The large series designs have been realized since 1978 up to now. Twenty-eight Generation II power units with VVER-1000 have been constructed and are in operation at NPPs.

The accidents at TMI-2 and Chernobyl-4 NPPs have shown that it is necessary to take into consideration the beyond design basis accidents (BDBA) during their design and operation. In 1988 a new V-1000 design was launched (V-392 Project), which focused on safety improvements in response to new requirements of regulatory documents in order to prevent occurrence of BDBAs and to mitigate their consequences in the case that they happened.

The idea was implemented in the RP design of V-392 Project incorporated into NPP-92 design. The main RP equipment of the V-392 design, including the reactor, was implemented in a set of RP V-428 at “Tianwan” NPP. The information on this NPP design was incorporated into the chapter on VVER-1000 reactors. The modifications to V-392 RP design can be found in the design of RP V-412, which are being implemented now at “Kudankulam” NPP. Designs of Units with RP V-392, V-428, and V-412 are referred to Generation III reactors. In both VVER-440 and VVER-1000 sections of the chapter, first, the main design parameters of these reactors are given. Second, the buildings and structures are described that house the reactor plant and auxiliary systems. As a special feature of VVER-440, two power units of this reactor type are incorporated into one main building of the NPP. Further, a tower, being a part of the reactor building with V-213 reactor plant, houses the vacuum-bubbler passive system to reduce pressure in the containment.

Quite comprehensive sections are devoted to the primary circuit systems and equipment. The reactor coolant system, reactor, main circulation pumps, pressurizer, steam generators, and chemical and volume control systems are described. While the VVER-440 reactors dispose of six primary circuit loops, the VVER-1000 has four loops.

Special attention is paid to the core and fuel design. Special features of the VVER-440 core design are the fuel assemblies with housings and control assemblies, which consist of two parts: an absorber part and a fuel follower. When the absorber part is withdrawn from the reactor core, the fuel follower is inserted into the core. In VVER-440, profiled fuel assemblies with Gd_2O_3 burnable absorber are used to decrease the power peaking factor in the core. The control elements for VVER-1000 reactors are of the cluster type, similar to western PWR designs. Typically, 18 absorber rods are placed in a control assembly.

In subsequent sections, the secondary circuit components (Main Steam Line System, Main Feedwater System, Turbine, Generator, and Moisture Separator Reheater) are described. The power units with VVER-440 are equipped with two turbines and generators of 220 MW electrical power and the power units with VVER-1000 have one 1,000-MW-turbine driving one generator.

Further I&C as well as electrical systems are briefly described. The instrumentation and control systems of some of the VVER-440 units have been recently updated. The refurbishments were mainly aimed at the introduction of advanced features for data processing, transmission, and archiving.

In ▶ Sects. 2.2 and ▶ 3.2, the safety philosophy and safety systems of VVER-440 and VVER-1000 are described. The applied concept of safety assurance for power units of Generations II and III is outlined. For the Generation III VVER designs, significant improvements were implemented in accordance with the up-to-date international requirements for NPP safety assurance.

The data on the VVER reactors under construction, operation, and decommissioning are presented in ▶ Sects. 2.3 and ▶ 3.3.

1 Introduction

VVER-type reactor development was started by OKB “GIDROPRESS” in 1955. The first reactor of 210 MW (el.) power was commissioned at Unit I of Novovoronezh NPP (NV NPP) in 1964. A number of basic engineering solutions developed for the first VVER were of original character and most of them became traditional features for subsequent VVER generations. Such solutions included the following:

- A hexagonal grid for the arrangement of fuel assemblies (FAs) in the reactor core and accordingly the shape of fuel assemblies is hexahedral; the fuel rods in fuel assembly are arranged in triangular grid,
- Zirconium–niobium alloy is used as the material for fuel rod claddings,
- Possibility to transport all large-sized equipment by railway to enable a complete manufacturing process under factory conditions,
- High-strength alloyed carbon steel, which is serviceable in high neutron radiation fluxes, is used as the reactor vessel material,
- The bottom part of reactor vessel, which has no nozzles or any other holes, contains the core,
- The reactor vessel is manufactured of solid-forged shells without longitudinal welds,
- CPS (control and protection system) drives, outlets of temperature and power control systems are arranged on the removable upper head unit of the reactor,
- An original design of horizontal type steam generators with a tube sheet in the form of two cylindrical heads,
- Austenitic stainless steel is used as the material of steam generator HX tubes.

The first VVER core had an equivalent diameter of 2.9 m, a height of 2.5 m, and a thermal power output of 760 MW without any special measures being provided in the design for neutron flux equalization. The resultant operation of the core showed that the capabilities of this design specification were still not exhausted. Using this experience, a reactor with a power of 365 MW (el.), which had a similar core size was designed for Novovoronezh NPP, Unit 2. The design considered measures for the equalization of the neutron flux. This Unit was commissioned in 1969.

The first VVER reactors were designed for a service life of 20 years and were decommissioned in 1984 and 1990, respectively.

The development of VVER-440 reactor started simultaneously with the design of Unit 2 of Novovoronezh NPP. It was assumed as the “standard” version for the construction of a number of NPPs with VVER. The core sizes and design were mainly similar to the VVER-365

reactor. The increase in the electrical power output of the units was mainly due to enhancements of the NPP efficiency relating to modifications to parameters associated with the primary coolant and steam, respectively. This was achieved by the application of other power equipment and some changes to the equipment used in reactor coolant system. The first VVER-440 (B-179) reactors were commissioned at Units 3 and 4 of Novovoronezh NPP in 1971 and 1972, respectively.

The second step in development of VVER-440 type reactors was the V-230 design, where the number of mechanical control rods was reduced from 73 to 37 due to introduction of boron as a moderator. From 1973 to 1982, in all 14 Units were constructed with the V-230 design.

Reactors V-179 and V-230 are referred to as the first generation of the standard VVER-440 reactors. The specifications of these plants provide a high quality of pipelines, equipment, and other reactor plant components that allowed the prevention of significant damage and thus the avoidance of the possibility of breaks in the large diameter primary pipelines. Accordingly, the safety systems of the reactors were designed for a limited size of leak in the primary circuit.

The third step in VVER-440 development was V-213 reactor design referred to as the second generation of the standard VVER-440 reactors; their design basis included a double-ended instantaneous guillotine break of the maximum diameter primary pipeline. The first two Units of this series were constructed at NPP “Loviisa” in Finland in 1977 and 1980, respectively. The containment of these Units presented a shell with ice condensers. The original vacuum-relief system where the building is directly connected to a sealed box of the reactor coolant system is used at other NPPs with V-213 reactor. At present, 16 of such Units are in operation.

The development of VVER-1000 reactors by OKB Gidropress was started in 1966. The first reactor with an electrical power of 1,000 MW (V-187 Project) was commissioned at Novovoronezh NPP Unit 5 in 1980. In the design, the traditional engineering solutions of VVER (see ► Chap. 1.4.A) were used with the appropriate modernization from the experience obtained in the design, manufacture, and operation of the VVER prototypes. The design concept was oriented to an increase in economic efficiency of the NPP construction and operation ensuring safety in accordance with the regulatory documents that were valid at the time. An instantaneous double-ended guillotine break of the main coolant pipeline was considered as the maximum design basis accident, similar to Project V-213. The reactor plant was placed into a containment of prestressed concrete.

Further design modifications resulted in the development of V-302 Reactor Plant, which was implemented at the South-Ukraine NPP, Unit 1, and the V-338 Reactor Plant was implemented at the South-Ukraine NPP, Unit 2, and Kalinin NPP, Units 1 and 2. The development of these projects was classified as “small series” designs and their realization took place between 1976 and 1987.

Since 1985, all Units operated with VVER-1000 have been constructed to a standard design. This included the standard V-320 reactor plant, which could be sited in seismic areas with earthquakes of up to magnitude 9 (SSE), and the standard modernized reactors constructed with the “small series” modifications. The design comprised D_{nom} 850 circulation loops without gate valves; “wet” reloading of internals, horizontal steam generators of Unit 5 of NV NPP; reactor coolant pumps GCN-195M (“large series”).

The main feature of the modernized standard VVER-1000 reactor is the application of jacket-free fuel assemblies with an increase in their number from 151 pieces to 163 pieces. There was also a decrease in the number of control rods from 109 pieces to 61 pieces (to 49 pcs. at South-Ukraine NPP, Unit 1) with CPS pitch electromagnetic drives applied to the control rods.

The “large series” designs have been realized since 1978. On the whole, 28 Units with VVER-1000 reactors have been constructed and they are currently in operation at NPPs. All these Units are referred to as VVER of Generation II.

The accidents at TMI-2 and Chernobyl-4 NPPs have shown that it is necessary to take into consideration the beyond design basis accidents (BDBAs) during their design and operation. This is despite the low probability of such accidents. Appropriate requirements were introduced into the new revisions of the regulatory documents on NPP safety assurance.

In 1988, a new V-1000 design was launched (V-392 Project), which focused on safety improvements in response to new requirements of regulatory documents in order to prevent occurrence of BDBAs and to mitigate their consequences in case they happened.

The idea that was implemented in V-392 Project and incorporated into NPP-92 design was given a EUR certificate. The design modification provided for an engineering embodiment of the safety systems andbdba management systems that conceptually differ through the different ratios of passive and active systems, which are applied for accident management.

The main RP equipment of the V-392 design, including the reactor, is now implemented in a set of RP V-428 at “Tianwan” NPP. Information on this NPP design is incorporated into the chapter on VVER-1000 reactors. The latest modifications to V-392 RP design can be found in the design of RP V-412, which are being implemented now at “Kudankulam” NPP. Units 1 and 2 of “Tianwan” NPP were constructed and commissioned in 2007.

Designs of Units with RP V-392, V-428, and V-412 are referred to as Generation III reactors. Data on the VVER reactors under construction, operation, and decommissioning are presented in [▶ Sects. 2.3](#) and [▶ 3.3](#).

2 VVER-440 Reactors

2.1 Design Description

2.1.1 Buildings and Structures

Reactor Building

Two power units of the type VVER-440 are incorporated into the main building of the NPP. The layout of the reactor compartment contains power units, which are reflected through the general transport corridor (➤ [Figs. 1](#) and ➤ [2](#); ➤ [Table 1](#)).

The main NPP building comprises of the reactor compartment, which includes a system of sealed rooms containing both power units, the turbine hall, a longitudinal stack of electric devices with forced ventilation equipment, two transverse stacks of electrotechnical devices, a stack of special ventilation, and two underground emergency boron inventory tanks. The main building is connected with an auxiliary building by a covered trestle. The trestle is adjoined to the reinforced-concrete ventilation duct of 120 m height. The total length of the reactor compartment comprising two Units with common facilities is 126 m (➤ [Fig. 3](#)).

All rooms of the main building are separated into two categories: restricted and free access areas according to radiation exposure standards. The rooms of reactor compartment, ventilation stack, and boron emergency inventory tank are defined as restricted areas. The turbine hall, the longitudinal and transverse stacks of electrotechnical devices are the free access areas. The reactor compartment includes the systems of sealed rooms in which both units are contained and between which common-unit rooms are located.

The attended reactor hall is common for both power units. The fresh fuel unit, the spent fuel pool, reactor units unloading, and inspection locations with other equipment for each unit are located in the reactor hall. The spent fuel and handling pool is not included in the system of sealed rooms. However, the outer walls of the pool and bottom floor including the facing on the side of SG box are included in the set of enclosure structures of the sealed rooms. The reactor hall is connected to the transport corridor via the system of removable floors.

The system of sealed rooms of a single unit includes the steam generators box, the reactor concrete cavity, the reactor coolant pump (RCP) and main gate valve(MGV) drives room, the inventory tank of emergency boron solution, and other rooms.

The base with rails for the fuel-handling machine is arranged above the upper part of the reactor concrete cavity and spent fuel pool. The fuel-handling machine is used for both reactor units. Equipment is transferred with the use of traveling cranes that is also common to both reactor units.

A VVER-440 reactor and the associated primary equipment are arranged in each set of sealed rooms in the reactor compartment. The sealed rooms are formed by airtight reinforced-concrete walls with a thickness of 1,500 mm, which are sealed by the covering of metal sheets. A protective bonnet hermetically seals reactor concrete cavity from the reactor hall. The upper part of the reactor unit protrudes into the reactor hall.

The equipment is mounted in the reactor concrete cavity that is intended for biological shielding against core radiation, reactor safe fastening, and thermal insulation. The concrete cavity is separated into top and bottom parts by an annular console. The upper part is connected with spent fuel pool by the transport corridor and is flooded with water during refueling. The upper part of the concrete cavity is isolated from the lower part by concrete truss with

metal bellows. The refueling transport corridor is sealed with a special partition during reactor operation.

In a V-230 reactor plant (Fig. 4), an annular tank filled with water is used as a reactor vessel support and for the radiation protection of external structures. The tank water volume is 90 m^3 ; the annular thickness is about 1 m. Cooling of the lower part of the concrete cavity and the annular tank is provided with an airflow rate of $50,000 \text{ m}^3/\text{h}$.

