac{\Sigma_s(E'')}{\Sigma_t(E'')} \frac{dE''}{E''}} dE' \right]. \quad (218)$$

However,

$$\int_E^{E'} \frac{\Sigma_s(E'')}{\Sigma_t(E'')} \frac{dE''}{E''} = \int_E^{E'} \frac{\Sigma_t(E'') - \Sigma_a(E'')}{\Sigma_t(E'')} \frac{dE''}{E''} = \left(\ln \frac{E'}{E} \right) - \int_E^{E'} \frac{\Sigma_a(E'')}{\Sigma_t(E'')} \frac{dE''}{E''},$$

so (218) can be written in the equivalent and more common form:

$$\phi(E) = \frac{1}{\Sigma_t(E)} \left[Q(E) + \frac{1}{E} \int_E^{E_0} Q(E') \frac{\Sigma_s(E')}{\Sigma_t(E')} e^{-\int_E^{E'} \frac{\Sigma_a(E'')}{\Sigma_t(E'')} \frac{dE''}{E''}} dE' \right]. \quad (219)$$

Unfortunately, for $A > 1$, it is not possible to perform these operations and solve (215). Thus, for $A > 1$, it is desirable to *accurately approximate* (215) in a form similar to (217), i.e., as an explicitly solvable first-order ordinary differential equation. Accomplishing this is the task at hand.

Before proceeding, we note that for any constant C ,

$$\mathcal{L} \left[\frac{C}{E\Sigma_s(E)} \right] = \int_E^{E/\alpha} \frac{C}{(1-\alpha)(E')^2} dE' - \frac{C}{E} = 0. \quad (220)$$

Thus, for $\Sigma_a(E) = 0$ and $Q(E) = 0$,

$$\phi_{eq}(E) = \frac{C}{E\Sigma_s(E)} \quad (221)$$

is an *equilibrium solution* of (215a). For intervals of energy in which $\Sigma_a(E) = 0$ and $Q(E) = 0$, $\phi(E)$ is very well approximated by (221), with a suitably defined C .

Also, for any $\phi(E)$, we have

$$\begin{aligned} \int_0^\infty \mathcal{L}\phi(E)dE &= \int_0^\infty \int_E^{E/\alpha} \frac{\Sigma_s(E')\phi(E')}{(1-\alpha)E'} dE' dE - \int_0^\infty \Sigma_s(E)\phi(E)dE \\ &= \int_{E'=0}^\infty \left(\int_{E=\alpha E'}^{E'} dE \right) \frac{\Sigma_s(E')\phi(E')}{(1-\alpha)E'} dE' - \int_0^\infty \Sigma_s(E)\phi(E)dE = 0. \end{aligned} \quad (222)$$

This equation states that scattering is *conservative*: the rate at which neutrons enter scattering events equals the rate at which neutrons exit scattering events.

In the following, we require any acceptable approximation of \mathcal{L} to satisfy (220) and (222). Thus, an approximate scattering operator should preserve the equilibrium solution $\phi_{eq}(E)$, and it should be conservative. (In fact, we will demand more, but we state these first two conditions here.)

7.2 The “Conservative” Form of the Neutron Transport Equation

The out-scattering (integral) operator in (215a) contains the differential scattering cross section:

$$\Sigma_s(E' \rightarrow E'') = \begin{cases} \frac{\Sigma_s(E')}{(1-\alpha)E'}, & E'' < E' < E''/\alpha \\ 0, & \text{otherwise.} \end{cases} \quad (223)$$

Using this, it is possible to determine the *slowing-down density* $F(E)$, defined by:

$$F(E) = \text{the rate per unit volume at which neutrons slow down from energies } (E') \text{ greater than } E \text{ to energies } (E'') \text{ less than } E. \quad (224)$$

As depicted in  Fig. 27, a neutron with energy E' in the interval $E < E' < E/\alpha$ can directly scatter into an energy $E'' < E$ only if E'' is in the interval $\alpha E' < E'' < E$.

■ **Figure 27**

Scattering from $E' > E$ to $E'' < E$

From (223), we have

$\Sigma_s(E' \rightarrow E'')\phi(E')dE'dE''$ = the rate per unit volume at which neutrons scatter from the interval $(E', E' + dE')$ to the interval $(E'', E'' + dE'')$.

Integrating this expression over $\alpha E' < E'' < E$ and then over $E < E' < E/\alpha$, and using the definition (224), we obtain:

$$F(E) = \int_{E'=E}^{E/\alpha} \int_{E''=\alpha E'}^E \frac{\Sigma_s(E')\phi(E')}{(1-\alpha)E'} dE'' dE' = \int_{E'=E}^{E/\alpha} \frac{E - \alpha E'}{(1-\alpha)E'} \Sigma_s(E')\phi(E') dE'. \quad (225)$$

Differentiating $F(E)$, we get:

$$\begin{aligned} \frac{dF}{dE}(E) &= \int_E^{E/\alpha} \frac{\Sigma_s(E')\phi(E')}{(1-\alpha)E'} dE' - \Sigma_s(E)\phi(E) \\ &= \mathcal{L}\phi(E). \end{aligned} \quad (226)$$

Therefore, the infinite-medium spectrum equation (215b) can be written in the advantageous *conservative* form:

$$\Sigma_a(E)\phi(E) = \frac{dF}{dE}(E) + Q(E), \quad (227a)$$

where:

$$F(E) = \frac{1}{1-\alpha} \int_{E'=E}^{E/\alpha} \frac{E - \alpha E'}{E'} \Sigma_s(E')\phi(E') dE'. \quad (227b)$$

To illustrate the utility of (227), let us consider for any mass number $A \geq 1$ a purely scattering problem [$\Sigma_a(E) = 0$] with $Q(E) > 0$ only for $E_1 < E < E_0$ (► Fig. 28). Then, operating on (227a) by $\int_E^{E_0} (\cdot) dE'$, we obtain for $E < E_1$:

$$F(E) = \int_{E_1}^{E_0} Q(E') dE' = \text{constant (independent of } E). \quad (228a)$$

However, since $\Sigma_a(E) = 0$ and $Q(E) = 0$ for $E < E_1$, then for $E \ll E_1$, $\phi_A(E)$ is very well-represented by (221):

$$\phi_A(E) \approx \frac{C}{E\Sigma_s(E)}, \quad (228b)$$

Figure 28
Purely scattering problem with $\Sigma_a(E) = 0$

where the constant C is undetermined. Assuming $E \ll E_1$, and introducing (228a) into the left side of (227b) and (228b) into the right side of (227b), we obtain

$$\begin{aligned} \int_{E_1}^{E_0} Q(E) dE &\approx \frac{1}{1-\alpha} \int_{E'=E}^{E/\alpha} \frac{E-\alpha E'}{E'} \left(\frac{C}{E'}\right) dE' \\ &= \frac{C}{1-\alpha} \int_{E'=E}^{E/\alpha} \frac{E-\alpha E'}{(E')^2} dE' = C\xi, \end{aligned} \tag{228c}$$

where (see Fig. 29):

$$\begin{aligned} \xi &= 1 + \frac{\alpha \ln \alpha}{1-\alpha} \\ &= \begin{cases} 1, & \alpha = 0 \quad (A = 1) \\ \frac{1-\alpha}{2} + O(1-\alpha)^2, & \alpha \approx 1 \quad (A \gg 1). \end{cases} \end{aligned} \tag{229}$$

Solving (228c) for C and introducing this expression into (228b), we obtain:

$$\phi_A(E) \approx \frac{1}{E\Sigma_s(E)} \left[\frac{1}{\xi} \int_{E_1}^{E_0} Q(E') dE' \right]. \tag{230}$$

Equation (230) is essentially exact for all α and for all $E < E_1$. We note that since $\xi = 1$ for $A = 1$ (see [229]), then (230) agrees with (219) for $A = 1$ and $\Sigma_a(E) = 0$.

As the mass number A of the scattering nuclei increases, α increases, so ξ decreases, and so $\phi(E)$ in (230) increases. Physically, this happens because for larger A , neutrons on the average lose less energy per collision, i.e., the slowing-down process becomes less efficient. Thus, neutrons increasingly “pile up” as they slow down. The constant ξ in (229) and (230) exactly calibrates this “piling-up” effect for the purely scattering problems considered above:

$$\frac{\phi_A(E)}{\phi_1(E)} = \frac{1}{\xi}, \quad E < E_1, \tag{231}$$

Figure 29
 ξ versus α

7.3 The Age Approximation

In (227), let us consider $A \gg 1$. Then

$$\alpha = \left(\frac{A-1}{A+1} \right)^2 = 1 - \frac{4}{A} + O\left(\frac{1}{A^2}\right), \quad (232)$$

so the width of the interval of integration in (225) is $O(1/A)$. (This implies $F(E) = O(1/A)$.) We approximate (225) as:

$$\begin{aligned} F(E) &= \int_{E'=E}^{E/\alpha} \frac{E - \alpha E'}{(1 - \alpha)(E')^2} [E' \Sigma_s(E') \phi(E')] dE' \\ &= \int_{E'=E}^{E/\alpha} \frac{E - \alpha E'}{(1 - \alpha)(E')^2} [E \Sigma_s(E) \phi(E) + O(E' - E)] dE' \\ &= \xi E \Sigma_s(E) \phi(E) + O\left(\frac{1}{A^2}\right). \end{aligned} \quad (233)$$

(The remainder term is $O(1/A^2)$ because $E' - E = O(1/A)$ and the interval of integration is $O(1/A)$.)

Introducing (233) into (227a) and ignoring the $O(1/A^2)$ terms, we obtain the following *Age Approximation* to the infinite-medium neutron spectrum equation:

$$\Sigma_a(E) \phi(E) = \xi \frac{d}{dE} E \Sigma_s(E) \phi(E) + Q(E). \quad (234)$$

(For electron transport problems, this result is called the *continuous slowing down* (CSD) approximation.) Equation (234) contains the basic approximation:

$$\mathcal{L}_A \phi(E) = \xi \frac{d}{dE} E \Sigma_s(E) \phi(E), \quad (235)$$

which satisfies (220) and (222), provided only that $E \Sigma_s(E) \phi(E)$ vanishes at $E = 0$ and ∞ .

The Age equation has $O(1/A^2)$ error for $A \gg 1$, so at this point its validity for small mass numbers A is unclear. For all A , (234), applied to the purely scattering problem discussed above yields the solution defined by (230) for all $E < E_1$. This shows that the Age approximation is valid for *some* problems for all A .

Equation (234) can be solved in closed form, yielding:

$$\phi(E) = \frac{1}{\xi E \Sigma_s(E)} \int_E^{E_0} e^{-\frac{1}{\xi} \int_E^{E'} \frac{\Sigma_a(E'')}{E'' \Sigma_s(E'')} dE''} Q(E') dE'. \quad (236)$$

For $A = 1$ ($\xi = 1$), this result reduces to the exact $A = 1$ solution given in (219) only if $E < E_1$ and $\Sigma_a(E) = 0$. Thus, the Age approximation is generally not accurate unless $A \gg 1$, $E < E_1$, and $\Sigma_a(E) \ll \Sigma_s(E)$.

A more accurate approximation, derived by Wigner, has the desirable features of the Age approximation *and* the additional desirable properties that it is exact for $A = 1$ and is generally much more accurate than the Age approximation. We discuss this next.

7.4 The Wigner Approximation

For $A \gg 1$, (234) holds with $O(1/A^2)$ error. Adding $\Sigma_s(E) \phi(E)$ to both sides of this equation and using $\xi = O(1/A)$, we obtain:

$$\begin{aligned} \Sigma_t(E) \phi(E) &= \left[\Sigma_s(E) \phi(E) + \xi \frac{d}{dE} E \Sigma_s(E) \phi(E) \right] + Q(E) + O\left(\frac{1}{A^2}\right) \\ &= \frac{1}{E} \left(I + \xi E \frac{d}{dE} \right) E \Sigma_s(E) \phi(E) + Q(E) + O\left(\frac{1}{A^2}\right) \\ &= \frac{1}{E} \left(I - \xi E \frac{d}{dE} \right)^{-1} E \Sigma_s(E) \phi(E) + Q(E) + O\left(\frac{1}{A^2}\right). \end{aligned} \quad (237)$$

Ignoring the $O(1/A^2)$ terms, we obtain the basic form of the *Wigner approximation* to the infinite-medium neutron spectrum equation:

$$\Sigma_t(E) \phi(E) = \frac{1}{E} \left(I - \xi E \frac{d}{dE} \right)^{-1} E \Sigma_s(E) \phi(E) + Q(E). \quad (238a)$$

The first term on the right side:

$$H_W(E) = \frac{1}{E} \left(I - \xi E \frac{d}{dE} \right)^{-1} E \Sigma_s(E) \phi(E) \quad (238b)$$

satisfies the first-order ordinary differential equation:

$$\left(I - \xi E \frac{d}{dE}\right) E H_W(E) = E \Sigma_s(E) \phi(E),$$

or:

$$H_W(E) - \xi \frac{d}{dE} E H_W(E) = \Sigma_s(E) \phi(E).$$

The solution of this equation is:

$$H_W(E) = \frac{1}{\xi E} \int_E^\infty \left(\frac{E}{E'}\right)^{1/\xi} \Sigma_s(E') \phi(E') dE'. \quad (238c)$$

Introducing (238c) into (238a), we get:

$$\Sigma_t(E) \phi(E) = \frac{1}{\xi E} \int_E^\infty \left(\frac{E}{E'}\right)^{1/\xi} \Sigma_s(E') \phi(E') dE' + Q(E). \quad (238d)$$

Thus, unlike the Age approximation, the Wigner approximation approximates the scattering integral by an actual integral, $H_W(E)$. For $A \gg 1$, $H_W(E)$ is an $O(1/A^2)$ approximation to the exact scattering integral in (215b):

$$H(E) = \frac{1}{1 - \alpha} \int_E^{E/\alpha} \frac{\Sigma_s(E') \phi(E')}{E'} dE'. \quad (239)$$

However, for $A = 1$, $\alpha = 0$ and $\xi = 1$, so $H_W(E) = H(E)$, and Wigner's approximation is exact!

Also, the Wigner approximation to the scattering operator \mathcal{L} :

$$\begin{aligned} \mathcal{L}_W \phi(E) &= \left[\frac{1}{E} \left(I - \xi E \frac{d}{dE} \right)^{-1} E - I \right] \Sigma_s(E) \phi(E) \\ &= \frac{1}{E} \left[\left(I - \xi E \frac{d}{dE} \right)^{-1} - I \right] E \Sigma_s(E) \phi(E) \end{aligned} \quad (240)$$

can be written in two equivalent forms:

$$\begin{aligned} \mathcal{L}_W \phi(E) &= \frac{1}{E} \left(I - \xi E \frac{d}{dE} \right)^{-1} \left[I - \left(I - \xi E \frac{d}{dE} \right) \right] E \Sigma_s(E) \phi(E) \\ &= \frac{\xi}{E} \left(I - \xi E \frac{d}{dE} \right)^{-1} E \frac{d}{dE} E \Sigma_s(E) \phi(E), \end{aligned} \quad (241)$$

and:

$$\begin{aligned} \mathcal{L}_W \phi(E) &= \frac{1}{E} \left[I - \left(I - \xi E \frac{d}{dE} \right) \right] \left(I - \xi E \frac{d}{dE} \right)^{-1} E \Sigma_s(E) \phi(E) \\ &= \xi \frac{d}{dE} \left(I - \xi E \frac{d}{dE} \right)^{-1} E \Sigma_s(E) \phi(E). \end{aligned} \quad (242)$$

Equation (241) shows that \mathcal{L}_W preserves $\phi_{eq}(E)$, and (242) shows that \mathcal{L}_W is conservative. Wigner's equation (238) can also be written:

$$\left(I - \xi E \frac{d}{dE}\right) E [\Sigma_t(E)\phi(E) - Q(E)] = E \Sigma_s(E)\phi(E),$$

or:

$$\Sigma_t(E)\phi(E) - Q(E) - \xi \frac{d}{dE} E [\Sigma_t(E)\phi(E) - Q(E)] = \Sigma_s(E)\phi(E)$$

or:

$$\Sigma_a(E)\phi(E) = \xi \frac{d}{dE} E [\Sigma_t(E)\phi(E) - Q(E)] + Q(E). \quad (243)$$

Solving this first-order ordinary differential equation with $\phi(E_0) = 0$, we obtain:

$$\phi_W(E) = \frac{1}{\Sigma_t(E)} \left[Q(E) + \frac{1}{\xi E} \int_E^{E_0} e^{-\frac{1}{\xi} \int_E^{E'} \frac{\Sigma_a(E'')}{E'' \Sigma_t(E'')} dE''} \frac{\Sigma_s(E')}{\Sigma_t(E')} Q(E') dE' \right]. \quad (244)$$

This result is exact for $A = 1$ and has $O(1/A^2)$ error for $A \gg 1$.

If we consider a monoenergetic source:

$$Q(E) = Q_0 \delta(E - E_0),$$

then for $E < E_0$, (244) can be written as the product of four factors:

$$\phi_W(E) = \left[\frac{Q_0}{\xi E \Sigma_s(E)} \right] \left[\frac{\Sigma_s(E_0)}{\Sigma_t(E_0)} \right] \left[e^{-\frac{1}{\xi} \int_E^{E_0} \frac{\Sigma_a(E')}{E' \Sigma_t(E')} dE'} \right] \left[\frac{\Sigma_s(E)}{\Sigma_t(E)} \right], \quad (245)$$

each of which has a straightforward physical interpretation.

The first factor is the equilibrium solution for a problem emitting Q_0 neutrons per cm^3 per s with $\Sigma_a(E) = 0$:

$$\phi_{eq}(E) = \frac{Q_0}{\xi E \Sigma_s(E)}. \quad (246a)$$

If $\Sigma_a(E) = 0$, the remaining three factors on the right side of (245) all equal unity, and then $\phi_W(E) = \phi_{eq}(E)$. The three terms suppress $\phi_W(E)$ in ways that account for absorption.

The second factor is the *scattering ratio at energy E_0* :

$$c(E_0) = \frac{\Sigma_s(E_0)}{\Sigma_t(E_0)} = \text{the probability that a (source) neutron with energy } E_0 \text{ will not be absorbed.} \quad (246b)$$

This factor is necessary because only the source neutrons (all of which are born at energy E_0) that scatter can contribute to $\phi(E)$. Effectively, the product

$$q_0 = Q_0 \frac{\Sigma_s(E_0)}{\Sigma_t(E_0)}$$

is a *reduced source rate*, which accounts for source neutrons born at E_0 that are immediately absorbed and hence do not slow down.

The third factor on the right side of (245) is the *resonance escape probability*:

$$p(E_0 \rightarrow E) = e^{-\frac{1}{\xi} \int_E^{E_0} \frac{\Sigma_a(E')}{E' \Sigma_t(E')} dE'}$$

= the probability that a neutron will not be absorbed
while slowing down from E_0 to E . (246c)

The fourth factor is the scattering ratio $c(E)$, to account for the suppression of $\phi(E)$ due to absorption at energy E .

Equation (245) is therefore not only an accurate result, but it has an intuitive physical interpretation. (The expression for the resonance escape probability in (245) is especially accurate and useful.) We now turn to providing a general sketch of $\phi_W(E)$.

For heavy nuclei, $\Sigma_a(E)$ often consists of narrow, isolated absorption resonances, while $\Sigma_s(E)$ is relatively constant (see \blacktriangleright Fig. 30). In this situation, $c(E)$ has the form depicted in \blacktriangleright Fig. 31, and $p(E_0 \rightarrow E)$ has the form depicted in \blacktriangleright Fig. 32. Combining these, the product $\phi(E)$ expressed in (245) has the form depicted in \blacktriangleright Fig. 33.

Hence, as neutrons slow down through each absorption resonance, $\phi_W(E)$ experiences a narrow “dip” within the resonance and returns to a new equilibrium solution below the resonance (the amplitude is reduced because of neutrons that are absorbed within the resonance).

Figure 30
 $\Sigma_a(E)$ and $\Sigma_s(E)$

Figure 31
 $c(E)$

Figure 32
 $\rho(E_0 \rightarrow E)$

Figure 33
 $\phi_W(E)$

The above Wigner depiction of $\phi(E)$ is surprisingly accurate. The simpler Age depiction of $\phi(E)$ is usually less accurate, unless $\Sigma_a(E) \ll \Sigma_s(E)$.

7.5 Discussion

We have derived the *Age* (or CSD) approximation (234), and the *Wigner* approximation (243) of the infinite-medium neutron spectrum equation (215a). The Age and Wigner approximations both:

1. Are conservative.
2. Preserve the equilibrium solution $\phi_{eq}(E)$.
3. Are $O(1/A^2)$ asymptotic approximations to the spectrum equation for $A \gg 1$.
4. Yield for $E < E_1$ the solution (230) of the purely scattering problem.

However, the Wigner approximation is generally more accurate than the Age approximation, for the following reasons:

1. The Wigner approximation $H_W(E)$ of the out-scattering integral $H(E)$ is itself an integral [see (238c) and (239)], and $H_W(E) = H(E)$ for $A = 1$.
2. Because the Wigner approximation is exact for $A = 1$ and highly accurate for $A \gg 1$, it is also quite accurate for intermediate values of A .

Therefore, the Wigner approximation is quite accurate for all values of A , whereas the simpler Age approximation is generally only accurate for $A \gg 1$.

8 The Diffusion Approximation

Because of its relative simplicity and range of applicability, the diffusion approximation to the Boltzmann transport equation is widely used for reactor core simulations. However, the diffusion approximation has several subtleties, and even today there are issues in its use that are not fully understood.

Here we derive the approximate diffusion equation for a 1-D planar-geometry problem, using a simplified version of asymptotic derivations that have been published during the past 35 years (Habetler and Matkowsky 1975; Larsen 1980; Larsen and Keller 1974; Larsen et al. 1996; Papanicolaou 1975). The choice of 1-D planar geometry enables us to perform the derivation with the Legendre polynomials, rather than the more complex spherical harmonic functions, which are necessary for 2-D, and 3-D problems. However, the basic underlying issues in 1-D, 2-D, and 3-D geometries are the same.

8.1 Derivation of the Diffusion Equation

We consider the energy-dependent, planar-geometry Boltzmann transport equation with anisotropic scattering:

$$\begin{aligned} & \mu \frac{\partial \psi}{\partial x}(x, \mu, E) + \Sigma_t(x, E)\psi(x, \mu, E) \\ &= \sum_{m=0}^{\infty} \frac{2m+1}{2} P_m(\mu) \int_0^{\infty} \int_{-1}^1 P_m(\mu') \Sigma_{s,m}(x, E' \rightarrow E) \psi(x, \mu', E') d\mu' dE' \\ &+ \frac{Q(x, E)}{2}, \end{aligned} \quad (247a)$$

on the system $0 \leq x \leq X$, with boundary conditions:

$$\psi(0, \mu, E) = \psi(0, -\mu, E), \quad 0 < \mu \leq 1, \quad (247b)$$

$$\psi(X, \mu, E) = \psi^b(\mu, E), \quad -1 \leq \mu < 0. \quad (247c)$$

(Equation [247b] is a reflection or symmetry boundary condition; [247c] specifies the incident flux $\psi^b(\mu, E)$ on the right boundary of the system.)

To initiate the derivation of the diffusion approximation to (247), let us first consider (247a) for an *infinite homogeneous* medium having no spatial dependence:

$$\Sigma_t(E)\psi(\mu, E) = \sum_{m=0}^{\infty} \frac{2m+1}{2} P_m(\mu) \int_0^{\infty} \int_{-1}^1 P_m(\mu') \Sigma_{s,m}(E' \rightarrow E) \psi(\mu', E') d\mu' dE' + \frac{Q(E)}{2}. \quad (248)$$

To represent the exact solution of (248), we operate on this equation by $\int_{-1}^1 P_n(\mu)(\cdot) d\mu$. Defining the n th Legendre moment of the angular flux as:

$$\int_{-1}^1 P_n(\mu) \psi(\mu, E) d\mu = \phi_n(E),$$

and using:

$$\int_{-1}^1 P_n(\mu) P_m(\mu) d\mu = \delta_{m,n},$$

we obtain the system of equations:

$$\Sigma_t(E)\phi_n(E) = \int_0^{\infty} \Sigma_{s,n}(E' \rightarrow E) \phi_n(E') dE' + Q(E)\delta_{n,0}, \quad 0 \leq n. \quad (249)$$

Hence, for $n \geq 1$, $\phi_n(E) = 0$, and:

$$\psi(\mu, E) = \sum_{n=0}^{\infty} \frac{2n+1}{2} P_n(\mu) \phi_n(E) = \frac{1}{2} \phi_0(E), \quad (250)$$

where $\phi_0(E)$ satisfies (249) with $n = 0$. Equations (248–250) show that *for an infinite, spatially uniform problem with an isotropic source, the angular flux is independent of both space (x) and angle (μ).*

We now return to (247) and assume that the spatial derivative in ψ is *small* in comparison to the other terms. (Physically, the net leakage rate from a spatial increment dx is assumed to be small in comparison to the collision rate and scattering rates in dx .) To analytically describe this, we write (247a) as:

$$\begin{aligned} \epsilon \mu \frac{\partial \psi}{\partial x}(x, \mu, E) + \Sigma_t(x, E) \psi(x, \mu, E) \\ = \sum_{m=0}^{\infty} \frac{2m+1}{2} P_m(\mu) \int_0^{\infty} \int_{-1}^1 P_m(\mu') \Sigma_{s,m}(x, E' \rightarrow E) \psi(x, \mu', E') d\mu' dE' \\ + \frac{Q(x, E)}{2}, \end{aligned} \quad (251)$$

where ϵ is a small dimensionless parameter, indicating that the leakage term is small. (At the conclusion of this analysis, we set $\epsilon = 1$.)

Because ψ has a weak spatial dependence, we anticipate that ψ should also have a weak angular dependence. (As the spatial derivative of ψ limits to zero, ψ should become isotropic.) Consistent with this expectation, we show that the solution of (251) has the Legendre polynomial expansion:

$$\psi(x, \mu, E) = \sum_{m=0}^{\infty} \frac{2m+1}{2} \epsilon^m P_m(\mu) \phi_m(x, E), \quad (252)$$

where $\phi_n(E) = O(1)$ for all n . (In (252), the m th Legendre moment of $\psi(x, \mu, E)$ is $\varepsilon^m \phi_m(x, E)$.)

Introducing (252) into (251), using the identity:

$$\mu P_m(\mu) = \frac{m+1}{2m+1} P_{m+1}(\mu) + \frac{m}{2m+1} P_{m-1}(\mu),$$

and operating by $\int_{-1}^1 P_n(\mu)(\cdot) d\mu$, we obtain for all $n \geq 0$:

$$\begin{aligned} \frac{n}{2n+1} \frac{\partial \phi_{n-1}}{\partial x}(x, E) + \varepsilon^2 \frac{n+1}{2n+1} \frac{\partial \phi_{n+1}}{\partial x}(x, E) + \Sigma_t(x, E) \phi_n(x, E) \\ = \int_0^\infty \Sigma_{s,n}(x, E' \rightarrow E) \phi_n(x, E') dE' + \delta_{n,0} Q(x, E). \end{aligned} \quad (253)$$

These equations are consistent with the assumption in (252) that $\phi_n(x, E) = O(1)$, and thus that the n th Legendre moment of ψ is $O(\varepsilon^n)$.

Specifically, (253) with $n = 0$ and $n = 1$ yields:

$$\varepsilon^2 \frac{\partial \phi_1}{\partial x}(x, E) + \Sigma_t(x, E) \phi_0(x, E) = \int_0^\infty \Sigma_{s,0}(x, E' \rightarrow E) \phi_0(x, E') dE' + Q(x, E), \quad (254a)$$

$$\frac{1}{3} \frac{\partial \phi_0}{\partial x}(x, E) + \frac{2\varepsilon^2}{3} \frac{\partial \phi_2}{\partial x}(x, E) + \Sigma_t(x, E) \phi_1(x, E) = \int_0^\infty \Sigma_{s,1}(x, E' \rightarrow E) \phi_1(x, E') dE'. \quad (254b)$$

To derive the diffusion equation, we make the following two approximations to (254b):

1. We set:

$$\varepsilon^2 \frac{\partial \phi_2}{\partial x}(x, E) \approx 0. \quad (255a)$$

(This introduces an error of $O(\varepsilon^2)$ in the equations for ϕ_0 and ϕ_1 .)

2. We introduce the approximation:

$$\Sigma_{s,1}(E' \rightarrow E) \approx \Sigma_{s,1}(x, E') \delta(E' - E), \quad (255b)$$

where:

$$\Sigma_{s,1}(x, E') = \int_0^\infty \Sigma_{s,1}(E' \rightarrow E) dE. \quad (256)$$

(This creates an error of undetermined order with respect to ε . However, the following integral is preserved:

$$\int_0^\infty [\Sigma_{s,1}(x, E' \rightarrow E)] dE = \int_0^\infty [\Sigma_{s,1}(x, E') \delta(E' - E)] dE = \Sigma_{s,1}(x, E'),$$

and thus the integral of the right side of (254) over E is preserved.)

Making these two approximations, (254b) becomes:

$$\frac{1}{3} \frac{\partial \phi_0}{\partial x}(x, E) + \Sigma_t(x, E) \phi_1(x, E) = \Sigma_{s,1}(x, E) \phi_1(x, E). \quad (257)$$

If we now define:

$$\Sigma_{tr}(x, E) = \Sigma_t(x, E) - \Sigma_{s,1}(x, E) = \text{transport cross section}, \quad (258a)$$

then (257) yields *Fick's Law*:

$$\phi_1(x, E) = -\frac{1}{3\Sigma_{tr}(x, E)} \frac{\partial \phi_0}{\partial x}(x, E). \quad (258b)$$

Introducing (258a) into (254a), we obtain the following *energy-dependent diffusion equation*:

$$-\varepsilon^2 \frac{\partial}{\partial x} \frac{1}{3\Sigma_{tr}(x, E)} \frac{\partial \phi_0}{\partial x}(x, E) + \Sigma_t(x, E) \phi_0(x, E) = \int_0^\infty \Sigma_{s,0}(x, E' \rightarrow E) \phi_n(x, E') dE' + Q(x, E). \quad (259)$$

Also, from (252) and (258), we have the following representation of ψ :

$$\psi(x, \mu, E) = \frac{1}{2} \phi_0(x, E) - \frac{\varepsilon \mu}{2\Sigma_{tr}(x, E)} \frac{\partial \phi_0}{\partial x}(x, E) + O(\varepsilon^2). \quad (260)$$

Ignoring the $O(\varepsilon^2)$ component of ψ , we see that the transport reflection boundary condition (247b) at $x = 0$ is satisfied by (260) if:

$$\frac{\partial \phi_0}{\partial x}(0, E) = 0. \quad (261)$$

This is the diffusion *reflection* or *symmetry* boundary condition.

However, since ϕ_0 is independent of μ , the transport boundary condition at $x = X$:

$$\begin{aligned} \psi^b(X, \mu) &= \psi(X, \mu) \\ &= \frac{1}{2} \phi_0(X, E) - \frac{\varepsilon \mu}{2\Sigma_{tr}(X, E)} \frac{\partial \phi_0}{\partial x}(X, E), \quad -1 \leq \mu < 0 \end{aligned}$$

cannot generally be satisfied. Operating on both sides of this equation by $\int_{-1}^0 w(|\mu|)(\cdot) d\mu$, where $w(\mu)$ is any positive function, which for convenience is normalized by $\int_0^1 w(\mu) d\mu = 1$, we obtain:

$$2 \int_{-1}^0 w(|\mu|) \psi^b(\mu, E) d\mu = \phi_0(X, E) + \frac{\varepsilon}{\Sigma_{tr}(X, E)} \left(\int_0^1 \mu w(\mu) d\mu \right) \frac{\partial \phi_0}{\partial x}(X, E), \quad (262)$$

and this boundary condition *can* be used to determine ϕ_0 . However, it is not clear how to choose $w(\mu)$.

A common, physically based choice of $w(\mu)$ is:

$$w(\mu) = 2\mu, \quad (263a)$$

which yields the *Marshak boundary condition*:

$$4J^-(X) = \phi_0(X, E) + \frac{2\varepsilon}{3\Sigma_{tr}(X, E)} \frac{\partial \phi_0}{\partial x}(X, E), \quad (263b)$$

where:

$$\begin{aligned} J^-(X) &= \int_{-1}^0 |\mu| \psi^b(\mu, E) d\mu \\ &= \text{incident partial current at } x = X. \end{aligned} \quad (263c)$$

This boundary condition preserves the rate at which neutrons enter the system on its incident-flux boundary.

A more accurate diffusion boundary condition can be obtained by appealing to transport theory, or to a variational analysis, which yields the following approximation to $w(\mu)$:

$$w(\mu) = \mu + \frac{3}{2}\mu^2. \quad (264a)$$

This yields:

$$2 \int_{-1}^0 w(|\mu|) \psi^b(\mu, E) d\mu = \phi_0(X, E) + \frac{17\varepsilon}{24\Sigma_{tr}(X, E)} \frac{\partial \phi_0}{\partial x}(X, E). \quad (264b)$$

Setting $\varepsilon = 1$ in (259–263), we obtain the standard energy-dependent diffusion equation with Marshak boundary conditions. If the boundary condition (263) is replaced by (264), one obtains a more accurate result.

The diffusion solution is accurate for transport problems in which the angular flux ψ has a weak space-dependence (its spatial derivatives are small). In this case, ψ also has a weak angle-dependence (is nearly isotropic). In the diffusion equations (259), (261), and (262) the angular variable is entirely eliminated. The constraint that ψ must have weak spatial and angular dependences is often valid in reactor cores, but not in shields. For this reason, the diffusion approximation, or variants thereof, are generally used to simulate neutron transport in nuclear reactor cores, but not in shields.

8.2 Homogenized Diffusion Theory

The “variants” of diffusion theory mentioned in the previous paragraph refer to other approximations used in practical reactor core simulations. In many problems, an extra step is included that is difficult to justify theoretically: each reactor assembly in a core is *homogenized*, i.e., approximated by a fictitious homogeneous system in which the homogenized cross sections are defined to preserve certain features of the original heterogeneous system. Then, the diffusion approximation is applied to the homogenized system.

The homogenization process is not unique because different quantities can be preserved, and there has been considerable debate about the proper manner in which homogenization should be done (Benoist 1964; Dorning 2003; Gelbard 1974; Larsen and Hughes 1980). Different definitions work acceptably for different applications, but no one definition seems to work best for all (or even most) applications. As a consequence, the optimal definition of homogenized diffusion coefficients remains an unsolved problem.

8.3 Spherical Harmonic (P_N) and Simplified Spherical Harmonic (SP_N) Approximations

The diffusion approximation is the simplest useful approximation that has been derived from (251) and (252). Other higher-order in angle approximations can also be derived.

In particular, the 1-D P_N approximation (for N odd and ≥ 3) can be derived from (251) and (252) by calculating the first $N + 1$ Legendre moments of (251) and using (252) with $\phi_n = 0$ for $n > N$ to truncate the series. The resulting equations are closely related to diffusion equations; for one-group problems, they can be written exactly as a coupled system of $(N + 1)/2$ diffusion equations. Unfortunately, this relatively simple form of the P_N equations does not hold for 2-D and 3-D problems. The greater complexity of the P_N equations for 2-D and 3-D geometries has been a significant factor to their relative unpopularity.

A different class of approximations, which are less accurate but simpler than the P_N approximations, and more accurate than the diffusion approximation, has been developed; this is the so-called *simplified spherical harmonic* (SP_N) equations, originally proposed by Gelbard (1960, 1961, 1962). The 1-D SP_N equations are identical to the diffusion form of the 1-D P_N equations described in the previous paragraph. The multidimensional SP_N equations can be formally derived from the 1-D P_N or SP_N equations by replacing, in each equation, the 1-D diffusion operator by the multidimensional diffusion operator:

$$\frac{d}{dx}D(x)\frac{d\phi}{dx}(x) \rightarrow \nabla \cdot D(\mathbf{x})\nabla\phi(\mathbf{x}).$$

(More mathematically rigorous derivations of the SP_N equations, using asymptotic and variational analyses, have been developed [Brantley and Larsen 2000; Larsen et al. 1996; Tomašević and Larsen 1996].) The multidimensional SP_N equations have the relatively simple form of coupled multidimensional diffusion equations, and they become equivalent to the P_N equations in 1-D.

Because of their diffusion form, the SP_N equations can be implemented in a multigroup diffusion code without significantly restructuring the code. In certain practical problems, the low-order SP_3 equations have been shown to capture “more than 80%” of the transport effects that are not present in the diffusion (P_1) solution (Gamino 1989, 1991). Generally, the SP_N equations are useful for problems in which the diffusion solution is a reasonable, but not sufficiently accurate, approximation to the transport solution. However, the SP_N equations are not always accurate for problems in which the diffusion solution is a poor approximation.

8.4 Discussion

The diffusion equation is used almost universally as an approximation to the Boltzmann transport equation for reactor core simulations, after the core has been suitably “homogenized.” The principal advantage of the diffusion approximation is that the angular variable Ω is eliminated, thereby greatly reducing the amount of work and the expense necessary to solve the approximate problem. However, the diffusion solution has limited accuracy, and the proper definition of homogenized diffusion coefficients remains an open question.

9 The Point Kinetics Approximation

The point kinetics equations (PKEs) are a classic approximation of the time-dependent neutron transport and precursor density equations (Bell and Glasstone 1970; Henry 1975; Hetrick 1993; Lewis and Miller 1993; Ott 1985). For a *critical* system, the (i) neutron transport and precursor and (ii) PKEs both have steady-state solutions. For systems that are *nearly critical* and have solutions that *vary slowly* in t , the solutions of the PKEs can accurately approximate the corresponding solutions of the time-dependent transport and precursor density equations. Also, the PKEs are much simpler than the transport and precursor density equations and can be solved much more efficiently. For these reasons, the PKEs are widely used in time-dependent reactor simulations and stability studies. Previously, the PKEs have been derived by *variational approximations*; here they are derived from the full transport and neutron precursor equations, using an asymptotic analysis that is related to the analyses used in [Sect. 8](#) to derive the diffusion approximation.

9.1 Preliminaries

We begin by restating the general time-dependent transport problem with neutron precursors for a system V with vacuum boundary conditions and no internal source. The problem consists of the time-dependent transport equation for the angular flux $\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)$:

$$\begin{aligned} & \frac{1}{v} \frac{\partial \psi}{\partial t}(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \boldsymbol{\Omega} \cdot \nabla \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \Sigma_t(\mathbf{x}, E, t) \psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \\ &= \int_0^\infty \int_{4\pi} \Sigma_s(\mathbf{x}, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}, E' \rightarrow E, t) \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\boldsymbol{\Omega}' dE' \\ &+ \frac{\chi_p(\mathbf{x}, E, t)}{4\pi} \int_0^\infty \int_{4\pi} [1 - \beta(\mathbf{x}, E', t)] v \Sigma_f(\mathbf{x}, E', t) \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\boldsymbol{\Omega}' dE' \\ &+ \frac{1}{4\pi} \sum_{j=1}^6 \chi_j(\mathbf{x}, E, t) \lambda_j C_j(\mathbf{x}, t), \quad \mathbf{x} \in V, \quad \boldsymbol{\Omega} \in 4\pi, \quad 0 < E < \infty, \quad 0 < t, \end{aligned} \quad (265)$$

the time-dependent equations for the neutron precursor densities $C_j(\mathbf{x}, t)$:

$$\begin{aligned} & \frac{\partial C_j}{\partial t}(\mathbf{x}, t) + \lambda_j C_j(\mathbf{x}, t) \\ &= \int_0^\infty \int_{4\pi} \beta_j(\mathbf{x}, E', t) v \Sigma_f(\mathbf{x}, E', t) \psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\boldsymbol{\Omega}' dE', \quad \mathbf{x} \in V, \quad 0 < t, \quad 1 \leq j \leq 6, \end{aligned} \quad (266)$$

the specified initial conditions for ψ and C_j :

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E, 0) = \psi^i(\mathbf{x}, \boldsymbol{\Omega}, E), \quad \mathbf{x} \in V, \quad \boldsymbol{\Omega} \in 4\pi, \quad 0 < E < \infty, \quad (267a)$$

$$C_j(\mathbf{x}, 0) = C_j^i(\mathbf{x}), \quad \mathbf{x} \in V, \quad 1 \leq j \leq 6, \quad (267b)$$

and the vacuum boundary condition for ψ :

$$\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) = 0, \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \quad 0 < E < \infty, \quad 0 < t. \quad (267c)$$

Also, β and β_j satisfy:

$$\beta(\mathbf{x}, E, t) = \sum_{n=1}^6 \beta_j(\mathbf{x}, E, t). \quad (268)$$

Equations (265) and (266) explicitly allow space- and time-dependence of all cross sections to account for the time-dependent movement of control rods within the core. However, we do not (for simplicity) include a nonlinear temperature-dependence of the cross sections, and we assume that the cross sections are specified for $t \geq 0$.

Because the cross sections are known for $t > 0$, it is in principle possible to calculate the reactivity $\rho(t)$ and the corresponding forward eigenfunction $\Psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ for $t > 0$. These are defined by the familiar eigenvalue problem:

$$\begin{aligned} & \boldsymbol{\Omega} \cdot \nabla \Psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \Sigma_t(\mathbf{x}, E, t) \Psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) \\ &= \int_0^\infty \int_{4\pi} \Sigma_s(\mathbf{x}, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}, E' \rightarrow E, t) \Psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\Omega' dE' \\ &+ [1 - \rho(t)] \frac{\chi_p(\mathbf{x}, E, t)}{4\pi} \int_0^\infty \int_{4\pi} \nu \Sigma_f(\mathbf{x}, E', t) \Psi(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\Omega' dE', \\ & \mathbf{x} \in V, \quad \boldsymbol{\Omega} \in 4\pi, \quad 0 < E < \infty, \end{aligned} \quad (269a)$$

$$\Psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) = 0, \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \quad 0 < E < \infty. \quad (269b)$$

In these equations, t appears only as a parameter, and we normalize the eigenfunction Ψ by:

$$\int \int_0^\infty \int_{4\pi} \frac{1}{\nu} \Psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) d\Omega dE dV = 1. \quad (269c)$$

Equations (269a) and (269b) have no external sources, and the eigenvalue $\rho(t)$ must be determined so that a positive solution Ψ exists. If $\rho(t) < 0$, the fission term in (269a) is increased by the factor $[1 - \rho(t)]$ to produce a steady-state solution, so the system is *subcritical*. If $\rho(t) > 0$, the fission term is reduced by the factor $[1 - \rho(t)]$ to produce a steady-state solution, so the system is *supercritical*. If $\rho(t) = 0$, then no adjustment to the fission term is made, and the system is *critical*.

The time-dependent cross sections, the reactivity $\rho(t)$, the forward eigenfunction $\Psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)$, and the adjoint eigenfunction $\Psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ (of the problem which is adjoint to [269]) all explicitly occur in the asymptotic analysis. In the following, we assume that all of these quantities are known. (Then the forward and adjoint scalar fluxes $\Phi(\mathbf{x}, E, t) = \int_{4\pi} \Psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) d\Omega$ and $\Phi^\dagger(\mathbf{x}, E, t) = \int_{4\pi} \Psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t) d\Omega$ are also known.) The asymptotic analysis determines time-dependent equations for ψ and C_j having coefficients that

are expressed in terms of the time-dependent cross sections $\Sigma(\mathbf{x}, E, t)$, reactivity $\rho(t)$, and eigenfunctions $\Psi(\mathbf{x}, \Omega, E, t)$ and $\Psi^\dagger(\mathbf{x}, \Omega, E, t)$.

9.2 The Scaled Transport and Neutron Precursor Equations

Next, we make physical assumptions that are consistent with the basic overall requirement that the system V be *nearly critical* and *slowly varying in time*.

- The reactivity $\rho(t)$ is small. (The system is *nearly critical* for all $t > 0$.)
- β_j and β are small. In practice, this assumption is valid; β is dimensionless and ≈ 0.01 .
- If t is measured on the timescale for precursor decay (e.g., in seconds), then the mean neutron speed is large. In practice, this assumption is valid.
- Since the mean neutron speed is large and $\psi = vN$, then ψ is large.
- All specified time-dependent quantities in (265–266) vary on the same slow timescale (seconds) on which the neutron precursors decay.

To express these conditions mathematically, we introduce a small positive dimensionless parameter ε and define:

$$\rho(t) = \varepsilon \hat{\rho}(t), \quad (270a)$$

$$\beta_j(\mathbf{x}, E, t) = \varepsilon \hat{\beta}_j(\mathbf{x}, E, t) \quad \text{and} \quad \beta(\mathbf{x}, E, t) = \varepsilon \hat{\beta}(\mathbf{x}, E, t), \quad (270b)$$

$$v = \frac{\hat{v}}{\varepsilon}, \quad (270c)$$

$$\psi(\mathbf{x}, \Omega, E, t) = \frac{\hat{\psi}(\mathbf{x}, \Omega, E, t)}{\varepsilon}, \quad (270d)$$

$$\psi^i(\mathbf{x}, \Omega, E, t) = \frac{\hat{\psi}^i(\mathbf{x}, \Omega, E, t)}{\varepsilon}. \quad (270e)$$

In these equations, all the hatted quantities are assumed to be $O(1)$.

Introducing (270) into (265–268), we obtain:

$$\begin{aligned} & \frac{1}{\hat{v}} \frac{\partial \hat{\psi}}{\partial t}(\mathbf{x}, \Omega, E, t) + \frac{1}{\varepsilon} \Omega \cdot \nabla \hat{\psi}(\mathbf{x}, \Omega, E, t) + \frac{1}{\varepsilon} \Sigma_t(\mathbf{x}, E, t) \hat{\psi}(\mathbf{x}, \Omega, E, t) \\ &= \frac{1}{\varepsilon} \int_0^\infty \int_{4\pi} \Sigma_s(\mathbf{x}, \Omega' \cdot \Omega, E' \rightarrow E, t) \hat{\psi}(\mathbf{x}, \Omega', E', t) d\Omega' dE' \\ & \quad + \frac{\chi_p(\mathbf{x}, E, t)}{4\pi\varepsilon} \int_0^\infty \int_{4\pi} [1 - \rho(t) + \varepsilon \hat{\rho}(t) - \varepsilon \hat{\beta}(\mathbf{x}, E', t)] \\ & \quad \times v \Sigma_f(\mathbf{x}, E', t) \hat{\psi}(\mathbf{x}, \Omega', E', t) d\Omega' dE' \\ & \quad + \frac{1}{4\pi} \sum_{j=1}^6 \chi_j(\mathbf{x}, E, t) \lambda_j C_j(\mathbf{x}, t) + \frac{Q(\mathbf{x}, E, t)}{4\pi}, \end{aligned} \quad (271a)$$

$$\frac{\partial C_j}{\partial t}(\mathbf{x}, t) + \lambda_j C_j(\mathbf{x}, t) = \int_0^\infty \int_{4\pi} \hat{\beta}_j(\mathbf{x}, E', t) v \Sigma_f(\mathbf{x}, E', t) \hat{\psi}(\mathbf{x}, \Omega', E', t) d\Omega' dE', \quad (271b)$$

where the expression $-\rho(t) + \varepsilon \hat{\rho}(t) = 0$ has been included in the integrand of the prompt fission term in (271a) so that the small reactivity $\rho(t) = \varepsilon \hat{\rho}(t)$ occurs in the scaled equations to leading order. We also have the boundary and initial conditions:

$$\hat{\psi}(\mathbf{x}, \boldsymbol{\Omega}, E, t) = 0, \quad \mathbf{x} \in \partial V, \quad \boldsymbol{\Omega} \cdot \mathbf{n} < 0, \quad 0 < E < \infty, \quad 0 < t, \quad (272)$$

$$\hat{\psi}(\mathbf{x}, \boldsymbol{\Omega}, E, 0) = \hat{\psi}^i(\mathbf{x}, \boldsymbol{\Omega}, E), \quad \mathbf{x} \in V, \quad \boldsymbol{\Omega} \in 4\pi, \quad 0 < E < \infty, \quad (273a)$$

$$C_j(\mathbf{x}, 0) = C_j^i(\mathbf{x}), \quad \mathbf{x} \in V, \quad (273b)$$

and:

$$\hat{\beta}(\mathbf{x}, E, t) = \sum_{j=1}^6 \hat{\beta}_j(\mathbf{x}, E, t). \quad (274)$$

The scaled equations (271–274) for $\hat{\psi}$ and C_j are equivalent to the original equations (265–268) for ψ and C_j ; no approximations have yet been made.

9.3 Asymptotic Derivation of the Point Kinetics Equations

To proceed, we introduce the *ansatz*:

$$\hat{\psi}(\mathbf{x}, \boldsymbol{\Omega}, E, t) = \sum_{n=0}^{\infty} \varepsilon^n \hat{\psi}_n(\mathbf{x}, \boldsymbol{\Omega}, E, t), \quad (275a)$$

$$C_j(\mathbf{x}, t) = \sum_{n=0}^{\infty} \varepsilon^n C_{j,n}(\mathbf{x}, t), \quad (275b)$$

into (271–273) and equate the coefficients of different powers of ε . The sole $O(\varepsilon^{-1})$ equation is:

$$\begin{aligned} & \boldsymbol{\Omega} \cdot \nabla \hat{\psi}_0(\mathbf{x}, \boldsymbol{\Omega}, E, t) + \Sigma_t(\mathbf{x}, E, t) \hat{\psi}_0(\mathbf{x}, \boldsymbol{\Omega}, E, t) \\ & - \int_0^{\infty} \int_{4\pi} \Sigma_s(\mathbf{x}, \boldsymbol{\Omega}' \cdot \boldsymbol{\Omega}, E' \rightarrow E, t) \hat{\psi}_0(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\boldsymbol{\Omega}' dE' \\ & - [1 - \rho(t)] \frac{\chi_p(\mathbf{x}, E, t)}{4\pi} \int_0^{\infty} \int_{4\pi} \nu \Sigma_f(\mathbf{x}, E', t) \hat{\psi}_0(\mathbf{x}, \boldsymbol{\Omega}', E', t) d\boldsymbol{\Omega}' dE' = 0, \end{aligned} \quad (276)$$

with the vacuum boundary condition for $\hat{\psi}_0$. By (269), the general solution of these equations is:

$$\hat{\psi}_0(\mathbf{x}, \boldsymbol{\Omega}, E, t) = \Psi(\mathbf{x}, \boldsymbol{\Omega}, E, t) N_0(t), \quad (277)$$

where $N_0(t)$ is, at this point, undetermined. We note that by (269c),

$$\int_V \int_0^{\infty} \int_{4\pi} \frac{1}{v} \hat{\psi}_0(\mathbf{x}, \boldsymbol{\Omega}, E, t) d\boldsymbol{\Omega} dE dV = N_0(t), \quad (278a)$$

so:

$$N_0(t) = \text{the number of neutrons in } V \text{ at time } t. \quad (278b)$$

Next, we introduce (277) for $\hat{\psi}_0$ into the $O(1)$ components of (271) and obtain the following equations for $\hat{\psi}_1$ and $C_{j,0}$:

$$\begin{aligned}
 & \Omega \cdot \nabla \hat{\psi}_1(\mathbf{x}, \Omega, E, t) + \Sigma_t(\mathbf{x}, E, t) \hat{\psi}_1(\mathbf{x}, \Omega, E, t) \\
 & - \int_0^\infty \int_{4\pi} \Sigma_s(\mathbf{x}, \Omega' \cdot \Omega, E' \rightarrow E, t) \hat{\psi}_1(\mathbf{x}, \Omega', E', t) d\Omega' dE' \\
 & - [1 - \rho(t)] \frac{\chi_p(\mathbf{x}, E, t)}{4\pi} \int_0^\infty \int_{4\pi} \nu \Sigma_f(\mathbf{x}, E', t) \hat{\psi}_1(\mathbf{x}, \Omega', E', t) d\Omega' dE' \\
 & = -\frac{1}{v} \frac{\partial}{\partial t} \Psi(\mathbf{x}, \Omega, E, t) N_0(t) \\
 & + \frac{\chi_p(\mathbf{x}, E, t)}{4\pi} \int_0^\infty [\hat{\rho}(t) - \hat{\beta}(\mathbf{x}, E', t)] \nu \Sigma_f(\mathbf{x}, E', t) \Phi(\mathbf{x}, E', t) dE' N_0(t) \\
 & + \frac{1}{4\pi} \sum_{j=1}^6 \chi_j(\mathbf{x}, E, t) \lambda_j C_{j,0}(\mathbf{x}, t) + \frac{Q(\mathbf{x}, E, t)}{4\pi}, \tag{279}
 \end{aligned}$$

$$\frac{\partial C_{j,0}}{\partial t}(\mathbf{x}, t) + \lambda_j C_{j,0}(\mathbf{x}, t) = \left(\int_0^\infty \hat{\beta}_j(\mathbf{x}, E', t) \nu \Sigma_f(\mathbf{x}, E', t) \Phi(\mathbf{x}, E', t) dE' \right) N_0(t). \tag{280}$$

The operator on the left side of (279) is the same as the operator on the left side of (276). Operating on both sides of (279) by:

$$\int \int_0^\infty \int_{4\pi} \Psi^\dagger(\mathbf{x}, \Omega, E, t) (\cdot) d\Omega dE dV,$$

the left side vanishes, and we obtain the *solvability condition*:

$$\begin{aligned}
 0 & = - \int \int_0^\infty \int_{4\pi} \Psi^\dagger \frac{1}{v} \frac{\partial}{\partial t} \Psi N_0(t) d\Omega dE dV \\
 & + \frac{\hat{\rho}(t)}{4\pi} \int \left(\int_0^\infty \Phi^\dagger \chi_p dE \right) \left(\int_0^\infty \nu \Sigma_f \Phi dE \right) dV N_0(t) \\
 & - \frac{1}{4\pi} \int \left(\int_0^\infty \Phi^\dagger \chi_p dE \right) \left(\int_0^\infty \hat{\beta} \nu \Sigma_f \Phi dE \right) dV N_0(t) \\
 & + \sum_j \frac{\lambda_j}{4\pi} \int \int_0^\infty \Phi^\dagger C_{j,0} \chi_j dE dV + \frac{1}{4\pi} \int \int_0^\infty \Phi^\dagger Q dE dV. \tag{281}
 \end{aligned}$$

To simplify this result, we define the functions:

$$\theta(t) = \frac{\int \int_0^\infty \int_{4\pi} \Psi^\dagger \frac{1}{v} \frac{d\Psi}{dt} d\Omega dE dV}{\int \int_0^\infty \int_{4\pi} \Psi^\dagger \frac{1}{v} \Psi d\Omega dE dV}, \tag{282a}$$

$$\frac{1}{\Lambda(t)} = \frac{\int \left(\int_0^\infty \Phi^\dagger \chi_p dE \right) \left(\int_0^\infty \nu \Sigma_f \Phi dE' \right) dV}{4\pi \int \int_0^\infty \int_{4\pi} \Psi^\dagger \frac{1}{v} \Psi d\Omega dE dV}, \tag{282b}$$

$$\hat{\beta}(t) = \frac{\int \left(\int_0^\infty \Phi^\dagger \chi_p dE \right) \left(\int_0^\infty \hat{\beta} \nu \Sigma_f \Phi dE' \right) dV}{\int \left(\int_0^\infty \Phi^\dagger \chi_p dE \right) \left(\int_0^\infty \nu \Sigma_f \Phi dE' \right) dV}, \tag{282c}$$

$$c_j(t) = \frac{\int \int_0^\infty \Phi^\dagger C_{j,0} \chi_j dE dV}{4\pi \int \int_0^\infty \int_{4\pi} \Psi^\dagger \frac{1}{v} \Psi d\Omega dE dV}, \tag{282d}$$

$$q(t) = \frac{\int \int_0^\infty \Phi^\dagger Q dE dV}{4\pi \int \int_0^\infty \int_{4\pi} \Psi^\dagger \frac{1}{v} \Psi d\Omega dE dV}; \quad (282e)$$

then (281) becomes:

$$\frac{dN_0}{dt}(t) + \theta(t)N_0(t) = \frac{\hat{\rho}(t) - \hat{\beta}(t)}{\Lambda(t)} N_0(t) + \sum_j \lambda_j c_j(t) + q(t). \quad (283)$$

To obtain equations for $c_j(t)$, we analytically solve (280) for $C_{j,0}(\mathbf{x}, t)$, obtaining:

$$C_{j,0}(\mathbf{x}, t) = C_j^i(\mathbf{x}) e^{-\lambda_j t} + \int_0^t e^{-\lambda_j(t-t')} \left(\int_0^\infty \hat{\beta}_j v \Sigma_f \Phi dE' \right) N_0(t') dt'.$$

Then we operate on this result by:

$$\frac{1}{4\pi \int \int_0^\infty \int_{4\pi} \Psi^\dagger \frac{1}{v} \Psi d\Omega dE dV} \int \int_0^\infty \Phi^\dagger \chi_j [\cdot] dE dV$$

and use the definition (282d) to obtain:

$$c_j(t) = c_j^i e^{-\lambda_j t} + \frac{\int \left(\int_0^\infty \Phi^\dagger \chi_j dE \right) \left[\int_0^t e^{-\lambda_j(t-t')} \left(\int_0^\infty \hat{\beta}_j v \Sigma_f \Phi dE' \right) N_0(t') dt' \right] dV}{4\pi \int \int_0^\infty \int_{4\pi} \Psi^\dagger \frac{1}{v} \Psi d\Omega dE dV}. \quad (284)$$

Equations (283) and (284) define $N_0(t)$ and $c_j(t)$ for $t > 0$.

Next, we convert these results back to the original unscaled (unhatted) variables. This is done by using (270) to systematically replace all scaled (hatted) quantities in (277) and (282–284) by unscaled (unhatted) quantities. Defining $N(t) = N_0(t)/\varepsilon$ and omitting the straightforward details, we obtain for $t > 0$:

$$\psi(\mathbf{x}, \Omega, E, t) \approx \Psi(\mathbf{x}, \Omega, E, t) N(t), \quad (285)$$

where $N(t)$ satisfies the equations:

$$\frac{dN}{dt}(t) + \theta(t)N(t) = \frac{\rho(t) - \beta(t)}{\Lambda(t)} N(t) + \sum_{j=1}^6 \lambda_j c_j(t) + q(t), \quad (286)$$

and:

$$c_j(t) = c_j^i e^{-\lambda_j t} + \frac{\int \left(\int_0^\infty \Phi^\dagger \chi_j dE \right) \left[\int_0^t e^{-\lambda_j(t-t')} \left(\int_0^\infty \beta_j v \Sigma_f \Phi dE' \right) N(t') dt' \right] dV}{4\pi \int \int_0^\infty \int_{4\pi} \Psi^\dagger \frac{1}{v} \Psi d\Omega dE dV}, \quad (287)$$

where:

$$\beta(t) = \frac{\int \left(\int_0^\infty \Phi^\dagger \chi_p dE \right) \left(\int_0^\infty \beta v \Sigma_f \Phi dE \right) dV}{\int \left(\int_0^\infty \Phi^\dagger \chi_p dE \right) \left(\int_0^\infty v \Sigma_f \Phi dE \right) dV}. \quad (288)$$

Also, (267), (285), and (282d) yield the following initial conditions for $N(t)$ and $c_j(t)$:

$$N(0) = \int \int_0^\infty \int_{4\pi} \frac{1}{v} \psi^i(\mathbf{x}, \boldsymbol{\Omega}, E) d\boldsymbol{\Omega} dE dV, \quad (289)$$

$$c_j(0) = c_j^i = \frac{\int \int_0^\infty \Phi^\dagger(\mathbf{x}, E, 0) C_j^i(\mathbf{x}) \chi(\mathbf{x}, E, 0) dE dV}{4\pi \int \int_0^\infty \int_{4\pi} \Psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, 0) \frac{1}{v} \Psi(\mathbf{x}, \boldsymbol{\Omega}, E, 0) d\boldsymbol{\Omega} dE dV}. \quad (290)$$

To obtain the standard PKEs, it is necessary to make two further assumptions. The first assumption is:

$$\frac{\partial}{\partial t} \left(\frac{\int_0^\infty \Phi^\dagger \chi_j dE}{\int \int_0^\infty \int_{4\pi} \Psi^\dagger \frac{1}{v} \Psi d\boldsymbol{\Omega} dE dV} \right) \approx 0. \quad (291)$$

Then (287) can be written:

$$c_j(t) = c_j^i e^{-\lambda_j t} + \int_0^t e^{-\lambda_j(t-t')} \frac{\beta_j(t')}{\Lambda(t')} N(t') dt', \quad (292)$$

where:

$$\beta_j(t) = \frac{\int \left(\int_0^\infty \Phi^\dagger \chi_p dE \right) \left(\int_0^\infty \beta_j v \Sigma_f \Phi dE \right) dV}{\int \left(\int_0^\infty \Phi^\dagger \chi_p dE \right) \left(\int_0^\infty v \Sigma_f \Phi dE \right) dV}. \quad (293)$$

The second assumption is:

$$\theta(t) = \frac{\int \int_0^\infty \int_{4\pi} \Psi^\dagger \frac{1}{v} \frac{d\Psi}{dt} d\boldsymbol{\Omega} dE dV}{\int \int_0^\infty \int_{4\pi} \Psi^\dagger \frac{1}{v} \Psi d\boldsymbol{\Omega} dE dV} \approx 0. \quad (294)$$

If (291) and (294) both hold, then (286) and (292) reduce to the standard PKEs:

$$\frac{dN}{dt}(t) = \frac{\rho(t) - \beta(t)}{\Lambda(t)} N(t) + \sum_{j=1}^6 \lambda_j c_j(t) + q(t), \quad (295a)$$

$$\frac{dc_j}{dt}(t) + \lambda_j c_j(t) = \frac{\beta_j(t)}{\Lambda(t)} N(t), \quad 1 \leq j \leq 6. \quad (295b)$$

Also, from (274), (288), and (293), we have:

$$\beta(t) = \sum_{n=1}^6 \beta_j(t). \quad (296)$$

Thus, the neutron angular flux $\psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ is asymptotically given by (285), where $N(t)$ is obtained by solving the PKEs (295) and (296), with initial conditions given by (289) and (290). Because of the very specific angular and energy dependence of the asymptotic solution (285), this solution cannot generally satisfy the arbitrary initial conditions specified in (267). This deficiency can be overcome by including an *initial-layer* solution, which describes the rapid transition from the general initial conditions for ψ and C_j to the near-equilibrium solution that forms the basis of the PKEs. The asymptotic initial-layer analysis is not presented here because this analysis has no effect on the PKEs.

9.4 Discussion

For a fissile system that is nearly critical and slowly varying, in the sense described by the scalings in (270), we have shown that the time-dependent angular flux is described asymptotically by (285–290). Furthermore, if (291) and (294) hold, then the approximating equations simplify to the standard PKEs (295), (296).

The PKEs have been obtained previously using derivations that are tantamount to variational approximations. In these earlier derivations, $\Psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ is called the *shape function* and is not necessarily an eigenfunction; it is chosen. Also, $\Psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ is called the *weight function*; it too is not necessarily an (adjoint) eigenfunction and is chosen. The subsequent derivations lead to equations of the form of (285) and (295), but with the coefficients in these equations usually defined differently than in (282) and (288). In particular, in the asymptotic analysis presented here, $\rho(t)$ is the true reactivity of the system at time t , as defined by the eigenvalue problem (269). In other formulations, $\rho(t)$ is not always the true reactivity. The analysis presented here suggests that these earlier formulations of the PKEs may not represent asymptotic approximations of the time-dependent transport equations. However, the asymptotic result derived here is potentially more expensive to implement because $\rho(t)$, $\Psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)$, and $\Psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ must be calculated by solving eigenvalue problems for each time t . (This point is discussed further below.) It is possible that by using a less sophisticated approximation to Ψ and ρ , one can reduce the cost of the calculation and still obtain acceptably accurate results.

In previous derivations of the PKEs, the shape and weight functions are often assumed to be independent of time (at least, for specified time intervals). If this were true in the asymptotic analysis, and if the time-dependent variations of the system occur only in non-fissile regions, then (291) and (294) would be valid. This situation can effectively occur if, for a critical reactor, control rods are *very slowly and slightly* moved in or out, thereby making the reactor slightly subcritical or supercritical. Then the temporal changes in $\Psi(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ and $\Psi^\dagger(\mathbf{x}, \boldsymbol{\Omega}, E, t)$ would be very small and, effectively, $\theta(t) = 0$, $\Lambda(t) = \Lambda = \text{constant}$, and $\beta_j(t) = \beta_j = \text{constant}$.

Also, we note that by suitably altering the normalization (269c) on Ψ , then by (277) and (278), $N(t) =$ the power output of the reactor at time t .

The asymptotic analysis shows that the neutron flux can be predicted by means of PKEs that depend on time-dependent knowledge of the cross sections, the reactivity, and the forward and adjoint eigenfunctions. Although it is not practical to calculate ρ , Ψ , and Ψ^\dagger *continuously* for all $t > 0$, it is possible to calculate these quantities at discrete times, e.g., $t_n = n\Delta t$, and to evaluate $\rho(t)$ and the time-dependent parameters in (288) by linearly interpolating between t_n and t_{n+1} . By doing this, the asymptotic result obtained here could be the basis of a realistic point kinetics model.

Other asymptotic expansions that lead to results of the form of the PKEs are possible. For example, in the analysis presented here, the reactivity ρ of the system is calculated by neglecting the delayed neutrons (see [269]). By including a steady-state term in (269) to account for the different energy spectrum of the delayed neutrons, a different and possibly more accurate expression for ρ might be obtained. Also, a more sophisticated asymptotic analysis could include temperature-dependent cross sections, with an extra equation relating the temperature $T(\mathbf{x}, t)$ within the reactor as a function of the neutron flux. In addition, an asymptotic derivation of the PKEs can be based on the α -eigenvalues and eigenfunctions of the transport

equation (Lewis and Miller 1984), rather than the k -eigenvalues and eigenfunctions. (Such a derivation would actually be more natural, because the α -eigenvalues are associated with the time-behavior of the system.) However, none of these generalizations can be discussed further here.

10 Computational Neutron Transport

Analytic solutions of the Boltzmann transport equation can be obtained only for the simplest problems. For realistic, multidimensional, energy-dependent problems, it is necessary to calculate numerical solutions as accurately and efficiently as possible. This can be an extremely daunting task. Research on computational methods for the Boltzmann transport equation has been actively pursued from the 1950s up to the present (Adams and Larsen 2002; Carlson and Lathrop 1968; Carter and Cashwell 1975; Haghighat and Wagner 2003; Kalos and Whitlock 1986; Larsen 1992; Larsen and Morel 2009; Lewis and Miller 1993; Lux and Koblinger 1991; Marchuk and Lebedev 1981; Sanchez and McCormick 1982; Spanier and Gelbard 2008; X-5 Monte Carlo Team 2003). During this time, the speed and memory of computers has increased by many orders of magnitude. Nonetheless, it has been argued that the gains in efficiency of simulations of particle transport problems, due to improvements in computational algorithms, exceeds the gains due to improvements in computer hardware. Here, we give a brief overview of the major advances in computational neutron transport algorithms. For details, we refer the reader to previous publications.

The history of computational transport methods is basically the history of two fundamentally different approaches, commonly called *stochastic* and *deterministic*. Stochastic (or *Monte Carlo*) methods are based on a probabilistic interpretation of the transport process. In this approach, the random *histories* of individual particles are calculated using pseudorandom number sequences and the results are averaged over a large number of histories. Stochastic methods have no need of a Boltzmann transport equation; they rely only on the detailed physics of interactions between individual neutrons and nuclei. Deterministic methods instead are based on (i) discretizing the Boltzmann transport equation in each of its independent variables, resulting in a (typically very large) algebraic system of equations, and then (ii) solving this algebraic system.

For the past 50 years, Monte Carlo and deterministic algorithms have been developed independently. The two approaches were viewed as being incompatible, and two basically disjoint technical communities evolved to develop codes for them. Major technical advances for one type of method (e.g., acceleration techniques for deterministic methods, variance reduction techniques for Monte Carlo methods) had no impact on the other method. Except for specialized applications, the two methods were not implemented in the same (production) computer code. Monte Carlo and deterministic methods became viewed as complementary: one approach was advantageous for certain problems, the other advantageous for different problems. Because of their complementarity, both methods have survived and matured.

However, during the past 10 years, it has become fairly widely understood that *hybrid* methods – which combine aspects of both Monte Carlo and deterministic methods – can be used to enhance the strengths and overcome the weaknesses of the individual approaches. Although hybrid methods are in the early stages of their development and implementation, they have already demonstrated that they can yield major improvements in efficiency and accuracy for difficult problems. It now appears that hybrid methods represent a promising third

approach, offering a way to significantly improve the efficiency and ease of simulations for difficult practical particle transport problems.

In the following, we discuss the general issues associated with deterministic, stochastic, and hybrid particle transport methodologies.

10.1 Monte Carlo Methods

In the physical process of *particle transport*, typically a *very* large number of particles undergo random and independent histories. Each element of an individual particle's history (distance to collision, probability of scattering, post-scattering energy, and direction of flight) has a specific probability distribution function. Because of this, the collective behavior of the particle population is predictable, with a small statistical noise that decreases as the number of particles $N \rightarrow \infty$.

Stochastic or *Monte Carlo* methods model this process by applying the known distribution functions to simulate the random histories of N_{MC} fictitious *Monte Carlo particles*, and averaging the results over the histories (Carter and Cashwell 1975; Kalos and Whitlock 1986; Lux and Koblinger 1991; Spanier and Gelbard 2008; X-5 Monte Carlo Team 2003). However, because the number of simulated particles [$N_{MC} \approx O(10^7)$] is usually much smaller than the number of physical particles [$N \approx O(10^{15})$], Monte Carlo simulations usually have orders of magnitude more statistical noise than the actual physical process. This is a significant issue when Monte Carlo methods are used to estimate *rare events*, such as the response rate in a detector located far from a source.

Nonetheless, Monte Carlo methods have certain basic advantages. If the geometry of the system and its cross sections are known, then the results of the Monte Carlo simulation contain only statistical errors. By processing a sufficient number of Monte Carlo particles, it is possible to reduce the probable statistical error below any specified level.

According to the *central limit theorem*, for any Monte Carlo simulation, the statistical error in the estimation of a given quantity is, with probability 0.68, bounded by:

$$\text{Statistical error} \leq \frac{\sigma}{\sqrt{N_{MC}}}, \quad (297)$$

where σ (the *standard deviation*) is specific to the given problem and the quantity estimated, and (297) holds only for N_{MC} sufficiently large. The positive feature of (297) is that as N_{MC} increases, the statistical error will, with high probability, also decrease. The negative feature is that the rate of decrease of the statistical error is slow. For instance, (297) shows that to decrease the statistical error by a factor of 10, it is necessary to increase N_{MC} (and hence the computational expense) by a factor of 100.

Monte Carlo methods are widely used because of their relative ease of implementation, their ability to treat complex geometries with great fidelity, and their ability to solve problems accurately with cross-sectional data that can have extremely complex energy-dependence. However, Monte Carlo simulations can be costly, both to set up and to run.

In particular, when attempting to calculate a rare event, such as a detector response far from a source, such a small fraction of the physical particles participate in this event that the number of Monte Carlo particles that create a “score” is *very* small – and the resulting statistical error is unacceptably large. In this situation, the “rules” of the Monte Carlo “game” can be

altered so that Monte Carlo particles are “encouraged” to travel from the source to the detector region. The result is that the desired response is estimated with smaller statistical error and computational effort. In effect, the Monte Carlo process is changed so that the estimate of the response is preserved, but the standard deviation in this estimate (the constant σ in [297]) is reduced.

To accomplish this alteration of the Monte Carlo process, the code user must input a (generally) large number of *biasing parameters* that successfully “encourage” Monte Carlo particles to migrate from the source to the specified detector region. These parameters are strongly problem-dependent, and generating them can be a slow and laborious task. For difficult problems, a lengthy process of trial and error may be necessary, and there is no guarantee that at the end of this process, the code user will have been successful.

Another difficulty with Monte Carlo simulations is that they operate most efficiently when calculating limited information, such as a single detector response. If several detector responses are desired, and the detectors are located far from the source and far from each other, then often the best solution is to run several different Monte Carlo simulations, each with its own specially defined set of biasing parameters.

Thus, while Monte Carlo codes are widely used, running these codes efficiently is problematic for complex problems. In these situations, Monte Carlo codes are not a “black box” into which a user can simply specify the problem, press the “start” button, and expect reliable answer in a short time. *In addition to specifying the physical problem, the user must also specify the problem-dependent biasing parameters*, and this can be a formidable task.

Historically, research on Monte Carlo methods has focused on new approaches that show hope of alleviating the major difficulties associated with the method. For example, different biasing methods to encourage Monte Carlo particles to travel toward specified detector regions have been developed and tested. Also, methods have been developed to obtain, via the Monte Carlo process itself, the biasing parameters for difficult problems. In addition, sophisticated statistical methods have been developed to analyze Monte Carlo simulations and better determine the magnitude of the statistical errors. (For example, obtaining accurate estimates of the standard deviation σ , and hence of the true statistical error, can be problematic, particularly for eigenvalue problems.)

During the past 50 years, many significant advances in Monte Carlo techniques have been developed and implemented in large-scale codes. However, the difficulties described above remain significant obstacles to running these codes optimally.

10.2 Deterministic Methods

Because the particle transport process is governed by specified probability distribution functions, the Boltzmann transport equation exists for predicting the *mean* or *average* flux of particles at each location in phase space. *Deterministic*, or *discrete-ordinates*, or S_N methods are based on discretizing the Boltzmann equation in each of its independent variables, and solving the resulting (typically very large) system of algebraic equations (Adams and Larsen 2002; Carlson and Lathrop 1968; Larsen 1992; Larsen and Morel 2009; Lewis and Miller 1993; Marchuk and Lebedev 1986; Sanchez and McCormick 1982).

Because the Boltzmann equation depends on its independent variables in significantly different ways, different methods have been developed for their discretization.

For time-dependent problems, the most common method for discretizing the time variable t is the *implicit*, or *backward Euler* method. Other methods are possible and have been tested, but the implicit method is the most widely used because of its simplicity and robustness.

Of all the independent variables in the transport equation, the energy variable E is the most problematic. The reason for this is that typically, the material cross sections, and hence the particle flux itself, have an extraordinarily complex energy-dependence. If the simple rule of thumb is followed that an energy grid should be chosen for which the solution varies in energy from one grid point to the next by no more than about 15%, then for typical problems, *millions* of grid points in E would be required. This constraint would render the solution of typical problems to be outside the range of possibility.

However, the *multigroup* method (discussed previously in [▶ Sect. 6](#)) has been developed to deal with this difficulty, and because of its success, it is almost universally used. This method requires the user to carefully specify a set of *multigroup* cross sections, whose values are determined by calculating integrals over E of the flux and the flux times the cross section. The optimal specification of a multigroup cross section depends on the given problem. From the user standpoint, determining accurate problem-dependent multigroup cross sections is the most challenging and time-consuming aspect of deterministic calculations.

The angular, or direction-of-flight variable Ω is generally discretized in one of two ways: *discrete-ordinates*, or *collocation* (or S_N) methods, and *spherical harmonic* (or P_N) methods. S_N methods are more commonly used because the structure of the resulting discrete equations is more closely linked to the innate physical interpretation of particle transport. (In Cartesian geometries, S_N methods can be interpreted as ones in which particles travel only in a finite, specified set of directions Ω_m .) However, S_N and P_N methods have characteristic errors. In particular, S_N methods have *ray effects*, which are most apparent in problems with strong absorption and localized sources. For problems whose solutions have a strong direction-dependence, such as neutron streaming through a voided channel, it is necessary to use a very high-order angular quadrature set. P_N methods also have angular truncation errors, but of a different nature. Like S_N methods, P_N methods cannot easily describe an angular flux with a complicated direction-dependence. Also, the P_N equations have a form and structure that are more difficult (than the S_N equations) to interpret in terms of the physics of particle transport.

The spatial variable x has probably been subjected to a greater variety of discretization methods than any other independent variable in the Boltzmann transport equation. In the early years, relatively simple *finite difference* (diamond difference and weighted diamond difference) methods were favored. Later, more sophisticated *finite element*, *nodal*, *characteristic*, and *corner balance* methods were introduced (Larsen and Morel 2009). Each of these types of methods tends to have its own advantages and disadvantages (Azmy 1992; Duo and Azmy 2007). For example, finite difference and (to a certain extent) nodal methods are relatively easy to implement on Cartesian (orthogonal, or box-like) spatial grids, while finite element, characteristic, and corner balance methods are better adapted to non-Cartesian (*triangular*, *tetrahedral*, or *unstructured*) spatial grids.

Cartesian grids were favored in early computer codes; but more recently, non-Cartesian grids have been employed, to better enable the spatial grid to fit the curved or non-right-angular surfaces occurring on material boundaries in many realistic applications.

A major issue in discretizing the spatial variable is the number of unknowns that must be calculated (and stored) per spatial cell. Methods that require a minimum amount of storage are generally less accurate on a specified grid, but the storage demand of particle transport problems is so high that in many problems, the simpler methods are preferred.

Another issue in spatial discretizations concerns accuracy in optically thick, scattering-dominated (*diffusive*) regions. For example, in electron and thermal radiation transport problems, the cross sections (or *opacities*) can be so high that it is not possible, due to computer storage limitations, to solve problems using a spatial grid in which the spatial cell widths are on the order of a mean free path or less. (In many neutron transport problems, spatial cell widths are chosen to be fractions of mean free paths.) Some discretization methods are significantly more accurate than others for problems in which the spatial grid is not optically thin; these methods tend to have a greater number of unknowns per cell (Adams et al. 1998; Adams 2001; Larsen 1992; Larsen and Morel 2009).

In practical neutron/photon transport problems, the total number of unknowns can be extraordinarily large. To estimate this number, let us consider a steady-state, 3-D, multigroup S_N problem.

The number G of energy groups can range from $G = 2$ for special light water reactor core problems to $G = 200$ for difficult shielding problems.

The number M of directions of flight in a typical 3-D S_N calculation varies, depending on the nature and order of the quadrature set. The 3-D S_N level-symmetric quadrature sets have $M = N(N + 2)$ directions. Thus, the commonly used S_4 and S_8 level-symmetric quadrature sets have 24 and 80 directions of flight, respectively.

The number of spatial cells can also vary. It is not atypical for a Cartesian spatial grid to have each independent variable (x , y , and z) defined on a grid of 100 points. Thus, the number I of discrete values of x is 100, and the same is true for $J =$ the number of discrete values of y and $K =$ the number of discrete values of z .

Thus, if we consider “typical” values $G = 20$, $M = 50$, and $I = J = K = 100$, then the total number N_{tot} of unknowns is

$$N_{\text{tot}} = G \times M \times I \times J \times K = 10^9.$$

This extremely large number (and in many problems the number is much higher) is a direct consequence of the fact that steady-state 3-D transport problems require a 6-D phase space.

To minimize the number of unknowns, computer codes have been written for 3-D problems with 1-D or 2-D spatial symmetry. This reduces the number of independent spatial variables from 3 to 2 or 1, and it possibly reduces the number of angular variables from 2 to 1. The problems that can be accurately treated by 1-D or 2-D codes are geometrically constrained but, fortunately, many important applications can be adequately represented by a 1-D or 2-D geometric model.

In addition to the issue of storing and processing the unknowns in the discretized Boltzmann equation, there is the fact that a linear algebraic system of equations with $N \approx 10^9$ equations and unknowns cannot be solved by direct matrix inversion. For most practical problems, it is necessary to use *iterative methods* to calculate solutions.

The simplest iteration strategy is based on *sweeping*, which itself is based on the observation that with standard discretization schemes, problems with no scattering or fission can be solved directly and noniteratively by *marching* through the spatial grid in the direction of particle flow. (Different directions of flow can require a different direction of marching, or sweeping.) The angular flux solution of such a problem is termed the *uncollided flux*; it consists of all particles that have not experienced a collision. (When a particle does experience a collision, it is absorbed. See  Subsect. 2.10.12.)

For problems with scattering, the *source iteration* strategy consists of performing sweeps and iterating on the scattering source. If the first sweep is performed with the scattering source

estimated to be zero, then at the end of the first sweep, the estimated angular flux is the uncollided flux. If this (uncollided) flux is used to estimate the scattering source and a second sweep is performed, then at the end of the second sweep, the estimated angular flux is the sum of the uncollided and the *once-collided* fluxes. At the end of N sweeps, the estimated angular flux $\psi^{(N)}$ is:

$$\psi^{(N)} = \sum_{n=0}^N \psi_n, \quad (298)$$

where ψ_n is the angular flux of particles that have scattered exactly n times. (See  Subject. 2.10.12.)

If a physical system is small and “leaky,” or has significant absorption, then particles will generally have short histories, and the series (298) will converge rapidly. However, if a problem has a subregion which is many mean free paths thick and dominated by scattering (rather than capture), then particles in that subregion will have long histories, and the series (298) will converge slowly. In the former case, the source iteration strategy converges rapidly, but in the latter case, source iteration converges slowly (Carlson and Lathrop 1968; Larsen and Morel 2009).

To speed up the convergence of source iterations for problems with optically thick, scattering-dominated subregions, *iterative acceleration* strategies have been devised. The earliest of these was the *Chebyshev acceleration*, a technique based on concepts from matrix algebra. This method worked to a limited extent, but it was not sufficiently efficient for many problems.

Later, the *rebalance* method was developed and used widely for a number of years. This method operates by calculating and applying, at the end of each sweep, *rebalance factors* on a fine or coarse space-energy grid. The rebalance method tends to become unstable when used on a fine space-energy grid, and to become stable but inefficient when used on a very coarse grid. The optimal (intermediate) grid is problem-dependent and must be found by trial and error. Even when the optimal grid is found, the resulting method is often not as efficient as desired (Adams and Larsen 2002).

Later still, *diffusion synthetic acceleration* (DSA) was developed to speed up the convergence of source iterations. DSA is based on the following concept. At the end of a transport sweep, an exact transport equation is derived for the iteration error (the difference between the latest iterate and the converged solution). This equation is just as difficult to solve as the original transport equation for the angular flux. In DSA, this *exact transport equation for the iteration error* is replaced by an *approximate diffusion equation for the iterative error*; the diffusion equation is solved; and the diffusion estimate of the iterative error is combined with the most recent estimate of the flux to obtain an updated and much more accurate estimate of the angular flux (Adams and Larsen 2002; Alcouffe 1977).

In practice, DSA is highly efficient for optically thin spatial grids. Unfortunately, unless great care is taken in the discretization of the diffusion part of the algorithm, it can become inefficient or unstable for optically thick spatial grids (Adams and Larsen 2002; Azmy 1998).

More recently, *Krylov methods* have been used, often in conjunction with DSA. Although Krylov methods require significant extra storage, they can be remarkably effective at stabilizing and speeding up the iterative convergence of methods based on source iterations, or on DSA (Adams and Larsen 2002; Faber and Mantueffel 1989).

All the work cited above describes advances in the basic mathematical algorithms for solving transport problems. Other equally important work has taken advantage of changes in computer architecture, i.e., on the details of how computers process arithmetic for large-scale problems

(Baker and Koch 1998). This type of research is becoming increasingly important as computers are becoming increasingly parallel in nature.

Historically, the research on S_N methods has tended to focus on (i) advanced discretization methods in space, angle, energy, and time, and (ii) advanced iterative methods that converge the iterative solution more rapidly and efficiently. In the past 50 years, major advances in all these areas have been made. The discretization and iteration schemes used in many advanced simulation codes today have little resemblance to the methods used 50 years ago.

However, a fundamental difficulty remains at the heart of deterministic calculations: the costly and time-consuming task of obtaining adequate multigroup cross sections for a specified difficult problem. This aspect of deterministic simulations remains the most significant obstacle to obtaining useful, accurate deterministic solutions of practical transport problems in a reliable, efficient, and user-friendly manner.

10.3 Hybrid Monte Carlo/Deterministic Methods

In the last 10–15 years, it has become understood that the most challenging aspect of difficult Monte Carlo simulations – the determination of problem-dependent biasing parameters – can be done efficiently by a deterministic simulation.

Specifically, for source-detector problems, the biasing parameters can be obtained by (i) solving an adjoint problem in which the detector response function is the source, as discussed in [▶ Sect. 5](#), and (ii) processing the resulting adjoint scalar or angular fluxes. The original “hybrid” concept is to use a deterministic code to perform this task (Chucas and Grimstone 1994; Haghghat and Wagner 2003; Smith and Wagner 2005; Van Riper et al. 1997).

The advantages to this procedure are that (i) it removes from the code user the burdensome task of calculating the biasing parameters, and (ii) the resulting computer-generated biasing parameters are usually much more efficient at reducing the Monte Carlo variance than the biasing parameters obtained by human trial and error (Smith and Wagner 2005).

The principal disadvantage is that two separate codes (Monte Carlo and deterministic) must be set up to run the same geometric problem, and the results of the deterministic code must be processed, formatted properly, and then input to the Monte Carlo code. This process can be unwieldy unless a suitable investment has been made in the computing infrastructure, enabling the process to occur automatically.

Most public particle transport codes are either Monte Carlo or deterministic, but a small number of user-friendly hybrid codes are now available. For example, the hybrid code MCBEND (Chucas and Grimstone 1994) uses a multigroup diffusion solver to determine weight windows for Monte Carlo simulation. Also, the recent SCALE 6.0 package from Oak Ridge National Laboratory contains software that enables, with one geometric input deck, deterministically generated multigroup S_N solutions to be calculated, turned into weight windows, and then used in Monte Carlo simulations (Haghghat and Wagner 2003; Smith and Wagner 2005).

The type of problem for which deterministic methods have been most widely used to derive biasing parameters for Monte Carlo simulations is the classic source-detector problem – in which particles are born in a source, and a single detector response, in a possibly distant detector, is desired. The biasing parameters for this problem “encourage” Monte Carlo particles to migrate from the source to the specified detector region in such a way that estimates of the desired response have a significantly reduced variance. The biasing parameters can be obtained by solving an adjoint transport problem. In the resulting *nonanalog* Monte Carlo simulations

of source-detector problems, Monte Carlo particles are discouraged from migrating to regions far from the detector. Consequently, estimates of reaction rates at these locations generally have larger variances than before.

One of the features of deterministic calculations is that at the end of a simulation, estimates of the flux are inherently available at *all* points in the 6-D phase space. For the reasons discussed in the previous paragraph, this *global* information is generally not considered to be available in a useful sense from Monte Carlo simulations.

However, recent work has shown that if weight windows are properly defined using information from both adjoint *and* forward calculations, then Monte Carlo particles are “encouraged” to become distributed throughout the system in a manner that is much more uniform than the distribution of physical particles. In this case, accurate (low-variance) estimates of reaction rates throughout a physical system can be obtained from a *single* Monte Carlo calculation (Becker and Larsen 2009; Cooper and Larsen 2001; Wagner et al. 2007, 2009).

To date, the term “hybrid” has implied a method in which a deterministic simulation is used to assist – through the calculation of biasing parameters – a Monte Carlo simulation. However, deterministic and Monte Carlo techniques can be merged in different advantageous ways. For example, it has been demonstrated that for source-detector problems, an adjoint calculation can be used to *actively* modify the physical scattering process, so that Monte Carlo particles are encouraged to scatter into directions and energies that will bring them from regions of low importance to regions of greater importance (Turner and Larsen 1997). This *local importance function transform* method requires a greater amount of computation per particle history. However, for optically thick, deep-penetration source-detector problems, the method can be significantly more efficient than a standard weight window. It has also been shown that for problems with high scattering ratios, hybrid methods based on variational principles can yield estimates of reaction rates and eigenvalues that are significantly more efficient than standard estimates (Densmore and Larsen 2004). In addition, recent work on the *functional Monte Carlo* method has shown that even more accurate estimates of eigenvalues and eigenfunctions can be obtained by a hybrid method in which the Monte Carlo simulation is *not* used to obtain estimates of the flux, but rather to obtain estimates of certain *nonlinear functionals*, which are then used to obtain estimates of the flux (Larsen and Yang 2008).

Is there a class of hybrid methods for which Monte Carlo can be used to directly assist the accurate calculation of deterministic solutions? Possibly, the answer to this question is *yes*. As discussed previously, the principal difficulty with deterministic methods is the laborious calculation of multigroup cross sections. If continuous-energy Monte Carlo simulations could be efficiently run, to automatically determine (problem-dependent) multigroup cross sections, then this would be a way in which Monte Carlo simulations could significantly influence deterministic solutions. Promising work in this area has recently been reported (Wolters et al. 2009; Yang and Larsen 2009).

If such methods can be developed, then it is possible to imagine a future particle transport code, containing both Monte Carlo and deterministic modules, in which the Monte Carlo module “supplies” multigroup cross sections to the deterministic module, and the deterministic module “supplies” biasing parameters to the Monte Carlo module. (It might be necessary to perform these tasks iteratively.) One would then have a particle transport code that is much closer to a “black box” than present-day transport codes; it would require the user to input neither the biasing parameters for Monte Carlo simulations, nor the multigroup cross sections for deterministic simulations; it would determine these quantities automatically, and more accurately.

In principle, a code containing these features could make effective use of future advances in Monte Carlo, deterministic, and hybrid methods. Such a hybrid code does not exist today, but it is a distinctly logical possibility, given the thrust of past and current research in computational particle transport methods and the practical difficulties experienced by current-day code users.

10.4 Discussion

During the past 50 years, computational methods for performing neutron and coupled neutron/photon simulations have been an active and vibrant area of research in the nuclear engineering community. Major advances in algorithms for Monte Carlo and deterministic simulations have been made. There is little doubt that, due to the increasing demands on increased realism in simulations, research will continue on different fronts to improve the accuracy and efficiency of these simulations. Also, hybrid methods may become a distinct third approach, which would have its own class of difficult problems for which it is best suited.

11 Concluding Remarks

This concludes the chapter on *general principles of neutron transport*. The theory and methods discussed here apply to photon as well as neutron transport, although photon transport is of practical interest mainly in radiation shields. Important topics could not be presented, including (for example) (i) a discussion on variational methods, which are heavily dependent on the adjoint transport equation discussed in [Sect. 5](#); (ii) a more complete discussion on homogenized diffusion theory, which is used in most practical reactor core simulations; and (iii) a detailed exposition of computational methods for neutron and photon transport. Nonetheless, the authors hope that the material presented in this chapter, and the references provided below, will give the reader a useful foundation for more applied techniques described in other chapters of this handbook, and elsewhere.

Abstract: Two types of materials are selected by the nuclear industry to be used in nuclear reactors: either materials having specific nuclear properties, or standard engineering alloys corresponding to the thermomechanical loadings and environment.

The first class corresponds to the fuels neutron absorbing isotopes or alloys of low neutron capture cross sections. These atomic properties do not preclude the chemical state of the species, and the best chemical state could be selected (e.g., B, a neutron absorber, can be used in water solution as boric acid or as refractory carbide: B₄C). The second class corresponds to alloys, such as structural steels, stainless steels (SS), aluminum alloys, etc. Few specific alloys have been developed for particular applications, such as Zr alloys in water reactors or vanadium alloys in fusion devices.

All these materials have to support the environment of a nuclear reactor. In addition to standard engineering constrains (mechanical loadings, corrosion, high temperatures, etc.), the irradiation itself induces major changes in structure, properties, and behavior of all the materials.

Irradiation damage includes chemical changes induced by irradiation, with the specificity of in situ He formation, by (n, α) reactions, promoting swelling. However, the major mechanism of irradiation damage is mostly due to elastic interaction of neutrons with the atoms, leading to displacement cascades and generation of point defects (PD). The migration and clustering of these PD induce major changes in microstructure with corresponding changes in behavior.

Irradiation hardening, reduction of ductility, irradiation creep and growth, and swelling are described in detail in their physical mechanisms and their specific characteristics for the alloys and ceramics for current use and of future interest. Other irradiation effects such as radiolysis on water, or changes in electrical properties of insulating ceramics are also described.

After a generic description of the physics of the transformations induced in the microstructures by irradiation, the phenomena of major concern are presented for the different components of various reactors. The corresponding conditions are analyzed for various types of experimental reactors, power reactors (thermal and breeder), and fusion devices.

1 Introduction

1.1 Definition of Nuclear Materials

The aim of this chapter is to provide the reader with a comprehensive view of the materials aspects of the nuclear reactor design and operations. Indeed, nuclear reactors require the selection of materials having good or outstanding engineering properties, in very specific environments (temperatures, irradiation, time scales, etc.). In addition, the neutron physics of the reactors leads to the selection of alloys having specific properties with respect to interaction with neutrons (interaction cross sections). Last, the irradiation itself induces transformations in the alloys, with evolutions of the microstructures and changes in mechanical and engineering properties. The field of nuclear materials covers therefore two different domains:

- The effect of irradiation on materials, whatever the type of materials, as long as they are exposed to an irradiation field. This will include the physics of irradiation damage, the

changes induced in microstructure and their effects on the properties. The alloys concerned are standard alloys used for their properties in numerous industrial environments.

- Other materials of concern are those of specific physical properties, namely the nuclear properties. Most of them are the materials used in the cores of the reactors. The first class includes the species corresponding to the fissile materials (U, Pu, etc.) and to the neutron absorbers (Cd, In, B, etc.) used to produce and control the nuclear chain reaction. The second class covers the materials selected for their low interactions with neutrons and having good engineering properties (Zr alloys, or moderators such as graphite, etc.). These materials are also subject to irradiation-induced transformation and property changes.

1.2 Radiation Fluxes in Nuclear Reactors

In the nuclear reactors, various types of irradiation fluxes can be observed, whose nature, spectra, and intensity can vary over large extends. The previous [▶ Chap. 1](#), [▶ 5–11](#) describe in detail the computation procedures used to obtain a full description of them. Indeed the neutron, electron and photon spectra are location, time, and reactor type dependent. In this section, typical values of the irradiation fluxes will be given, with special emphasis on areas where their effects will be significant for the behavior of the materials.

In fission reactors, the neutrons produced during fission have high energies, typically a few MeV. In fast neutron reactors, the neutrons are maintained in this energy range, and their spectra in the core have very low contributions at low energies. However, due to the low fission cross sections in the high energy range, very high neutron fluxes are required for their operation.

In the core of the thermal reactors, the energies of the neutrons are reduced by series of elastic interactions with light, nonabsorbing elements, i.e., the moderator. The result is a much higher contribution of the low energy neutrons, and lower fast neutron intensity. Typical spectra of neutron energies are given in [▶ Fig. 1](#). Maximal values of fast neutrons flux ($E > 1$ MeV) are roughly 5×10^{16} and $6 \times 10^{19} \text{ n} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$, for thermal and fast neutron reactors, respectively.

In the very specific case of the future fusion reactors, the fission products have very different characteristics. The neutrons, produced in the D-T reaction with an energy of 14.1 MeV, escape from the plasma without interaction and interact with the walls and structural materials by various processes, while the α 's, in spite of their high energies, due to their charged nature, are trapped by the magnetic field and will not interact immediately with the walls of the vacuum vessel. They will only interact with the surface of the divertor, at much lower energies after having heated the plasma. Due to the unusual processes relevant to the fusion reactor irradiation damage mechanisms, corresponding to extreme conditions of the mechanisms described in fission reactors, they will be described in [▶ Sect. 5](#).

The neutrons fluxes and energy spectra depend on the location where they are analyzed. In fast reactors, the flux gradient is high and neutron doses are very different within the core. The surrounding structures, such as the containment vessel, are far apart and therefore almost free of irradiation damage. In thermal reactors, the flux in-core is roughly constant, but the pressure vessel is close to the core and despite the gradient at the periphery of the core, radiation damage is observed in the internals and in the pressure vessels. Therefore any analysis of the effects of irradiation should consider the exact neutron history and characteristics, at the location of the material considered.

■ **Figure 1**
Neutron flux spectra in fission reactors (fast breeder and LWR)

For the different mechanisms of modification of the behavior of the materials under irradiation, the parameters to be considered may not be the same. Thus, irradiation can be considered at two different time scales. Instantaneously, the parameter is the neutron flux (Φ), expressed in units of $\text{n} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$. The time integral is called the fluence (Φt , units: $\text{n} \cdot \text{m}^{-2}$). These two parameters act differently and the same fluence, obtained with different fluxes over different time spans, can lead to very different irradiation effects. Similarly, the flux itself can control specific behaviors, such as irradiation creep or transport properties.

As it will be detailed in the following section, the major contribution to irradiation damage is due to the high energy part of the neutron spectrum. This is the reason why the neutron fluxes are usually described by their high energy parts. The link between neutron flux and damage integrates all the mechanisms of damage formation and specific procedures have to be used to reduce the whole spectrum to a reduced neutron flux of a given energy. This will be detailed in

➤ [Sect. 2.1.4.](#)

In addition to the neutrons, other irradiation fields have to be considered.

- High energy photons are released by nuclei during the fission process, by decay of fission products or other neutron inelastic interactions. Created with well-defined energies, their energy distribution is degraded by successive Compton interactions, leading to a continuous in-core spectrum of γ photons. The fractional contribution of the γ photons to the total energy release is about 6–7%, with a wide energy range (0–2 MeV).
- The electron flux is induced either by β^- decay or by Compton interactions of the γ photons. The major part of the β^- decay electrons is released within the fuel and, due to the low range of the corresponding electrons, remains localized inside the fuel elements. The Compton

electrons and photoelectrons are produced everywhere in the core and around. They are formed by the natural degradation processes of the photons interacting with matter. The β^- decay mechanism produces in addition a neutrino that has a too low interaction cross section with matter to be of concern. The neutrino flux will therefore not be considered further in this chapter.

- The last irradiation flux to be considered is formed by the heavy ions. They are created either directly during fission, where the fission fragments will have energies of 100–70 MeV, respectively for the light and heavy recoils. Having recoil ranges shorter than 10 μm , they remain within the fuel, and induce damage localized only in the fuel material. Other energetic heavy ions are the α and associated recoil atom, during any (n, α) reaction.

2 Radiation Damage

2.1 Irradiation Damage by Neutrons

The interaction of a neutron with the atoms occurs only with the nucleus. Two different mechanism may occur: either inelastic interaction, where the neutron reacts with the nucleus, producing nuclear interaction (capture, (n, α) , fission or any other reactions, etc.) or elastic interaction where the neutron hits the nucleus and transfers to it only part of its momentum and kinetic energy.

All these processes are characterized by the interaction cross section, σ , describing the probability of interaction for each process. This quantity is dependent of the exact process considered, of the nature of the target (chemical and isotopic state) and of the energy of the impacting neutron. The reaction rate is thus given in the following equation:

$$N_i = N_v \sigma(E) \varphi_n(E) \quad (1)$$

where N_i is the number of interactions occurring per unit volume and unit time, N_v is the number of atoms that could interact in the unit volume, $\sigma(E)$ is the interaction cross section, and $\varphi_n(E)$ is the neutron flux at the energy range considered.

2.1.1 Inelastic Interactions: Chemical Changes

Inelastic interactions are either positively searched for operation of the reactor, such as neutron absorption for reactivity control, fission for energy generation, or are suffered for their contribution for chemical changes, damage, etc.

Except the case of the (n, α) reactions that concerns almost all the chemical species at high neutron energies, the changes in chemistry induced by the inelastic interactions are limited to very specific cases. A few of them will be presented in this section, for illustration purposes.

- Control rods and absorbers.

The absorbers are designed with a specific constrain of high neutron trapping efficiency. This means a high capture cross section in the energy range concerned. B, In, Cd are the major absorber materials used in fission reactors. These species are used either as compounds (B_4C) or as alloys (AIC, for silver-indium-cadmium). For safety reasons, the control rods, that contain

the absorbing materials, are partly inserted in the core and their extremities are thus subject to a significant neutron flux. Therefore, captures occur, in consistency with the aim of these devices.

- AIC in PWR

In the case of AIC PWR control rods, the change in chemistry induced by such captures is a matter of concern. An AIC control rod consists of a stainless steel tube filled with an Ag-In-Cd alloy. The initial composition is typically the following: Ag 80, Cd 5, In 15 (w %). It corresponds to a single phase fcc solid solution.

The different neutron capture reaction mechanisms induce large changes in composition, with decrease in Ag and In, increase in Cd and formation of a new component: Sn, shifting, after a few years in reactor, to typical compositions such as Ag 72, Cd 8–10, In 10–12, Sn 2–5 (w %). The quaternary phase diagram of these alloys forecasts a phase change from the dense fcc structure, for high Ag content, to an hexagonal close packed (hcp) structure of lower density (Bourgouin et al. 1999). The corresponding swelling induces hoop stresses in the SS cladding, leading to stress corrosion cracking (SCC), leaking absorber rod, and corrosive interaction of the coolant with the absorber alloy.

- B₄C in thermal and fast reactors.

Boron is a very efficient neutron absorber, with a thermal neutron absorption cross section larger than 1,000 barns, decreasing with the energy of the incident neutron down below 0.5 barn for 1 MeV neutrons. The principal reaction is described as $^{10}\text{B}(n, \alpha)^7\text{Li}$ and produces an He atom and releases 2.8 MeV of energy. The generation of He bubbles in B₄C reduces its thermal conductivity and induces matrix swelling. High temperatures and He supersaturation drives the release of He out of this material. At low temperatures, He in solid solution induces internal lattice strains (Simeone et al. 1999), and at higher temperatures, He precipitates as elongated bubbles, inducing swelling (Stoto et al. 1990).

- Other specific cases

In material testing pool reactors, the structural parts are often made out of Al-alloys of 5xxx type, where Mg in solid solution enhances mechanical strength and corrosion resistance. Under thermal neutron irradiation, an (n, γ) reaction occurs on Al, leading to in-situ formation of Si (up to a few % for long irradiations). This change in chemistry shifts the alloy to the 6xxx class, where the mechanical strength is obtained by small Mg₂Si precipitates. An irradiation hardening is therefore observed, whose origin lies in the chemically induced change in microstructure (Farrell 1981).

The (n, α) reactions are common with fast neutrons. They have very high importance, as they continuously dope the alloys with He. Their consequences will be considered in the section devoted to stainless steels and swelling (➤ 4.1.2). In the case of materials for fusion reactors, the high energy of the neutrons leads to high cross section of these reactions and therefore very high He creation for the same irradiation damage. It should however be remembered that more complex He production mechanisms can be obtained: in thermal reactors, and in the outer part of the breeders, a double reaction occurs on Ni, with high cross section for thermal and epithermal neutrons: A first capture $^{58}\text{Ni}(n, \gamma)^{59}\text{Ni}$, is followed by the $^{59}\text{Ni}(n, \alpha)^{56}\text{Fe}$ reaction, and formation of an atom of helium.

In the case of tungsten, considered for specific fusion applications, the high capture cross sections on the different isotopes of this element, lead to significant chemical changes: After 2.5 years of exposure, up to 25% of the W is transformed in Os and Re, inducing a structural change in the alloy, with formation of a brittle σ phase (Forty et al. 1994).

2.1.2 Elastic Interactions by Neutrons

Although chemical changes induced by irradiation can affect the behavior of alloys, the main mechanisms of irradiation damage are connected to the displacement of atoms following an interaction with fast neutrons. The aim of the following sections is to describe the physical phenomena controlling the ballistic irradiation effects.

- Energy transfer, displacement cross sections

In this case, there is no modification of the structure of the nucleus, but part of the kinetic energy of the neutron is transferred to the target atom, according to (2):

$$E_T = 4E_n \cos^2 \theta \frac{m_n \cdot m_T}{(m_n + m_T)^2} \quad (2)$$

where E_T is the energy transferred to the target, m_n and m_T are the masses of the neutron and of the target atom, E_n is the kinetic energy of the neutron before impact, and θ is the scattering angle expressed in the centre of mass coordinates (► Fig. 2). The ratio between the maximum transferred energy and E_n is often called the energy transfer parameter, Λ . The mean value of the transferred energy, for all the different scattering angles, is roughly equal to half of the maximal value.

The transfer of energy induces different consequences, depending on its relative value. It has to be compared to a critical value required for atomic displacement out of the crystal lattice site.

For low values of the energy transferred, the target atom cannot leave its position in the crystal. The increase in kinetic energy only increases its vibration amplitude within the lattice site. The impact is thus only a source of local vibrations, a phonon, i.e., nothing but a local source of heat that will diffuse in the alloy, by propagation of the phonons.

If the energy transferred is larger than a critical value, called the displacement energy E_d , which is for common metals close to 20–40 eV, the target atom can escape from its lattice site.

The displacement energies were measured experimentally on different alloys using electron irradiation at various accelerating voltage. The minimum transferred energy above which a change in physical property can be observed (usually electric resistivity) gives the displacement energy, E_d . It was found that E_d varies with species, and crystallographic orientation (Urban and Yoshida 1981). Since the computation of irradiation damage is scaled with the displacement energy, it is highly recommended to use the standard values listed in ASTM standard E 521 for

■ Figure 2

Schematics of an elastic interaction between a neutron and a target atom (center of mass frame)

a unified computation of the irradiation damage (ASTM Standards E-521-96 2003), whatever the irradiation mechanism (neutron, electron, or heavy ions).

Following the impact and energy transfer to the target atom, different phenomena occur:

- For a low transferred energy (a few E_d), it will not disturb the other atoms from their sites and only loses energy along its path, to stop as an interstitial when its energy is too low for further motion. At the end of the process, the final damage is the combination of a vacancy, the former location of the atom, and an interstitial, which is not necessarily the initial atom hit. This pair of point defects is called a Frenkel pair. Typically, this is what will occur during high-energy electron irradiation, where the transferred energies are of the order of a few tens of eV.
- For high values of the energy transferred, the target atom, called now the primary knocked-on atom (pka), interacts with the other atoms of the alloy along its track. For each interaction, it transfers on the average half its current energy on the secondary target, as they have equal masses. Each of them will similarly interact with other atoms and a cascade of interactions occurs. The result is a large number of atoms displaced (up to a few hundreds), in a “displacement cascade.” After a few picoseconds, the highly damaged area restructures itself, leaving a few isolated, surviving PD and clusters of PD.

Overall, the irradiation by neutrons results in a continuous creation of point defects, and heat, in the bulk of the alloys. These PDs cannot increase in concentration without limits. The PD can recombine, migrate, agglomerate as large clusters of PD or disappear on various sinks such as free surfaces, grain boundaries, or dislocations.

A good knowledge of the radiation damage requires therefore an accurate description of the various quantities involved in these processes. In the following sections, the probability of interaction (cross sections), the displacement energies E_d , the PD energies and mobilities, the cascade configurations, and the strengths of the sinks where they can disappear will be described in detail for generic alloys. These data will be used to describe the formation of the resultant microstructures (dislocation loop formation, precipitation, phase instability, etc.), by combination of all the processes involved in radiation damage. Then it will be possible to illustrate the consequences for the properties of the alloys and their modified behavior under and after irradiation.

- Vacancy and interstitials, Frenkel pairs

The net result of the displacement of atoms in a crystallized material is the formation of a pair of opposite defects, the vacancy, and the interstitial.

Compared to the interstitial, the vacancy has a low formation energy (typically $E_{f-v} \sim 0.7\text{--}1.2$ eV) and a high migration energy ($E_{m-v} \sim 0.8\text{--}1.5$ eV). Due to the low formation energy of the vacancies, a low concentration of vacancies is thermally obtained at high temperature (around $10^{-3}\text{--}10^{-4}$ near the melting temperatures). Around a vacancy, the surrounding atoms only slightly relax their positions, and the relaxation volume of a vacancy is only a small fraction of the atomic volume. Their migration energies restrict their mobilities to the high temperature domains ($T > 1/3 \cdot T/T_m$).

The insertion of an interstitial atom in the lattice requires large displacements of the surrounding atoms. It has therefore a high formation energy (typically $E_{f-i} \sim 3\text{--}4$ eV). Being more than an extra atom inserted in a disturbed site within the packed atoms of the crystal, the atomistic geometry of the interstitial consists usually in a pair of atoms sharing the same lattice site, in a highly crowded configuration. Often the two atoms form a dumbbell along specific

crystallographic directions (e.g., $\langle 100 \rangle$ in fcc or $\langle 110 \rangle$ dumbbells in bcc Fe) or extended defects such as $\langle 111 \rangle$ crowdion in non magnetic bcc crystals. One atom of this pair can easily jump to any next lattice site, forming a similar configuration with another atom, leading to the migration of the defect. Therefore the interstitials are observed to be highly mobile and usually can migrate well below room temperature ($E_{m-i} \sim 0.05\text{--}0.3\text{ eV}$). The relaxation volume of the interstitial is usually of the order of the atomic volume or larger.

For low transferred energies, the target atom cannot induce significant displacement of the surrounding atoms to remove them from their own lattice sites. It moves only slightly away from its position, transferring part of its energy to the atoms hit along its track, until it cannot migrate anymore, where it forms the interstitial defect. If the final distance between the vacancy and the interstitial is too low, the configuration of the pair of PD's is elastically unstable and the two opposite PD's recombine instantaneously, and the two defects disappear, releasing their energies as a phonon diffusing in the lattice. The volume in which two opposite PD's elastically recombine is called the recombination volume. The size of the recombination volume is in the range of 100–150 atomic volumes. It has been measured by the observation of a saturation of PD concentration during low temperature irradiations, and confirmed by molecular dynamics (MD) computations.

If the distance between the initial location of the target atom, now the vacancy, and the stopping site of the interstitial is high enough, the result is the creation of a stable pair of correlated opposite defects, the Frenkel pair.

- Displacement cascades

For typical fast neutrons, energies transferred to the pka atom of structural materials are in the range of a few tens of keV. For these kinetic energies, the pka has very high interaction cross sections with any atoms along its track. Since the atoms knocked by the pka have similar masses as the pka, and according to (2), the energy of the pka is, on average, shared between the target atom and the pka. The two interacting atoms usually will repeat the interaction process with surrounding atoms, leading to a cascade of displacements. The process is repeated unless the transferred energy is lower than the displacement energy.

Simple partition of the kinetic energy between all the interacting atoms leads to the number of atoms displaced in a cascade as proposed by Norgett et al. (1975). According to this modeling, the number of atoms displaced in a cascade is simply:

$$N_{\text{NRT}} = 0.8 \cdot \frac{E_{\text{pka}}}{E_d} \quad (3)$$

Typical values amount for a few hundreds of displaced atoms in a cascade. Following a given irradiation, the fraction of atoms hit by neutron to form pka multiplied by this value of N_{NRT} gives the irradiation damage, in term of displacement per atoms (dpa_{NRT}).

$$\text{dpa}_{\text{NRT}} = \frac{\rho \cdot N}{M_a} \cdot \sigma \cdot \phi \cdot \frac{E_n}{E_d} \cdot \frac{1.6 \cdot (m_T + m_n)}{(m_T \cdot m_n)^2} \quad (4)$$

where ρ is the specific mass of the alloy, N is the Avogadro's number, M_a is the atomic mass of the alloy, σ is the diffusion cross section at the energy considered, ϕ is the neutron flux, E_n is the kinetic energy of the incident neutron, E_t is the mass of the target atom, m_T and m_n are the masses of the target atom and the neutron, respectively.

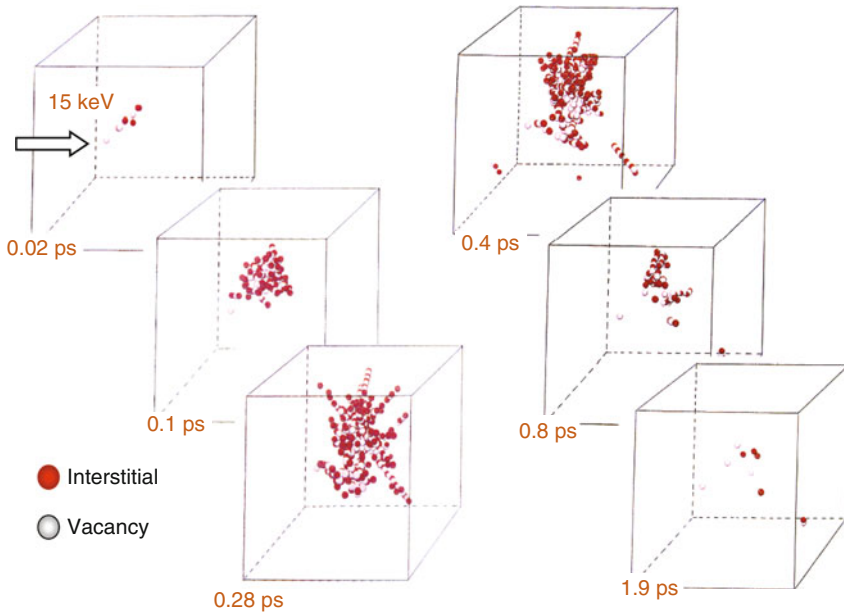

Figure 3

Time evolution of a displacement cascade in Fe (15 keV) (Molecular dynamics simulation, after Souidi et al. 2001)

Advanced description of the behavior of a cascade is obtained using molecular dynamics computations (Bacon et al. 1995). These computations allow deriving important features of the cascades (e.g., see Fig. 3):

- The life of a cascade is short. The development period (ballistic phase), at the end of which all the atoms have kinetic energies similar to the thermal energy last 0.2–0.8 ps, depending of the pka energy. Within 5–10 ps, the highly damaged area recovers and, due to the locally very high density of PD, most of them recombine, and a very low number of isolated PD survive to the cascade.
- For low energy cascades, significant spatial extension of the cascade can be observed, induced by focusing sequences, while at high energies, the cascades have a tendency to split into a few sub-cascades slightly separated, that behave independently (Voskoboinikov et al. 2008).
- The efficiency of the cascade, i.e., the number of free defects normalized to the displaced atoms, decreases with the energy of the pka. For most of the alloys a simple relationship exists between the energy of the cascade and the number of Frenkel pairs N_F . The ratio between the number of atom displaced (N_{NRT}) to the number of remaining defects is the cascade efficiency. Typical values are in the range of 0.1–0.15. It is observed to decrease with cascade energy (Bacon et al. 1995; Voskoboinikov et al. 2008; Gao et al. 2008). A simple relationship exists between the number of Frenkel pairs and the energy of the pka:

$$N_F = A \cdot (E_{pka})^m \quad (5)$$

■ Figure 4

Size of the PD clusters in Zr cascades as computed for cascades of different pka energies in Zr (From Gao et al. 2001)

- The values of A and m have been obtained for various metals (Bacon et al. 1995).
- At the end of high energy cascades, clusters of PD of the same types may be formed, such as small interstitial or vacancy loops, stacking fault tetrahedra in fcc, etc. The higher the energy of the cascade, the higher the fraction of surviving PD's trapped in such clusters (Bacon et al. 1995; Gao et al. 2001).
 - Of course, the results of MD computations are dependent of the interatomic potentials chosen, but the tendency of the physical phenomena remains qualitatively similar using different potentials (Becquart et al. 2000). For alloys the results remain similar, but special phenomena, such as preferential species for the PD, can be observed (Malerba et al. 2004).

As an example, the size distributions of PD in Zr after various cascades are plotted in **Fig. 4**. Large clusters of the two types, either interstitials or vacancies were observed. A difference is noticeable between the two types of PD. In the case of vacancies, the number of surviving vacancies as individual or di-vacancies is high, and the number of vacancy clusters low. The reverse was obtained for the interstitials.

A major consequence, clearly seen in **Fig. 4**, is that the number of surviving isolated defects is not the same for the two types of PD. Isolated and free vacancies are released by the cascades in much higher number. This effect is known as the *production bias* that has to be considered when solving the rate equations in the mean-field approach of PD evolution described latter (8) (Woo and Singh 1995).

The number of remaining point defects and clusters of interstitials or vacancies are the initial conditions for the thermal evolution of the alloys under irradiation. Indeed, for a larger time scale than the evolution of the cascade, the point defects will migrate and recombine, cluster or annihilate on various sinks. Major changes in the microstructure will result, inducing modification of the properties, as will be described below.

2.1.3 Damage Cross Section

The irradiation damage is often expressed in the form of fast neutron fluence ($n \cdot m^{-2}$) and an indication of the “fast” neutron energy limit, or with the effective damage in dpa. The conversion

factor will vary according to the exact neutron physics of each reactor, i.e., according to the exact neutron energy spectra. In water reactors, a rough conversion factor between fast dose and displacement damage corresponds to 1 dpa being induced by a fluence of $5 \times 10^{24} \text{ n} \cdot \text{m}^{-2}$ ($E > 1 \text{ MeV}$) for Zr. In fast reactors, the different spectrum and the use of SS leads to 1 dpa $\sim 2 \times 10^{25} \text{ n} \cdot \text{m}^{-2}$ ($E > 0.1 \text{ MeV}$) on Fe atoms.

Therefore a detailed conversion procedure is required to compare irradiations performed in different reactors. Indeed, the impact of irradiation on various properties can be determined by testing materials in different reactors (e.g., LWR power plants, material testing reactors or fast breeders for high fluence irradiations). In addition, basic irradiation studies are often performed using electron or heavy ion irradiations and the results obtained have to be compared with the reactor irradiations.

The irradiation damage is mainly obtained by elastic interaction between fast neutrons and the atoms of the alloy. Indeed, the low energy neutrons (below a few hundred eV) do not transfer enough energy to induce atomic displacement. However, nuclear interactions can occur of (n, γ) , (n, α) , (n, n') or $(n, 2n)$ types, the later being significant only at high energies. The contribution of these reactions, and their decay followers, has to be computed with consideration of the detailed neutron energy spectrum of each reactor, if not each location inside the reactor (Greenwood and Garner 2004). The irradiation damage is thus computed considering all these processes inducing displacements. The rate of formation of displaced atoms is simply equal to the expansion of the previous equations (4) to the full energy range of the neutrons:

$$R_d = N \int_{E_d/\Lambda}^{\infty} \varphi(E_n) dE_n \int_{E_d}^{\Lambda E_n} \sigma_n(E_n, T) v(T) dT \quad (6)$$

where N is the number of atoms per unit volume, Λ is the energy transfer parameter defined in (2), and the other terms described earlier. The second integral allows defining the displacement cross section, σ_d .

$$\sigma_d(E_n) = \int_{E_d}^{\Lambda E_n} \sigma_n(E_n, T) v(T) dT \quad (7)$$

This displacement cross section has been determined for several chemical species using the nuclear data tables ENDF-BV. It is available for most of the components of structural materials (Greenwood and Smither 1985). As an example, it is given for Zr in  Fig. 5.

The rate of irradiation damage is the integral of the product of this displacement cross section by the neutron flux for each energy of the neutrons. Since different reactors have different neutron spectra, the ratio between damage formation rate and neutron flux varies accordingly (Piercy 1969; Greenwood 1994). Care should be taken to the fact that $\sigma_d(E_n)$ includes also a hidden parameter, the displacement energy E_d . The recommended value is 40 eV, but basic studies have sometimes used the other values, like the minimal E_d for detection of irradiation damage (25 eV) (Pecheur 1993; de Carlan 1996).

2.1.4 Computation of Damage for Power Reactors

Since it is impossible to describe the full spectrum of neutrons for each irradiation ( Fig. 1), it is common to characterize the neutron flux (or fluence) only by its fast neutron contribution, since it is responsible for most of the collision damage. This simplified approach induces a bias due to the definition of the “fast” neutron. In fast neutron reactors, a cut-off value of $E > 0.1 \text{ MeV}$ is

Figure 5
Displacement cross section $\sigma_d(E_n)$ for Zr, with $E_d = 40$ eV

usual, while $E > 1$ MeV is commonly preferred in LWR. Other limits have also been historically used (0.85 MeV).

Computation of the damage requires an accurate knowledge of the neutron flux history and spectra at the exact location where the damage is to be computed. This is the aim of neutron physics codes and dosimetry survey. In addition the damage cross section is to be known, as described in the preceding section. A standard procedure has been developed for pressure vessel of LWR and should be used for intercomparisons of tests of different origins (ASTM Standards E-693-01 2007). For other components, a similar procedure is recommended.

Selecting such a limit for the fast neutrons does not mean that only these neutrons are considered for damage, but is just a way to scale the flux intensity. Decreasing the energy limit for the fast neutrons value increases the flux considered, but does not change the damage. Therefore irradiations to the same fluences, but expressed as $E > 1$ MeV and $E > 0.1$ MeV correspond to different damages, the later being smaller, by a factor of about 2 (Table 1).

In old publications, a special unit can be found: nv or nvt. It stands for number (of neutrons per unit volume), velocity, and time. The product of n neutrons (in number-cm⁻³) by the velocity (cm · s⁻¹) is indeed similar to a flux (cm⁻² · s⁻¹). Once multiplied by the time, a flux integral (fluence) is obtained. The velocity of the neutrons is obtained from their kinetic energies ($1/2 mv^2$). Similar problems occurred for the selection of the mean energy of the fast neutrons. In the early days, the French scientists used also a special dose index: the dpa_F, with an equivalence of $1 \text{ dpa}_F \approx 0.77 \text{ dpa}_{\text{NRT}}$ in stainless steel claddings.

For the fuel cladding materials (Zr alloys in water reactors, and stainless steels in fast liquid metal reactors), the irradiation is also often expressed using a quantity related to the fuel irradiation: the fuel burn-up (BU). It is expressed in term of energy produced by unit mass of fuel (MW · d · t⁻¹). The correspondence between BU and dpa is much more reactor dependent than the flux – dpa ratio, due to the major contribution of the thermal neutrons to the fission. A fair

■ **Table 1**
Neutron fluences ($n \cdot m^{-2}$) for 1 dpa in various reactors

Type of reactor	Atom	$E > 0.1$	$E > 1 \text{ MeV}$
LWR pressure vessel	Fe		7×10^{24}
PWR BWR (steam 40%)	Zr	1.3×10^{25}	6.4×10^{24}
Na fast reactor	Fe Cr	$\approx 2.2 \times 10^{25}$	
HT GCR	Si C	0.8×10^{25}	

conversion factor is: 1 dpa in Zr is obtained in the cladding for a BU of about $4\text{--}5 \text{ GW} \cdot \text{d} \cdot \text{t}^{-1} \text{U}$ in a LWR. In Na-cooled SFR, 1 dpa is obtained for a fluence of $2 \times 10^{25} \text{ n} \cdot \text{m}^{-2}$, for which a typical BU would be $1 \text{ GW} \cdot \text{d} \cdot \text{t}^{-1} \text{ox}$ corresponding to a fraction of fissioned atoms of 0.1 FIMA (fissions per initial metal atom).

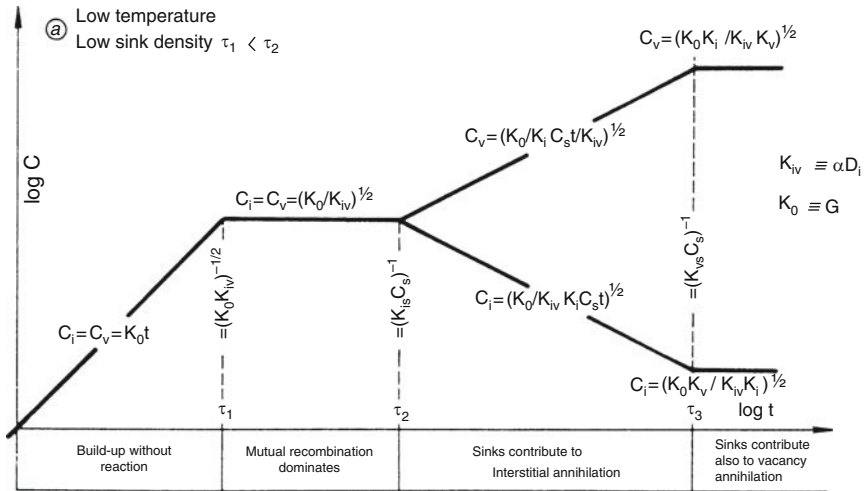

2.1.5 Time Evolution of the Point Defects

In power reactors, the continuous irradiation induces a steady state creation rate of PD's resulting from the final evolution of the cascades. The remaining defects form either isolated defects or small cluster of interstitials or vacancies. Since these two types of PD's are mobile, their migration occurs under thermal activation. The interstitial are highly mobile and their migration occurs well below room temperature, while the vacancies diffuse more slowly and their mobility is activated at higher temperatures (250–600 K). The computation of the time evolution of these defects requires the knowledge of their migration kinetics and of all their interactions with all the microstructure singularities on which they could disappear or interact (other PD's or different atoms, small PD clusters, dislocations, any interfaces, etc.).

The isolated point defects can migrate anywhere in the alloy and interact with any other crystal defects: An interstitial diffusing to the recombination volume of a vacancy will annihilate there, but they can also merge with other interstitials and form clusters of interstitials, acting as nuclei for interstitial dislocation loops, and similarly for vacancies. In addition, for intermetallic compounds, exchange of species can occur when an interstitial atom falls in the vacancy site of another chemical specie (anti-site). This leads to chemical disorder, a driving force for phase changes, including amorphous transformation.

Clustering of interstitials leads necessarily to planar dislocation loops, while vacancies can produce 2D and 3D defects (i.e., dislocation loops and cavities). The later induce material swelling. When the dislocations present in the alloy act as sinks for interstitials and vacancies, the trapping of PD's on dislocations results in the climb of these dislocations, inducing locally some irreversible strain. If the directions of the strain induced by climbs are not isotropic, this results in a macroscopic strain. When the anisotropy is induced by applied stresses, irradiation creep occurs. In the absence of applied stress, but for anisotropic materials having a crystallographic texture, growth can be observed (e.g., Zr or U alloys, etc).

The classical approach to model PD evolution under irradiation is to solve the kinetics equations for their interaction with the extended defects (Sizmann 1978). A set to two coupled equations is obtained, in which, for each species (vacancies or interstitials), the concentration

■ Figure 6

Evolution of PD population with irradiation time (From Stoller and Mansur 1990)

evolution is controlled the balance between PD generation by irradiation, G , and their disappearance either mutually with the opposite type of defect, or on any kind of sinks. Each sink can be assigned its own strength leading to a kinetic coefficient k . The set of equations obtained is the following:

$$\begin{aligned} \frac{\partial c_v}{\partial t} &= G_v - R_{iv} D_i c_i c_v - \sum_j k_{j,v} D_v c_v + \sum_j k_{j,v} D_v c_{vj}^e \\ \frac{\partial c_i}{\partial t} &= G_i - R_{iv} D_i c_i c_v - \sum_j k_{j,i} D_i c_i \end{aligned} \quad (8)$$

For the vacancies, a thermal release from the dislocations and free surfaces has also to be considered: $\sum_j k_{j,v} D_v c_{vj}^e$. This contribution to the vacancy concentration is important only for high temperature irradiations. However, this term is of high importance for PD annealing occurring during post irradiation heat treatments, since then the thermal vacancies are the only PD's responsible for atom mobility in the absence of irradiation.

The solution of this system of coupled differential equations gives a description of the evolution of the PD with time, but it assumes that the sink concentration (i.e., the dislocations and loops) remains constant. The steady state solution of this system gives a concentration of vacancies in the range of $c_v \approx 10^{-5}$ and, as expected, a much lower value for the interstitials: $c_i \approx 10^{-10}$ for a Zr cladding in a typical LWR (Stoller and Mansur 1990). Typical asymptotic solutions are sketched in ► Fig. 6.

PD Clustering

The trapping of a PD by loops or cavities results in a net change in their sizes. The change in loop or cavity size is an important feature of the microstructural change induced by irradiation

(dislocation density for loop growth and swelling for cavities). Therefore an accurate modeling of their evolution is important to forecast the evolution of the microstructure, and as a consequence, of the properties. The change in size is due to the net flux of PD that will increase or decrease their sizes. For instance, for a cavity the trapping of a vacancy is an increase in cavity size, while an interstitial trapped by the cavity decreases its volume. Detailed procedure of such modeling is given below for the loop size evolution. For the cavities, the impact of He atoms (generated by (n, α) reactions) enhancing the nucleation of cavities (Mansur and Coghlan 1983) is detailed in a specific section devoted to swelling (4.1.2).

The size evolution of a single loop, considered isolated in an infinite medium surrounded by a given concentration of interstitials and vacancies, can be computed by methods based upon the balance of fluxes at the sink formed by the dislocation (Mansur 1994). The interaction energy between PD's and the dislocation loops is found to be decreasing with the loop size. However, it is suggested that the loop sink strength (i.e., the efficiency of PD trapping, function of loop size, density, orientation, etc.), which controls the size evolution rate through the $k_{j,i}$ and $k_{j,v}$ factors, is increasing strongly for the large ones, due to the increased density of dislocation lines. In addition, the sink strength depends of the type of PD considered. The loop growth is therefore expected to be dependent on the size and type of the loops. For interstitial loops, the net flux of PD's leads to a limited growth for small loops and early saturation, while for vacancy loops, a more continuous growth is expected (Bullough et al. 1979). The calculated loop growth rate is forecasted to be proportional to the root of the irradiation time $(\varphi \cdot t) \approx 0.5$, corresponding well to the observations in high voltage TEM (HV-TEM) on Ni (Yoo and Stiegler 1978).

For the extended defects, such as dislocation loops, interacting with each other via the fluxes of PD's, the computation of their concentrations and size distributions has to be done using another method: the cluster dynamics approach, in which the rate of growth and shrinkage of each loop is analyzed by condensation and emission of individual PD. The modeling is based on an extension of the equations (8), with the reactions of the PD analyzed on all the loops of different sizes. This leads to a much larger system of equations, since all the dislocation loop types and sizes have to be considered individually. The change in concentration of interstitial loops of size n is due to the balance in the growth of the loops of size $n - 1$ by absorption of an interstitial, the shrinkage of the loops of size $n + 1$ by absorption of a vacancy, and the disappearance of a loop of size n by the two former processes. The symmetric mechanisms hold for the vacancy loops:

$$\begin{aligned} \frac{dc_{n,i}}{dt} &= \beta_{n-1,i}^i D_i c_i c_{n-1,i} + \beta_{n+1,i}^v D_v c_v c_{n+1,i} - (\beta_{n,i}^v D_v c_v + \beta_{n,i}^i D_i c_i) c_{n,i} \\ \frac{dc_{n,v}}{dt} &= \beta_{n-1,v}^v D_v c_v c_{n-1,v} + \beta_{n+1,v}^i D_i c_i c_{n+1,v} - (\beta_{n,v}^v D_v c_v + \beta_{n,i}^i D_i c_i) c_{n,v} \end{aligned} \quad (9)$$

Due to the computing limitations induced by such large systems (more than a few hundred classes of loop sizes), the system of discrete sizes is transformed in a continuous distribution for the largest loops considered (Hardouin Duparc et al. 2002). One of the critical aspects of this approach is to obtain a good description of the kinetic coefficients $\beta_{n,PD}^{PD}$. In the case of Zr, a choice of suitable parameters for the evaluation of the β 's, permitted an explanation of the simultaneous stability of the two types of loops (interstitial and vacancy types) (Dubinko et al. 2006).

2.2 Effects on Microstructure and Engineering Properties

Physical Properties

During the irradiation the creation and the evolution of the PD's induce changes in the microstructure at various scales: PD concentrations are increased (mainly vacancies, but also interstitials while at lower concentrations), clustering of PD leads to formation of dislocations loops that may interact during their growth, leading to a dense dislocation network, cavities will induce swelling, segregations occur by flux coupling of alloying elements and PD diffusing to the sinks. These changes in microstructure induce significant evolution of the properties of the alloys under irradiation.

The effect of PD concentration on physical properties is very limited and can be measured only on electrical resistivity ρ_e at low temperatures. Indeed the PD act as diffusing centers for the electrons and the increase in electric resistivity is directly proportional to their concentration. The resistivity is indeed easily measured and the accuracy in resistivity changes allow to measure concentrations of Frenkel pairs as low as 10^{-10} in pure metals. In the early days of irradiation experiments, the changes in ρ_e were used to measure accurately the displacement energy, observing the minimum accelerating voltage during electron irradiation to induce measurable damage at low temperature (4–20 K). In addition, during recovery, the temperature evolution of ρ_e allows to measure the migration energies of these PD or their interaction energies with alloying elements or impurities (Balluffi 1978; Kraut et al. 1971; Takaki et al. 1983; Dimitrov et al. 1976; Neely 1970).

The other physical properties, such as specific mass, modulus of elasticity, or thermal expansion coefficient are not affected significantly by PD concentrations.

Diffusion Under Irradiation

Since the diffusion is the displacement of atoms from one lattice site to another one, any mechanism of atom displacement has to be considered to contribute to diffusion. Under irradiation at low temperature, the diffusion is enhanced and can be faster than thermal diffusion by several orders of magnitude (● Fig. 7). The mechanisms to be considered are the following:

- At very low temperature, the PD, whatever the type, are immobile and cannot contribute in any manner to the migration of the atoms. However the mixing occurring inside the cascades induces a diffusion mechanism (ballistic diffusion). The corresponding diffusion coefficient is proportional to the irradiation flux and is strictly temperature independent. This is for instance the regime of ion beam mixing in compounds (Averback 1986). Then the ballistic diffusion coefficient is roughly given by the following expression:

$$D_{\text{ball}} \text{ (m}^2 \cdot \text{s}^{-1}\text{)} \approx 10^{-17 \text{ to } -16} k_0 \quad (10)$$

where k_0 is the Frenkel pair production rate expressed as fractional lattice sites per seconds ($\text{dpa} \cdot \text{s}^{-1}$) (Macht et al. 1981).

- At intermediate temperatures and irradiation fluxes, two specific regimes exist in which the migration of PD's created by irradiation is thermally controlled (Sizmann 1978):
 - When the sink density is low (i.e., the PD concentration is controlled by their recombination kinetics), the vacancy and interstitial concentrations, obtained from equations (8) are given as:

Figure 7

(a) The different regimes of diffusion under irradiation. (b) Radiation-induced diffusion of dilute elements in Cu (From Wollenberger 1994)

$c_v = \sqrt{\frac{\Omega G k_i}{2\pi r_r k_v D_v}}$ and $c_i = \sqrt{\frac{\Omega G k_v}{2\pi r_r k_i D_i^2}}$ where Ω is the atomic volume and r_r the recombination volume. Since the diffusion coefficient D is the sum of the two diffusion mechanisms induced by vacancy and interstitial mobilities, it can be expressed as: $D = c_i D_i + c_v D_v$ and the diffusion coefficient reduces to $D_{irr} = \beta \sqrt{\Omega G D_v / 2\pi r_r}$, where β is the function of the relative sink efficiency for vacancies and interstitials. As a consequence of D_{irr} being proportional to the root of the thermal diffusion of vacancies, the apparent activation energy for irradiation diffusion in this regime is equal to half the activation energy for the thermal diffusion.

- For high sink densities (i.e., the PD concentration is controlled by the dislocation density), the vacancy and interstitial concentrations, obtained from equations (8) are simply: $c_v = G/k_v D_v$ and $c_i = G/k_i D_i$. The diffusion coefficient reduces to $D_{irr} = G/k_v$, and the diffusion in this regime is then proportional to the irradiation flux and decreases with increasing dislocation density.
- At high temperatures and low irradiation intensity, the concentration of PD due to irradiation is small compared to the thermal equilibrium concentration of vacancies and the thermal diffusion regime is dominant. The corresponding diffusion coefficients are the standard thermal diffusion coefficients.

The enhanced diffusion under irradiation impacts all the transport controlled phenomena, such as the kinetics of phase transformation (dissolution or precipitation) and creep.

2.2.1 PD Clustering, Dislocation Loop, and Cavities

The migration and clustering of PD induce various evolutions of the microstructures under irradiation.

- The nucleation and growth of dislocation loops by clustering of PD leads to a microstructure specific to irradiated materials. Typical geometries of the loops are usually fine in size (3–20 nm) and of high volume density ($10^{21-23} \text{ m}^{-3}$) (► Fig. 8). Depending of the crystallography of the alloys, the loops may have different habit planes, and in fcc alloys with low stacking fault energies, stacking fault tetrahedra can be observed. During their growth, the dislocation loops may interact within each other, resulting in a new dislocation network, whose structure tends to stabilize with characteristics independent of the initial microstructure. This new dislocation structure affects strongly the mechanical properties, as described latter. In the case of anisotropic distribution of the loops (due to applied stress or textured materials), permanent strain can be induced (irradiation creep and growth).
- The normal clustering of vacancies would lead to planar defects, i.e., dislocation loops, due to the energy balance between separated and gathered PD's: During the clustering of vacancies as a loop or a cavity, the formation energy of the vacancies is recovered, but either a dislocation line or a free surface is created, requiring their respective formation energies. The balance is in favor of the loop formation in standard cases. In the case of gas present in the alloys (e.g., produced in situ by (n,α) reactions), gas atoms enhance the nucleation of cavities and the clustering of vacancies leads to the formation of 3D defects, i.e., cavities,

■ Figure 8

Observation of fine dislocation loops in neutron irradiated 304 stainless steel (From Pokor et al. 2004a)

inducing swelling. Such cavities can be observed in oxygen doped copper irradiated with Cu^+ ions (► Fig. 9). The swelling induce changes of the geometry of the component, of the specific mass. It has an impact on mechanical strength and induces a reduction in ductility.

2.2.2 Segregations, Phase Transformations, and Amorphization

Solute Transport and Segregations

In addition to the development of the dislocation network or cavities, the migration of PD's occurring under irradiation has direct impacts on the microstructure, either by forced ballistic mixing, or by the coupling of alloying element and PD fluxes. Radiation-induced segregations (RIS), shifts in phase diagram boundaries, occurrence of new phases, or amorphous transformation can be observed (Russell 1984).

Radiation-induced segregations are due to the coupling of PD fluxes with alloying elements or impurities. The diffusion of PD's results in a net flux of PD's to their sinks, where they disappear. If an interaction exists between a vacancy and a solute, the migration of the vacancy drags the solute in its motion, inducing segregation to the sink. This phenomenon can occur at different scales and on different sinks:

- Free surfaces are perfect sinks for any PD and such transport of solute can be observed on thin samples, such as TEM foils. Following HV-TEM (or heavy ion) irradiation, the free

■ Figure 9

Formation of cavities in Cu irradiated at 500°C with 500 keV Cu ions at $3 \times 10^{-3} \text{ dpa} \cdot \text{s}^{-1}$; oxygen content 30, 70, and 110 ppm (From Glowinski and Fiche 1976)

surfaces of the sample can be enriched of one element, to a large range of concentrations, leading to segregation or, in limit cases to surface precipitations.

- Grain boundaries are strong sinks present in the bulk of large samples. The same mechanisms can induce similar effects and large changes in GB composition have been observed. Such radiation-induced segregations are often combined with a sister phenomenon: the *inverse Kirkendall effect*: The jump of a vacancy from one site to the next one requires the migration of an atom counterpart in the opposite direction. In a solution, the fastest species will be the one the most frequently involved. Thus the flux of vacancies from the bulk of the grains to the GB induces an opposite flux of fast diffusing species from the GB to the bulk. The net result is a depletion of this element at the GB. In stainless steels, for a specific temperature range, the two processes induce an increase of Si and Ni by the former process and a decrease of Cr and Fe by the later. The impact is a lower resistance of the GB to corrosion (see ► 3.2.2).
- Inside the grains, and therefore at a finer scale, similar phenomena occurs with the line sinks formed by the dislocations. The disappearance of the PD in the dislocations results in their climb. But, in addition, in the case of coupling the PD and solute migration, segregation at dislocations can be observed. A very specific phenomenon can be induced when the recombination rate of the PD's is solute concentration dependent. The diffusion of the PD's to the areas of high recombination rate drags simultaneously the solute to this location,

increasing its concentration and thus the local recombination rate. Then a patterning of solute distribution, up to precipitation in the extreme cases, can be observed for specific alloys and temperatures under irradiation (Enrique and Bellon 2000).

The phenomena described above are radiation-induced phenomena that have to be distinguished from radiation-enhanced phenomena. In particular higher diffusion coefficients are observed under irradiation and the kinetics of structure changes due to complex temperature histories may be increased by irradiation. For instance, in two phase alloys, in the case of an increase of solute content at high temperatures, the kinetics of solute depletion in the major phase, or of solute precipitation, can be much faster than thermal recovery. This is for instance the case of (Cu-Mn-Ni) precipitates in pressure vessel steels, for which these elements were homogenized in the temper heat treatment, and the operating temperature is too low of thermal reprecipitation. In a similar way, a very fine precipitation of Nb in Zr-Nb alloys is observed after long irradiations in fuel claddings or pressure tubes. These precipitates could only be observed with thermal treatments of much longer durations.

Phase Diagrams Under Irradiation

With respect to phase diagrams, the classical thermodynamics states that the equilibrium of a system is obtained as the best compromise for the minimal stored internal energy and lowest ordering. This is obtained by minimizing the Helmholtz free energy. To fulfill this condition, the system explores the space of possible configurations by individual changes of atom locations. This is possible due to the Maxwell distribution of the atom energies ($\sim eV$). This allows thermally activated statistical changes in atom locations.

Under irradiation new conditions arise: The system is not anymore isolated, as it receives a continuous flow of energy from the irradiating particles, the concentration of PD is clearly out of thermal equilibrium and the large impulse transferred to the hit atoms allows the exploration of configurations of very different energies ($\sim keV$), giving access to metastable configurations that would never have been obtained thermally. Therefore, a strict treatment of a system under irradiation cannot be performed solely using classical thermodynamics. Indeed the ballistic jumps occur in parallel with the thermally activated ones. Based on the consideration of these two different contributions (thermal and ballistic), specific potentials can be proposed, whose minima allow a description of the state of the system under irradiation (Martin and Bellon 1997).

For a rough approximation of the effect of irradiation on a system, the relative values of the thermal and irradiation diffusion coefficients (D_{th}/D_{irr}) allows to define the effective temperature T_{eff} that gives the shift in temperature to be applied to the equilibrium phase diagrams (Martin 1984). Under generic conditions, a system under irradiation behaves as if it would be at the effective temperature:

$$T_{eff} = T \left(1 + \frac{D_{irr}}{D_{th}} \right). \quad (11)$$

This equation allows rationalizing numerous results of irradiation. At high temperatures, and not too high irradiation flux, the thermal diffusion, large compared to the irradiation contribution, drives the system and the irradiation effects are surpassed by the thermal ones: The system behaves as if it would be without irradiation. For low temperatures and high enough irradiation fluxes, the effective temperature increases drastically and, for instance, in two phase

alloys will tend to disordered state or liquid like, i.e., amorphous. This approach can only be used as a “rule of thumb” in order to explain or forecast structures, but in numerous cases the predications are surprisingly accurate.

Extensive reviews of the phase changes under irradiation are available and different behaviors have been reported (Russell 1984).

- At low temperatures, the irradiation can induce the jump of atoms out of the precipitates by ballistic mixing, at a rate larger than the reformation of the precipitate. A homogeneous structure is finally obtained with a ballistic re-resolution of the fine precipitates.
- Phase boundaries are shifted leading to higher solubility under high irradiation fluxes.
- Unexpected phases can be observed, thermally unexpected.
- Lastly amorphous transformation can be observed, usually in compounds.

The amorphous transformation under irradiation has been first observed on U_6Fe precipitates in metallic U matrix, that itself remained crystalline (Bloch 1962). This first observation raised the importance of the disorder build-up as the driving force for the amorphous transformation. The amorphous transformation is easily obtained in compounds and especially in ionic ones (► Sect. 2.3). The basic mechanisms of the amorphous transformations are still only partly understood and deserve further investigation.

A minimal irradiation dose is required for amorphous transformation. The irradiation dose for amorphous transformation decreases at low temperatures, but a limit is observed above which amorphous transformation cannot be observed anymore. This dose is crystallographic structure dependent and large differences can be observed on similar compounds.

It can occur locally at the cascade location and, as the irradiation proceeds, covers all the material, or start at an interface and grow to the bulk of the grain or precipitate. ► Figure 10 gives an example of an amorphous transformation occurring in a $Zr(Fe,Cr)_2$ precipitate embedded in a Zr matrix (Motta et al. 1991). An amorphous layer is observed that grows at constant speed (about $10\text{ nm} \cdot \text{dpa}^{-1}$) and absorbs the crystalline core (Motta and Lemaignan 1992). The consequences of this amorphous transformation on the chemical evolution (release of Fe to the matrix), corrosion behavior and accelerated growth will be described in the Zr section (► 4.2.4).

2.2.3 Computational Techniques for Nuclear Material Science

The development of computer simulations of physical phenomena is increasing in any scientific field. Material sciences do not avoid this tendency, with significant success. In the specific case of nuclear materials, the cost, difficulties, and durations of experiments on irradiated materials increase the interest of such developments. In addition the importance of phenomena occurring at atomic scales (e.g., PD creation and mobilities, intra cascade behavior, or clustering) requires reaching descriptions of the phenomena at these scales. Therefore a large volume of R&D has been devoted to the area of computational materials science focused in nuclear materials and irradiation effects.

Although typical results provided by these techniques are presented throughout this entire chapter, this section intends to describe the basics of the different procedures used in these computations. Starting at the cohesion of atoms, using quantum physics approaches, they scale up to the collective strain behavior of a cluster of grains under applied stresses.

■ Figure 10

Amorphous transformation of a $\text{Zr}(\text{Fe}, \text{Cr})_2$ precipitate induced by neutron irradiation (From Motta et al. 1991)

First Principle (Ab Initio)

The basis of the ab-initio techniques is to solve the Schrödinger's equation on a given number of atoms. The inputs are simply limited to the location of the nuclei, assumed to be immobile, and their charges. The computation of the orbitals leads to the energy of the systems, for this geometry. The changes in energy with changes in geometry allow computing the interatomic potentials. Since any geometry can be assumed, such as different crystallographic phases or the presence of PD (vacancies, interstitials, or different atoms), the most stable phase can be predicted, as well as the formation energies of the different PD. Relaxation of the initial structure is required in order to obtain the real configuration and not to maintain the initial geometry assumed for the structure. Migration energies can be obtained by forcing the migration of one atom from a site to a new one.

Unfortunately the Schrödinger's equation cannot be solved analytically and the exact numerical solutions would require computation resources far behind the capabilities available in a foreseeable future. Therefore approximations are required to simplify the computation:

- Only the valence electrons are taken into account to solve the equation, i.e., the core electrons are treated as producing potentials only, being approximated by their fundamental state.
- The interactions of the electrons between each other are treated using the density functional theory (DFT) (Kohn and Sham 1965). This theory states that the energy of a system of electrons is a functional of the electronic density only. This approximation does not allow the consideration of the contribution of motion correlations and energy exchanges between electrons in the computation of the energy. Improved accuracy is obtained with a fine description

of the electron density (local density approximation – LDA) or by considerations of the gradient in electron density (generalized gradient approximation – GGA).