As the containment of RP V-230 in the building of the two units arrangement was not designed for the pressure experienced under maximum design basis accident ($D_{\text{nom}} 500$ break), a system of depressurization was introduced into the containment for V-213 reactor plants. This

■ **Figure 5**
Containment of V-213 reactor plant

comprises of an active sprinkler system and passive vacuum–relief system. The vacuum–relief system is located in a special tower for pressure relief (► [Fig. 5](#)).

The V-213 reactor vessel support is a supporting truss, which was designed for the loading conditions it would have received under a break of D_{nom} 500 pipeline. External structural protection against core radiation is provided by the dry shielding made in the form of circular metalwork filled with serpentine concrete.

Unlike the V-230 reactor plant, ducts are provided for emergency steam discharge from the upper part of the reactor concrete cavity into SG box. Gaps can be enlarged in the thermal insulation for performing inspections of the reactor vessel. These gaps are located at the nozzle, the vessel bottom, and the lower part of the vessel (► [Fig. 6](#)).

Pressure Relief Tower

The vacuum–relief system comprises of a relief tank and catching chambers arranged in an independent construction (i.e., the pressure relief tower). The tower dimensions are 39×21.5 m² with a height of 41.9 m. The tower is connected with the sealed rooms of reactor compartment with a channel of cross section 11.5×6.2 m and length of 15 m. The tower with sealed rooms presents a compact closed structure.

The pressure relief tower is a reinforced-concrete structure with a wall and ceiling thickness of 1,500 mm. The tower is separated by a wall axially into the relief tank room, which is 39×8.55 m² and rooms of four catching chambers with dimensions of 39×11.45 m².

The relief tank room has a total volume of 13,970 m³ and the total volume of the catching chambers is 16,465 m³. The inner walls of the relief tank are covered with metal sheets fixed

■ Figure 6

Reactor plant V-213. 1 – Protective bonnet, 2 – Steam emergency discharge ducts, 3 – Reactor, 4 – Nozzle area thermal insulation, 5 – Supporting truss, 6 – Dry shielding

■ Figure 7

Vacuum-relief operating pattern

on structural reinforcement. All inner walls, ceilings, and floors of catching chambers are also covered with metal sheets providing maximum impermeability of the structure.

The vacuum-relief system (☉ Fig. 7) is a passive system of pressure relief in the containment area, which works in coordination with the sprinkler system when accidents with large leaks of primary and secondary coolant into the containment ensue. Under accident situations, which originate in the SG box, the pressure increase in the vacuum-relief system provides for the following:

- The containment pressure relief by steam condensation in bubbling chutes,
- Localization of non-condensable gases in catching chambers,
- Capture of radioactive fission materials in bubbling chutes.

The system dimensions were selected for the suppression of the pressure increase that could occur under maximum design basis event. This was determined to be a double-ended break with primary coolant leak through two cross sections of D_{nom} 500 mm into the sealed rooms. Such a passive operation system should provide the capability to withstand dynamic impacts of jets of steam-water mixtures. It must absorb a considerable portion of the thermal energy that is released by the break. The associated pressure increase must also be automatically decreased. The intention of the system is to prevent the loss of leak-tightness of the sealed room and, consequently, reduce the possibility of a release of radioactive materials outside the containment with any deterioration of radiation situation.

The vacuum-relief system must be in a state of permanent readiness for operation (i.e., bubbling chutes should be filled with boric acid solution) during NPP normal operation.

The load-bearing structure for placing the inventory of water required for steam condensation and for supporting 12 floors of bubbling chutes is installed in the relief tank building. Each relief tank floor has one independent outlet of air and non-condensable gases into the capture chamber via double check valve (D_{nom} 500) that is equipped with a guiding inlet nozzle on the side of relief tank. There is one common capture chamber for every three adjacent floors of the relief tank.

The space above the chutes is also connected with the relief tank cavity by two relief valves ($D_{\text{nom}} 250$) that remain in a closed position when the pressure in the relief tank cavity exceeds 165 kPa. When the pressure decreases below this value, the valves are unlocked and pressure above the chutes level is equalized with the pressure in the relief tank cavity.

Auxiliary Building

The auxiliary building is intended for arrangement of the equipment for the preparation, cleaning, and treatment of the water used in the reactor coolant and interrelated systems and for radioactive waste storage. The building is divided into two parts: specific water treatment and radioactive waste storage. The building size is 102×36 m. The building is a rigid box-shaped structure of solid reinforced concrete from the base plate to the ceiling top.

The tanks for the storage of radioactive liquids are made in the form of metal tanks installed in the rooms with enclosure structures of solid reinforced concrete with metal facings. This approach uses the principle “tank in tank” with the purpose of monitoring occasional leaks of the main tank and preventing ingress of radioactive liquids into concrete. The thickness of walls and ceilings is determined to satisfy the requirements of biological shielding.

The auxiliary building is connected to the main building by a two-tier trestle. An air duct connects the upper tier of the auxiliary building to the ventilation channel at an elevation of +10.500 m. Trestle lower tier is separated into “clean” and “contaminated” areas. The “clean” area is intended to provide for access of operators into the auxiliary building. The pipeline is a connection between main and special buildings, which is provided via “contaminated” area. The thickness of structures in this trestle part is governed by the requirements of biological shielding.

Turbine Building

The turbine hall is referred to as a nonrestricted access area of the main building. The length of turbine hall for two reactor units is 246 m. The span of the turbine hall is 39 m. The turbine hall is equipped with three bridge electrical cranes of load carrying capacity 125/20 t each, with a span of 36.5 m.

The longitudinal stack of electrotechnical devices, above which the secondary pipelines (steam lines, feedwater lines) are arranged, is located between the reactor and the turbine hall.

The turbine generators are oriented axially along the length of the turbine hall.

2.1.2 Systems of the Primary Circuit

Reactor Coolant System

Under normal operating conditions both V-230 and V-213 reactor types are cooled by six circulation loops of the main coolant pipeline (MCP). The pipelines are located in an airtight compartment around reactor concrete cavity. Each circulation loop is welded to the inlet and outlet nozzles of reactor vessel. The pipelines contain a reactor coolant pump (RCP) and a steam generator connected by $D_{\text{nom}} 500$ pipelines. The pipelines are made of stainless steel (08Kh18N19T).

➤ *Figure 8* above shows the circulation loop with the pressurizer to be attached; the other loops are of similar size and layout.

■ **Figure 8**
Circulation loop 1 of reactor V-213

The cold and hot legs of the circulation loops are equipped with main gate valves (MGVs) (► Fig. 9) to isolate the loop from the circulation circuit or to limit the reverse flow of coolant in the case of a tripped RCP.

The time required for the opening and closure of an MGv is as follows:

- Manual – 280 s,
- Automatic – 80 s.

Coolant inventory in the hot leg is 2.75 m^3 . Coolant inventory in the cold leg (without RCP) is 3.25 m^3 .

In VVER-440 reactors, all the line-to-MCP joints are equipped with primary leak restriction devices in case of pipeline breaks.

Reactor Vessel and Internals

The VVER-440 reactor vessel design is based on meeting the following requirements:

- Proven materials and structures,
- Complete manufacture of the vessel with workshop testing included,
- Possibility of vessel transport by railway,
- Possibility of vessel in-service inspection.

The vessel is made of heat-resistant chromium–molybdenum steel of Grade 15Kh2MFA. The steel and the welding materials were chosen from the results of numerous analyses of mechanical properties, the absence of susceptibility to brittle fracture, the absence of thermal embrittlement, durability, and irradiation resistance. The steel was proven in manufacturing and it has been used in the fabrication of all VVER-440 reactor vessels.

The upper cylindrical part of V-230 reactor vessel has 6 inlet and 6 outlet D_{nom} 500 nozzles for coolant to flow and one D_{nom} 100 nozzle for pressure-measurement pulse tubes and level gauge. The D_{nom} 500 nozzles are located in two rows away from the area of maximum neutron irradiation.

Four D_{nom} 250 nozzles were additionally included in the design for the V-213 reactor vessel for the application of the emergency core cooling system (ECCS). Two nozzles of this diameter are placed in each row of D_{nom} 500 nozzles.

■ Figure 9
Main gate valve

There is an annular shoulder on the internal surface of the vessel, which is located between the rows of nozzles that separate the inlet and outlet coolant flows. The shoulder allows the alignment of the core barrel with respect to the vessel. Corrosion-resistant cladding of internal surface was only applied to the area of vessel-to-top head joint in the first V-230 reactor vessels (6 vessels). All other vessels were covered with corrosion-resistant cladding all over the internal surface.

The support shoulder on the external surface of the vessel is below the lower row of the nozzles and it serves as the flange upon which the vessel is installed on the support ring that is fastened to the support structure in the concrete cavity.

The reactor vessel and top head are sealed through a pressure ring with 60 M140 studs. The vessel-to-top head joint is sealed with two nickel-wire gaskets, which are 5 mm in diameter. Spherical top head of reactor vessel is part of the upper unit. Thirty seven housings for ERC (emergency reactor control) drives are installed on the top head as well as the nozzles for temperature monitoring sensor and neutron flux measuring channel installation and associated seals. ERC drive cooling systems and systems for air removal at reactor filling up are also mounted on the top head.

Electrical-mechanical ERC drives of rack-and-pinion type are used in VVER-440 reactors. In the drive, the rotational motion of electric motor rotor is converted with a reducer into the translational motion of the rack. The ERC drives of V-230 reactor are equipped with the electric motor installed down and induction linear position indicator. The ERC drive for VVER-213 reactors is equipped with a low-speed electric motor placed in the upper position and linear position indicator installed on the electric motor flange. The design has simplified the kinematic diagram of the drive and the drive-to-ERC assembly engagement and disengagement procedures. Both drives provide the normal motion of the ERC assembly at a velocity of 20 mm/s and an emergency drop rate of the rack with FA of 200–300 mm/s. The time required to accelerate the rack to a velocity of 200 mm/s after the drive de-energization at a scram does not exceed 0.7 s.

The reactor internals comprise the following:

- Reactor core barrel with the bottom that defines coolant flow arrangement inside reactor and supports,
- The basket that houses the core,
- A protective tube unit (PTU) that serves to fix the fuel assemblies in the core and protect the extension shafts, drives, and ERC fuel assemblies from the action of the coolant flow.

The design of internals and their mutual and in-pile fastening make it possible to extract all the units to examine the internal surface and vessel metal inspection. The material for all the internals is stainless steel Grade 0Kh18N10T.

The separation area for inlet and outlet coolant flow is sealed due to the difference between the temperature expansion of stainless steel and carbon steel vessel. The upper part of the core barrel between the flange and flow separator has many perforations for the coolant velocity field leveling upstream of reactor vessel outlet nozzles. The lower part of the core barrel is aligned and fastened to reactor vessel with eight keys fixed to the vessel. Unlike the V-230 reactor, the V-213 core barrel is provided with channels to install reactor vessel metal surveillance specimens.

The core barrel bottom contains the top and bottom grids linked with a shell and 37 tubes to install the ERC assemblies. Hydraulic snubbers reduce the impact of the dropping fuel assemblies. Unlike the V-230 reactor, the core barrel of V-213 reactor has an elliptical perforated bottom that levels coolant flow profiles as it turns out of the downcomer.  *Figure 10* illustrates the observed structures of coolant flow in reactor lower plenum. The images were obtained with the hydrodynamic model without the elliptic bottom (top) and with the elliptic bottom (bottom). In the flat bottom design, major vortices arise at the inlet to the core bottom, which lead to unsteady coolant flow. The perforated elliptic bottom eliminates these vortices and equalizes the coolant velocities over the core radius. The elliptical bottom also reduces the effect of the vibration load on the structure.

■ **Figure 10**
Picture of coolant flow in the reactor lower plenum

A removable basket is installed on the core barrel bottom to house the core fuel assemblies. The lower plate of the basket has perforations to install the working assemblies and hexahedral openings for ERC assemblies to pass. A faceted belt with a core baffle over the entire height of working assemblies is welded over the core perimeter on the internal surface of the basket.

A protective tube unit is installed on the faceted belt of the basket and it is pressed with reactor upper unit through the spring units placed in the upper unit top part. Housings for coolant temperature monitoring thermocouples at the working assembly outlets and the axial channels, which are used in the measurement of core power, are routed among the protective tubes. There are 12 channels of this type in V-230 reactor and their number is increased to 36 in V-213 reactor. All the housings and channels are assembled and fastened in bundles that have sealed outlets. They are located in the corresponding nozzles of reactor top head unit.

Reactor Core

The VVER-440 reactor core (🔍 [Fig. 11](#)) contains 349 fuel assemblies, of which 312 are working assemblies (WAs) (➤ [Fig. 12](#)), and 🔍 37 are ERC assemblies (➤ [Fig. 13](#)).