Various codes are now available for such computations (SIESTA, WASP, etc.). Their use requires a good skill in interpreting the results, especially in the case of transition metals, of magnetic materials or ionic compounds. However they provide data of high values for the knowledge of PD energy and migration. A typical result can be given by the computation of migration energies of various interstitial clusters in Fe that perfectly match the experimental peaks observed during thermal recovery of pure Fe irradiated at low temperature (Fu et al. 2005).

Molecular Dynamics

The molecular dynamic simulation computes the trajectories of a large set of atoms maintained in a given volume, and interacting between each others according to interatomic potentials. The system of equations to be solved is simply the equation of motion for each atom:

$$m_i \frac{\partial^2 r_i}{\partial t^2} = \frac{\partial U(r_{i,j})}{\partial r_i}, \quad i = 1, \dots, N \quad (12)$$

where m_i is the mass of the atom, r_i is its position in space, and $U(r_{i,j})$ is the potential energy function.

The critical point is the description of the interatomic potential $U(r_{i,j})$. Usually empirical pair potentials are used, that describes the interaction as a simple function of the interatomic distance. The parameters describing the potentials are tuned to the bulk properties, such as crystallographic data, elastic constants or other specific properties. In the case of computations aiming at irradiation effect simulations, care should be taken for a good description of the repulsive part of the potential, as it contribute strongly to the behavior of interstitials, and is poorly assessed from bulk properties.

The MD techniques have been used very early for a detailed understanding of the damage evolution in cascades, or displacement energies for low energy impacts. Among the first uses of the MD computations, descriptions of cascades have been undertaken (Gibson et al. 1960). They were initially limited to very low pka energies (a few 100 eV), but have continuously been increased in number of atoms and pka energies. The current computations consider very large sets of atoms (several millions) allowing the study of large cascades induced by the high energy pka's produced by fast neutrons (Bacon et al. 2000). The time evolution of the cascades gives information on the number and states of the surviving PD after thermal recovery of the cascade (Fig. 3). The required computation times restricts analyzing the dynamic behavior for only a few 10^{-12} s. at most. In order to compute the average number of surviving PD during irradiation, a large number of computations have to be performed for various pka energies, impact orientations and temperatures (Fig. 4). These results are used as input for the kinetic evolution of the PD (8) (Osetsyky et al. 2002).

The MD techniques have been used to analyze the dynamic behavior of dislocations, either alone in perfect crystals, to compute the friction stresses versus temperature, mechanisms of Peierls friction during glide, or interaction of a gliding dislocation with a cluster of PD's, such as dislocation loop or stacking fault tetrahedra (Rodney and Martin 2000).

Monte Carlo

The Monte-Carlo method is used when a statistical description of the phenomena is sufficient and there is no specific requirement for a deterministic approach. For the simulation of microstructure evolution, a set of configurations is generated as input and its evolution is analyzed with time, considering the probability of change from one configuration to the next one. A random number generator is used to test if the transition should occur, according to its probability of occurrence. The latter is obtained from the knowledge of the energies of the configurations. For instance, the jumps of an atom from one site to the next vacancy has a probability of occurrence of $\exp(-\Delta H/kT)$ and a frequency of attack given by the Debye frequency. The knowledge of the activation energies for each process of configuration changes is therefore the most critical point.

Among the phenomena studied with the MC methods, significant success have been obtained on the migration of PD, diffusion, clustering of PD and solute atoms (Vincent et al. 2008), including GB segregation (Soisson 2006), swelling, or growth (► Fig. 11).

2.2.4 Impact of Irradiation on Engineering Design Properties

Irradiation effects on the engineering properties of materials have been considered and observed since the early days of the nuclear industry. Changes in geometry (due to swelling or growth), increase in yield strength and reduction in ductility, or irradiation enhanced creep are the most frequent changes reported. The aim of this section is to give a general overview of the mechanisms involved in these processes.

Thermoelastic Properties

Irradiation has not observable impact on the elastic properties, except the special case of swelling, where the presence of cavities or bubbles reduces the stiffness of the materials in proportion to the reduction of solid fraction. For fractional volume of cavities below 15%, the reduction of equivalent Young modulus can be expressed as (Kachanov 1993):

$$E(\pi) = E_0 (1 - k\pi) \quad (13)$$

where π is the porosity and k is a coefficient function of pore sizes and shapes. For $\pi < 0.15$ and spherical cavities, typical values of k would be: $k \sim 2-2.5$. Since the heat flow in a thermal gradient corresponds to the same type of continuous behavior under a constant potential, a similar degradation of the heat conductivity λ_{th} with porosity is expected and is observed (Cunningham and Peddicord 1981). These irradiation effects induce mandatory corrections for design considerations in the case of the high heat flows found in fuel pellets and claddings.

The thermal expansion coefficients are not affected by irradiation, for the same reason as the absence of effect on the modulus of elasticity: both quantities relate to collective interatomic behaviors induced by the curvature of the interatomic potential. Even if the irradiation has induced numerous PD's and changes the microstructure, as described above, their densities are far too small to affect the mean interatomic distances and therefore E or ν .

■ Figure 11
Monte Carlo simulation of the grain boundary segregation in an A-B alloy at different irradiation damage (From Soisson 2006)

Radiation Hardening and Plastic Behavior

The buildup of isolated PD's in the crystals due to the irradiation has limited impact on mechanical strength, and concerns only pure metals at low temperature. Indeed such sort-range obstacles induce only local interactions with the dislocations, and their pinning strength is reduced by thermal activation. However PD hardening has been observed on Al and Cu single crystal irradiated with high energy electrons and tested below 30 K. The irradiation conditions allowed only PD's to be created and no clustering occurred. The increase in yield strength has been found to increase proportionally as the square-root of electron irradiation dose and was attributed to the presence of the interstitials (Ono et al. 1968). This increase in yield strength, only due to high concentration of isolated PD, remains of limited impact for engineering aspects. The major effects in mechanical properties to be considered are restricted to

the effects induced by the changes in microstructure resulting from PD clustering, as described below.

The basic mechanisms of radiation hardening are related to the formation of various types of PD clusters that act as pinning centers for the dislocations. The consequence is an increase in yield strength with irradiation dose.

Following the classical dislocation theory, any crystallographic defect along the glide plane of a dislocation induces a force to the dislocation, reducing its mobility. The increase in shear strength is given by the following relationship:

$$\Delta\tau = \frac{\alpha\mu b}{L} \quad (14)$$

where μ is the shear modulus of the crystal, b is the Burgers vector of the dislocation, and L is the average distance between obstacles along the gliding plane. α is defined as the strength of the obstacle, always lower than 1, but with actual value depending of the obstacle types, as discussed later.

In the case of the typical obstacles obtained after irradiation, i.e., dislocation loops, the separation distance between the obstacles can be deduced from the loop diameter d , and loop density ρ_L : $L = (d\rho_L)^{1/2}$. In the case of a forest of dislocation of density ρ_\perp , this expression reduces to $L = (\rho_\perp)^{1/2}$.

Expressed in engineering terms of yield strength, the irradiation-induced microstructure defects are the sums of all the hardening due to all the types of PD clusters and larger defects.

In the case of small loops and small clusters, the increase in yield strength is thus given by the following relation:

$$\Delta\sigma_Y = M\alpha\mu b(d\rho_L)^{1/2} \quad (15)$$

and in the case of a dislocation forest:

$$\Delta\sigma_Y = M\alpha\mu b(\rho_\perp)^{1/2} \quad (16)$$

In these expressions M is the so-called Taylor factor that links the shear strength on a given glide plane of a single crystal τ , to the yield strength of polycrystals ($M \approx 3$ for alloys of interest (Lucas 1993)).

The strengths of each type of PD clusters differ according mostly to their sizes. For large voids or precipitates, the strength α is close to 1 and there are considered as strong obstacles. Medium strength obstacles correspond to Frank loops in fcc alloys or fine loops in bcc and dispersion phases ($\alpha \approx 0.3-0.4$), while dislocations and very small loops and clusters are considered as weak barriers for the dislocations ($\alpha \approx 0.12-0.22$).

Knowing the distribution of the PD clusters obtained after irradiation the contribution of all these clusters to the reduction of mobility of the dislocations can be computed. An increase in yield strength can be explained, and the results follow, at least qualitatively, the actual behavior of the alloys after irradiation. Typical example of such analysis can be found in [Fig. 12](#).

In addition to the increase in strength, large changes in plastic behavior are often observed. The strain hardening is drastically reduced, the plastic deformation is more localized and the uniform and total ductility are reduced ([Fig. 13](#)). This behavior is explained by the different behavior of the dislocations during plastic strain for unirradiated and irradiated materials. For the former, the interaction of dislocations with obstacles (other dislocations, precipitates, etc.)

■ Figure 12

Computed contribution of the different mechanisms to radiation hardening in austenitic SS irradiated at 673 K (From Lucas 1993)

■ Figure 13

Irradiation hardening of pure Cu under fast neutron irradiation (From Makin 1967)

leads to the multiplication of dislocations, and therefore to a general trend in strain hardening, and large uniform elongation, up to necking. In the case of irradiated materials, however, the interaction of the dislocations with the irradiation-induced obstacles (loops, clusters of PD's, etc.) can lead to the annihilation of these defects. The obstacles responsible of the radiation hardening are therefore removed in the areas of plastic deformation and easy, localized plastic deformation is observed (➤ Fig. 14).

Figure 14

Channeling on Zry4 strained at RT after neutron irradiation in a PWR (From Regnard et al. 2002)

A reduction of the value of the hardening exponent is observed (it can reduce to almost 0) inducing a drastic reduction in uniform ductility. However, such reduction of uniform elongation does not correspond to an embrittlement. The local strain in the areas of localized deformation remains very high and the engineering strain reduction is only due to the drastic reduction of the volume concerned by plastic strain. Strains larger than unity have indeed been reported in the location of intense dislocation glide, such as the channels.

Various mechanisms of interactions between radiation defects and gliding dislocations have been proposed for the elimination of these loops. The general trend is an inclusion of the loops in the gliding dislocations, resulting in a jog, or a drag of the loops along its gliding cylinder, out of its initial position (Lucas 1993). Molecular dynamics computations have confirmed the physical processes and inclusion of interstitial loops in gliding dislocations have been simulated (Rodney and Martin 2000).

On a larger scale, discrete dislocation dynamics allowed simulating the pinning of dislocations by irradiation-induced clusters of defects, subsequent unpinning as defects are absorbed by the dislocations, and cross-slip of the latter as the stress is again increased. Loop free channels were also obtained, the width of which remaining limited by the interaction among opposing dislocation dipole segments and the remaining defect clusters (Diaz de la Rubia et al. 2000).

Embrittlement and Reduction in Ductility

In addition to the reduction of uniform ductility described above, which is due to the intrinsic plastic strain behavior of the irradiated materials, specific mechanisms of embrittlement can be observed in irradiated materials.

One major concern with respect to the irradiation embrittlement relates to the case of bcc materials (e.g., structural steels such as pressure vessel steels or vanadium alloys considered for specific components of fusion reactors). For this crystallographic structure a transition exists in fracture behavior, between brittle at low temperature, governed by cleavage, and ductile fracture with plastic strain and dimple fracture at higher temperatures. The competition of the two

mechanisms occurs at a given temperature, for which cleavage is easier than plastic deformation. Indeed, in bcc crystals, the plastic strain mechanisms are highly thermoactivated and the stress level for plastic strain increases strongly as the temperature is reduced or the strain rate is increased. The cleavage stress however remains practically independent of the temperature. The transition is referred as the ductile–brittle transition temperature (DBTT). It is measured by the simple Charpy test or more advanced techniques such as the fracture toughness curve (K_{IC}) or the Pellini drop weight test (RT_{NDT}).

Any process by which the stress required to activate plastic strain is increased enhances the tendency for easier cleavage compared to ductile plastic deformation. The formation of various types of PD clusters induced by irradiation is one way of increasing the yield strength of the alloys. This results in a shift in the DBTT to higher temperatures, known as radiation embrittlement. In the case of typical pressure vessel steels, for light water reactors, this shift is of the order of 0.6 K for each MPa of increase in yield strength. Shifts as high as 150–250 K can be observed for steels prone to radiation embrittlement. Such major changes in mechanical properties have to be strictly controlled and monitored in industrial reactors, and this phenomenon remains a major source of concern for the designers and operators. Therefore a detailed description of this phenomenon and the procedures used to deal with will be given in [3.1.3](#).

For the fcc crystallographic structures, not concerned by the DBTT, irradiation embrittlement can be observed. The main origins of this complex phenomenon, are due to the production of He by (n, α) reactions, and to the swelling (see [4.1.2](#)), or to channel deformation mechanisms. In austenitic SS, large reductions in ductility are observed, whose values are strongly dependent on irradiation and testing temperatures.

For irradiation and testing near 350–400°C, channel fracture is reported, where the planar transgranular fracture occurs along glide planes. These planes are the former loop free channels described in the previous section (Hamilton et al. 1987).

For alloys irradiated at the maximum swelling rates (420–470°C), the reduction in ductility is directly correlated to the swelling. Above 6% swelling, the uniform and total ductility's are equal, i.e., the ruptures occur without reduction of area. Above 10% swelling, the ductility cannot be measured anymore and the fracture is brittle ([Fig. 15](#)) (Fissolo et al. 1990). Numerous cases of brittle failure have been reported during handling in hot cells, for highly swelled steel (above 15%) (Neustroev and Garner 2009). The loss of ductility is clearly linked to the cavities formed during swelling that act as nucleation centers for the dimples of the locally ductile fracture. Some effects of segregation of Ni on the surface or the cavities, inducing a local formation of brittle martensite has also been observed and could contribute to the irradiation embrittlement (Hamilton et al. 1987).

Irradiation Creep

Under nonhydrostatic stress, at moderate temperature, a specific creep phenomenon is observed under irradiation. The irradiation creep rate can be much larger than for thermal creep and has to be considered in detail for operation design. The mechanism of creep rate increase under irradiation is not directly due to an increase in diffusion or vacancy concentrations, but to the impact of the anisotropic flux of interstitials on dislocations, where they disappear, inducing their climb.

The stress-induced preferred absorption mechanism of irradiation creep has been proposed and improved continuously (Mansur 1979). In the early approaches, the basic mechanism is the change in bias induced on the edge dislocations with respect to their orientation with respect

■ Figure 15

Correlation between loss of ductility and swelling in various 316 Ti SS irradiated in the Phénix SFR (From Fissolo et al. 1990)

to applied tensile or compressive stress. The differences in interaction energies between an interstitial and two edge dislocations, parallel and perpendicular to the applied stress, is proportional to the magnitude of this stress. Considering the balance in the fluxes of interstitials and vacancies to these dislocations, a climb velocity can be computed, which, averaged over all the dislocations, leads to a macroscopic deformation rate:

$$\dot{\epsilon}_{\text{SIPA}} = \alpha c_i D_i Z_{0i} \frac{\sigma}{\mu \Delta \Omega_i} \rho_{\perp} \quad (17)$$

where α is a geometrical factor, c_i is the flux of the interstitials, D_i is proportional to the irradiation flux ϕ , and $\Delta \Omega_i$ is the elastic distortion induced by an interstitial. This expression can be reduced to a simple linear relation between strain rate, applied stress, and irradiation flux:

$$\dot{\epsilon}_{\text{SIPA}} = K_1 \sigma \rho_{\perp} \phi \quad (18)$$

An example of irradiation creep on Zry cladding pressurized capsules irradiated in a test reactor is given in ► Fig. 16. A clear linear dependency of the creep rate with the flux intensity can be observed.

In the case of formation of cavities and swelling, the biases at cavity surfaces and dislocations allow a net difference between interstitial and vacancy fluxes to the dislocations, inducing their climb. They can then be unpinned from the obstacles and glide along the slip plane, under shear component of the stresses (Matthews and Finnis 1988). This “climb and glide” type of irradiation creep has many variants, but all reduce to similar simple expressions:

$$\dot{\epsilon}_{\text{CG}} = K_1 \sigma^2 \rho_{\perp}^{1/2} \phi \quad (19)$$

■ Figure 16

Irradiation creep of CW Zry2 at different neutron fluxes showing the linear dependence of strain rate with flux (118 MPa, 553 K) (From Fidleris 1988)

The stress and dislocation density dependency of the creep rates of these two mechanisms are different. However both are temperature independent and, compared to the thermal creep, have a low sensitivity to the applied stress (exponent between 1 and 2). Therefore irradiation creep is mostly observed at low temperatures and low stresses. At higher temperatures and stresses, the thermal creep out pass the irradiation creep rates.

2.3 Irradiation Damage in Ceramics

2.3.1 General Aspects

The reactor components are mostly made out of metallic alloys. However ceramics are also present and their behavior under irradiation should be analyzed. The different types of materials to be considered is increasing as new reactor designs appear. The most important ceramic to consider is the fuel itself: UO_2 , mixed oxide and other compounds such as carbides or nitrides.

Important from the neutron physics point of view, the absorbents, such as pellets of boron carbide (B_4C), are also ceramics used for the nuclear reaction control. For these specific materials, a strong contribution of the chemical changes (fission products, He production by (n, α) reactions, etc.) impacts the behavior under irradiation.

A renewal of the interest of the ceramics as structural materials for nuclear application is linked to the development of new designs for power reactors operated at high temperatures, to the concern with end of cycle (waste management, storage, and recycling) and to the R&D connected to fusion devices: High-temperature reactors use silicon carbide (SiC) for fuel particle claddings and the fusion devices require insulators or transparent windows, such as alumina or silica, or tritium breeding ceramics, such as Li_4SiO_4 or variants. The selection of the waste immobilization matrixes is still an open matter, but natural or advanced ceramics are strongly considered and their long term stability under self irradiation remains a critical criterion (Weber et al. 1998).

Most of the engineering properties of these materials are described in detail in the relevant chapters of this Handbook of Nuclear Engineering (➤ Chaps. 6, ➤ 7, ➤ 10, ➤ 19, ➤ 21, ➤ 22 and ➤ 24). However common mechanisms control their behavior under irradiation and their generic aspects deserve to be described in details, due to a few specificities compared to metallic alloys.

Indeed sharp differences exist between ceramics and metallic alloys that affect strongly the mechanisms of irradiation damage build-up and recovery:

- The type of interatomic bonding: ceramic materials exhibit either ionic or covalent bonds, or any mixture of them. A consequence is that their valence electrons are strongly localized (they behave as insulators) and, due to the absence of free electrons, any electronic damage is hardly recoverable and may remain as a local charge defect, a configuration nonexistent in alloys. Therefore ionizing irradiations could induce damage, either as local charge defect or by atomic displacement induced by these local charge defects.
- Ceramics are usually compounds of several chemical species, each with each own charge state (cations and anions). Their crystallography may be complex, due to the balance between Coulomb interactions and geometrical packing. Thus, the crystals may be considered as compact (e.g., MgO), open or complex. Indeed, the conservation of stoichiometry may require that possible positions are not occupied (e.g., 1/3 of the octahedral Al sites in Al_2O_3 are empty). Such crystallographic constraints affect the displacement mechanisms or point defect configuration (e.g., very high energy of any antisite) (Pells 1994a). In addition, if the bindings have significant covalent contributions, their directionality has to be taken into account.

2.3.2 Irradiation Damage

Ionization mechanisms, described below, may induce atom displacement in specific materials such as alkali halides or silicon oxide (Hobbs et al. 1994). Radiolytically induced displacements are obtained when an anion is ionized and recombines with another anion to build a molecule such as Cl_2 (in NaCl) or O_2 (in SiO_2), occupying the site of one former anion (H center) or forming a peroxy linkage $-O-O-$ between Si atoms, leaving an empty O site (E' center), charged with one or two electrons. Such recombination's, energetically more favorable than the charge mismatch at lattice location, are very efficient in these materials. They lead to migration of atoms, without transfer of momentum to the nuclei.

■ **Table 2**

Displacement energies for various oxides {computed values, questionable}

Compound	UO ₂	Al ₂ O ₃	ZrSiO ₄	La ₂ Zr ₂ O ₇	MgO	MgAl ₂ O ₄
E_{d-O} (eV)	20	65	38	38 and 68 (2 # sites)	60	60
E_{d-M} (eV)	40–59	20	90(Zr) 92(Si)	150(La) 188(Zr)	53	20–30
References	Weber et al. (1998) and MacEwen et al. (1984)	Weber et al. (1998) and Pells (1994)	Meis (2001)	Chartier et al. (2003)	Weber et al. (1998) and Wilks (1968)	Weber et al. (1998) and Summers et al. (1980)

Due to this process, measurements of the displacement energies in these materials are difficult: Indeed, during electron irradiation, a displacement may be induced by electron–electron interaction, inducing ionization and activating the process described above, while the momentum transfer to the nucleus remains below the displacement energy (Zinkle and Kinoshita 1997).

Displacement energies are often very different for the different ionic species. No general rules can be given and the highest E_d can correspond to any ion. ▶ **Table 2** summarizes typical displacement energies for ionic compounds. The crystallographic structure explains at least qualitatively this behavior: The presence of an empty site in the vicinity of the displaced ion allows easy migration and reduces its displacement energy. For instance, Al ions in Al₂O₃ have an occupancy of 2/3 of the sites and the corresponding displacement energy ($E_{d-Al} = 20$ eV) is low compared to 65 eV for O. However in the fluorite structure of UO₂, the occupancy of the octahedral sites of U is only 1/2, but the O ions are easier to displace: $E_{d-O} = 20$ eV for O in UO₂ and 53 for U (Meis and Chartier 2005).

Due to the largely different displacement energies of the different ions, electron irradiations can be performed at accelerating voltages allowing the displacement of only one given type of ions. Then, large unbalance in point defect production occurs, with Frenkel pairs of only one species, and then the PD production does not respect the stoichiometry. Due to the fact that all these PD have the same charge, they cannot cluster to form loops, unless Coulomb interactions induce migration of the ions of opposite charges in order to maintain electroneutrality. Then dislocation loops of large Burgers vectors, requiring the migration of both the cations and the anions, can be observed, even if the ballistic displacements occurred only for one type of ions (Stathopoulos and Pells 1983).

For high energy transfers and development of cascades, an even formation of PD of the different species is roughly obtained. However, contrarily to metals and alloys, the recombination of a vacancy and an interstitial is not possible for PD's of different natures. The Coulomb energy of such antisite would be much larger than the elastic energy of a PD and the balance is in favor of either molecular interactions, as described above with clusters of atoms in metallic state and O₂ molecules in gaseous phase, or major recombination and Coulomb-induced displacement of ions, with loop formation. However their nucleation is very difficult, due to their large Burgers vectors required to avoid space charges (Pells 1994b).

2.3.3 Changes in Microstructure

Macroscopic behaviors induced by irradiation damage in ceramics are very different according to the crystallography and properties of the different compounds:

- A few compounds appear to be very resistant to any irradiation damage. Spinel (MgAl_2O_4), for instance, appears to be very resistant to irradiation, and only scarce complex dislocations have been observed after high temperatures irradiation at high doses (Hobbs et al. 1994). Swellings reported for spinel, if any, remain within the measurements scatters (Konings et al. 1998).
- No visible, or very limited, damage induced by point defects (dislocation loops or cavities) can be observed in specific compounds, such as UO_2 or B_4C , when irradiated in conditions preventing nuclear reactions (e^- or ion irradiations). Under neutron irradiation, their evolution is due to the production of high quantities of insoluble fission gases (Xe, Kr, or He). In UO_2 , the high mobility of O^{2-} ions allows easy recombination of O Frenkel defects, improving the resistance to irradiation damage. Irradiation of CeO_2 , a similar structure without nuclear reaction revealed only a low density of dislocation loops (Konings et al. 1998). In B_4C , the PD are assumed to be too mobile, even at low temperature, to allow nucleation of clusters (Stoto et al. 1985), and the damage observed is only due to the clustering of He atoms as helium bubbles, that tend to exhibit a disc morphology with the plane of the discs parallel to (111) (Jostsons et al. 1973). Strong lattice strain fields ($\epsilon > 5 \times 10^{-3}$) around the lenticular bubbles evidenced a high internal pressure, above 5 GPa (Stoto et al. 1990). The high density of these lenticular bubbles induces swelling as high as 15% for He atom creation above 10^{28} m^{-3} . The high strain field associated with these pressurized bubbles can be released by thermal annealings above 1,400°C (Simeone et al. 1999), but the swelling, and the microcracking induced remains a matter of concern for long term operation of B_4C control rods in FBR.
- Dislocation loops may be observed on several ceramics, with very different densities according to irradiation conditions. The ability to develop dislocation loops is correlated to the complexity of the crystalline structure: size of the Burgers vector, atomic packing dependency of the stacking fault energy, mobility of the different types of PD's (Hobbs et al. 1994), etc. Loops are easily observed in MgO after any type of irradiation, without any dimensional change. Grain boundaries are assumed to be efficient sinks for PD, impeding swelling (Pells 1994a). For Al_2O_3 , the behavior is slightly more complex. Loops are also observed at low doses, but swelling is observed at high doses (Pells 1994b). The lattice parameter measured in the dislocation sink regime shows an expansion in the c -axis, induced by the clustering of interstitials along the basal planes. Since the usual processing of alumina does not induce any crystallographic texture, this anisotropic behavior does not induce growth. However the anisotropic grain dilation leads to extensive grain boundary separation, due to strain incompatibility between adjacent grains (Hobbs et al. 1994). Above ~ 0.3 dpa, at 950 K, voids nucleate randomly and act as sinks for vacancies. They tend to order as planar arrays of cavities along the c -planes above 10 dpa. Swelling larger than 5% can be observed above 5 dpa (🔍 Fig. 17). As for alloys, swelling is restricted to a narrow temperature range. For zircon (ZrSiO_4), swelling up to 15–20% has been reported in Pu doped materials and in natural minerals, and has been shown to be induced by α self-irradiation when He content is above 1,000 appm (Weber et al. 1998).

■ Figure 17

Macroscopic volume swelling of alumina as a function of neutron fluence (From Pells 1994; updated by Yano et al. 2000)

- Amorphous transformation is frequent in ceramics irradiated at temperatures low enough to avoid thermal recovery. Usually easier amorphization occurs in materials where recovery is difficult. This corresponds to a balance between PD formation and migration energies (Chartier et al. 2003). Analyzed in detail for silica, zircon, and several materials of potential interest for waste immobilization, different mechanisms of amorphous transformation have been identified:
 - Progressive accumulation of PD's and homogeneous transformation
 - Interface controlled reaction, leading to linear dose dependence
 - Cascade overlaps (a process occurring in zircon)
 - In-cascade amorphization (apatite)

Each process has its own dose dependence, and they have been indeed identified. Typical values of the dose for full amorphous transformations are in the range of fractions of dpa to a few dpa (► Fig. 18). In the case of silica (quartz SiO_2), the amorphous transformation leads to vitreous silica, with an increase in specific volume of 14% corresponding exactly to the change in density between the vitreous and crystallized forms of SiO_2 (Weber et al. 1998).

2.3.4 Change in Properties

In additions to the changes in geometry described above, important physical properties are affected by the irradiation. The heat conductivity is usually degraded after irradiation due to a combination of PD's (or nuclear reaction products) acting as diffusing centers for the phonons

■ Figure 18

Temperature dependence of amorphization for several compound irradiated with 1.5 MeV Kr⁺ ions (From Weber et al. 1998)

(e.g., alumina (Pells 1994b)) or to the presence of cavities or bubbles acting as thermal barriers for heat flow (e.g., B₄C (Stoto et al. 1990)). Mechanical property measurements in ceramics are too much procedure dependent in such brittle materials for quantitative reliable measurements. The general trends of hardening and reduction of fracture strength with dose are even questionable (Pells 1994b).

A change in electrical conductivity after irradiation has been observed in pure aluminum oxide (Al₂O₃), after a few 10⁻⁵ – 10⁻³ dpa, depending of dose rate, when the irradiation is performed under a strong electrical field (~10⁵ V · m⁻¹) (Hodgson 1994). The effect called “radiation-induced electrical degradation” (RIED) has been observed in different oxide ceramics as a large and permanent increase in the electrical conductivity of ceramics, only if they have been irradiated under a large electric field applied (Hobbs et al. 1994). RIED is clearly observed in many other ceramics, and appears to be frequent in doped materials. This phenomenon differs from of radiation-induced conductivity (RIC) phenomenon (described in the next section), in that the increase in RIED conductivity persists after the radiation is stopped.

The RIED phenomenon has been studied by many research groups, with extreme variability in the results, therefore it remains controversial. For the single case of alumina, minor changes in purity allowed to report conductivity after irradiation (10⁻³ – 10⁻¹ dpa under an electric field of 1–5 × 10⁵ V · m⁻¹) varying from no measurable changes to an increase in conductivity up to 10⁻⁴ S · m⁻¹ (Zinkle et al. 1997). The discrepancies in the results reflect the lack of understanding of the phenomenon. Differences in chemistry of the materials, irradiation conditions and sample geometries have been claimed to rationalize the different behavior observed. No common agreement can be found with respect to this phenomenon. The absence of any sound understanding of RIED rises questions with respect to the capability to forecast the behavior of such insulators for fusion device applications (Hodgson 2002).

Various explanations for the occurrence of RIED have been proposed, and seem applicable to specific cases, but should be considered with caution, as no common behavior can be considered (Kinoshita and Zinkle 1996). They are linked to the following phenomena:

- Formation of colloids under irradiation, with small metallic precipitates, that would enhance the electronic conductivity
- Electron fast diffusion along various dislocations, whose cores would have high local charge defects
- Large electric fields around PD's, allowing dielectric breakdown
- Space charge induced by PD clustering and internal microcracking providing short circuits on the bulk of the materials

2.4 Irradiation Damage by Photons and Electrons

2.4.1 Radiation-Induced Conductivity in Ceramics

The irradiation of insulators such as ceramics or polymers by electrons or γ photons has a strong impact on the electrical conductivity of these materials. The RIC occurs due to the transfer of valence electrons to the conduction band. Under γ (or e^- , H^+ , etc.) irradiations, the interaction of the irradiation particles with electrons results in the formation of electron-hole pairs. The free electron, whose typical lifetimes are of the order of $10^{-11} - 10^{-9}$ s, can migrate under the applied electrical field and allows charge migration, i.e., a significant conductivity is observed (Hobbs et al. 1994). Due to the short lifetime of the electrons freed by the photons and to their absence without irradiation, the conductivity observed occurs immediately under γ irradiation and stops as soon as the irradiation is stopped.

This electronic conductivity σ_e is a direct function of the γ irradiation intensity R , according to the simple relation:

$$\sigma_e = KR^\delta \quad (20)$$

The value of the exponent δ depends slightly on temperature or irradiation intensity, but remains close to unity, in the range of temperatures of industrial interest (500–900 K). The effect of temperature is due the thermal untrapping of the electrons from shallow and deeper traps. Indeed, local point defects trap electrons by changing their charge state (e.g., in Cr-doped Al_2O_3 : $Cr^{3+} + e^- \Rightarrow Cr^{2+}$).

The RIC coefficient K is in the range of $K \sim 10^{-10 \pm 1} S \cdot s \cdot Gy^{-1} \cdot m^{-1}$, and is reduced in the presence of point defects (i.e., in the case of chemically doped or neutron irradiated materials (Klaffky et al. 1980; White et al. 1998)). Typical values of RIC for pure oxide ceramics are given in  Fig. 19. Recent measurements on other types of oxide ceramics gave the same orders of magnitude for various irradiation modes (Tanaka et al. 2006).

The physics of the RIC explains this simple relationship: The formation of each electron-hole pair requires an energy of the order of twice the gap energy. Since all the insulators have gap energies in the same range, around 10 eV, the rate of electron-hole formation by γ irradiation is similar in different materials for the same energy deposition rate, leading to similar RIC. However the trapping of holes, and to a lesser extend of electrons, by various point defects reduces their mobilities, and therefore the induced electron mobility, for materials of low purity or for pure materials after irradiation. In these cases, a reduction of the K factor by up to two orders of magnitude can be observed (Klaffky et al. 1980).

Figure 19

RIC behavior of pure oxides γ and e^- irradiated at RT (From Hobbs et al. 1994)

2.4.2 Radiolysis: Water and Polymers

The chemical evolution of water under irradiation is of uppermost importance for various engineering aspects of the nuclear equipments (stability, chemical potentials of oxidizing species, corrosion, etc.). The irradiation effects on water solutions and polymers have therefore been studied in detail since the earliest days of the nuclear science (Curie and Debiere 1901). Known as “radiolysis,” the chemical evolution of these covalent compounds is now well understood. Phenomenological descriptions of the chemical evolution were available in the 1980s and detailed description at picosecond and atomic scales are now widely accepted (LaVerne 2000).

The interaction of ionizing particles, such as phonons, electrons or heavy ions, on matter is mostly controlled by the reactions on electrons. Due to the local role of the electrons for the atomic binding of covalent molecules, this type of irradiations induces major damages in these compounds at the molecular scales. Radiolysis consists in series of processes by which covalent molecules are perturbed by ionizing irradiation particles and evolve chemically afterwards, leading to a new chemistry under irradiation.

Radiolysis occurs in numerous environments: water as coolant and/or moderator in power reactors, water in cements and bitumen for wastes, polymers for instrumentation and insulators, chemical solutions in the reprocessing plants, not forgetting the complex molecules of the living organisms (DNA, proteins, etc.). Limiting the analysis to the cases of the nuclear energy cycle, the physical processes and their consequences on industrial aspects will be described.

Mechanisms of Radiolysis

The most frequent interaction of a high energy photon with an electron is the Compton process, by which part of the energy of the photon is transferred to the electron, leading usually to its ejection from its orbital (ionization: $\text{H}_2\text{O}^+ + e^-$). The Compton electron, ejected from the molecule by this reaction, will induce similar reactions in other remote locations along its track. For the rare case of energy transfer too low for ionization, only mechanical excitation of the molecule occurs (H_2O^*). This first step of interaction, controlled by physical processes, is fast ($\sim 10^{-15}$ s) and leaves the water molecule in a very unstable state. The energy deposition in the molecule by this process is in the range of 50–80 eV. In metals, the availability of replacement electrons captured from the conduction band reservoir allows almost instantaneous easy reconfiguration of the core orbitals and the damage ends up as heat. In covalent molecules, the electronic defect induces major evolution of the molecule:

In the case of the water molecule, the first step is the reconfiguration of the constituents in metastable free radicals. It forms the physicochemical step ($\sim 10^{-12}$ s). This occurs very locally, at the location of the primary interaction and ionizations or excitations, and these species are therefore very heterogeneously created, in so-called “spurs” along the track of the incident electrons:

These free radicals, formed in the spurs, react very fast with the surrounding water molecules and their diffusion trend to homogenize the distribution of these species. They are called the “primary species” (e^- , H, OH, H_3O^+ , OH^- , H_2 , H_2O_2) and include two stable molecules (H_2 and H_2O_2). The “solvated electron” is a thermalized electron surrounded by a cluster of water molecules, due to their polar nature. This heterogeneous chemistry step of the radiolysis ends within 10^{-6} s and the result is an homogenous distribution of the primary species in the water (Swiatla-Wojcik and Buxton 1995).

For neutron irradiation, the damage induced by the incident neutron is restricted to momentum transfer to nuclei, mostly on the H atoms of the water molecule. The mechanisms of water molecule destruction are therefore different but the final results are similar, and the primary species formed are the same, but with different fractions (► Table 3).

The quantity of primary species generated is simply a linear function of the energy released in the water by the irradiation. The generation rates of each species (G) give the amount of

■ Table 3
Radiolytic yields in water at room temperature

Effect of temperature on the radiolysis yields for γ irradiation of water (From Elliot et al. 1993)

atomic or molecular species formed for each 100 eV released in the water. Table 3 gives the recommended values of the G 's at room temperature.

The G values depend slightly on pH, but the reported variations remain questionable (Fer-radini and Jay-Gerin 2000). The G 's depend more on temperature (Elliot et al. 1993; Sunaryo et al. 1995a) and on the linear density of energy deposition rate (LET) of the particle inducing radiolysis (LaVerne 2000). These effects are due to the diffusion kinetics within the spurs and to the linear density of spurs along the track of the particle, respectively. Indeed at high temperature, the radicals escape easily from the spurs to the surrounding water and, for high LET, the spurs are closer and a higher fraction of the free radicals reacts within the closely located spurs before diffusing in the surrounding water to form the primary species (LaVerne and Pim-blott 1993). The evolution of G 's with temperature for γ irradiation in pure water is plotted in Fig. 20.

The G values are measured using various techniques, and therefore the G 's may come from different experiments or irradiation conditions. It is important to recall that the formation of the primary species results from the decomposition of water molecules and therefore that species and charges cannot be created ex-nihilo. The relation (22) between G 's expresses the corresponding conservations in terms of equal quantities of oxidizing and reducing species formed by radiolysis:

The primary species, obtained by the processes described above within a few microseconds after the interaction, form the initial condition for homogenous chemical evolution of the

species. Numerous chemical reactions can occur in solution: About 30 chemical reactions are known for the pure water and many others for water solutions of technical or scientific interest. All of them have very large ranges of kinetics.

Among them a few are of high importance for long term radiochemical evolution under steady state irradiation. For pure water, the main reactions leading to a steady state concentration of radiolytic species is known as the Allen chain: The radiolytic molecular H_2 reacts with the very oxidizing radical OH:

and the H radical recombines with hydrogen peroxide:

The summation of the these two reactions corresponds to the recombination of the two molecular species as two water molecules:

For the radicals, specific reactions control their consumption:

However, for a detailed knowledge of the chemical evolution at small time or space scales, or with varying irradiation conditions (e.g., coolant water circulating in- and out-of-core in the primary circuit), all the equations, with they specific kinetic constants have to be considered. In the case of solution containing specific additions, such as Li, B, or metallic ions in the reactor coolant or mineral species for the mineral water surrounding nuclear waste in storage, the contribution of reactions involving the corresponding species could affect strongly the radiolytic yields (G 's) and the final chemistry under irradiation (Cai et al. 2001; Pastina et al. 1999).

As shown in the equations described above, each chemical species could be involved in different reactions, being either the reactant or the product of the reactions. Thus the chemical evolution of the water under irradiation is obtained solving a set of 30–50 coupled differentials equations (Buxton et al. 1995). In order to solve them, various dedicated softwares have been developed, such as MAKSIMA-CHEMIST (Carver et al. 1979), FACSIMILE (Chance et al. 1977) or CHEMSIMUL (Kirkegaard et al. 2007), with similar efficiencies in computing the chemical evolution of water and solutions under irradiation.

Under continuous irradiation, the chemical evolution of water under irradiation reaches a steady state within a minute and is strongly dependent of the initial conditions. For pure water, large amount of oxidizing species are obtained. These conditions correspond to the case of BWR chemistry, for which additives, such as H_2 , cannot be maintained in water. On the other hand, since H_2 can act as catalyzer for recombination of the oxidizing species OH and H_2O_2 (reactions 23–24), small additions of H_2 in water solutions would enhance their recombination.

► *Figure 21* gives two illustrations of the radiolytic evolution of chemistry of water at 250°C under a dose rate of 450 Gy · h⁻¹ (Sunaryo et al. 1995b). The addition of H_2 clearly dims the oxidizing conditions induced by the radiolysis within a minute.

Figure 21

Effect of H₂ addition on the radiolysis of pure water (γ irradiation at 250°C, dose rate 0.125 Gy · s⁻¹) (From Sunaryo et al. 1995b; IAEA 1993)

Technological Impact of Water Radiolysis for the Nuclear industry

For water power reactors, the chemistry of the coolant depends of the type of reactor. In PWR, the single liquid phase of the coolant allows additions, such as boric acid for reactivity control, lithium hydroxide for pH adjustment and H₂ for mitigation of radiolysis. In BWR, the continuous escape of volatile species in the steam inhibits simple control of the chemistry.

In PWR the chemical additives induce several contribution to the radiolysis to be considered, induced by photons, fast neutrons and alpha from boron. Typical values of their contributions are given in Table 4: The H₂ dissolved enhances the recombination of oxidizing species, and, in addition, allows the recombination of initial O₂ dissolved in water. Therefore the primary coolant in PWR exhibits a rather strong reducing character. Recommended concentrations of H₂ in PWR primary coolant are in the range of 2.2–4.5 ppm (25–50 cm³ · STP · kg⁻¹).

In BWR, the energy deposition induced by the (n, α) reactions does not exist due to the absence of boron in the coolant. In addition, due to the absence of H_2 dissolved in the coolant, the radiolysis enhances the oxidizing character of the water (Yeh et al. 1995), leading to frequent problems of stress corrosion cracking of stainless steel pipings in different locations of the primary circuit (● Sect. 3.2), or to faster corrosion of Zr alloys (Burns and Moore 1976). The mitigation procedure is to introduce continuously H_2 in the feed water. This delicate procedure, known as “Hydrogen Water Chemistry (HWC)” has been implemented with success in various BWR plants (Burns and Moore 1976; Wada et al. 1999).

For wastes stored after the irradiation, the β, γ decay of the fission products of the fuel releases enough energy to induce radiolysis in its surrounding environment. Although this radiolysis occurs with kinetics and temperatures very different from reactor cores, it still induces sufficient consequences to be considered for design and during operations:

- Radiolysis impacts the technical aspects of transport of irradiated fuel in wet casks, due to the build-up of internal pressure of hydrogen (Bonin et al. 2000; Huang 1996).
- The reprocessing of spent nuclear fuel involves the use of extractants and diluents (solvent) for separation of the reusable actinides from the unwanted fission products. The most widely used processes employ tributyl phosphate (TBP) diluted with normal-paraffin hydrocarbon. Long-term irradiation of the solvent induces very complex radiolytic chemical reactions, reducing extraction efficiency. A review of the mechanisms of the degradations of the solvent system and the consequences for operations of the reprocessing plants can be found in (Tahraoui and Morris 1995).
- For long-term disposal (concrete in geological pits), the radiolytic phenomena are complicated by the interactions of the radiolytic primary species with the ions and complexes dissolved from the components of the cements in the pores (Bouniol and Bjergbakke 2008).

Radiolysis in Polymers

The polymers such as alkanes, or other chains of higher complexities such as PMMA, epoxy, etc., up to DNA, are also sensitive to γ irradiation and suffer radiolysis. However, the reactions that could occur following the interaction with a photon are much more complex than for the simple water molecule.

For instance, in alkanes, among the possibilities, interatomic bond failure leads to frequent C–H scissions, but also to fewer C–C ruptures. Free H^\bullet atoms can react with each other, forming H_2 molecules or many other volatile hydrocarbons or simple molecules, such as CH_4 , CO , CO_2 , depending on the species building the chain of the polymer, etc. The gas release corresponds to an internal formation of molecular gases within the polymer. The thermal reptation of the chains may allow the pending $R-C^\bullet-R$ radicals to encounter and to rebuilt links, leading to cross-links and formation of reticulated polymers of much higher strength (Ungar 1981). This phenomenon is in particular activated for the production of heat shrinkable polymers. A typical dose would be for polyethylene films an electron irradiation of about 200 kGy (Drobny 2003). The G values for the reactions described above are given in ► Table 5 for polyethylene.

The release of H_2 and other gaseous species due to radiolysis are also responsible for swelling of the bitumen used in the early days for waste conditioning, leading to the formation of foams (Phillips et al. 1984). Additions of cobalt sulphide (CoS) can be used to fix the hydrogen released and thus to avoid spills out of the storage tanks (Pichon et al. 2007).

Polymers having less localized electrons, such as chains of aromatic monomers, have electrons loosely localized and therefore available for recovery of the bonds after the excitation.

■ Table 5

Radiolysis yield for the different primary processes observed in polyethylene under γ irradiation

Process	H ₂ release	Cross link	Chain break
G values	4.1	2	1.8

They are therefore less prone to radiation damage (Tavlet et al. 1998). Based on this approach, specific polymers have been developed for use in satellites, where the long duration irradiations with high energy cosmic ions induce significant irradiation damage to the polymers selected for the structural parts (Dole 1991).

3 Impact of Irradiation Damage on Structural Material Behavior

3.1 Ferritic Steels (LWR Pressure Vessel)

3.1.1 General Aspects

The reactor pressure vessel (RPV) steels used in LWR are variants of standard Mn, Mo, Ni structural steels used in chemical industry for intermediate temperatures, with good strength and creep resistance up to 400°C: ASTM A 508 Cl. 3 in the USA, similar alloys in other major nuclear countries (16 MND5 in France, 20 MnMoNi in FRG, or 15Kh2NMFA in Russia). The pressure vessel fabrication includes forging, welding, and the standard quench and temper heat treatment of ferritic steels. The microstructure is a tempered bainite that satisfies the code requirement of yield strength above 300 MPa and UTS above 500 MPa at 350°C.

Due to the size and load supported by the pressure vessel, a critical property of the steel used is its capability to resist to crack propagation and brittle fracture. Therefore strict requirements are mandatory with respect to the fracture toughness and the DBTT. Indeed in ferritic steels, a transition exist between the low temperature behavior, where cleavage is easy and fracture occurs with low energy dissipation and the high temperature, where easy plastic deformation accommodates the stress singularity at the crack tips, increasing the fracture toughness.

The later point is a matter of concern for the pressure vessels. Indeed they surround the cores and are therefore slightly irradiated. The irradiation damage is in the range of 0.1 dpa at the end of the design life. Due to irradiation hardening obtained at this dose, the DBTT is shifted to higher temperatures. This phenomenon is called the irradiation embrittlement, and requires a good knowledge of the mechanisms, of the kinetics of DBTT shift and a rigorous surveillance program of the actual behavior of the steel (Odette 2001).

3.1.2 Microstructural Aspects

The hardening of ferritic steels, and the shift in DBTT, has been studied since the beginning of LWR development (Steele 1966; Hunter and Williams 1971). The irradiation effect is increasing with irradiation dose, with a strong tendency for saturation, usually expressed by a fluence dependency to the 1/2 power roughly. It is strongly influenced by irradiation temperature: the lower the irradiation temperature, the higher the embrittlement.

It has been early recognized that the main mechanism inducing irradiation hardening and embrittlement was connected to the Cu content (Ficher and Buswell 1987). Although the content of Cu in the pressure vessel steels is normally low, few early vessel steels have rather high content ($(\text{Cu}) > 0.3\%$). The solubility of Cu in bcc α -Fe is very small: Substitutional solid solution of copper in the iron matrix is saturated at about 0.3% at $\sim 600^\circ\text{C}$, but decreases strongly at lower temperatures, down to below 0.01% at $\sim 290^\circ\text{C}$. Thus, during the final tempering heat treatment all the Cu present in the alloy forms a solid solution within the α matrix, but this later is supersaturated at operating temperatures. During the decades of operation, the mobility of atoms, enhanced by the high concentration of vacancies occurring under irradiation, allows the migration of Cu atoms to form clusters (Odette 1985). For high Cu content, irradiation-enhanced precipitation of Cu occurs, while, at low Cu content, an irradiation-induced segregation of Cu atoms on PD clusters is observed. Such clusters or precipitates can clearly be imaged using atomic microprobe (Auger et al. 1985). The cascades are considered to act a nucleation sites for the formation of these clusters (Radiguet et al. 2007). Although they do not precipitate as a second phase (the Cu clusters remain with a bcc structure (Radiguet et al. 2007)), they act as barriers for the gliding dislocations (Auger et al. 2000). Significant increase in yield strength is thus obtained, which has for consequence a correlated increase in DBTT.

The actual pressure vessel steels are more complex steels than simple model binary Fe-Cu alloys used to understand the physical mechanisms of irradiation effects. The complex chemistry of the reactor steels leads to various types of clusters, containing other species such as Mn, Ni, Si, P (Odette 2001; Auger et al. 2000; Miller and Russell 2007). These clusters have average diameters in the range of 1.5–3 nm and densities of $N = 10^{23-24} \text{ m}^{-3}$, depending of irradiation time and temperatures (Odette and Lucas 1998). Phosphorus is also found to segregate at dislocations and grain boundaries, as it can be observed in  Fig. 22.

 Figure 22

Complex cluster in a pressure vessel steel after irradiation (From Auger et al. 2000)

These clusters interact with the dislocations and, reducing their mobility, increase the yield strength of the alloys. At engineering temperatures, the stress required on a dislocation to glide along its slip plane is controlled by the distance between pinning centers. For obstacles of spherical shapes, the yield strength is given by the Orowan expression:

$$\sigma_y = \beta \mu b (Nd)^{1/2} \quad (29)$$

where β is an efficiency parameter of the obstacle (~ 0.1 – 0.2 for the clusters), μ is the shear modulus, b is the Burgers vector of the dislocation, N is the volume density of clusters, and d is their mean diameters. The observed cluster sizes and densities, induce hardening in the range of 200–300 MPa.

Since the solubility and the mobility of the atoms clustered increase with temperature, annealing heat treatments can be performed on pressure vessels after that an irradiation has induced embrittlement not acceptable for further safe operation. These heat treatments induce a mixture of resolution of Cu and Cu cluster coarsening, reducing the density of dislocation pinning defects and therefore the irradiation hardening (Odette 2001).

Early US PWR and Russian VVER are reactors for which such heat treatments have been studied and, for a few of them, realized. Various studies have shown that the recovery can reach 80% following 160 h at 460°C, for steels in which the major process of embrittlement is due to Cu cluster formation (Odette 2001; Miller et al. 2006). The effect of this recovery treatment is to activate the coarsening of the Cu clusters, reducing their density and strengthening effect. In the case of Ni richer alloys, such as the one selected for the VVER 1000, the Ni-Mn-Cu clusters appear to be more stable and require a higher temperature for full recovery of the toughness (Kryukov et al. 1998).

3.1.3 Pressure Vessel Steel Embrittlement

The effect of irradiation hardening is an increase in the DBTT. This temperature is measured using the standard Charpy test, easy to perform since it uses samples of small size ($10 \times 10 \times 55$ mm). The energy absorbed during the impact of such a notched sample is plotted versus sample temperature. The transition occurs in pressure vessel steels over a temperature range of (50–100°C). At low temperature, the fracture occurs without significant plastic strain, by separation of {100} crystallographic planes. The fracture surface exhibits cleavage planes on each grains and no deformation of the sample. At higher temperature, plastic strain occurred at a strain rate compatible with loading rate, and the fracture surface consists of ductile dimples. The dimples are highly deformed and the high impact energy corresponds to the energy dissipated in plastic strain.

The competition between the two behaviors controls the DBTT: The stress level to induce cleavage is weakly temperature dependent, while the plastic strain is thermally activated and easier at higher temperatures. At a given temperature, the tendency for cleavage or plastic strain is therefore affected by any mechanisms of strengthening. The clusters described above interact with dislocations and increase the strength, inducing irradiation embrittlement. The balance between cleavage cracking and plastic deformation is such that, for typical RPV steels, an increase in yield strength of 1 MPa increases the DBTT by 0.5–0.7°C. On a physical point of view, the effect of irradiation is a strengthening, but for practical purposes, the DBTT shift is

■ **Figure 23**

Shift in Charpy curve of a PWR pressure vessel steel with irradiation dose

considered. However, the increase in yield strength is the critical aim of the physical modeling of the irradiation embrittlement.

The transition temperature is often chosen as the temperature for a given absorbed energy, corresponding roughly to half of the upper shelf energy, whose exact value may vary according to specific engineering standards (e.g., 41 J, 68 J, or $70 \text{ J} \cdot \text{cm}^{-2}$). Due to the expected shift in DBTT, the initial DBTT has to occur at low temperatures. This is usually obtained by the request of minimal Charpy values at low temperatures (ASME code: 41 J at 4.4°C ; RCCM code: 56 J at 0°C , etc.).

Following fast neutron irradiation, a shift is observed. For RPV steels prone to irradiation embrittlement, it has been observed to be as high as 200°C for standard irradiation histories. In [▶ Fig. 23](#), the main physical phenomena of irradiation embrittlement can be observed: The Charpy transition curve moves to higher temperatures, the super shelf energy is lowered and the shift in DBTT is not linear with irradiation dose, but seems to saturate. Indeed, the two highest irradiation doses induce only marginal embrittlement, compared to the lowest irradiation, while the ratio of the different doses are 1/2/7. Saturation of the RPV steel embrittlement is presented in more detail in [▶ Fig. 24](#).

Very large international irradiation programs have been undertaken along the development of the nuclear power industry. PWR, and to a lesser extent BWR, pressure vessels are concerned by the irradiation embrittlement. Among the main parameters controlling the irradiation embrittlement, chemistry and dose were easily identified.

- As described previously, the Cu atoms cluster under irradiation, as well as other minor elements in solid solution. Therefore the chemical composition is considered for embrittlement forecast. The alloying elements considered in the embrittlement formulae, are Cu and Ni. The interaction of Ni in Cu clusters, leads to a synergistic effect: the embrittlement contribution

■ Figure 24

Saturation of the DBTT shift with irradiation dose

of Ni or Cu is only increased for high Cu or Ni content, respectively. For the impurities, P is known to play a detrimental role.

- The sub-linear dose effect of the irradiation embrittlement is due to many factors. One is linked to the completeness of the clustering of Cu in solid solution, leading to depletion of Cu from the matrix. The coarsening phenomenon that has to follow is too slow to induce significant recovery of the mechanical properties. For design and operation, this saturation is usually expressed by a dependency of the DBTT shift with irradiation dose such as ΔT^n , with $n \sim 0.3-0.5$.
- Various equations are available for the change in transition temperature that include irradiation temperature, neutron flux and fluence, steel composition and nature (plate, forgings, welds, etc.). Safety regulations vary with countries, but the differences are minor and international comparisons of the different rules showed a very high consistency of the different laws (Steele 1993). As a typical example, the “high irradiation formula” used by EDF is the following for the PWRs designed by AREVA:

$$\Delta RT_{\text{NDT}} = 8 + \{24 + 1537 (P-0.008) + 238 (Cu-0.08) + 191Ni^2Cu\} (F/10^{19})^{0.35} \quad (30)$$

It is valid only for irradiation temperatures between 275°C and 300°C , fluences between 10^{18} and $10^{19} \text{ n}\cdot\text{cm}^{-2}$ and for P and Cu contents above 0.008% and 0.08% respectively (Rupa et al. 2006). The actual shifts in DBTT are found to remain below the values expected from these expressions.

Fracture Mechanics

In order to be able to design the pressure vessel, or to analyze its ability to support high stresses in the presence of a defect, the knowledge of the irradiation embrittlement, as measured by the Charpy test is not sufficient. Fracture mechanics concepts have to be used. They have been developed with the aim of describing the stress singularity in the vicinity of a crack tip, and to characterize the capability of the material to support this singularity. At the tip of any crack under external loadings, a stress singularity exists: At a point P in the vicinity of the crack tip, the stress state can be expressed by the following equation:

$$\sigma_{loc}(r, \theta) = \frac{K_I}{\sqrt{2\pi r}} \cdot f(\theta) \quad \left| \begin{array}{c} \square P \\ \text{---} r \text{---} \\ \text{---} \theta \text{---} \\ \text{---} a \text{---} \end{array} \right. \quad (31a)$$

$$K_I = \sigma \sqrt{\pi a} \quad (31b)$$

where K_I is the so-called the stress intensity factor. The local stress distribution $\sigma_{loc}(r, \theta)$ is fully described by the knowledge of K_I . This quantity includes the geometry of the crack of size a , and the macroscopic stress state that would have existed without the crack (σ). In the case of single ribbon crack of width $2a$ in an infinite medium, the value of the stress intensity factor is given in (31b). For actual cases of more complex geometries, either at the surface or internal cracks, several atlases or design rules exist for accurate computations of the value of K_I . For a rough estimate of the stress intensity factor, (31b) can be used for any crack geometry.

For a given material, the presence of a crack does not mean that failure will be obtained, whatever the stress level. Actually, any material can sustain the stress singularity induced by a crack, as long as the corresponding K_I remains below a critical value. The fracture toughness of a material, K_{IC} , is the critical value of K_I for which unstable crack propagation occurs. For brittle ceramics or glasses, the value of K_{IC} is in the range of 0.5–2 MPa · m^{1/2}. For metallic alloys, thanks to the plastic strain at the crack tip that accommodates the stress singularity, much higher values of K_{IC} are observed, in the range of up to 50–200 MPa · m^{1/2}. In the case of structural steels, including RPV steels, the values of K_{IC} follow the trend observed for Charpy, and a transition is observed: low values at low temperatures and transition up to a tough plateau.

For all the RPV steels, the temperature dependence of the K_{IC} is described by the same equation, normalized to a reference temperature, whose value is connected to the Charpy DBTT. This “Master Curve” is described by (32). Its determination recognizes the physical nature of the scatter in the results (see  Fig. 25) (ASTM Standards E-1921-97 1998):

$$K_{IC}(T) = 36.5 + 3.1 \exp[0.036(T - RT_{NDT} + 55.5)] \text{ MPa} \cdot \text{m}^{1/2} \quad (32)$$

$$K_{IC \text{ max}} = 220 \text{ MPa} \cdot \text{m}^{1/2}$$

Before irradiation the reference temperature of nil ductility transition RT_{NDT} , is measured on extra-lengths of the pressure vessel forgings, out of which coupons are machined. The value of RT_{NDT} is determined by the combination of two tests, the Pellini crack arrest temperature test and the Charpy curves:

- The crack arrest drop weight test consists of impacting a large sample of steel (16 mm thick) with heavy hammer. At the external surface of the sample, a crack starter is obtained by machining a notch on a weld embrittled by P doping. Tests at various temperatures, in 5°C

■ Figure 25

Experimental international data base for actual toughness of RPV steels, as a function of temperature, scaled to RT_{NDT} (From Rupa et al. 2006)

steps, allow to determine the nil ductility temperature (NDT) above which a crack cannot propagate in the material.

- It is also required to determine the temperature TCV for which three Charpy tests have an impact energy above $86 \text{ J} \cdot \text{cm}^{-2}$ and a lateral expansion of the sample larger than 0.9 mm.
- Then the RT_{NDT} is given by $RT_{NDT} = \min \{NDT, (TCV-33)\}$. Its knowledge gives the temperature evolution of the K_{IC} of the steel, as plotted in ► Fig. 25.

The temperature shift induced by irradiation on RT_{NDT} is assessed using equations such as (30). During the operation life of the power plant, the irradiation embrittlement is also controlled on coupons, machined out of extra-lengths of the RPV steel and irradiated inside the pressure vessel itself. The irradiation is performed on special holding stages, closer to the core than the pressure vessel, allowing an anticipation factor of about 3. This surveillance program allows comparing the actual shift in DBTT with the anticipated one. This shift in DBTT measured with the Charpy specimens is applied to the RT_{NDT} and thus the value of K_{IC} for the irradiated materials is known at any temperature.

For safety aspects, an important point is to obtain a detailed knowledge of the exact irradiation dose received by the vessel at any location, and to forecast its behavior in the design life. In addition to advanced neutron physics computations, flux integrators are positioned in the boxes containing the surveillance program steel samples. These neutron detectors are used to benchmark the neutron physics computations and give confidence in the irradiation doses forecasted in any location of the pressure vessels.

Once the K_{IC} is known at any location and time of the RPV, nondestructive examination (NDE) techniques, usually ultrasonic testing, are used to detect any defect in the pressure vessel, to characterize their exact shapes and to monitor their potential evolution of geometry with

time. The mechanical (and thermomechanical) loadings are used to deduce the values of K_I at all the crack tips, for any configuration (normal operations, accidental conditions, etc.). The values of K_I should always remain below the K_{IC} at the dose and temperature studied. This requirement impacts, for instance, the pressure/temperature route for the starting procedures of the plant (Ahlf et al. 1989).

Master Curve and New Issues

As described above the DBTT is controlled by the balance between cleavage and plastic flow at a given temperature. The mechanism of cleavage crack initiation has an intrinsic stochastic behavior. Indeed, whatever the physical process of crack initiation (cracking of MnS inclusions or carbides, pile-up of dislocations at grain boundaries, etc.), the exact conditions that trigger the initial cleavage crack formation are changing with the location of concern (exact position and geometry of the inclusions, grain size, relative orientations of the grains, etc.). Therefore, the transition temperature data obtained from Charpy or K_{IC} samples exhibit a large scatter (e.g., [Figs. 23](#) and [25](#)), that is intrinsic to the transition and not due to any experimental inaccuracy.

In order to take into account this physical scatter, statistical approaches have been developed, that include the distribution of the data in their analysis. The two major models assume that the sample will fail when initiation has occurred:

- Considering that the probability of cracking of inclusions or carbides is proportional to the plastic local strain in the plastic zone ahead of the crack tip (whose size is K_I dependent), Wallin obtained a fracture probability given by

$$P_f = 1 - \exp \left[-\frac{B}{B_0} \left\{ \frac{K_I - K_{\min}}{K_I - K_{\min}} \right\}^4 \right] \quad (33)$$

where B_0 and K_0 are normalization constants and K_{\min} is the lowest K value for cleavage, typically $20 \text{ MPa} \cdot \text{m}^{1/2}$ (Wallin 1993).

- Using a weakest link behavior for cleavage fracture, described with a Weibull distribution function, Beremin and Pineau obtained a failure probability of similar form:

$$P_f = 1 - \exp - \frac{K_{IC}^4 B \sigma_Y^{m-4} C_m}{V_u \sigma_u^m} \quad (34)$$

where m is the Weibull modulus, V_u is an arbitrary unit volume, σ_u is the average cleavage strength of that unit volume, σ_Y is the yield strength, and B is the thickness of the specimen (Pineau 2006).

It is interesting to remark that both models lead to very similar failure probabilities, while deduced from different analysis. Combined with the exponential shape of the K_{IC} vs. temperature curves for RPV steels (32), a general equation expressing the probability of failure (X) at given K_I and temperature can be obtained:

$$K_I(X) = 20 + \left[\ln \frac{1}{1-X} \right]^{1/4} \{11 + 77 \exp [0.019 (T - T_0)]\} \quad (35)$$

where T_0 is the temperature at which $K_I(0.5) = 100 \text{ MPa} \cdot \text{m}^{1/2}$.

■ Figure 26

K_{IC} data with Master Curves (5%, median and 95% bounds) and comparison with the standard K_{IC} analysis (From Yoon et al. 2001)

This equation is the basis of the “Master Curve” analysis. A standard procedure has been developed and is under extensive use for statistical analysis of the RPV steel toughness and radiation embrittlement (ASTM Standards 1998). Since the shape of the $K_{IC}(T)$ curve is not affected by the irradiation, but only translated to higher temperatures, the behavior of irradiated steel can be measured directly on small CT specimens provided by the surveillance programs, by scaling the above equation with experimental data (► Fig. 26). Details of this procedure to implement the Master Curve testing for the RPV steels has been provided by the IAEA (2005).

The value of K_{IC} is affected by all the thermomechanical history of the material studied. Among the different impacts, the plastic deformation and strain hardening induces major changes in mechanical properties. In the specific conditions of the presence of a crack, tensile stresses applied induce a plastic zone ahead of the crack tip that increases locally the strength. Therefore, higher toughness could be expected. An important question is therefore related to the effect of prestressing, at temperatures high enough to avoid brittle failure, on further loading at lower temperature. This phenomenon, known as warm prestress (WPS) corresponds to the case where high K_I is applied at high temperature T_1 , where K_{IC} is high $K_I(T_1) < K_{IC}(T_1)$, before testing at lower temperature T_2 . If the WPS is high enough, large improvement in K_{IC} are commonly observed and the new $K_{IC}(T_2)$ value is above the value of the loading at T_1 (Wallin 2003). Inclusion of this beneficial behavior that improves the pressure vessel integrity would require to record all the pressure-temperature histories of the reactors and to consider K_{IC} as a function of the full history of the component.

Similarly, the behavior of a crack initiated in a cold part and propagating in a warmer area could lead to crack arrest due to the large increase in K_{IC} with temperature. Conditions such as pressurized thermal shocks (PTS) are leading to possible crack arrest and should be analyzed accordingly (Bass et al. 2005).

3.2 Austenitic Stainless Steels (LWR Internals)

The use of austenitic SS in water-cooled nuclear reactor corresponds to their excellent resistance to corrosion in hot water and steam and for their good mechanical properties at the operating temperatures. The uniform corrosion behavior of these steels is excellent and no problems have been identified with that respect. However, for components very close to the core subject to high irradiation doses, such as the baffle, large changes have been observed on the dislocation microstructure, increasing the yield strength and reducing the uniform ductility. In addition, radiation-induced changes in chemistry are observed at the grain boundaries. These segregations are responsible for enhancing intergranular stress corrosion cracking. The aim of this section is to provide information on the mechanisms and consequences of these phenomena.

3.2.1 Changes in Microstructure and Mechanical Properties

In light water reactors, large components are located close to the core. Usually made out of austenitic stainless steels (SA 304 or CW 316), they are exposed to high neutron fluxes. For instance the high exposure points in the baffle of a PWR receive up to $2 \text{ dpa} \cdot \text{y}^{-1}$. Since these components are designed for the life of the reactor, doses larger than 80 dpa could be expected.

TEM examination of samples machined out of components from actual reactors, as well as tests samples irradiated in various MTR in the temperature range of 300–360°C, allowed a good description of the changes induced by the irradiation: After neutron irradiation, the initial dislocation network present in CW materials is completely removed. The mechanisms of this annealing of the initial dislocation structure appear to be due to dislocation climb by trapping of interstitials and mutual annihilation. A new dislocation microstructure is observed, consisting of small dislocation loops of Frank type (interstitial faulted loops on $\{111\}$ planes with $1/3 \langle 111 \rangle$ Burgers vectors). Their size is small, increasing slowly with dose, to saturate around 5–10 nm for 5–10 dpa, depending on the exact irradiation conditions. Their density is high: $1\text{--}5 \times 10^{22} \text{ m}^{-3}$. Very rare cavities were only observed in the most irradiated and hottest locations (Pokor et al. 2004a).

This high density of Frank loops induced a large increase in mechanical properties. For the two materials used, the yield strength and the UTS are increased, and the total ductility is reduced. The uniform ductility may even vanish (► Fig. 27). Above 10–20 dpa, saturation occurs: the yield strength and UTS become close to 900–1,000 MPa and no further changes are observed up to 100 dpa (Pokor et al. 2004b). The increase in yield strength can be described and modeled to be due to the interactions of the gliding dislocations with the Frank loops,

■ Figure 27

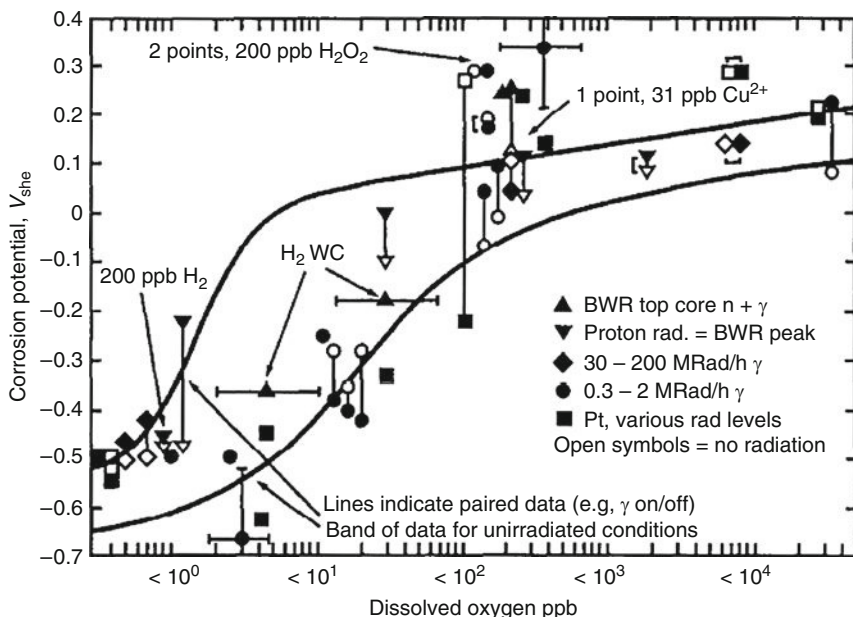

Engineering stress–strain curves for the SA 304L and CW 316 steels irradiated in BOR-60 reactor at 320°C and 20 dpa (From Pokor et al. 2004b)

while the reduction in uniform ductility corresponds to the clearing of the loops by the gliding dislocations and to the development of channels.

Irradiation-Assisted Stress Corrosion Cracking

Intergranular irradiation-assisted stress corrosion cracking (IASCC) has been observed since the use of austenitic SS stressed under irradiation in LWR (Scott 1994): 304 SS fuel cladding stressed by fuel swelling, bolts and springs under service loadings, etc. The conditions for such cracking are a minimum irradiation dose ($\phi > 5 \times 10^{24} \text{ n} \cdot \text{m}^{-2}$, $E > 1 \text{ MeV}$ or 0.7 dpa in BWR and slightly higher in PWR $\phi > 1\text{--}2 \times 10^{25} \text{ n} \cdot \text{m}^{-2}$), a corrosive water environment (e.g., high O_2 content induced by radiolysis in BWR, leading to a high electrical conductivity of the water $\sigma_{\text{elec}} > 2\text{--}5 \times 10^{-5} \text{ S} \cdot \text{m}^{-1}$), and usually a stressed material (service load or material swelling). Tensile tests of materials exhibiting IASCC, performed in hot cells after irradiation showed ductile failure with dimples fractures, confirming the absence of mechanical embrittlement, but a tendency to intergranular cracking in weakly corrosive environments.

The effect of irradiation on water chemistry has been described in 2.4.2. In the case of BWR environments, the high oxygen content cannot be reduced by the recombination enhanced by hydrogen additions. The corrosion potential is therefore increased to levels of easy corrosion. Moreover, the irradiation itself increases the corrosion potential by about 200 mV (Fig. 28). Many cases of enhanced corrosion of various pipes, welds, or bolts located outside irradiated areas are due to these changes in water chemistry. Grain boundaries sensitized to localized corrosion, due to carbide precipitation, and reduced chromium content in the matrix, at the grain boundaries during heat treatments were found to develop intergranular cracking when exposed to such conditions.

■ Figure 28

Effect of irradiation on the corrosion potential of 304 SS versus oxygen content (From Andersen 1996)

3.2.2 Radiation-Induced Segregation

Under neutron irradiation, the PD's surviving from the cascades migrate and disappear on various sinks. Among them grain boundaries are important ones, as phenomena such as coupled diffusion fluxes induce transport of specific species to and from the grain boundaries (GB).

The RIS phenomenon has been observed in austenitic SS under specific conditions. It occurs in ranges of temperatures and irradiation fluxes such that thermal emission of vacancies is too low to avoid thermal recovery of any segregation and re-homogenization, and high enough to activate their mobility and to avoid recombination of Frenkel pairs in the bulk of the grains. Unfortunately these conditions are best fulfilled in typical LWR environments and very narrow band of high segregations at GB's are observed.

During their migration from the bulk of the grains to the GB's, interstitials can interact with alloying elements, inducing a net flux of such species to the GB's. This is specifically the case for the atoms considered to be present in solution as interstitials, such as Si or P, and to a lesser extent S. These elements are dragged by the interstitials as they move to the GB's. Enrichments by factors of 3 and 10 for Si and P respectively have been observed. The impact of these enrichments on corrosion resistance seems however to be limited (Andersen 1996). For sulfur, impurity levels maintained below 20 ppm appear beneficial for the resistance to IASCC (Chung and Shack 2006).

Figure 29

Typical composition profile across the grain boundary of a 304 SS after irradiation (From Bruemmer et al. 1999)

On the other hand, the migration of vacancies requires a flux of atoms in the opposite direction. The backwards migration atoms are those exhibiting the fastest diffusion rates. This mechanism, known as “inverse Kirkendall effect” induces a depletion from the GB’s of such species. The local Cr and Fe concentrations are decreased, while Ni is increased, due to the conservation of lattice sites (➤ Fig. 29). Since the chromium content is the major parameter of corrosion resistance in SS, the local decrease induced, below the level required for good corrosion resistance, allow GB corrosion and crack propagation along the GB’s.

The reduction of Cr content at the GB’s is clearly not due to the formation of carbides, but is an intrinsic behavior under irradiation. Mitigation of this phenomenon using stabilized SS by additions of Ti or Nb (SS 321 or 347) would be irrelevant. However, additions of large substitutional atoms, such as Zr or Hf, are promising solutions by reduction of the vacancy mobility (Fournier et al. 2003).

Other radiation-induced phenomena are also considered as possibly affecting the intergranular corrosion resistance of SS. Among them the followings have been demonstrated to affect the cracking tendency:

- Increase of yield strength due to the formation of clusters of PD and He build up inducing He embrittlement (Scott 1994).
- Localized strain with formation of channels. The channel glide induces very high localized strains, near the GB, that can enhance dissolution at GB, when a crack is growing in the corresponding area (Was and Busby 2005).
- Enhanced increase in corrosion potential under irradiation due to confined radiolysis and chemistry (Urquidi-Macdonald et al. 2007).

4 Reactor Core Materials

4.1 Stainless Steels in SFR

In the sodium-cooled fast reactors, the structural components to be considered are metallic parts of the fuel assemblies: The fuel assembly wrapper (also called duct) and the fuel cladding tubes. The later is a critical component since its aim is to ensure the structural integrity of the fuel and the confinement of the radioactive fuel and fission products. Therefore the mechanical behavior during the entire life of the fuel has to remain good enough to inhibit any cladding failure. Indeed in case of cladding failure in Na-cooled reactor, the Na flows inside the fuel pin by capillarity and reacts with the fuel and the fission products, to form loose sodium (-cesium) urano-plutonates of generic compositions $\text{Na}_3(\text{U, Pu})\text{O}_4$. The high volume expansion and swelling character of this reaction induces tensile stresses on the cladding adjacent to the initial defect, inducing its propagation and major degradation of the entire fuel pin, with dispersion of fuel power in the coolant. Therefore very severe requirements have been set up for the design of these components. The selection criteria include the followings:

- Good mechanical properties (i.e., strength, creep resistance, geometrical stability, etc.) in the temperature range of consideration (400–700°C)
- Compatibility with the coolant (Na) and with the fuel and the fission products.
- Capability to support high fast neutron flux and fluences: The next generation of SFR has a target irradiation dose of 200 dpa for the fuel cladding.
- In order to improve the neutron efficiency of these reactors, a low capture cross section of the alloys for a fast neutron spectrum. This constrain induces a tendency to reduce Ni and Mo contents in austenitic SS, but does not support Zr as in LWR, since its capture cross section for fast neutrons is not lower than the components in SS.

The good behavior of the austenitic SS under these conditions has induced the selection of the 316 CW as the first material for these components. The discovery of microstructure evolution and significant swelling above 50 dpa, described in the next sections, has been a major driving force for understanding the mechanism of these microstructure and geometrical evolutions and for R&D aiming at developing low swelling alloys.

4.1.1 Changes in Microstructure

The austenitic stainless steels are stable in fcc structure at room temperature by addition of austenite stabilizing elements such as Ni, Mn, etc. Depending on the concentration of such elements, the stability of this phase may be limited and, following a solution anneal treatment, long thermal treatments at moderate temperature could induce phase evolution of the alloy, such as bcc phase formation or intermetallic compound precipitation.

In reactor, irradiation-enhanced or -induced precipitations have been observed in these steels (Russell 1984; Brager and Garner 1982). Among the various transformations observed, the most important are the followings:

- Precipitation of carbides: $(\text{Cr, Fe})_{23}\text{C}_6$ whose precipitation is retarded under irradiation, while the precipitation of $(\text{Cr, Ni, Si})_6\text{C}$ is irradiation enhanced, or $(\text{Ti, Nb})\text{C}$ in stabilized alloys.

Figure 30

Saturation of dislocation density in both SA and 20%CW 316 SS under irradiation at 500°C (From Brager et al. 1977)

- Precipitation of specific phases due to composition changes. Due to the segregations induced by irradiation at grain boundaries (3.2.2), chemical evolutions at the GB's consist of reduction of Cr and increase in Ni and Si. This induces the formation of γ' or G phases of composition $\text{Ni}_3(\text{Ti},\text{Si})$ and $(\text{Ti}, \text{Nb}, \text{Mn})_6\text{Ni}_{16}\text{Si}_7$. Formation of ferrite has also been observed in 321 SS.

After processing, the SS components have very large differences in dislocation densities. The solution annealed alloys are completely recrystallized and have low dislocation densities, while the cold worked materials have been strained usually around 20% and their dislocation densities are in the range of $10^{15-16} \text{ m}^{-2}$. Under irradiation the initial dislocation structure is completely modified and above 20 dpa stabilizes around $6 \pm 2 \times 10^{14} \text{ m}^{-2}$, whatever the initial conditions of irradiation temperature, neutron flux, and spectrum, within the normal range of SFR conditions (Fig. 30) (Brager et al. 1977).

The presence of these precipitates and the evolution of the dislocation network impact the PD evolution under irradiation. Indeed the dislocation density and the presence of incoherent interfaces around the precipitates control the strength of the sinks for the PD, and the bias. Higher strength of the dislocations in favor of the interstitials induces, as described earlier, higher concentrations of vacancies, compared to interstitials. As a consequence, the clustering of the vacancies induces swelling, a phenomenon of major concern for the SFR. It is described in the next section.

4.1.2 Swelling

- General aspects:

The early designs of the fuel elements for sodium-cooled fast neutron reactors selected austenitic stainless steels as reference materials for the cladding and structural parts such as

the assembly ducts. As soon the first stainless steels components were examined after significant fast neutron exposure, an isotropic expansion of the alloy due to the formation of internal microscopic cavities has been evidenced. This swelling phenomenon became then a matter of critical concern, since it affects directly the geometry and the performance of the core. While He was suspected to play a role, it was noticed very early that the amount of He created by the (n,α) reactions is not sufficient to explain the size and density of the cavities observed by TEM, and that He only acts in the nucleation process of the cavities where the vacancies cluster (Cawthorne and Fulton 1967).

A large amount of international work has been performed on the subject of swelling of austenitic stainless steels, with the aim of understanding the physical phenomena involved in order to control and reduce the swelling behavior of the alloys. Following two decades of irradiations, simulation experiments and modeling, a fair understanding of the mechanisms and of the role of the parameters is now commonly accepted (Lucas 1993; Zinkle et al. 1993; Mansur 1993; Garner 1994).

The swelling is observed as a homogenous decrease of the density of the alloy, leading to an increase of the dimensions of the component under consideration. The swelling occurs after a minimum incubation time, is only significant in a given temperature range and is strongly dependent of the metallurgical state of the alloy (composition, microstructure, thermomechanical treatment, etc.). The mechanism of swelling is linked to the clustering of vacancies in 3D cavities, whose nucleation is enhanced by supersaturation of He created by (n,α) reactions. After the nucleation process, under steady state operation, the swelling usually reaches a rate close to $1\% \text{ dpa}^{-1}$.

- Microstructural mechanisms

The concentrations of PD's described in (8) are mainly controlled by the mechanisms of PD disappearance, either by recombination or by annihilation on sinks. The relative efficiency of these mechanisms is controlled by PD mobility, which is temperature dependent, and is also controlled by the density and strength of the sinks.

As many interstitials are created as the vacancies, but an unbalance exists for the annihilation efficiency of the DP on sinks. Indeed the interstitials have a higher elastic interaction with the dislocations and annihilate faster on them than vacancies. The net result is an increase in vacancy concentration, and a higher probability for the vacancy to cluster together. They can form clusters of 2D or 3D geometries (loops or cavities). Nucleation energy barrier considerations show that vacancies should cluster as loops and cannot nucleate cavities. This is indeed what is observed in alloys whose isotopic composition avoids formation of He during irradiation.

In austenitic stainless steels, the high Ni content allows in-situ formation of He by (n,α) reactions at measurable levels. As it would be expected for a rare gas, He is almost insoluble in metallic alloys and tends to precipitate, at a geometrical scale controlled by diffusion kinetics. He atoms, either located as interstitials or linked to vacancies, can migrate slowly, to form mixed clusters of He atoms and vacancies. These clusters of He atoms can then be considered as nanometric bubbles. Helium bubble nucleation occurs either homogeneously or heterogeneously. However, the low diffusion coefficient of He in fcc stainless steels does not allow long range diffusion of He for large bubble nucleation, and most of the nuclei are formed homogeneously, except in the case of very high density of heterogeneous nucleation centers (fine numerous precipitates or interfaces, etc.).

The nucleation of these He bubbles requires a minimal driving force, i.e., a minimal supersaturation of He, therefore it occurs only after a minimal dose of irradiation. Then nuclei of a few hundreds of He atoms form, with typical nucleus volume densities of $10^{21-24} \text{ m}^{-3}$. The formation of these nuclei does not affect appreciably the volume of the alloy and is not directly linked to the swelling itself. The importance of He generation is highlighted in future fusion reactor materials for which interaction of 14.1 MeV neutrons with steel components have much higher cross sections for the (n, α) reactions.

Following the formation of these He bubbles, the major concern, with respect to swelling, is related to their size/composition history. The size evolution of such nuclei is controlled by the balance between vacancy trapping, which will increase the size of the cavity, and the trapping of interstitials or thermal emission of vacancies, reducing it. Helium atoms can only be trapped by the cavities and cannot return to the matrix. If the evolution of the PD concentration is such that vacancies and interstitials are in equal concentration, the trapping at equal rates of the two types of PD lives the nuclei at their original sizes and no swelling occurs.

Detail analysis of the driving forces and trapping efficiency shows that a critical radius exists (or equivalently a critical number of He atoms clustered), function of irradiation conditions and microstructure, above which the cavity becomes unstable and grows by trapping of vacancies (Mansur 1993). The analysis of the size distribution of the cavities and bubbles in irradiated SS confirm a bimodal distribution of bubbles/cavities (Zinkle et al. 1993; Mansur 1993). Some bubbles are very small and contain mainly He atoms, their radii remaining below the critical radius for growth. They form the population of stable bubbles, emitting vacancies faster than trapping them, and therefore unable to grow. Above the critical radius, i.e., for a high enough number of trapped He atoms, vacancy absorption rate overcomes emission and these bubbles can grow as cavities at a rate controlled by the balanced flux of vacancies – interstitials to their surfaces (► Fig. 31).

For this growth to occur, annihilation of vacancy on cavities should be dominant. This requires a regime of balance strength of the annihilation sites (dislocation and voids). Indeed the PD's disappear by recombination or annihilation on sinks. The parameter controlling the relative rate of the two processes is the ratio of the efficiency of PD capture on the dislocations and on the cavities, Q . It is related to the density of these sinks:

$$Q = \frac{L}{4\pi r_c N_c} \quad (36)$$

where L is the total dislocation length, and r_c and N_c are the radius and total number of cavities. Large Q means that the PD's annihilate on dislocations, because there are very few cavities, low Q means that the PD's annihilate on cavities for the reverse reason. For these two cases, the vacancies and the interstitials disappear at the same rates and there is no swelling. In the case of equivalent importance of the sinks, the PD's annihilate on the two types of sinks; but a bias occurs: The interaction of interstitials with dislocations is higher than for the vacancies and the interstitials annihilate more frequently on dislocations, i.e., vacancies annihilate more on cavities, allowing the cavities to grow (Brailsford and Bullough 1972; Lee and Mansur 1990).

■ Figure 31

Calculated growth rate of cavities containing increasing numbers of He atoms (curves 1, 2, 3). For a critical number of He atoms and a critical size, the cavity grows unstable, below it shrinks. For gas contents below n_g^* , there are two roots, r_c^s , and r_c^c (curve 1). Above n_g^* , the cavity exhibits positive growth rate at all sizes (curve 3). r_c^0 is the critical radius for no gas (From Mansur 1993)

This approach explains, at least qualitatively, the results observed on irradiated alloys:

- At low temperature, swelling is not observed. The reason is a too low migration rate of the vacancies. Being not mobile, they cannot migrate and disappear only by recombination with interstitials diffusing randomly in the matrix. This is the recombination regime.
- Reduction of swelling (by delay of the onset of swelling) is obtained in cold worked materials in which the dislocation density are 6–8 orders of magnitude larger than in solution annealed alloys. This leads to a very high Q parameter (Zinkle et al. 1993).
- Similarly, delay for swelling is obtained by numerous and very fine precipitates such as M_2P , that can act as nucleation sites for He bubbles and allow a high density of such bubbles (Mansur 1993; Dubuisson et al. 1992). They act as traps for both types of PD and the corresponding low Q delays swelling occurrence.
- Once the He bubbles have passed their critical radii, their growth rates are maximal for Q values close to 1 and the swelling rates observed are almost constant and proportional to the dose rate (Garner 1994). Therefore the only way to avoid swelling is to delay as much as possible the dose for unstable cavity growth.
- At high temperatures the swelling disappears, due to the thermal emission of vacancies from the cavities. This occurs when vacancy formation can just be thermally activated.
- Although early observations raised the hope of some saturation in swelling, detailed reexamination of the data confirmed a continuous swelling rate once the incubation period has been reached (Garner and Black 2000). Swelling above 55% have even been observed in standard austenitic stainless steel ducts irradiated in BOR 60 up to 67 dpa

■ Figure 32

Influence of the temperature on cavity structure and void swelling of 15–15 Ti SA austenitic steel neutron irradiated to 11–13 dpa with a high He generation rate (From Maziasz 1993)

(Neustroev and Garner 2008). For high swelling values, in addition to the expected degradation of mechanical properties, all the physical properties (E , ν , ρ_{elec} , λ_{th} , etc.) are affected (Balachov et al. 2004).

- Parameters controlling swelling:

The crystal structure is known to affect the swelling behavior: after the onset of swelling, a constant swelling rate of about $1\% \times \text{dpa}^{-1}$ is observed in austenitic steels. In ferritic steels (e.g., Fe-Cr alloys), the nucleation of swelling occurs late and the swelling rate is lower (probably $< 0.1\% \times \text{dpa}^{-1}$) (Gelles 1995). Lower swelling rates were observed for more complex alloys leading to ferritic/martensitic structures, probably at the onset of swelling (Odette 1988). This behavior is not intrinsic to the bcc structure (V or Mo alloys do swell), and various reasons for this resistance swelling are proposed: the lower He generation rate, due to low Ni content, the more open bcc structure exhibits higher diffusion coefficients, the crystallographic structure of the dislocations in bcc could induce a lower bias for interstitial capture, PD trapping by solute atoms such as carbon and the very fine microstructure of martensitic steels, where the high density of lath boundaries may act as sinks for PD's (Little 1993). Hcp alloys (Zr, Ti, Mg, Zn, etc.) do not exhibit swelling, but only formation of dislocation loops, responsible for growth (dimension change at constant volume, see ► 4.2.2) (Griffiths 1993).

The temperature controls the swelling behavior for reasons explained earlier. Roughly, swelling is only observed in metallic alloys for reduce temperature in the range of $0.3 < T/T_f > 0.65$. Unfortunately, this temperature range corresponds, for industrial steels, to the design temperatures of fast reactor cores. It is observed that the maximal swelling is observed in SFR in the upper part of the fuel assemblies, slightly above mid-core plane, corresponding to the best combination of neutron flux and temperature. The influence of temperature on swelling is clearly evidenced on ► Fig. 32. The possibility of very limited swelling of internals in PWR operating at much lower temperatures is still an open question (Garner and Toloczko 1997; Garner and Makenas 2006).

The metallurgical state of the alloy is an important controlling parameter of the swelling behavior. Almost any feature of the microstructure may affect the evolution of the PD created

■ Figure 33

Influence of cold work and temperature on swelling of 316 austenitic stainless steel irradiated in SFR (From Dupouy et al. 1978)

during irradiation. Dislocations, interfaces, grain boundaries or free surfaces, including cavities, act as sinks for the PD.

The effect of cold work in reducing the swelling has been clearly evidenced very early and the advantage of high strength, due to strain hardened structure, and low swelling lead to the use of cold worked alloys very early. ➤ Figures 33 and ➤ 34 illustrate the strong effect of cold work. However, this effect is only effective for the incubation phase (Garner 1993; Dupouy et al. 1978). Actually, the irradiation induces changes in the microstructure, modifying the initial dislocation arrangements and inducing a new dislocation network, whose density is almost independent of the initial structure (Zinkle et al. 1993). This is the reason why the post incubation swelling rate is independent from the initial microstructure (Garner 1994).

The chemical compositions of the alloys have been naturally considered as variables for swelling control. From the standard composition of 304 and 316 austenitic stainless steels, variants have been considered, with changes in the major alloying elements (Cr, Ni, Mo, etc.) and minor additions (Ti, Si, C, P, etc.). The effect of variations in chemistry is rather complex and only limited generic rules can be extracted from the large amount of experimental data's

■ Figure 34

Influence of cold work on swelling of 15-15 austenitic stainless steel irradiated at 650°C with 1 MeV Cr ions (From Garner 1993)

(Garner 1994). The chemical changes affect only the incubation dose and not the steady state swelling rate.

- The major impact is obtained with Ni: increasing the Ni content reduces drastically the swelling. Initially observed with ion irradiation, the effect is confirmed under neutron irradiation. Ni contents in the range of 30–50% correspond to the most efficient alloys, but an increase to 15–20% appears to be enough for industrial applications, when other additions are considered (Seran et al. 1992).
- Chromium has exactly the reverse effect: the swelling rate is increased with Cr content. However Cr content has to remain high enough for corrosion resistance. The effect of Ni and Cr contents are not fully explained, the changes in diffusion coefficients associated with the composition shifts are too low to explain such reduction in swelling (Rothman et al. 1980). The change in stacking fault energy with composition may affect the interaction energy between interstitials and dislocations, reducing their bias.
- Molybdenum, a usual component of 316 SS, induces a complex behavior: it reduces weakly the swelling at low temperatures, but increases it at high temperatures.
- Titanium is usually added in these alloys for stabilization by precipitation of TiC instead of chromium carbides. Due to the interactions of C with Ti, the states of these elements (solid solution or carbides) vary with temperature and change their role as sinks for PD's. Ti increases swelling at low temperatures (420–470°C), while it reduce it in the higher range (530–630°C) and the reverse occurs for C.

■ Figure 35

Influence composition and structure on swelling of stainless steel irradiated in the Phénix fast reactor (From Seran et al. 1992)

- Silicon and phosphorus show a swelling increase at low concentrations, but then reduce swelling. Si has to be above 0.5% to be efficient in reducing swelling, and P above 0.05%. For these two minor additions, the state of the component is very important (in solid solution, or as precipitates). The mechanisms involved in their effects on swelling associate PD interactions with the atoms in solute solution, or the efficiency of precipitate matrix interfaces as sinks for PD's and highly dense heterogeneous nucleation sites for He bubbles (Zinkle et al. 1993; Dubuisson et al. 1992). By increasing the number of cavities for He precipitation, the number of He atoms in each bubble is reduced and a higher dose is required for them to reach the critical radii (Mansur 1993).

The dose rate controls the concentration of PD's, and therefore their ability to recombine and to inhibit cavity nucleation. At high dose rate the peak swelling is observed at higher temperatures. This can be observed with ion irradiation, having very high rates compared to reactor irradiations. Two orders in magnitude increase in dose rate, correspond to a shift in peak swelling temperature of 100 K (Mansur 1993; Westmoreland et al. 1975). Similarly, the high dose rate gradient characteristic of SFR cores allows the reveal the effect of dose rates on swelling: The highest dose rates reduce the onset of swelling (Seran and Dupouy 1982).

The saturation of swelling that has been reported at high neutron doses has been reanalyzed and appears now to be due to an artifact due to dose measurements or bias in extrapolations (Garner et al. 2000).

The slow industrial evolution of SS composition allowed the introduction of high Ni alloys with specific additions, such as Ti, Si, P, or other less publicized. The historical evolution of the performance of SS claddings for the French SFR program is shown in Fig. 35. The reactors of

the next generation (GEN-IV) will require very low swellings at very high doses, and the choice will be between advanced high Ni austenitic steels or ferritic/martensitic steels.

4.1.3 Irradiation Hardening and Irradiation Creep

Irradiation Hardening

During irradiation, the change in dislocation microstructure is the main mechanism inducing hardening or softening. For solution annealed or cold worked materials, which initial dislocation densities differ by several orders of magnitude, the dislocation densities stabilizes after a moderate irradiation (15–25 dpa) at a dislocation density of $3 \times 10^{14-15} \text{ m}^{-2}$ whatever the initial state, but with a tendency for lower dislocation densities at higher irradiation temperatures (Garner 1994). The same behavior has been confirmed under different types of irradiation (Mazey et al. 1971; Azam et al. 1973).

Since the mechanical strength is controlled by the pinning efficiency of the obstacles for dislocation glide, the change in dislocation microstructure induces a similar change in mechanical properties. Indeed, the strength of cavities as pinning centers for the dislocations is much lower than the dislocation of the forest and can be forgiven. For SA alloys, the low initial dislocation density is largely exceeded by the dislocation network formed during the growth and interaction of the dislocation loops generated by irradiation. This leads to a large radiation hardening and the yield strength is observed to increase with dose to reach a saturation value close to 900 MPa after about 15–20 dpa at 370°C. For higher irradiation temperatures, an in-situ recovery of the dislocation network allows a reduction in yield strength (Fish and Holmes 1973; Garner et al. 1981).

For cold worked material, the initial dense dislocation network is completely restructured during irradiation and a new steady state dislocation network forms, rather similar to the one observed for saturation of SA alloys. This leads to some irradiation softening and the strength of the two types of microstructures (SA and CW) exhibit similar properties at high doses (Garner et al. 1981) (► Figs. 36 and ► 37).

An expected correlation can be verified between the dislocation loop density (or the dislocation network density) and the mechanical properties (yield strength), corresponding to the standard strengthening by a geometrical density of obstacles on dislocation motion (Yoshida et al. 1991; Brager et al. 1984).

$$\Delta\sigma = \alpha \cdot \mu \cdot \vec{b} \cdot (\rho_d)^{1/2} \quad (37)$$

This confirms the major role of the dislocations on mechanical properties.

In addition to the strengthening induced by the dislocations, different other mechanisms affect the mechanical properties:

- Due to the saturation in dislocation density at high doses, strain hardening does not occur anymore, (some strain softening could even occur) and the result is a localized strain and very low uniform elongation, leading to low ductility of engineering concern (Crawford et al. 2007; Fissolo et al. 1994).
- Cavities responsible for swelling act as nucleation centers for dimples in the ductile fracture process, therefore high swelling induces a very low ductility. The consequence is a restriction

■ Figure 36

Convergence of the yield strength at high doses for cold worked and SA 316 SS under fast neutron irradiation (From Garner et al. 1981)

in total swelling below 6% (Hamilton et al. 1967). At 10% swelling, the steel does not exhibit any ductility anymore. For these conditions, the fracture appearance is transgranular, with planar zones, corresponding to “channel fracture,” perpendicular to the tensile axis. These areas are not cleavage surfaces, but planes of intense dislocation channeling where the cavities are completely flattened and merge by localized intense shear (see [Fig. 15](#)) (Garner 1994; Fissolo et al. 1994).

- The He precipitated or segregated at grain boundaries induces an embrittlement and grain boundaries separation is observed for high temperature creep testing.

Irradiation Creep

Irradiation creep of the steels used for cladding and assembly ducts is a complex process to study, due to the difficulties in performing creep experiments in material testing reactors and due to the interaction between creep and swelling. In the ranges of temperatures, stresses and dose rates relevant to actual fuel assembly components, the stress-induced preferential absorption (SIPA) mechanism is responsible for the majority of the strain among the different irradiation creep mechanisms that could be considered (Matthews and Finnis 1988; Garner 1994). Other minor components of strain at the beginning of the loading (primary creep), due to the evolution of the dislocation microstructure or to strain associated with radiation-induced precipitation, will not be described here.

Figure 37

Effect of temperature on the variation of mechanical properties of 316 cold worked austenitic SS under irradiation (From Garner et al. 1981)

The SIPA considers that the elastic interaction of interstitials with dislocations is modified by the applied stress and that this anisotropic contribution leads to preferential annihilation of the interstitials on dislocations whose climb induces strain in the direction of applied tensile stress. In a similar way to annihilation of vacancies on cavities for swelling, it states that SIPA creep occurs when interstitials disappear on dislocations, i.e., when the dislocation density is high and recombination mechanisms low. Therefore irradiation creep occurs faster on high dislocation density materials such as cold worked materials or only after a given irradiation for the development of a dense network of dislocations (Bullough and Willis 1975). The creep rate of SIPA irradiation creep is derived to be proportional to the dislocation density and to the flux of PD's arriving to the dislocations, itself proportional to the PD generation rate G (38).

$$\dot{\epsilon}_{\text{SIPA}} = C \frac{\sigma}{\mu} \rho_{\text{disl}} G F(\eta) \quad (38)$$

where μ is the shear modulus, and $F(\eta)$ a quantity expressing the balance of recombination and thermal emission of the defect population.

This irradiation-induced SIPA creep is temperature independent. The reason is that it is controlled by interstitial mobility, a process of very low activation energy. This has been confirmed by careful measurements of temperature dependence of irradiation creep. It was indeed found

an activation energy of irradiation creep corresponding to 0.13 eV in austenitic SS (Wassilew et al. 1987). The increase in irradiation creep with higher dislocation density ρ_{disl} has been confirmed in a large number of observations, as well as the linear dependence with fast neutron flux (Garner 1994). Since the density of dislocations has a tendency to stabilize around $10^{14-15} \text{ m}^{-2}$ after a few dpa, the creep rate appears to be only dependent of irradiation dose and is imply expressed as:

$$\dot{\epsilon} = B_0 \sigma G \quad (39)$$

where B_0 has been measured close to $10^{-6} \text{ MPa}^{-1} \cdot \text{dpa}^{-1}$ in austenitic SS and to $0.5 \times 10^{-6} \text{ MPa}^{-1} \cdot \text{dpa}^{-1}$ in ferritic SS (Garner 1994; Seran et al. 1992).

The occurrence of swelling affects the irradiation creep and very strong correlation has been found between creep rate increase and swelling. Thus a more accurate description of the irradiation creep equation should include the swelling rate:

$$\dot{\epsilon} = \sigma (B_0 G + D \dot{S}) \quad (40)$$

where \dot{S} is the instantaneous swelling rate. In the French analysis, the coefficient D is replaced by α , which is applied to the total swelling rate. D is in the close to $0.5 \times 10^{-2} \text{ MPa}^{-1}$ and is the same for austenitic and ferritic SS (Seran et al. 1992).

The reason for an increase in creep rate when swelling starts is linked to the behavior of the interstitials. As described above, the swelling is induced by higher vacancy trapping at cavities, due to preferential annihilation of the interstitials on dislocations. Then the bias of interstitials on the dislocations enhances the climb of the dislocations and, as matter of consequence, the strain by SIPA creep (Woo and Garner 1992).

It is usually difficult to predict the creep of fuel pin cladding only based upon the swelling and creep behavior obtained with simple irradiation tests. This is due to a major difference in stress history between creep or swelling experiments and fuel pin: In a pressurized capsule the stress state remains constant during all the experiment, while the internal pressure of a fuel pin increases as the burn-up and fission gas release increases. In the former case, creep starts before swelling, while in fuel pins, swelling can appear before significant creep strain (Seran et al. 1990; Garner et al. 1987). In addition, at high doses, the creep rate has a tendency for reduction in strain rate, and can even vanish, adding a degree of complexity in the modeling of the actual behavior (Garner et al. 1987).

4.1.4 Development of Low Swelling Alloys

During the decades of operation of fast reactors, a large number of variants of austenitic steels have been tested in order to reduce the swelling rates. Advanced alloys, with high Ni content and various additives (Ti, P, etc.) have shown promising behaviors. Alloys for cladding in such reactors are available for doses close to 150 dpa. However the design of advanced fast reactors of GEN IV will require much lower swelling due to geometrical requirements induced by their advanced neutron physics.

The ferritic steels were observed to be highly resistant to swelling in the rare experiments performed with these alloys. The bcc structure of these steels cannot be the main reason for

Figure 38

Microstructure of ODS steels, with yttria dispersions and corresponding increase in creep resistance. The pinning of the dislocations by the dispersoids leads to a drastic increase in creep resistance (From Yamamoto et al. 2007)

such a behavior. Indeed, V or Mo alloys do exhibit swelling. Early measurements of ferritic steel swelling reported low swelling rates, close to $0.05\% \text{ dpa}^{-1}$. However voids were observed at higher doses (Gelles 1995). A detailed survey of all the data related to swelling of steels lead to the conclusion that the ferritic steels exhibit roughly the same behavior as the austenitic ones. They have usually a much longer incubation period, strongly Cr content dependant. The shortest incubation (100 dpa) are obtained with 8–10% Cr, while 15% Cr leads to a delay in the onset of swelling above 170 dpa. However, after the incubation dose is reached, the swelling rates are similar, but smaller than the fcc steels, i.e., close to $0.2\% \text{ dpa}^{-1}$, and possibly higher (Garner et al. 2000).

Whatever their swelling resistance, the high Cr ferritic steels will be susceptible to radiation embrittlement, i.e., increase in DBTT with dose. This drawback, currently not analyzed in detail, would be a matter of concern for the handling of the fuel after irradiation.

For fast Na-cooled reactors, the high core temperatures require a cladding material of high resistance to creep. Due to the large thermal activation of the deformation mechanisms in bcc steels, their creep resistance at operating temperatures would not fulfill the design requirements.

For specific applications, these ferritic steels have been strengthened by dispersion of non-soluble oxides such as Y, Ti, or Mg oxides (ODS steels), a structure obtained by mechanical alloying followed by high temperature and high isostatic pressure sintering. They show a very high creep resistance (► Fig. 38). The high PD sink density induced by the very fine structure of the oxide dispersoids is expected to reduce the swelling rates. Preliminary tests are promising (Yamamoto et al. 2007). This microstructure of the ODS, preliminarily proposed for ferritic steels has been proposed as a possible route for improvement of austenitic steels (Rowcliffe 2009). Among the problems to be solved, the high dose stability of these oxide dispersoids appears to remain an open question. Indeed while the oxide particles inserted by mechanical alloying are fully insoluble and therefore highly stable, with no dissolution and coarsening at high temperature, the ballistic mixing can induce diffusion of the components of these particles back into the matrix (Monnet et al. 2004).

4.2 Zirconium Alloys in Water Reactors

Zirconium has been selected for LWR early in the history of the nuclear industry. In the process of selecting new structural alloys for water reactors, zirconium and its alloys were chosen because of the conjunction of the following properties: low thermal neutron capture cross section, high resistance to corrosion in high temperature water and relatively high mechanical strength.

4.2.1 Zirconium Alloys: Zircaloy and Zr-Nb

In the usual ore (zircon: ZrSiO_4) zirconium is commonly found associated with its lower row counterpart in the periodic table, hafnium, at a concentration of 1.5–2.5%. Due the high thermal neutron capture cross section of Hf ($\sigma = 105 \pm 5$ barns), it has to be removed from Zr for nuclear applications.

The processing of Zr alloy industrial components is rather difficult because of the high reactivity of the metal with oxygen. The first step is to transform the zircon into ZrCl_4 , through a carbo-chlorination process. After, Zr and Hf are separated using a vapor phase distillation, at 350°C . Zr metal is obtained by the reduction of ZrCl_4 in gaseous form by liquid magnesium, giving the sponge cake. This is the base product for alloy ingot preparation. Sponge fragments are compacted with the alloying elements – O (in the form of ZrO_2), Sn, Fe, Cr, Ni, and Nb – to the desired composition. It is melted in a consumable electrode vacuum furnace, three to four times.

Industrial use of Zr alloys requires either tube- or plate-shaped material. The first step in mechanical processing is forging or hot rolling in the β phase, at a temperature close to $1,050^\circ\text{C}$, or lower in the $\alpha + \beta$ range. Hot extrusion followed by one cold reduction step is used to obtain tube shells or TREX (tube reduced extrusions), while hot rolling is used for flat products. Further reduction in size is obtained by cold rolling either on pilgrim-rolling or flat mills. Low temperature ($500\text{--}700^\circ\text{C}$) annealings are performed between the steps.

Industrial Alloys

Pure zirconium crystallizes at ambient temperatures in the hcp system, with a c/a ratio of 1.593 (α phase). Lattice parameters are $a = 0.323$ nm and $c = 0.515$ nm. The β bcc phase appears above 865°C for pure Zr.

The zirconium alloys in use today for nuclear applications are limited in number: The alloys are based upon the two systems giving significant solid solutions: Zr-Sn: the Zircaloy's series and Zr-Nb either 1% or 2.5% (► [Table 6](#)).

Oxygen is clearly an alloying element. It induces an increase in the yield strength by solution strengthening: a typical addition of 1,200 ppm oxygen addition increases the yield strength by 180 MPa at room temperature, compared to O-free Zr.

Tin, at a concentration of 1.2–1.7%, was originally added to increase the corrosion resistance, especially by mitigating the deleterious effects of nitrogen. It increases the creep resistance of the alloys. There is a modern tendency to reduce its content.

Iron, Chromium, and Nickel, at their usual concentrations (below 0.5% total content), are fully soluble in the β phase. In the α phase their solubility is very low: about 120 ppm for

■ **Table 6**

ASTM specifications for Zr and Zr alloys in nuclear industry

Alloy	Sn (%)	Nb (%)	O (ppm)	Fe (%)	Cr (%)	Ni (%)
Zry 2	1.2-1.7		1,200–1,400	0.07–0.20	0.05–0.15	0.03–0.08
Zry 4	1.2-1.7		1,200–1,400	0.18–0.24	0.07–0.13	
Zr-1Nb		1	1,200–1,400			
Zr-2.5Nb		2.4–2.8	1,200–1,400			

Fe and 200 ppm for Cr at the maximum solubility temperature. In the Zircaloy's, they form intermetallic compounds: $Zr_2(Ni, Fe)$ and $Zr(Cr, Fe)_2$.

Niobium (columbium) is a β stabilizer. A monotectoid transformation occurs at about 620°C and around 18.5 at % Nb. By water quenching from the β or upper $\alpha + \beta$ regions, the β Nb-rich grains transform by martensitic decomposition into an α' supersaturated hcp phase; subsequent heat treatment below the monotectoid temperature leads to the precipitation of β' Nb precipitates at twin boundaries of α' needles.

Microstructure

After ingot melting, the thermomechanical processing commonly used for industrial alloys is the following:

- Hot forging in the β range (1,000–1,050°C)
- Water quenching from the homogeneous β phase (above 1,000°C)
- Intermediate temperature (upper α) forging and rolling, or extrusion for tubes
- A series of cold temperature rolling steps followed by intermediate anneals under vacuum

Homogenization in the β phase leads to the complete dissolution of all the second phase particles, but induces significant grain growth. During the water quench, the β grains transform into α needles by bainitic transformation according to the cooling rates of the large ingots involved. The β -eutectoid elements are repelled by the transformation front and precipitate at the boundaries of those needles. This β quench is a reference state for further processing (► *Fig. 39*). The cold working steps and intermediate anneals allow further control of the precipitate size whose size distribution is critical for corrosion control.

In Zr-1%Nb alloys used for cladding material, such as E110 or M5[®], the α -Zr structure is close to fully recrystallized after the final anneal at 580°C. The structure of the tubes reveals finely dispersed β -Nb precipitates along boundaries of α -Zr grains and in the matrix, but the α -Zr phase itself is supersaturated in Nb and an irradiation-induced precipitation occurs, which is considered to be the origin of the improvement of corrosion resistance after irradiation of these alloys.

Advanced multicomponent alloys are under development. Based on Zry, Zirlo[®] or E635, the multicomponent Zr 1%Nb 0.7-1.3%Sn 0.2-0.6 %Fe alloys, proposed as cladding and pressure tube material, are claimed to exhibit a higher corrosion resistance than the Zircaloy's in specific

■ Figure 39

Microstructure of a β -quenched Zr alloy. The four orientations of the α grains come from the same former β grain (polarized light)

environments. This is caused by the availability of intermetallic particles containing Zr, Nb, Fe in the form of $Zr(Nb, Fe)_2$ or $(Zr, Nb)_4Fe_2$ types.

Deformation Processing and Textures

The room temperature deformation mechanisms of the hexagonal Zr follow two main mechanisms, depending on the relative orientations of the grains in the stress field. Plastic deformation of Zr alloys is obtained either by dislocation slip, mostly with glide on prism planes or by twinning during cold rolling. At higher deformations and temperatures, $(c+a)$ -type slip is activated on pyramidal planes.

At the large strains obtained during mechanical processing, steady state interactions occur between the twinning and slip systems that tend to align the basal planes parallel to the direction of the main deformation. For cold-rolled materials (sheets or tubes), the crystallographic textures are such that the majority of the grains have their c -axis tilted $30\text{--}40^\circ$ away from the normal of the sheet, or of the tube surface, towards the tangential direction, as can be seen in the $\langle 0001 \rangle$ pole figure sketched in ► Fig. 40. During tube rolling, the spread of the texture can be reduced by action on the ratio of the thickness to diameter reduction (Q factor): a reduction in thickness higher than the reduction in diameter gives a more radial texture, i.e., a texture with the $\langle c \rangle$ poles closer to the radial direction.

Mechanical Properties

At room temperature, in the annealed state, pure, oxygen-free Zr, has a low yield strength of 150 MPa. This yield strength can be increased by solution strengthening, using alloying elements of high solubility: Oxygen, tin, and niobium. As a result, the Zircaloy's have minimal yield strengths in the range of 250–300 MPa and the Zr 2.5%-Nb alloy of 300 MPa. Additional strength is obtained by cold working, with yield strength above 400–450 MPa. In order to restore ductility without drastic reduction in strength, a final stress-relief heat treatment is often

■ **Figure 40**
Effect of the Q ratio on the crystallographic texture of Zr alloy tubes (From Cook et al. 1991)

performed. Finally, the texture itself can increase the material strength by changing the Schmid factor for slip or twinning.

4.2.2 Dislocation Loops: Growth and Irradiation Creep

Irradiation Effects in the Zr Matrix

Contrary to the behavior of stainless steel, Zircaloy does not exhibit significant void formation under neutron irradiation. Dislocation loops developing under irradiation are mostly $\langle a \rangle$ type $1/3 \langle 11\bar{2}0 \rangle$ loops, as shown in ► [Fig. 41](#). Both vacancy and interstitial loops have been reported, in roughly comparable proportions (Northwood 2005; Griffiths et al. 1983). This is an unusual feature of microstructural development under irradiation specific to Zr and its alloys, as compared to cubic metals and other hcp metals, where only one type of loop usually grows.

After neutron irradiation to around $3 \times 10^{25} \text{ n} \cdot \text{m}^{-2}$ at temperatures between 560 K and 773 K, $\langle c \rangle$ -component dislocations start to develop in annealed Zircaloy-2. They are located on the basal plane, are vacancy in character and have a $1/6 \langle 20\bar{2}3 \rangle$ Burgers vector. Some of those $\langle c \rangle$ -type loops are shown developing near dissolving amorphous precipitates (see ► [Fig. 42](#)). They have been linked to the occurrence of breakaway growth.

Irradiation Effects on Second Phases

An important effects of irradiation on Zr alloys is the crystalline to amorphous transformation (amorphization) observed in the intermetallic precipitates $\text{Zr}(\text{Cr}, \text{Fe})_2$ and $\text{Zr}_2(\text{Ni}, \text{Fe})$ (see ► [Fig. 10](#)). At 350 K, both types of precipitates are completely amorphous after very low

■ Figure 41
Alignment of $\langle a \rangle$ loops in Zircaloy irradiated at a low dose (From Northwood 2005)

■ Figure 42
 $\langle c \rangle$ -type dislocation loops in the vicinity of an amorphous precipitate (From de Carlan 1996)

fluences (0.5–1 dpa). At the higher temperature range, the $Zr_2(Ni,Fe)$ precipitates are completely crystalline, while the $Zr(Cr,Fe)_2$ precipitates are partially amorphous having developed a “duplex” structure, consisting of an amorphous layer that starts at the precipitate–matrix interface, and gradually moves into the precipitate until the precipitate is completely amorphous (Griffiths 1988). Amorphization is associated with a depletion of iron from the amorphous layer into the Zr matrix, while the Cr concentration in the precipitate remains constant.

Irradiation Growth

Irradiation growth refers to the dimensional changes at constant volume of an unstressed material under irradiation. Irradiation growth is due to the partitioning of interstitials and vacancies to different sinks that are not isotropically distributed in the material: cold-work- or irradiation-induced dislocations and grain boundaries of different orientations.

For Zr single crystals, irradiation growth consists of an expansion along the $\langle a \rangle$ direction, and corresponding contraction along the $\langle c \rangle$ axis. In polycrystalline materials the situation is more complex, since grain boundaries can act as biased sinks for point defects, so that grain shape and orientation play also a role (Fidleris 1988).

The fabrication process of Zr alloy components induces a crystallographic texture: For Zircaloy cladding tubes, prism planes are preferentially aligned perpendicular to the axial (longitudinal) direction. Thus, irradiation growth causes the axial length to increase and the cladding thickness to diminish. Irradiation growth is influenced by microstructural variables such as amount of cold work, residual stresses and alloying additions, as well as by irradiation variables such as flux and temperature. In addition to “normal growth,” after a fluence of about $3 \times 10^{25} \text{ n} \cdot \text{m}^{-2}$ a “breakaway phenomenon” is observed, which has been linked to the development of $\langle c \rangle$ component dislocations (► Fig. 42) (Griffiths et al. 1989; Christien and Barbu 2009).

Irradiation Creep

Irradiation creep refers to the steady deformation rate observed under external stresses experienced by materials under irradiation. A large amount of creep tests has been performed in materials test reactors, as well as in detailed examinations of structural material behavior of power reactors. For practical purposes and for typical ranges of operating parameters, the thermal and irradiation creep strains may be added and described accurately with a simple equation of the form:

$$\dot{\epsilon} = A\sigma^n \cdot \exp\left(\frac{-Q}{kT}\right) + B\sigma^m \phi^n \quad (41)$$

where the effect of flux, stress, and temperature can be separated. The standard values of those exponents are $m = 0.6\text{--}1$ and n near $2\text{--}4$. The activation energy, Q , is low, in the range of $0.05\text{--}0.16 \text{ eV} \cdot \text{at}^{-1}$. It is thought that irradiation creep deformation occurs by dislocation climb and glide, the climb being controlled by the stress-modified absorption of point defects at dislocations (Ribis et al. 2009; Gilbon et al. 2005; Causey 1981). According to the so-called SIPA mechanism, dislocations that have their Burgers vectors parallel to the applied stress preferentially annihilate interstitials better than vacancies, leading to dimensional changes due to the dislocation climb itself and to the subsequent dislocation glide. In addition, migration anisotropy of interstitials in an applied stress field has to be taken into account.

4.2.3 Postirradiation Plastic Behavior

Due to the high concentration of PD clusters produced by neutron irradiation (point defects and dislocation loops), dislocation slip is inhibited and thus the yield strength increases after irradiation. This effect is rapidly saturated at fluences which vary with irradiation temperatures. For power reactors, the increase of the yield strength or UTS saturates above

Figure 43
Effect of irradiation on the mechanical properties of Zry4 (From Regnard et al. 2002)

about $5 \times 10^{24-25} \text{ n} \cdot \text{m}^{-2}$. This saturation value is the same for both SR and RX Zircaloy's: The increased density of dislocation loops increases the critical shear stress for dislocation glide. Since the increase in loop concentration under neutron irradiation saturates rapidly due to overlap of their influence volumes, the increase in yield strength saturates as well.

This increase in yield strength is associated with a reduction in ductility, affecting both the uniform elongation (through a reduction of the strain hardening exponent), and the total elongation, decreasing from about 20% to a few % (► Fig. 43) (Adamson and Bell 1985; Adamson 2000).

The reduction in strain hardening exponent can lead to a strain softening behavior after irradiation. The high density of dislocation loops in the prismatic planes inhibits the mobility of the gliding dislocations along these planes and a basal slip is activated. The interaction between the loops and these gliding dislocations, of identical Burgers' vector, leads to the annealing of the loops (Carpenter 1976; Onimus et al. 2004). The result is the formation of loop free channels along which easy basal slip is obtained (see ► Fig. 14).

4.2.4 Corrosion Behavior and Effects of Irradiation on Corrosion

General Corrosion Behavior

Zr alloys are highly resistant to corrosion in common media and are used for that reason in the chemical industry. Those alloys are however not immune to oxidation and in the high temperature water environment found in a power reactors (water at 280–340°C and 10–15 MPa), corrosion is a critical design parameter for the fuel rods and other components.

In the early stages of oxidation in such environments, a thin compact black oxide film develops that is protective and inhibits further oxidation. The kinetics of this first corrosion step follows a power law, usually described by a thermally activated power law:

$$\varepsilon_{\text{ZrO}_2} = k_c t^n \exp\left(\frac{-Q}{kT}\right) \quad (42)$$

Figure 44

Corrosion kinetics of Zry, showing the transition at about $2\ \mu\text{m}$ (From Cheng et al. 1994)

The activation energy of $1.35\ \text{eV}\cdot\text{at}^{-1}$, for corrosion in the dense oxide regime, is equivalent to activation of the diffusion of oxygen in zirconia. Oxygen is indeed considered to diffuse from the free surface of the oxide as O^{-2} , by a vacancy mechanism through the zirconia layer along the grain boundaries, and to react with the zirconium at the matrix–oxide interface (Cox et al. 2008).

The inner dense layer of zirconia is rich in the tetragonal allotropic form, a phase normally stable at high pressure and temperature. The swelling induced by oxidation (Pilling–Bedworth ratio of 1.56) leads to the build-up of compressive stresses that stabilize this high pressure phase (Bouvier et al. 2002). As the oxidation proceeds, the compressive stresses in the oxide layer cannot be counterbalanced by the tensile stresses in the metallic substrate and plastic yield in the metal limits the compression in the oxide. The tetragonal phase becomes unstable and the oxide transforms to the monoclinic form. In connection with this transformation, a very fine interconnected porosity develops and allows the oxidizing water to access closer to the corrosion interface (Parise et al. 1998; Petigny et al. 2000). Once this transformation has occurred, only a portion of the oxide layer remains protective. The corrosion kinetics is therefore now controlled by diffusion of oxygen through the dense protective oxide layer only. Since the thickness of this layer remains constant, in the range of $1\ \mu\text{m}$, the corrosion rate is constant after this transition (Fig. 44).

■ Figure 45

Impact of precipitate size and environment on the corrosion kinetics of Zry (From Garzarolli et al. 1994)

In this dense oxide layer the structure of the zirconia, which controls the post-transition corrosion kinetics, is complex and still under discussion. Starting from the metal–oxide interface, a very thin layer of questionable amorphous oxide has been reported under particular conditions, a few nm in thickness. It is followed by a zone of very small zirconia crystallites, 10–20 nm, that become larger in diameter and columnar in shape further into the oxide layer. For thick oxide layers, in excess of 100 μm , the oxide may spall-out.

The intermetallic precipitates are known to remain unoxidized in the dense oxide layer. During their oxidation, they are supposed to act as Fe reservoirs, improving the protective behavior of the zirconia layer. Such behavior would explain the impact of precipitate size on corrosion behavior (► Fig. 45) (Iltis et al. 1995; Pecheur et al. 1994).

In BWR's, nodular corrosion has been a design limiting phenomenon. Several mechanisms have been proposed for the nucleation of those nodules, leading to various possible sites for nodule nucleation: metallic matrix grain boundaries, local rupture of the continuous dense oxide at an early stage of growth, local variations in composition and precipitates densities or crystallographic orientation of clusters of grains (Kruger et al. 1992).

For the Zr-Nb alloys, the corrosion behavior is slightly different, with a less pronounced transition and a beneficial effect of irradiation. Indeed the corrosion kinetics seems to be more controlled by surface reaction kinetics than by the migration of O^{2-} through the Zr layer. Under irradiation, the Nb that was left in supersaturation after the final heat treatments can precipitate by an irradiation-enhanced mechanism. Indeed the kinetics of thermal precipitation is very

low, but the faster diffusion under irradiation allows an acceleration of diffusion and precipitation. The microstructure obtained has a better corrosion resistance (Jeong et al. 2003). Thus in opposite of the Zry's, Zr-Nb alloys usually exhibit an improvement in corrosion resistance after irradiation (Lin and Woo 2000; Doriot et al. 2005).

Hydrogen Pick-Up

During oxidation of Zr alloy, H is released according to:

The reduction of the water molecules at the coolant-oxide interface releases hydrogen as radicals H^+ . Most of them recombine creating hydrogen molecules that escape through the pore and dissolve into the coolant. A limited amount (5–40% of the H formed) can ingress in the oxide, migrate through to the metallic matrix and then react with Zr for the formation of hydrides.

A consequence of the H pick-up is the hydride embrittlement. The high concentration of H dissolved in the Zr alloy after corrosion can exceed the solubility in temperature, but H will always precipitate at room temperature. Indeed, the solubility of H in Zr alloys is strongly temperature dependent. Higher than 200 ppm at operating temperature, it is below 1 ppm at room temperature. During cooling, H precipitates as fine platelets of hydrides Zr $\text{H}_{1.6}$. This phase is brittle at low temperatures and high H concentrations can lead to a brittle behavior during fuel maneuvering or other low temperature operations (Singh et al. 2004; Bertolino et al. 2003).

4.2.5 Interaction with Fission Products I-SCC and PCI Failure

Pellet cladding Interaction (PCI) is a mode of water reactor fuel rod failure that has been observed after fast power transients. Early observations of PCI on BWR's was rapidly analyzed as a mechanical interaction between the cladding and the expanding UO_2 pellet, associated with chemical interaction of some fission products with the Zircaloy cladding (Cox 1990). A combined contribution of stresses induced by fuel pellet expansion due to linear heat generation rate (LHGR) increase and the presence of an active corrosion agent, the iodine, created in the fuel rod as a fission product, induces failure by stress corrosion cracking (SCC).

Fuel rods of various design and irradiation histories were tested in irradiation devices of test reactors. The maximum power allowable for a fuel rod of BU above $20 \text{ GW} \cdot \text{d} \cdot \text{t}^{-1}$, is in the range of $40\text{--}47 \text{ kW} \cdot \text{m}^{-1}$.

In fuel rods, the closure of the internal gap due to cladding creep-down requires in PWR's and BWR's a year or two. Once the gap is closed, any change in pellet dimension is transferred to the cladding. For a power change from 20 to $40 \text{ kW} \cdot \text{m}^{-1}$, the increase in temperatures induces a thermal expansion of about 0.5%, high enough to induce stresses close to or above the yield strength in the cladding. In the presence of iodine, SCC is expected to occur. Indeed iodine, as well as the other halogens, is known to induce such failure mechanisms in Zr and Ti alloys (Fournier et al. 2009; Fregonese et al. 2000; Sidky 1998).

The fracture surfaces are transgranular and consist mostly of large pseudo-cleavage areas along the basal planes, interconnected by fluted walls in which plastic deformation is evident. Thus the relative orientation of the basal plane with respect to the applied tensile stresses is

■ **Figure 46**
Effect of texture on I-SCC (From Schuster et al. 1993)

critical, and the effect of the texture on I-SCC is remarkable (Haddad and Dorado 1994). Constant stress and fracture mechanics tests have indeed shown that when the c -type planes tend to be aligned with the macroscopic crack surface, the susceptibility to SCC increases (Schuster et al. 1993). For cladding tubes, where the tensile stresses are the hoop stresses due to the pellet expansion, the best texture corresponds to a maximum intensity of the c direction in the radial direction (🔍 Fig. 46).

A simple solution to the PCI problem is to reduce the power change rates. Specific procedures have been implemented with success, but the drawback is a loss of power availability. For practical purposes, remedies have been found and tested to avoid PCI-type failures. For BWR's "barrier" fuel rods contain an internal layer of pure recrystallized Zr that is coextruded with the trex and is cold rolled with the base Zircaloy metal to obtain a perfect metallurgical bond.

4.3 Carbon and Graphite

4.3.1 Nuclear Graphite

The physical properties of carbon are of interest for nuclear reactors: Its atomic mass (12) and very low capture cross section (3.3×10^{-3} barn) make it a fairly good candidate for moderation. In addition, its very high temperature behavior (sublimation temperature $\sim 2,500$ K, melting around 4,700 K) allows the use of graphite for high temperature applications. Therefore graphite is used in thermal neutron reactors as moderators or structural components (UNGG, AGR, HTR, RBMK, etc.).

Graphite is the stable form of carbon. It crystallizes in a hexagonal P 63/mmc system, consisting in parallel planes of strongly bound carbon atoms in hexagonal patterns. Within the plane the bounds are covalent hybridized sp^2 links, while between planes interatomic interaction are weaker, similar to Van der Waals bounds. Therefore the graphite crystals exhibit a very high degree of anisotropy (Wang and Zheng 2007): For the thermoelastic properties, a stiff behavior is observed in plane and a soft behavior perpendicular to the hexagonal planes. For instance the interatomic distance is 0.142 nm in the basal plane, while these planes are 0.323 nm apart. The modulus of elasticity is near 1,060 GPa in plane and only 36 GPa perpendicular.

Similarly, the thermal expansion coefficient is $-1.1 \times 10^{-6} \text{ K}^{-1}$ in plane and $26 \times 10^{-6} \text{ K}^{-1}$ perpendicular. Due to the delocalized electrons within the hexagonal planes, thermal and electrical conductivities are also much larger in plane and strongly anisotropic, with differences as large as a factor of 200. Therefore the properties of industrial materials will highly depend on the crystallographic texture of the material. The consequence is that the processing routes will allow, at least partly, controlling and reducing the anisotropy.

The source of graphite for the fabrication of nuclear reactor components is restricted to a synthetic processing obtained by transformation of coke obtained from petroleum or gilsonite heated at 1,300–1,400°C. This gives a high purity for the raw material, compared to natural graphite that would not be suitable for nuclear applications. Specifically sulfur, boron, cobalt, and other neutron absorber have to be strictly controlled (Eu, Gd, Li, etc.). Blended with pitch, the coke is extruded for green shapes, before sintering and cooking at 800°C. The final product is obtained after graphitization obtained during a long treatment at very high temperature (several weeks at 2,800°C). During this process, most of the volatile impurities are removed, the crystal structure is closer to the ideal graphite structure and the density is increased. It remains however low compared to the ideal crystallographic density ($\rho_{\text{ind.}} \sim 1.7\text{--}1.8 \text{ kg} \cdot \text{dm}^{-3}$ and $\rho_{\text{theo.}} \sim 2.26 \text{ kg} \cdot \text{dm}^{-3}$) providing evidence of a sizable remaining porosity.

4.3.2 Behavior Under Irradiation

Under irradiation, damage by atom displacement occurs once the momentum transferred to the pka is above the displacement energy ($E_d \sim 30 \text{ eV}$; Iwata and Nihira 1971). The formation and migration energies of the PD have been evaluated by various means in graphite: The formation energies are high due to the covalent contribution of the bounds in the vicinity of the PD ($E_{\text{fv}} \sim 7.8 \text{ eV}$ and $E_{\text{fi}} 5.5\text{--}7 \text{ eV}$), leading to a high energy of the Frankel pairs ($E_{\text{FrankP}} \sim 14 \text{ eV}$). The interstitials are located between the hexagonal planes that are apart enough to avoid large strains for insertion and they are rather mobiles with migration energies reported between 0.1 and 1.4 eV (Telling et al. 2003). The reason for such large range of values, seems to be connected to the stability of complex clusters of these interstitial (Latham et al. 2008). The development of these clusters of interstitials between the basal planes induces the formation of interstitial dislocation loops and therefore deformations under irradiation in textured materials. For single crystals at low temperatures ($T_{\text{irr}} < 200^\circ\text{C}$), dilations are observed perpendicular to the basal planes, saturating at values as large as 25–30% for doses $> 10^{25} \text{ n} \cdot \text{m}^{-2}$ ($E > 50 \text{ keV}$), while smaller but continuous decrease in the basal directions are observed (Marsden 1995).

Similar to the growth in its mechanism, the irradiation-induced deformation of graphite begins however with a general reduction in dimension parallel and perpendicular to the processing direction, due to a reduction of the processing porosity, followed by an increase in the perpendicular direction above a dose of $1.5\text{--}2 \times 10^{26} \text{ n} \cdot \text{m}^{-2}$ ($E > 50 \text{ keV}$). Reduction in volume by 5% can be observed, followed by swelling up to 5% (► Fig. 47). The actual values are temperature and processing history dependent. For fabrication conditions leading to isotropic textures, reduced irradiation-induced strains and swelling can be obtained (Burchell and Snead 2007). These changes are associated with an increase in elastic stiffness, roughly a factor 2 for irradiation at 500°C, but lower at higher temperatures (50% increase for irradiation at 1,100–1,200°C).

■ Figure 47

Irradiation-induced volume changes for a nuclear graphite at two irradiation temperatures (From Burchell and Snead 2007)

4.3.3 Creep and Wigner Effect

Graphite is known to creep under irradiation. Two contributions on the creep strain are considered and the general equation for graphite creep is the sum of a steady state creep rate, proportional to the irradiation flux, and a transient creep, that has been found to be thermally recoverable (44)

$$\varepsilon_{\text{creep}} = \frac{\sigma}{E_0} \left[\alpha \varphi + \left(1 - e^{-\beta \varphi} \right) \right], \quad (44)$$

where α and β are parameters dependent of the type of graphite (processing) and of the temperature. Typical values of the coefficients for standard irradiation temperatures (150–650°C) are $\alpha \sim 0.20$, $\beta \sim 4$ when the fluence is expressed in $10^{24} \text{ n} \cdot \text{m}^{-2}$ EDN (equivalent DIDO nickel: $\phi \text{ EDN} \sim 0.9 \phi (E > 1 \text{ MeV})$) (Marsden 1995). The irradiation creep could induce deformations equivalent to several times the initial elastic strain.

A minimum creep rate is observed at intermediate temperatures (400–500°C) and the effect of crystallographic texture on the elastic stiffness induces a correlation between creep strain and thermal expansion, both varying in opposite directions (Davies and Bradford 2008).

An important effect of irradiation in graphite is known as the Wigner effect. It corresponds to the increase in concentration in PD and increase of internal energy induced by the build-up of this irradiation damage, and to the kinetics of the release of the corresponding energy during heat treatments: For irradiation below 200°C, any further heat treatment performed 50°C above the irradiation temperature will enhance the mobility of the PD's, allowing their recombination and the release of the corresponding energy of the Frankel pairs. Accumulations of internal energy by formation of PD's higher than $2,600 \text{ J} \cdot \text{g}^{-1}$ have been recorded. Would this energy be released adiabatically, a temperature rise of more than 1,500 K could be reached (Simmons 1965). To avoid such phenomenon to occur, with potential dramatic consequences, scheduled

thermal recoveries of the irradiated structures are programmed along the life of the reactors operating at low temperatures. Careful monitoring of the process is mandatory to avoid uncontrolled evolution of this recovery process. Such unwanted event occurred however in Windscale (UK) in 1957, leading to important release of radioactive materials in the environment (Garland and Wakeford 2007).

4.3.4 Corrosion

Graphite cannot be considered as an inert material in the reactor environment: CO₂, used as coolant in the corresponding reactors, can react with graphite. In HTR and variants using He as coolant, the impurities present in the cooling gas (traces of H₂O, CO₂, H₂, etc.) will also interact with graphite, leading to its corrosion. In addition, uncontrolled contaminations of the coolant by air or cooling water have to be considered during safety analysis.

The kinetics of graphite corrosion depends on its structure and on the temperature (Zherdev et al. 1992; Kelly 1985). Below 500–600°C, the step controlling process is the chemical interaction between the gaseous molecule and the graphite at any free surface. At higher temperature, and up to 1,000°C, the diffusion of gaseous species within the pores of the graphite controls the kinetics. Internal oxidation can then occur with homogeneous degradation of the properties of the component. Above 1,000°C, any gaseous oxidant will react with the carbon atoms of the graphite, and the kinetics of the reaction is only controlled by the supply of oxidant to the surface of component. Then only the external surface reacts and the component shrinks in size by external ablation.

5 Fusion Reactor Materials

5.1 Specific Environment of the Fusion Reactors

For any foreseeable future, the fusion reaction to be considered in any power fusion plants will operate with deuterium and tritium, according to the nuclear reaction:

This equation states the origins of the constraints and difficulties that the fusion reactor environment will apply to the materials. These are due to the production of tritium, and to the presence of high energy neutrons. Due to their high energy, in addition to the irradiation damage described earlier, fusion neutrons induce nuclear reactions at much higher rates than in fission reactors, inducing He and H doping, as well as large changes in composition due to transmutations. This would be the case for tungsten, changing from pure W to a W-Os-Re alloy, with more than 15% of alloying elements after 5 years of 14 MeV neutron irradiation, or Cu to Cu-Ni-Zr, Ta to Ta-W, or V to V-Cr-Ti.

The kinetic energy required for the deuterium and tritium nuclei to interact in a fusion reaction has to be higher than the Columbian repulsive energy. This is obtained within the hot plasma magnetically confined in a device called “Tokomak.” The main components of concern are the plasma facing and high heat flux components, the ³T breeding blanket, the first wall and the blanket structural parts, not forgetting all the numerous diagnostics and electromagnetic control devices.

Since for decades the R&D on fusion was mostly focused on the physical aspects (plasma behavior: heating and stability, superconducting coils, etc.) and performed on devices running far less than 100 h a year, the impact on materials remained limited and irradiation damage and long term behavior of the materials were not limiting. Material aspects have been matters of major research only recently. A consequence is that numerous design options are still open and the selection of alloys, or the class of alloys to develop, for the various components of a fusion device or a common agreement within the scientific community is still under intense international debate and cooperation (Baluc et al. 2007).

5.2 Plasma Facing and High Heat Flux Components

Depending of the location within the reactor, the interaction with the plasma and the heat flux is a strong engineering challenge. The interaction with ions escaping from the plasma leads to surface irradiation damage and sputtering, a phenomenon by which atoms of the surfaces are released when a high energy ion track is crossing the surface (Davis and Haasz 1997). In addition these elements receive a heat flux in the range of $0.5\text{--}10\text{ MW} \cdot \text{m}^{-2}$. For the highest heat fluxes, corresponding to the plasma limiters during incidental conditions, highly conducting alloys are considered, based on Cu, doped with different additions to increase the mechanical strength in temperature (Davis and Kalinin 1998).

5.3 First Wall and the Blanket Structures

For the structural components, such as the first wall and the blanket structures, the high heat and fast neutron fluxes, austenitic SS are considered due to the large data base on their behaviors. If the fast neutrons will induce a displacement damage similar to what obtained in FBR (a few hundred dpa), the high contribution of (n,α) and (n,p) reactions would significantly increase the tendency to swelling. Indeed, for a commercial fusion reactor, He and H production in these alloys could reach 6,000 and 20,000 appm respectively. The ratio of the He production to the irradiation damage is therefore more than 100-fold higher than for fission neutron irradiation, and the simulation of this high He production ratio required specific irradiation devices (Ishino 1996). Since He clusters act as nuclei for cavity nucleation (see ► 4.1.2), a higher tendency to swelling (lower incubation doses) should be expected.

Alloys for long-term development could include ferritic–martensitic steels, vanadium alloys, or SiC/SiC composites. Indeed, a potential interest of the fusion reactors is the lack of radioactive wastes produced by the fuel. Therefore, low or reduced activation materials would be of high interest to confirm fusion as a “clean” energy source.

- Low activation ferritic–martensitic steels should exhibit a low swelling rate and satisfactory high temperature strength. Variant of the standard 9Cr-1Mo alloy (EM10), such as Eurofer 97 or F82H, where Mo has been replaced by W and with minor additions of V and Ta, have shown promising behaviors (Schaaf et al. 2009). ODS variants of these alloys are considered for improvements in creep behavior and reduced swelling tendency.
- Vanadium has a low activation tendency, with short decay and can be used as base metal for low activation structural alloys. Combined with Cr and Ti, as main alloying elements, V-4Cr-4Ti alloys have been developed, with compositions and structures optimized for low

irradiation embrittlement and high creep resistance. In these alloys, minor interstitial elements such as C, O, or N affect significantly the mechanical and structural behavior and their content should sharply be controlled (Kurtz et al. 2004).

- SiC–SiC fiber composites are considered for structural components of the divertor. The low activation of both Si and C, as well as the high temperature potential, would be of interest for the high thermal flux of the divertor. However the sputtering allows C and Si atoms to react with the plasma, forming methane and other hydrocarbons, which can condense in cold spots of the device, trapping H isotopes, including tritium. In case of vacuum vessel leakage, these molecules would oxidize, releasing tritiated water in the environment. The radiological consequences of such process would probably limit the potential use of C or SiC in the future fusion reactors (Rubel 2004).

5.4 Blankets and Tritium Breeding Materials

Since the fusion reaction requires tritium at a rate of about 300 g per day in a standard power plant, the fusion reactor has to produce it at the same rate as it is consumed. This is performed using nuclear reactions by high energy neutrons on Li, according to the reactions:

Due to the unavoidable neutron leakage, the continuous production of tritium at the rate it is burned requires a neutron multiplication procedure. This is obtained, with 14.1 MeV neutrons interacting with Pb or Be, for which a (n,2n) reaction occurs with significant cross section for the fusion neutrons (2 and 0.5 mbarn, respectively for 14.1 MeV neutrons).

Different design options are under consideration for the blankets, either using molten salts (Flibe, i.e., Li_2BeF_4), liquid Li–Pb alloys, or porous ceramics, swept by H_2 and He to extract tritium (Ihli et al. 2009). The radiological constraints associated with tritium handling requires an extraction–purification procedure absolutely leak proof. This technological requirement has to be achieved with consideration of the diffusion of tritium through all the high temperature metallic alloys.

6 Corrosion in Nuclear Environments

In addition to the classical corrosion phenomena observed in any industrial environment, the irradiation affects the corrosion performance of the alloys in many ways:

- Change in the corrosiveness of the environment. As described in [2.4.2](#), radiolysis in the coolant water increases the oxidizing power of the coolant. The impact is drastically evidenced in BWR's, in which numerous cracking of SS components have been reported.
- Formation of new species by nuclear reactions. For instance in fuel elements the fission products can react with the cladding. The process can be either SCC, inducing failure of the Zr alloys due to iodine, or uniform corrosion by a blend of fission products in FBR fuel pins (fuel-cladding chemical interaction) (Götzmann 1979).
- Operation of materials under chemical environment not found in other industries: primary coolant chemistry, liquid metal at high temperatures, etc.

In BWR's, the oxidizing coolant enhances the intergranular corrosion observed in sensitized SS. Numerous failures have been reported in shroud supports, control rod drives, recirculation pipes, etc. To mitigate the SCC mechanisms, actions in the three terms of SCC have been taken: Reduction of residual stresses by heat treatments after welding, grinding, or forming; reduction of sensibility of the alloys by high temperature heat treatments for solution annealing and reduction of the aggressiveness of the environment by additions (Zn injection in noble water chemistry or H₂ injection in HWC). In these environments, the crack propagation rate of SCC, is stress intensity factor dependent and can be expressed as

$$\frac{da}{dt} = 2 \times 10^{-11} K_I^2 \quad (47)$$

where da/dt is obtained in $m \cdot s^{-1}$ for K_I in $MPa \cdot m^{1/2}$.

In PWR's, corrosion in steel is of lower concern for the internals but has been a problem for the steam generators (SG). Initially made of alloy 600, the SG's have been damaged a rate much higher than anticipated by design. Intergranular cracking has been observed on the inner side of the U-bend tubes. This was induced by long incubation period of the SCC in this alloy of low Cr content.

On the secondary coolant side, environment in favor of SCC developed in various locations: denting on tube plates, inducing stresses by oxide swelling or at tube ends where the crevice configurations allowed sludge's rich in magnetite and silica to form, inducing the development of complex corrosive chemistries (NaOH, KOH, S-bearing species, carbonates, and degradation products of the resins, etc.). Design and material changes of the tube plates suppressed the denting and special procedures for swaging of the SG tubes to the tube support plate allowed to reduce the residual stresses; regular sludge lance cleaning helped in controlling the local chemistry and high Cr content alloys were used to design SG of extended operational life.

More impressive, corrosion problems induced by various leaks of primary water occurred in PWR's. The primary coolant contains boric acid: Due to leaks near the welds or due to cracking of control rod vessel penetration nozzles by SCC, primary water went in contact with the structural steel, inducing classical uniform corrosion by concentrated boric acid solution (Beznau-1, Switzerland, 1971; D. Besse, Ohio 1998–2002, etc.). Major corrosion occurred, leading to mandatory changes of the pressure vessel closing heads in numerous power plants (<http://www.nrc.gov/reactors/operating/ops-experience/vessel-head-degradation.html>). Other cases of corrosion can be found in dedicated reports. They also concern the nonnuclear parts of the plants.

7 Prospects

As in any industry, the performances of the materials used in the nuclear reactors are of uppermost importance for a sustainable operation and confidence. With that respect, the industrial operation of nuclear plants adds very severe conditions, compared to the other industrial fields. In addition to the irradiation, which is very specific to this industry and cannot be avoided to test any new alloy, the nuclear industry has two other specificities: First, due to long decay of some of the radioactive materials produced by irradiation, the behavior of the materials has to be analyzed at time scales far behind common practices; second, the dramatic consequences of potential failure requires a level of reliability only shared with the aerospace industry.

The phenomena of irradiation damage and irradiation-induced changes in behaviors are fairly well understood, at least qualitatively, and in many cases quantitatively. If the actual behaviors of alloys are not always predictable from theory, the large body of experimental testing and industrial feedback is sound enough for a safe design and operation of the industrial units.

However the material science is a science of complexity. Any industrial alloy contains 10–15 species and the microstructures, for a given composition, can be very different according to processing histories. The behavior itself is also depending of the thermomechanical loadings and of the irradiation histories. Bifurcations in behavior have been observed and care should be taken in fast screening tests. The experimental testing of these materials is becoming unfortunately more and more difficult and expensive, due to regulatory restrictions and reduced availability of material testing reactors and hot cells. In addition, irradiations cannot always be accelerated without loss of confidences. Therefore the nuclear material R&D has long experiment and testing cycles. Typically 10 years are required between the melting of a new alloy, its irradiation, analysis in hot cells, detailed results and their interpretations of the improvement of the leading composition, and a new cycle.

Therefore the current development of computational material science is a major opportunity for in depth understanding and forecasting of the mechanisms of irradiation damage under irradiation. In that direction multiscale modeling is particularly suited to nuclear materials. The scientific community of nuclear materials has already started to include these tools in their standard research methodologies. Improvements in the computations capabilities should allow extending these results, obtained on model alloys, to complex industrial alloys. One expectation would be to propose, using these techniques, nuclear grade variants of the alloys used in nonnuclear industry or to improve the ones already known, for a better behavior or extended design life. The current international reactivation of the nuclear projects is expecting important progresses in materials for more efficient and reliable plants that would require such efficient approaches.

List of Acronyms

AIC	Silver-indium-cadmium alloy for control rods
CW	Cold worked
DBTT	Ductile–brittle transition temperature
FBR	Fast breeder reactor
FIMA	Fission per initial metallic atom
GB	Grain boundary
HWC	Hydrogen water chemistry
IASCC	Irradiation-assisted stress corrosion cracking
LET	Linear energy deposition rate (radiolysis)
LHGR	Linear heat generation rate (fuel rod power)
LWR	Light water reactor
MD	Molecular dynamics
MTR	Material testing reactor
NDE	Nondestructive examination

PCI	Pellet cladding interaction
PD	Point defect
pka	Primary knock-on atom
RIC	Radiation-induced conductivity
RIED	Radiation-induced electrical degradation
RIS	Radiation-induced segregation
RPV	Reactor pressure vessel
RT_{NDT}	Reference temperature for nil ductility transition
SCC	Stress corrosion cracking
SFR	Sodium-cooled fast neutron reactor
SG	Steam generator
SIPA	Stress-induced preferential absorption (creep)
SS	Stainless steel
TREX	Tube-reduced extrusions (Zr fuel cladding processing)
WPS	Warm pre-stress

Appendix

Industrial Steels for Reactor Design

► *Tables A1–A3* are given for general information and orders of magnitudes. The compositions given correspond to the standard values. For design, actual values of composition and mechanical properties have to be verified and to fulfill the requirements of the classical design codes, such as ASME or RCCM, and be approved by the regulatory bodies having domestic authority.

Abstract: This chapter intends to provide a ready reference to mathematical concepts and tools customarily used in nuclear science and engineering, thus facilitating the reading of the other chapters in this handbook. The material presented in this chapter addresses the mathematical requisites at the graduate level in nuclear engineering, summarizing the following topics: vectors and vector spaces, matrices and matrix methods, linear operators and their adjoints in finite and infinite dimensional vector spaces, differential calculus in vector spaces, optimization, least squares estimation, special functions of mathematical physics, integral transforms, and probability theory. A list of suggested textbooks, covering many of the details omitted in this chapter, is provided in the Bibliography Section.

1 Finite-Dimensional Vector Spaces

1.1 Vectors: Definitions and Operations

A *number field* \mathcal{F} is defined as an arbitrary collection of numbers within which the four operations of addition, subtraction, multiplication, and division by a nonzero number can always be carried out. Examples of number fields are the set of all integer numbers, the set of all rational numbers, the set of all real numbers, and the set of all complex numbers.

Vectors: Let \mathbb{R} denote the set of all *real* numbers. A *real row vector* \mathbf{x} is an ordered m -tuple of real numbers (x_1, x_2, \dots, x_m) arranged in a row $\mathbf{x} = (x_1, x_2, \dots, x_m)$. The term x_i is called the i^{th} -*component* or the *coordinate* (with respect to the standard coordinate system) of the row vector \mathbf{x} of *size* or *order* or *dimension* m . The *column vector* $\mathbf{x} = (x_1, x_2, \dots, x_m)^T$ is obtained by transposing a row vector; in this context, “ T ” denotes transposition. By convention, the vectors considered in this chapter are column vectors (unless specified otherwise), and \mathbb{R}^m denotes the *set of all m -dimensional real column vectors*. The *null* or *zero* vector is the vector with all components zero, and is denoted by $\mathbf{0}$. A *real scalar* is defined as a real vector having just one component. Similarly, \mathbb{C} denotes the set of all *complex* numbers, and \mathbb{C}^m denotes the set of all complex vectors of size m .