Figure 11
 Reactor core arrangement. 1 – Vessel, 2 – Fixing of Core Barrel, 3 – Core barrel, 4 – Basket, 5 – ERC assembly, 6 – Working assembly

An ERC assembly is the actuating component of reactor control and protection system. The ERC assembly performs the following main functions:

- Ensures a quick termination of chain fission reaction by quick insertion of a neutron absorber into the core with a simultaneous withdrawal of assembly fuel-containing portion out of the core,
- Participates in automatic control of maintaining reactor power at the assigned level and its changeover from level to level,
- Compensates for quick reactivity changes (temperature, power effects, poisoning, etc.).

The WA and ERC are positioned in a hexagonal grid with a spacing of 147 mm.

All the fuel assemblies are hexahedral and the fuel rods are placed in the assembly in a triangular grid pattern. The fuel rod bundle of the assembly is enclosed in a hexahedral jacket with the width across the flats equal to 144 mm.

As the core is assembled, the working assemblies are installed into the holes in reactor basket plates. The ERC fuel assemblies pass through the hexahedral holes of the basket and they are installed in protective tubes at the core barrel bottom.

The ERC assemblies are divided into six groups. In the working position, the first five groups of six assemblies are withdrawn to the outermost upper level and are used to perform the scram function. The sixth group containing seven assemblies is left in an intermediate position and is used to control the reactor power. The time an ERC assembly takes to drop from the upper position is from 8 to 13 s.

■ Figure 12

Working assembly. 1 – Top nozzle, 2 – Upper grid, 3 – Fuel rod, 4 – Spacer grid, 5 – Jacket, 6 – Lower grid, 7 – Bottom nozzle

The working assembly contains a top nozzle, a bottom nozzle, jacketed tube, and fuel rod bundle. The top nozzle has fingers for fuel handling via machine grips and spring-loaded dowels that keep the working assembly from lifting up and therefore compensate for the effects of thermal expansion and the process tolerances of reactor internals. The working assembly is installed into the basket bottom seat with the bottom nozzle, which is a spherical surface that is supported by a seat cone.

The fuel rods are located in the bundle in a triangular grid pattern with a pitch of 12.2 mm. Spacer grids of the cell type are mechanically fastened onto the central tube and the fuel rods are slotted into the gaps in the grid. The lower support grid is welded to the bottom nozzle. The upper spacer grid has a wide rim in order to center the bundle in the top part of the tube jacket. The protrusions are specially intended for this purpose in the hexahedral tube. It eliminates the effect of upper grid deformation in case of nonuniform fuel rod radiation growth in the bundle.

The fuel rod claddings and spacer grids are made of the E110 zirconium alloy (Zr + 1% Nb), while the jacket tubes of the WA and FA are made of the E125 zirconium alloy (Zr + 2.5% Nb).

■ **Figure 13**
ERC assembly. 1 – Absorber follower, 2 – Fuel assembly

The ERC assembly consists of two parts: an absorber follower and a fuel assembly. The ERC assembly is moved with the ERC drive via the intermediate rod engaged with the gripping device located at the FA top nozzle. The intermediate rod passes through the alignment sleeves of the follower, which is installed on the FA top nozzle. The intermediate rod-to-FA top nozzle engagement is of a bayonet type, which interlocks to prevent rotation and disengagement.

The design and fastening of the fuel rod bundle in the FA found in the ERC assembly are the same as those of the working assembly. There is a thimble in the FA bottom nozzle that together with the dowel in the core barrel protective bottom provides the hydraulic damping of the assembly in case it drops in an intermediate rod break accident.

Hafnium plates are placed on the inside surface of the top part of the jacket tube to limit power ramps in the working assembly fuel rods that surround the ERC working group when it is located in an intermediate position along the core axis.

The absorber follower is a welded hexahedral stainless steel structure that houses hexahedral insertions of boronized steel. The insertion is a hexahedral tube 7.1 mm thick and 102 mm high with the width across the flats equal to 137 mm. The boronized steel insertions are based on chromium–nickel stainless steel with 1.6–2.0% of natural boron added to the mass.

■ **Figure 14**
Fuel pellet

Each fuel rod is a cylindrical shell plugged on the edges with Thomson welding. The outside diameter of cladding is 9.1 mm, the inside diameter is 7.73 mm. The cladding houses a fuel column assembled of uranium dioxide pellets. The fuel column is fixed with a spring-type lock, which protects the fuel pellets (➤ [Fig. 14](#)) from displacement during transportation and installation.

The rods are filled with helium at a pressure of 0.5–0.7 MPa. The fuel pellet density is 10.4–10.7 g/cm³. The total length of each fuel rod is 2,536 mm.

The operating experience of VVER-440 reactor cores has shown that the neutron–physical and thermal–hydraulic characteristics are such that the actual (calculated and measured) power peaking factors of assemblies and fuel rods are, as a rule, less than the design values. The design of Generation II fuel assemblies was developed to improve the efficiency of operation that possesses the following features:

- The number of fuel pellets inside the fuel rod was increased,
- The water–uranium ratio was optimized due to an increase in the pitch of fuel rod location in the bundle from 12.2 to 12.3 mm,
- Harmful neutron absorbance was reduced by reductions of the hafnium content of the zirconium cladding from 0.05 to 0.01%,
- FA jacket thickness in the ERC assembly (➤ [Fig. 15](#)) was reduced to 1.5 mm.

A decrease in the power peaking factor in the core is reached by the use of profiled fuel assemblies. A Gd₂O₃ absorber is integrated with a content of 3.35% into a number of fuel assemblies to aid fuel profiling.

The development of the Generation II fuel assemblies enables the switch over to a new fuel cycle with fuel assemblies capable of operating for 5 years. The fuel rod bundles in the assemblies used over the fuel cycle are composed of 120 rods of which 6 fuel rods contain Gadolinium that give the profiled enrichment. The average enrichment of a WA fuel bundle is 4.25% (➤ [Fig. 16](#)). The average enrichment of an ERC assembly fuel bundle is 3.84% (➤ [Fig. 17](#)).

A parallel task was to increase the vibration resistance of the fuel assembly. The introduction of the method of fuel rod installation in the support grid with an elastic tip and the change in the unit of jacket-to-bottom nozzle fastening in the WA provides a possibility to disassemble the fuel assembly of the given design.

■ Figure 15
Dimensions of ERC assembly fuel rod (up) and working assembly (down)

■ Figure 16
Profiling diagram for fuel rod bundle of 4.25% average enrichment

The results of the trial operation of the new fuel show that the operational limits of the standard fuel are not exceeded at its introduction, which corroborates the compatibility of the new and standard fuel.

Another step in the development of the Generation II fuel is a transfer to a higher fuel enrichment in the WA and FA. It is here that the application of the Generation III fuel rods differs in principle from Generation II fuel rods, which is most promising. The Generation III fuel rods allow an increased fuel loading by removing the centerline hole in the fuel pellet and increasing the pellet diameter.

An alternative option for the development of fuel for VVER-440 NPP is the creation and introduction of Generation III fuel assemblies (➤ Fig. 18) that use an angled skeleton instead of hexahedral jacket.

Reactor Coolant Pump

Reactor plants of the V-230 type are featured with centrifugal one-stage vertical pumps of the packless type with an integrated electric drive of type GCN-310. The pumps (RCP) (Fig. 19) are used in the primary coolant circuit. Such leakproof pumps have been proved to be highly reliable with no leaks of radioactive primary water and they are simple in operation. Disadvantages of these pumps include low efficiency due to the high electromagnetic losses on sealing metal partition of electric motor and a small inertia coastdown in the case of the loss of power. Note that with reactor plants of the type V-230, the coastdown of four RCPs in case of loss of power together with coastdown of the turbine generators, power supply to these RCPs is provided by the terminals of the station service generator located on one shaft with the main generator (Tables 2 and 3).

Reactor plant V-213 is featured with pumps of GCN-317 (Fig. 20) having mechanical sealing of the shaft, equipped with flywheels. The pump of GCN-317 is equipped with antireversing mechanism.

Pressurizer

VVER-440 reactor plants are provided with steam pressurizers. The pressurizer is connected to a non-isolated part of the hot leg of one of the primary recirculation loops. Controlled injections of coolant are provided into the pressurizer steam space from a non-isolated part of cold leg of

■ Figure 19

the same loop. The electric heaters for generating steam pressure are arranged in the lower part of the pressurizer.

The internal volume of the pressurizer on a V-230 reactor plant is 38 m³ of which 18 m³ is occupied by steam under nominal conditions. Electric heaters are organized into two start-up groups with a power of 540 kW each, two operating groups with a power of 90 kW each, and two control groups with a power of 45 kW each.

■ **Figure 20**
GCN-317

The internal volume of the pressurizer is larger on a V-213 reactor plant with a volume of 44 m³, while the steam volume is smaller with 16 m³ under nominal conditions. Electric heaters are broken down into five groups: two groups with a power of 180 kW each, two groups with power of a 360 kW, and one group with a power of 540 kW.

The pressurizer is equipped with two pilot-operated relief valves with the main purpose of providing overpressure protection in the primary circuit. Some pressurizers of the V-213 reactor plants have one more relief valve in addition to the safety valves that also serve as an overpressure protection for the reactor vessel when it is in a cold state.

Steam dumping from safety devices is provided into a dedicated relief tank whose total volume amounts to 15 m³, of which a volume of 11 m³ is water. The water inventory is cooled by an intermediate circuit that provides an operational temperature within the range of 25–50 °C.

Steam Generator

The basic structural feature of VVER steam generators (Fig. 21) is the horizontal arrangement of the cylindrical vessel, the submerged heating tube bundle, the cylindrical vertical collectors of the tubes, natural circulation of the boiler water, and an integrated steam separation system.

Tube bundle consists of 5,146 stainless tubes with the outer diameter of 16 mm and wall thickness of 1.4 mm. The entire heat exchange surface is equal to 2,570 m².

The important advantage of horizontal steam generators is that there is a large water inventory in the secondary circuit. This large water volume provides favorable inertial characteristics for the whole of the reactor plant under transient and accident processes, thereby essentially enhancing its safety (Table 4).

Chemical and Volume Control System

The chemical and volume control system is intended for

- Compensation of the identified and non-identified leaks from the primary circuit;
- Compensation of reactivity changes by supply of boric concentrate or pure condensate into the primary circuit;
- Arranging the primary coolant cleaning;
- Filling, draining, and hydrotests of the primary circuit;

- Pressurizer level maintenance under reactor power variation;
- Pressurizer cooling down.

Operational reliability of the system is ensured by twofold redundancy of the equipment for deaeration and cooling of makeup water, equipment for blowdown and pipeline routes.

The basic technical data of the chemical and volume control system for a V-213 reactor plant is

Makeup pump	
Maximum flowrate	60 m ³ /h
Suction pressure, nominal	0.67–0.70 MPa
Pressure head, max	14.7 MPa
Blowdown pump	
Flowrate	50 m ³ /h
Maximum permissible suction pressure	1 MPa
Pressure head	0.6 MPa

2.1.3 Systems of the Secondary Circuit

Main Steam Line System

The main steam line system comprises of six steam lines with dimensions of $\phi 456 \times 16$ mm. The steam is transported through the steam lines from six steam generators of the primary system to the main steam header (MSH), which has dimensions of $\phi 521 \times 16$ mm and operates with a maximum pressure of 4.4 MPa. The steam lines from the odd numbered steam generators are connected to one half of MSH, while steam lines from the even numbered steam generators are attached to the other half of MSH. The steam lines from 1, 3 and 2, 4 steam generators are extended as supply pipelines of dimensions $\phi 521 \times 16$ mm to the stop and control gate valve units of two turbine generators.

Each steam line of the relevant steam generator is equipped with pilot-operated relief valves that act against excessive pressure. Thus, in the case of a pressure increase above the permissible limit, steam is dumped to the atmosphere via a common discharge pipeline, which has outlets on the building roof.

The SG steam lines are furnished with quick-acting valves that are controlled by high-pressure air. The main steam gate valves with bypasses are initiated when it is necessary to disconnect the relevant steam generator from MSH.

The main steam header is separated with three quick-acting isolation valves, which are controlled by high-pressure air. Each half of MSH is arranged with one steam dump valve to atmosphere (BRU-A) via a discharge pipeline of dimensions $\phi 530 \times 8$ mm, where the outlets are located on the building roof. Note that the BRU-A of the last units built of the V-213 type are placed on each SG steam line near to the safety valves.

The main steam headers of the neighboring units are isolated from each other by electric gate valves.

Main Feedwater System

The main feedwater system consists of five feedwater pumps (FWPs) with connecting pipelines. Four pumps meet the full power of the reactor unit; the fifth pump provides backup cover. The feedwater inventory is stored in two feedwater tanks per reactor unit. The feedwater is transferred from each tank via a $\phi 630 \times 8$ mm pipeline into the suction collector, which is separated into two halves by two electric valves. Collector has a $\phi 426 \times 8$ mm branch for each FWP.