Operations on vectors: Consider the vectors $\mathbf{x} = (x_1, x_2, \dots, x_m)^T$, $\mathbf{y} = (y_1, y_2, \dots, y_m)^T$ and $\mathbf{z} = (z_1, z_2, \dots, z_m)^T$, together with the real scalars a , b , and c . The component-wise *sum* or *addition* of vectors is defined as $\mathbf{z} = \mathbf{x} + \mathbf{y}$, where $z_i = x_i + y_i$ for $i = 1, \dots, m$. The *vector difference* is also defined similarly. The *scalar multiplication* of a vector \mathbf{x} by a real number a is defined as $\mathbf{z} = a\mathbf{x}$, where $z_i = ax_i$, for $i = 1, \dots, m$.

Linear vector space: A *set* or a *collection*, \mathcal{V} , of real vectors of size m is called a (*linear*) *vector space* if the following conditions are fulfilled:

- (a) $\mathbf{x} + \mathbf{y} \in \mathcal{V}$ whenever $\mathbf{x}, \mathbf{y} \in \mathcal{V}$; \mathcal{V} is *closed* under addition.
- (b) $(\mathbf{x} + \mathbf{y}) + \mathbf{z} = \mathbf{x} + (\mathbf{y} + \mathbf{z})$; addition is *associative*.
- (c) $\mathbf{x} + \mathbf{y} = \mathbf{y} + \mathbf{x}$; addition is *commutative*.
- (d) \mathcal{V} contains the null vector $\mathbf{0}$ and $\mathbf{x} + \mathbf{0} = \mathbf{0} + \mathbf{x} = \mathbf{x}$.
- (e) For every \mathbf{x} , there is a *unique* \mathbf{y} in \mathcal{V} such that $\mathbf{x} + \mathbf{y} = \mathbf{y} + \mathbf{x} = \mathbf{0}$; \mathbf{y} is called the (*additive*) *inverse* of \mathbf{x} and is denoted by $-\mathbf{x}$.
- (f) $a\mathbf{x}$ is in \mathcal{V} if \mathbf{x} is in \mathcal{V} ; \mathcal{V} is closed under *scalar* multiplication.
- (g) $a(b\mathbf{x}) = (ab)\mathbf{x}$, for all $\mathbf{x} \in \mathcal{V}$, and $a, b \in \mathbb{R}$.
- (h) $1(\mathbf{x}) = \mathbf{x}$, where 1 is the real number 1, for all $\mathbf{x} \in \mathcal{V}$.
- (i) $a(\mathbf{x} + \mathbf{y}) = a\mathbf{x} + a\mathbf{y}$; *distributivity*.
- (j) $(a + b)\mathbf{x} = a\mathbf{x} + b\mathbf{x}$; *distributivity*.

The space \mathcal{V} is called a complex vector space if the scalar field is the set of all complex numbers, \mathbb{C} , or a real vector space if the scalar field is the set of all real numbers, \mathbb{R} . The members \mathbf{x} , \mathbf{y} , and \mathbf{z} of \mathcal{V} are called points, elements, or vectors depending on the respective context. If there exists a positive integer n such that \mathcal{V} contains n , but not $n + 1$ linearly independent vectors, then \mathcal{V} is said to be *finite dimensional* with dimension n ; \mathcal{V} is *infinite dimensional* if and only if (iff) it is not finite dimensional. The *finite-dimensional vector space of dimension n* is denoted by \mathbb{R}^n , for every $n \geq 1$. The finite set \mathcal{S} of vectors in an n -dimensional space \mathcal{V} is called a *basis* of \mathcal{V} iff \mathcal{S} is linearly independent, and each element of \mathcal{V} may be written as $\sum_1^n \alpha_j \mathbf{x}_j$ for some $\alpha_1, \dots, \alpha_n \in \mathbb{C}$ and $\mathbf{x}_1, \dots, \mathbf{x}_n \in \mathcal{S}$. An infinite-dimensional space is obtained by generalizing \mathbb{R}^n or \mathbb{C}^n , and taking infinite sequences $\mathbf{x} = (\mathbf{x}_n)$ as the elements of the space. This space is known as a *sequence space* and is usually denoted by ℓ .

For an infinite sequence $\mathbf{x} = \{x_0, x_1, x_2, \dots\}$, such that $\sum_{i=0}^{\infty} x_i^2 < \infty$, the sequence \mathbf{x} is called *square summable*. The set of all square summable sequences is denoted by l_2 , and constitutes a vector space under component-wise addition and scalar multiplication.

Consider that \mathcal{S} is a subset of \mathcal{V} , and define its complement \mathcal{V}/\mathcal{S} as the set of all elements in \mathcal{V} that do not belong to \mathcal{S} . Next, define a new subset $\bar{\mathcal{S}} \subset \mathcal{V}$, called the closure of \mathcal{S} , by requiring that $\mathbf{x} \in \bar{\mathcal{S}}$ iff there is a sequence of (not necessarily distinct) points of \mathcal{S} converging to \mathbf{x} . The set \mathcal{S} is called closed iff $\mathcal{S} = \bar{\mathcal{S}}$. A subset \mathcal{S} of \mathcal{V} is said to be open iff its complement \mathcal{V}/\mathcal{S} is closed. If $\mathcal{S}_1 \subset \mathcal{S}_2 \subset \mathcal{V}$, then \mathcal{S}_1 is said to be *open* in \mathcal{S}_2 iff it is the intersection of an open set with \mathcal{S}_2 . A *neighborhood* of a point is any set that contains an open set that itself contains the point. A point \mathbf{x} is an *interior point* of $\mathcal{S} \subset \mathcal{V}$ iff there is a neighborhood of \mathbf{x} contained in \mathcal{S} . The *interior* \mathcal{S}° of \mathcal{S} is the set of interior points of \mathcal{S} (and is open). A point \mathbf{x} is a *boundary point* of \mathcal{S} iff every neighborhood of \mathbf{x} contains points of both \mathcal{S} and its complement \mathcal{V}/\mathcal{S} . The *boundary* $\partial\mathcal{S}$ of \mathcal{S} is the set of boundary points of \mathcal{S} .

Inner Product: The *inner* or *scalar* product of two vectors \mathbf{x} and \mathbf{y} in \mathbb{R}^m , denoted by $\langle \mathbf{x}, \mathbf{y} \rangle$ and/or $\mathbf{x}^T \mathbf{y}$, is defined as

$$\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{x}^T \mathbf{y} = \sum_{i=1}^m x_i y_i = \sum_{i=1}^m y_i x_i = \mathbf{y}^T \mathbf{x} = \langle \mathbf{y}, \mathbf{x} \rangle$$

and satisfies the following properties:

- Positive definite:* $\langle \mathbf{x}, \mathbf{y} \rangle > 0$ if $\mathbf{x} \neq \mathbf{0}$; $\langle \mathbf{x}, \mathbf{y} \rangle = 0$ if and only if $\mathbf{x} = \mathbf{0}$.
- Commutative:* $\langle \mathbf{x}, \mathbf{y} \rangle = \langle \mathbf{y}, \mathbf{x} \rangle$.
- Additive:* $\langle \mathbf{x} + \mathbf{y}, \mathbf{z} \rangle = \langle \mathbf{x}, \mathbf{z} \rangle + \langle \mathbf{y}, \mathbf{z} \rangle$.
- Homogeneous:* $\langle a\mathbf{x}, \mathbf{y} \rangle = a \langle \mathbf{x}, \mathbf{y} \rangle = \langle \mathbf{x}, a\mathbf{y} \rangle$.

If $\langle \mathbf{x}, \mathbf{z} \rangle = \langle \mathbf{y}, \mathbf{z} \rangle$ for \mathbf{x} , \mathbf{y} , \mathbf{z} in \mathbb{R}^m , then $\mathbf{x} = \mathbf{y}$. When \mathbf{x} and \mathbf{y} are *complex vectors*, then the inner product is defined as $\langle \mathbf{x}, \mathbf{y} \rangle = \sum_{i=1}^m x_i \bar{y}_i$ where \bar{y}_i is the complex conjugate of y_i .

Outer Product: The *outer product* of \mathbf{x} and \mathbf{y} in \mathbb{R}^m is denoted by $\mathbf{x}\mathbf{y}^T$ and is defined as the $m \times m$ matrix

$$\begin{aligned} \mathbf{x}\mathbf{y}^T &= \begin{pmatrix} x_1 \\ x_2 \\ \dots \\ x_m \end{pmatrix} (y_1, y_2, \dots, y_m) = [\mathbf{x}y_1, \mathbf{x}y_2, \dots, \mathbf{x}y_m] = \begin{bmatrix} x_1\mathbf{y}^T \\ x_2\mathbf{y}^T \\ \dots \\ x_m\mathbf{y}^T \end{bmatrix} \\ &= \begin{bmatrix} x_1y_1 & x_1y_2 & \dots & x_1y_m \\ x_2y_1 & x_2y_2 & \dots & x_2y_m \\ \vdots & \vdots & \vdots & \vdots \\ x_my_1 & x_my_2 & \dots & x_my_m \end{bmatrix}. \end{aligned}$$

Norm: The *norm* of a vector $\mathbf{x} \in \mathbb{R}^m$, denoted by $\|\mathbf{x}\|$, is a nonnegative real scalar that indicates the size or the length of the vector \mathbf{x} , and satisfies the following properties:

1. *Positive definite:* $\|\mathbf{x}\| > 0$ if $\mathbf{x} \neq \mathbf{0}$; $\|\mathbf{x}\| = 0$ if $\mathbf{x} = \mathbf{0}$.
2. *Homogeneous:* $\|a\mathbf{x}\| = |a| \|\mathbf{x}\|$.
3. *Triangle inequality:* $\|\mathbf{x} + \mathbf{y}\| \leq \|\mathbf{x}\| + \|\mathbf{y}\|$.

A vector space \mathcal{V} endowed with a norm as defined above is called a *normed* vector space. For finite dimensional spaces, the most frequently used vector norm is the *Hölder* or ℓ_p -*norm*, defined as

$$\|\mathbf{x}\|_p = \left(\sum_{i=1}^n |x_i|^p \right)^{1/p}, \quad p > 0.$$

The most frequently used norms are

- (a) *Euclidian or 2-norm* $\|\mathbf{x}\|_2 = \sqrt{\sum_{i=1}^n |x_i|^2}$; note that $\|\mathbf{x}\|_2^2 = \langle \mathbf{x}, \mathbf{x} \rangle = \mathbf{x}^T \mathbf{x}$.
- (b) *Manhattan or 1-norm* $\|\mathbf{x}\|_1 = \sum_{i=1}^m |x_i|$.
- (c) *Chebyshev or ∞ -norm* $\|\mathbf{x}\|_\infty = \max_i |x_i|$.
- (d) *Energy norm* $\|\mathbf{x}\|_A = \langle \mathbf{x}, A\mathbf{x} \rangle^{1/2} = (\mathbf{x}^T A \mathbf{x})^{1/2}$, where $A \in \mathfrak{R}^{m \times m}$ is a *real, symmetric and positive definite* matrix.

Note that the 2-norm satisfies the *parallelogram identity*

$$\|\mathbf{x} + \mathbf{y}\|_2^2 + \|\mathbf{x} - \mathbf{y}\|_2^2 = 2(\|\mathbf{x}\|_2^2 + \|\mathbf{y}\|_2^2).$$

If the length of a vector \mathbf{x} is finite in one norm and is also finite in another norm, the two norms are said to be *equivalent*. The 2-norm, 1-norm, and ∞ -norm are all equivalent, and are related through the following inequalities: $\|\mathbf{x}\|_2 \leq \|\mathbf{x}\|_1 \leq \sqrt{n} \|\mathbf{x}\|_2$; $\|\mathbf{x}\|_\infty \leq \|\mathbf{x}\|_2 \leq \sqrt{n} \|\mathbf{x}\|_\infty$; $\|\mathbf{x}\|_\infty \leq \|\mathbf{x}\|_1 \leq n \|\mathbf{x}\|_\infty$.

The *distance* between two vectors \mathbf{x} and \mathbf{y} , denoted by $d(\mathbf{x}, \mathbf{y})$, is defined as $d(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|$. In particular, the \mathbb{R}^n -space endowed with the 2-norm is called the *finite-dimensional Euclidean space*. The *unit vector*, $\hat{\mathbf{x}}$, in the direction of \mathbf{x} , $\mathbf{x} \in \mathbb{R}^m$, is given by $\hat{\mathbf{x}} = \mathbf{x} / \|\mathbf{x}\|_2 = (\hat{x}_1, \hat{x}_2, \dots, \hat{x}_m)^T$, where the components \hat{x}_i are called the *direction cosines* (the cosine of the angle made by the vector \mathbf{x} with respect to the i^{th} -coordinate axis, for $i = 1, \dots, m$). If p and q are such that $1/p + 1/q = 1$, then the *Minkowski inequality* $\mathbf{x}^T \mathbf{y} \leq \|\mathbf{x}\|_p \|\mathbf{y}\|_q$ holds; The special case $p = q = 2$ is called the *Cauchy-Schwartz inequality*:

$$\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{x}^T \mathbf{y} = \|\mathbf{x}\|_2 \|\mathbf{y}\|_2 \cos \theta \leq \|\mathbf{x}\|_2 \|\mathbf{y}\|_2; \quad \theta \text{ is the angle between } \mathbf{x} \text{ and } \mathbf{y}.$$

Assuming that the basic operations – *add, subtract, multiply, divide* and *compare*, take an equal amount of time that is taken as the unit of time, the number of *floating point operations (FLOP)* for the various vector operations are as follows: vector sum/difference (m FLOPs); scalar times a vector (m FLOPs); inner product ($2m-1$ FLOPs); outer product (m^2 FLOPs); 2-norm squared ($2m-1$ FLOPs).

Orthogonality: two vectors \mathbf{x} and \mathbf{y} are called *orthogonal*, and denoted as $\mathbf{x} \perp \mathbf{y}$, if their inner product is zero:

$$\mathbf{x} \perp \mathbf{y} \text{ if } \langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{x}^T \mathbf{y} = 0.$$

In a set of n vectors, $\mathcal{S} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n\}$, $\mathbf{x}_i \in \mathbb{R}^m$, the respective vectors are called *mutually orthogonal* if they are pairwise orthogonal, i. e.,

$$\langle \mathbf{x}_i, \mathbf{x}_j \rangle = \mathbf{x}_i^T \mathbf{x}_j = \begin{cases} 0, & \text{for } i \neq j, \\ \|\mathbf{x}_i\|_2, & \text{for } i = j. \end{cases}$$

If the vectors in \mathcal{S} are also normalized to have unit length, then \mathcal{S} is called an *orthonormal* set.

Conjugacy Two vectors \mathbf{x} and \mathbf{y} in \mathbb{R}^m are called *A-conjugate* if $\langle \mathbf{x}, \mathbf{A}\mathbf{y} \rangle = \mathbf{x}^T \mathbf{A}\mathbf{y} = 0$, where $\mathbf{A} \in \mathbb{R}^{m \times m}$ is a *symmetric positive definite matrix*. Similarly, a set of n vectors, $\mathcal{S} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n\}$, $\mathbf{x}_i \in \mathbb{R}^m$, is called *A-conjugate* if

$$\langle \mathbf{x}_i, \mathbf{A}\mathbf{x}_j \rangle = \begin{cases} 0, & \text{for } i \neq j, \\ \mathbf{x}_i^T \mathbf{A}\mathbf{x}_i = \|\mathbf{x}_i\|_A^2, & \text{for } i = j. \end{cases}$$

Linear combination: The vector \mathbf{y} , defined as $\mathbf{y} = a_1\mathbf{x}_1 + a_2\mathbf{x}_2 + \dots + a_n\mathbf{x}_n$, where $\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{im})^T$ are vectors in a set $\mathcal{S} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n\}$, $\mathbf{x}_i \in \mathbb{R}^m$, and where a_1, a_2, \dots, a_n denote scalars, is called a *linear combination* of vectors in \mathcal{S} . If this linear combination is zero when *not all* the scalars a_i are zero, then the vectors in \mathcal{S} are said to be *linearly dependent*. On the other hand, if \mathbf{y} is zero only when all the scalars a_i are zero, then the vectors in \mathcal{S} are called *linearly independent*.

Span and subspace: The *span* of a set $\mathcal{S} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n\}$, $\mathbf{x}_i \in \mathbb{R}^m$, denotes the set of all linear combination of vectors in \mathcal{S} , i.e., $\text{Span}(\mathcal{S}) = \{\mathbf{y} | \mathbf{y} = \sum_{i=1}^n a_i \mathbf{x}_i, a_i \in \mathbb{R}^m\}$. $\text{Span}(\mathcal{S})$ is a linear vector space (generated by vectors in \mathcal{S}) called the *subspace* of \mathbb{R}^m , i.e., $\text{Span}(\mathcal{S}) \subseteq \mathbb{R}^m$. The null vector $\mathbf{0}$ belongs to $\text{Span}(\mathcal{S})$; furthermore, the set $\{\mathbf{0}\}$, consisting of all null vector, is also a subspace of \mathbb{R}^m , called the *trivial subspace*.

Basis and dimension: Consider that \mathcal{V} is a vector space and \mathcal{S} is a subset of linearly independent vectors in \mathcal{V} . If every vector in \mathcal{V} can be uniquely expressed as a linear combination of those in \mathcal{S} , then \mathcal{S} is called a *basis* for \mathcal{V} . The number of linearly independent vectors in \mathcal{S} is called the *dimension* of \mathcal{V} , denoted by $\text{Dim}(\mathcal{V})$. If the vectors of \mathcal{S} are orthogonal (orthonormal), then \mathcal{S} is called an orthogonal (orthonormal) *basis* for \mathcal{V} .

Standard unit vectors and basis: the set $\mathcal{S} = \{\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_m\}$, where $\mathbf{e}_i = (0, 0, \dots, 1, 0, \dots, 0)^T \in \mathbb{R}^m$ is a vector with 1 as its i^{th} -element, is called the *standard basis* for \mathbb{R}^m ; the vector \mathbf{e}_i is called the *standard unit vector* for \mathbb{R}^m . Any vector $\mathbf{x} = (x_1, x_2, \dots, x_m)^T$ in \mathbb{R}^m can be written as $\mathbf{x} = \{x_1\mathbf{e}_1, x_2\mathbf{e}_2, \dots, x_m\mathbf{e}_m\}$; the scalar x_i is called the i^{th} -coordinate of \mathbf{x} .

Direct sum and orthogonal complement: Consider two vector spaces, \mathcal{V}_1 and \mathcal{V}_2 . If every vector in \mathcal{V}_1 is also a vector in \mathcal{V}_2 , but *not* vice versa, then \mathcal{V}_1 is called the *proper subspace* of \mathcal{V}_2 , and is denoted by $\mathcal{V}_1 \subset \mathcal{V}_2$. The following relation holds: $\text{Dim}(\mathcal{V}_1 \cup \mathcal{V}_2) = \text{Dim}(\mathcal{V}_1) + \text{Dim}(\mathcal{V}_2) - \text{Dim}(\mathcal{V}_1 \cap \mathcal{V}_2)$. Consider now that $\mathcal{S} \subset \mathcal{V}$ is a subspace of a vector space \mathcal{V} . The set \mathcal{S}^\perp of all vectors in \mathcal{V} that are orthogonal to those in \mathcal{S} is called the *orthogonal complement* of \mathcal{S} in \mathcal{V} . The following relation holds: $\mathcal{V} = \mathcal{S} \oplus \mathcal{S}^\perp$, an operation called the *direct sum* of \mathcal{S} and \mathcal{S}^\perp . Note that $\mathcal{S} \cap \mathcal{S}^\perp = \{\mathbf{0}\}$ and $\text{Dim}(\mathcal{V}) = \text{Dim}(\mathcal{S}) + \text{Dim}(\mathcal{S}^\perp)$.

Completion theorem: Consider that $\mathcal{S}_1 = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n\}$ is a set of n linearly independent vectors in a vector space \mathcal{V} of dimension $m, n < m$. Then there exists a set $\mathcal{S}_2 = \{\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_{m-n}\}$ of linearly independent vectors (distinct from \mathcal{S}_1), such that $\mathcal{S} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n, \mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_{m-n}\}$ is a set of m linearly independent vector that constitutes a basis for \mathcal{V} .

Projection of a vector: Consider a *unit vector* $\mathbf{h} \in \mathbb{R}^m$ together with an arbitrary vector $\mathbf{z} \in \mathbb{R}^m$; the vector $(\mathbf{z}^T \mathbf{h}) \mathbf{h}$ is the representation of \mathbf{z} in the direction \mathbf{h} and is called the *projection of \mathbf{z} onto \mathbf{h}* . The inner product $\mathbf{z}^T \mathbf{h}$ is called the magnitude of the projection of \mathbf{z} onto the direction of \mathbf{h} . Consider next that \mathcal{S} is a subspace of a vector space \mathcal{V} . For any vector $\mathbf{z} \in \mathcal{V}$, the norm $\|\mathbf{z} - \mathbf{z}^*\|_2$, with $\mathbf{z}^* \in \mathcal{S}$, is minimized exactly when the vector $(\mathbf{z} - \mathbf{z}^*)$ is orthogonal to \mathcal{S} . Such a vector \mathbf{z}^* is called the *orthogonal projection* of \mathbf{z} onto \mathcal{S} .

Bessel's inequality and Parseval's identity: Consider that $\mathcal{S} = \{\mathbf{h}_1, \mathbf{h}_2, \dots, \mathbf{h}_n\}$ is an orthonormal set of vectors in \mathbb{R}^m . The vector $\mathbf{z}^* = (\mathbf{z}^T \mathbf{h}_1) \mathbf{h}_1 + (\mathbf{z}^T \mathbf{h}_2) \mathbf{h}_2 + \dots + (\mathbf{z}^T \mathbf{h}_n) \mathbf{h}_n$ is called the projection of the vector $\mathbf{z} \in \mathbb{R}^m$ onto \mathcal{S} . The vector $(\mathbf{z} - \mathbf{z}^*)$ is *orthogonal* to \mathcal{S} , and *Bessel's inequality* $\sum_{i=1}^n (\mathbf{z}^T \mathbf{h}_i)^2 \leq \|\mathbf{z}\|^2$ holds. If the orthonormal set \mathcal{S} is such that $\sum_{i=1}^n (\mathbf{z}^T \mathbf{h}_i)^2 = \|\mathbf{z}\|^2$, then \mathcal{S} is called a *complete orthonormal set*, and this relation is called *Parseval's identity*.

Fourier expansion: The representation of a vector $\mathbf{z} \in \mathbb{R}^m$ in the form

$$\mathbf{z} = \sum_{i=1}^m (\mathbf{z}^T \mathbf{h}_i) \mathbf{h}_i,$$

where $\mathcal{S} = \{\mathbf{h}_1, \mathbf{h}_2, \dots, \mathbf{h}_m\}$ is any complete orthonormal basis, is called the *Fourier expansion* of \mathbf{z} ; the inner products $(\mathbf{z}^T \mathbf{h}_i)$ are called the *Fourier coefficients*. The right-side of the above representation is called the *spectral expansion* of \mathbf{z} . Parseval's identity indicates that the total energy in any representation remains unchanged when \mathcal{S} is a complete orthonormal basis.

1.2 Matrices: Basic Definitions and Properties

A *number field* \mathcal{F} is defined as an arbitrary collection of numbers within which the four operations of addition, subtraction, multiplication, and division by a nonzero number can always be carried out. Examples of number fields are the set of all integer numbers, the set of all rational numbers, the set of all real numbers, and the set of all complex numbers.

A rectangular array of numbers of the field \mathcal{F} , composed of m rows and n columns

$$\mathbf{A} = \begin{pmatrix} a_{11} & a_{12} \cdots a_{1n} \\ a_{21} & a_{22} \cdots a_{2n} \\ \dots & \dots \\ a_{m1} & a_{m2} \cdots a_{mn} \end{pmatrix}$$

is called a *rectangular matrix* of dimension $m \times n$. The numbers $a_{ij}, (i = 1, 2, \dots, m; j = 1, 2, \dots, n)$; are called the elements of \mathbf{A} . The set of all real $m \times n$ matrices is denoted by $\mathbb{R}^{m \times n}$. When $m = n$, the matrix \mathbf{A} is called square and the number m , equal to n , is called the order of \mathbf{A} . The *null* or *zero* matrix has all of its elements zero. The order of the subscripts is important in the double-subscript notation for the elements a_{ij} : the first subscript, i , denotes the row, while the second subscript, j , denotes the column containing the given element. The set of elements $(a_{11}, a_{22}, \dots, a_{mm})$ is called the *principal or main diagonal* of \mathbf{A} . Diagonals parallel to this principal diagonal and *above* (*below*) the main diagonal are called *super* (*sub*) diagonals. Often, the notation for the matrix defined above is abbreviated as

$$\mathbf{A} = (a_{ij}), (i = 1, 2, \dots, m, j = 1, 2, \dots, n),$$

or simply \mathbf{A} , when its elements and dimensions are understood from context.

A *column matrix* is a rectangular matrix consisting of a single column,

$$\begin{pmatrix} x_1 \\ x_2 \\ \dots \\ x_n \end{pmatrix},$$

while a *row matrix* is a rectangular matrix consisting of a single row,

$$(a_1, a_2, \dots, a_n).$$

A *diagonal matrix*, \mathbf{D} , is a square matrix with zero off-diagonal elements: $a_{ij} = 0$, for $i \neq j$. Note that the diagonal elements $a_{ii} = d_i$ may (or may not) be different from 0. Note also that $\mathbf{D} = (d_i \delta_{ik})$, where (δ_{ik}) is the Kronecker symbol,

$$\delta_{ik} = \begin{cases} 1, & i = k, \\ 0, & i \neq k. \end{cases}$$

A *unit (or identity) matrix*, \mathbf{I} , is a diagonal matrix with $a_{ii} = 1$, for all i , i.e., $\mathbf{I} = (\delta_{ik})$. A *zero matrix*, $\mathbf{0}$, is a matrix with all its elements zero. A *lower triangular matrix* is a matrix with elements $a_{ij} = 0$, for $i < j$, while an *upper triangular matrix* is a matrix with elements $a_{ij} = 0$, for $i > j$. Two matrices \mathbf{A} and \mathbf{B} are said to be equal if their corresponding elements are equal, i.e., if $a_{ij} = b_{ij}$, for all $i = 1, \dots, m$ and $j = 1, \dots, n$. The *transpose* \mathbf{A}^T of a matrix $\mathbf{A} = (a_{ik})$, ($i = 1, 2, \dots, m; k = 1, 2, \dots, n$), is defined as $\mathbf{A}^T = (a_{ki})$, ($i = 1, 2, \dots, m; k = 1, 2, \dots, n$). The following properties of the operation of transposition are often encountered in applications: $(\mathbf{A} + \mathbf{B})^T = \mathbf{A}^T + \mathbf{B}^T$, $(a\mathbf{A})^T = a\mathbf{A}^T$, $(\mathbf{AB})^T = \mathbf{B}^T \mathbf{A}^T$. A square matrix \mathbf{S} that coincides with its transpose, i.e., $a_{ij} = a_{ji}$, for all i, j , is called a *symmetric matrix*. A *skew-symmetric matrix* is a matrix with elements $a_{ij} = -a_{ji}$, for all i, j . A *hermitian matrix* is a matrix with elements $a_{ij} = \bar{a}_{ji}$, for all i, j ; here, the overbar denotes complex conjugation. This definition implies that the diagonal elements of a hermitian matrix are real. A *skew-hermitian matrix* is a matrix with elements $a_{ij} = -\bar{a}_{ji}$, for all i, j ; this definition indicates that the diagonal elements of a skew-hermitian matrix are purely imaginary.

Linear transformation: If m quantities y_1, y_2, \dots, y_m have linear and homogeneous expressions in terms of n other quantities x_1, x_2, \dots, x_n such that

$$\left. \begin{aligned} y_1 &= a_{11}x_1 + a_{12}x_2 + \dots + a_{1n}x_n \\ y_2 &= a_{21}x_1 + a_{22}x_2 + \dots + a_{2n}x_n \\ &\dots\dots\dots \\ y_m &= a_{m1}x_1 + a_{m2}x_2 + \dots + a_{mn}x_n \end{aligned} \right\},$$

then the transformation of the quantities x_1, x_2, \dots, x_n into the quantities y_1, y_2, \dots, y_m by means of the above formulas is called a *linear transformation*. The coefficients of the above transformation form the rectangular matrix of dimension $m \times n$. Note that this linear transformation determines the corresponding matrix uniquely, and vice versa.

Operations on matrices: The basic operations on matrices are: *addition (summation)* of matrices, *scalar multiplication of a matrix by a number*, and *multiplication* of matrices. Thus,

the *sum/difference* of two rectangular matrices $\mathbf{A} = (a_{ik})$ and $\mathbf{B} = (b_{ik})$, both of dimension $m \times n$, is the matrix $\mathbf{C} = (c_{ik})$, of the same dimension, whose elements are

$$\mathbf{C} = \mathbf{A} \pm \mathbf{B}, \text{ with } c_{ik} = a_{ik} \pm b_{ik}, (i = 1, \dots, m, \text{ and } k = 1, \dots, n).$$

The matrix addition of arbitrary rectangular matrices of equal dimensions is commutative and associative: $\mathbf{A} + \mathbf{B} = \mathbf{B} + \mathbf{A}$, and $(\mathbf{A} + \mathbf{B}) + \mathbf{C} = \mathbf{A} + (\mathbf{B} + \mathbf{C})$.

The *scalar multiplication* of a matrix $\mathbf{A} = (a_{ik})$ by a number β of \mathcal{F} is the matrix $\mathbf{C} = (c_{ik})$ such that

$$\mathbf{C} = \beta \mathbf{A}, \text{ with } c_{ik} = \beta a_{ik}, (i = 1, \dots, m, \text{ and } k = 1, \dots, n).$$

The *matrix-vector product* is defined as $\mathbf{A}\mathbf{x} = \mathbf{y}$, where the i^{th} -element of \mathbf{y} is defined to be the *inner product* of the i^{th} -row of \mathbf{A} with \mathbf{x} , i.e., $y_i = \sum_{j=1}^n a_{ij}x_j$ for $1 \leq i \leq m$.

The **matrix-matrix product** $\mathbf{C} = \mathbf{A}\mathbf{B} \in \mathbb{R}^{m \times r}$ of two matrices, $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{B} \in \mathbb{R}^{n \times r}$, can be defined in three equivalent ways, as follows

1. *Inner product*: The element c_{ij} is the *inner product* of the i^{th} row of \mathbf{A} , and j^{th} column of \mathbf{B} :

$$c_{ij} = \sum_{k=1}^n a_{ik}b_{kj}, \quad 1 \leq i \leq m, \quad 1 \leq j \leq r.$$

2. *Scalar times a vector*: The j^{th} -column c_{*j} of \mathbf{C} is the *linear combination of the columns of \mathbf{A}* , using the elements of the j^{th} -column of \mathbf{B} as the coefficients:

$$c_{*j} = \sum_{i=1}^n a_{*j}b_{ij}, \quad 1 \leq j \leq r.$$

3. *Outer product*: The product matrix \mathbf{C} can also be expressed as the sum of n *outer product* matrices obtained by the j^{th} -column of \mathbf{A} and j^{th} -row of \mathbf{B} as

$$\mathbf{C} = \sum_{j=1}^n a_{*j}b_{j*}.$$

The above operations satisfy the following properties:

- (a) $\mathbf{A} + \mathbf{B} = \mathbf{B} + \mathbf{A}$
- (b) $p\mathbf{A} = \mathbf{A}p$
- (c) $\mathbf{A}\mathbf{B} \neq \mathbf{B}\mathbf{A}$; in the special case when $\mathbf{A}\mathbf{B} = \mathbf{B}\mathbf{A}$, the matrices \mathbf{A} and \mathbf{B} are called *permutable* or *commuting*
- (d) $\mathbf{A}(\mathbf{x} + \mathbf{y}) = \mathbf{A}\mathbf{x} + \mathbf{A}\mathbf{y}$
- (e) $(\mathbf{A} + \mathbf{B})\mathbf{C} = \mathbf{A}\mathbf{C} + \mathbf{B}\mathbf{C}$
- (f) $(p + q)\mathbf{A} = p\mathbf{A} + q\mathbf{A}$
- (g) $(\mathbf{A}\mathbf{B})\mathbf{C} = \mathbf{A}(\mathbf{B}\mathbf{C})$
- (h) $\mathbf{A} + (-\mathbf{A}) = \mathbf{0}$
- (i) $p(\mathbf{A} + \mathbf{B}) = p\mathbf{A} + p\mathbf{B}$

Power of a square matrix: the p^{th} -power of a matrix $A = (a_{ik})$ is defined as

$$A^p = \underbrace{AA \cdots A}_p, \quad (p = 1, 2, \dots); \quad \text{with } A^0 \equiv I.$$

Since matrix multiplication is associative, it follows that $A^p A^q = A^{p+q}$, for p and q arbitrary nonnegative integers. A square matrix A is called *nilpotent* iff there is an integer p such that $A^p = 0$. The smallest such integer p is called the *index of nilpotence*.

Consider now a polynomial $f(t)$ with coefficients in the field \mathcal{F} , namely $f(t) = \alpha_0 t^m + \alpha_1 t^{m-1} + \cdots + \alpha_m$. Then a *polynomial, $f(A)$, in a matrix A* , is defined to be the matrix

$$f(A) = \alpha_0 A^m + \alpha_1 A^{m-1} + \cdots + \alpha_m I.$$

Determinant of a square matrix: The *determinant* of a square matrix A is a scalar quantity, denoted by $\det A$ or $|A|$, and is given by

$$|A| = \sum_{j_1, j_2, \dots, j_n} p(j_1, j_2, \dots, j_n) a_{1j_1} a_{2j_2} \cdots a_{nj_n},$$

where $p(j_1, j_2, \dots, j_n)$ is a permutation equal to ± 1 , written in general as $p(j_1, j_2, \dots, j_n) = \text{sign} \prod_{1 \leq s < r \leq n} (j_r - j_s)$. The determinant can also be written in the alternative forms

$$|A| = \sum_{j=1}^n a_{ij} C_{ij}, \quad i = \text{constant}, \quad \text{or} \quad |A| = \sum_{i=1}^n a_{ij} C_{ij}, \quad j = \text{constant},$$

where C_{ij} is called the *cofactor* of the element a_{ij} . Note also that $C_{ij} = (-1)^{i+j} M_{ij}$, where M_{ij} , called the *minor*, is the determinant of the submatrix obtained from the matrix A by deleting the i^{th} row and j^{th} column. When the rows and columns deleted from A have the same indices, the resulting submatrix is located symmetrically with respect to the main diagonal of A , and the corresponding minor is called the *principal minor* of A . The minor

$$\begin{vmatrix} a_{11} & \cdots & a_{1r} \\ \vdots & & \vdots \\ a_{r1} & \cdots & a_{rr} \end{vmatrix}$$

is called the *leading principal minor* of A of order r .

Commonly used properties of determinants are as follows:

1. $|A| = |A^T|$.
2. If any column or row of A is multiplied by a scalar α , then the determinant of the new matrix becomes $\alpha |A|$.
3. If any column or row of A is zero, then $|A| = 0$.
4. If two rows or columns of A are interchanged, then the determinant of the new matrix has the same absolute value but opposite sign to the original determinant.
5. If two rows or columns in A are identical, then $|A| = 0$.
6. If a matrix A has elements $a_{sj} = c_{sj} + b_{sj}$, for all $j = 1, 2, \dots, n$, then the determinant of A is equal to the sum of two determinants such that the first determinant is obtained by

replacing a_{sj} in \mathbf{A} by c_{sj} for all $j = 1, 2, \dots, n$, while the second determinant is obtained by replacing a_{sj} in \mathbf{A} by b_{sj} for all $j = 1, \dots, n$.

7. $|\mathbf{AB}| = |\mathbf{A}||\mathbf{B}|$.
8. The sum of the product of the elements of a row by the cofactors of another row is equal to zero, i.e., $\sum_{j=1}^n a_{ij}C_{kj} = 0$, for all $i \neq k$.
9. The determinant of a matrix \mathbf{A} does not change if the elements of any row are multiplied by a constant and then added to another row.
10. The derivative $(d|\mathbf{A}(\lambda)|/d\lambda)$, of a determinant $|\mathbf{A}(\lambda)| = \sum_{j_1, \dots, j_n} p(j_1, \dots, j_n) a_{1j_1}(\lambda) \dots a_{nj_n}(\lambda)$, with respect to a parameter λ , is obtained as the sum of the determinants obtained by differentiating the rows of \mathbf{A} with respect to λ one at a time, i.e.,

$$\begin{aligned} \frac{d}{d\lambda} |\mathbf{A}| &= \sum_{j_1, \dots, j_n} p(j_1, \dots, j_n) \frac{da_{1j_1}(\lambda)}{d\lambda} a_{2j_2}(\lambda) \dots a_{nj_n}(\lambda) \\ &+ \sum_{j_1, \dots, j_n} p(j_1, \dots, j_n) a_{1j_1}(\lambda) \frac{da_{2j_2}(\lambda)}{d\lambda} \dots a_{nj_n}(\lambda) \\ &+ \dots + \sum_{j_1, \dots, j_n} p(j_1, \dots, j_n) a_{1j_1}(\lambda) \dots a_{n-1j_{n-1}}(\lambda) \frac{da_{nj_n}(\lambda)}{d\lambda}. \end{aligned}$$

Rank of a matrix $\mathbf{A} \in \mathbb{R}^{m \times n}$: The number of *linearly independent columns (rows)* of \mathbf{A} is called the *column (row) rank* of \mathbf{A} . Thus, the column (row) rank of \mathbf{A} is less than or equal to n (m). For any given matrix \mathbf{A} , its column and row ranks are always equal; this common integer value is called the *rank* of \mathbf{A} , and is denoted by $\text{Rank}(\mathbf{A})$, i.e.,

$$0 \leq \text{Rank}(\mathbf{A}) \leq \min\{m, n\}.$$

If $\text{Rank}(\mathbf{A}) = \min\{m, n\}$, then \mathbf{A} is called a matrix of *full rank*, otherwise it is called *rank-deficient*. Several important properties of rank are:

$$\begin{aligned} \text{Rank}(\mathbf{A}^T) &= \text{Rank}(\mathbf{A}), \\ \text{Rank}(\mathbf{A} + \mathbf{B}) &\leq \text{Rank}(\mathbf{A}) + \text{Rank}(\mathbf{B}), \\ \text{Rank}(\mathbf{A} - \mathbf{B}) &\geq |\text{Rank}(\mathbf{A}) - \text{Rank}(\mathbf{B})|. \end{aligned}$$

If $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{B} \in \mathbb{R}^{n \times r}$, then $\text{Rank}(\mathbf{AB}) \leq \min\{\text{Rank}(\mathbf{A}), \text{Rank}(\mathbf{B})\}$. In particular, if $\mathbf{x}, \mathbf{y} \in \mathbb{R}^m$, then their outer product matrix has $\text{Rank}(\mathbf{xy}^T) = 1$.

Singular/nonsingular matrix: A square matrix $\mathbf{A} \in \mathbb{R}^{n \times n}$ is called *nonsingular* if (i) $\det(\mathbf{A}) \neq 0$, or, (equivalently), if (ii) all columns (rows) of \mathbf{A} are linearly independent, or if (iii) $\text{Rank}(\mathbf{A}) = n$. Otherwise, \mathbf{A} is called *singular* (e.g., if $|\mathbf{A}| = 0$).

Consider the linear transformation

$$y_i = \sum_{k=1}^n a_{ik}x_k, \quad (i = 1, 2, \dots, n),$$

with $\mathbf{A} = (a_{ik})$ being nonsingular, i.e., $|\mathbf{A}| \neq 0$. Regarding the above system as equations for x_1, x_2, \dots, x_n , and solving them in terms of y_1, y_2, \dots, y_n , yields:

$$x_i = \frac{1}{|\mathbf{A}|} \begin{vmatrix} a_{11} \dots a_{1,i-1} & y_1 & a_{1,i+1} \dots a_{1n} \\ a_{21} \dots a_{2,i-1} & y_2 & a_{2,i+1} \dots a_{2n} \\ \dots & \dots & \dots \\ a_{n1} \dots a_{n,i-1} & y_n & a_{n,i+1} \dots a_{nn} \end{vmatrix} \equiv \sum_{k=1}^n a_{ik}^{(-1)} y_k \quad (i = 1, 2, \dots, n).$$

The transformation yielding the quantities x_i in terms of the quantities y_k is the “inverse” of the transformation for the quantities y_i . The coefficient matrix

$$\mathbf{A}^{-1} = \left(a_{ik}^{(-1)} \right) \text{ with } a_{ik}^{(-1)} = \frac{A_{ki}}{|\mathbf{A}|}, \quad (i, k = 1, 2, \dots, n),$$

is called the *inverse matrix* of \mathbf{A} , and A_{ki} is the algebraic complement (the cofactor) of the elements a_{ki} ($i, k = 1, 2, \dots, n$) in the determinant $|\mathbf{A}|$.

The composite transformation of the transformations for \mathbf{x} and \mathbf{y} , in either order, gives the identity transformation $\mathbf{A}\mathbf{A}^{-1} = \mathbf{A}^{-1}\mathbf{A} = \mathbf{I}$. Note that the matrix equations $\mathbf{A}\mathbf{X} = \mathbf{I}$ and $\mathbf{X}\mathbf{A} = \mathbf{I}$, $|\mathbf{A}| \neq 0$ admit only the solution $\mathbf{X} = \mathbf{A}^{-1}$. Note also that $|\mathbf{A}^{-1}| = 1/|\mathbf{A}|$, $(\mathbf{A}\mathbf{B})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$, and $(\mathbf{A}^{-1})^T = (\mathbf{A}^T)^{-1}$.

Trace of a matrix: the *trace* of $\mathbf{A} \in \mathbb{R}^{m \times m}$, denoted by $\text{tr}(\mathbf{A})$, is a scalar defined by the sum of the diagonal elements of \mathbf{A} :

$$\text{tr}(\mathbf{A}) = \sum_{i=1}^m a_{ii}.$$

Notable properties of $\text{tr}(\mathbf{A})$ are:

$$\begin{aligned} \text{tr}(\mathbf{A}) &= \text{tr}(\mathbf{A}^T), \quad \text{tr}(\mathbf{A} + \mathbf{B}) = \text{tr}(\mathbf{A}) + \text{tr}(\mathbf{B}), \quad \text{tr}(\alpha\mathbf{A}) = \alpha \text{tr}(\mathbf{A}), \\ \text{tr}(\mathbf{A}\mathbf{B}) &= \text{tr}(\mathbf{B}\mathbf{A}), \quad \text{tr}(\mathbf{A}\mathbf{B}\mathbf{C}) = \text{tr}(\mathbf{B}\mathbf{C}\mathbf{A}) = \text{tr}(\mathbf{C}\mathbf{A}\mathbf{B}), \quad \text{tr}(\mathbf{A}^{-1}\mathbf{B}\mathbf{A}) = \text{tr}(\mathbf{B}). \end{aligned}$$

Useful identities: Adding an outer-product matrix $\mathbf{c}\mathbf{d}^T$, where $\mathbf{c}, \mathbf{d} \in \mathbb{R}^m$, to a non-singular matrix \mathbf{A} is called the *rank-one perturbation*. In the following identities, the matrices \mathbf{A} and \mathbf{B} are considered to be invertible, and $\mathbf{C} \in \mathbb{R}^{m \times k}$ and $\mathbf{D} \in \mathbb{R}^{m \times k}$ are matrices of rank k :

$$\begin{aligned} (\mathbf{I}_m + \mathbf{c}\mathbf{d}^T)^{-1} &= \mathbf{I}_m - \frac{\mathbf{c}\mathbf{d}^T}{1 + \mathbf{d}^T\mathbf{c}}, \\ (\mathbf{A} + \mathbf{c}\mathbf{d}^T)^{-1} &= \mathbf{A}^{-1} - \frac{\mathbf{A}^{-1}\mathbf{c}\mathbf{d}^T\mathbf{A}^{-1}}{1 + \mathbf{d}^T\mathbf{A}^{-1}\mathbf{c}} \quad (\text{Sherman-Morrison formula}), \\ (\mathbf{A} + \mathbf{C}\mathbf{D}^T)^{-1} &= \mathbf{A}^{-1} - \mathbf{A}^{-1}\mathbf{C}[\mathbf{I}_k + \mathbf{D}^T\mathbf{A}^{-1}\mathbf{C}]^{-1}\mathbf{D}^T\mathbf{A}^{-1} \quad (\text{Woodbury's extension}), \\ (\mathbf{A} + \mathbf{C}\mathbf{B}\mathbf{D}^T)^{-1} &= \mathbf{A}^{-1} - \mathbf{A}^{-1}\mathbf{C}[\mathbf{B}^{-1} + \mathbf{D}^T\mathbf{A}^{-1}\mathbf{C}]^{-1}\mathbf{D}^T\mathbf{A}^{-1}, \\ [\mathbf{A}^T\mathbf{B}^{-1}\mathbf{A} + \mathbf{D}^{-1}]\mathbf{A}^T\mathbf{B}^{-1} &= \mathbf{D}\mathbf{A}^T[\mathbf{B} + \mathbf{A}\mathbf{D}\mathbf{A}^T]^{-1}. \end{aligned}$$

Moore-Penrose generalized inverse: The matrix $\mathbf{A}^+ \in \mathbb{R}^{n \times m}$ is called the *Moore-Penrose inverse* of the matrix $\mathbf{A} \in \mathbb{R}^{m \times n}$ if the following four conditions hold:

1. $\mathbf{A}\mathbf{A}^+\mathbf{A} = \mathbf{A}$.
2. $\mathbf{A}^+\mathbf{A}\mathbf{A}^+ = \mathbf{A}^+$.
3. $(\mathbf{A}^+\mathbf{A})^T = \mathbf{A}^+\mathbf{A}$, ($\mathbf{A}^+\mathbf{A}$ is a symmetric matrix).
4. $(\mathbf{A}\mathbf{A}^+)^T = \mathbf{A}\mathbf{A}^+$, ($\mathbf{A}\mathbf{A}^+$ is a symmetric matrix).

The symmetric matrix $\mathbf{A}\mathbf{A}^+ \in \mathbb{R}^{m \times m}$ represents the orthogonal projection onto the subspace spanned by the columns of \mathbf{A} , which is called the *range space* of \mathbf{A} , and is denoted as $R(\mathbf{A})$.

Similarly, the symmetric matrix $\mathbf{A}^+\mathbf{A} \in \mathbb{R}^{n \times n}$ represents the orthogonal projection on to the subspace spanned by the rows of \mathbf{A} , which is called the range space of \mathbf{A}^T , and is denoted as $R(\mathbf{A}^T)$. When $\mathbf{A} \in \mathbb{R}^{m \times m}$ is non-singular, then $\mathbf{A}^+ = \mathbf{A}^{-1}$ and $\mathbf{A}\mathbf{A}^{-1} = \mathbf{A}^{-1}\mathbf{A} = \mathbf{I}_m$.

Range and null space of a matrix: Consider two vector spaces $\mathcal{V} \subseteq \mathbb{R}^n$ and $\mathcal{W} \subseteq \mathbb{R}^m$ and a matrix $\mathbf{A} \in \mathbb{R}^{m \times n}$, $\mathbf{A} : \mathcal{V} \rightarrow \mathcal{W}$. The range of \mathbf{A} , also known as *column space* of \mathbf{A} , is usually denoted by $R(\mathbf{A})$, and is defined as

$$R(\mathbf{A}) = \{ \mathbf{y} \in \mathbb{R}^m \mid \mathbf{y} = \mathbf{A}\mathbf{x} \text{ for all } \mathbf{x} \in \mathcal{V} \} \subseteq \mathcal{W}$$

is the set of linear combinations of the columns of \mathbf{A} . That is, $R(\mathbf{A})$ is the linear vector space generated by the columns of \mathbf{A} and, hence, is called the *image* of \mathcal{V} under \mathbf{A} or (simply as) the *image space* of \mathbf{A} . The range of \mathbf{A}^T , defined as

$$R(\mathbf{A}^T) = \{ \mathbf{x} \in \mathbb{R}^n \mid \mathbf{x} = \mathbf{A}^T \mathbf{y} \text{ for all } \mathbf{y} \in \mathbb{R}^m \} \subseteq \mathcal{V}$$

is also called the *row space* of \mathbf{A} . The *null space* of \mathbf{A} , denoted by $N(\mathbf{A})$, is defined as

$$N(\mathbf{A}) = \{ \mathbf{x} \in \mathbb{R}^n \mid \mathbf{A}\mathbf{x} = \mathbf{0} \} \subseteq \mathcal{V}.$$

Thus, $N(\mathbf{A})$ consists of all solutions to the homogeneous systems $\mathbf{A}\mathbf{x} = \mathbf{0}$, and is also called the *kernel* of \mathbf{A} . It can be verified that $N(\mathbf{A})$ is a vector space. The null space of \mathbf{A}^T is defined as

$$N(\mathbf{A}^T) = \{ \mathbf{y} \in \mathbb{R}^m \mid \mathbf{A}^T \mathbf{y} = \mathbf{0} \} \subseteq \mathcal{W}.$$

The following relations hold between the four vector spaces $R(\mathbf{A})$, $R(\mathbf{A}^T)$, $N(\mathbf{A})$; and $N(\mathbf{A}^T)$; associated with a matrix $\mathbf{A} \in \mathbb{R}^{m \times n}$.

1. The null space of \mathbf{A} is orthogonal to the range space of \mathbf{A}^T : $N(\mathbf{A}) = R^\perp(\mathbf{A}^T)$; similarly, $N(\mathbf{A}^T) = R^\perp(\mathbf{A})$.
2. When \mathbf{A} is a square symmetric matrix, then $R(\mathbf{A}) = R(\mathbf{A}^T)$, $N(\mathbf{A}) = N(\mathbf{A}^T)$, and $N(\mathbf{A}) = R^\perp(\mathbf{A}^T)$.
3. $\text{Dim}[R(\mathbf{A})] = \text{Rank}(\mathbf{A}) = \text{Dim}[R(\mathbf{A}^T)]$.
4. $\text{Dim}[N(\mathbf{A})] = n - r$, where $r = \text{Rank}(\mathbf{A})$, is called the *nullity* of \mathbf{A} ;
5. $\text{Dim}[R(\mathbf{A})] + \text{Dim}[N(\mathbf{A})] = n$, for all $\mathbf{A} \in \mathbb{R}^{m \times n}$.
6. $\text{Dim}[N(\mathbf{A})] = 0$ when \mathbf{A} is square and non-singular.
7. $\text{Dim}[N(\mathbf{A}^T)] = m - r$.

In many applications, it is convenient to use matrices that are partitioned into rectangular parts, or “cells” or “blocks.” An arbitrary rectangular matrix $\mathbf{A} = (a_{ik})$ ($i = 1, 2, \dots, m; k = 1, 2, \dots, n$) can be partitioned into rectangular blocks by means of horizontal and vertical lines, as follows:

$$\mathbf{A} = \begin{pmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} & \cdots & \mathbf{A}_{1t} \\ \mathbf{A}_{21} & \mathbf{A}_{22} & \cdots & \mathbf{A}_{2t} \\ \cdots & \cdots & \cdots & \cdots \\ \mathbf{A}_{s1} & \mathbf{A}_{s2} & \cdots & \mathbf{A}_{st} \end{pmatrix} \begin{matrix} \} & m_1 \\ \} & m_2 \\ & \vdots \\ \} & m_s \end{matrix}.$$

$n_1 \qquad n_2 \qquad n_t$

The matrix A above is said to be *partitioned* into $s \times t$ blocks (or *cells*) $A_{\alpha\beta}$ of dimensions $m_\alpha \times n_\beta$ ($\alpha = 1, 2, \dots, s$; $\beta = 1, 2, \dots, t$), or that it is represented in the form of a *partitioned*, or *blocked*, matrix. By analogy with the customary notation for matrices, the matrix A is written as $A = (A_{\alpha\beta})$, ($\alpha = 1, 2, \dots, s$; $\beta = 1, 2, \dots, t$). When $s = t$, then A is a square block matrix, denoted as $A = (A_{\alpha\beta})_s^s$, or simply $A = (A_{\alpha\beta})$, when the meaning of s is clear from the context. Operations on partitioned matrices are performed using the same formal rules as used for matrices that have scalar elements instead of blocks. For example, the operation of addition of two rectangular matrices $A = (A_{\alpha\beta})$, $B = (B_{\alpha\beta})$, ($\alpha = 1, 2, \dots, s$; $\beta = 1, 2, \dots, t$) becomes $A + B = (A_{\alpha\beta} + B_{\alpha\beta})$.

For block-multiplication of two rectangular matrices A and B , the length of the rows of the first factor A must be the same as the height of the columns of the second factor B , and the partitioning into blocks must ensure that the horizontal dimensions in the first factor are the same as the corresponding vertical dimensions in the second:

$$A = \left(\begin{array}{ccc} \overbrace{A_{11}}^{n_1} & \overbrace{A_{12}}^{n_2} & \cdots & \overbrace{A_{1t}}^{n_t} \\ \overbrace{A_{21}}^{n_1} & \overbrace{A_{22}}^{n_2} & \cdots & \overbrace{A_{2t}}^{n_t} \\ \cdots & \cdots & \cdots & \cdots \\ \overbrace{A_{s1}}^{n_1} & \overbrace{A_{s2}}^{n_2} & \cdots & \overbrace{A_{st}}^{n_t} \end{array} \right) \left. \begin{array}{l} \} \\ \} \\ \vdots \\ \} \end{array} \right\} \begin{array}{l} m_1 \\ m_2 \\ \vdots \\ m_s \end{array}, \quad B = \left(\begin{array}{ccc} \overbrace{B_{11}}^{p_1} & \overbrace{B_{12}}^{p_2} & \cdots & \overbrace{B_{1u}}^{p_u} \\ \overbrace{B_{21}}^{p_1} & \overbrace{B_{22}}^{p_2} & \cdots & \overbrace{B_{2u}}^{p_u} \\ \cdots & \cdots & \cdots & \cdots \\ \overbrace{B_{t1}}^{p_1} & \overbrace{B_{t2}}^{p_2} & \cdots & \overbrace{B_{tu}}^{p_u} \end{array} \right) \left. \begin{array}{l} \} \\ \} \\ \vdots \\ \} \end{array} \right\} \begin{array}{l} n_1 \\ n_2 \\ \vdots \\ n_t \end{array}.$$

The operation of block-multiplication can then be written in the customary form, namely:

$$AB = C = (C_{\alpha\beta}), \quad \text{where} \quad C_{\alpha\beta} = \sum_{\delta=1}^t A_{\alpha\delta} B_{\delta\beta} \quad \left(\begin{array}{l} \alpha = 1, 2, \dots, s \\ \beta = 1, 2, \dots, u \end{array} \right).$$

When A is a *quasi-diagonal* matrix (with $s = t$ and $A_{\alpha\beta} = 0$ when $\alpha \neq \beta$), then the above equation reduces to $C_{\alpha\beta} = A_{\alpha\alpha} B_{\alpha\beta}$, ($\alpha = 1, 2, \dots, s$; $\beta = 1, 2, \dots, u$). Similarly, when B is a quasi-diagonal matrix (with $t = u$ and $B_{\alpha\beta} = 0$ for $\alpha \neq \beta$), then the above equation becomes $C_{\alpha\beta} = A_{\alpha\beta} B_{\beta\beta}$. The partitioned matrix from the above equation is called *upper (lower) quasi-triangular* if $s = t$ and $A_{\alpha\beta} = 0$ for $\alpha > \beta$ ($\alpha < \beta$). A quasi-diagonal matrix is a special case of a quasi-triangular matrix. Note that the product of two upper (lower) quasi-triangular matrices is itself an upper (lower) quasi-triangular matrix. Furthermore, the determinant of a quasi-triangular matrix (or, in particular, a quasi-diagonal matrix) is equal to the product of the determinant of the diagonal cells:

$$|A| = |A_{11}| |A_{22}| \cdots |A_{ss}|.$$

Consider that the block A_{11} of the partitioned matrix A is square and nonsingular ($|A_{11}| \neq 0$). The block A_{21} can be eliminated by multiplying the first row of A on the left by $-A_{\alpha 1} A_{11}^{-1}$ ($\alpha = 2, \dots, s$) and adding the result to the α th row of A . If the matrix $A_{22}^{(1)}$ is square and nonsingular, the process can be continued. This procedure is called Gauss elimination for block-matrices, and provides a method for computing the determinant of a partitioned matrix:

$$|A| = |B_1| = |A_{11}| \left| \begin{array}{c} A_{22}^{(1)} \cdots A_{2t}^{(1)} \\ \cdots \cdots \cdots \\ A_{s2}^{(1)} \cdots A_{st}^{(1)} \end{array} \right|.$$

The above formula reduces the computation of the determinant $|A|$, consisting of $s \times t$ blocks, to the computation of a determinant of lower order, consisting of $(s-1) \times (t-1)$ blocks.

If $A_{22}^{(1)}$ is a square matrix and $|A_{22}^{(1)}| \neq 0$, then this determinant of $(s - 1)(t - 1)$ blocks can again be subjected to the same procedure as above. As a particular example, consider a determinant Δ partitioned into four blocks, namely: $\Delta = \begin{vmatrix} A & B \\ C & D \end{vmatrix}$, where A and D are square matrices, with $|A| \neq 0$. Multiplying the first row on the left by CA^{-1} and subtracting it from the second row yields

$$\Delta = \begin{vmatrix} A & B \\ \mathbf{0} & D - CA^{-1}B \end{vmatrix} = |A| |D - CA^{-1}B|.$$

On the other hand, if $|D| \neq 0$, then the Gauss elimination procedure can be applied to the second row of Δ , leading to

$$\Delta = \begin{vmatrix} A - BD^{-1}C & \mathbf{0} \\ C & D \end{vmatrix} = |A - BD^{-1}C| |D|.$$

In the special case in which all four matrices, A , B , C , and D , are square matrices of order n , then these equations become $\Delta = |AD - ACA^{-1}B|$, when $|A| \neq 0$ or $\Delta = |AD - BD^{-1}CD|$, when $|D| \neq 0$, respectively. These results are known as the *formulas of Schur*, and they reduce the computation of a determinant of order $2n$ to the computation of a determinant of order n .

Two matrices A and B connected by the relation $B = T^{-1}AT$, where T is a nonsingular matrix, are called *similar*, and have the following three properties: *reflexivity* (a matrix A is always similar to itself); *symmetry* (if A is similar to B , then B is similar to A); and *transitivity* (if A is similar to B , and B is similar to C , then A is similar to C). Two similar matrices have equal determinants, since $|B| = |T|^{-1}|A||T| = |A|$. However, the equality $|B| = |A|$ is only a necessary but not a sufficient condition for the matrices A and B to be similar.

Under certain conditions, it is possible to define *elementary functions of a matrix A*, just as one defines functions of a scalar. The matrix functions most commonly encountered in practical applications are:

$$\begin{aligned} e^A &= I + A + \frac{A^2}{2!} + \dots, & \sin A &= A - \frac{A^3}{3!} + \frac{A^5}{5!} - \dots, \\ \cos A &= I - \frac{A^2}{2!} + \frac{A^4}{4!} - \dots, \\ \sinh A &= A + \frac{A^3}{3!} + \frac{A^5}{5!} + \dots, & \cosh A &= I + \frac{A^2}{2!} + \frac{A^4}{4!} + \dots, \\ \tan A &= (\cos A)^{-1} \sin A, & \tanh A &= (\cosh A)^{-1} \sinh A, \\ \log(I + A) &= A - \frac{A^2}{2} + \frac{A^3}{3} - \dots, & (I - A)^{-1} &= I + A + A^2 + \dots \end{aligned}$$

Bilinear form: The scalar-valued function $f_A(\mathbf{x}, \mathbf{y}) : \mathbb{R}^m \times \mathbb{R}^n \rightarrow \mathbb{R}$ of two vectors defined by:

$$f_A = \mathbf{x}^T A \mathbf{y},$$

where $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{x} \in \mathbb{R}^m$ and $\mathbf{y} \in \mathbb{R}^n$ is called a *bilinear form*, since the components of the vectors \mathbf{x} and \mathbf{y} appear in their first degree in $f_A(\mathbf{x}, \mathbf{y})$. In particular, when $\mathbf{A} \in \mathbb{R}^{m \times m}$ and $\mathbf{x} \in \mathbb{R}^m$, the scalar-valued function $Q_A: \mathbb{R}^m \rightarrow \mathbb{R}$ defined as

$$Q_A(\mathbf{x}) = \mathbf{x}^T \mathbf{A} \mathbf{x}$$

is a second-degree multivariate polynomial in the elements of \mathbf{x} , called a *quadratic form*.

Positive/negative definite matrix: A real symmetric matrix $\mathbf{A} \in \mathbb{R}^{m \times m}$ is said to be *positive definite* if

$$\mathbf{x}^T \mathbf{A} \mathbf{x} \begin{cases} > 0, & \text{if } \mathbf{x} \neq 0, \\ = 0, & \text{exactly when } \mathbf{x} = 0. \end{cases}$$

A real symmetric matrix \mathbf{A} is said to be *positive semi-definite* if $\mathbf{x}^T \mathbf{A} \mathbf{x} \geq 0$ for all $\mathbf{x} \in \mathbb{R}^m$. A real symmetric matrix \mathbf{A} is said to be *negative definite* and *negative semi-definite*, if the above properties hold with the inequalities reversed. The matrix \mathbf{A} is said to be *indefinite* if $\mathbf{x}^T \mathbf{A} \mathbf{x} \geq 0$ for some $\mathbf{x} \in \mathbb{R}^m$ and < 0 for some other values of \mathbf{x} . The diagonal elements, the principal minors of all orders and the determinant of a positive definite matrix are all positive. If \mathbf{A} is positive definite then the inverse matrix \mathbf{A}^{-1} is also positive definite. If \mathbf{A} is positive definite and \mathbf{B} is non-singular, then $(\mathbf{B}^{-1})^T \mathbf{A} \mathbf{B}^{-1}$ is positive definite. The eigenvalues of a real-symmetric and positive definite matrix are all real and positive, and those of a positive semi-definite matrix are real and non-negative. If \mathbf{A} is a symmetric and positive definite, then there exists an orthogonal matrix \mathbf{Q} such that $\mathbf{Q}^T \mathbf{A} \mathbf{Q} = \mathbf{\Lambda} = \text{Diag}(\lambda_1, \lambda_2, \dots, \lambda_m)$ where $\lambda_i > 0$ are the eigenvalues of \mathbf{A} and the columns of \mathbf{Q} are the corresponding orthonormal set of eigenvectors, furthermore, the relation $\mathbf{Q}^T \mathbf{A} \mathbf{Q} = \mathbf{\Lambda}$ implies the decomposition

$$\mathbf{A} = \mathbf{Q} \mathbf{\Lambda} \mathbf{Q}^T = \mathbf{Q} \mathbf{\Lambda}^{1/2} \mathbf{\Lambda}^{1/2} \mathbf{Q}^T = (\mathbf{Q} \mathbf{\Lambda}^{1/2}) (\mathbf{Q} \mathbf{\Lambda}^{1/2})^T = \mathbf{C} \mathbf{C}^T.$$

Diagonally dominant matrix: A square matrix $\mathbf{A} \in \mathbb{R}^{m \times m}$ is said to be *diagonally dominant* if

$$|a_{ii}| \geq \sum_{j \neq i} |a_{ij}|$$

and *strictly diagonally dominant* if strict inequality holds for all $i = 1, 2, \dots, m$. It can be shown that a diagonally dominant matrix is non-singular.

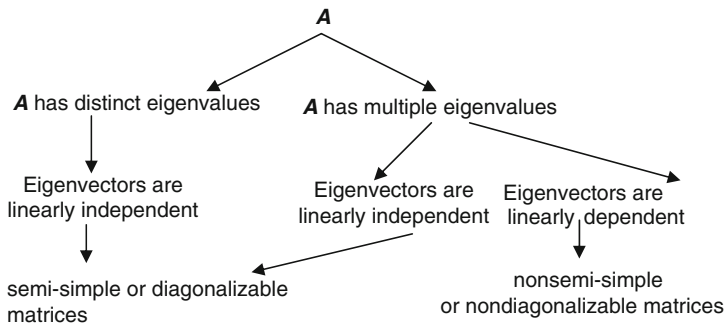

Orthogonal matrix: A matrix $\mathbf{Q} \in \mathbb{R}^{m \times m}$ is called an *orthogonal* matrix, if $\mathbf{Q}^{-1} = \mathbf{Q}^T$, i.e., $\mathbf{Q}^T \mathbf{Q} = \mathbf{Q} \mathbf{Q}^T = \mathbf{I}_m$. An orthogonal matrix \mathbf{Q} has the following properties:

- \mathbf{Q} is non-singular.
- The columns (rows) of $\mathbf{Q} \in \mathbb{R}^{m \times m}$ form a complete orthonormal basis for \mathbb{R}^m .
- $\det(\mathbf{Q}^T \mathbf{A} \mathbf{Q}) = \det(\mathbf{A})$.
- If $\mathbf{x} \in \mathbb{R}^m$, then the Euclidean norm $\|\mathbf{x}\|_2 = \|\mathbf{Q} \mathbf{x}\|_2$ is *invariant* under an orthogonal transformation; hence, orthogonal transformations are called *isometric* transformations, and represent a rigid body rotations.
- If \mathbf{Q}_1 and \mathbf{Q}_2 are orthogonal, then $\mathbf{Q}_1 \mathbf{Q}_2$ is also an orthogonal matrix.

Permutation matrix: The matrix $\mathbf{P} = [\mathbf{p}_{ij}] \in \mathbb{R}^{m \times m}$ is a *permutation* matrix if $\mathbf{p}_{ij} \in \{0, 1\}$ and there is only one 1 in each row and in each column. Some important properties of permutation matrices are as follows.

and $\text{tr}(\mathbf{A}) = m_1\lambda_1 + m_2\lambda_2 + \dots + m_k\lambda_k$, where m_i , is the *algebraic multiplicity* of λ_i . Similar matrices have the same set of eigenvalues; thus, if (λ, \mathbf{x}) is an eigen-pair of $\mathbf{B}^{-1}\mathbf{A}\mathbf{B}$, then $(\lambda, \mathbf{B}\mathbf{x})$ is the corresponding pair for \mathbf{A} .

In general, the characteristic equation admits three kinds of eigenvalues: (1) distinct eigenvalues with corresponding linearly independent eigenvectors, (2) multiple eigenvalues with corresponding linearly independent eigenvectors, and (3) multiple eigenvalues with linearly dependent eigenvectors. The first two kinds are called *semi-simple* eigenvalues and the last ones are called *nonsemi-simple* eigenvalues. The diagram below shows all possibilities for a matrix \mathbf{A} .

Solution of linear systems: Given $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{b} \in \mathbb{R}^m$, the problem of finding the vector $\mathbf{x} \in \mathbb{R}^n$ such that $\mathbf{A}\mathbf{x} = \mathbf{b}$ requires the solution of a set of m equations in n unknowns for determining the components of \mathbf{x} . If the vector $\mathbf{b} \in R(\mathbf{A})$, then \mathbf{b} must be expressible as a linear combination of the columns of \mathbf{A} and the coefficients of this linear combination constitutes the components of the vector \mathbf{x} we are seeking. In this case, the linear system $\mathbf{A}\mathbf{x} = \mathbf{b}$ is called a *consistent* system. If \mathbf{b} does *not* belong to $R(\mathbf{A})$, then there does *not* exist a vector $\mathbf{x} \in \mathbb{R}^n$ such that $\mathbf{A}\mathbf{x} = \mathbf{b}$ and in this case it is termed as an *inconsistent* system. When the vector $\mathbf{b} = 0$, the linear system $\mathbf{A}\mathbf{x} = 0$ is called a *homogeneous system*; otherwise, it is known as a *non-homogeneous system*. Recall that $\text{Rank}(\mathbf{A}) \leq \min(m, n)$. If $\text{Rank}(\mathbf{A}) = \min(m, n)$, then the linear system is said to be of *full rank*; otherwise, it is called *rank deficient*. If m , the *number of equations*, is equal to n , the *number of variables*, the $\mathbf{A}\mathbf{x} = \mathbf{b}$ it is called a *determined* system; if $m > n$, it is called an *over-determined* system, and if $m < n$, it is called an *under-determined* system. Combining these various attributes (consistent/inconsistent, homogeneous/non-homogeneous, full-rank/rank-deficient, and determined/over or under-determined) yields the following cases:

- If $m = n$, and \mathbf{A} is of full rank, the system is always consistent and the solution exists and is unique. If $\mathbf{b} \neq 0$, then $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b}$ and if $\mathbf{b} = 0$, $\mathbf{x} = 0$ is the only solution.
- If $m > n$, the system is over-determined. The unique solution is given by $\mathbf{x} = \mathbf{A}^+\mathbf{b}$ where \mathbf{A}^+ is the Moore–Penrose inverse of \mathbf{A} . In the special case when \mathbf{A} is of full rank, this generalized inverse is given by $\mathbf{A}^+ = (\mathbf{A}^T\mathbf{A})^{-1}\mathbf{A}^T$.
- If $m < n$, the system is under-determined. The unique solution is given by $\mathbf{x} = \mathbf{A}^+\mathbf{b}$, where \mathbf{A}^+ is the Moore–Penrose inverse. In the special case when \mathbf{A} is of full rank, this generalized inverse is given by $\mathbf{A}^+ = \mathbf{A}^T(\mathbf{A}\mathbf{A}^T)^{-1}$.

A matrix A has a generalized inverse A^i , iff $AA^iA = A$, where $A^i = P \begin{bmatrix} I_\rho & U \\ V & W \end{bmatrix} R$, where:

(1) ρ is the rank of A , (2) P and R are selected such that $RAP = \begin{bmatrix} I_\rho & 0 \\ 0 & 0 \end{bmatrix}$, and (3) U , V , and W are arbitrary matrices. The generalized inverse A^i is used to solve a set of linear simultaneous equations $Ax = b$, where A is of order (m, n) . The solution is given by $x = A^i b$, or, equivalently,

$$x = A^i b + (I - A^i A) z,$$

where z is an arbitrary vector (which accounts for U , V , and W), and A^t is the part of A^i that does not depend on U , V , and W . In general, A^t is obtained from A^i by setting U , V , and W to

zero, or, equivalently, by partitioning P and R in the form $P = [P_1 : P_2]$, $R = \begin{bmatrix} R_1 \\ \dots \\ R_2 \end{bmatrix}$, where P_1 and R_1 are respectively of order (n, ρ) and (ρ, m) , so that $A^t = P_1 R_1$.

Symmetric matrices play a prominent role in several nuclear engineering fields, including numerical simulations, model validation, data assimilation for best-estimate parameter calibration, uncertainty analysis, and predictive estimation. In particular, covariance matrices are symmetric and also positive-definite. Several important properties of eigenvectors and eigenvalues of a *symmetric matrix* $A \in \mathbb{R}^{m \times m}$ are summarized in the following:

- (a) The number of non-zero eigenvalues of $A = \text{Rank}(A)$.
- (a) The eigenvalues of A are real and orthogonal.
- (c) $AP = PA$, where $P = [x_1, x_2, \dots, x_m]$ denotes the orthonormal matrix of the m eigenvectors of A , and $\Lambda = \text{Diag}(\lambda_1, \lambda_2, \dots, \lambda_n)$ denotes the diagonal matrix of the eigenvalues of A .
- (d) Spectral decomposition: Since P is orthogonal, it follows that

$$A = PAP^T = [x_1, x_2, \dots, x_m] \begin{bmatrix} \lambda_1 & & & \\ & \lambda_2 & & \\ & & \ddots & \\ & & & \lambda_m \end{bmatrix} \begin{bmatrix} x_1^T \\ x_2^T \\ \vdots \\ x_m^T \end{bmatrix} = \sum_{i=1}^m \lambda_i x_i x_i^T = \sum_{i=1}^m \lambda_i P_i,$$

where the *rank-one outer-product* matrices $P_i = x_i x_i^T$ are *orthogonal projection matrices* onto the $\text{Span}\{x_i\}$. The above expansion of A as the linear combination of the orthogonal projection matrices is called the *spectral decomposition* of A .

If $A \in \mathbb{R}^{m \times m}$ and $B \in \mathbb{R}^{m \times m}$ are two permutable symmetric matrices (i.e., $AB = BA$), then there exists a common orthogonal matrix P such that $AP = P\Lambda$ and $BP = P\Sigma$, where Λ and Σ are diagonal matrices of eigenvalues of A and B , respectively.

All eigenvalues of a *symmetric and positive (negative) definite matrix* $A \in \mathbb{R}^{m \times m}$ are positive (negative). The bilinear form $Q(x) = x^T Ax$ defines a *hyper-ellipsoid* in \mathbb{R}^m ; $Q(x) = x^T (P\Lambda P^T) x = (Px)^T \Lambda (Px)$, where $\Lambda = \text{Diag}(\lambda_1, \lambda_2, \dots, \lambda_n)$ and $P = [x_1, x_2, \dots, x_m]$. Therefore, if $x = P^T y$ or $Px = y$ (representing a rigid-body rotation of the standard coordinate system using the orthogonal matrix P), then $Q(x)$ is the hyper-ellipsoid whose m principal axes coincide with the m orthogonal eigenvectors of A and $1/\sqrt{\lambda_i}$ denotes the length of the semi-axis in the i^{th} principal direction, i.e., $Q(x) = Q(P^T y) = y^T \Lambda y = \sum_{i=1}^m \lambda_i y_i^2$.