The discharge pipelines are connected to the common discharge collector, which has dimensions of $\phi 457 \times 20$. All FWPs have a minimum bypass that provides safe operation of the FWP when there is a reduction in the amount of feedwater fed or when an FWP is operated with a closed valve. The feedwater is transferred from discharge collector for high-pressure regeneration of both TGs. After heating, it flows to the main feedwater collector, which has dimensions of $\phi 457 \times 20$ mm.

The feedwater is supplied from the main feedwater collector to the steam generators via D_{nom} 250 pipelines through six big control valves or via D_{nom} 100 pipelines through six small control valves. There are quick-acting valves and check valves between the valves and the SG. The control valves are used to maintain a constant level in the SG under different operating conditions.

Basic performances of feedwater pump	
Operational range of flowrate	150–900 t/h
Suction pressure	0.84 MPa
Pressure head	6.6 MPa
Pump rotational speed	2,975 rpm

Turbine

Each VVER-440 Unit has two turbine plants. Each turbine plant includes a turbine, a condenser, regeneration system, separator–superheaters, and other auxiliary equipment.

A K-220-44-3 type steam turbine is a single-shaft three-cylinder set involving a high-pressure cylinder (HPC) and two low-pressure two-flow cylinders (LPCs) with four steam outlets in two condensers. Between the HPC and the LPC, there are separator–superheaters, wherein a two-stage steam superheating occurs.

The turbine operates with dry saturated steam at a pressure of 4.3 MPa upstream of the stop valves and there are eight noncontrolled steam outlets intended for feedwater heating and for other NPP auxiliaries.

Basic performance of the steam turbine	
Nominal power, on generator terminals	220 MW
Nominal steam flowrate	1,322 t/h
Nominal steam pressure upstream of StV	4.3 MPa
Pressure at HPC outlet	0.4 MPa
Nominal steam pressure upstream of LPC valves	0.37 MPa
Nominal steam temperature upstream of LPC valves	216.5 °C
Nominal revolutions	3,000 rpm

Generator

The output of the electric generators is 220 MW as alternating current. The generators have an end face design where the bearings are located in the stator faces. It has a combined cooling system with hydrogen and water used as the coolants. The rotor of the generator is connected to the rotor of low-pressure cylinder of the steam turbine with a rigid coupling. The stator has internal and external frames, due to access required for mounting and repair.

The cooling water is applied to stator winding while hydrogen coolant is used in the other parts of the generator. The stator winding is directly cooled by condensate from the turbine circuit. Some conductors are made in the form of copper rectangular tubes where cooling water is transferred.

The parts other than the stator winding, which are cooled by pressurized hydrogen, include a rotor, stator metal, and frontal parts of the stator. The rotor winding is made from hollow conductors, where hydrogen is fed into conductors and released into the gas gap in the middle part of the device. The stator metal is cooled by an axial hydrogen flow. The condensate flows via hydrogen cooler.

Basic performances of generator	
Nominal active power	220,000 kW
Nominal $\cos \varphi$	0.85
Nominal voltage	$15,750 \pm 5\% V$
Nominal phase current of stator	9,500 A
Nominal frequency	50 Hz
Maximum hydrogen temperature	40 °C
Condensate flowrate for hydrogen coolant	250 m ³ /h
Condensate flowrate for stator winding cooling	120 m ³ /h

Moisture Separator–Reheater

The moisture separator–reheater (MSR) is intended to remove moisture and to reheat the incoming steam from the high-pressure cylinder of the turbine. Each MSR consists of two vertical vessels with 3.4 m diameter and 14 m height that are connected in parallel to heating and heated steam. The main components of the separator are corrugated stainless steel plates with a thickness of 1 mm. The plates are arranged in the upper part of vessel.

The heating is performed over two stages. The first stage is heated by steam from the seventh outlet and the second stage is heated from the eighth outlet. Both stages of the heater are made from steel tubes with longitudinal ribs welded-on. The heating is driven by the condensation of steam on the inside of the tubes.

The separated moisture is bled into low-pressure heater. The steam condensate from the hot side of the first stage is transferred into the feed tank and the steam condensate from the hot side of the second stage is passed to the feedwater high-pressure heater.

The MSR includes a separated moisture tank, a pump for separated moisture delivery, and a tank for collecting condensate from the first and second heating stages.

2.1.4 Instrumentation and Electrical Systems

Instrumentation and Control Systems

Instrumentation and control systems (I& C) provide plant data acquisition, its transformation, distribution, processing, displaying to operating personnel, logging and archiving, as well as automatic and remote control of systems in all modes of operation. Automation of protective actions has priority over the operator's commands.

The following belongs to the main instrumentation and control systems:

- Reactor trip system (emergency protection);
- Reactor power limitation system;
- Unit power control system;
- Safety assurance system;
- Engineered safety feature actuation systems (ESFASs) of the unit equipment;
- Systems for pressure and level control in individual equipment of the unit.

Signals of reactor trip and safety assurance systems are generated independently in two self-supporting protection networks. The signals of the same value come into both networks but from different, mutually independent measurement circuits. For scram and activation of safety systems, it is significant that at least one of the two networks would generate an emergency signal. The reliability of signal generation is ensured via the "two out of three" principle.

The core neutron power is measured with the help of ionization chambers placed in 24 channels outside the reactor vessel. The in-core instrumentation system (ICIS) includes neutron flux sensors that are mounted in the central tubes of the working assemblies (36 at reactor V-213) and 216 temperature sensors for coolant temperature measurement at the outlet of the working assemblies.

Core power is controlled with the help of an automatic power controller (APC) and a power governor (PG).

The instrumentation and control systems of some of the VVER-440 Units have been recently refurbished. The "Siemens" and "Areva" companies were involved in the refurbishments, which were mainly related to introduction of advanced features for data processing, transmission, and archiving.

Main Control Room

The monitoring of reactor plant state, control of reactor plant, as well as monitoring and control of associated engineered systems of the unit under normal operating conditions, anticipated operational occurrences, and accidents is performed from main control room (MCR).

All the required information is displayed in MCR; this information provides reliable control of safety systems, normal operation systems important to safety, as well as the normal operation systems that provide the generation of electric power.

The control of power unit is a man-machine system wherein the man plays an important part from the viewpoint of safety. The MCR is a central element of this man-machine system,

it is designed to create reliable instrumentation and control system, to provide easy work of operator, and to decrease the probability of an erroneous action of the operator. This is achieved due to improvement of control automation level, as well as displaying the information in easy and concentrated form.

The composition and architecture of the MCR equipment used at various NPPs of the VVER-440 type is different from one another, as development and upgrading of the instrumentation and control system has been implemented by different companies.

There is an emergency control room (ECR) at each NPP in the event that the MCR should become unavailable.

Electrical Systems

The output of electrical power generated in the turbine generators of the unit to the electrical system as well as the supply of electrical power from the electrical system to the auxiliaries systems in the unit is performed by the transformers, which convert the 15.75 kV electric power produced in generators to the voltage of electrical system.

Two units of generator–transformer are united on the high-voltage side. A generator breaker is mounted between the generator and the transformer. An auxiliary transformer is connected between the generator breaker and the unit transformer. A provision is made for a standby transformer connected to the outdoor switchgear, which can be used as a source for standby power supply to the auxiliaries.

The essential energy-consuming systems that ensure the nuclear safety of the unit are fed from reliable category I power supply systems. In the case of the loss of the working power supply, a standby source of storage batteries supplies the energy-consuming systems when the power supply interrupted. This mode is limited by the storage battery capacity, which is sufficient to provide power demand to the corresponding systems for at least 2 h. Automatic insertion of rectifiers and charging of storage batteries occurs after recovery of the working power supply.

The reliable supply of power of the category I classification consists of equivalent three independent structures and procedures, which belong to the safety systems.

The usage of inertial RCP with a coastdown is sufficient for the changeover to natural circulation at V-213 type plants, which makes it possible to consider the system as a power consumer; thus, this allows the imposition of less stringent requirements on its uninterrupted power supply. These RCPs are connected to the sections of auxiliary transformers. At V-230 type plants with inertialess RCPs, four of the RCPs are connected to the turbine generator terminals. Coastdown of these RCPs is implemented together with the coastdown of the turbine generator.

The reliable power supply system of the category II classification also consists of three equivalent independent systems, which belong to safety systems. A power supply source of each category II system is a diesel generator (DG), which is started up in response to signals that indicate the loss of normal power supply to the unit. The time required from signal initiation for the reliable supply of power from the DG is at the most 15 s. A stepwise start-up automatically connects the consumers temporarily to the switchgears of category II system after changeover to power supply from DG in order to avoid prohibitive overloading of DG. It therefore avoids any subsequent shutdown by the system protections or from any damage. Power supply to the safety system equipment is immediately provided.

2.2 Basic Safety Properties

2.2.1 Safety Philosophy

One of the most important trends related to nuclear power engineering safety is to neutralize the potential danger of the uncontrolled distribution of radioactive substances that are generated inside the nuclear reactor.

In the evolution of the NPP safety concept in Russia, three specific periods may be singled out. The first one refers to the initial stage of the development of nuclear power engineering, when it was supposed that because of the high quality of the reactor plant equipment, pipelines, and other components, it might be possible to avoid significant damage, thereby, excluding the possibility of severe accidents.

At the initial stage, a high emphasis in the domestic nuclear engineering industry was placed on a special technical regulation, which was based on the enhanced requirements for equipment and systems quality. This included the development of new techniques. It was ultimately aimed at reaching a high-level of reliability. In using these specifications, it was possible to determine that the increase in the quality and reliability indices was many times that compared to the traditional heat-and-power engineering. As a result of this, the first VVER-type reactor designs considered the ultimate size of the coolant leak as the maximum design basis accident and, respectively, the requirements for the accident localization system were restricted.

The second period of safety concept evolution is characterized by formation of a comprehensive approach to the NPP as an enhanced hazard that demands development and application of the special measures for safety assurance. During this period, the specifications of the emergency cooling systems and accident localization systems for the calculated instantaneous break of main coolant pipeline were created.

The third period is related to a new safety concept that covered beyond design basis accidents and possible severe core damages.

For a choice of technical solutions and parameters of nuclear power installations both a conservative approach, and the use of significant margins to dangerous design parameters, were identified as of great importance. Such a status was accepted for designing the VVER-440 reactor. The reactor features related to the design and operational safety basis are as follows:

- Reduced core power density;
- Significant heat-engineering margins to the limiting values;
- Spatial power distribution stability;
- Negative reactivity coefficients for the operational parameters;
- Steady natural coolant circulation without falling outside the design parameters to 10% of thermal power;
- High redundancy of the capital equipment (6 reactor cooling loops) with the possible long-term operation at the decreased power (to 3 loops);
- Large water inventory above the core and in the circulation circuit that facilitates the running of the emergency loss-of-coolant processes;
- Horizontal steam generators with a large water inventory that ensures residual heat removal within about 4–5 h without makeup in the case of a complete loss of NPP power;
- Reactor vessel is made of steel of improved radiation strength without longitudinal welds;
- Vessel lower part does not have insertions in the form of nozzles;
- Primary circuit pipelines are made of stainless steel that allows the realization of the “leak-before-break” concept.

2.2.2 Safety Systems and Properties

- a. The V-230 reactor plant was designed during the first period of safety concept development. The break of the main coolant pipeline made of stainless steel not being subject to brittle fracture was not considered in the project. The accident localization system consisted of the leak-tight rooms was designed for excess pressure in case of limited leak and the sprinkling system was intended for condensation of steam released during the accident.

During loss-of-coolant accident (LOCA) in the V-230 reactor plant, the emergency core cooling system in the primary circuit is brought into operation. This system includes three channels each consisting of two emergency makeup pumps and a delivery pipeline D_{nom} 100, which supply borated water into the non-disconnected part of the first, third, and fifth circulation loops, respectively. Each of the process emergency makeup channels is connected to the respective individual channel of reliable electrical power supply, control, and monitoring.

The emergency makeup pump characteristics are as follows:

- Capacity of $48 \text{ m}^3/\text{h}$;
- Pressure head not less than 110 kgf/cm^2 ,
- Pumped liquid temperature not more than 75°C .

The suction pipelines of the emergency makeup pumps are connected to the emergency boron solution tank, which is a part of the leak-tight volume and connected to the primary circuit box through the box floor draining sumps.

The emergency primary circuit makeup system is automatically connected in response to one of three signals, which characterize the loss-of-coolant accident:

- Primary pressure $\leq 90 \text{ kgf/cm}^2$,
- Simultaneous primary pressure decrease ($\leq 110 \text{ kgf/cm}^2$) and a pressurizer level 2.56 m below the nominal level,
- Decrease in the pressurizer level to -2.7 m of the nominal.

By the activation of the emergency signals in each channel, two pumps are connected with prohibition of their disconnection.

- b. The V-213 reactor plant was designed during the second period of safety concept development.

In this reactor plant, the project provides for emergency core cooling system (ECCS) that consists of

- A passive system of two individual and functionally similar subsystems (100% redundancy). Each subsystem consists of two hydraulic accumulators (HAs), one of which supplies water into the reactor volume above the core and the other supplies the volume under the core. The passive emergency core cooling system is brought into operation without the initiating signals and power supply. When the reactor pressure decreases below the HA pressure, the working medium is displaced due to expansion of the compressed nitrogen from HA into the reactor. To prevent the nitrogen from getting into the reactor, the HAs are provided with a ball-floating valve (➤ [Table 5](#)).
- Two active high- and low-pressure systems, each having three individual and functionally similar subsystems (200% redundancy) (➤ [Table 6](#)).

Table 5
Technical characteristics of hydraulic accumulators (HAs)

Nominal pressure, MPa	3.5
Working solution volume, m ³	40–43.5
Nominal temperature, °C	55–60
Boric acid concentration, g/kg	12
Nitrogen volume, m ³	30

Table 6
Technical characteristics of the high-pressure emergency core cooling system (ECCS) pump

Flowrate, m ³ /h	65 under backpressure of 12.7 MPa 115 under backpressure of 9.4 MPa
Pressure under delivery side, MPa	Min. 9.17; Max. 14.3
Medium temperature, °C	Max. 70

Table 7
Technical characteristics of low-pressure emergency core cooling system (ECCS) pump

Flowrate, m ³ /h	280 under backpressure of 0.71 MPa 360 under backpressure of 0.63 MPa
Medium temperature, °C	Max. 90

The pump pressure head is connected to the non-disconnected parts of cold legs in the relevant circulation loops. The pumps are connected in response to a “LB LOCA” signal, a “SB LOCA” signal, or a “MSH rupture” signal and simultaneously the quick-acting valves open in response to these signals. The time required from the pump start-up to supply the whole coolant amount into the primary circuit is 10.5 s. The minimum concentration of H₃BO₃ in the emergency tanks is 39 g/kg (🔍 [Table 7](#)).

The pump pressure head is connected to the reactor vessel above and under the core and separated from the reactor by a set of check valves. The pumps are connected in response to a “LB LOCA” signal, a “SG compartment pressure” signal, or a “medium size leak” signal and simultaneously the quick-acting valves open in response to these signals. The time required from the pump start-up to supply the whole coolant amount into the primary circuit under

primary pressure of 0.75 MPa is 10.5 s. The minimum concentration of H_3BO_3 in the emergency tanks is 12 g/kg.

- SG super-emergency feedwater system (EFWP) consists of the working and backup pumps connected by the “feedwater loss” signal and supplying demineralized water at a temperature of about 20°C from three tanks with a volume of $1,000\text{ m}^3$. The super-emergency feedwater pipelines are not connected to the SG main and emergency feedwater. The cold water is supplied into the steam generators through a special nozzle (➔ [Table 8](#)).
- A system of emergency gas removal from the primary circuit that allows for the gas blanket in the emergency cases to be efficiently removed from the reactor and SG collectors into the pressurizer system through the special tubes connected to the air vents. The signal appearing on the level indicator of the reactor is generated by the special indicators, which are the part of the ICIS.

2.2.3 Maximum Design Basis Accident

The maximum design basis accident of a V-230 reactor plant had as the proceeding from the supporting structures, the possibility of a primary coolant blowdown being equivalent to 32 mm diameter. Thus, all the main coolant pipeline insertions were provided with devices limiting the leak from the primary circuit up to this value.

An instantaneous double-ended guillotine break of the main coolant pipeline $D_{\text{nom}} 500$ was assumed as the maximum design basis accident in the V-213 reactor plants.

2.2.4 Severe Accidents

In the VVER-440 reactor plant design, the severe accidents with fuel melting were not considered because of the features of these plants specified in ➔ [Sect. 1](#) that make the accidents of such kind improbable. The conservative safety analyses that were made showed an absence of core damage beyond the safety criteria. This included an analysis of a reactor scram failure.

However, in connection with introduction of the new requirements that prescribe the consideration of severe accidents at some VVER-440 Units, the possibility that reactor vessel cooling from outside is considered for the case of an improbable severe accident.

The long-term and efficient reactor vessel cooling implemented at the units in operation is a very difficult problem. This is because any such operation should be performed in the restricted space of the reactor concrete cavity in the presence of the irradiated equipment.

■ **Table 8**

Technical characteristics of pump (EFWR)

Flowrate, m^3/h	60.0
Pressure at the pressure head, MPa	5.5

A similar design was supposed to be realized at “Mochovce” NPP, Units 3, 4 in Slovakia. According to this design, the following measures that ensure that the flooding of the reactor concrete cavity during the severe accident as intended:

- Configuration changes in the pipeline for air supply to cool the reactor concrete cavity (this pipeline is designed to be mounted inside the concrete structures) and the additional valves on this pipeline with their control and signaling that restricts water getting into the ventilation post;
- Reconstruction of thermal insulation of the reactor vessel bottom head to ensure the gap required;
- New structural decision on thermal insulation in the reactor vessel nozzle area to ensure a free steam discharge from the reactor concrete cavity;
- Reconstruction of the penetrations in the reactor concrete cavity and modification of the doors entering the concrete cavity;
- Sufficiently low-pressure loss for coolant flow;
- Reconstruction of drainage line from the reactor concrete cavity and control of its closing before the onset of flooding.

Modifications were also proposed to the chute drainage set of the bubbler–vacuum system to control drainage of the water from the chutes onto the box floor. A further system of additional coolant tanks and pumps that are common to both operating units were constructed in order to feed the coolant into the containment area through the sprinkling system.

2.2.5 Seismic Design

The seismic stability of a VVER-440 reactor plant is justified both by calculations using the response spectra and floor-response accelerograms, and by a set of experimental studies of the small-scale models and at full-scale equipment. The full-scale studies make it possible to determine the main modes and frequencies of vibrations and the quantitative values of the factors (mounting gaps, nonlinearities, etc.), which influence the overload caused by seismic impacts. The results of full-scale studies at various NPPs enabled the statistically validated data to be used in the calculations of reactor plant equipment and pipelines for seismic impacts. The calculation to check the strength of the equipment and the pipelines is performed by considering the combined effect of operational and seismic loads.

Experimental studies to justify the earthquake resistance of the primary equipment for VVER-440 NPP were performed with small-scale and large-scale metal models. A 1:20 scale reactor model and a 1:25 scale model of the circulation loop were studied.

The results of calculations and the experimental activities showed that the additional fastening of the reactor internals was required to reduce their displacement with respect to each other. The supports of tube bundle in steam generator were also strengthened due to these studies. Fastenings that reduced the effect of seismic impacts were introduced for circulation loop equipment (MGV, RCP, SG), where snubbers were used to also prevent buckling through the thermal expansion of a loop.

The scram signal is introduced in case of operating basis earthquake (OBE).

2.3 Operational Experience and Decommissioning

2.3.1 Operational Experience

NPP	Unit and reactor type	Electric power, MW	Commissioning	Decommissioning	Gross generation till 2009, GW h

	Unit 2, V-213	388	11.04.2000	–	14,789

Nowadays the increase in power of VVER-440 Units is a high-priority task. In transition to the operation at increased power, it is reasonable to use the fuel assemblies with an extended height of fuel column (second-generation assemblies). The results of a pilot study on the viability of the new fuel configuration show that during the implementation of the second-generation fuel, the operational limits for the standard fuel are not violated. This confirms the compatibility of new and standard fuel assemblies.

Numerous experimental studies, performed for the fuel with burnup of (50–60) MW·day/kg-U under transient and accident conditions, as well as post-reactor studies of assemblies, the fuel rods, and the fuel pellets of 5-years operation, confirm a high reliability of fuel, availability of high margins for the state of fuel column that promotes operation of the reactor at increased power.

At present, Units 1, 2, 4 of Kola NPP and Unit 2 of Rovno NPP have experience in operating reactors under increased power. The Units of “Loviisa” NPP are operated at 109% power.

By the beginning of 2009, the second-generation fuel had been implemented at a number of NPP Units with VVER-440. The safety justification of operation at the increased power has been made for the reactor cores of the following NPPs: NPP B2 “Bohunice” (Units 3 & 4), NPP “Mohovce” (Units 1 & 2), NPP “Dukovany” (Units 1–4), NPP “Kola” (Units 3 & 4).

2.3.2 Life-Time Extension

The design service life of the VVER-440 reactors is 30 years. In 2000, a set of regulatory and guiding documents was established in Russia wherein the basic criteria and requirements are stated for evaluation of a possible service life extension, as well as safety measures to be taken during the period of extended operation.

According to these requirements, the following shall be done for each power Unit:

- The studies shall be performed to determine the residual life of non-recoverable components of a Unit and the measures shall be taken on the extension of the residual life of these components;
- The reports shall be prepared on the in-depth safety assessment considering all measures implemented on modernization including deterministic safety analysis, probabilistic safety assessment (PSA) of level one, and an analysis of the operating history.

Such complex activities were performed for Units 3 & 4 of Novovoronezh NPP and Units 1 & 2 of Kola NPP where the design life expired between 2002 and 2005. The license was obtained for an extension of their respective service life for further 15 years.

At present, the appropriate activities are conducted at NPPs with V-213. Their service life is planned to be extended for 25–30 years.

3.1.1 Buildings and Structures

The building layout of the Tianwan NPP Unit is presented in [Figs. 24](#) and [25](#).

The key building that determines the power unit layout is the reactor building ([Figs. 22](#) and [23](#); [Table 9](#)).

Safety-related buildings are located around reactor building: the steam cell, the safety building, and the control building. The emergency diesel power station is sited behind the safety building and it is aligned across reactor axis.

■ **Table 9**

Main design characteristics of V-320 and V-428 reactor plants

Parameter	Value	
Reactor plant type	V-320	V-428
Thermal power (nom.), MW	3,000	
Primary pressure, MPa	15.7	
Secondary pressure, MPa	6.27

Coolant temperature at reactor outlet, °C	320	321
Quantity of fuel assemblies, pcs.	163	
Quantity of control rod drives, pcs.	61	121
Uranium loading, t	80	
Fuel enrichment with isotope U-235, %	4.4	
RP service life, years	30	40

The auxiliary system building, the fresh fuel storage, the solid radioactive waste storage, and the nuclear service building are located in the sector, which borders on the control building, the reactor building, and the safety building.

The turbine building is sited behind the steam cell.

The NPP Unit also comprises a vent tube, a treated water storage tank, and a separate water tank to store water for the extinguishing of fire, transformers, and underground structures.

The architecture of Units at NPPs with V-428 and V-320 Project designs is almost identical.

Reactor Building

The reactor building is the main construction of the NPP around which the other buildings are sited. It houses the nuclear steam supply station and all the emergency systems required to cool down the reactor.

Apart from the load bearing and enclosure functions, the structures of the reactor building simultaneously perform protective and isolation functions. The building is a spacious construction combining two protective envelopes, internal and external. The structures inside the building are used to hold the equipment. The foundation slab must support the erected envelopes and internal structures.

A single-envelope containment made of prestressed concrete is used in the NPPs with V-320 reactor. The double-envelope containment minimizes the release of emergency radioactivity into the environment. The external envelope serves for physical protection of the internal confinement and the equipment it houses from all external impacts. The internal confinement provides airtightness of the space inside containment under all the conditions of NPP operation, including accidents.

Figure 24
 Layout of the Unit buildings at the elevation mark +20.4

Figure 25
Cross section of the Unit buildings. Section 1-1

■ Figure 26

Reactor building. 1 – External envelope, 2 – Confinement, 3 – Spent fuel and refueling pond, 4 – Reactor, 5 – Inspection wells of upper unit and internals

The internal envelope is a prestressed concrete structure in the form of a cylinder with a semispherical dome. The internal surface of the envelope is covered with 6-mm carbon steel to provide airtightness.

The containment rests on the foundation plate. Both the internal confinement and the foundation contribute to the hermetically sealed space with its integrity assured for a maximum design basis loss-of-coolant accident.

The external envelope physically protects the prestressed concrete confinement from outside impacts and ensures the reduction of emergency release into the environment by the creation of an envelope-to-envelope gap to localize any emergency leaks through the internal confinement barrier.

The external envelope is made of monolithic reinforced concrete. The envelope consists of a cylinder with a gently sloped dome. The annular gap between the inside and outside envelopes is 1,800 mm wide in the cylindrical part. In the dome, the gap width varies owing to differences between the internal and external dome configurations.

The external envelope is separated from the adjacent buildings with an aseismic seam, which includes the safety building, the control building, the steam cell, and the auxiliary building.

The containment houses all the equipment of reactor plant. The reactor is installed in the concrete cavity on a support truss. Annular metalwork filled with serpentine concrete forms the dry shielding to protect the structures against irradiation. The core catcher is located in the bottom part of the concrete cavity. A core catcher was not included in the NPP design with the V-320 reactor plant.

The general layout of the containment with the equipment of V-320 RP design and main rooms it houses is shown in  Fig. 26.

Auxiliary Building

The auxiliary building is located in the central part of the station. It is adjacent to the control building, the nuclear service center, the safety building, the solid radioactive waste storage, and fresh fuel storage.