Krylov Subspace: Let $\mathbf{y} \in \mathbb{R}^m$ be any vector. Then, there exists an eigenvector \mathbf{x} of \mathbf{A} that belongs to the vector space

$$K_A(\mathbf{A}, \mathbf{y}) = \{\mathbf{y}, \mathbf{A}\mathbf{y}, \mathbf{A}^2\mathbf{y}, \dots, \mathbf{A}^{r-1}\mathbf{y}\}$$

for some integer $r \geq 0$, called the *Krylov subspace*. Krylov subspaces are intimately related to matrix-polynomials, and are important in reduced-space computations and error estimation.

Rayleigh coefficient: For a symmetric matrix $\mathbf{A} \in \mathbb{R}^{n \times n}$, the quantity $r(\mathbf{x}) = \mathbf{x}^T \mathbf{A} \mathbf{x} / \mathbf{x}^T \mathbf{x}$ is called the *Rayleigh coefficient*. If $\mathbf{A} \in \mathbb{R}^{n \times n}$ and $\mathbf{B} \in \mathbb{R}^{n \times n}$ are two symmetric and positive definite matrices, and $\lambda \in \mathbb{R}$ and $\mathbf{x} \in \mathbb{R}^n$ are the *generalized eigenvalue* and *generalized eigenvector* of the pair (\mathbf{A}, \mathbf{B}) , i.e., $\mathbf{A}\mathbf{x} = \lambda\mathbf{B}\mathbf{x}$, then λ is given by Rayleigh coefficient $\lambda = r(\mathbf{x}) = \mathbf{x}^T \mathbf{A} \mathbf{x} / \mathbf{x}^T \mathbf{B} \mathbf{x}$. Furthermore, $r(\mathbf{x})$ minimizes the norm $g(\lambda) = \|(\mathbf{A} - \lambda\mathbf{B})\mathbf{x}\|_{\mathbf{B}^{-1}}^2$.

The **norm of a square matrix** \mathbf{A} , denoted by $\|\mathbf{A}\|$, is a nonnegative real scalar that satisfies the following relations:

1. $\|\mathbf{A}\| > 0$, if $\mathbf{A} \neq \mathbf{0}$ (nonnegative);
2. $\|\alpha\mathbf{A}\| = |\alpha| \|\mathbf{A}\|$, for any complex scalar α (homogeneous);
3. $\|\mathbf{A} + \mathbf{B}\| \leq \|\mathbf{A}\| + \|\mathbf{B}\|$, (triangle inequality);
4. $\|\mathbf{A}\mathbf{B}\| \leq \|\mathbf{A}\| \|\mathbf{B}\|$, (sub-multiplicative).

There are many matrix norms that satisfy the above relations. The most frequently used norm is the *matrix-Hölder norm induced by (or subordinate to) the Hölder vector norm*, defined as

$$\|\mathbf{A}\|_p \equiv \max_x \frac{\|\mathbf{A}\mathbf{x}\|_p}{\|\mathbf{x}\|_p}.$$

The most widely used matrix-Hölder norms are those obtained for the following values of p :

- (a) $p = 1$, the *maximum column sum matrix norm*, induced by the ℓ_1 vector norm:

$$\|\mathbf{A}\|_1 \equiv \max_x \frac{\|\mathbf{A}\mathbf{x}\|_1}{\|\mathbf{x}\|_1} = \max_j \sum_{i=1}^n |a_{ij}|.$$

- (b) $p = 2$, the *spectral norm*, induced by the ℓ_2 vector norm:

$$\|\mathbf{A}\|_2 \equiv \max_x \frac{\|\mathbf{A}\mathbf{x}\|_2}{\|\mathbf{x}\|_2} = \max_\lambda \{\sqrt{\lambda}\}, \text{ where } \lambda \text{ is an eigenvalue of } (\mathbf{A}^*)\mathbf{A}.$$

- (c) $p = \infty$, the *maximum row sum matrix norm*, induced by the ℓ_∞ vector norm:

$$\|\mathbf{A}\|_\infty \equiv \max_x \frac{\|\mathbf{A}\mathbf{x}\|_\infty}{\|\mathbf{x}\|_\infty} = \max_i \sum_{j=1}^n |a_{ij}|.$$

The *condition number* of a square matrix \mathbf{A} is a nonnegative real scalar defined in connection with the Hölder matrix and vector norms as

$$\gamma_p(\mathbf{A}) \equiv \max_{\mathbf{u}, \mathbf{v}} \frac{\|\mathbf{A}\mathbf{u}\|_p}{\|\mathbf{A}\mathbf{v}\|_p}, \|\mathbf{u}\|_p = \|\mathbf{v}\|_p = 1.$$

A geometrical interpretation of the condition number $\gamma_p(\mathbf{A})$ can be envisaged by considering that the surface $\|\mathbf{x}\| = 1$ is mapped by the linear transformation $\mathbf{y} = \mathbf{A}\mathbf{x}$ onto some surface S . Then, the condition number $\gamma_p(\mathbf{A})$ is the ratio of the largest to the smallest distances from the origin to points on S . This interpretation indicates that $\gamma_p(\mathbf{A}) \geq 1$, when \mathbf{A} is nonsingular, and $\gamma_p(\mathbf{A}) = \infty$, when \mathbf{A} is singular. Rearranging the above definition leads to $\gamma_p(\mathbf{A}) = |\mathbf{A}^{-1}| \|\mathbf{A}\|$, which implies that $\gamma_p(\mathbf{A})$ becomes large when $|\mathbf{A}|$ is small; in such cases, the matrix \mathbf{A} is called *ill-conditioned*. Ill-conditioning may be regarded as an approach towards singularity, a situation that causes considerable difficulties when solving linear simultaneous equations, since a small change in the coefficients of the equations causes a large displacement in the solution, leading to loss of solution accuracy due to the loss of significant figures during the computation.

Reduced singular value decomposition (SVD) of a rectangular matrix $\mathbf{A}^{m \times n}$ of full rank:

$$\mathbf{A} = \mathbf{U}\sqrt{\boldsymbol{\Lambda}}\mathbf{V}^T = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n] \begin{bmatrix} \sqrt{\lambda_1} & 0 & \dots & 0 \\ 0 & \sqrt{\lambda_2} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \sqrt{\lambda_n} \end{bmatrix} \begin{bmatrix} \mathbf{v}_1^T \\ \mathbf{v}_2^T \\ \vdots \\ \mathbf{v}_n^T \end{bmatrix} = \sum_{i=1}^n \sqrt{\lambda_i} \mathbf{u}_i \mathbf{v}_i^T,$$

where

$$\begin{aligned} (\mathbf{A}^T \mathbf{A}) \mathbf{v}_i &= \lambda_i \mathbf{v}_i, & \mathbf{v}_i &\in \mathbb{R}^n, & \mathbf{V} &= [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n] \in \mathbb{R}^{m \times n}, \\ (\mathbf{A}\mathbf{A}^T) \mathbf{u}_i &= \lambda_i \mathbf{u}_i, & \mathbf{u}_i &\in \mathbb{R}^m, & \mathbf{U} &= [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n] \in \mathbb{R}^{m \times n}, \\ \mathbf{A} &= \text{Diag}[\lambda_1, \lambda_2, \dots, \lambda_n] \in \mathbb{R}^{n \times n}. \end{aligned}$$

The columns of \mathbf{U} and those of \mathbf{V} are called the *left* and the *right singular vectors* of \mathbf{A} , respectively, while $\sqrt{\lambda_i}$ are called the *singular values*; note that the outer product $\mathbf{u}_i \mathbf{v}_i^T$, is a *rank-one* matrix.

In the particular case when $\mathbf{A} \in \mathbb{R}^{n \times n}$ is symmetric, $\mathbf{A} = \mathbf{A}^T$, and $\mathbf{A}^T \mathbf{A} = \mathbf{A}\mathbf{A}^T = \mathbf{A}^2$, so that $\mathbf{u}_i = \mathbf{v}_i$, while λ_i is the eigenvalue of \mathbf{A}^2 , and $\sqrt{\lambda_i}$ that of \mathbf{A} . In this case, the expansion $\mathbf{U}\sqrt{\boldsymbol{\Lambda}}\mathbf{V}^T$ becomes $\mathbf{A} = \sum_{i=1}^n \sqrt{\lambda_i} \mathbf{u}_i \mathbf{u}_i^T$.

If $\mathbf{A}^{m \times n}$ is not of full rank, e.g., $\text{Rank}(\mathbf{A}) = r$, where $r < \min\{m, n\}$, then $\mathbf{A} = \mathbf{U}_1 \sqrt{\boldsymbol{\Sigma}_{11}} \mathbf{V}_1^T$, where \mathbf{U}_1 contains the first r columns of \mathbf{U} , $\boldsymbol{\Sigma}_{11} \in \mathbb{R}^{r \times r}$ is a diagonal matrix containing the r singular values, and $\mathbf{V}_1^T \in \mathbb{R}^{r \times n}$ contains the first r columns of \mathbf{A} .

2 Elements of Functional Analysis

2.1 Operators in Vector Spaces

A nonempty set \mathcal{V} is called a vector space if any pair of elements $f, g \in \mathcal{V}$ can be:

- (i) added together by an operation called addition to give an element $f + g$ in \mathcal{V} , such that, for any $f, g, h \in \mathcal{V}$, the following properties hold:

$$\begin{aligned} f + g &= g + f, \\ f + (g + h) &= (f + g) + h. \end{aligned}$$

There is a unique element 0 in \mathcal{V} such that $f + 0 = f$ for all $f \in \mathcal{V}$; For each $f \in \mathcal{V}$ there is a unique element $(-f)$ in \mathcal{V} such that $f + (-f) = 0$.

- (ii) Multiplied by any scalar α of a field \mathcal{F} to give an element αf in \mathcal{V} ; furthermore, for any scalars α, β , the following properties must hold:

$$\begin{aligned}\alpha(f + g) &= \alpha f + \alpha g, \\ (\alpha + \beta)f &= \alpha f + \beta f, \\ (\alpha\beta)f &= \alpha(\beta f), \\ 1 \times f &= f.\end{aligned}$$

The *norm* of a vector $f \in \mathcal{V}$, denoted by $\|f\|$, is a nonnegative real scalar that satisfies the following relations, for all $f, g \in \mathcal{V}$:

$$\begin{aligned}\|f\| &= 0 \text{ iff } f = 0, \\ \|\alpha f\| &= |\alpha| \|f\| \text{ for any scalar } \alpha, \\ \|f + g\| &\leq \|f\| + \|g\| \text{ (the triangle inequality)}.\end{aligned}$$

A vector space \mathcal{V} endowed with a norm as defined above is called a *normed vector space*; the notation $\|\bullet\|$ highlights the role of the norm as a generalization of the customary distance in \mathbb{R}^3 .

The infinite-dimensional space obtained by generalizing \mathbb{R}^n or \mathbb{C}^n , and taking infinite sequences $f = (f_n)$ as the elements of the space is known as a *sequence space* and is usually denoted by ℓ . In the *sequence space* ℓ_p , the quantity $\|\bullet\|_p$, defined as

$$\begin{aligned}\|f\|_p &= \left\{ \sum |f_n|^p \right\}^{1/p}, \quad (1 \leq p < \infty), \\ \|f\|_\infty &= \sup |f_n|\end{aligned}$$

is a norm on the subset of those f where $\|f\|_p$ is finite. Two numbers, p, q , with $1 \leq p, q \leq \infty$, are called *conjugate indices* iff $p^{-1} + q^{-1} = 1$; if $p = 1$, then $q = \infty$. When $1 \leq p \leq \infty$, and q is the conjugate index, the following inequalities hold for any $f, g \in \ell_p$ (infinite values being allowed):

$$\begin{aligned}\|fg\|_1 &\leq \|f\|_p \|g\|_q \text{ (Hölder's inequality)}, \\ \|f + g\|_p &\leq \|f\|_p + \|g\|_p \text{ (Minkowski's inequality)}.\end{aligned}$$

A complex valued function f , defined on $\Omega \in \mathbb{R}^n$, is called *continuous at the point* $x_0 \in \Omega$ iff for each $\varepsilon > 0$ there exists $\delta > 0$ such that $|f(x) - f(x_0)| < \varepsilon$ whenever $x \in \Omega$ and $|x - x_0| < \delta$. The function f is said to be *uniformly continuous* on Ω iff for each $\varepsilon > 0$ there exists a $\delta > 0$ such that $|f(x) - f(x_0)| < \varepsilon$, whenever $x, x_0 \in \Omega$ and $|x - x_0| < \delta$.

Thus, when Ω is the finite interval $[a, b]$, continuity at a or b is to be interpreted as continuity from the right or left, respectively. If f is continuous on $[a, b]$, then it is bounded, but f need not be bounded if it is continuous only on (a, b) . For functions of several variables, continuity in the sense of the above definition is sometimes referred to as “joint continuity” to distinguish it from “separate continuity;” the latter terminology means that the function is continuous in each variable in turn when the other variables are fixed. For example, if f is a function of two variables, separate continuity requires only that $f(x, \bullet)$ and $f(\bullet, y)$ should be continuous for

fixed x and y , respectively. (The notation $f(x, \bullet)$ indicates that x is fixed, and the function is regarded as a function of its second argument only.) Uniform continuity is in general stronger than continuity, since the same δ must serve for every $x_0 \in \Omega$, but if $\Omega \subset \mathbb{R}^n$ is closed and bounded, then these concepts are equivalent.

The vector space of bounded continuous complex valued functions defined on $\Omega \subset \mathbb{R}^n$ is denoted by $\mathcal{C}(\Omega)$. The space $\mathcal{C}(\Omega)$ may be normed in several ways. The sup norm $\|\bullet\|$, defined as

$$\|f\| = \sup_{x \in \Omega} |f(x)|,$$

is most often used in practical applications. Generalizations of $\mathcal{C}(\Omega)$ are often used for treating differential equations. Thus, $\mathcal{C}(\Omega, \mathbb{R}^m)$ denotes the normed vector space of \mathbb{R}^m -valued functions equipped with the sup norm

$$\|f\| = \max_{1 \leq j \leq m} \sup_{x \in \Omega} |f_j(x)|.$$

The vector space denoted by $\mathcal{C}^k(\Omega, \mathbb{R}^m)$ consists of all \mathbb{R}^m -valued functions defined on Ω such that all partial derivatives up to and including those of order $k > 0$ of all components are bounded and continuous. The vector space $\mathcal{C}^\infty(\Omega, \mathbb{R}^m)$ consists of functions in $\mathcal{C}^k(\Omega, \mathbb{R}^m)$ such that $\mathcal{C}^\infty(\Omega, \mathbb{R}^m) = \cap_{k=1}^\infty \mathcal{C}^k(\Omega, \mathbb{R}^m)$. The space $\mathcal{C}^k(\bar{\Omega}, \mathbb{R}^m)$ consists of those continuous functions defined on $\bar{\Omega}$ which on Ω have bounded and uniformly continuous partial derivatives up to and including those of order k . (For $n > 1$, this convention avoids difficulties with the definition of derivatives on $\partial\Omega$, which is not necessarily a smooth set.) It also follows that $\mathcal{C}^\infty(\bar{\Omega}, \mathbb{R}^m) = \cap_{k=1}^\infty \mathcal{C}^k(\bar{\Omega}, \mathbb{R}^m)$.

The spaces $\mathcal{C}_0^\infty(\Omega', \mathbb{R}^m)$, where $\Omega \subset \Omega' \subset \bar{\Omega}$, are used when it is convenient to exclude the boundary from consideration. These spaces consist of those functions in $\mathcal{C}^k(\Omega, \mathbb{R}^m)$ that have bounded support contained in the interior of Ω' . (Recall that the support of a function is the closure of the set on which the function is nonzero; the support may vary from function to function.)

For example, for the finite interval $[a, b]$, a function is in $\mathcal{C}^1([a, b])$ if and only if (iff) it has a continuous derivative on (a, b) and has left and right derivatives at b and a , respectively, which are the limits of the derivatives in the interior. Another possibility is to take $\Omega = (a, b)$ and to set

$$\|f\|_{\mathcal{C}^k} = \sum_{j=0}^k \sup_{x \in [a, b]} |f^{(j)}(x)|,$$

where $f^{(j)}$ denotes the j^{th} derivative of f . The above norm is often used as a basis for analysis in $\mathcal{C}^k(\bar{\Omega})$. Corresponding norms may be defined when Ω is a subset of \mathbb{R}^n for $n > 1$ by summing over the partial derivatives.

A comparison of the concept of “closeness” for two functions f and g in the sup norm and in $\|\bullet\|_1$ shows that the sup norm bounds the difference $|f(x) - g(x)|$ for every x , whereas $\|\bullet\|_1$ only restricts the average value of this difference. Convergence in sup norm is a very strong condition and implies convergence in $\|\bullet\|_1$; the converse implication is not true.

A sequence of functions (f_n) in a normed vector space \mathcal{V} is called a Cauchy sequence iff $\lim_{m, n \rightarrow \infty} \|f_n - f_m\| = 0$. A set \mathcal{S} in a normed vector space \mathcal{V} is said to be complete iff each

Cauchy sequence in \mathcal{S} converges to a point of \mathcal{S} . A complete normed vector space \mathcal{V} is usually called a *Banach space*.

An *inner product*, denoted by (\bullet, \bullet) , on a normed vector space \mathcal{V} is a complex (respectively, real) valued function on $\mathcal{V} \times \mathcal{V}$ such that for all $f, g, h \in \mathcal{V}$ and $\alpha \in \mathbb{C}$ (respectively, $\alpha \in \mathbb{R}$) the following properties hold:

1. $(f, f) \geq 0$; the equality $(f, f) = 0$ holds iff $f = 0$.
2. $(f, g + h) = (f, g) + (f, h)$.
3. $(f, g) = \overline{(g, f)}$, where the overbar denotes complex conjugation.
4. $(\alpha f, g) = \alpha (f, g)$.

Pre-Hilbert or inner product space: A space \mathcal{V} equipped with an inner product is called a *pre-Hilbert* or *inner product space*. If \mathcal{V} is a real vector space, and the inner product is real-valued, then the respective space is called a *real pre-Hilbert space*.

Hilbert space: A pre-Hilbert space that is *complete with respect to the norm* is called a *Hilbert space*, and is usually denoted as \mathcal{H} . The spaces \mathbb{R}^n and \mathbb{C}^n with the usual inner product are Hilbert spaces, and so is the infinite sequence space equipped with the inner product

$$(f, g) = \sum f_n \bar{g}_n,$$

where $f = (f_1, f_2, \dots)$, $g = (g_1, g_2, \dots)$.

A set \mathcal{K} of vectors in \mathcal{H} is said to be *complete* iff $(f, \varphi) = 0$ for all $\varphi \in \mathcal{K}$ implies that $f = 0$. A countable set $\mathcal{K} = \{\varphi_n\}_{n=1}^{\infty}$ is called *orthonormal* iff $(\varphi_n, \varphi_m) = \delta_{nm}$ for all $m, n \geq 1$. The numbers (f, φ_n) are called the *Fourier coefficients* of f (with respect to \mathcal{K}), and the *Fourier series* of f is the formal series $\sum_n (f, \varphi_n) \varphi_n$.

Orthonormal basis: An orthonormal set $\mathcal{K} = \{\varphi_n\}$ is called an *orthonormal basis* of \mathcal{H} iff every $f \in \mathcal{H}$ can be represented in the *Fourier series*

$$f = \sum_n (f, \varphi_n) \varphi_n.$$

A sequence of vectors $\mathbf{x}_1, \mathbf{x}_2, \dots$ is called *nondegenerate* if, for every p , the vectors $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_p$ are linearly independent. A sequence of vectors is called *orthogonal* if any two vectors of the sequence are orthogonal; *orthogonalization* of a sequence of vectors is the process of replacing the sequence by an equivalent orthogonal sequence. Every nondegenerate sequence of vectors can be orthogonalized. The orthogonalization process leads to vectors that are uniquely determined to within scalar multiples.

Every finite-dimensional subspace \mathcal{S} (and, in particular, the entire space \mathbb{R} if it is finite-dimensional) has an orthonormal basis; in such a basis, the coordinates of a vector are equal to its projections onto the corresponding basis vectors:

$$\mathbf{x} = \sum_{i=1}^n (\mathbf{x}, \mathbf{e}_i) \mathbf{e}_i.$$

Consider that $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$ and $\mathbf{x}'_1, \mathbf{x}'_2, \dots, \mathbf{x}'_n$ are the coordinates of the same vector \mathbf{x} in two different orthonormal bases $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n$ and $\mathbf{e}'_1, \mathbf{e}'_2, \dots, \mathbf{e}'_n$ of a unitary space \mathbb{R} . The transformation between the two coordinate systems is given by

$$\mathbf{x}_i = \sum_{k=1}^n u_{ik} \mathbf{x}'_k \quad (i = 1, 2, \dots, n),$$

where the coefficients $u_{1k}, u_{2k}, \dots, u_{nk}$ satisfy the relations

$$\sum_{i=1}^n u_{ik} \bar{u}_{il} = \delta_{kl} = \begin{cases} 1, & \text{for } k = l, \\ 0, & \text{for } k \neq l. \end{cases}$$

The above transformation is called *unitary* and the corresponding matrix $U = (u_{ik})$ is called a *unitary matrix*. Thus, in an n -dimensional unitary space the transition from one orthonormal basis to another is effected by a unitary coordinate transformation. In an n -dimensional Euclidean space, the transition from one orthonormal basis to another is effected by an *orthogonal* coordinate transformation, and the matrix underlying an orthogonal transformation is called an *orthogonal matrix*.

For example, orthogonalization of the sequence of powers $1, x, x^2, x^3, \dots$, using the inner product $(f, g) = \int_a^b f(x) g(x) \tau(x) dx$, where $\tau(x) \geq 0$ and $a \leq x \leq b$, yields sequences of orthogonal polynomials. For example, using $a = -1, b = 1$, and $\tau(x) = 1$ leads to the Legendre polynomials

$$P_0(x) = 1, P_m(x) = \frac{1}{2^m m!} \frac{d^m (x^2 - 1)^m}{dx^m} \quad (m = 1, 2, \dots).$$

On the other hand, using $a = -1, b = 1$, and $\tau(x) = 1/\sqrt{1 - x^2}$ leads to the Tchebyshev (Chebyshev) polynomials $T_n(x) = \cos(n \arccos x)/(2^{n-1})$. Furthermore, using $a = -\infty, b = +\infty$, and $\tau(x) = e^{-x^2}$ leads to the Hermite polynomials, and so on.

Consider an arbitrary vector \mathbf{x} , an orthonormal sequence of vectors $\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_p, \dots$, with $p = (1, 2, \dots)$; consider also the sequence $\xi_p \equiv (\mathbf{x}, \mathbf{z}_p)$. If the limit

$$\lim_{p \rightarrow \infty} \left(\|\mathbf{x}\| - \sum_{k=1}^p |\xi_k|^2 \right)^{1/2} = 0$$

holds, then the series $\sum_{k=1}^{\infty} \xi_k \mathbf{z}_k$ is said to converge in the mean (or with respect to the norm) to the vector \mathbf{x} , and the norm of \mathbf{x} is given by:

$$\|\mathbf{x}\| = |\mathbf{x}|^2 = \sum_{k=1}^{\infty} |\xi_k|^2.$$

If, for every vector \mathbf{x} of \mathbb{R} , the series $\sum_{k=1}^{\infty} \xi_k \mathbf{z}_k$ converges in the mean to \mathbf{x} , then the orthonormal sequence of vectors $\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_p, \dots$ is complete. In terms of such a complete orthonormal sequence \mathbf{z}_k , the scalar product of two vectors \mathbf{x} and \mathbf{y} in \mathbb{R} becomes

$$(\mathbf{x}, \mathbf{y}) = \sum_{k=1}^{\infty} \xi_k \bar{\eta}_k \quad (\xi_k = \langle \mathbf{x}, \mathbf{z}_k \rangle, \eta_k = \langle \mathbf{y}, \mathbf{z}_k \rangle, k = 1, 2, \dots).$$

As a further example, consider the space of all complex functions $f(t)$, where t is a real variable, that are piecewise continuous in the closed interval $[0, 2\pi]$, with the norm and the scalar product defined, respectively, as $\|f\| = \int_0^{2\pi} |f(t)|^2 dt$, and $(f, g) = \int_0^{2\pi} f(t) \bar{g}(t) dt$. Consider now the infinite sequence of orthogonal and complete functions $e^{ikt}/\sqrt{2\pi}$, ($k = 0, \pm 1, \pm 2, \dots$). Then, the *Fourier series* of $f(t)$, namely $\sum_{k=-\infty}^{\infty} f_k e^{ikt}$, with

Fourier coefficients $f_k = (\int_0^{2\pi} f(t) e^{-ikt} dt)/2\pi$, ($k = 0, \pm 1, \pm 2, \dots$), converges in the mean to $f(t)$ in the interval $[0, 2\pi]$. The condition of completeness for the function f is called Parseval's equality:

$$\int_0^{2\pi} f(t) \overline{g(t)} dt = \sum_{k=-\infty}^{+\infty} \frac{1}{2\pi} \int_0^{2\pi} f(t) e^{-ikt} dt \int_0^{2\pi} \overline{g(t)} e^{ikt} dt.$$

If $f(t)$ is a real function, then f_0 is real, and f_k and f_{-k} are conjugate complex numbers. Therefore, for a real function $f(t)$, the Fourier series becomes $f(t) = a_0/2 + \sum_{k=1}^{\infty} (a_k \cos kt + b_k \sin kt)$, where $a_k = (\int_0^{2\pi} f(t) \cos kt)/\pi$ and $b_k = (\int_0^{2\pi} f(t) \sin kt)/\pi$, for $k = 0, 1, 2, \dots$

The space \mathcal{L}_p (or $\mathcal{L}_p(X)$, if X needs emphasis) is defined to be the set of measurable functions f such that $\|f\|_p < \infty$, where

$$\|f\|_p = \left\{ \int |f|^p d\mu \right\}^{1/p}, \quad (1 \leq p < \infty),$$

$$\|f\|_\infty = \text{ess sup } |f|.$$

Frequently, X will be an interval of the real line with end points a and b , while μ will be the Lebesgue measure; in this case, the space will be denoted by $\mathcal{L}_p(a, b)$. Two functions f and g in $\mathcal{L}_p(X)$ are said to be equal iff $f = g$ almost everywhere. Thus, all functions in $\mathcal{L}_p(X)$ are finite almost everywhere. When $p = \infty$, then $\|f\|_\infty = \sup |f(x)|$, for f continuous and μ representing the Lebesgue measure. Thus, the continuous bounded functions with the sup norm form a closed subspace of \mathcal{L}_∞ . If a function f in \mathcal{L}_∞ is not continuous, the measure of the set for which $|f(x)| > \|f\|_\infty$ is zero. The space \mathcal{L}_p may be thought of as the continuous analogue of the sequence space, with integration replacing summation; for $p \geq 1$, \mathcal{L}_p is a Banach space under the norm $\|\bullet\|_p$. Furthermore, \mathcal{L}_p is separable if $1 \leq p < \infty$; in particular, \mathcal{L}_2 is a Hilbert space when equipped with the inner product $(f, g) = \int f \bar{g} d\mu$.

The set $\mathcal{D}(A)$ (sometimes denoted just by \mathcal{D} if there is only one mapping under consideration) is called the *domain* of a mapping A . For $f \in \mathcal{D}(A)$, the element Af is called the *image* of f . Likewise, the image $A(S)$ of a set $S \subset \mathcal{D}(A)$ is the set of the images of all the elements of S . In particular, the image of $\mathcal{D}(A)$ is called the *range* of A and is written as $\mathcal{R}(A)$. The *preimage* of a set $\mathcal{S}_1 \subset \mathcal{W}$ is the set $A^{-1}(\mathcal{S}_1) = \{f : f \in \mathcal{D}(A), Af \in \mathcal{S}_1\}$.

Operator, function, functional: The mapping A is called an *operator* or a *function* from \mathcal{V} into \mathcal{W} . The notation $A : \mathcal{S} \rightarrow \mathcal{W}$ indicates that A is an operator with domain \mathcal{S} and range in \mathcal{W} , or, equivalently, that A maps \mathcal{S} into \mathcal{W} . Note that an operator is always single-valued, in that it assigns exactly one element of its range to each element in its domain. Furthermore, although there is no strict distinction between "operator" and "function," it is customary to reserve "function" for the case when \mathcal{V} and \mathcal{W} are finite dimensional and to use "operator" otherwise. In view of its importance, one particular type of operator is given a name of its own: *the operator from \mathcal{V} into the field \mathcal{F} of scalars (real or complex) is called a functional.*

An operator A from \mathcal{V} into \mathcal{W} is called *injective* iff for each $g \in \mathcal{R}(A)$, there is exactly one $f \in \mathcal{D}(A)$ such that $Af = g$; A is called *surjective* iff $\mathcal{R}(A) = \mathcal{W}$, and A is called *bijective* iff it is both injective and surjective. The terms "one-to-one," "onto," "one-to-one and onto," respectively, are common alternatives in the literature. An operator A from \mathcal{V} into \mathcal{W} is *continuous at the point $f_0 \in \mathcal{D}(A)$* iff for each $\varepsilon > 0$, there is a $\delta > 0$ such that $\|Af - Af_0\| < \varepsilon$ if $f \in \mathcal{D}(A)$ and $\|f - f_0\| < \delta$; A is said to be *continuous* iff it is continuous at every point of $\mathcal{D}(A)$.

An operator L from \mathcal{V} into \mathcal{W} with domain $\mathcal{D}(L)$ is called *linear* iff $L(\alpha f + \beta g) = \alpha Lf + \beta Lg$ for all $\alpha, \beta \in \mathbb{C}$ (or $\alpha, \beta \in \mathbb{R}$, if \mathcal{V} and \mathcal{W} are real spaces), and all $f, g \in \mathcal{D}(L)$. A linear operator is the vector space analogue of a function in one dimension represented by a straight line through the origin, that is, a function $\varphi : \mathbb{R} \rightarrow \mathbb{R}$ where $\varphi(x) = \lambda x$ for some $\lambda \in \mathbb{R}$. In particular, the *identity* operator, denoted by I , is the operator from \mathcal{V} onto itself such that $If = f$ for all $f \in \mathbb{R}$.

A wide variety of equations may be written in the form $Lf = g$, with L a linear operator. For example, the simultaneous algebraic equations

$$\sum_{j=1}^n \alpha_{ij} f_j = g_i, \quad (i = 1, \dots, m),$$

define the operator L via the relation

$$(Lf)_i = \sum_{j=1}^n \alpha_{ij} f_j, \quad (i = 1, \dots, m).$$

In this case, $L : \mathbb{C}^n \rightarrow \mathbb{C}^m$ is a linear operator and the above equation can be written as $Lf = g$. Conversely, every linear operator $\mathbb{C}^n \rightarrow \mathbb{C}^m$ may be expressed in the above form by choosing bases for \mathbb{C}^n and \mathbb{C}^m . The above equations may also be put in matrix form, but note that there is a distinction between the matrix, which depends on the chosen basis, and the operator L , which does not.

As a further example, the Fredholm integral equation $f(x) - \int_0^1 k(x, y) f(y) dy = g(x)$, $0 \leq x \leq 1$, where k and g are given and f is the unknown function, can also be written in operator form as $f - Kf = g$, where K is a linear operator. Similarly, the differential equation $a_0 f''(x) + a_1 f'(x) + a_2 f(x) = g(x)$, $0 \leq x \leq 1$, where $a_0, a_1, a_2 \in \mathbb{C}$, and g is a given continuous function, can be written in the form $Lf = g$, with $L : \mathbb{C}^2([0, 1]) \rightarrow \mathbb{C}([0, 1])$ being a linear operator.

The operator equation $Lf = g$, where L is a linear operator from \mathcal{V} into \mathcal{W} with domain $\mathcal{D}(L)$, may or may not have a solution f for every $g \in \mathcal{R}(L)$, depending on the following possibilities:

- (i) L is *not injective*, in which case a reasonable interpretation of the inverse operator L^{-1} is not possible. The equation $Lf = g$ always has more than one solution if $g \in \mathcal{R}(L)$.
- (ii) L is *injective but not surjective*. In this case, the equation $Lf = g$ has exactly one solution if $g \in \mathcal{R}(L)$, but no solution otherwise. The inverse L^{-1} is the operator with domain $\mathcal{R}(L)$ and range $\mathcal{D}(L)$ defined by $f = L^{-1}g$. The set $\mathcal{N}(L) \subset \mathcal{D}(L)$ of solutions of the equation $Lf = 0$ is called the *null space* of L . Note that $\mathcal{N}(L)$ is a linear subspace, and $\mathcal{N}(L) = 0$ iff L is injective.
- (iii) L is *bijective*. In this case, L^{-1} is a linear operator with domain \mathcal{W} , and $Lf = g$ has exactly one solution for each $g \in \mathcal{W}$.

If a linear operator L from \mathcal{V} into \mathcal{W} is continuous at some point $f \in \mathcal{D}(L)$, then L is continuous everywhere. A linear operator L is *bounded* on $\mathcal{D}(L)$ iff there is a finite number m such that $\|Lf\| \leq m \|f\|$, with $f \in \mathcal{D}(L)$. If L is not bounded on $\mathcal{D}(L)$, it is said to be *unbounded*. The infimum of all constants m such that this inequality holds is denoted by $\|L\|$, and is called the operator norm of L . Note that $\|Lf\| \leq \|L\| \|f\|$; this relationship may be compared with the relation $|\varphi(x)| = |\lambda x| = |\lambda| |x|$ for a linear operator $\varphi(x) = \lambda x$, $\varphi : \mathbb{R} \rightarrow \mathbb{R}$. Since $|\lambda|$ is a measure of the gradient of φ , the norm of the operator L may therefore be thought of as its maximum gradient.

Suppose that L is a (possibly unbounded) linear operator from a Banach space \mathcal{B} into \mathcal{B} . The set $\rho(L)$ of complex numbers for which $(\lambda I - L)^{-1}$ belongs to the space of linear operators on \mathcal{B} is called the *resolvent set* of L . For $\lambda \in \rho(L)$, the operator $R(\lambda; L) \equiv (\lambda I - L)^{-1}$ is known as the *resolvent* of L . The complement $\sigma(L)$ in \mathcal{C} of $\rho(L)$ is the *spectrum* of L . A complex number λ is called an *eigenvalue* (*characteristic value*) of L iff the equation $\lambda f - Lf = 0$ has a nonzero solution. The corresponding nonzero solutions are called *eigenfunctions* (*characteristic functions*), and the linear subspace spanned by these is called the *eigenspace* (*characteristic space*) corresponding to λ . The set $\sigma_p(L)$ of eigenvalues is known as the *point spectrum* of L . The set consisting of those $\lambda \in \sigma(L)$ for which $(\lambda I - L)$ is injective and $R(\lambda I - L)$ is dense (respectively, not dense) in \mathcal{B} is called the *continuous spectrum* (respectively, the *residual spectrum*). Thus, $\lambda \in \rho(L)$ iff $\lambda I - L$ is bijective; in this case $\sigma(L)$ is the union of the point, continuous and residual spectra, which are disjoint sets. If \mathcal{B} is finite dimensional, then $\sigma(L) = \sigma_p(L)$.

Formal differential operators: The operator

$$l = \sum_{r=0}^n p_r(x) \left(\frac{d}{dx} \right)^r,$$

where p_r ($r = 0, 1, \dots, n$) are given functions on \mathbb{R} , is called a *formal ordinary differential operator* of order n . In a Hilbert space, it is convenient to refer loosely to any operator L obtained from l by setting $Lf = lf(x) = \sum_{r=0}^n p_r(x) f^{(r)}(x)$, for f in some specified domain, as a *differential operator*. For a general *partial differential equation* in n dimensions, the notational complexity can be reduced considerably by the use of multi-indices, which are defined as follows: a *multi-index* α is an n -tuple $(\alpha_1, \dots, \alpha_n)$ of nonnegative integers. It is also convenient to use the notation $|\alpha| = \alpha_1 + \dots + \alpha_n$ for a multi-index; even though this notation conflicts with the notation for the Euclidean distance \mathbb{R}^n , the meaning will always be clear from the context.

In the following, multi-indices will be denoted by α and β , and a point in \mathbb{R}^n will be denoted as $x = (x_1, \dots, x_n)$, with $x^\alpha = x_1^{\alpha_1} \dots x_n^{\alpha_n}$. The notation used for derivatives is $D_j = \partial/\partial x_j$ and $D^\alpha = D_1^{\alpha_1} \dots D_n^{\alpha_n}$. Consider that $p_{\alpha\beta} \neq 0$ are complex-valued variable coefficients such that $p_{\alpha\beta} \in C^\infty(\overline{\Omega})$, for multi-indices α and β , with $|\alpha| = |\beta| = m$. Consider, in addition, a function $\phi \in C^{2m}$; then, the *formal partial differential operator* l of order $2m$ is defined as

$$l\phi \equiv \sum_{|\alpha|, |\beta| \leq m} (-1)^{|\alpha|} D^\alpha (p_{\alpha\beta} D^\beta \phi).$$

The operator l_p , defined as

$$l_p\phi \equiv (-1)^m \sum_{|\alpha|=|\beta|=m} D^\alpha (p_{\alpha\beta} D^\beta \phi),$$

is called the *principal part* of the formal partial differential operator l .

Formal adjoint operator: Furthermore, the operator l^+ defined as

$$l^+\phi \equiv \sum_{|\alpha|, |\beta| \leq m} (-1)^{|\alpha|} D^\alpha (\overline{p_{\beta\alpha}} D^\beta \phi) \quad (\phi \in C^{2m})$$

is called the *formal adjoint* of l . Iff $l = l^+$, then l is called *formally self-adjoint*.

Define \mathcal{L}_p^{loc} to be the set of all functions that lie in $\mathcal{L}_p(\mathcal{S})$ for every set \mathcal{S} bounded and closed in \mathbb{R}^n . Then, a function f in \mathcal{L}_2^{loc} has a α^{th} weak derivative iff there exists a function $g \in \mathcal{L}_0^{loc}$ such that

$$\int_{\Omega} g\phi \, dx = (-1)^{|\alpha|} \int_{\Omega} f \cdot (D^{\alpha} \phi) \, dx$$

for all $\phi \in C_0^{\infty}$; the function g is called the α^{th} weak derivative of f , and we write $D^{\alpha} f = g$. Weak derivatives are unique in the context of \mathcal{L}_2 spaces, in the sense that if g_1 and g_2 are both weak α^{th} derivatives of f , then

$$\int_{\Omega} (g_1 - g_2) \phi \, dx = 0 \quad (\phi \in C_0^{\infty}),$$

which implies that $g_1 = g_2$ almost everywhere in Ω . The above relation also implies that if a function has an α^{th} derivative g in the ordinary sense in \mathcal{L}_2^{loc} , then g is the weak α^{th} derivative of f . The weak derivatives may be thought of as averaging out the discontinuities in f . Consequently, it is permissible to exchange the order of differentiation: $D_i D_j f = D_j D_i f$. In one dimension, a function has a weak first derivative iff it is absolutely continuous and has a first derivative in \mathcal{L}_2^{loc} . However, note that f may have an ordinary derivative almost everywhere without having a weak derivative. For example, if $f(x) = 1$ for $x > 0$ and $f(x) = 0$ for $x < 0$, then $\int_{-1}^1 f\phi' \, dx = \int_0^1 \phi' \, dx = -\phi(0)$, but f does not have a weak derivative since there is no $g \in \mathcal{L}_0^{loc}$ such that $\phi(0) = \int_{-1}^1 g\phi \, dx$ for all $\phi \in C_0^{\infty}$.

Sobolev spaces: The analysis of differential operators is carried out in special Hilbert spaces, called Sobolev spaces. The Sobolev space \mathcal{H}^m (or $\mathcal{H}^m(\Omega)$ if the domain requires emphasis) of order m , where m is a nonnegative integer, consists of the set of functions f such that for $0 \leq |\alpha| \leq m$, all the weak derivatives $D^{\alpha} f$ exist and are in \mathcal{L}_2 ; furthermore, \mathcal{H}^m is equipped with an inner product and a norm defined, respectively, as:

$$(f, g)_m = \sum_{|\alpha| \leq m} \int_{\Omega} D^{\alpha} f \cdot \overline{D^{\alpha} g} \, dx,$$

$$\|f\|_m^2 = (f, f)_m = \sum_{|\alpha| \leq m} \int_{\Omega} |D^{\alpha} f|^2 \, dx.$$

The above norm may be regarded as measuring the average value of the weak derivatives. Note that \mathcal{H}^m is a proper subset of the set of functions with m^{th} weak derivatives, since the derivatives $D^{\alpha} f$ are required to be in \mathcal{L}_2 , and not merely in \mathcal{L}_2^{loc} . The closure of C^{∞} in $\|\cdot\|_m$ is \mathcal{H}^m , and the closure in \mathcal{H}^m of C_0^{∞} is the Sobolev space \mathcal{H}_0^m , of order m . The following chains of inclusions hold for the higher order Sobolev spaces:

$$C^{\infty} \subset \dots \subset \mathcal{H}^{m+1} \subset \mathcal{H}^m \subset \dots \subset \mathcal{H}^0 = \mathcal{L}_2,$$

$$C_0^{\infty} \subset \dots \subset \mathcal{H}_0^{m+1} \subset \mathcal{H}_0^m \subset \dots \subset \mathcal{H}_0^0 = \mathcal{L}_2.$$

Bilinear form: The bilinear form, $B[f, \phi]$, associated with the formal differential operator l is defined for all functions $f, \phi \in \mathcal{H}_0^m$ as

$$B[f, \phi] = \sum_{|\alpha|, |\beta| \leq m} \left(p_{\alpha\beta} D^{\alpha} f, D^{\beta} \phi \right)_0.$$

Note that $B[f, \phi]$ is a bounded bilinear form on $\mathcal{H}_0^m \times \mathcal{H}_0^m$. The problem of finding $f \in \mathcal{H}_0^m$ such that $B[f, \phi] = (g, \phi)_0$ for all $\phi \in \mathcal{H}_0^m$ and $g \in \mathcal{L}_2$ is called the *generalized Dirichlet problem*.

Adjoint operators: The space of continuous linear functionals on a Banach space \mathcal{B} is called the *dual* of \mathcal{B} , and is denoted here by \mathcal{B}^+ . For a bounded linear operator $L : \mathcal{B} \rightarrow \mathcal{C}$, the relation

$$g^+(Lf) = L^+g^+(f),$$

required to hold for all $f \in \mathcal{B}$ and all $g^+ \in \mathcal{C}^+$, defines an operator L^+ from \mathcal{C}^+ into \mathcal{B}^+ , called the *adjoint* of L . For example, the adjoint of an integral operator of the form $Kf(x) = \int_0^1 k(x, y)f(y) dy$, for a continuous kernel $k : [0, 1] \times [0, 1] \rightarrow \mathbb{R}$, is the operator $K^+ : \mathcal{L}_\infty(0, 1) \rightarrow \mathcal{L}_\infty(0, 1)$ defined as $K^+g^+(y) = \int_0^1 k(x, y)g^+(x) dx$.

As the next example, consider the finite dimensional operator $L : \ell_1^{(n)} \rightarrow \ell_1^{(n)}$ corresponding to the matrix (α_{ij}) , namely

$$(Lf)_i = \sum_{j=1}^n \alpha_{ij}f_j, \quad (i = 1, \dots, n).$$

The corresponding adjoint operator, $L^+ : \ell_\infty^{(n)} \rightarrow \ell_\infty^{(n)}$, is represented by the transposed matrix $(\alpha_{ij})^T$, as can be seen by applying the definition of the adjoint operator:

$$g^+(Lf) = \sum_{i=1}^n (Lf)_i g_i^+ = \sum_{i=1}^n g_i^+ \sum_{j=1}^n \alpha_{ij}f_j = \sum_{j=1}^n f_j \sum_{i=1}^n \alpha_{ij}g_i^+ = (L^+g^+)(f).$$

Thus, even in finite dimensions, the adjoint operator depends on the norm of the space and has more significance than the algebraic “transpose.” For example, the relation $\|L\| = \|L^+\|$ will only hold if the dual space is correctly selected.

In an n -dimensional unitary space \mathbb{R} , the linear operator A^+ is called *adjoint* to the operator A iff, for any two vectors \mathbf{x}, \mathbf{y} of \mathbb{R} , the following relationship holds

$$(A\mathbf{x}, \mathbf{y}) = (\mathbf{x}, A^+\mathbf{y}).$$

In an orthonormal basis $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n$ in \mathbb{R} , the adjoint operator A^+ can be represented *uniquely* in the form

$$A^+\mathbf{y} = \sum_{k=1}^n \langle \mathbf{y}, A\mathbf{e}_k \rangle \mathbf{e}_k,$$

for any vector \mathbf{y} of \mathbb{R} . Consider that A is a linear operator in a unitary space and that $A = \|a_{ik}\|_i^n$ is the corresponding matrix that represents A in an orthonormal basis $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n$. Then, the matrix A^+ corresponding to the representation of the adjoint operator A^+ in the same basis is the complex conjugate of the transpose of A , i.e.,

$$A^+ = \overline{A}^T.$$

The matrix A^+ is called the *adjoint* of A . Thus, *in an orthonormal basis, adjoint matrices correspond to adjoint operators*. The adjoint operator has the following properties:

1. $(A^+)^+ = A$,
2. $(A + B)^+ = A^+ + B^+$,
3. $(\alpha A)^+ = \bar{\alpha}A^+$ (α a scalar),
4. $(AB)^+ = B^+A^+$,
5. If an arbitrary subspace \mathcal{S} of \mathbb{R} is invariant with respect to A , then the orthogonal complement \mathcal{T} of the subspace \mathcal{S} is invariant with respect to A^+ .

Two systems of vectors $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$ and $\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_n$ are by definition *bi-orthogonal* if

$$\langle \mathbf{x}_i, \mathbf{y}_k \rangle = \delta_{ik}, (i, k = 1, 2, \dots, m),$$

where δ_{ik} is the Kronecker symbol.

If A is a linear operator of simple structure, then the adjoint operator A^+ is also of simple structure; therefore, complete systems of characteristic vectors $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$ and $\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_n$ of A and A^+ , respectively, can be chosen such that they are bi-orthogonal:

$$A\mathbf{x}_i = \lambda_i\mathbf{x}_i, \quad A^+\mathbf{y}_i = \lambda_i\mathbf{y}_i, \quad \langle \mathbf{x}_i, \mathbf{y}_k \rangle = \delta_{ik}, (i, k = 1, 2, \dots, n).$$

Furthermore, if the operators A and A^+ have a common characteristic vector, then the corresponding characteristic values are complex conjugates. A linear operator A is called *normal* if it commutes with its adjoint:

$$AA^+ = A^+A.$$

A linear operator H is called *hermitian* if it is equal to its adjoint:

$$H^+ = H.$$

A linear operator U is called *unitary* if it is inverse to its adjoint:

$$UU^+ = I.$$

From the above definitions, it follows that (i) the product of two unitary operators is itself a unitary operator, (ii) the unit operator I is unitary, and (iii) the inverse of a unitary operator is also unitary. Therefore the set of all unitary operators forms a group, called the *unitary group*. Note that hermitian and unitary operators are special cases of a normal operator. Note also that a hermitian operator H is called *positive semidefinite* if the inequality $\langle H\mathbf{x}, \mathbf{x} \rangle \geq 0$ holds for every vector \mathbf{x} of \mathbb{R} ; H is called *positive definite* if the *strict* inequality $\langle H\mathbf{x}, \mathbf{x} \rangle > 0$ holds for every vector $\mathbf{x} \neq \mathbf{0}$ of \mathbb{R} .

Just as in the case of operators, a matrix is called *normal* if it commutes with its adjoint, *hermitian* if it is equal to its adjoint, and *unitary* if it is inverse to its adjoint. Thus, in an orthonormal basis, a normal (hermitian, unitary) operator corresponds to a normal (hermitian, unitary) matrix. Note that every characteristic vector of a normal operator A is a characteristic vector of the adjoint operator A^+ , i.e., if A is a normal operator, then A and A^+ have the same characteristic vectors. Furthermore, a linear operator is normal iff it has a complete orthonormal

system of characteristic vectors. If A is a normal operator, then each of the operators A and A^+ can be represented as a polynomial in the other; these two polynomials are determined by the characteristic values of A .

Hermitian and unitary operators can also be characterized in terms of their respective spectra. Thus, a linear operator is hermitian iff it has a complete orthonormal system of characteristic vectors with real characteristic values. Furthermore, a linear operator is unitary iff it has a complete orthonormal system of characteristic vectors with characteristic values of modulus 1. Consequently, a matrix A is normal iff it is unitarily similar to a diagonal matrix,

$$A = U \|\lambda_i \delta_{ik}\|_1^n U^{-1}, \quad U^+ = U^{-1}.$$

A matrix H is hermitian iff it is unitarily similar to a diagonal matrix with real diagonal elements:

$$H = U \|\lambda_i \delta_{ik}\|_1^n U^{-1}, \quad U^+ = U^{-1}, \quad \lambda_i = \bar{\lambda}_i, \quad (i = 1, 2, \dots, n).$$

Finally, a matrix U is unitary iff it is unitarily similar to a diagonal matrix with diagonal elements of modulus 1:

$$U = U_1 \|\lambda_i \delta_{ik}\|_1^n U_1^{-1}, \quad U_1^+ = U_1^{-1}, \quad |\lambda_i| = 1, \quad (i = 1, 2, \dots, n).$$

Note also that a hermitian operator is positive semidefinite (positive definite) iff all its characteristic values are nonnegative (positive).

In a Hilbert space \mathcal{H} , the relation $g^+(Lf) = L^+g^+(f)$ becomes

$$(Lf, g) = (f, L^+g),$$

for all f and $g \in \mathcal{H}$; thus, the above relation defines the bounded linear operator L^+ , called the (*Hilbert space*) *adjoint* of L . The *Riesz Representation Theorem* ensures that for every element g^+ of the dual \mathcal{H}^+ of a Hilbert space \mathcal{H} , there is a unique element g of \mathcal{H} such that $g^+(f) = (f, g)$ for all $f \in \mathcal{H}$. The equality $\|g^+\| = \|g\|$ also holds.

Self-adjoint operator: The class of bounded operators from a Hilbert space \mathcal{H} into itself is particularly important. Thus, if L is a linear operator on the Hilbert space \mathcal{H} , then L is said to be *self-adjoint* iff $L = L^+$. For example, for $\sum \sum |\alpha_{ij}|^2 < \infty$, the operator $L : \mathcal{L}_2 \rightarrow \mathcal{L}_2$ defined as $(Lf)_i = \sum_{j=1}^{\infty} \alpha_{ij} f_j$ is self-adjoint iff $\alpha_{ij} = \bar{\alpha}_{ji}$, ($i, j = 1, 2, \dots$), that is, iff the infinite matrix (α_{ij}) is *hermitian*, since $(L^+g)_j = \sum_{i=1}^{\infty} \bar{\alpha}_{ij} g_i$. The adjoint $L^+ : \mathcal{L}_2 \rightarrow \mathcal{L}_2$ is therefore represented by the conjugate transpose of the infinite matrix (α_{ij}) . As another example, the integral operator $Kf(x) = \int_0^1 k(x, y) f(y) dy$, $K : \mathcal{L}_2(0, 1) \rightarrow \mathcal{L}_2(0, 1)$ is bounded and is self-adjoint iff the kernel is, in the complex case, *hermitian*: $k(x, y) = \overline{k(y, x)}$, or, in the real case, *symmetric*: $k(x, y) = k(y, x)$.

Fredholm alternative theorem: The existence of solutions for operator equations involving linear compact operators is elucidated by the *Fredholm Alternative Theorem* (in a Hilbert space \mathcal{H}), which can be formulated as follows: consider that $L : \mathcal{H} \rightarrow \mathcal{H}$ is a linear compact operator, and consider the equation

$$(\lambda I - L)g = g, \quad g \in \mathcal{H}, \quad \lambda \neq 0.$$

Then, one of the following alternatives holds:

- (a) The homogeneous equation has only the zero solution; in this case, $\lambda \in \rho(L)$, where $\rho(L)$ denotes the *resolvent set* of L , implying thus that λ cannot be an eigenvalue of L . Furthermore, $(\lambda I - L)^{-1}$ is bounded, and the inhomogeneous equation has exactly one solution $f = (\lambda I - L)^{-1}g$, for each $g \in \mathcal{H}$.
- (b) The homogeneous equation has a nonzero solution; in this case, the inhomogeneous equation has a solution, necessarily nonunique, iff $\langle g, \varphi^+ \rangle = 0$, for every solution φ^+ of the adjoint equation $\lambda \varphi^+ = L^+ \varphi^+$, where L^+ denotes the operator adjoint to L , and $\langle \cdot, \cdot \rangle$ denotes the inner product in the respective Hilbert space \mathcal{H} .

Adjoint of an unbounded linear operator: Consider now that L denotes an *unbounded* linear operator from \mathcal{H} into \mathcal{H} , with domain $\mathcal{D}(L)$ dense in \mathcal{H} . Recall that the specification of a domain is an essential part of the definition of an unbounded operator. Define $\mathcal{D}(L^+)$ to be the set of elements g such that there is an h with $(Lf, g) = (f, h)$ for all $f \in \mathcal{D}(L)$. Let L^+ be the operator with domain $\mathcal{D}(L^+)$ and with $L^+g = h$ on $\mathcal{D}(L^+)$, or, equivalently, consider that L^+ satisfies the relation

$$(Lf, g) = (f, L^+g), \quad f \in \mathcal{D}(L), \quad g \in \mathcal{D}(L^+).$$

Then the operator L^+ is called the *adjoint* of L . Furthermore, a densely defined linear operator L from a Hilbert space into itself is called *self-adjoint* iff $L = L^+$. Note that necessarily $\mathcal{D}(L) = \mathcal{D}(L^+)$ for self-adjoint operators.

It is important to note that the operator theoretic concept of “adjoint” involves the boundary conditions in an essential manner, and is therefore a more comprehensive concept than the *formal adjoint operator*, which merely described the coefficients of a certain differential operator. To illustrate the difference between the (operator theoretic) adjoint of an unbounded operator and the underlying formal adjoint operator, consider the formal differential operator $l = id/dx$ on the interval $[0, 1]$, and consider the operator $Lf = if$. Furthermore, denote by \mathcal{A} the linear subspace of $\mathcal{H} = \mathcal{L}_2(0, 1)$ consisting of absolutely continuous functions with derivatives in $\mathcal{L}_2(0, 1)$. Suppose first that no boundary conditions are specified for L , so that $\mathcal{D}(L) = \mathcal{A}$; in this case, the proper adjoint boundary conditions are $\mathcal{D}(L^+) = \{g : g \in \mathcal{A}, g(0) = g(1) = 0\}$. On the other hand, suppose that the boundary conditions imposed on L are $\mathcal{D}(L) = \{f : f \in \mathcal{A}, f(0) = f(1) = 0\}$; in this case, the proper adjoint boundary conditions are $\mathcal{D}(L^+) = \mathcal{A}$. Note that L is not equal to L^+ , in either of these two examples, although l is “self-adjoint” in the sense of classical differential equation theory. To construct a self-adjoint operator from the formal operator $l = id/dx$ on $[0, 1]$, it is necessary to choose boundary conditions so as to ensure that $\mathcal{D}(L) = \mathcal{D}(L^+)$, implying that the proper domain is $\mathcal{D}(L) = \{f : f \in \mathcal{A}, f(1) = e^{i\theta}f(0), \theta \in \mathbb{R}\}$, which means that there are infinitely many self-adjoint operators based on the formal operator id/dx on the interval $[0, 1]$.

2.2 Differential Calculus

Gâteaux and Fréchet variations, differentials and derivatives: Consider that I is an open interval of the real line and \mathcal{V} is a normed real space. The *derivative* of a mapping (or operator) $\phi : I \rightarrow \mathcal{V}$ at $t_0 \in I$ is defined as $\lim_{t \rightarrow t_0} (\phi(t) - \phi(t_0))/(t - t_0)$ if this limit exists, and

is denoted by $\phi'(t_0)$. The limit is to be understood in the sense of the norm in \mathcal{V} , namely $\|(\phi(t) - \phi(t_0))/(t - t_0) - \phi'(t_0)\| \rightarrow 0$ as $t \rightarrow 0$. Consider next that \mathcal{V} and \mathcal{W} are normed real spaces and \mathcal{D} is an open subset of \mathcal{V} . Consider that $x_0 \in \mathcal{D}$, and h is a fixed nonzero element in \mathcal{V} . Since \mathcal{D} is open, there exists an interval $I = (-\tau, \tau)$ for some $\tau > 0$ such that if $t \in I$, then $x_0 + th \in \mathcal{D}$. If the mapping $\phi : I \rightarrow \mathcal{V}$ defined by $\phi(t) = F(x_0 + th)$ has a derivative at $t = 0$, then $\phi'(0)$ is called the *Gâteaux variation* of F at x_0 with increment h , and is denoted by $\delta F(x_0; h)$, i.e.,

$$\delta F(x_0; h) \equiv \left. \frac{d}{dt} F(x_0 + th) \right|_{t=0} = \lim_{t \rightarrow 0} \frac{1}{t} \{F(x_0 + th) - F(x_0)\}.$$

The above relation may be used to define $\delta F(x_0; h)$ when \mathcal{V} is any linear space, not necessarily normed. When $\delta F(x_0; h)$ exists, it is homogeneous in h of degree one, i.e., for each real number λ , $\delta F(x_0; \lambda h)$ exists and is equal to $\lambda \delta F(x_0; h)$. The Gâteaux variation is a generalization of the notion of the directional derivative in calculus and of the notion of the first variation arising in the calculus of variations. The existence of the Gâteaux variation at $x_0 \in \mathcal{D}$ provides a local approximation property in the following sense:

$$F(x_0 + h) - F(x_0) = \delta F(x_0; h) + r(x_0; h), \quad \text{where } \lim_{t \rightarrow 0} \frac{r(x_0; th)}{t} = 0.$$

The existence of $\delta F(x_0; h)$ implies the *directional continuity* of F at x_0 , i.e.,

$$\|F(x_0 + th) - F(x_0)\| \rightarrow 0 \text{ as } t \rightarrow 0 \text{ for fixed } h,$$

but does not imply that F is continuous at x_0 . This is equivalent to saying that, in general, the above limit does not hold uniformly with respect to h on the bounded set $\{h : \|h\| = 1\}$. Note also that the operator $h \rightarrow \delta F(x_0; h)$ is not necessarily linear or continuous in h .

If F and G have a Gâteaux variation at x_0 , then so does the operator $T = \alpha F + \beta G$, where α, β are real numbers, and the relation $\delta T(x_0; h) = \alpha \delta F(x_0; h) + \beta \delta G(x_0; h)$ holds. However, the chain rule for the differentiation of a composite function does not hold in general.

An operator F has a *Gâteaux differential* at x_0 if $\delta F(x_0; \bullet)$ is linear and continuous; in this case, $\delta F(x_0; \bullet)$ is denoted by $DF(x_0)$ and is called the *Gâteaux derivative*. The necessary and sufficient condition for $\delta F(x_0; h)$ to be linear and continuous in h is that F satisfies the following two relations:

- To each h , there corresponds $\delta(h)$ such that $|t| \leq \delta$ implies $\|F(x_0 + th) - F(x_0)\| \leq M \|th\|$, where M does not depend on h .
- $F(x_0 + th_1 + th_2) - F(x_0 + th_1) - F(x_0 + th_2) + F(x_0) = o(t)$.

Note that the chain rule does not necessarily hold for Gâteaux derivatives. Note also that if $\delta F(x_0; \bullet)$ is additive, then $\delta F(x_0; h)$ is directionally continuous in h , i.e.,

$$\lim_{\tau \rightarrow 0} \delta F(x_0; h + \tau k) = \delta F(x_0; h).$$

An operator $F : \mathcal{D} \rightarrow \mathcal{W}$, where \mathcal{D} is an open subset of \mathcal{V} and \mathcal{V} and \mathcal{W} are normed real linear spaces, is called *Fréchet differentiable* at $x_0 \in \mathcal{D}$ if there exists a continuous linear operator $L(x_0) : \mathcal{V} \rightarrow \mathcal{W}$ such that the following representation holds for every $h \in \mathcal{V}$ with $x_0 + h \in \mathcal{D}$:

$$F(x_0 + h) - F(x_0) = L(x_0)h + r(x_0; h), \quad \text{with } \lim_{h \rightarrow 0} \frac{\|r(x_0; h)\|}{\|h\|} = 0.$$

The unique operator $L(x_0)h$ in the above equation is called the *Fréchet differential* of F at x_0 and is usually denoted by $dF(x_0; h)$. The linear operator $F'(x_0) : \mathcal{V} \rightarrow \mathcal{W}$ defined by $h \rightarrow dF(x_0; h)$ is called the *Fréchet derivative* of F at x_0 , and $dF(x_0; h) = F'(x_0)h$.

The Fréchet differential has the usual properties of the classical differential of a function of one or several variables. In particular, the chain rule holds for $F \bullet G$ if F has a Fréchet differential and G has a Gâteaux differential. Note that the chain rule may not hold for $F \bullet G$ if F has a Gâteaux differential and G has a Fréchet differential. Fréchet differentiability of F at x_0 implies continuity of F at x_0 .

Consider an operator $F : \mathcal{V} \rightarrow \mathcal{W}$, where \mathcal{V} is an open subset of the product space $\mathcal{P} = \mathcal{E}_1 \times \dots \times \mathcal{E}_n$. The *Gâteaux partial differential* at $u \equiv (u_1, \dots, u_n)$ of F with respect to u_i is the bounded linear operator $D_i F(u_1, \dots, u_n; h_i) : \mathcal{E}_i \rightarrow \mathcal{W}$ defined such that the following relation holds:

$$F(u_1, \dots, u_{i-1}, u_i + h_i, u_{i+1}, \dots, u_n) - F(u_1, \dots, u_n) = D_i F(u_1, \dots, u_n; h_i) + R(u_1, \dots, u_n; h_i)$$

with $\lim_{t \rightarrow 0} R(u_1, \dots, u_n; th_i) / t = 0$.

The operator F is said to be *totally Gâteaux differentiable* at u_0 if F , considered as a mapping on $\mathcal{V} \subset \mathcal{P}$ into \mathcal{W} , is Gâteaux differentiable at u_0 . This means that

$$F(u_1 + h_1, \dots, u_n + h_n) - F(u_1, \dots, u_n) = L(u_1, \dots, u_n; h_1, \dots, h_n) + R(u_1, \dots, u_n; h_1, \dots, h_n),$$

where the total Gâteaux differential L is a continuous linear operator in $h = (h_1 \dots h_n)$ and where $\lim_{t \rightarrow 0} (t^{-1}) R(u_1, \dots, u_n; th_1, \dots, th_n) = 0$.

The *Fréchet partial differential* at (u_1, \dots, u_n) of F with respect to u_i is the bounded linear operator $d_i F(u_1, \dots, u_n; h_i)$ defined such that, for all $h_i \in \mathcal{E}_i$, with $(u_1, \dots, u_{i-1}, u_i + h_i, u_{i+1}, \dots, u_n) \in \mathcal{V}$, the following relation holds:

$$F(u_1, \dots, u_{i-1}, u_i + h_i, \dots, u_n) - F(u_1, \dots, u_n) = d_i F(u_1, \dots, u_n; h_i) + R(u_1, \dots, u_n; h_i),$$

where $\|R(u_1, \dots, u_n; h_i)\| / \|h_i\| \rightarrow 0$ as $h_i \rightarrow 0$.

The *total Fréchet differential* of F is denoted by $dF(u_1, \dots, u_n; h_1, \dots, h_n)$ and is defined as the linear mapping on $\mathcal{V} \subset \mathcal{E}_1 \times \dots \times \mathcal{E}_n$ into \mathcal{W} , which is continuous in $h = (h_1, \dots, h_n)$, such that the following relation holds:

$$\lim_{h \rightarrow 0} \frac{\|F(u_1 + h_1, \dots, u_n + h_n) - F(u_1, \dots, u_n) - dF(u_1, \dots, u_n; h_1, \dots, h_n)\|}{\|h_1\| + \dots + \|h_n\|} = 0.$$

An operator $F : \mathcal{V} \subset \mathcal{P} \rightarrow \mathcal{W}$ that is totally differentiable at (u_1, \dots, u_n) , is partially differentiable with respect to each variable, and its total differential is the sum of the differentials with respect to each of the variables. If F is totally differentiable at each point of \mathcal{V} , then a necessary and sufficient condition for $F' : \mathcal{V} \rightarrow L(\mathcal{E}_1 \times \dots \times \mathcal{E}_n; \mathcal{W})$ to be continuous is that the partial derivatives $F'_i : \mathcal{V} \rightarrow L(\mathcal{E}_i; \mathcal{W})$, $(i = 1, \dots, n)$, be continuous.

Higher order partial derivatives are defined by induction. Note, in particular, that if $F : \mathcal{V} \rightarrow \mathcal{W}$ is twice Fréchet (totally) differentiable at x_0 , then the second order partial derivatives $\partial^2 F(x_0) / \partial x_i \partial x_j \in L(\mathcal{E}_i, \mathcal{E}_j, \mathcal{W})$, ($i, j = 1, \dots, n$) exist, and

$$d^2 F(x_0; k_1, \dots, k_n; h_1, \dots, h_n) = \sum_{i,j=1}^n \frac{\partial^2 F(x_0)}{\partial x_i \partial x_j} k_i h_j.$$

Thus the second order derivative $F''(x_0)$ may be represented by the array $\{\partial^2 F(x_0) / \partial x_i \partial x_j; (i, j = 1, \dots, n)\}$. Note that $d^2 F(x_0; h, k)$ is symmetric in h and k ; consequently, the mixed partial derivatives are also symmetric, i.e.,

$$\frac{\partial^2 F(x_0)}{\partial x_i \partial x_j} = \frac{\partial^2 F(x_0)}{\partial x_j \partial x_i}, (i, j = 1, \dots, n).$$

If the operator $F : \mathcal{D} \rightarrow \mathcal{W}$ has a n th-variation on \mathcal{D} , $\delta^n F(x_0 + th; h)$, which is continuous in t on $[0, 1]$, then the following Taylor-expansion with integral remainder holds for $x_0, x_0 + h \in \mathcal{D}$:

$$F(x_0 + h) = F(x_0) + \delta F(x_0; h) + \frac{1}{2} \delta^2 F(x_0; h) + \dots + \frac{1}{(n-1)!} \delta^{n-1} F(x_0; h) + \int_0^1 \frac{(1-t)^{n-1}}{(n-1)!} \delta^n F(x_0 + th; h) dt.$$

Note that the above integral exists and is a Banach space-valued integral in the Riemann sense; note also that $\delta^k F(x_0; h) = \delta^k F(x_0; h_1, \dots, h_k)$ for $h_1 = \dots = h_k = h$. Furthermore, if an operator $F : \mathcal{D} \rightarrow \mathcal{W}$ has a n th-order Fréchet differential, and if the map $\varphi : [0, 1] \rightarrow F^{(n)}(x_0 + th)$ is bounded and its set of discontinuities is of measure zero, then the Taylor expansion becomes

$$F(x_0 + h) = F(x_0) + F'(x_0) h + \frac{1}{2} F''(x_0) h^2 + \dots + \frac{1}{(n-1)!} F^{(n-1)}(x_0) h^{n-1} + \int_0^1 \frac{(1-t)^{n-1}}{(n-1)!} F^{(n)}(x_0 + th) h^n dt.$$

In the above expansion, $F^{(k)}(x_0) h^k$ denotes the value of the k -linear operator $F^{(k)}$ at (h, \dots, h) . The relation between the various differentiation concepts for a nonlinear operator F is shown schematically below, where “uniform in h ” indicates the validity of the relation $\lim_{h \rightarrow 0} \|F(x+h) - F(x) - \delta F(x; h)\| / \|h\| = 0$:

$$\begin{array}{ccccc} \text{G-differential} & \xrightarrow{\text{uniform in } h} & \text{F-differential} & \xrightarrow{\text{linear in } h} & \text{F-derivative,} \\ \text{G-differential} & \xrightarrow{\text{linear in } h} & \text{G-derivative} & \xrightarrow{\text{uniform in } h} & \text{F-derivative.} \end{array}$$

Gradient and Hessian: If the scalar-valued function of a vector ϕ , $\phi : \mathbb{R}^n \rightarrow \mathbb{R}$, has continuous partial derivatives in the neighborhood of \mathbf{x} , then ϕ is differentiable at \mathbf{x} , and the *gradient* of ϕ , denoted by $\nabla \phi(\mathbf{x})$, is defined as:

$$\nabla \phi(\mathbf{x}) = \left(\frac{\partial \phi}{\partial x_1}, \frac{\partial \phi}{\partial x_2}, \dots, \frac{\partial \phi}{\partial x_n} \right)^T.$$

The *directional derivative of $\phi(\mathbf{x})$ of second order* with respect to two directions \mathbf{z} and \mathbf{w} , denoted by $\phi''(\mathbf{x}; \mathbf{z}, \mathbf{w})$, is defined as the directional derivative in the direction \mathbf{w} of the directional derivative in the direction \mathbf{z} of ϕ at the point \mathbf{x} , where \mathbf{z} and \mathbf{w} are two unit vectors in \mathbb{R}^n , and is given by the expression

$$\begin{aligned} \phi''(\mathbf{x}; \mathbf{z}, \mathbf{w}) &= \mathbf{w}^T \nabla \left(\mathbf{z}^T \nabla \phi(\mathbf{x}) \right) = \sum_{i=1}^n w_i \frac{\partial}{\partial x_i} \left(\sum_{j=1}^n z_j \frac{\partial \phi}{\partial x_j} \right) \\ &= \sum_{i=1}^n \sum_{j=1}^n w_i z_j \left(\frac{\partial^2 \phi}{\partial x_i \partial x_j} \right) = \mathbf{w}^T \left[\nabla^2 \phi(\mathbf{x}) \right] \mathbf{z} \\ \nabla^2 \phi(\mathbf{x}) &= \left[\frac{\partial^2 \phi}{\partial x_i \partial x_j} \right], \text{ for } 1 \leq i, j \leq n. \end{aligned}$$

The $n \times n$ symmetric matrix, $\nabla^2 \phi(\mathbf{x})$, of second partial derivatives of $\phi(\mathbf{x})$, is called the *Hessian* of $\phi(\mathbf{x})$. Note that $\phi''(\mathbf{x}; \mathbf{z}, \mathbf{w})$ is a bilinear form in \mathbf{z} and \mathbf{w} ; $\mathbf{z} = \mathbf{w}$, then $\phi''(\mathbf{x}; \mathbf{z}, \mathbf{w}) = \mathbf{z}^T \left[\nabla^2 \phi(\mathbf{x}) \right] \mathbf{z}$ is a quadratic form in \mathbf{z} .

Jacobian: Assuming that each component function $\phi_i(\mathbf{x})$, $1 \leq i \leq m$, $\mathbf{x} = (x_1, x_2, \dots, x_n)^T$, of a vector-valued function $\phi(\mathbf{x}) = (\phi_1(\mathbf{x}), \phi_2(\mathbf{x}), \dots, \phi_m(\mathbf{x}))^T$, $\phi: \mathbb{R}^n \rightarrow \mathbb{R}^m$ satisfies the conditions for the existence of directional derivatives in the direction of a unit vector $\mathbf{z} \in \mathbb{R}^n$, the directional derivative $\phi'(\mathbf{x}; \mathbf{z})$ of $\phi(\mathbf{x})$ in the direction \mathbf{z} is a *column vector* defined by $\phi'(\mathbf{x}; \mathbf{z}) = (\phi'_1(\mathbf{x}; \mathbf{z}), \phi'_2(\mathbf{x}; \mathbf{z}), \dots, \phi'_m(\mathbf{x}; \mathbf{z}))^T$. Since each $\phi_i: \mathbb{R}^n \rightarrow \mathbb{R}$, it follows that

$$\phi'(\mathbf{x}; \mathbf{z}) = \begin{pmatrix} \mathbf{z}^T \nabla \phi_1(\mathbf{x}) \\ \mathbf{z}^T \nabla \phi_2(\mathbf{x}) \\ \vdots \\ \mathbf{z}^T \nabla \phi_m(\mathbf{x}) \end{pmatrix} = \begin{pmatrix} \frac{\partial \phi_1}{\partial x_1} & \frac{\partial \phi_1}{\partial x_2} & \dots & \frac{\partial \phi_1}{\partial x_n} \\ \frac{\partial \phi_2}{\partial x_1} & \frac{\partial \phi_2}{\partial x_2} & \dots & \frac{\partial \phi_2}{\partial x_n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial \phi_m}{\partial x_1} & \frac{\partial \phi_m}{\partial x_2} & \dots & \frac{\partial \phi_m}{\partial x_n} \end{pmatrix} \begin{pmatrix} z_1 \\ z_2 \\ \vdots \\ z_n \end{pmatrix} = \mathbf{D}_\phi(\mathbf{x}) \mathbf{z}.$$

The $m \times n$ matrix $\mathbf{D}_\phi(\mathbf{x}) = \left[\frac{\partial \phi_i}{\partial x_j} \right]$, $1 \leq i \leq m$; $1 \leq j \leq n$, is called the *Jacobian* of $\phi(\mathbf{x})$. In particular, when $m = 1$, $\mathbf{D}_\phi(\mathbf{x}) = \left[\nabla \phi(\mathbf{x}) \right]^T$, is the transpose of the gradient of $\phi(\mathbf{x})$.