The building houses the primary-side auxiliary systems, water purification systems, liquid radioactive waste collection and storage systems, and equipment of venting systems of the limited access area.

Turbine Building

The turbine building belongs to the free access area. It houses a turbine, a generator, and their auxiliary systems, such as separation and intermediate superheating, condensate purification, the high- and low-pressure regeneration systems, the feedwater system, the station auxiliaries steam collector, and the oil systems for the turbine and generator.

3.1.2 Systems of Primary Circuit

Reactor Coolant System

The system of reactor cooling for the V-428 and V-320 reactor plants under normal operating conditions (primary side) consists of four circulation loops ( Figs. 27 and  28). Each circulation loop comprises a reactor coolant pump (RCP) and a steam generator. Each loop has two pipeline sections defined as hot and cold legs. The pipe section from the reactor outlet nozzle-to-steam generator collector is the hot leg. The pipe sections from the steam generator outlet nozzle-to-RCP inlet (suction) nozzle and the RCP outlet (discharge) nozzle-to-reactor inlet nozzle make the cold leg.

A 426 × 40-mm surge line connects the hot leg of the fourth circulation loop to the pressurizer. A 219 × 20 mm line connects the hot leg of the third circulation loop to the pressurizer and it is an injection line.

The MCP ( Table 10) is made of 10GN2MFA alloy structural steel. The internal pipe surface is clad with corrosion-resistant 04X20N10G2B stainless steel not susceptible to intergranular corrosion by the coolant.

Cold leg length, m	26

Reactor Vessel and Internals

A reactor is a vertical pressurized vessel that houses a core barrel with the baffle, protective tube unit, fuel assemblies, reactor trip system control assemblies that are engaged with extension shafts of the drive motion units and detectors for the in-core instrumentation system.

The reactor flange supports top head of the reactor, which has the housings and electro-magnet units attached to outside to allow for axial movement of the reactor control assemblies (RCCAs) in the core.

The VVER-1000 reactor vessel design is based on meeting the following requirements:

- Proven manufacturing process and structural materials;
- Complete in-shop manufacture of the vessel, tests included;
- Possibility of vessel transport by railway and by sea;
- Possibility of periodic in-service inspection of vessel state.

The reactor vessel consists of several forged shells welded to each other, an elliptic bottom head, and a flange. The reactor is sealed with bar gaskets and tightened with 54 M170 studs.

Two of the vessel shells each have four D_{nom} 850 nozzles, which are connected to the main coolant pipeline of reactor coolant system. Thus, the vessel shells make outer surface of the inlet and outlet chambers for the reactor coolant.

A ring welded to the vessel internal surface clad from austenitic steel serves to separate the inlet and outlet chambers. Barrel-mated keys are used to keep the ring from undergoing radial displacements. Hermetically sealed casks are installed on hangers to hold the vessel steel surveillance specimens.

The reactor vessel is made of heat-resistant alloy steel Grade 15Kh2NMFA. The reactor vessel steel and welding materials were chosen on the basis of mechanical property analysis, the lack of susceptibility to brittle fracture, its durability, and its irradiation stability.

The core barrel is a welded cylindrical shell with a supporting bottom and a flange, which supports the barrel at the vessel shoulder. The perforated elliptical bottom of the core barrel, 163 perforated support tubes, and the support grid contribute to the structures that support and space the FAs.

A core baffle is placed next to the barrel at the core level. It is approximately the distance of the structural gap of an FA from the periphery row. The baffle serves as a displacer and as a protective screen. The core baffle is made of several massive rings that are mechanically attached to each other and to the bottom of the core barrel.

The longitudinal channels are used to ensure that the flowing coolant can effectively decrease any swelling of the metal in the core barrel metal. The swelling is caused by the working temperature range and the accumulated neutron fluence over the service life of the vessel.

A protective tube unit (PTU) is installed on the top of the core. It is pressed against the core barrel flange with the force of the elastic element installed between the PTU and the top head of the vessel. The PTU and elastic element are compressed as reactor main joint is sealed.

The perforated shell of the PTU with plates and protective tubes make a rigid support structure that spaces the FAs and prevents them from lifting up. The protective tubes house RCCAs, in-core instrumentation detectors (ICID), and in-core instrumentation system detectors.

The internals are made of corrosion-resistant steels of the austenitic grade.

The upper unit structurally integrates an elliptical head with a flange. Nozzles are inserted for RCCA drives, metalworks, and crosspieces.

The pitch electromagnetic drive of the ShEM-3 type moves the control rods at a rate of 2 cm/s.

The quantity of drives installed in the upper unit for a V-428 reactor can be varied from 85 to 121 pcs., the amount of which is dependent on the fuel loading. For V-320 type reactors the number of drives is fixed at 61 pcs. The core is made of 163 FAs that are identical in structure but different in fuel enrichment.

Reactor Core

The VVER-1000 reactor cores contain 163 hexagonal fuel assemblies (FAs). The lattice pitch is 23.6 cm. The fuel rods are arranged in a hexagonal structure inside FA. Note that the FAs are jacket-free. A welded skeleton is formed from the spacer grids, control rod guide tubes, angle-pieces, and other smaller parts that make the assembly rigid. One important aim of FA development was the improvement of the skeleton for ensuring the long-term reliability. Bowing problems that were experienced in the first years of their use were eliminated by such

■ Figure 29

Enrichment pattern in the FA

Table 11

Main stages of VVER-1000 fuel evolution

Commissioning/year	Before 1997	1998–2000	Since 2003/2003	Since 2006
FA type	TVS (TVS-M)	UTVS	TVSA/TVS-2	TVSA-ALFA/TVS-2M
Bundle type	Blocked absorber	U-Gd	U-Gd	U-Gd
Reload batch average enrichment [% ^{235}U]	4.31	3.74	~ 4.26	4.83/4.88
Spacer grid pitch (mm)	1.275	1.275	1.275	1.275

developments. The FAs contain 331 rod positions. In the currently typical case, the central position is a tube with water, one position is used for in-core measurements, guide tubes of movable control rods are placed into 18 positions, and the 312 positions are filled with fuel rods. Six of the fuel rods can contain burnable absorbers. The pattern is profiled as shown in Fig. 29.

The control rods can move in the guide tubes. They are fully inserted into the core when the reactor is in the shutdown state, while for power operation they can be pulled upward out of the core.

Burnable absorbers must be included in VVER-1000 reactors, since the excess reactivity of the initial core design without burnable absorbers could not be adequately compensated by diluted boric acid. This enabled a negative reactivity feedback coefficient. Removable boron rods were chosen as the blocked burnable absorbers. They were placed into the guide tubes of control rods and were removed after 1 year of operation. In order to improve neutron economics, stainless steel FA components were replaced with components made from zirconium alloy. Switching the component materials enabled a decrease in the enrichment of the fuel rod. Therefore, blocks of burnable absorber rods were no longer required. The rods that contain burnable absorber in the form of gadolinium could be placed into optimum positions within the fuel assembly.

A general view of fuel assembly is provided in Fig. 30.

The main stages of VVER-1000 fuel development are shown in Table 11.

Alternative fuel assembly (AFA) advance fuel assemblies are used in RP V-428 design. All types of fuel are used in V-320 design.

■ Figure 31

VVER-1000 fuel rod. 1 – Lower plug, 2 – Fuel pellet, 3 – Cladding, 4 – Gas space, 5 – Upper plug

■ Figure 32

VVER-1000 pellet

Fuel Rods The fuel rods are closed cylinders with an outer diameter of 9.1 mm and an inner diameter of 7.73 mm. The length of the fuel rods is 3,840 mm. The length of the fuel stack is 3,530 mm. The fuel rods are filled with helium at a pressure of 2.0–2.5 MPa. ➤ *Figure 31* shows the fuel rod.

The fuel pellets are made of sintered UO_2 with or without a central hole. The outer diameter is 7.56 mm. The height of the pellet is 12 mm. The UO_2 density is not less than 10.2 g/cm. The configuration of the rod can be seen in ➤ *Fig. 32*. Fuel rods with various uranium enrichments are available. The fuel enrichment, which is typically used has values of 1.6%, 2.4%, 3.3%, 3.7%, and 4.1%. FAs with fuel of 1.6 and 2.4% enrichment are not profiled and they are used mostly in the first cycles. FAs with fuel of 3.7 and 4.1% enrichment are profiled with the placing of fuel rods that have 3.3 and 3.7% enrichment, respectively, into the outermost row of the FA and into the first neighbor position in the corners.

VVER-1000 fuel cladding is made of the E110 zirconium alloy (with a niobium content of 0.9–1.1%). This material is well known because of its very low hydrogen uptake during normal operating conditions, which leads to a high reliability concerning their long-term operation and in respect to reactivity-induced accidents.

Burnable Absorbers The 18 guide tubes in the FA can be used to load burnable absorbers into the core for a given cycle. In the case of using blocked burnable absorbers, 42 FAs are typically loaded with them in the first cycle. The number of burnable absorbers is later reduced to 18 FAs. The blocked burnable absorber is chromium diboride (CrB_2) in matrix of aluminum alloy with three different natural boron contents (0.020 g/cc, 0.036 g/cc, 0.050 g/cc). The higher the enrichment in the FA the greater the amount of boron loaded into the FAs.

Rods containing Gd absorber have the same dimensions as those of the usual fuel rods. The Gd content in the burnable absorber rods is 8 wt%, while the uranium enrichment is 3.6 wt%.

Control Rod Clusters Boron carbide (B_4C) powder is used to manufacture the control rods for VVER-1000 reactors. This material is used in the top of the rods with a pellet length of 320 mm. The bottom part, which is 30 cm long, is made of dysprosium titanate. In the first phase of developing VVER-1000 reactors, other materials (e.g., europium oxide [Eu_2O_3]) were also used as absorbers.

The 18 control rods in a FA form a cluster. Control rod clusters are typically placed in 103 FAs. Note that 85 FAs are used in the first cycle. These numbers have been varied with time and NPP unit. The control rod clusters are grouped into 10 groups, which move together. Each of them contains 6–12 clusters. Reactor power and power distribution are controlled with the help of a group of clusters partly inserted into the core. The other groups are fully withdrawn during power operation. Typical core pattern for RP V-428 reactor is shown in  Fig. 33.

The time taken for a control rod drop at reactor scram does not exceed 4 s.

FA type	Average enrichment in U_{235} , % mass
24	2, 40
41	4, 10
36	3, 62
36G7	3, 61
40G7	4, 00

Reactor Coolant Pump

The RCP is a one-stage centrifugal pump, which is aligned vertically (➤ [Table 12](#)). The RCP consists of a pump casing, an electric motor, a sealed drive shaft and gears, a flywheel, top and bottom insertions, supports, and auxiliary systems.

The electric motor is of the vertical asynchronous double-speed type. To prevent the reverse rotation of the rotor, the RCP is provided with a cam-and-ratchet mechanism. RCP is also supplied with a flywheel to provide inertia coastdown.

General view of RCP is provided in ➤ [Fig. 34](#).

GTsN-195M pumps are used in the V-320 RP design, while GTsN-1391 pumps are used in the V-428 RP design.

The GTsN-1391 pump is a further evolution of GTsN-195M design and its enhancements are described as follows:

- Main thrust bearing is water-cooled and water-lubricated;
- Application of double-speed electric motor decreases grid loading at pump start-up;
- The applied shaft sealing ensures cold and hot standby with an unlimited outage on condition of intermediate circuit locking and sealing water is supplied also on the condition that the outage following an NPP blackout (loss of cooling) under coolant nominal parameters is for not less than 24 h providing leaks through the sealing are not above 50 l/h.

Pressurizer

The steam pressurizer that is installed at V-428 and V-320 reactor plants is a vertical vessel with electrical heaters to increase primary pressure (➤ [Table 13](#)).

The pressurizer vessel is made of carbon steel with corrosion-resistant austenitic cladding of the internal surfaces.

Two independent nozzles with spray devices are installed in the upper part of the pressurizer in V-428 design while a single nozzle was employed in the V-320 design. They ensured the water injection into steam space from the following sources:

- The RCP discharge line under normal operating conditions and under anticipated operational occurrences;
- The discharge line of the high-pressure emergency injection pumps under design-basis and beyond-design basis accidents.

The pressurizer is connected to the hot leg of the main coolant pipeline through the lower nozzle of D_{nom} 350 surge line.

There is a nozzle in the top section of the pressurizer to attach the overpressure protection system that consists of three pilot-operated relieve valves.

A general view of the pressurizer is given in ➤ [Fig. 35](#).

Steam Generator

The steam generators employed in the both V-320 and V-428 Projects are of the PGV-1000M type. It is a single-vessel recuperative heat exchanger, which is aligned horizontally, what ensures that the heat transfer surfaces are submerged. A general view of steam generator is presented in

➤ [Fig. 36](#).

Figure 36

General view of APGV-1000M steam generator. 1 – Vessel, 2 – Heat transfer surface, 3 – Primary-side collectors, 4 – Main feedwater distribution devices, 5 – Emergency feedwater distribution devices, 6 – Steam-receiving perforated plate, 7 – Submerged perforated plate

Table 14

PGV-1000M steam generator nominal operation performance

Parameter	Value
Steam capacity, t/h	1,470
Steam pressure in SG vessel, MPa	6.39
Steam pressure at SG outlet, MPa	6.28
Primary coolant temperature at the SG inlet, °C	321
Primary coolant temperature at the SG outlet, °C	291
Feedwater temperature, °C	220
Feedwater temperature with high-pressure heaters switched off, °C	164
Steam moisture at SG outlet, %, not above	0.20

The steam generator is designed to house the heat transfer surface, which contacts the primary coolant with the secondary coolant. Its vessel consists of forged shells, stamped elliptic bottoms, and forged nozzles that are joined by welding. The vessel design provides easy access to examine the internal structures from the secondary side.

The heat transfer surface comprises of 10,978 U-tubes 16×1.5 mm in diameter that are arranged in coils and positioned horizontally in a staggered order. The coils are connected to primary-side collectors. The U-tube ends are hydraulically expanded over the collector wall thickness and are argon-arc welded onto the inside surface of the collectors. Austenitic steel is used as the material of the tubes.

The primary-side collectors are designed to distribute the coolant in the heat exchange tubes, collect, and evacuate it.

The internal surface of the collector has two layers of corrosion-resistant cladding.

The steam-receiving perforated plate is installed in the top section of the vessel.

The steam load is leveled with the perforated plate positioned under the SG water level.

Any water that has an increased salt concentration and fouling is accumulated inside the SG close to one of the bottoms (in the so-called salt pocket). This is due to an appropriate arrangement of feedwater and SG blowdown.

A large inventory of water is the merit of PGV-1000 steam generator. It provides favorable dynamic characteristics of all the reactor plants in the case of a loss-of-feedwater accident (☛ [Table 14](#)).

Chemical and Volume Control System

The chemical and volume control system comprises of

- Two high-capacity pumps;
- Three low-capacity pumps;
- Regenerative heat exchanger of blowdown steam;
- Pipelines and related valves;
- A makeup deaerator.

The low-capacity pumps are not applied in NPPs where V-320 reactors are operated.

The blowdown pipelines are connected to the cold legs of circulation loops 1 and 4 on the discharge side of reactor coolant pumps.

Makeup pumps are connected to the cold legs of all four loops at RCP suction nozzle (☛ [Tables 15–17](#)).

3.1.3 Secondary-Side Systems

Main Steam Line System

Steam from the main pipelines enters the turbine via four 630×25 mm nozzles.

The main steam header (MSH) equalizes the steam pressure upstream of the turbine. Steam is tapped for station auxiliaries by a dedicated steam dump device, to the turbine bypass system, a separation, and intermediate superheating system.

The main parameters of main steam are	
Steam pressure at steam generator outlet, MPa	6.27
Steam temperature at steam generator outlet, °C	278.5
Steam pressure upstream of the stop valves, MPa	5.88
Steam temperature upstream of the stop valves, °C	274.3
SG capacity, t/h	1,470

The valves of the steam generator in the Tianwan NPP are installed in the following sequence on each steam line:

- Main steam valve unit, shut-off valves on the main steam isolation valve (MSIV) bypass;
- Isolation valves;
- Main steam gate valve;
- Valves on the main steam gate valve bypass.

The main steam valve unit comprises of the MSIV, the steam generator safety valves, the steam dump valve to the atmosphere, and the shut-off valve upstream of it.

For NPP with V-320 reactors, the main steam isolation valve, the steam generator safety valves, and the steam dump valve are treated as separate equipment.

Main Feedwater System

The main feedwater system comprises of the following unit operations:

- Main electric feedwater pumps;
- Deaerator plant;
- Pipelines and valves (shut-off, control, safety).

Feedwater is supplied to steam generators via the deaerator plant, where the condensate from turbine is also supplied.

Five feedwater pumps are connected to the deaerator plant.

Each pump is equipped with a recirculation line to deaerator that provides pump testing and a possibility of its operation under pump transient operation with low flows.

Feedwater is supplied from the pressure collector of feedwater pumps through two $D_{\text{nom}} 500$ lines to the high-pressure heaters on the turbine. Downstream of the high-pressure heaters, the feedwater is supplied to $D_{\text{nom}} 500$ collectors and then passed on to the steam generators along four $D_{\text{nom}} 400$ pipelines.

The control valves are installed outside the containment on the lines of feedwater supply to each steam generator to maintain the nominal level in the SGs at power operation.

Five electric feedwater pumps (four in operation, one in standby) are installed at NPPs operated with V-428 reactors.

Two turbine-driven feedwater pumps are installed at NPPs operated with V-320 reactors, their capacity being 3,000 m³/h each.

Electric feedwater pumps are designed to supply feedwater to steam generators under normal operating conditions.

The pumps are of the centrifugal type. They are aligned horizontally with two casings. The pumps have four stages.

The main performance of feedwater pump	
Capacity, m ³ /h	1,650
Pressure head, MPa	9.1
Pumped liquid temperature	172

Deaerator is designed to remove corrosive gases and to heat up the turbine condensate under nominal, start-up, and transient conditions of operation.

Deaerator performance	
Capacity, t/h	6,000
Working pressure, MPa, abs.	0.824

Turbine

At all NPP Units operated with V-320 reactors both low-speed K-1000-60/1500 and high-speed K-1000-60/3000 turbines are installed. At the NPP Units with V-428 K-1000-60/3000 steam turbines are installed. It is a condensation type turbine, with one-shaft, five cylinders (2 low-pressure cylinders + 1 high-pressure cylinder + 2 low-pressure cylinders), intermediate separation, and steam superheating. The turbines have a nominal power of 1,000 MW with a rotational speed of 50 Hz or 3,000 rev./min. The energy of the steam supplied to the turbine is used to drive a TVV-1000-2 AC generator directly. The generator is mounted on the same foundation as the turbine.

The scheme of the turbine has 2 LPCs + 1 HPC + 2 LPCs.

Steam is supplied from the HPC along four D_{nom} 1,600 steam lines to four separator-superheaters (SSHs). The separation and steam superheating are performed in one stage. Downstream of the SSH steam is supplied to each of the four low-pressure cylinders. The

Main parameters of the turbine plant	
Nominal power at generator terminals, MW	1,000
Steam flowrate through turbine, t/h	5,870
Steam pressure upstream of HPC valves, MPa	5.88
Steam pressure upstream of LPC, MPa	0.516
Steam temperature upstream of the LPC	250.0
Nominal revolutions, rev./min	3,000

butterfly gates installed in this path perform the functions of stop valves and regulating valves.

Steam is dumped out of each LPC to a dedicated condenser. The condensers are of the surface type. They are basement-positioned, two-flow, and subdivided for pressure. The steam-receiving devices are built-in into the condenser and they accept the SG steam dumped to condenser via steam dump station under start-up and transient operating conditions.

The turbine is also equipped with a regenerative plant to heat up the condensate and feedwater with separator–heaters. Uncontrolled steam extractions can be performed to the regeneration systems, heaters, and to the station auxiliaries.

Generator

The TVV-1000-2UZ generator is installed at each power unit with a nominal power of 1,000 MW, $\cos \varphi$ 0.9, voltage 24 kV.

Separator–Superheater

The K-1000-60/3000 turbine is equipped with a special system of intermediate separation and superheating of the steam after it leaves the HPC and before the steam enters the LPC. The task of the separator–superheater is to separate and evacuate moisture. Moisture is separated in the upstream separators wall moisture built-in into crossover steam lines that supply each SSH. Moisture is also separated in speed separators that collect the suspended moisture, which contacts the SSH casing. Main steam extracted from the lines upstream of the turbine is heated up to 250 °C in order for it to be supplied to LPC. The separated water is pumped out of the sump shared by the four SSH to the main condensate path. Heating obtained from steam condensate in the condensate sump, which is shared with the SSH, is supplied to feedwater path downstream of the high-pressure heater.

3.1.4 I&C and Electrical Systems

I&C System

The I&C system comprises of all the systems, hardware, and actions that are required to measure the process parameters, signal processing, the generation of emergency signals and messages on the state of closed and open control circuits, and limiting conditions of operation, as well as implementation of protective actions and provision of appropriate power supply.

I&C incorporates the following main systems:

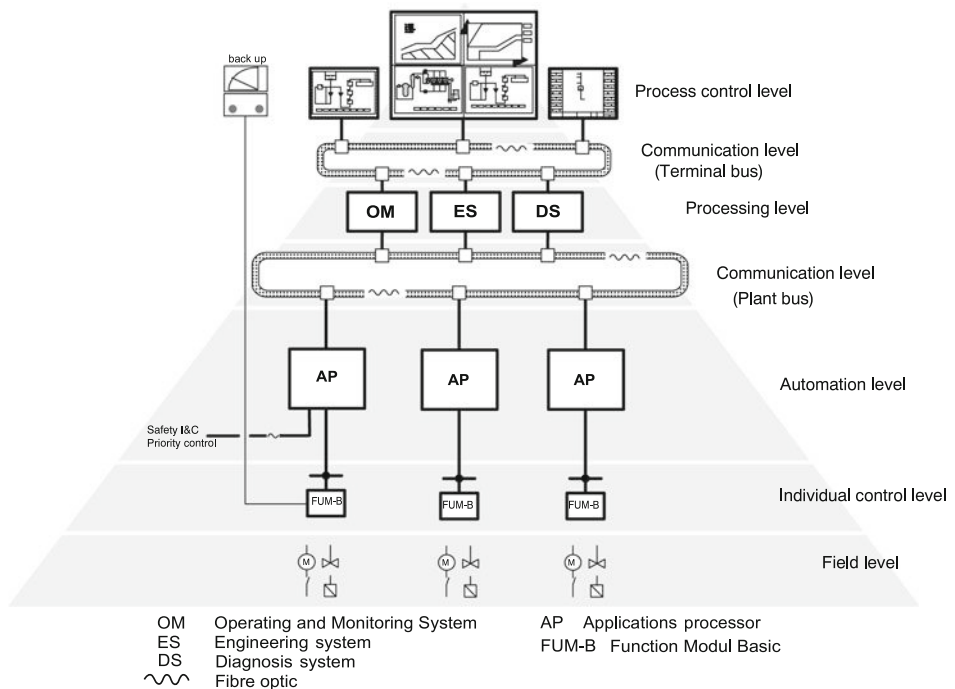

- Reactor trip system (reactor scram);
- Reactor power limitation system;
- Reactor and unit power control system;
- Monitoring, control, and diagnostics system;
- I&C safety system;
- Engineered safety feature actuation system (ESFAS);
- Level and pressure control systems in individual unit equipment.

A simplified structure of the I&C system is presented in ► Fig. 37.

Two system families TELEPERM XP (TXP) and TELEPERM XS (TXS) provide the basis of the general architecture of RP V-428 I&C systems.

TXS is mainly used to perform the functions of the reactor trip system (reactor scram and actuation of engineered safety features). It is given the highest safety qualification and integrity requirements. It is also used for such specific nuclear functions as the systems of reactor power operation including the automatic power controller.

TXP is an automated system for all other applications of the NPP that require control by automation processors and functional modules dealing with data acquisition and processing, drive actuation, and drive control. These functions cover the safety-related I&C area and normal operation I&C, which includes control of the turbine and some independent control

■ Figure 37

Simplified structure of I&C system engineered features

systems. The system performs automated functions such as consequent control, regulation, signal processing, drive monitoring, and control.

The system also actuates the Operation Monitoring (OM) I&C system to monitor the process on visual display units. The system consists of a set of processors that process signals dealing with the man-machine interface and short-time data recording. The server saves data for the OM and a number of operator stations are designed to display all the monitored functions in the VDUs. Each monitor is capable of performing all the I&C functions (control, emergency signal presentation, information display, archiving, and digital registration). The terminal bus provides communication between the processors and the operator terminals.

The traditional equipment of the man-machine interface (Mosaic panels) is used for control in case of a postulated failure of the OM system.

The I&C in the V-320 design differs from the features given below:

Before 2000, the I&C safety systems for the NPP operated with V-320 reactor were created on the basis of hardwired logic and the application of information systems only at the top level of the unit. After 2000, the structures, hardware, and software of the I&C systems are similar to V-428 design:

- Two of four logic with four sensors is applied in the I&C safety systems of V-428 design;
- Two of three logic with three sensors in each safety train is applied in the I&C safety systems of V-320 design.
- There are two sets of reactor trip system.

Main Control Room

For the operator, the main control room is the center of units' control and process monitoring via the I&C systems. It is sited in the control building.

The main control room is divided into several working areas. It gives a possibility of strict separation between the process control panels and the panels of other functions needed for NPP operation.

The operators and shift chief engineer monitor all the events on the displays. There is a possibility to overview all the system control consoles and panels in the main control area.