The second-order directional derivative of $\phi(\mathbf{x}) = (\phi_1(\mathbf{x}), \phi_2(\mathbf{x}), \dots, \phi_m(\mathbf{x}))^T$ in the directions of two unit vectors \mathbf{z} and \mathbf{w} in \mathbb{R}^n , denoted by $\phi''(\mathbf{x}; \mathbf{z}, \mathbf{w})$ or, interchangeably, $\mathbf{D}_\phi^2(\mathbf{x}; \mathbf{z}, \mathbf{w})$, is defined as the directional derivative in the direction \mathbf{w} of the vector-valued function $\phi'(\mathbf{x}; \mathbf{z})$. This gives

$$\phi''(\mathbf{x}; \mathbf{z}, \mathbf{w}) = \begin{pmatrix} \mathbf{w}^T \nabla \phi'_1(\mathbf{x}; \mathbf{z}) \\ \mathbf{w}^T \nabla \phi'_2(\mathbf{x}; \mathbf{z}) \\ \vdots \\ \mathbf{w}^T \nabla \phi'_m(\mathbf{x}; \mathbf{z}) \end{pmatrix} = \begin{pmatrix} \mathbf{w}^T \nabla^2 \phi_1(\mathbf{x}) \mathbf{z} \\ \mathbf{w}^T \nabla^2 \phi_2(\mathbf{x}) \mathbf{z} \\ \vdots \\ \mathbf{w}^T \nabla^2 \phi_m(\mathbf{x}) \mathbf{z} \end{pmatrix} \triangleq \mathbf{D}_\phi^2(\mathbf{x}; \mathbf{z}, \mathbf{w})$$

In particular, when $\mathbf{w} = \mathbf{z}$, then $\phi''(\mathbf{x}; \mathbf{z}, \mathbf{z}) = \mathbf{D}_\phi^2(\mathbf{x}; \mathbf{z})$.

Second order Taylor series: The second order Taylor series of a scalar-valued function of a vector $\phi : \mathbb{R}^n \rightarrow \mathbb{R}$ in C_2 , for any $\mathbf{y} \in \mathbb{R}^n$, such that $\|\mathbf{y}\|$ is small, can be written as

$$\phi(\mathbf{x} + \mathbf{y}) \approx \phi(\mathbf{x}) + \langle \mathbf{y}, \nabla \phi(\mathbf{x}) \rangle + \frac{1}{2} \langle \mathbf{y}, \nabla^2 \phi(\mathbf{x}) \mathbf{y} \rangle.$$

Similarly, the second order Taylor series of a vector-valued function of a vector $\phi : \mathbb{R}^n \rightarrow \mathbb{R}^m$, with each component of ϕ in C_2 , can be written for any $\mathbf{y} \in \mathbb{R}^n$, such that $\|\mathbf{y}\|$ is small, in the form

$$\phi(\mathbf{x} + \mathbf{y}) \approx \phi(\mathbf{x}) + \mathbf{D}_\phi(\mathbf{x}) \mathbf{y} + \frac{1}{2} \mathbf{D}_\phi^2(\mathbf{x}; \mathbf{y}).$$

First and second variations: For a vector-valued function $\phi(\mathbf{x}) = (\phi_1(\mathbf{x}), \phi_2(\mathbf{x}), \dots, \phi_m(\mathbf{x}))^T$, $\phi : \mathbb{R}^n \rightarrow \mathbb{R}^m$ and $\mathbf{x} \in \mathbb{R}^n$, the *first variation* $\delta\phi(\mathbf{x})$ is a vector given by

$$\delta\phi = \begin{pmatrix} \delta\phi_1 \\ \delta\phi_2 \\ \vdots \\ \delta\phi_m \end{pmatrix} = \begin{pmatrix} \langle \delta\mathbf{x}, \nabla\phi_1(\mathbf{x}) \rangle \\ \langle \delta\mathbf{x}, \nabla\phi_2(\mathbf{x}) \rangle \\ \vdots \\ \langle \delta\mathbf{x}, \nabla\phi_m(\mathbf{x}) \rangle \end{pmatrix} = \mathbf{D}_\phi(\mathbf{x}) \delta\mathbf{x},$$

where $\mathbf{D}_\phi \in \mathbb{R}^{m \times n}$ is the Jacobian of ϕ . Similarly, the *second variation* of ϕ is given by

$$\delta^2\phi(\mathbf{x}) = \delta[\delta\phi(\mathbf{x})] = \begin{pmatrix} \delta[\delta\phi_1(\mathbf{x})] \\ \delta[\delta\phi_2(\mathbf{x})] \\ \vdots \\ \delta[\delta\phi_m(\mathbf{x})] \end{pmatrix} = \begin{pmatrix} \langle \delta\mathbf{x}, [\nabla^2\phi_1(\mathbf{x})] \delta(\mathbf{x}) \rangle \\ \langle \delta\mathbf{x}, [\nabla^2\phi_2(\mathbf{x})] \delta(\mathbf{x}) \rangle \\ \vdots \\ \langle \delta\mathbf{x}, [\nabla^2\phi_m(\mathbf{x})] \delta(\mathbf{x}) \rangle \end{pmatrix} = \|\delta\mathbf{x}\|^2 \mathbf{D}_\phi^2(\mathbf{x}; \mathbf{z})$$

First derivative of a matrix-valued function of a scalar: Consider a matrix $\mathbf{F}(\mathbf{x}) = [F_{ij}(\mathbf{x})] \in \mathbb{R}^{n \times n}$ of functions $F_{ij} : \mathbb{R} \rightarrow \mathbb{R}$, $1 \leq i, j \leq n$, $\mathbf{x} \in \mathbb{R}$; the derivative is given by

$$\frac{d\mathbf{F}(\mathbf{x})}{d\mathbf{x}} = \left[\frac{dF_{ij}(\mathbf{x})}{d\mathbf{x}} \right].$$

First derivative of a scalar-valued function of a matrix: Consider that $F : \mathbb{R}^{n \times n} \rightarrow \mathbb{R}$ is a scalar-valued function of the elements of a matrix $\mathbf{X} = [x_{ij}] \in \mathbb{R}^{n \times n}$. Examples of such functions include the trace and determinant of matrices. The derivative of F with respect to the matrix \mathbf{X} denoted by $\partial F / \partial \mathbf{X}$ is a matrix given by

$$\frac{\partial F}{\partial \mathbf{X}} = \left[\frac{\partial F}{\partial x_{ij}} \right].$$

First derivative of the trace of a matrix-valued function of a matrix: Consider the trace, $\text{tr}[\mathbf{F}(\mathbf{X})] = \sum_{i=1}^n F_{ii}(\mathbf{X})$, of $\mathbf{F}(\mathbf{X}) = [F_{ij}(\mathbf{X})]$, $\mathbf{F} : \mathbb{R}^{n \times n} \rightarrow \mathbb{R}^{n \times n}$, $\mathbf{X} \in \mathbb{R}^{n \times n}$ and $F_{ij} : \mathbb{R}^{n \times n} \rightarrow \mathbb{R}$. Then,

$$\frac{\partial \text{tr}[\mathbf{F}(\mathbf{X})]}{\partial \mathbf{X}} = \frac{\partial}{\partial \mathbf{X}} \left[\sum_{i=1}^n F_{ii}(\mathbf{X}) \right] = \sum_{i=1}^n \frac{\partial F_{ii}(\mathbf{X})}{\partial \mathbf{X}}$$

Taking into account that $\text{tr}(\mathbf{A}) = \text{tr}(\mathbf{A}^T)$ and $\text{tr}(\mathbf{AB}) = \text{tr}(\mathbf{BA})$, some particular cases which are often encountered in practice are listed below:

$$\begin{aligned} \frac{\partial \text{tr}(\mathbf{AX})}{\partial \mathbf{X}} &= \mathbf{A}^T = \frac{\partial \text{tr}(\mathbf{XA})}{\partial \mathbf{X}} = \frac{\partial \text{tr}(\mathbf{A}^T \mathbf{X}^T)}{\partial \mathbf{X}} = \frac{\partial \text{tr}(\mathbf{X}^T \mathbf{A}^T)}{\partial \mathbf{X}}, \\ \frac{\partial \text{tr}(\mathbf{A}^T \mathbf{X})}{\partial \mathbf{X}} &= \mathbf{A} = \frac{\partial \text{tr}(\mathbf{XA}^T)}{\partial \mathbf{X}} = \frac{\partial \text{tr}(\mathbf{AX}^T)}{\partial \mathbf{X}} = \frac{\partial \text{tr}(\mathbf{X}^T \mathbf{A})}{\partial \mathbf{X}}, \\ \frac{\partial \text{tr}(\mathbf{ABX})}{\partial \mathbf{X}} &= \mathbf{B}^T \mathbf{A}^T = \frac{\partial \text{tr}(\mathbf{XAB})}{\partial \mathbf{X}} = \frac{\partial \text{tr}(\mathbf{BXA})}{\partial \mathbf{X}}, \\ \frac{\partial \text{tr}(\mathbf{XAX}^T)}{\partial \mathbf{X}} &= 2\mathbf{XA}^T, \\ \frac{\partial \text{tr}(\mathbf{X}^T \mathbf{AX})}{\partial \mathbf{X}} &= 2\mathbf{AX} = \frac{\partial \text{tr}(\mathbf{XX}^T \mathbf{A})}{\partial \mathbf{X}} = \frac{\partial \text{tr}(\mathbf{AXX}^T)}{\partial \mathbf{X}} = \frac{\partial \text{tr}(\mathbf{X}^T \mathbf{A}^T \mathbf{X})}{\partial \mathbf{X}} \\ &= \frac{\partial \text{tr}(\mathbf{XX}^T \mathbf{A})}{\partial \mathbf{X}} = \frac{\partial \text{tr}(\mathbf{AXX}^T)}{\partial \mathbf{X}}. \end{aligned}$$

Optimization in a finite-dimensional vector space: One of the most important applications of gradients and Hessians of functions is in optimization problems. A function $\phi(\mathbf{x})$ is said to attain a *relative* or *local minimum* at $\mathbf{x} = \hat{\mathbf{x}}$ in a domain Ω , if the inequality

$$\phi(\hat{\mathbf{x}}) \leq \phi(\mathbf{x})$$

holds for all points \mathbf{x} in a sufficiently small neighborhood $N_\epsilon(\hat{\mathbf{x}}) = \{\mathbf{x} \mid \|\mathbf{x} - \hat{\mathbf{x}}\| < \epsilon\}$. If strict inequality $\phi(\hat{\mathbf{x}}) < \phi(\mathbf{x})$ holds for all $N_\epsilon(\hat{\mathbf{x}})$ except $\hat{\mathbf{x}}$, then $\hat{\mathbf{x}}$ is called a *strict local minimum*. If $\phi(\hat{\mathbf{x}}) \leq \phi(\mathbf{x})$ holds for all $\mathbf{x} \in \Omega$, then $\hat{\mathbf{x}}$ is called the *absolute* or *global minimum*. If strict inequality $\phi(\hat{\mathbf{x}}) < \phi(\mathbf{x})$ holds for all $\mathbf{x} \in \Omega$ except for $\hat{\mathbf{x}}$, then $\hat{\mathbf{x}}$ is the *strict global minimum*. A minimization problem involves finding the point (or set of points) in Ω where $\phi(\mathbf{x})$ attains minimum value. If Ω is a proper subset of \mathbb{R}^n , then the problem is called a *constrained minimization* problem, otherwise, when $\Omega = \mathbb{R}^n$, it is called an *unconstrained minimization* problem. The necessary and sufficient conditions for a real-valued functional $\phi(\mathbf{x}) : \Omega \rightarrow \mathbb{R}$ of a vector $\mathbf{x} = (x_1, x_2, \dots, x_n)^T$, where Ω denotes a subset of \mathbb{R}^n , to attain a minimum are obtained by expanding the functional in a Taylor series of the form

$$\Delta\phi(\mathbf{x}) = \phi(\mathbf{x} + \Delta\mathbf{x}) - \phi(\mathbf{x}) = (\Delta\mathbf{x})^T \nabla\phi(\mathbf{x}) + \frac{1}{2} (\Delta\mathbf{x})^T \nabla^2\phi(\mathbf{x}) \Delta\mathbf{x},$$

where the gradient $\nabla\phi(\mathbf{x})$ and the Hessian $\nabla^2\phi(\mathbf{x})$ are assumed to exist. Setting the gradient to zero and examining the Hessian leads to the following *necessary condition*: $\phi(\mathbf{x})$ attains a local minimum at $\hat{\mathbf{x}}$ if $\nabla\phi(\hat{\mathbf{x}}) = 0$ and $\nabla^2\phi(\hat{\mathbf{x}})$ is non-negative definite. The *sufficient condition* for $\phi(\mathbf{x})$ to attain a local minimum at $\hat{\mathbf{x}}$ is that $\nabla\phi(\hat{\mathbf{x}}) = 0$ and $\nabla^2\phi(\hat{\mathbf{x}})$ be positive definite.

Lagrange's method for minimization subject to equality constraints: When Ω is specified by a collection of k equality constraints of the form

$$f_i(\mathbf{x}) = 0, \quad 1 \leq i \leq k$$

where each $f_i(\mathbf{x})$ is twice differentiable, the constrained minimization of $\phi(\mathbf{x})$ can be transformed into an unconstrained minimization problem by using a vector $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_k)^T$ of

Lagrange multipliers λ_i , to construct the Lagrangian functional

$$L(\mathbf{x}, \lambda) = \phi(\mathbf{x}) + \sum_{i=1}^k \lambda_i f_i(\mathbf{x}).$$

The arguments for the unconstrained case can now be applied to the above Lagrangian to obtain the following first-order necessary conditions

$$\begin{aligned} \nabla_{\mathbf{x}} L(\mathbf{x}, \lambda) &\equiv \nabla_{\mathbf{x}} \phi(\mathbf{x}) + \sum_{i=1}^k \lambda_i \nabla_{\mathbf{x}} f_i(\mathbf{x}) = 0, \\ \nabla_{\lambda} L(\mathbf{x}, \lambda) &= f_i(\mathbf{x}) = 0, \quad \text{for } 1 \leq i \leq k. \end{aligned}$$

The values of the $(n+k)$ variables at a relative minimum $\hat{\mathbf{x}}$ of $\phi(\mathbf{x})$ are obtained as the solution of the $(n+k)$ equations represented by $\nabla_{\mathbf{x}} L = 0$ and $\nabla_{\lambda} L = 0$. The equation $\nabla_{\lambda} L = 0$ ensures that the constraints are satisfied at the minimum, while $\nabla_{\mathbf{x}} L = 0$ implies that, at the minimum, $\nabla_{\mathbf{x}} \phi(\mathbf{x})$ is a linear combination of the gradient $\nabla_{\mathbf{x}} f_i(\mathbf{x})$ of the constraint function $f_i(\mathbf{x})$ for $1 \leq i \leq k$. In addition to the necessary conditions represented by the equations $\nabla_{\mathbf{x}} L = 0$ and $\nabla_{\lambda} L = 0$, the second-order sufficiency condition for a relative minimum \mathbf{x}^* of $\phi(\mathbf{x})$ under the equality constraints requires that the matrix

$$H(\mathbf{x}^*) \triangleq \nabla^2 \phi(\mathbf{x}^*) + \sum_{i=1}^k \lambda_i \nabla^2 f_i(\mathbf{x}^*)$$

be positive definite on the tangent plane to $f_i(\mathbf{x})$ at \mathbf{x}^* , i.e., $\mathbf{y}G(\mathbf{x}^*)\mathbf{y} > 0$ for any $\mathbf{y} \neq \mathbf{0}$ and $\mathbf{y} \in \{\mathbf{y} | \mathbf{y}^T \nabla f_i(\mathbf{x}^*) = 0, 1 \leq i \leq k\}$, comprising all vectors \mathbf{y} that are orthogonal to $\nabla f_i(\mathbf{x})$, $1 \leq i \leq k$.

3 Special Functions

3.1 The Gamma Function: $\Gamma(z)$

Definition: The gamma function $\Gamma(z)$ can be defined by one of the following expressions:

$$\begin{aligned} \Gamma(z) &= \int_0^{\infty} e^{-t} t^{z-1} dt = \int_0^1 (\log 1/t)^{z-1} dt, \quad \text{Re } z > 0, \\ \Gamma(z) &= \lim_{n \rightarrow \infty} \frac{n! n^z}{z(z+1)\cdots(z+n)} = \lim_{n \rightarrow \infty} \frac{n^z}{z(1+z)(1+\frac{1}{2}z)\cdots(1+z/n)} \\ &= z^{-1} \prod_{n=1}^{\infty} \left[(1+1/n)^z (1+z/n)^{-1} \right], \\ 1/\Gamma(z) &= z e^{\gamma z} \prod_{n=1}^{\infty} \left[(1+z/n) e^{-z/n} \right], \\ \gamma &= \lim_{m \rightarrow \infty} \left(\sum_{n=1}^m 1/n - \log m \right) = 0.5772156649\dots \end{aligned}$$

In the above expression, $\gamma = 0.5772156649\dots$ is Euler's constant. Note that $\Gamma(z)$ has simple poles at $z = -n$, ($n = 0, 1, 2, \dots$), with residues $(-1)^n/n!$.

Functional relations: The basic relation satisfied by the Gamma Function is $\Gamma(1+z) = z\Gamma(z)$. Other relations often used in practice, in which n is a positive integer, are:

$$\begin{aligned} \Gamma(z) \Gamma(-z) &= -\pi z^{-1} \csc(\pi z), & \Gamma(z) \Gamma(1-z) &= \pi \csc(\pi z), \\ \Gamma(1/2+z) \Gamma(1/2-z) &= \pi \sec(\pi z), \\ \frac{\Gamma(n+z) \Gamma(n-z)}{[(n-1)!]^2} &= \frac{\pi z}{\sin(\pi z)} \prod_{m=1}^{n-1} (1 - z^2/m^2), \quad n = 1, 2, 3, \dots, \\ \frac{\Gamma(n+1/2+z) \Gamma(n+1/2-z)}{[\Gamma(n+1/2)]^2} &= \frac{1}{\cos(\pi z)} \prod_{m=1}^n \left[1 - \frac{4z^2}{(2m-1)^2} \right], \quad n = 1, 2, 3, \dots, \\ \Gamma(z+n) &= z(z+1)(z+2)\dots(z+n-1)\Gamma(z), & \Gamma(n+1) &= 1 \cdot 2 \cdot 3 \dots n = n!, \\ \Gamma(z)/\Gamma(z-n) &= (z-1)(z-2)\dots(z-n) = (-1)^n \Gamma(-z+n+1)/\Gamma(-z+1), \\ \Gamma(-z+n)/\Gamma(-z) &= (-1)^n z(z-1)\dots(z-n+1) = (-1)^n \Gamma(z+1)/\Gamma(z-n+1). \end{aligned}$$

Particular values: $\Gamma(1) = \int_0^\infty e^{-t} dt = 1$; $\Gamma(1/2) = 2 \int_0^\infty e^{-v^2} dv = \sqrt{\pi}$.

The multiplication formula of Gauss:

$$\prod_{r=0}^{m-1} \Gamma(z+r/m) = (2\pi)^{\frac{1}{2}(m-1)} m^{\frac{1}{2}-mz} \Gamma(mz), \quad m = 2, 3, 4, \dots$$

Particular case, $m = 2$ (Legendre's formula):

$$\Gamma(2z) = 2^{2z-1} \pi^{-1/2} \Gamma(z) \Gamma(z+1/2).$$

Note also the integrals:

$$\begin{aligned} \int_0^\infty e^{i\delta} t^{\alpha-1} e^{-st} dt &= \Gamma(\alpha) s^{-\alpha}, \quad \text{Re } \alpha > 0, -\left(\frac{1}{2}\pi + \delta\right) < \arg s < \frac{1}{2}\pi - \delta, \\ \int_0^\infty t^{\alpha-1} e^{-ct \cos \beta} \cos(ct \sin \beta) dt &= \Gamma(\alpha) c^{-\alpha} \cos(\alpha\beta), \\ c > 0, \quad \text{Re } \alpha > 0, -\frac{1}{2}\pi < \beta < \frac{1}{2}\pi, \\ \int_0^\infty t^{\alpha-1} e^{-ct \cos \beta} \sin(ct \sin \beta) dt &= \Gamma(\alpha) c^{-\alpha} \sin(\alpha\beta) \\ c > 0, \quad \text{Re } \alpha > -1, -\frac{1}{2}\pi < \beta < \frac{1}{2}\pi. \\ \int_0^\infty t^{\alpha-1} \cos(ct) dt &= c^{-\alpha} \Gamma(\alpha) \cos\left(\frac{1}{2}\pi\alpha\right), \quad 0 < \text{Re } \alpha < 1, \\ \int_0^\infty t^{\alpha-1} \sin(ct) dt &= c^{-\alpha} \Gamma(\alpha) \sin\left(\frac{1}{2}\pi\alpha\right), \quad -1 < \text{Re } \alpha < 1, \end{aligned}$$

$$\int_0^{\infty} \cos(at^p) dt = (p a^{1/p})^{-1} \Gamma(1/p) \cos[\pi(2p)^{-1}], \quad a > 0, p > 1,$$

$$\int_0^{\infty} \sin(at^p) dt = (p a^{1/p})^{-1} \Gamma(1/p) \sin[\pi(2p)^{-1}],$$

$$\int_x^{x+n} \log \Gamma(x) dx = x \log x + (x+1) \log(x+1) + \dots + (x+n-1) \log(x+n-1) \\ - nx - \frac{1}{2}n(n-1) + \frac{1}{2}n \log(2\pi), \quad n = 1, 2, 3, \dots,$$

$$\int_0^1 \log \Gamma(x) dx = \frac{1}{2} \log(2\pi),$$

$$\int_0^1 \log \Gamma(x) \sin(2\pi n x) dx = \frac{\gamma + \log(2\pi n)}{2\pi n},$$

$$\int_0^1 \log \Gamma(x) \cos(2\pi n x) dx = \frac{1}{4n}, \quad n = 1, 2, 3, \dots$$

Asymptotic expansions:

$$\Gamma(z) = e^{-z} e^{(z-(1/2)) \log z} (2\pi)^{\frac{1}{2}} \left[1 + \frac{z^{-1}}{12} + \frac{z^{-2}}{288} - \frac{139z^{-3}}{51840} - O(z^{-4}) \right],$$

$$|\arg z| < \pi,$$

$$\log \Gamma(z) = \left(z - \frac{1}{2}\right) \log z - z + \frac{1}{2} \log(2\pi) + \sum_{n=1}^m B_{2n} / [(2n-1)(2n)z^{2n-1}] \\ + O(z^{-2m-1}), \quad |\arg z| < \pi,$$

$$\log \Gamma(z) = \left(z - \frac{1}{2}\right) \log \left(z - \frac{1}{2}\right) - z - \frac{1}{2} + \frac{1}{2} \log(2\pi) \\ - \sum_{n=1}^{\infty} \frac{\zeta(2n, z)}{[2^{2n} 2n(2n+1)]}, \quad \operatorname{Re} z \geq -\frac{1}{2},$$

$$\log \Gamma(z + \alpha) = \left(z + \alpha - \frac{1}{2}\right) \log z - z + \frac{1}{2} \log(2\pi) + O(z^{-1}),$$

$$\frac{\Gamma(z + \alpha)}{\Gamma(z + \beta)} = z^{\alpha-\beta} \left[1 + \frac{1}{2} z^{-1} (\alpha - \beta)(\alpha + \beta - 1) + O(z^{-2}) \right],$$

$$\log \Gamma(z + \alpha) = \left(z + \alpha - \frac{1}{2}\right) \log z - z + \frac{1}{2} \log(2\pi) + \frac{B_2(\alpha)z^{-1}}{1 \cdot 2} \\ - \dots + \frac{(-1)^{n+1} B_{n+1}(\alpha)z^{-n}}{n(n+1)} + O(z^{-n-1}), \quad |\arg z| < \pi, n = 1, 2, 3, \dots,$$

$$\lim_{|z| \rightarrow \infty} e^{-\alpha \log z} \frac{\Gamma(z + \alpha)}{\Gamma(z)} = 1, \quad \lim_{|y| \rightarrow \infty} |\Gamma(x + iy)| e^{(1/2)\pi|y|} |y|^{\frac{1}{2}-x} = (2\pi)^{\frac{1}{2}}, \quad x, y \text{ real.}$$

3.2 The Beta Function

Definition: The beta function is defined by the integral

$$B(x, y) = \int_0^1 t^{x-1} (1-t)^{y-1} dt, \quad \operatorname{Re} x > 0, \operatorname{Re} y > 0.$$

Substituting $t = v/(1 + v)$ in the above definition yields the following equivalent relations:

$$B(x, y) = \int_0^\infty v^{x-1}(1 + v)^{-x-y} dv = \int_0^1 (v^{x-1} + v^{y-1})(1 + v)^{-x-y} dv, \\ \text{Re } x > 0, \text{ Re } y > 0.$$

The relation between beta and gamma functions is

$$B(x, y) = \frac{\Gamma(x)\Gamma(y)}{\Gamma(x + y)} = B(y, x), \\ B(x, y + 1) = (y/x)B(x + 1, y) = \left[\frac{y}{(x + y)} \right] B(x, y), \\ B(x, y)B(x + y, z) = B(y, z)B(y + z, x) = B(z, x)B(x + z, y), \\ B(x, y)B(x + y, z)B(x + y + z, u) = \frac{\Gamma(x)\Gamma(y)\Gamma(z)\Gamma(u)}{\Gamma(x + y + z + u)}, \\ \frac{1}{B(n, m)} = m \binom{n + m - 1}{n - 1} = n \binom{n + m - 1}{m - 1}, \quad n, m, \text{ positive integers.}$$

3.3 The ψ Function

The function $\psi(z)$ is the logarithmic derivative of the gamma function $\Gamma(z)$:

$$\psi(z) = \frac{d \log \Gamma(z)}{dz} = \frac{\Gamma'(z)}{\Gamma(z)}, \quad \text{or} \quad \log \Gamma(z) = \int_1^z \psi(z) dz.$$

The ψ function is meromorphic with simple poles at $z = 0, -1, -2, \dots$

$$\psi(z) = \lim_{n \rightarrow \infty} \left[\log n - \frac{1}{z} - \frac{1}{z + 1} - \frac{1}{z + 2} - \dots - \frac{1}{z + n} \right], \\ \psi(z) = -\gamma - (1/z) + \sum_{n=1}^\infty z/[n(z + n)] = -\gamma + (z - 1) \sum_{n=0}^\infty 1/[(n + 1)(z + n)], \\ \psi(z) = \log z - \sum_{n=0}^\infty \left\{ (n + z)^{-1} - \log \left[1 + \frac{1}{(n + z)} \right] \right\}, \\ \gamma = -\psi(1) = \sum_{n=1}^\infty [n^{-1} - \log(1 + n^{-1})] = - \int_0^\infty e^{-t} \log t dt.$$

Functional equations for $\psi(z)$:

$$\begin{aligned}\psi(z) &= \psi(1+z) - \frac{1}{z}, \quad \psi(z) - \psi(1-z) = -\pi \operatorname{ctn}(\pi z), \\ \psi\left(\frac{1}{2} + z\right) - \psi\left(\frac{1}{2} - z\right) &= \pi \tan(\pi z), \\ \psi(z) - \psi(-z) &= -\pi \operatorname{ctn}(\pi z) - 1/z, \quad \psi(1+z) - \psi(1-z) = z^{-1} - \pi \operatorname{ctn}(\pi z), \\ \psi(z+n) &= \frac{1}{z} + \frac{1}{z+1} + \cdots + \frac{1}{z+n-1} + \psi(z), \quad n = 1, 2, 3, \dots, \\ \psi(1+n) &= 1 + \frac{1}{2} + \frac{1}{3} + \cdots + \frac{1}{n} - \gamma, \\ \psi(mz) &= m^{-1} \sum_{r=0}^{m-1} \psi(z+r/m) + \log m. \\ \psi(z) &= -\gamma + \int_0^1 (1-t^{z-1})(1-t)^{-1} dt, \quad \operatorname{Re} z > 0.\end{aligned}$$

Asymptotic expansion: $\psi(z) = \log z - (2z)^{-1} - \sum_{n=1}^m B_{2n} z^{-2n} / (2n) + O(z^{-2m-2})$.

3.4 The Generalized Zeta and Riemann's Zeta Functions

Definition: The generalized zeta function is defined by the equation

$$\zeta(s, \nu) = \sum_{n=0}^{\infty} (\nu + n)^{-s}, \quad \operatorname{Re} s > 0, \nu \neq 0, -1, -2, \dots$$

Special case when $\nu = 1$: Riemann's zeta-function $\zeta(s)$:

$$\zeta(s) = \zeta(s, 1) = \Phi(1, s, 1) = \sum_{n=1}^{\infty} (1/n^s), \quad \operatorname{Re} s > 1.$$

Special case $s = -m$:

$$\zeta(-m, \nu) = -\frac{B_{m+1}(\nu)}{m+1}, \quad m = 0, 1, 2, \dots, \quad B_m(\nu) = \text{Bernoulli's polynomials.}$$

Functional equation:

$$\begin{aligned}\zeta(s, \nu) &= \zeta(s, m+\nu) + \sum_{n=0}^{m-1} (n+\nu)^{-s}, \quad m = 1, 2, 3, \dots, \\ \zeta(s) &= \frac{2\Gamma(1-s)}{(2\pi)^{1-s}} \sin(\pi s/2) \zeta(1-s), \quad \zeta(1-s) = (2\pi)^{-s} 2\Gamma(s) \cos(\pi s/2) \zeta(s).\end{aligned}$$

Particular values:

$$\begin{aligned}\zeta(0) &= -\frac{1}{2}, \quad \zeta'(0) = -\frac{1}{2} \log(2\pi), \quad \lim_{s \rightarrow 1} [\zeta(s) - 1/(s-1)] = -\psi(1) = \gamma, \\ \zeta(-2m) &= 0, \quad \zeta(2m) = (-1)^{m+1} (2\pi)^{2m} \frac{B_{2m}}{2(2m)!}, \quad m = 1, 2, 3, \dots, \\ \zeta[-(2m-1)] &= -\frac{B_{2m}}{2m}, \quad \zeta(-m) = -\frac{B_{m+1}}{m+1}, \quad m = 1, 2, 3, \dots\end{aligned}$$

Integrals:

$$\begin{aligned} \Gamma(s)\zeta(s) &= \int_0^\infty t^{s-1}(e^t - 1)^{-1} dt = 2^{s-1} \int_0^\infty e^{-t} t^{s-1} \operatorname{csch} t dt, \quad \operatorname{Re} s > 1, \\ (1 - 2^{1-s})\Gamma(s)\zeta(s) &= \int_0^\infty t^{s-1}(e^t + 1)^{-1} dt = 2^{s-1} \int_0^\infty e^{-t} t^{s-1} \operatorname{sech} t dt, \quad \operatorname{Re} s > 0, \\ 2\Gamma(s)(1 - 2^{-s})\zeta(s) &= \int_0^\infty t^{s-1} \operatorname{csch} t dt, \quad \operatorname{Re} s > 1. \end{aligned}$$

Asymptotic expansion of $\zeta(s, \nu)$ for large values of $|\nu|$ with $|\arg \nu| < \pi$:

$$\begin{aligned} \zeta(s, \nu) &= [1/\Gamma(s)] \left\{ \nu^{1-s} \Gamma(s-1) + \frac{1}{2} \nu^{-s} \Gamma(s) \right. \\ &\quad \left. + \sum_{n=1}^m B_{2n} \Gamma(s+2n-1) / [(2n)! \nu^{2n+s-1}] + O(\nu^{-2m-s-1}) \right\}, \quad \operatorname{Re} s > 1. \end{aligned}$$

3.5 Bernoulli's Numbers and Polynomials

Definition: The Bernoulli numbers B_n are defined as the coefficients in the expansion $z(e^z - 1)^{-1} = \sum_{n=0}^\infty B_n z^n / n!$ for $z < 2\pi$. The Bernoulli polynomials $B_n(x)$ are defined as the coefficients in the expansion $ze^{xz}(e^z - 1)^{-1} = \sum_{n=0}^\infty B_n(x) z^n / n!$ for $|z| < 2\pi$.

Functional relation:

$$\begin{aligned} B_n(x) &= x^n + \binom{n}{1} B_1 x^{n-1} + \dots + \binom{n}{n-1} B_{n-1} x + \binom{n}{n} \\ B_n &= \sum_{r=0}^n \binom{n}{r} B_r x^{n-r}, \\ B'_n(x) &= n B_{n-1}(x), \\ B_0(x+1) &= B_0(x), \quad B_1(x+1) - B_1(x) = 1, \quad B_n(x+1) - B_n(x) = nx^{n-1}, \\ &\quad n = 2, 3, 4, \dots, \\ \sum_{r=0}^n \binom{n}{r} B_r(x) &= B_n(x+1), \quad \sum_{r=0}^{n-1} \binom{n}{r} B_r(x) = nx^{n-1}, \quad n = 2, 3, 4, \dots \end{aligned}$$

Particular values:

$$\begin{aligned} B_0(x) &= 1, \quad B_1(x) = x - 1/2, \quad B_2(x) = x^2 - x + 1/6, \\ B_3(x) &= x^3 - 3/2x^2 + x/2, \quad B_4(x) = x^4 - 2x^3 + x^2 - 1/30, \\ B_n(0) &= B_n, \quad B_n(1) = B_n(0) = B_n \quad \text{for } n \geq 2. \end{aligned}$$

Integrals:

$$\begin{aligned} \int_x^y B_n(t) dt &= \frac{B_{n+1}(y) - B_{n+1}(x)}{n+1}, \quad \int_x^{x+1} B_n(t) dt = x^n, \\ \sum_{r=0}^{m-1} r^n &= \sum_{r=0}^{m-1} \int_r^{r+1} B_n(t) dt = \int_0^m B_n(t) dt = \frac{B_{n+1}(m) - B_{n+1}}{n+1}, \quad n = 2, 3, 4, \dots \end{aligned}$$

4 Bessel Functions

4.1 Bessel Functions of General Order

Bessel functions are solutions of Bessel's differential equation

$$\nabla_v w \equiv z^2 \frac{d^2 w}{dz^2} + z \frac{dw}{dz} + (z^2 - v^2)w = z \frac{d}{dz} \left(z \frac{dw}{dz} \right) + (z^2 - v^2)w = 0.$$

When v, z are unrestricted, the above differential equation has a regular singularity at $z = 0$ and an irregular singularity at $z = \infty$; all other points are ordinary points. In the neighborhood of a regular singularity, Bessel's equation admits the solutions $J_{-v}(z)$ and $J_v(z)$, respectively, defined as

$$J_v(z) = \sum_{m=0}^{\infty} (-1)^m \frac{\left(\frac{1}{2}z\right)^{2m+v}}{m! \Gamma(m+v+1)}.$$

The solution $J_v(z)$ is called the Bessel function of the first kind; z is the *variable* and v is the *order* of the Bessel function. The series $z^{-v} J_v(z)$ converges absolutely and uniformly in any bounded domain of z . The following linear combinations are also solutions of Bessel's equation:

$$\begin{aligned} Y_v(z) &= (\sin v\pi)^{-1} [J_v(z) \cos(v\pi) - J_{-v}(z)], \\ H_v^{(1)}(z) &= J_v(z) + iY_v(z) = [i \sin(v\pi)]^{-1} [J_{-v}(z) - J_v(z) e^{-iv\pi}], \\ H_v^{(2)}(z) &= J_v(z) - iY_v(z) = (i \sin v\pi)^{-1} [J_v(z) e^{iv\pi} - J_{-v}(z)]. \end{aligned}$$

The function Y_v is called the *Bessel function of the second kind* or *Neumann's function*, while $H_v^{(1)}$ and $H_v^{(2)}$ are the *Bessel functions of the third kind*, respectively; they are also called the *first and second Hankel functions*. In particular, J_v and Y_v are real if the order, v , is real and the variable z is positive. All four Bessel functions are single-valued in the z -plane cut along the negative real axis from 0 to $-\infty$. For a general v , they all have branch points at $z = 0$. The Bessel function of the first kind is an entire function of v ; for integer $v = n$, the Bessel functions of the second and third kind are also entire functions of $v = n$.

4.2 Modified Bessel Functions of General Order

Definition: Replacing z by iz yields the modified Bessel differential equation

$$z^2 \frac{d^2 w}{dz^2} + z \frac{dw}{dz} - (z^2 + v^2)w = 0.$$

When ν is not an integer, $J_\nu(iz)$ and $J_{-\nu}(iz)$ are two linearly independent solutions in the above equation. Customarily, however, the functions $I_\nu(z)$ and $I_{-\nu}(z)$ are used as two independent solutions, with $I_\nu(z)$ defined as

$$\begin{aligned} I_\nu(z) &= e^{-i\frac{\nu\pi}{2}} J_\nu\left(ze^{i\frac{\nu\pi}{2}}\right) = \sum_{m=0}^{\infty} \left(\frac{1}{2}z\right)^{2m+\nu} \Big/ [m!\Gamma(m+\nu+1)] \\ &= \frac{\left(\frac{1}{2}z\right)^\nu}{\Gamma(\nu+1)} {}_0F_1\left(\nu+1; \frac{1}{4}z^2\right) = \frac{\left(\frac{1}{2}z\right)^\nu e^{-z}}{\Gamma(\nu+1)} {}_1F_1\left(\nu+\frac{1}{2}; 2\nu+1; 2z\right) \\ &= 2^{-2\nu-\frac{1}{2}} z^{-\frac{1}{2}} M_{0,\nu}(2z)/\Gamma(\nu+1). \end{aligned}$$

The functions $I_\nu(z)$ and $I_{-\nu}(z)$ are called the *modified Bessel functions of the first kind*, and are real when ν is real and z is positive. The function $K_\nu(z)$, defined as

$$K_\nu(z) = \frac{1}{2}\pi(\sin \nu\pi)^{-1}[I_{-\nu}(z) - I_\nu(z)] = \left(\frac{1}{2}\frac{\pi}{z}\right)^{\frac{1}{2}} W_{0,\nu}(2z),$$

is also a solution of the modified Bessel equation, and is called a *Bessel function of the third kind* or *Bessel's function*. All Bessel functions are entire functions of ν . Note that $K_\nu(z)$ is real when ν is real and z is positive,

$$K_{-\nu}(z) = K_\nu(z) \quad \text{and} \quad K_\nu(z) = \frac{1}{2}i\pi e^{i\frac{\nu\pi}{2}} H_\nu^{(1)}\left(ze^{i\frac{\nu\pi}{2}}\right) = -\frac{1}{2}i\pi e^{-i\frac{\nu\pi}{2}} H_\nu^{(2)}\left(ze^{-i\frac{\nu\pi}{2}}\right).$$

Recurrence and differentiation formulas:

$$\begin{aligned} \left(\frac{d}{zdz}\right)^m [z^\nu I_\nu(z)] &= z^{\nu-m} I_{\nu-m}(z), \quad \left(\frac{d}{zdz}\right)^m [z^{-\nu} I_\nu(z)] = z^{-\nu-m} I_{\nu+m}(z), \\ \left(\frac{d}{zdz}\right)^m [z^\nu K_\nu(z)] &= (-1)^m z^{\nu-m} K_{\nu-m}(z), \\ \left(\frac{d}{zdz}\right)^m [z^{-\nu} K_\nu(z)] &= (-1)^m z^{-\nu-m} K_{\nu+m}(z), \\ I_{\nu-1}(z) - I_{\nu+1}(z) &= 2\nu z^{-1} I_\nu(z), \quad I_{\nu-1}(z) + I_{\nu+1}(z) = 2I'_\nu(z), \\ K_{\nu-1}(z) - K_{\nu+1}(z) &= -2\nu z^{-1} K_\nu(z), \quad K_{\nu-1}(z) + K_{\nu+1}(z) = -2K'_\nu(z). \end{aligned}$$

4.3 Bessel Functions of Integer Order

Definition: Bessel functions of the *first kind of integer order* are called *Bessel coefficients*, and are generated by the expansion of $\exp\left[\frac{1}{2}z(t-t^{-1})\right]$ in powers of t , i.e., $\exp\left[\frac{1}{2}z(t-t^{-1})\right] = \sum_{n=-\infty}^{\infty} t^n J_n(z)$, $J_{-n}(z) = (-1)^n J_n(z)$.

Note also that

$$Y_n(z) = \pi^{-1} \left[\frac{\partial J_\nu}{\partial \nu} - (-1)^n \frac{\partial J_{-\nu}}{\partial \nu} \right]_{\nu=n}, \quad Y_{-n}(z) = (-1)^n Y_n(z), \quad n = 1, 2, 3, \dots$$

4.4 Modified Bessel Functions of Integer Order

The modified Bessel functions of integer order are the functions $I_n(z)$ and $K_n(z)$, satisfying the relations

$$I_{-n}(z) = I_n(z), \quad K_n(z) = (-1)^n \frac{1}{2} \left[\frac{\partial I_{-v}}{\partial v} - \frac{\partial I_v}{\partial v} \right]_{v=n} \quad \text{for } n = 1, 2, 3, \dots$$

4.5 Spherical Bessel Functions

The Bessel functions and modified Bessel functions reduce to combinations of elementary functions when ν is half of an odd integer, i.e., $\nu = n + 1/2$ for $n = 0, 1, 2, \dots$. These functions often occur in connection with spherical waves, hence the name.

$$\begin{aligned} K_{n+(1/2)}(z) &= \left(\frac{\pi}{2z}\right)^{1/2} \frac{e^{-z}}{n!} \int_0^\infty e^{-t} (1+t/2z)^n t^n dt \\ &= \left(\frac{\pi}{2z}\right)^{1/2} e^{-z} \sum_{m=0}^n (2z)^{-m} \frac{\Gamma(n+m+1)}{m! \Gamma(n+1-m)}, \\ J_{n+(1/2)}(z) &= \left(\frac{1}{2}\pi z\right)^{-1/2} \left[\sin\left(z - \frac{n\pi}{2}\right) \sum_{m=0}^{\leq(1/2)n} (-1)^m \left(n + \frac{1}{2}, 2m\right) (2z)^{-2m} \right. \\ &\quad \left. + \cos\left(z - \frac{n\pi}{2}\right) \sum_{m=0}^{\leq(1/2)n-(1/2)} (-1)^m \left(n + \frac{1}{2}, 2m+1\right) (2z)^{-2m-1} \right], \\ Y_{n+1/2}(z) &= \left(\frac{\pi z}{2}\right)^{-1/2} \left[\sin\left(z - \frac{n\pi}{2}\right) \sum_{m=0}^{\leq(1/2)n-(1/2)} (-1)^m \left(n + \frac{1}{2}, 2m+1\right) (2z)^{-2m-1} \right. \\ &\quad \left. - \cos\left(z - \frac{n\pi}{2}\right) \sum_{m=0}^{\leq(1/2)n} (-1)^m \left(n + \frac{1}{2}, 2m\right) (2z)^{-2m} \right], \\ H_{n+(1/2)}^{(1)}(z) &= \left(\frac{\pi z}{2}\right)^{-1/2} i^{-n-1} e^{iz} \sum_{m=0}^n i^m \left(n + \frac{1}{2}, m\right) (2z)^{-m}, \\ H_{n+(1/2)}^{(2)}(z) &= \left(\frac{\pi z}{2}\right)^{-1/2} i^{n+1} e^{-iz} \sum_{m=0}^n (-i)^m \left(n + \frac{1}{2}, m\right) (2z)^{-m}, \\ J_{-n-(1/2)}(z) &= (-1)^{n+1} Y_{n+(1/2)}(z), \quad Y_{-n-(1/2)}(z) = (-1)^n J_{n+(1/2)}(z), \\ H_{-n-(1/2)}^{(1)}(z) &= i(-1)^n H_{n+(1/2)}^{(1)}(z), \quad H_{-n-(1/2)}^{(2)}(z) = -i(-1)^n H_{n+(1/2)}^{(2)}(z), \\ J_{1/2}(z) &= Y_{-1/2}(z) = \left(\frac{\pi z}{2}\right)^{-1/2} \sin z, \quad Y_{1/2}(z) = -J_{-1/2}(z) = -\left(\frac{\pi z}{2}\right)^{-1/2} \cos z, \\ I_{1/2}(z) &= \left(\frac{\pi z}{2}\right)^{-1/2} \sinh z, \\ H_{1/2}^{(1)}(z) &= -iH_{-1/2}^{(1)}(z) = -i\left(\frac{\pi z}{2}\right)^{-1/2} e^{iz}, \\ H_{1/2}^{(2)}(z) &= iH_{-1/2}^{(2)}(z) = i\left(\frac{\pi z}{2}\right)^{-1/2} e^{-iz}. \end{aligned}$$

4.6 Miscellaneous Formulas

Products of Bessel functions:

$$\Gamma(\nu + 1)J_\nu(\beta z)J_\mu(\alpha z) = \left(\frac{\alpha z}{2}\right)^\mu \left(\frac{\beta z}{2}\right)^\nu \sum_{m=0}^\infty \frac{(-1)^m \left(\frac{\alpha z}{2}\right)^{2m}}{m! \Gamma(\mu + m + 1)} {}_2F_1(-m, -\mu - m; \nu + 1; \beta^2 \alpha^{-2}).$$

When $\beta = \alpha$, the above formula becomes

$$\begin{aligned} J_\nu(z)J_\mu(z) &= \sum_{m=0}^\infty \frac{(-1)^m \left(\frac{z}{2}\right)^{\nu+\mu+2m} \Gamma(\nu + \mu + 2m + 1)}{m! \Gamma(\mu + m + 1) \Gamma(\nu + m + 1) \Gamma(\nu + \mu + m + 1)} \\ &= [\Gamma(\nu + 1) \Gamma(\mu + 1)]^{-1} \left(\frac{z}{2}\right)^{\nu+\mu} {}_2F_3\left(\frac{1}{2} + \frac{\nu}{2} + \frac{\mu}{2}, 1 + \frac{\nu}{2} + \frac{\mu}{2}; 1 + \nu, 1 + \mu, 1 + \nu + \mu; -z^2\right), \\ e^{\pm iz} J_\nu(z) &= \pi^{-1/2} (2z)^\nu \sum_{n=0}^\infty \frac{\Gamma(\nu + n + 1/2) (\pm 2iz)^n}{n! \Gamma(2\nu + n + 1)}, \\ \left(\frac{d}{zdz}\right)^m [z^\nu J_\nu(z)] &= z^{\nu-m} J_{\nu-m}(z), \quad m = 1, 2, 3, \dots, \\ \left(\frac{d}{zdz}\right)^m [z^{-\nu} J_\nu(z)] &= (-1)^m z^{-\nu-m} J_{\nu+m}(z), \quad m = 1, 2, 3, \dots, \\ J_{\nu-1}(z) + J_{\nu+1}(z) &= 2\nu z^{-1} J_\nu(z), \quad J_{\nu-1}(z) - J_{\nu+1}(z) = 2 \frac{dJ_\nu(z)}{dz}. \end{aligned}$$

Wronskians: The Wronskian of two solutions w_1 and w_2 of Bessel's equation is a constant multiple of $\exp[-\int z^{-1} dz]$; $W(w_1, w_2) \equiv w_1 w_2' - w_2 w_1' = Cz^{-1}$. The constant C can be computed from the first terms of the series expansions of the solutions involved. The most important cases are listed below.

$$\begin{aligned} W(J_\nu, J_{-\nu}) &= -2(\pi z)^{-1} \sin(\nu\pi), \quad W(J_\nu, Y_\nu) = 2(\pi z)^{-1}, \quad W(I_\nu, K_\nu) = -z^{-1}, \\ W\left(J_\nu, H_\nu^{(1),(2)}\right) &= \pm 2i(\pi z)^{-1}, \quad W\left(H_\nu^{(1)}, H_\nu^{(2)}\right) = -4i(\pi z)^{-1}, \\ W(I_\nu, I_{-\nu}) &= -2(\pi z)^{-1} \sin(\nu\pi) = I_\nu(z)I_{-\nu+1}(z) - I_{-\nu}(z)I_{\nu-1}(z), \\ J_\nu(z)J_{-\nu+1}(z) + J_{-\nu}(z)J_{\nu-1}(z) &= 2(\pi z)^{-1} \sin(\nu\pi), \\ J_\nu(z)Y_{\nu-1}(z) - Y_\nu(z)J_{\nu-1}(z) &= 2(\pi z)^{-1}, \quad K_{\nu+1}(z)I_\nu(z) + K_\nu(z)I_{\nu+1}(z) = z^{-1}, \\ H_\nu^{(1)}(z)H_{\nu-1}^{(2)}(z) - H_{\nu-1}^{(1)}(z)H_\nu^{(2)}(z) &= -4i(\pi z)^{-1}, \\ J_{\nu-1}(z)H_\nu^{(1)}(z) - J_\nu(z)H_{\nu-1}^{(1)}(z) &= 2(\pi iz)^{-1}, \\ J_\nu(z)H_{\nu-1}^{(2)}(z) - J_{\nu-1}(z)H_\nu^{(2)}(z) &= 2(\pi iz)^{-1}. \end{aligned}$$

4.7 Zeros of Bessel Functions

Bessel functions of the first kind: For real ν , $J_\nu(z)$ has an infinite number of real zeros. The zeros of $J_\nu(z)$ and $J'_\nu(z)$ are symmetric with respect to the axes of coordinates. If $\gamma_{\nu,1}, \gamma_{\nu,2}, \dots$ are the

positive zeros of $J_\nu(x)$ arranged in ascending order of magnitude, then

$$0 < \gamma_{\nu,1} < \gamma_{\nu+1,1} < \gamma_{\nu,2} < \gamma_{\nu+1,2} < \gamma_{\nu,3} < \dots, \quad \nu > -1.$$

Asymptotic formula for γ_ν : $\gamma_\nu = \nu + 1, 855, 757\nu^{1/3} + 103, 315\nu^{-1/3} + O(\nu^{-1})$.

When $\nu > -1$ and A, B, C, D are real numbers such that $AD - BC \neq 0$, then the positive zeros of $AJ_\nu(x) + BxJ'_\nu(x)$ and $CJ_\nu(x) + DxJ'_\nu(x)$ separate one another and no function of this type can have a repeated zero other than $x = 0$. When A and B are real and $\nu > -1$, the function $AJ_\nu(x) + BzJ'_\nu(z)$ has only real zeros except for two purely imaginary zeros when $A/B + \nu < 0$. For $\nu > 1$, the function $J_{-\nu}(z)$ has an infinity of real zeros and also $2[\nu]$ conjugate complex zeros, among them two pure imaginary zeros when $[\nu]$ is an odd integer.

The principal branch of the function

$$AJ_\nu(z) + BJ_{-\nu}(z), \quad (A, B, \text{ real}, B \neq 0, \nu > 0)$$

has $[\nu]$ complex zeros with a positive real part in case $[\nu]$ is even; when $[\nu]$ is odd, there exist $[\nu] - 1$ or $[\nu] + 1$ complex zeros with a positive real part accordingly $(A/B) > / < 0$. The function $J_\nu(z)$ and $J_{\nu+m}(z)$ ($m = 1, 2, 3, \dots$) have no common roots other than zero. For positive fixed real values of z , the zeros ν_n of $J_\nu(z)$ are real and simple functions of ν , asymptotically approaching negative integers. The graph of $J_\nu(x)$ for fixed $\nu > -1$ and variable $x \geq 0$ resembles the graph of a damped oscillation. The successive areas of "half-waves" above and below the axis $x \geq 0$ form a decreasing sequence. If γ_ν , γ'_ν , and γ''_ν denote the smallest positive zeros of $J_\nu(x)$, $J'_\nu(x)$, and $J''_\nu(x)$ respectively; then the following inequalities hold:

$$\begin{aligned} [\nu(\nu + 2)]^{1/2} < \gamma_\nu < [2(\nu + 1)(\nu + 3)]^{1/2}, \quad \nu > 0, \\ [\nu(\nu + 2)]^{1/2} < \gamma'_\nu < [2\nu(\nu + 1)]^{1/2}, \quad \nu > 0, \\ [\nu(\nu - 1)]^{1/2} < \gamma''_\nu < (\nu^2 - 1)^{1/2}, \quad \nu > 1. \end{aligned}$$

Bessel functions of the second kind: Thus $Y_{2n}(z)$ and $Y_{2n+1}(z)$ ($n = 0, 1, 2, \dots$) have $2n$ complex zeros in $|\arg z| \leq 1/2\pi$; $Y_\nu(z)$ has positive real zeros on the principal branch only if ν is rational but not an integer.

Bessel functions of the third kind: The function $H_\nu^{(1)}(z)$, $\nu \geq 0$, has no zeros in $0 \leq \arg z \leq \pi$. The zeros, for $\nu \geq 0$, of $H_\nu^{(1)}$ in $-\pi < \arg z < 0$ and those of $H_\nu^{(2)}$ in $0 < \arg z < \pi$ lie symmetrically with respect to the imaginary axis. There are no pure imaginary zeros except when $\nu = (2k - 1) + 1/2$ ($k = 1, 2, 3, \dots$) in which case there is one such zero. The total number of the zeros of $H_\nu^{(1),(2)}(z)$ on the principal branch is: 0 if $0 \leq \nu < 3/2$; $2k - 1$, if $\nu = (2k - 1) + 1/2$; and $2k$, if $(2k - 1) + 1/2 < \nu < 2k + 1/2$; for $k = 1, 2, 3, \dots$ furthermore, $H_\nu^{(1),(2)}(x)$ and $H_{\nu+m}^{(1),(2)}(x)$ have no common zeros when ν is real ≥ -1 and $m = 1, 2, 3, \dots$

Modified Bessel functions of the third kind: For $\nu \geq 0$, $K_\nu(z)$ has no zeros for which $|\arg z| \leq \pi/2$. The number of zeros in $|\arg z| < \pi$ is the even integer nearest to $\nu - 1/2$ unless $\nu - 1/2$ is an integer, in which case the number is $\nu - 1/2$. When $\nu + 1$ is positive real, and m a positive integer, $K_\nu(z)$ and $K_{\nu+m}(z)$ have no common zero.

4.8 Fourier-Bessel and Dini Series

Denoting two positive zeros of $J_\nu(x)$ by $x = \gamma_m$ and $x = \gamma_n$ (in this case all the zeros of $J_\nu(x)$ are real), the following orthogonal relation holds for $\nu > -1$:

$$\int_0^1 t J_\nu(\gamma_m t) J_\nu(\gamma_n t) dt = \begin{cases} 0, & n \neq m, \\ \frac{1}{2} [J_{\nu+1}(\gamma_m)]^2, & n = m. \end{cases}$$

Similarly, if λ_m and λ_n denote two positive zeros of the function $zJ'_\nu(z) + aJ_\nu(z)$, the following orthogonality relation holds for a given constant a and $\nu \geq -1/2$:

$$\int_0^1 t J_\nu(\lambda_m t) J_\nu(\lambda_n t) dt = \begin{cases} 0, & n \neq m, \\ \frac{1}{2} \lambda_m^{-2} \{ \lambda_m^2 [J'_\nu(\lambda_m)]^2 + (\lambda_m^2 - \nu^2) [J_\nu(\lambda_m)]^2 \}, & n = m. \end{cases}$$

Fourier-Bessel expansion: An arbitrary function $f(x)$ of a real variable x can be written as

$$f(x) = \sum_{m=1}^\infty a_m J_\nu(\gamma_m x), \quad \text{with } \frac{1}{2} [J_{\nu+1}(\gamma_m)]^2 a_m = \int_0^1 t f(t) J_\nu(\gamma_m t) dt,$$

where $\gamma_1, \gamma_2, \gamma_3, \dots$ are the positive zeros of the function $J_\nu(x)$ arranged in ascending order of magnitude.

Dini expansion: An arbitrary function $f(x)$ of a real variable x can be written as

$$f(x) = \sum_{m=1}^\infty b_m J_\nu(\lambda_m x),$$

with $\{ \lambda_m^2 [J'_\nu(\lambda_m)]^2 + (\lambda_m^2 - \nu^2) [J_\nu(\lambda_m)]^2 \} b_m = 2\lambda_m^2 \int_0^1 t J_\nu(\lambda_m t) f(t) dt$, where $\nu \geq -1/2$ and $\lambda_1, \lambda_2, \dots$ are the positive zeros of the function $zJ'_\nu(z) + aJ_\nu(z)$ arranged in ascending order of magnitude.

A function $f(x)$ defined for $a < x < b (a > 0)$ can be expanded in the series

$$f(x) = \sum_{m=1}^\infty a_m [J_\nu(\gamma_m x) Y_\nu(\gamma_m b) - Y_\nu(\gamma_m x) J_\nu(\gamma_m b)],$$

where $z = \gamma_m$ is the m th positive root of $J_\nu(az) Y_\nu(bz) - Y_\nu(az) J_\nu(bz) = 0$, and

$$\begin{aligned} & \{ [J_\nu(\gamma_m a)]^2 - [J_\nu(\gamma_m b)]^2 \} a_m \\ &= \frac{1}{2} \pi \gamma_m^2 [J_\nu(\gamma_m a)]^2 \int_a^b [J_\nu(\gamma_m t) Y_\nu(\gamma_m b) - Y_\nu(\gamma_m t) J_\nu(\gamma_m b)] t f(t) dt. \end{aligned}$$

4.9 Asymptotic Expansions

Asymptotic expansions for large variable:

$$\begin{aligned} \left(\frac{\pi z}{2}\right)^{\frac{1}{2}} J_\nu(z) &= \cos\left(z - \frac{\nu\pi}{2} - \pi\right) \left[\sum_{m=0}^{M-1} (-1)^m (v, 2m) (2z)^{-2m} + O(|z|^{-2M}) \right] \\ &\quad - \sin\left(z - \frac{\nu\pi}{2} - \frac{\pi}{4}\right) \left[\sum_{m=0}^{M-1} (-1)^m (v, 2m+1) (2z)^{-2m-1} \right. \\ &\quad \left. + O(|z|^{-2M-1}) \right], \quad -\pi < \arg z < \pi, \end{aligned}$$

$$\begin{aligned} \left(\frac{\pi z}{2}\right)^{\frac{1}{2}} Y_\nu(z) &= \sin\left(z - \frac{\nu\pi}{2} - \frac{\pi}{4}\right) \left[\sum_{m=0}^{M-1} (-1)^m (v, 2m) (2z)^{-2m} + O(|z|^{-2M}) \right] \\ &\quad \times \cos\left(z - \frac{\nu\pi}{2} - \frac{\pi}{4}\right) \left[\sum_{m=0}^{M-1} (-1)^m (v, 2m+1) (2z)^{-2m-1} \right. \\ &\quad \left. + O(|z|^{-2M-1}) \right], \quad -\pi < \arg z < \pi, \end{aligned}$$

$$\begin{aligned} (2\pi z)^{\frac{1}{2}} I_\nu(z) &= e^z \left[\sum_{m=0}^{M-1} (-1)^m (v, m) (2z)^{-m} + O(|z|^{-M}) \right] \\ &\quad + i e^{-z+iv\pi} \left[\sum_{m=0}^{M-1} (v, m) (2z)^{-m} + O(|z|^{-M}) \right], \\ &\quad -\pi/2 < \arg z < 3\pi/2, \end{aligned}$$

$$\begin{aligned} (2z)^{\frac{1}{2}} \pi^{\frac{3}{2}} [\cos(\pi\nu)]^{-1} I_\nu(z) &= \sum_{m=0}^{M-1} [e^z - i] (-1)^m e^{-i\pi\nu z} \Gamma\left(m + \frac{1}{2} - \nu\right) \Gamma\left(m + \frac{1}{2} + \nu\right) \\ &\quad \times (2z)^{-m} / m! + e^z O(|z|^{-M}), \quad 3\pi/2 < \arg z < \pi/2, \end{aligned}$$

$$\begin{aligned} K_\nu(z) &= \left(\frac{\pi}{2z}\right)^{\frac{1}{2}} e^{-z} \left[\sum_{m=0}^{M-1} (v, m) (2z)^{-m} + O(|z|^{-M}) \right], \\ &\quad -3\pi/2 < \arg z < 3\pi/2. \end{aligned}$$

The following notation has been used in the above formulas:

$$(v, m) = 2^{-2m} \frac{\{(4v^2 - 1)(4v^2 - 3^2) \cdots [4v^2 - (2m-1)^2]\}}{m!} = \frac{\Gamma\left(\frac{1}{2} + v + m\right)}{m! \Gamma\left(\frac{1}{2} + v - m\right)}.$$

Asymptotic expansions for large order:

$$\begin{aligned} 2\pi I_p(x) &= 2^{\frac{1}{2}} (p^2 + x^2)^{-\frac{1}{4}} \exp[(p^2 + x^2)^{\frac{1}{2}} - p \sinh^{-1}(p/x)] \\ &\quad \times \left[\sum_{m=0}^{M-1} (-2)^m a_m \Gamma\left(m + \frac{1}{2}\right) (p^2 + x^2)^{-\frac{1}{2}m} + O(x^{-M}) \right], \quad p, x > 0, \end{aligned}$$

$$\begin{aligned} K_p(x) &= 2^{-\frac{1}{2}} (p^2 + x^2)^{-\frac{1}{4}} \exp[-(p^2 + x^2)^{\frac{1}{2}} + p \sinh^{-1}(p/x)] \\ &\quad \times \left[\sum_{m=0}^{M-1} 2^m a_m \Gamma\left(m + \frac{1}{2}\right) (p^2 + x^2)^{-\frac{1}{2}m} + O(x^{-M}) \right], \quad p, x > 0. \end{aligned}$$

In the above formulas, the first few coefficients a_m are as follows:

$$\begin{aligned}
 a_0 &= 1, \quad a_1 = -\frac{1}{8} + \frac{5}{24} \left(1 + \frac{x^2}{p^2}\right)^{-1}, \quad a_2 = \frac{3}{128} - \frac{77}{576} \left(1 + \frac{x^2}{p^2}\right)^{-1} + \frac{385}{3,456} \left(1 + \frac{x^2}{p^2}\right)^{-2}, \\
 \pi H_p^{(1)}(x) &= 2^{\frac{1}{2}} (x^2 - p^2)^{-\frac{1}{4}} \exp[i(x^2 - p^2)^{\frac{1}{2}} + ip \sinh^{-1}(p/x)] \\
 &\quad \times e^{-i\frac{\pi}{2}(p+\frac{1}{2})} \left[\sum_{m=0}^{M-1} 2^m b_m \Gamma\left(m + \frac{1}{2}\right) (-i)^m (x^2 - p^2)^{-\frac{1}{2}m} + O(x^{-M}) \right], \quad x > p > 0, \\
 \pi H_p^{(1)}(x) &= -i2^{\frac{1}{2}} (p^2 - x^2)^{-\frac{1}{4}} \exp[-(p^2 - x^2)^{\frac{1}{2}} + p \cosh^{-1}(p/x)] \\
 &\quad \times \left[\sum_{m=0}^{M-1} (-1)^m 2^m b_m \Gamma\left(m + \frac{1}{2}\right) (p^2 - x^2)^{-m/2} + O(x^{-M}) \right], \quad p > x > 0, \\
 2\pi J_p(x) &= 2^{\frac{1}{2}} (p^2 - x^2)^{-\frac{1}{4}} \exp[(p^2 - x^2)^{\frac{1}{2}} - p \sinh^{-1}(p/x)] \\
 &\quad \times \left[\sum_{m=0}^{M-1} 2^m b_m \Gamma\left(m + \frac{1}{2}\right) (p^2 - x^2)^{-\frac{m}{2}} + O(x^{-M}) \right], \quad p > x > 0.
 \end{aligned}$$

In the above formulas, the first few coefficients b_m are as follows:

$$\begin{aligned}
 b_0 &= 1, \quad b_1 = \frac{1}{8} - \frac{5}{24} \left(1 - \frac{x^2}{p^2}\right)^{-1}, \quad b_2 = \frac{3}{128} - \frac{77}{576} \left(1 - \frac{x^2}{p^2}\right)^{-1} + \frac{385}{3,456} \left(1 - \frac{x^2}{p^2}\right)^{-2}, \\
 \pi H_p^{(1)}(x) &\sim -\frac{2}{3} \sum_{m=0}^{\infty} e^{2(m+1)\pi i/3} B_m(\varepsilon x) \sin\left[(m+1)\frac{\pi}{3}\right] \Gamma\left(m + \frac{1}{3}\right) \left(\frac{x}{6}\right)^{-(m+1)/3}, \\
 p &\approx x, \quad p, x > 0, \quad \varepsilon = 1 - \frac{p}{x}, \quad \varepsilon = o(x^{-2/3}).
 \end{aligned}$$

In the above formula, the first few coefficients $B_m(\varepsilon x)$ are as follows:

$$\begin{aligned}
 B_0(\varepsilon x) &= 1, \quad B_1(\varepsilon x) = \varepsilon x, \quad B_2(\varepsilon x) = \frac{1}{2}(\varepsilon x)^2 - \frac{1}{20}, \\
 B_3(\varepsilon x) &= \frac{1}{6}(\varepsilon x)^3 - \frac{1}{15}\varepsilon x, \quad B_4(\varepsilon x) = \frac{1}{24}(\varepsilon x)^4 - \frac{1}{24}(\varepsilon x)^2 + \frac{1}{280}, \\
 B_5(\varepsilon x) &= \frac{1}{120}(\varepsilon x)^5 - \frac{1}{60}(\varepsilon x)^3 + \frac{43}{8400}\varepsilon x.
 \end{aligned}$$

4.10 Integrals

$$\begin{aligned}
 \int z^{\nu+1} I_\nu(z) dz &= z^{\nu+1} I_{\nu+1}(z), \quad \int z^{-\nu+1} I_\nu(z) dz = z^{-\nu+1} I_{\nu-1}(z), \\
 \int z^{\nu+1} K_\nu(z) dz &= -z^{\nu+1} K_{\nu+1}(z), \quad \int z^{-\nu+1} K_\nu(z) dz = -z^{-\nu+1} K_{\nu-1}(z), \\
 \int z^\nu J_\nu(z) dz &= 2^{\nu-1} \pi^{\frac{1}{2}} \Gamma\left(\nu + \frac{1}{2}\right) z [J_\nu(z) \mathbf{H}_{\nu-1}(z) - \mathbf{H}_\nu(z) J_{\nu-1}(z)], \\
 \int z^\nu K_\nu(z) dz &= 2^{\nu-1} \pi^{\frac{1}{2}} \Gamma\left(\nu + \frac{1}{2}\right) z [K_\nu(z) \mathbf{L}_{\nu-1}(z) + \mathbf{L}_\nu(z) K_{\nu-1}(z)].
 \end{aligned}$$

The following integral relations are satisfied by any Bessel functions $w_\nu(z)$ and $W_\mu(z)$ of the first, second, or third kind, and order ν and/or μ , respectively:

$$\begin{aligned} \int \left[(\beta^2 - \alpha^2)z + \frac{\nu^2 - \mu^2}{z} \right] w_\nu(\alpha z) W_\mu(\beta z) dz &= z[\alpha W_\mu(\beta z) w'_\nu(\alpha z) - \beta w_\nu(\alpha z) W'_\mu(\beta z)] \\ &= \alpha z W_\mu(\beta z) w_{\nu-1}(\alpha z) - \beta z W_{\mu-1}(\beta z) w_\nu(\alpha z) + (\mu - \nu) W_\mu(\beta z) w_\nu(\alpha z), \\ \int z w_\nu(\alpha z) W_\nu(\beta z) dz &= z(\beta^2 - \alpha^2)^{-1} [\beta W_{\nu+1}(\beta z) w_\nu(\alpha z) - \alpha W_\nu(\beta z) w_{\nu+1}(\alpha z)], \\ \int z w_\nu(\alpha z) W_\nu(\alpha z) dz &= \frac{z^2}{4} [[2w_\nu(\alpha z) W_\nu(\alpha z) - w_{\nu+1}(\alpha z) W_{\nu-1}(\alpha z) \\ &\quad - w_{\nu-1}(\alpha z) W_{\nu+1}(\alpha z)], \\ \int z^{-1} w_\nu(\alpha z) W_\nu(\alpha z) dz &= (2\nu)^{-1} w_\nu(\alpha z) W_\nu(\alpha z) \\ &\quad + (2\nu)^{-1} \alpha z \left[w_{\nu+1}(\alpha z) \frac{\partial W_\nu(\alpha z)}{\partial \nu} - w_\nu(\alpha z) \frac{\partial W_{\nu+1}(\alpha z)}{\partial \nu} \right]. \end{aligned}$$

The following integrals are satisfied by any modified Bessel function of the first or second kind $v_\nu(z)$ and $V_\mu(z)$, of order ν and μ , respectively:

$$\begin{aligned} \int \left[(\beta^2 - \alpha^2)z + \frac{\mu^2 - \nu^2}{z} \right] v_\nu(\alpha z) V_\mu(\beta z) dz &= z[-\alpha V_\mu(\beta z) v'_\nu(\alpha z) + \beta v_\nu(\alpha z) V'_\mu(\beta z)], \\ \int z [v_\nu(\alpha z)]^2 dz &= -\frac{1}{2} z^2 \{ [v'_\nu(\alpha z)]^2 - [v_\nu(\alpha z)]^2 (1 + \alpha^{-2} z^{-2} \nu^{-2}) \}, \\ \int_0^\infty Y_{2\nu}(\alpha t) e^{-\gamma^2 t^2} dt &= -\frac{1}{2} \pi^{\frac{1}{2}} \gamma^{-1} \exp\left(-\frac{1}{8} \alpha^2 / \gamma^2\right) \\ &\quad \times \left[I_\nu\left(\frac{\alpha^2}{8\gamma^2}\right) \tan \nu\pi + \frac{1}{\pi} K_\nu\left(\frac{\alpha^2}{8\gamma^2}\right) \sec \nu\pi \right], \quad |\operatorname{Re} \nu| < \frac{1}{2}, \\ \int_0^\infty e^{-t} t^{-1} H_\nu^{(1)}\left(\frac{2x^2}{t}\right) dt &= 2K_\nu(2x) H_\nu^{(1)}(2x), \\ \int_0^\infty I_\nu(\alpha t) e^{-\gamma^2 t^2} dt &= \frac{1}{2} \pi^{\frac{1}{2}} \gamma^{-1} \exp\left(\frac{\alpha^2}{8\gamma^2}\right) I_{(1/2)\nu}\left(\frac{\alpha^2}{8\gamma^2}\right), \quad \operatorname{Re} \nu > -1, \operatorname{Re} \gamma^2 > 0, \\ \int_0^\infty t^{-1} J_\mu(\alpha t) \sin(bt) dt &= \begin{cases} \mu^{-1} \sin[\mu \sin^{-1}(b/a)], & b < a, \\ a^\mu \mu^{-1} \sin\left(\frac{\mu\pi}{2}\right) [b + (b^2 - a^2)^{\frac{1}{2}}]^{-\mu}, & b > a, \end{cases} \\ \operatorname{Re} \mu > -1, \\ \int_0^\infty t^{-1} J_\mu(\alpha t) \cos(bt) dt &= \begin{cases} \mu^{-1} \cos[\mu \sin^{-1}(b/a)], & b < a, \\ a^\mu \mu^{-1} \cos\left(\frac{\mu\pi}{2}\right) [b + (b^2 - a^2)^{\frac{1}{2}}]^{-\mu}, & b > a, \end{cases} \\ \operatorname{Re} \mu > 0, \\ \int_0^\infty J_\mu(\alpha t) \sin(bt) dt &= \begin{cases} (a^2 - b^2)^{-1/2} \sin[\mu \sin^{-1}(b/a)], & b < a, \\ a^\mu \cos\left(\frac{\mu\pi}{2}\right) (b^2 - a^2)^{-1/2} [b + (b^2 - a^2)^{1/2}]^{-\mu}, & b > a, \end{cases} \\ \operatorname{Re} \mu > -2, \end{aligned}$$

$$\int_0^\infty J_\mu(at) \cos(bt) dt = \begin{cases} (a^2 - b^2)^{-1/2} \cos[\mu \sin^{-1}(b/a)], & b < a, \\ -a^\mu \sin\left(\frac{\mu\pi}{2}\right) (a^2 - b^2)^{-1/2} [b + (b^2 - a^2)^{1/2}]^{-\mu}, & b > a, \end{cases}$$

$$\operatorname{Re} \mu > -1,$$

$$\frac{1}{2} \pi (v^2 - \mu^2) \int_0^\infty J_\mu(at) J_\nu(at) t^{-1} dt = \sin \frac{(v - \mu)\pi}{2}, \quad \operatorname{Re}(v + \mu) > 0,$$

$$\int_0^\infty J_\mu(at) J_\nu(at) t^{-(v+\mu)} dt = \frac{\pi^{1/2} \left(\frac{a}{2}\right)^{v+\mu} \Gamma(\mu + \nu)}{a \Gamma\left(\frac{1}{2} + v + \mu\right) \Gamma\left(\mu + \frac{1}{2}\right) \Gamma\left(\nu + \frac{1}{2}\right)}, \quad \operatorname{Re}(v + \mu) > 0,$$

$$\int_0^\infty J_\mu(at) J_\nu(bt) t^{\mu-v+1} dt = \begin{cases} \frac{2^{\mu-v+1}}{\Gamma(v - \mu)} a^\mu b^{-v} (b^2 - a^2)^{v-\mu-1}, & b > a, \\ 0, & b < a, \end{cases}$$

$$\operatorname{Re} v > \operatorname{Re} \mu > -1.$$

4.11 Additional Theorems and Related Series

$$J_0((z^2 + Z^2 - 2zZ \cos \phi)^{1/2}) = J_0(z)J_0(Z) + 2 \sum_{n=1}^\infty J_n(z)J_n(Z) \cos(n\phi),$$

$$\left(2z \sin \frac{\phi}{2}\right)^{-v} J_v\left(2z \sin \frac{\phi}{2}\right) = 2^v \Gamma(v) \sum_{n=0}^\infty (v+n) [z^{-v} J_{v+n}(z)]^2 C_n^v(\cos \phi),$$

$$v \neq 0, -1, -2, \dots,$$

$$J_0\left(2z \sin \frac{\phi}{2}\right) = [J_0(z)]^2 + 2 \sum_{n=1}^\infty [J_n(z)]^2 \cos(n\phi),$$

$$z^v e^{yz} = 2^v \Gamma(v) \sum_{n=0}^\infty (v+n) C_n^v(y) I_{v+n}(z),$$

$$\left(\frac{z}{2}\right)^{\mu-v} J_\nu(z) = \sum_{n=0}^\infty \frac{\Gamma(\mu+n)\Gamma(v+1-\mu)(\mu+2n)}{n! \Gamma(v+1-\mu-n)\Gamma(v+n+1)} J_{\mu+2n}(z),$$

$$J_\nu(z \sin \theta) = \left(\frac{\pi z}{2}\right)^{-\frac{1}{2}} (\sin \theta)^v \sum_{n=0}^\infty \frac{\left(v + \frac{1}{2} + 2n\right) \Gamma\left(n + \frac{1}{2}\right)}{\Gamma(n + v + 1)} \Gamma\left(v + \frac{1}{2}\right) \\ \times C_{2n}^{v+\frac{1}{2}}(\cos \theta) J_{v+\frac{1}{2}+2n}(z).$$

5 Associated Legendre Functions

5.1 Differential Equation

Definition: An associated Legendre function is a solution of the differential equation

$$(1 - z^2) \frac{d^2 u}{dz^2} - 2z \frac{du}{dz} + \left[v(v+1) - \frac{\mu^2}{1 - z^2} \right] u = 0,$$

in which z denotes an arbitrary complex variable, while ν and μ denote arbitrary complex constants unless the contrary is explicitly stated. The points $+1, -1, \infty$, are ordinary branch points (i.e., singular points) of the above equation. It is customary to use the following notations: the letter x ($x = \cos \varphi$, where φ is a real number) denotes a real variable that varies over the interval $[-1, +1]$. The symbols $P_\nu^\mu(z)$, $Q_\nu^\mu(z)$ customarily denote those solutions of the above equation which are single-valued and regular for $|z| < 1$; in particular, these are uniquely determined for $z = x$. The symbols $P_\nu^\mu(z)$, $Q_\nu^\mu(z)$ customarily denote those solutions which are single-valued and regular for $\text{Re} z > 1$. When these functions cannot be unrestrictedly extended without violating their single-valuedness, a cut along the real axis is made to the left of the point $z = 1$. The values of the functions $P_\nu^\mu(z)$ and $Q_\nu^\mu(z)$ on the upper and lower boundaries of that portion of the cut lying between the points -1 and $+1$ are denoted respectively by $P_\nu^\mu(x \pm i0)$, $Q_\nu^\mu(x \pm i0)$. The letters n and m denote natural numbers or zero, while the letters ν and μ denote arbitrary complex numbers. The upper index is omitted when it is equal to zero, i.e.,

$$P_\nu^0(z) = P_\nu(z), \quad Q_\nu^0(z) = Q_\nu(z), \quad P_\nu^0(z) = P_\nu(z), \quad P_\nu^0(z) = Q_\nu(z).$$

Associated Legendre (or spherical) functions of the first and second kinds $P_\nu^\mu(z)$ and $Q_\nu^\mu(z)$: These functions are defined as the two *linearly independent* solutions of the above differential equation, namely

$$P_\nu^\mu(z) = \frac{1}{\Gamma(1-\mu)} \left(\frac{z+1}{z-1}\right)^{\mu/2} F\left(-\nu, \nu+1; 1-\mu; \frac{1-z}{2}\right), \quad \arg \frac{z+1}{z-1} = 0, \quad z > 1, \text{ real},$$

$$Q_\nu^\mu(z) = \frac{e^{\mu\pi i} \Gamma(\nu+\mu+1) \Gamma(\frac{1}{2})}{2^{\nu+1} \Gamma(\nu+\frac{3}{2})} (z^2-1)^{\mu/2} z^{-\nu-\mu-1} \times F\left(\frac{\nu+\mu+2}{2}, \frac{\nu+\mu+1}{2}; \nu+\frac{3}{2}; \frac{1}{z^2}\right),$$

with $\arg(z^2-1) = 0$ when z is real and greater than 1; or $\arg z = 0$ when z is real and greater than zero. These functions are uniquely defined, respectively, in the intervals $|1-z| < 2$ and $|z| > 1$ with the portion of the real axis that lies between $-\infty$ and $+1$ excluded. They can be extended by means of hypergeometric series to the entire z -plane where the above-mentioned cut was made. These expressions for $P_\nu^\mu(z)$ and $Q_\nu^\mu(z)$ lose their meaning when $1-\mu$ and $\nu+\frac{3}{2}$ are non-positive integers, respectively. When $z = x = \cos \varphi$ is a real number lying on the interval $[-1, +1]$, the following functions are taken as the linearly independent solutions:

$$P_\nu^\mu(x) = \frac{1}{2} \left[e^{\frac{1}{2}\mu\pi i} P_\nu^\mu(\cos \varphi + i0) + e^{-\frac{1}{2}\mu\pi i} P_\nu^\mu(\cos \varphi - i0) \right]$$

$$= \frac{1}{\Gamma(1-\mu)} \left(\frac{1+x}{1-x}\right)^{\mu/2} F\left(-\nu, \nu+1; 1-\mu; \frac{1-x}{2}\right),$$

$$Q_\nu^\mu(x) = \frac{1}{2} e^{-\mu\pi i} \left[e^{-\frac{1}{2}\mu\pi i} Q_\nu^\mu(x+i0) + e^{\frac{1}{2}\mu\pi i} Q_\nu^\mu(x-i0) \right]$$

$$= \frac{\pi}{2 \sin \mu\pi} \left[P_\nu^\mu(x) \cos \mu\pi - \frac{\Gamma(\nu+\mu+1)}{\Gamma(\nu-\mu+1)} P_\nu^{-\mu}(x) \right].$$

When $\mu = \pm m$ is an integer, the last equation loses its meaning, so that $Q_\nu^\mu(x)$ is defined as follows:

$$Q_\nu^m(x) = \left(-1^m (1-x^2)^{m/2} \frac{d^m}{dx^m} Q_\nu(x) \right), \quad Q_\nu^{-m}(x) = (-1)^m \frac{\Gamma(\nu-m+1)}{\Gamma(\nu+m+1)} Q_\nu^m(x).$$

The functions $Q_v^\mu(z)$ are not defined when $\nu + \mu$ is equal to a negative integer. Therefore, the cases $\nu + \mu = -1, -2, -3, \dots$ are excluded in the above formulas.

The functions

$$P_v^{\pm\mu}(\pm z), \quad Q_v^{\pm\mu}(\pm z), \quad P_{-\nu-1}^{\pm\mu}(\pm z), \quad Q_{-\nu-1}^{\pm\mu}(\pm z)$$

are linearly independent solutions of the differential equation for $\nu + \mu \neq 0, \pm 1, \pm 2, \dots$

5.2 Asymptotic Series for Large Values of $|\nu|$

The series

$$P_v^\mu(\cos \varphi) = \frac{2}{\sqrt{\pi}} \Gamma(\nu + \mu + 1) \sum_{k=0}^{\infty} \frac{\Gamma(\mu + k + \frac{1}{2}) \cos[(\nu + k + \frac{1}{2})\varphi - \frac{\pi}{4}(2k + 1) + \frac{\mu\pi}{2}]}{\Gamma(\mu - k + \frac{1}{2}) k! \Gamma(\nu - k + \frac{3}{2}) (2 \sin \varphi)^{k + \frac{1}{2}}},$$

$$\nu + \mu \neq -1, -2, -3, \dots; \nu \neq -\frac{3}{2}, -\frac{5}{2}, -\frac{7}{2}, \dots; \text{for } \frac{\pi}{6} < \varphi < \frac{5\pi}{6},$$

$$Q_v^\mu(\cos \varphi) = \sqrt{\pi} \Gamma(\nu + \mu + 1) \sum_{k=0}^{\infty} (-1)^k \frac{\Gamma(\mu + k + \frac{1}{2}) \cos[(\nu + k + \frac{1}{2})\varphi + \frac{\pi}{4}(2k + 1) + \frac{\mu\pi}{2}]}{\Gamma(\mu - k + \frac{1}{2}) k! \Gamma(\nu - k + \frac{3}{2}) (2 \sin \varphi)^{k + \frac{1}{2}}},$$

$$\nu + \mu \neq -1, -2, -3, \dots; \nu \neq -\frac{3}{2}, \frac{5}{2}, -\frac{7}{2}, \dots; \text{for } \frac{\pi}{6} < \varphi < \frac{5\pi}{6}$$

are both convergent for complex and real values of ν and μ , such that $|\nu| \gg 1, |\nu| \gg |\mu|, |\arg \nu| < \pi$. In the remaining cases, they are asymptotic expansions for $\nu > 0, \mu > 0$, and $0 < \varepsilon \leq \varphi \leq \pi - \varepsilon$. Note also the following asymptotic series, which hold for $0 < \varepsilon \leq \varphi \leq \pi - \varepsilon, |\nu| \gg 1/\varepsilon$:

$$P_v^\mu(\cos \varphi) = \frac{2}{\sqrt{\pi}} \frac{\Gamma(\nu + \mu + 1)}{\Gamma(\nu + \frac{3}{2})} \frac{\cos[(\nu + \frac{1}{2})\varphi - \frac{\pi}{4} + \frac{\mu\pi}{2}]}{\sqrt{2 \sin \varphi}} \left[1 + O\left(\frac{1}{\nu}\right) \right],$$

$$\nu^{-\mu} P_v^\mu(\cos \varphi) = \sqrt{\frac{2}{\nu \pi \sin \varphi}} \cos\left[\left(\nu + \frac{1}{2}\right)\varphi - \frac{\pi}{4} + \frac{\mu\pi}{2}\right] + O\left(\frac{1}{\sqrt{\nu^3}}\right),$$

$$\nu^{-\mu} Q_v^\mu(\cos \varphi) = \sqrt{\frac{\pi}{2\nu \sin \varphi}} \cos\left[\left(\nu + \frac{1}{2}\right)\varphi + \frac{\pi}{4} + \frac{\mu\pi}{2}\right] + O\left(\frac{1}{\sqrt{\nu^3}}\right).$$

For small values of φ sufficiently close to 0 or π , such that $\nu\varphi$ or $\nu(\pi - \varphi)$ is much smaller than 1, the above asymptotic formulas become unsuitable, and should be replaced by the following asymptotic representation for $\mu \geq 0, \nu \gg 1$, where $\eta = (2\nu + 1) \sin \frac{\varphi}{2}$:

$$\left[\left(\nu + \frac{1}{2}\right) \cos \frac{\varphi}{2} \right]^\mu P_v^{-\mu}(\cos \varphi) = J_\mu(\eta) + \sin^2 \frac{\varphi}{2} \left[\frac{J_{\mu+1}(\eta)}{2\eta} - J_{\mu+2}(\eta) + \frac{\eta}{6} J_{\mu+3}(\eta) \right] + O\left(\sin^4 \frac{\varphi}{2}\right).$$

In particular, the above expansion indicates that $\lim_{\nu \rightarrow \infty} \nu^\mu P_v^{-\mu}(\cos x/\nu) = J_\mu(x)$.

5.3 Recursion Relations

Among the many known relations involving Legendre function, some of the most frequently used for a complex argument z are the following:

$$(z^2 - 1) \frac{dP_v^\mu(z)}{dz} = (v - \mu + 1)P_{v+1}^\mu(z) - (v + 1)zP_v^\mu(z),$$

$$(2v + 1)zP_v^\mu(z) = (v - \mu + 1)P_{v+1}^\mu(z) + (v + \mu)P_{v-1}^\mu(z),$$

$$P_v^{\mu+2}(z) + 2(\mu + 1) \frac{z}{\sqrt{z^2 - 1}} P_v^{\mu+1}(z) = (v - \mu)(v + \mu + 1)P_v^\mu(z),$$

$$P_{v+1}^\mu(z) - P_{v-1}^\mu(z) = (2v + 1)\sqrt{z^2 - 1}P_v^{\mu-1}(z), \quad P_{-v-1}^\mu(z) = P_v^\mu(z),$$

$$(z^2 - 1) \frac{dQ_v^\mu(z)}{dz} = (v - \mu + 1)Q_{v+1}^\mu(z) - (v + 1)zQ_v^\mu(z),$$

$$(2v + 1)zQ_v^\mu(z) = (v - \mu + 1)Q_{v+1}^\mu(z) + (v + \mu)zQ_{v-1}^\mu(z),$$

$$Q_v^{\mu+2}(z) + 2(\mu + 1) \frac{z}{\sqrt{z^2 - 1}} Q_v^{\mu+1}(z) = (v - \mu)(v + \mu + 1)Q_v^\mu(z),$$

$$Q_{v-1}^\mu(z) - Q_{v+1}^\mu(z) = -(2v + 1)\sqrt{z^2 - 1}Q_v^{\mu-1}(z),$$

$$e^{-\mu\pi i} Q_v^\mu(x \pm i0) = e^{\pm \frac{1}{2}\mu\pi i} \left[Q_v^\mu(x) \mp i \frac{\pi}{2} P_v^\mu(x) \right],$$

$$\frac{\partial P_v^{-\mu}(x)}{\partial v} = \frac{1}{\Gamma(\mu + 1)} \left(\frac{1-x}{1+x} \right)^{\frac{\mu}{2}} \sum_{n=1}^{\infty} \frac{(-v)(1-v)\dots(n-1-v)(v+1)(v+2)\dots(v+n)}{(\mu+1)(\mu+2)\dots(\mu+n)1 \cdot 2 \cdot \dots \cdot n} \\ \times [\psi(v+n+1) - \psi(v-n+1)] \left(\frac{1-x}{2} \right)^n \quad [v \neq 0, \pm 1, \pm 2, \dots; \operatorname{Re} \mu > -1],$$

$$\left[\frac{\partial P_v(\cos \varphi)}{\partial v} \right]_{v=0} = 2 \ln \cos \frac{\varphi}{2}, \quad \left[\frac{\partial P_v^{-1}(\cos \varphi)}{\partial v} \right]_{v=0} = -\operatorname{tg} \frac{\varphi}{2} - 2 \operatorname{ctg} \frac{\varphi}{2} \ln \cos \frac{\varphi}{2},$$

$$P_v^{-\mu}(x) \frac{dP_v^\mu(x)}{dx} - P_v^\mu(x) \frac{dP_v^{-\mu}(x)}{dx} = \frac{2 \sin \mu\pi}{\pi(1-x^2)},$$

$$P_v^\mu(x) \frac{dQ_v^\mu(x)}{dx} - Q_v^\mu(x) \frac{dP_v^\mu(x)}{dx} = \frac{2^{2\mu}}{1-x^2} \frac{\Gamma\left(\frac{v+\mu+1}{2}\right) \Gamma\left(\frac{v+\mu}{2}+1\right)}{\Gamma\left(\frac{v-\mu+1}{2}\right) \Gamma\left(\frac{v-\mu}{2}+1\right)},$$

$$P_v^\mu(0) = \frac{2^\mu \sqrt{\pi}}{\Gamma\left(\frac{v-\mu}{2}+1\right) \Gamma\left(\frac{-v-\mu+1}{2}\right)}, \quad \frac{dP_v^\mu(0)}{dx} = \frac{2^{\mu+1} \sin \frac{(v+\mu)\pi}{2} \Gamma\left(\frac{v+\mu}{2}+1\right)}{\sqrt{\pi} \Gamma\left(\frac{v-\mu+1}{2}\right)},$$

$$Q_v^\mu(0) = -2^{\mu-1} \sqrt{\pi} \sin \frac{(v+\mu)\pi}{2} \frac{\Gamma\left(\frac{v+\mu+1}{2}\right)}{\Gamma\left(\frac{v-\mu}{2}+1\right)},$$

$$\frac{dQ_v^\mu(0)}{dx} = 2^\mu \sqrt{\pi} \cos \frac{(v+\mu)\pi}{2} \frac{\Gamma\left(\frac{v+\mu}{2}+1\right)}{\Gamma\left(\frac{v-\mu+1}{2}\right)}.$$

5.4 Spherical Functions (Associated Legendre Functions with Integral Indices)

For real x and *integral* values of ν and μ , $|\nu| > |\mu|$, the Legendre differential equation has as solutions the functions $P_n^m(x)$ which are called *associated Legendre functions* (or *spherical functions*) of the first kind. The number n is called the *degree* and the number m is called the *order* of the function $P_n^m(x)$. The functions $\cos m\vartheta P_n^m(\cos \varphi)$, $\sin m\vartheta P_n^m(\cos \varphi)$, which depend on the angles φ and ϑ , are called *tesseral harmonics* for $m < n$ and *sectoral harmonics* for $m = n$. The sectoral harmonics are periodic with respect to the angles φ and ϑ , with periods π and 2π , respectively. These functions are single-valued and continuous everywhere on the surface of the unit sphere $x_1^2 + x_2^2 + x_3^2 = 1$ (where $x_1 = \sin \varphi \cos \vartheta$, $x_2 = \sin \varphi \sin \vartheta$, and $x_3 = \cos \varphi$), and are solutions of the differential equation

$$\frac{1}{\sin \varphi} \frac{\partial}{\partial \varphi} \left(\sin \varphi \frac{\partial Y}{\partial \varphi} \right) + \frac{1}{\sin^2 \varphi} \frac{\partial^2 Y}{\partial \vartheta^2} + n(n+1)Y = 0.$$

The expressions of the first few spherical functions are:

$$P_1^1(x) = -(1-x^2)^{\frac{1}{2}} = -\sin \varphi, \quad P_2^1(x) = -3(1-x^2)^{\frac{1}{2}}x = -\frac{3}{2}\sin 2\varphi,$$

$$P_2^2(x) = -3(1-x^2)^{\frac{1}{2}}x = -\frac{3}{2}\sin 2\varphi, \quad P_2^0(x) = 3(1-x^2) = \frac{3}{2}(1-\cos 2\varphi).$$

Orthogonality relations:

$$\int_{-1}^1 P_n^m(x)P_k^m(x) dx = \begin{cases} 0, & n \neq k, \\ \frac{2}{2n+1} \frac{(n+m)!}{(n-m)!}, & n = k, \end{cases}$$

$$\int_{-1}^1 P_\nu(x)P_\sigma(x) dx = \begin{cases} \frac{2\pi \sin \pi(\sigma - \nu) + 4 \sin(\pi\nu) \sin(\pi\sigma) [\psi(\nu+1) - \psi(\sigma+1)]}{\pi^2(\sigma - \nu)(\sigma + \nu + 1)}, & \sigma + \nu + 1 \neq 0, \\ \frac{\pi^2 - 2(\sin \pi\nu)^2 \psi'(\nu+1)}{\pi^2 \left(\nu + \frac{1}{2}\right)}, & \sigma = \nu, \end{cases}$$

$$\int_{-1}^1 Q_n^m(x)P_k^m(x) dx = (-1)^m \frac{1 - (-1)^{n+k} (n+m)!}{(k-n)(k+n+1)(n-m)!}.$$

Two functions $Y_{n_1}(\varphi, \vartheta)$ and $Z_{n_2}(\varphi, \vartheta)$, defined as

$$Y_{n_1}(\varphi, \vartheta) = a_0 P_{n_1}(\cos \varphi) + \sum_{m=1}^{n_1} (a_m \cos m\vartheta + b_m \sin m\vartheta) P_{n_1}^m(\cos \varphi),$$

$$Z_{n_2}(\varphi, \vartheta) = \alpha_0 P_{n_2}(\cos \varphi) + \sum_{m=1}^{n_2} (\alpha_m \cos m\vartheta + \beta_m \sin m\vartheta) P_{n_2}^m(\cos \varphi),$$

satisfy the following integral relations:

$$\int_0^{2\pi} d\vartheta \int_0^\pi \sin \varphi d\varphi Y_{n_1}(\varphi, \vartheta) Z_{n_2}(\varphi, \vartheta) = 0,$$

$$\int_0^{2\pi} d\vartheta \int_0^\pi \sin \varphi d\varphi Y_n(\varphi, \vartheta) P_n[\cos \varphi \cos \psi + \sin \varphi \sin \psi \cos(\vartheta - \theta)] = \frac{4\pi}{2n+1} Y_n(\psi, \theta).$$

The spherical functions satisfy the following important “addition” theorems:

$$(\cos \varphi + i \sin \varphi \cos \vartheta)^n = P_n(\cos \varphi) + 2 \sum_{m=1}^n (-1)^m \frac{n!}{(n+m)!} \cos m\vartheta P_n^m(\cos \varphi),$$

$$P_n(\cos \varphi_1 \cos \varphi_2 + \sin \varphi_1 \sin \varphi_2 \cos \Theta) = P_n(\cos \varphi_1) P_n(\cos \varphi_2) + 2 \sum_{m=1}^n \frac{(n-m)!}{(n+m)!} P_n^m(\cos \varphi_1) \\ \times P_n^m(\cos \varphi_2) \cos m\Theta,$$

$$\int_0^1 [P_v^{n-v}(x)]^2 \frac{dx}{1-x^2} = -\frac{n!}{2(n-v)\Gamma(1-n+2v)}, \quad n = 0, 1, 2, \dots, \operatorname{Re} v > n,$$

$$\int_{-1}^1 P_n^m(x) P_n^k(x) \frac{dx}{1-x^2} = 0, \quad 0 \leq m \leq n, 0 \leq k \leq n, m \neq k.$$

Legendre functions of the first and second kind $P_\nu(z)$ and $Q_\nu(z)$ are the two linearly independent solutions of the differential equation

$$\frac{d}{dz} \left[(1-z^2) \frac{du}{dz} \right] + \nu(\nu+1)u = 0,$$

where the parameter ν can be an arbitrary number and are expressed in terms of hypergeometric functions as follows:

$$P_\nu(z) = F\left(-\nu, \nu+1; 1; \frac{1-z}{2}\right),$$

$$Q_\nu(z) = \frac{\Gamma(\nu+1)\Gamma\left(\frac{1}{2}\right)}{2^{\nu+1}\Gamma\left(\nu+\frac{3}{2}\right)} z^{-\nu-1} F\left(\frac{\nu+2}{2}, \frac{\nu+1}{2}; \frac{2\nu+3}{2}; \frac{1}{z^2}\right).$$

When ν is not an integer, $\nu \neq 0, 1, 2, \dots$, the function $Q_\nu(z)$ has branch points at the points $z = \pm 1$ and $z = \infty$, while the function $P_\nu(z)$ has singularities at $z = -1$ and $z = \infty$. On the other hand, if $\nu = n = 0, 1, 2, \dots$, the function $Q_n(z)$ is single-valued for $|z| > 1$ and regular for $z = \infty$, while the function $P_\nu(z)$ becomes the *Legendre polynomial* $P_n(z)$. For $\nu = -n = -1, -2, \dots$, the relation $P_{-n-1}(z) = P_n(z)$ holds. The first few functions take on the following forms and special values:

$$Q_0(x) = \frac{1}{2} \ln \frac{1+x}{1-x} = \operatorname{Arth} x, \quad Q_1(x) = \frac{x}{2} \ln \frac{1+x}{1-x} - 1,$$

$$Q_2(x) = \frac{1}{4} (3x^2 - 1) \ln \frac{1+x}{1-x} - \frac{3}{2}x, \quad Q_3(x) = \frac{1}{4} (5x^3 - 3x) \ln \frac{1+x}{1-x} - \frac{5}{2}x^2 + \frac{2}{3},$$

$$\begin{aligned}
 P_\nu(1) &= 1, \quad P_\nu(0) = -\frac{1}{2} \frac{\sin \nu\pi}{\sqrt{\pi^3}} \Gamma\left(\frac{\nu+1}{2}\right) \Gamma\left(-\frac{\nu}{2}\right), \\
 Q_\nu(0) &= \frac{1}{4\sqrt{\pi}} (1 - \cos \nu\pi) \Gamma\left(\frac{\nu+1}{2}\right) \Gamma\left(-\frac{\nu}{2}\right), \\
 Q_\nu(x) &= \frac{\pi}{2 \sin \nu\pi} [\cos \nu\pi P_\nu(x) - P_\nu(-x)], \quad \nu \neq 0, \pm 1, \pm 2, \dots, \\
 Q_n(x) &= \frac{1}{2} P_n(x) \ln \frac{1+x}{1-x} - W_{n-1}(x),
 \end{aligned}$$

where $W_{-1}(x) \equiv 0$, and

$$W_{n-1}(x) = \sum_{k=0}^{2E(\frac{n-1}{2})} \frac{2(n-2k)-1}{(2k+1)(n-k)} P_{n-2k-1}(x) = \sum_{k=1}^n \frac{1}{k} P_{k-1}(x) P_{n-k}(x), \quad n = 0, 1, 2, \dots,$$

$$(z^2 - 1) \frac{dP_\nu(z)}{dz} = (\nu + 1)[P_{\nu+1}(z) - zP_\nu(z)], \quad (2\nu + 1)zP_\nu(z) = (\nu + 1)P_{\nu+1}(z) + \nu P_{\nu-1}(z),$$

$$(z^2 - 1) \frac{dQ_\nu(z)}{dz} = (\nu + 1)[Q_{\nu+1}(z) - zQ_\nu(z)], \quad (2\nu + 1)zQ_\nu(z) = (\nu + 1)Q_{\nu+1}(z) + \nu Q_{\nu-1}(z).$$

Integrals:

$$\int_{\cos \varphi}^1 P_\nu(x) dx = \sin \varphi P_\nu^{-1}(\cos \varphi),$$

$$\int_{-1}^1 P_\nu(x) Q_\sigma(x) dx = \begin{cases} \frac{1 - \cos \pi(\sigma - \nu) - 2\pi^{-1} \sin(\pi\nu) \cos(\pi\sigma) [\psi(\nu + 1) - \psi(\sigma + 1)]}{(\nu - \sigma)(\nu + \sigma + 1)}, & \text{Re } \nu > 0, \text{ Re } \sigma > 0, \sigma \neq \nu, \\ -\frac{\sin(2\nu\pi) \psi'(\nu + 1)}{\pi(2\nu + 1)}, & \text{Re } \nu > 0, \sigma = \nu, \end{cases}$$

$$\int_{-1}^1 Q_\nu(x) Q_\sigma(x) dx = \begin{cases} \frac{[\psi(\nu + 1) - \psi(\sigma + 1)][1 + \cos(\pi\sigma) \cos(\nu\pi)] - \frac{\pi}{2} \sin \pi(\nu - \sigma)}{(\sigma - \nu)(\sigma + \nu + 1)}, & \sigma + \nu + 1 \neq 0; \\ & \nu, \sigma \neq -1, -2, -3, \dots, \\ \frac{\frac{1}{2} \pi^2 - \psi'(\nu + 1)[1 + (\cos \nu\pi)^2]}{2\nu + 1}, & \nu = \sigma, \nu \neq -1, -2, -3, \dots \end{cases}$$

Notation: $C = \frac{\Gamma((1+\nu)/2)\Gamma(1+(\sigma/2))}{\Gamma((1+\sigma)/2)\Gamma(1+(\nu/2))}$; $[\text{Re } \nu > 0, \text{ Re } \sigma > 0]$

$$\int_0^1 P_\nu(x) P_\sigma(x) dx = \frac{C \sin \frac{\pi\sigma}{2} \cos \frac{\pi\nu}{2} - C^{-1} \sin \frac{\pi\nu}{2} \cos \frac{\pi\sigma}{2}}{\frac{1}{2} \pi(\sigma - \nu)(\sigma + \nu + 1)},$$

$$\int_0^1 Q_\nu(x)Q_\sigma(x) dx = \frac{\psi(\nu+1) - \psi(\sigma+1) - \frac{\pi}{2} \left[(C - C^{-1}) \sin \frac{\pi(\sigma+\nu)}{2} - (C + C^{-1}) \sin \frac{\pi(\sigma-\nu)}{2} \right]}{(\sigma-\nu)(\sigma+\nu+1)} \quad \begin{array}{l} \text{Re} \nu > 0, \\ \text{Re} \sigma > 0, \end{array}$$

$$\int_0^1 P_\nu(x)Q_\sigma(x) dx = \frac{A^{-1} \cos \frac{\pi(\nu-\sigma)}{2} - 1}{(\sigma-\nu)(\sigma+\nu+1)}, \quad \text{Re} \nu > 0, \text{Re} \sigma > 0,$$

$$\int_1^\infty P_\nu(x)Q_\sigma(x) dx = \frac{1}{(\sigma-\nu)(\sigma+\nu+1)}, \quad \text{Re}(\sigma-\nu) > 0, \text{Re}(\sigma+\nu) > -1,$$

$$\int_1^\infty Q_\nu(x)Q_\sigma(x) dx = \frac{\psi(\sigma+1) - \psi(\nu+1)}{(\sigma-\nu)(\sigma+\nu+1)}, \quad \text{Re}(\nu+\sigma) > -1, \sigma, \nu \neq -1, -2, -3, \dots,$$

$$\int_1^\infty Q_\nu(x) dx = \frac{1}{\nu(\nu+1)}, \quad \text{Re} \nu > 0.$$

6 Orthogonal Polynomials

General properties: Consider a nonnegative real function $w(x) \geq 0$ of a real variable x such that the integral $\int_a^b w(x) dx > 0$, with (a, b) a fixed interval on the x -axis. If the integral $\int_a^b x^n w(x) dx$ exists for $n = 0, 1, 2, \dots$ then there exists a *system of orthogonal polynomials* $p_n(x)$, $n = 0, 1, 2, \dots$, on the interval (a, b) with the weight function $w(x)$; this sequence is uniquely determined by the following conditions:

1. $p_n(x)$ is a polynomial of degree n and the coefficient of x^n in this polynomial is positive
2. The polynomials $p_0(x), p_1(x), \dots$ are orthonormal, i.e.,

$$\int_a^b p_n(x)p_m(x)w(x) dx = \begin{cases} 0, & \text{for } n \neq m, \\ 1, & \text{for } n = m. \end{cases}$$

Darboux-Christoffel formula: Denoting the coefficient of x^n in the polynomials $p_n(x)$ by q_n , the following summation formulas hold

$$\sum_{k=0}^n p_k(x)p_k(y) = \frac{q_n}{q_{n+1}} \frac{p_{n+1}(x)p_n(y) - p_n(x)p_{n+1}(y)}{x-y},$$

$$\sum_{k=0}^n [p_k(x)]^2 = \frac{q_n}{q_{n+1}} [p_n(x)p'_{n+1}(x) - p'_n(x)p_{n+1}(x)].$$

Recursion formula: Three consecutive orthogonal polynomials satisfy the recursion relation

$$p_n(x) = (A_n x + B_n)p_{n-1}(x) - C_n p_{n-2}(x), \quad A_n = \frac{q_n}{q_{n-1}}, \quad C_n = \frac{q_n q_{n-2}}{q_{n-1}^2}, \quad n = 2, 3, 4, \dots$$

Special systems of normalized orthogonal polynomials:

1. Normalized Legendre polynomials:

$$\left(n + \frac{1}{2}\right)^{\frac{1}{2}} P_n(x), \quad (a, b) \rightarrow (-1, +1), \quad \text{weight} : w(x) = 1.$$

2. Normalized Gegenbauer polynomials:

$$2^\lambda \Gamma(\lambda) \left[\frac{(n+\lambda)n!}{2\pi\Gamma(2\lambda+n)} \right]^{\frac{1}{2}} C_n^\lambda(x), \quad (a, b) \rightarrow (-1, +1), \quad w(x) = (1-x^2)^{\lambda-\frac{1}{2}}.$$

3. Normalized Chebyshev polynomials:

$$\sqrt{\frac{\varepsilon_n}{\pi}} T_n(x); \quad \varepsilon_0 = 1, \quad \varepsilon_n = 2; \quad \text{for } n = 1, 2, 3, \dots, \quad (a, b) \rightarrow (-1, +1), \quad w(x) = (1-x^2)^{-\frac{1}{2}}.$$

4. Normalized Hermite polynomials:

$$2^{-\frac{n}{2}} \pi^{-\frac{1}{4}} (n!)^{-\frac{1}{2}} H_n(x), \quad (a, b) \rightarrow (-\infty, +\infty), \quad w(x) = e^{-x^2}.$$

5. Normalized Jacobi polynomials:

$$\left[\frac{\Gamma(n+1)\Gamma(\alpha+\beta+1+n)(\alpha+\beta+1+2n)}{\Gamma(\alpha+1+n)\Gamma(\beta+1+n)2^{\alpha+\beta+1}} \right]^{\frac{1}{2}} P_n^{(\alpha, \beta)}(x), \quad (a, b) \rightarrow (-1, +1),$$

$$w(x) = (1-x)^\alpha (1+x)^\beta.$$

6. Normalized Laguerre polynomials:

$$\left[\frac{\Gamma(n+1)}{\Gamma(\alpha+n+1)} \right]^{\frac{1}{2}} L_n^\alpha(x), \quad (a, b) \rightarrow (0, +\infty), \quad w(x) = x^\alpha e^{-x}.$$

6.1 Legendre Polynomials: $P_n(z)$

The differential equation

$$(1-z^2) \frac{d^2 u}{dz^2} - 2z \frac{du}{dz} + n(n+1)u = 0$$

admits polynomial solutions if, and only if, n is an integer; these polynomial solutions are the *Legendre polynomials* $P_n(z)$, which are hence special types of associated Legendre functions of degree n , of the form

$$P_n(z) = \frac{1}{2^n n!} \frac{d^n}{dz^n} (z^2 - 1)^n.$$

Written as a function of $z = \cos \varphi$, the Legendre polynomials $P_n(z)$ take on the forms:

$$\begin{aligned} P_n(z) &= \frac{1}{2^n} \sum_{k=0}^{E(\frac{n}{2})} \frac{(-1)^k (2n-2k)!}{k!(n-k)!(n-2k)!} z^{n-2k} \\ &= \frac{(2n-1)!!}{n!} z^n F\left(-\frac{n}{2}, \frac{1-n}{2}; \frac{1}{2}-n; \frac{1}{z^2}\right) \\ &= \sum_{k=0}^n \frac{(-1)^k (n+k)!}{(n-k)!(k!)2^{2k+1}} [(1-z)^k + (-1)^n (1+z)^k], \\ P_n(\cos \varphi) &= \frac{(2n-1)!!}{2^n n!} \left(\cos n\varphi + \frac{1}{2} \frac{n}{2n-1} \cos(n-2)\varphi + \frac{1 \cdot 3}{1 \cdot 2} \frac{n(n-1)}{(2n-1)(2n-3)} \cos(n-4)\varphi \right. \\ &\quad \left. + \frac{1 \cdot 3 \cdot 5}{1 \cdot 2 \cdot 3} \frac{n(n-1)(n-2)}{(2n-1)(2n-3)(2n-5)} \cos(n-6)\varphi - \dots \right). \end{aligned}$$

Special cases:

$$\begin{aligned} P_0(x) &= 1, \quad P_1(x) = x = \cos \varphi, \quad P_2(x) = \frac{1}{2}(3x^2 - 1) = \frac{1}{4}(3 \cos 2\varphi + 1), \\ P_3(x) &= \frac{1}{2}(5x^3 - 3x) = \frac{1}{8}(5 \cos 3\varphi + 3 \cos \varphi), \\ P_4(x) &= \frac{1}{8}(35x^4 - 30x^2 + 3) = \frac{1}{64}(35 \cos 4\varphi + 20 \cos 2\varphi + 9), \\ P_5(x) &= \frac{1}{8}(63x^5 - 70x^3 + 15x) = \frac{1}{128}(63 \cos 5\varphi + 35 \cos 3\varphi + 30 \cos \varphi). \end{aligned}$$

The generating function:

$$\begin{aligned} \frac{1}{\sqrt{1-2tz+t^2}} &= \sum_{k=0}^{\infty} t^k P_k(z), \quad \text{for } [|t| < \min |z \pm \sqrt{z^2-1}|] \\ &= \sum_{k=0}^{\infty} \frac{1}{t^{k+1}} P_k(z), \quad \text{for } [|t| > \max |z \pm \sqrt{z^2-1}|]. \end{aligned}$$

Inequalities:

$$\begin{aligned} \text{For } x > 1: \quad & P_0(x) < P_1(x) < P_2(x) < \dots < P_n(x) < \dots, \\ \text{For } x > -1: \quad & P_0(x) + P_1(x) + \dots + P_n(x) > 0, \\ [P_n(\cos \varphi)]^2 &> \frac{\sin(2n+1)\varphi}{(2n+1)\sin \varphi}, \quad [0 < \varphi < \pi], \\ \sqrt{n \sin \varphi} |P_n(\cos \varphi)| &\leq 1, \quad |P_n(\cos \varphi)| \leq 1. \end{aligned}$$

Recurrence relations:

$$\begin{aligned} (n+1)P_{n+1}(z) - (2n+1)zP_n(z) + nP_{n-1}(z) &= 0, \\ (z^2-1) \frac{dP_n}{dz} &= n[zP_n(z) - P_{n-1}(z)] = \frac{n(n+1)}{2n+1} [P_{n+1}(z) - P_{n-1}(z)]. \end{aligned}$$

Summations and series:

$$\begin{aligned} \sum_{k=0}^n (2k+1)P_k(x)P_k(y) &= (n+1) \frac{P_n(x)P_{n+1}(y) - P_n(y)P_{n+1}(x)}{y-x}, \\ z^{2n} &= \frac{1}{2n+1}P_0(z) + \sum_{k=1}^{\infty} (4k+1) \frac{2n(2n-2)\dots(2n-2k+2)}{(2n+1)(2n+3)\dots(2n+2k+1)}P_{2k}(z), \\ z^{2n+1} &= \frac{3}{2n+3}P_1(z) + \sum_{k=1}^{\infty} (4k+3) \frac{2n(2n-2)\dots(2n-2k+2)}{(2n+3)(2n+5)\dots(2n+2k+3)}P_{2k+1}(z), \\ \sum_{n=1}^{\infty} \frac{1}{n}P_n(\cos \theta) &= \ln \frac{2tg \frac{\pi-\theta}{4}}{\sin \theta} = -\ln \sin \frac{\theta}{2} - \ln \left(1 + \sin \frac{\theta}{2}\right), \\ \sum_{n=1}^{\infty} \frac{1}{n+1}P_n(\cos \theta) &= \ln \frac{1 + \sin \frac{\theta}{2}}{\sin \frac{\theta}{2}} - 1. \end{aligned}$$

Integrals:

$$\begin{aligned} P_n(\cos \varphi) &= \frac{2}{\pi} \int_{\varphi}^{\pi} \frac{\sin \left(n + \frac{1}{2}\right) t}{\sqrt{2(\cos \varphi - \cos t)}} dt, \\ \int_{-1}^1 P_n(x)P_m(x) dx &= \frac{2}{2n+1} \delta_{mn}, \\ \int_0^1 P_n(x)P_m(x) dx &= \frac{1}{2n+1} [m = n] \\ &= 0 [n - m \text{ is even, } m \neq n] \\ &= \frac{(-1)^{\frac{1}{2}(m+n-1)} m!n!}{2^{m+n-1}(n-m)(n+m+1) \left[\left(\frac{n}{2}\right)! \left(\frac{m-1}{2}\right)!\right]^2} [n = \text{even, } m = \text{odd}], \\ \int_0^{2\pi} P_{2n}(\cos \varphi) d\varphi &= 2\pi \left[\binom{2n}{n} 2^{-2n}\right]^2, \\ \int_{-1}^1 x^m P_n(x) dx &= 0, \quad \text{for } m < n, \\ \int_{-1}^1 (1+x)^{m+n} P_m(x)P_n(x) dx &= \frac{2^{m+n+1} [(m+n)!]^4}{(m!n!)^2 (2m+2n+1)!}, \\ \int_{-1}^1 (1+x)^{m-n-1} P_m(x)P_n(x) dx &= 0, \quad m > n, \\ \int_{-1}^1 (1-x^2)^n P_{2m}(x) dx &= \frac{2n^2}{(n-m)(2m+2n+1)} \int_{-1}^1 (1-x^2)^{n-1} P_{2m}(x) dx \quad m < n, \\ \int_{-1}^1 \frac{1}{z-x} \{P_n(x)P_{n-1}(z) - P_{n-1}(x)P_n(z)\} dx &= -\frac{2}{n}, \\ \int_{-1}^x (x-t)^{-\frac{1}{2}} P_n(t) dt &= \left(n + \frac{1}{2}\right)^{-1} (1+x)^{-\frac{1}{2}} [T_n(x) + T_{n+1}(x)], \\ \int_x^1 (t-x)^{-\frac{1}{2}} P_n(t) dt &= \left(n + \frac{1}{2}\right)^{-1} (1-x)^{-\frac{1}{2}} [T_n(x) - T_{n+1}(x)]. \end{aligned}$$

In the following integrals, z belongs to the complex plane with a discontinuity along the interval from -1 to $+1$.

$$\int_{-1}^1 (z-x)^{-1} P_n(x) dx = 2Q_n(z), \quad \int_{-1}^1 x(z-x)^{-1} P_0(x) dx = 2Q_1(z),$$

$$\int_{-1}^1 x(z-x)^{-1} P_m(x) P_n(x) dx = 2zP_m(z)Q_n(z), \quad m < n,$$

$$\int_{-1}^1 x(z-x)^{-1} [P_n(x)]^2 dx = 2zP_n(z)Q_n(z) - \frac{2}{2n+1}.$$

6.2 Gegenbauer Polynomials: $C_n^\lambda(t)$

The *Gegenbauer polynomials* $C_n^\lambda(t)$ of degree n represent a *generalization of the Legendre polynomials*, being defined as the coefficients of α^n in the power-series expansion of the function

$$(1 - 2t\alpha + \alpha^2)^{-\lambda} = \sum_{n=0}^{\infty} C_n^\lambda(t) \alpha^n.$$

Recursion formulas:

$$(n+2)C_{n+2}^\lambda(t) = 2(\lambda+n+1)tC_{n+1}^\lambda(t) - (2\lambda+n)C_n^\lambda(t),$$

$$nC_n^\lambda(t) = 2\lambda[tC_{n-1}^{\lambda+1}(t) - C_{n-2}^{\lambda+1}(t)],$$

$$(2\lambda+n)C_n^\lambda(t) = 2\lambda[C_n^{\lambda+1}(t) - tC_{n-1}^{\lambda+1}(t)],$$

$$nC_n^\lambda(t) = (2\lambda+n-1)tC_{n-1}^\lambda(t) - 2\lambda(1-t^2)C_{n-2}^{\lambda-1}(t).$$

Summation theorem:

$$C_n^\lambda(\cos\psi \cos\vartheta + \sin\psi \sin\vartheta \cos\varphi)$$

$$= \frac{\Gamma(2\lambda-1)}{[\Gamma(\lambda)]^2} \sum_{k=0}^n \frac{2^{2k}(n-k)![\Gamma(\lambda+k)]^2}{\Gamma(2\lambda+n+k)} (2\lambda+2k-1) \sin^k\psi \sin^k\vartheta$$

$$\times C_{n-k}^{\lambda+k}(\cos\psi) C_{n-k}^{\lambda+k}(\cos\vartheta) C_k^{\lambda-\frac{1}{2}}(\cos\varphi), \quad \psi, \vartheta, \varphi \text{ real; } \lambda \neq \frac{1}{2},$$

$$\frac{d^k}{dt^k} C_n^\lambda(t) = 2^k \frac{\Gamma(\lambda+k)}{\Gamma(\lambda)} C_{n-k}^{\lambda+k}(t),$$

$$C_n^\lambda(t) = \frac{\Gamma(2\lambda+n)\Gamma(\lambda+\frac{1}{2})}{\Gamma(2\lambda)\Gamma(n+1)} \left\{ \frac{1}{4}(t^2-1) \right\}^{\frac{1}{4}-\frac{\lambda}{2}} P_{\lambda+n-\frac{1}{2}}^{\frac{1}{2}-\lambda}(t),$$

$$\lim_{\lambda \rightarrow 0} \Gamma(\lambda) C_n^\lambda(\cos\varphi) = \frac{2 \cos n\varphi}{n}, \quad \lim_{\lambda \rightarrow \infty} \lambda^{-\frac{n}{2}} C_n^{\frac{\lambda}{2}} \left(t \sqrt{\frac{2}{\lambda}} \right) = \frac{2^{-\frac{n}{2}}}{n!} H_n(t),$$

$$\lim_{\lambda \rightarrow \infty} \lambda^{-\frac{n}{2}} C_n^{\frac{\lambda}{2}} \left(t \sqrt{\frac{2}{\lambda}} \right) = \frac{2^{-\frac{n}{2}}}{n!} H_n(t).$$

Special cases:

$$C_n^1(\cos\varphi) = \frac{\sin(n+1)\varphi}{\sin\varphi}, \quad C_0^0(\cos\varphi) = 1, C_0^\lambda(t) \equiv 1, C_n^\lambda(1) = \binom{2\lambda+n-1}{n},$$

$$\int_{-1}^1 (1-x^2)^{\nu-\frac{1}{2}} C_n^\nu(x) dx = 0, \quad n > 0, \operatorname{Re} \nu > -\frac{1}{2},$$

$$\int_0^1 x^{n+2\rho} (1-x^2)^{\nu-\frac{1}{2}} C_n^\nu(x) dx = \frac{\Gamma(2\nu+n)\Gamma(2\rho+n+1)\Gamma\left(\nu+\frac{1}{2}\right)\Gamma\left(\rho+\frac{1}{2}\right)}{2^{n+1}\Gamma(2\nu)\Gamma(2\rho+1)n!\Gamma(n+\nu+\rho+1)}, \quad \operatorname{Re} \rho > -\frac{1}{2}, \operatorname{Re} \nu > -\frac{1}{2},$$

$$\int_{-1}^1 (1-x)^{\nu-\frac{1}{2}} (1+x)^\beta C_n^\nu(x) dx = \frac{2^{\beta+\nu+\frac{1}{2}}\Gamma(\beta+1)\Gamma\left(\nu+\frac{1}{2}\right)\Gamma(2\nu+n)\Gamma\left(\beta-\nu+\frac{3}{2}\right)}{n!\Gamma(2\nu)\Gamma\left(\beta-\nu-n+\frac{3}{2}\right)\Gamma\left(\beta+\nu+n+\frac{3}{2}\right)}, \quad \operatorname{Re} \beta > -1, \operatorname{Re} \nu > -\frac{1}{2},$$

$$\int_{-1}^1 (1-x^2)^{\nu-\frac{1}{2}} C_m^\nu(x) C_n^\nu(x) dx = \frac{\pi 2^{1-2\nu}\Gamma(2\nu+n)}{n!(n+\nu)[\Gamma(\nu)]^2} \delta_{mn}, \quad \operatorname{Re} \nu > -\frac{1}{2}.$$

6.3 Chebyshev Polynomials $T_n(x)$ and $U_n(x)$

Definition: The Chebyshev's polynomials of the first kind, $T_n(x)$, are defined as

$$T_n(x) = \cos(n \arccos x) = \frac{1}{2} \left[(x + i\sqrt{1-x^2})^n + (x - i\sqrt{1-x^2})^n \right]$$

$$= x^n - \binom{n}{2} x^{n-2} (1-x^2) + \binom{n}{4} x^{n-4} (1-x^2)^2 - \binom{n}{6} x^{n-6} (1-x^2)^3 + \dots.$$

The Chebyshev's polynomials of the second kind, $U_n(x)$, are defined as:

$$U_n(x) = \frac{\sin[(n+1) \arccos x]}{\sin[\arccos x]} = \frac{1}{2i\sqrt{1-x^2}} \left[(x + i\sqrt{1-x^2})^{n+1} - (x - i\sqrt{1-x^2})^{n+1} \right]$$

$$= \binom{n+1}{1} x^n - \binom{n+1}{3} x^{n-2} (1-x^2) + \binom{n+1}{5} x^{n-4} (1-x^2)^2 - \dots.$$

All zeros of $T_n(x)$ and $U_n(x)$ are real, simple, and lie within the interval $(-1, +1)$. Of all polynomials of degree n with leading coefficient equal to 1, the one that deviates the least from zero on the interval $[-1, +1]$ is the polynomial $2^{-n+1} T_n(x)$. The functions $T_n(x)$ and $\sqrt{1-x^2} U_{n-1}(x)$ are two linearly independent solutions of the differential equation

$$(1-x^2) \frac{d^2 y}{dx^2} - x \frac{dy}{dx} + n^2 y = 0.$$

Generating functions:

$$\frac{1-t^2}{1-2tx+t^2} = T_0(x) + 2 \sum_{k=1}^{\infty} T_k(x) t^k, \quad \frac{1}{1-2tx+t^2} = \sum_{k=0}^{\infty} U_k(x) t^k.$$

Recursion formulas:

$$T_{n+1}(x) - 2xT_n(x) + T_{n-1}(x) = 0, \quad U_{n+1}(x) - 2xU_n(x) + U_{n-1}(x) = 0,$$

$$T_n(x) = U_n(x) - xU_{n-1}(x), \quad (1-x^2)U_{n-1}(x) = xT_n(x) - T_{n+1}(x).$$

Special cases:

$$T_0(x) = 1, \quad T_1(x) = x, \quad T_2(x) = 2x^2 - 1, \quad T_3(x) = 4x^3 - 3x,$$

$$T_4(x) = 8x^4 - 8x^2 + 1, \quad T_5(x) = 16x^5 - 20x^3 + 5x,$$

$$U_0(x) = 1, \quad U_1(x) = 2x, \quad U_2(x) = 4x^2 - 1,$$

$$U_3(x) = 8x^3 - 4x, \quad U_4(x) = 16x^4 - 12x^2 + 1,$$

$$T_n(1) = 1, \quad T_n(-1) = (-1)^n, \quad T_{2n}(0) = (-1)^n, \quad T_{2n+1}(0) = 0,$$

$$U_{2n+1}(0) = 0, \quad U_{2n}(0) = (-1)^n.$$

Integrals:

$$\int_{-1}^1 T_n(x)T_m(x) \frac{dx}{\sqrt{1-x^2}} = \begin{cases} 0, & m \neq n, \\ \frac{\pi}{2}, & m = n \neq 0, \\ \pi, & m = n = 0, \end{cases}$$

$$\int_{-1}^1 \sqrt{1-x^2} U_n(x)U_m(x) dx = \begin{cases} 0, & m \neq n \text{ or } m = n = 0, \\ \frac{\pi}{2}, & m = n \neq 0, \end{cases}$$

$$\int_{-1}^1 [T_n(x)]^2 dx = 1 - (4n^2 - 1)^{-1},$$

$$\int_{-1}^1 U_n[x(1-y^2)^{\frac{1}{2}}(1-z^2)^{\frac{1}{2}} + yz] dx = \frac{2}{n+1} U_n(y)U_n(z), \quad |y| < 1, |z| < 1,$$

$$\int_{-1}^1 (1-x)^{-\frac{1}{2}}(1+x)^{m-n-\frac{3}{2}} T_m(x)T_n(x) dx = 0, \quad m > n,$$

$$\int_{-1}^1 (1-x)^{-\frac{1}{2}}(1+x)^{m+n-\frac{3}{2}} T_m(x)T_n(x) dx = \frac{\pi(2m+2n-2)!}{2^{m+n}(2m-1)!(2n-1)!}, \quad m+n \neq 0,$$

$$\int_{-1}^1 (1-x)^{\frac{1}{2}}(1+x)^{m+n+\frac{3}{2}} U_m(x)U_n(x) dx = \frac{\pi(2m+2n+2)!}{2^{m+n+2}(2m+1)!(2n+1)!},$$

$$\int_{-1}^1 (1-x)^{\frac{1}{2}}(1+x)^{m-n-\frac{1}{2}} U_m(x)U_n(x) dx = 0, \quad m > n.$$

6.4 Hermite Polynomials $H_n(x)$

Definition: The Hermite polynomials $H_n(x)$ are defined via the following expressions:

$$H_n(x) = (-1)^n e^{x^2} \frac{d^n}{dx^n} (e^{-x^2}), \quad H_n(x) = \frac{2^n}{\sqrt{\pi}} \int_{-\infty}^{\infty} (x+it)^n e^{-t^2} dt,$$

$$H_n(x) = 2^n x^n - 2^{n-1} \binom{n}{2} x^{n-2} + 2^{n-2} \cdot 1 \cdot 3 \cdot \binom{n}{4} x^{n-4} - 2^{n-3} \cdot 1 \cdot 3 \cdot 5 \cdot \binom{n}{6} x^{n-6} + \dots$$

The Hermite polynomials satisfy the differential equation

$$\frac{d^2 u_n}{dx^2} - 2x \frac{du_n}{dx} + 2n u_n = 0.$$

A second solution of this differential equation is provided by the functions:

$$u_{2n} = (-1)^n A x \Phi\left(\frac{1}{2} - n; \frac{3}{2}; x^2\right), \quad u_{2n+1} = (-1)^n B \Phi\left(-\frac{1}{2} - n; \frac{1}{2}; x^2\right),$$

$A, B = \text{const.}$

Recursion formulas:

$$\frac{dH_n(x)}{dx} = 2nH_{n-1}(x), \quad H_{n+1}(x) = 2xH_n(x) - 2nH_{n-1}(x).$$

Generating function: $\exp(-t^2 + 2tx) = \sum_{k=0}^{\infty} (t^k/k!)H_k(x)$.

Special cases:

$$H_0(x) = 1, \quad H_1(x) = 2x, \quad H_2(x) = 4x^2 - 2, \quad H_3(x) = 8x^3 - 12x,$$

$$H_4(x) = 16x^4 - 48x^2 + 12,$$

$$H_{2n}(0) = (-1)^n 2^n (2n-1)!!, \quad H_{2n+1}(0) = 0.$$

Inequalities:

$$|H_n(x)| \leq 2^{\frac{n}{2} - E(\frac{n}{2})} \frac{n!}{\left[E\left(\frac{n}{2}\right)\right]!} e^{2x\sqrt{E(\frac{n}{2})}} \quad [x > 0].$$

Asymptotic representation:

$$H_{2n}(x) = (-1)^n 2^n (2n-1)!! e^{\frac{x^2}{2}} \left[\cos(\sqrt{4n+1}x) + O\left(\frac{1}{\sqrt[4]{n}}\right) \right],$$

$$H_{2n+1}(x) = (-1)^n 2^{n+\frac{1}{2}} (2n-1)!! \sqrt{2n+1} e^{\frac{x^2}{2}} \left[\sin(\sqrt{4n+3}x) + O\left(\frac{1}{\sqrt[4]{n}}\right) \right].$$

Summation theorem:

$$\frac{\left(\sum_{k=1}^r a_k^2\right)^{\frac{n}{2}}}{n!} H_n\left(\frac{\sum_{k=1}^r a_k x_k}{\sqrt{\sum_{k=1}^r a_k^2}}\right) = \sum_{m_1+m_2+\dots+m_r=n} \prod_{k=1}^r \left\{ \frac{a_k^{m_k}}{m_k!} H_{m_k}(x_k) \right\}.$$

Integrals:

$$\int_{-\infty}^{\infty} e^{-x^2} H_m(x) H_n(x) dx = \begin{cases} 0, & m \neq n, \\ 2^n \cdot n! \sqrt{\pi}, & m = n, \end{cases}$$

$$\int_{-\infty}^{\infty} e^{-2x^2} H_m(x) H_n(x) dx = (-1)^{\frac{1}{2}(m+n)} 2^{\frac{m+n-1}{2}} \Gamma\left(\frac{m+n+1}{2}\right), \quad m+n \text{ is even,}$$

$$\int_{-\infty}^{\infty} e^{-x^2} H_m(ax) H_n(x) dx = 0, \quad m < n,$$

$$\int_0^x e^{-y^2} H_n(y) dy = H_{n-1}(0) - e^{-x^2} H_{n-1}(x),$$

$$\int_{-\infty}^{\infty} e^{-x^2} H_{2m}(xy) dx = \sqrt{\pi} \frac{(2m)!}{m!} (y^2 - 1)^m.$$

6.5 Laguerre Polynomials

Definition: The Laguerre polynomials $L_n^\alpha(x)$ are defined as

$$L_n^\alpha(x) = \frac{1}{n!} e^x x^{-\alpha} \frac{d^n}{dx^n} (e^{-x} x^{n+\alpha}) = \sum_{m=0}^n (-1)^m \binom{n+\alpha}{n-m} \frac{x^m}{m!}, \quad L_n^0(x) = L_n(x).$$

The Laguerre polynomials satisfy the differential equation

$$x \frac{d^2 u}{dx^2} + (\alpha - x + 1) \frac{du}{dx} + nu = 0.$$

Recursion formulas:

$$\frac{d}{dx} [L_n^\alpha(x) - L_{n+1}^\alpha(x)] = L_n^\alpha(x), \quad \frac{d}{dx} L_n^\alpha(x) = -L_{n-1}^{\alpha+1}(x),$$

$$x \frac{d}{dx} L_n^\alpha(x) = n L_n^\alpha(x) - (n + \alpha) L_{n-1}^\alpha(x) = (n + 1) L_{n+1}^\alpha(x) - (n + \alpha + 1 - x) L_n^\alpha(x),$$

$$x L_n^{\alpha+1}(x) = (n + \alpha + 1) L_n^\alpha(x) - (n + 1) L_{n+1}^\alpha(x) = (n + \alpha) L_{n-1}^\alpha(x) - (n - x) L_n^\alpha(x),$$

$$(n + 1) L_{n+1}^\alpha(x) - (2n + \alpha + 1 - x) L_n^\alpha(x) + (n + \alpha) L_{n-1}^\alpha(x) = 0, \quad n = 1, 2, \dots,$$

$$L_n^{\alpha-1}(x) = L_n^\alpha(x) - L_{n-1}^\alpha(x).$$

Connections with Hermite polynomials:

$$H_{2n}(x) = (-1)^n 2^{2n} n! L_n^{-\frac{1}{2}}(x^2), \quad H_{2n+1}(x) = (-1)^n 2^{2n+1} n! x L_n^{\frac{1}{2}}(x^2).$$

Special cases:

$$L_0^\alpha(x) = 1, \quad L_1^\alpha(x) = \alpha + 1 - x, \quad L_n^{-n}(x) = (-1)^n \frac{x^n}{n!}, \quad L_n^\alpha(0) = \binom{n+\alpha}{n},$$

$$L_1(x) = 1 - x, \quad L_2(x) = 1 - 2x + \frac{x^2}{2}.$$

Summations:

$$L_n^{\alpha_1+\alpha_2+\dots+\alpha_k+k-1}(x_1+x_2+\dots+x_k) = \sum_{(i_1+i_2+\dots+i_k=n)} L_{i_1}^{\alpha_1}(x_1)L_{i_2}^{\alpha_2}(x_2)\dots L_{i_k}^{\alpha_k}(x_k),$$

$$L_n^\alpha(x+y) = e^y \sum_{k=0}^\infty \frac{(-1)^k}{k!} y^k L_n^{\alpha+k}(x),$$

$$\sum_{m=0}^n \frac{m!}{\Gamma(m+\alpha+1)} L_m^\alpha(x)L_m^\alpha(y) = \frac{(n+1)!}{\Gamma(n+\alpha+1)(x-y)} [L_n^\alpha(x)L_{n+1}^\alpha(y) - L_{n+1}^\alpha(x)L_n^\alpha(y)],$$

$$\sum_{m=0}^n L_m^\alpha(x) = L_n^{\alpha+1}(x), \quad \sum_{m=0}^n L_m^\alpha(x)L_{n-m}^\beta(y) = L_n^{\alpha+\beta+1}(x+y),$$

$$(1-z)^{-\alpha-1} \exp \frac{xz}{z-1} = \sum_{n=0}^\infty L_n^\alpha(x)z^n, \quad |z| < 1,$$

$$e^{-xz}(1+z)^\alpha = \sum_{n=0}^\infty L_n^{\alpha-n}(x)z^n, \quad |z| < 1, \quad J_\alpha(2\sqrt{xz})e^z(xz)^{-\frac{1}{2}\alpha}$$

$$= \sum_{n=0}^\infty \frac{z^n}{\Gamma(n+\alpha+1)} L_n^\alpha(x), \quad \alpha > -1,$$

$$\sum_{n=0}^\infty n! \frac{L_n^\alpha(x)L_n^\alpha(y)z^n}{\Gamma(n+\alpha+1)} = \frac{(xyz)^{-\frac{1}{2}\alpha}}{1-z} \exp\left(-z\frac{x+y}{1-z}\right) I_\alpha\left(2\frac{\sqrt{xyz}}{1-z}\right), \quad |z| < 1,$$

$$\sum_{n=0}^\infty \frac{L_n^\alpha(x)}{n+1} = e^x x^{-\alpha} \Gamma(\alpha, x), \quad \alpha > -1, x > 0.$$

Asymptotic behavior:

$$L_n^\alpha(x) = \lim_{\beta \rightarrow \infty} P_n^{(\alpha, \beta)}\left(1 - \frac{2x}{\beta}\right), \quad \lim_{n \rightarrow \infty} \left[n^{-\alpha} L_n^\alpha\left(\frac{x}{n}\right)\right] = x^{-\frac{1}{2}\alpha} J_\alpha(2\sqrt{x}),$$

$$L_n^\alpha(x) = \frac{1}{\sqrt{\pi}} e^{\frac{1}{2}x} x^{-\frac{1}{2}\alpha - \frac{1}{4}} n^{\frac{1}{2}\alpha - \frac{1}{4}} \cos\left[2\sqrt{nx} - \frac{\alpha\pi}{2} - \frac{\pi}{4}\right] + O\left(n^{\frac{1}{2}\alpha - \frac{3}{4}}\right), \quad \text{Im } \alpha = 0, x > 0.$$

Integrals:

$$\int_0^t L_n^\alpha(x) dx = L_n^\alpha(t) - L_{n+1}^\alpha(t) - \binom{n+\alpha}{n} + \binom{n+1+\alpha}{n+1},$$

$$\int_0^t L_{n-1}^{\alpha+1}(x) dx = -L_n^\alpha(t) + \binom{n+\alpha}{n},$$

$$\int_0^t L_m(x)L_n(t-x) dx = L_{m+n}(t) - L_{m+n+1}(t),$$

$$\int_0^1 x^\alpha(1-x)^\beta L_m^\alpha(xy)L_n^\beta[(1-x)y] dx$$

$$= \frac{(m+n)!\Gamma(\alpha+m+1)\Gamma(\beta+n+1)}{m!n!\Gamma(\alpha+\beta+m+n+2)} L_{m+n}^{\alpha+\beta+1}(y), \quad \text{Re } \alpha > -1, \text{Re } \beta > -1,$$

$$\int_y^\infty e^{-x} L_n^\alpha(x) dx = e^{-y} [L_n^\alpha(y) - L_{n-1}^\alpha(y)],$$

$$\int_0^\infty e^{-bx} L_n(\lambda x) L_n(\mu x) dx = \frac{(b - \lambda - \mu)^n}{b^{n+1}} P_n \left[\frac{b^2 - (\lambda + \mu)b + 2\lambda\mu}{b(b - \lambda - \mu)} \right], \quad \operatorname{Re} b > 0,$$

$$\int_0^\infty e^{-x} x^\alpha L_n^\alpha(x) L_m^\alpha(x) dx = \begin{cases} 0, & m \neq n, \quad \operatorname{Re} \alpha > -1, \\ \frac{\Gamma(\alpha + n + 1)}{n!}, & m = n, \quad \operatorname{Re} \alpha > 0. \end{cases}$$

7 Probability Theory and Statistical Estimation

7.1 Introduction

Probability theory is a branch of mathematical sciences that provides a model for describing the process of observation. The need for probability theory arises from the fact that most observations of natural phenomena do not lead to uniquely predictable results. Probability theory provides the tools for dealing with actual variations in the outcome of realistic observations and measurements. The challenging pursuit to develop a theory of probability that is mathematically rigorous and describes many phenomena observable in nature has generated over the years notable disputes over conceptual and logical problems. Modern probability theory is based on postulates constructed from three axioms attributed to A. Kolmogorov, all of which are consistent with the notion of frequency of occurrence of events. The alternative approach, traceable to P. Laplace, is based on the concept that probability is simply a way of providing a numerical scale to quantify our reasonable beliefs about a situation which we do not know completely. This approach is consistent with Bayes' theorem, conditional probabilities, and inductive reasoning. Either approach to probability theory would completely describe a natural phenomenon if sufficient information were available to determine the underlying probability distribution exactly. In practice, though, such exact knowledge is seldom available, so that the features of the probability distribution underlying the physical phenomenon under consideration must be estimated. Such estimations form the study object of statistics, which is defined as the branch of mathematical sciences that uses the results of observations and measurements to estimate, in a mathematically well-defined manner, the essential features of probability distributions.

Both statistics and probability theory use certain generic terms for defining the objects or phenomena under study. A system is the object or phenomena under study. It represents the largest unit being considered. A system can refer to a nuclear reactor, corporation, chemical process, mechanical device, biological mechanism, society, economy, or any other conceivable object that is under study. The output or response of a system is a result that can be measured quantitatively or enumerated. The temperature of a nuclear reactor, the profit of a corporation, yield of a chemical process, torque of a motor, life span of an organism, and the inflation rate of an economy are all examples of system outputs. A model is a mathematical idealization that is used as an approximation to represent the output of a system. Models can be quite simple or highly complex; they can be expressed in terms of a single variable, many variables, or sets of nonlinear integro-differential equations. Regardless of its complexity, the model is an idealization of the system, so it cannot be exact; usually, the more complex the system is the less exact

the model becomes, particularly because the ability to solve exactly the highly complex mathematical expressions diminishes with increasing complexity. The dilemma facing the analyst is: the more the model is simplified, the easier it is to analyze but the less precise the results.

A statistical model comprises mathematical formulations that express the various outputs of a system in terms of probabilities. Usually, a statistical model is used when the output of the system cannot be expressed as a fixed function of the input variables. Statistical models are particularly useful for representing the behavior of a system based on a limited number of measurements, and for summarizing and/or analyzing a set of data obtained experimentally or numerically.

The group study to be measured or counted, or the conceptual entity for which predictions are to be made, is called *population*. A *parameter* of a model is a quantity that expresses a characteristic of the system; a parameter could be constant or variable. A sample is a subset of the population selected for study. An experiment is a sequence of a limited (or, occasionally, unlimited) number of trials. An event is an outcome of an experiment. The set of all events (i.e., the set that represents all outcomes of an experiment) is called the event space or sample space of the experiment; the respective events are also referred to as sample points.

In order to consider multiple events, the following basic ideas from set theory need to be recalled: if $(\mathcal{E}_1, \mathcal{E}_2, \dots, \mathcal{E}_k)$ denote any k events (sets) in an event space \mathcal{S} , then:

1. The event consisting of all sample points belonging to either \mathcal{E}_1 or \mathcal{E}_2, \dots , or \mathcal{E}_k is called the union of the events $(\mathcal{E}_1, \mathcal{E}_2, \dots, \mathcal{E}_k)$ and is denoted as $\cup_{i=1}^k \mathcal{E}_i$.
2. The event consisting of all sample points belonging to \mathcal{E}_1 and \mathcal{E}_2, \dots , and \mathcal{E}_k is called the intersection of the events $(\mathcal{E}_1, \mathcal{E}_2, \dots, \mathcal{E}_k)$ and is denoted as $\cap_{i=1}^k \mathcal{E}_i$.
3. The null event is the event \emptyset that contains no sample points; \emptyset is also termed the vacuous event, the empty event, i.e., the event that never occurs.
4. The universal event is the same as the entire sample space \mathcal{S} , i.e., it is the set of all sample points in the sample space.
5. If \mathcal{E} is any event, then the complement of \mathcal{E} , denoted as $\bar{\mathcal{E}}$, is the event consisting of all sample points in the sample space \mathcal{S} that do not belong to \mathcal{E} .
6. The event \mathcal{E}_1 is said to be a subevent of \mathcal{E}_2 , denoted as $\mathcal{E}_1 \subset \mathcal{E}_2$, if every sample point of \mathcal{E}_1 is also a sample point of \mathcal{E}_2 . If the relations $\mathcal{E}_2 \subset \mathcal{E}_1$ and $\mathcal{E}_1 \subset \mathcal{E}_2$ hold simultaneously, then \mathcal{E}_2 and \mathcal{E}_1 contain the same sample points, i.e., $\mathcal{E}_1 = \mathcal{E}_2$.
7. The event $\mathcal{E}_1 - \mathcal{E}_2$ is the set of all sample points that belong to \mathcal{E}_1 but not to \mathcal{E}_2 . Equivalently, $\mathcal{E}_1 - \mathcal{E}_2 = \mathcal{E}_1 \cap \bar{\mathcal{E}}_2$.
8. Two events \mathcal{E}_1 and \mathcal{E}_2 are said to be mutually exclusive if their intersection is the null event, i.e., if $\mathcal{E}_1 \cap \mathcal{E}_2 = \emptyset$.

The outcome of experiments and/or observations is described in terms of compound events, consisting of combinations of elementary events. In turn, the combinations of elementary events are analyzed in terms of k -tuples; a k -tuple is a collection of k quantities generated from elementary events in a space \mathcal{S} . If the position of every event in the k -tuple is unimportant, then the respective k -tuple is called unordered; otherwise, the respective k -tuple is called ordered (or an arrangement). Two k -tuples containing the same elementary events are called distinguishable if ordering is considered; otherwise, they are called undistinguishable.

In statistical, nuclear, or particle physics, it is useful to visualize k -tuples in terms of a collection of unique cells, which may or may not be occupied. Then, a k -tuple is equivalent to a k -fold specification of the occupancy of these cells. The k elements occupying these cells may or may not be distinct and multiple occupancy of cells may or may not be allowed. This way, for

example, the basis for the Maxwell–Boltzmann law of classical statistical physics is obtained by calculating the number, Z_{MB} , of ordered k -tuples that can be formed by selecting events (atoms or molecules) with replacements (i.e., the atoms or molecules are “distinguishable!”) from an event set (the classical gas) \mathcal{S} of finite size n ; this yields $Z_{MB} = n^k$. On the other hand, nonclassical particles such as fermions behave like indistinguishable particles that are forbidden (by Pauli’s exclusion principle) to multiply occupy a cell. The corresponding Fermi–Dirac statistics, obtained by calculating the number, Z_{FD} , of unordered k -tuples in which multiple occupancy of available states is forbidden, is given by $Z_{FD} = C_k^n = n!/[k!(n-k)!]$. The bosons are also nonclassical particles (i.e., they too are “indistinguishable”) but, in contradistinction to fermions, bosons favor multiple occupancies of available energy states. Counting, in this case, the total number, Z_{BE} , of unordered k -tuples with replacement and multiple occupancy of cells gives $Z_{BE} = C_k^{n+k-1}$.

When a process operates on an event space such that the individual outcomes of the observations cannot be controlled, the respective process is called a *random process* and the respective events are called *random events*. Although the exact outcome of any single random trial is unpredictable, a sample of random trials of reasonable size is expected to yield a pattern of outcomes. In other words, randomness implies lack of deterministic regularity but existence of statistical regularity. Thus, random phenomena must be distinguished from totally unpredictable phenomena, for which no pattern can be construed, even for exceedingly large samples. Observations of physical phenomena tend to fall somewhere between total unpredictability, at the one extreme, and statistically well-behaved processes, at the other extreme. For this reason, experimentalists must invest a considerable effort to identify and eliminate, as much as possible, statistically unpredictable effects (e.g., malfunctioning equipment), to perform experiments under controlled conditions conducive to generating statistically meaningful results.

The quantitative analysis of statistical models relies on concepts of probability theory. The basic concepts of probability theory can be introduced in several ways, ranging from the intuitive notion of *frequency* of occurrence to the *axiomatic* development initiated by A. Kolmogorov in 1933, including the *subjective inductive reasoning* ideas based on “degree of belief” as originally formulated by Laplace and Bayes. All three of these interpretations of probability are employed in nuclear science and engineering to take advantage of their respective strengths. From a mathematical point of view, however, the concepts of probability theory are optimally introduced by using Kolmogorov’s axiomatic approach, in which probability is postulated in terms of abstract functions operating on well-defined event spaces. This axiomatic approach avoids both the mathematical ambiguities inherent to the concept of relative frequencies and the pitfalls of inadvertently misusing the concept of inductive reasoning.