In case of a postulated OM system failure, the required and safety-related information is displayed in the control panels. Based on the information given, the operator can maintain the station in steady-state operating conditions for a certain period of time or shut the reactor down and bring it to a safe state. Control panels are mainly used to perform this task. The system provides the operator with all the information to monitor the systems that are important for safety and manual process control. In the case that it is impossible to realize monitoring with the OM system, the mosaic panels provide basic information to exercise control with the traditional hardware interface in the main control room with indicators, recorders, signaling system elements, and control keys. The amount of information displayed in the mosaic panel is sufficient to implement the safety functions, as a minimum.

The principles of the main control room architecture are similar for NPPs operated with both V-428 and V-320 reactor plant designs.

Electrical Systems

The electrical systems of the plant include the electric power generation, the supply system, and the power supply for the station service system.

■ **Table 18**
Electrical system performance

Parameter	Value
<i>Generator and transformer system</i>	
Main generators	
Quantity, pcs.	1
Power, MV A	1,178
Quantity of main transformers, pcs.	1
<i>Station power supply systems</i>	
Quantity and power of emergency diesel-generators, pcs. × MW	4 × 5.5
Quantity and power of station diesel-generators, pcs. × MW	2 × 5.0

NPP power output is realized at a voltage of 500 kV. NPP 500 kV switchgear is connected to the electricity grid with three 500 kV transmission lines.

The power supply redundancy of NPP station service consumers is obtained from the external power grid at a voltage of 220 kV.

The electric power generation and supply system for each NPP unit includes a turbine generator of the type TVV-1000-2UZ and a unit step-up transformer, which is connected to it.

The power supply system of the station service consists of three systems:

- Normal operation power supply system;
- Reliable normal operation power supply system;
- Emergency power supply system.

The power supply system for the reliable normal operation of the station service of each unit is broken down into two channels with similar basic components and similar functions that must be fulfilled. Each channel of the power supply system for reliable normal operation includes a diesel generator plant, storage batteries, uninterrupted power supply devices, low-voltage transformers, 6.3 kV switchgears, and AC and DC low-voltage switchgears.

The emergency power supply system of each NPP unit is broken down into four identical channels. Each channel of the emergency power supply system includes a diesel generator plant, storage batteries, uninterrupted power supply devices, low-voltage transformers, 6.3 kV switchgears, and AC and DC low-voltage switchgears (🔗 [Table 18](#)).

3.2 Main Aspects of VVER-1000 Safety

3.2.1 Safety Philosophy

In accordance with the conceptual approach to safety assurance covered in 🔗 [Sect. 2](#), throughout its development, the VVER-1000 reactor design can be attributed to the second and third Generations of nuclear reactor technology. This involved the application of the defense-in-depth principle that assigns top priority to the prevention of unfavorable events and the

mitigation of the consequences in the case of a failure to prevent them. The principle is realized through engineering and organizational measures that are specified in the regulatory documents for each of the five levels of defense-in-depth.

The tasks stated for Level 1 (prevention of anticipated operational occurrences) and Level 2 (prevention of design basis accidents) were to increase the reliability of the equipment and the systems of normal operation. These Levels were devised to improve the operational characteristics of the VVER-1000. This included an increase in the parameters that characterized the plant in comparison to VVER-440 plants.

The task stated for Level 3 (prevention of beyond-design basis accidents by safety systems) was to justify and ensure the efficiency of safety systems in coping with design basis accidents, while maintaining the single failure criterion as the basic principle of designing these systems.

The task stated for Level 4 (beyond-design basis accident management) was to justify and ensure the efficiency of the applied systems and engineering features of BDBA management. The principle of single failure criterion is not applied to BDBA, but considerations of the requirements, which stem from common-cause failures, are made.

For the Generation III designs, the task was solved through using passive systems, which were not previously applied in Generation II designs. An example of such a system is a core catcher for corium outside reactor vessel. The core catcher and other BDBA management systems were not envisaged in Generation II designs and the procedures of BDBA management are based on the application of engineering features envisaged in the design.

A conservative approach was used to justify the design solutions for their application within the normal operating conditions and the anticipated operational occurrences as before, except for DBDA/BDBA where the realistic approach was used.

The main differences in Generation II and Generation III VVER-1000 designs are described as follows:

- Application of the main equipment of reactor plant that had been improved on the basis of new regulatory and technical documents;
- Application of improved, a more economic and reliable core that eliminates any positive reactivity effects because of parameter feedback;
- Improvement of the active safety systems and the application of new passive systems of BDBA management;
- Application of new enhanced automated process control systems and diagnostics systems;
- Application of leak-before-break concept for primary pipelines larger than D_{nom} 200 mm;
- Application of spent fuel pond with compact fuel storage and improved refueling system;
- Applications of a containment system with two envelopes and a core catcher to retain corium melt.

3.2.2 Safety Systems and Distinctive Features

Protective, localizing, supporting, and control safety systems are provided for the prevention or the limitation of reactor plant damage and the localization of radioactive substances within NPP. Technical data of these systems for “Tianwan” NPP design with V-428 RP are given below. The V-320 design differs from the V-428 design, both in number of channels and in technical characteristics. The V-320 design assumes a three-channel concept of safety systems.

Protective Systems

Emergency core cooling system (ECCS) is intended to provide reactor core cooling under loss-of-coolant accidents. ECCS consists of the following subsystems:

- High-pressure emergency cooling system;
- Passive emergency core cooling system;
- Low-pressure emergency cooling system;

The ECCS consists of four similar channels being completely independent of each other.

High-pressure emergency cooling system is intended for the supply of borated water to the primary circuit under LOCAs conditions in the primary circuit and leaks from the secondary circuit. The pumps on pressure head side are connected to the cold legs of circulation loops. The start-up of pumps is realized by a control safety system (CSS) initiating system, which responds to Primary in secondary (PRISE) leak signals.

Characteristics of high-pressure emergency injection pump	
Nominal capacity, t/h	150
Pressure head at nominal supply, MPa	6.5
Maximum capacity, t/h	260
Pressure at maximum capacity, MPa	3.5
Boric acid concentration, g/kg	16
Operating temperature of medium, °C	70–95

Characteristics of low-pressure emergency boron injection pump	
Nominal capacity, t/h	800
Pressure head at nominal supply, MPa	1.5
Maximum capacity, t/h	900
Pressure head at maximum capacity, MPa	1.2
Operating temperature, °C	70–95

Passive ECCS provides a quick supply of boric acid solution into the reactor for core cooling and its flooding under loss-of-coolant accidents when primary pressure drops below 5.9 MPa.

Passive part consists of four hydroaccumulators and pipelines with valves (two check valves and two quick-acting shut-off valves in each line). Two of the hydroaccumulators are connected to the reactor vessel to supply water for core bottom flooding and the other two hydroaccumulators are used for core top flooding. The system is based on a passive principle of action. When the pressure in the reactor decreases below that in hydroaccumulator, then the check valves open and a working medium is pressed out into the reactor due to the pressure of nitrogen blanket. Nitrogen injection into the reactor is prevented by the isolation of hydroaccumulator with quick-acting valves when the level drops below the permissible value.

Technical characteristics of hydroaccumulator	
Nominal pressure, MPa	5.9
Total volume, m ³	60
Water volume in the tank, m ³	50
Boric acid concentration in water, g/kg	16
Water temperature in tank, °C	55–60

Low-pressure emergency cooling system provides supply of borated water to the primary circuit for reactor core cooling undergoing loss-of-coolant accidents after the primary pressure has decreased to 2.5 MPa.

Each channel is featured with a pump and pipelines with valves. The system consists of 4 × 100% channels. Start-up of the system is realized from a CSS initiating part and by a stepwise start-up program when there is a loss of power to the plant.

Each channel is connected to the storage tanks of borated water having 16 g/kg boric acid concentration with a volume of 1,200 m³ as well as to the containment sump.

All channels are connected to the reactor coolant system in such a way that they uniformly distribute the cooling water supply to the core top and bottom due to the following reasons:

- Two channels are connected to RCS loops so that one half of the flowrate is directed to the cold leg and the other one to the hot leg;
- Two channels are connected between two check valves, which are located on the pipelines from the hydroaccumulators. There are two hydroaccumulators per channel for core top and bottom flooding.

Emergency boron injection system is intended for injection of borated water into the pressurizer under a PRISE leak signal and for the fast transition of the reactor plant into a subcritical state under the conditions with anticipated operational occurrences that are accompanied with a failure of the reactor scram. In the latter case, the boron solution injection is provided in the cold leg of the main coolant pipeline.

The system consists of four similar and completely independent channels. Each channel of the system is connected using a pipeline connected to one out of two storage tanks with 150 m³ of borated water in each tank that has a concentration 40 g H₃BO₃/kg H₂O.

The discharge pipelines of each channel are connected to the cold legs of the main circulation loops and to the steam space of pressurizer. The connection of the system to Pressurizer (PRZ) injection line is provided automatically or manually.

Characteristics of emergency boron injection pump	
Number of pumps, pcs.	4
Type of the pump	Piston
Flowrate, m ³ /h	145
Operating temperature, °C	70
Boric acid concentration of the pumped boron solution, g/kg	40

Characteristics of the emergency feedwater pump	
Nominal capacity, m ³ /h	150
Pressure head at nominal supply, MPa	9.0
Maximum capacity, m ³ /h	275
Pressure head at maximum capacity, MPa	3.71

Emergency feedwater system is intended for providing the steam generators with feedwater under anticipated operational occurrences and design basis accidents when the feedwater supply from the main and auxiliary systems is impossible.

The system consists of four similar and completely independent channels.

Each channel is provided with an emergency feedwater pump, associated valves, and pipelines.

Each channel is connected to a storage tank of demineralized water with a volume 700 m³. The assigned temperature of demineralized water in the tanks is maintained between 25 and 35 °C.

Emergency gas removal system is intended for the removal of steam–gas mixture from the primary circuit and to decrease the pressure below the beyond design basis conditions.

The system consists of a set of valves, pipelines connected to the primary circuit equipment. With various combinations of open valves, there is a possibility of online removal of gas blanket from the reactor and the steam generator collectors into the pressurizing system and from the reactor, pressurizer, and the steam generator collectors into the relief tank. The signal on occurrence of emergency level in the reactor is generated by special indicators.

There are also overpressure protection systems installed on the primary and secondary circuit.

Localizing Systems

The localizing systems are intended to prevent or limit the spread of radioactive substances that might be released during accidents inside the NPP and into the environment.

The reactor containment is double in structure. The design value of a leak into the space between the confinement wall and the external envelope after a postulated accident amounts to 0.2% of the air mass in the building for 24 h. The design pressure of the confinement amounts to 0.50 MPa and the design temperature is 150 °C.

The sprinkler system fulfills the following functions:

- Pressure decrease in the mode of injection and recirculation after the design basis accident with the aim of maintaining the pressure in the containment at values below the design pressure;
- Post-accident decay heat removal from the containment;
- Removal of radioactive aerosols and iodines from the containment atmosphere thereby reducing their release into the environment due to the leaks through any breaches in the double containment;
- Control of water temperature in the containment sump under accident conditions with a primary coolant leak.

The system of hydrogen removal from the containment is intended to decrease the hydrogen content of the containment atmosphere after loss-of-coolant accident, which includes severe accidents. The aim of hydrogen removal is to prevent an uncontrolled hydrogen ignition, which can be the cause of loss of containment integrity.

Supporting Systems

The supporting systems are intended for the provision of safety systems with power, a working medium, and the conditions for their operation.

The basic supporting systems involve the following:

An intermediate cooling circuit system of essential consumers provides cooling of the reactor plant equipment, its auxiliary and safety systems under normal operating conditions, anticipated operational occurrences, and design basis accidents. The system provides a barrier between the auxiliary systems of the reactor plant, containing radioactive media, and service water system.

- Service water system for essential consumers removes heat from intermediate cooling circuit system of essential consumers to the ultimate heat sink under all NPP operating conditions;
- Emergency power supply system; and
- Others.

Control Systems

Control systems include

- Engineered safety feature actuation system;
- Reactor trip system.

3.2.3 Maximum Design Basis Accident

A double-ended instantaneous guillotine break of a cold leg of a circulation loop with a diameter of D_{nom} 850 mm is assumed as maximum design basis accident. (This term is not applied in the latest revisions of the Russian regulatory documents). Justification of NPP safety and the determination of design characteristics of the safety systems were realized both for this initiating event and for the others specified in regulatory documents (RDs) and the technical requirements of the operating organizations.

The leak before break (LBB) concept for the pipeline $\geq D_{\text{nom}}$ 200 is applied in the V-428 design unlike the V-320 design.

3.2.4 Severe Accidents

With the justification of meeting current regulatory documents (RD) requirements, a device for corium localization is provided in the design of NPP “Tianwan”. It is regarded as an engineered feature (measure), which is intended for the management of severe accidents where corium spreads beyond the boundaries of the reactor vessel.

The device for corium localization confines the corium and any solid fragments of the destroyed core, parts of reactor vessel, and other internals. Localization and cooling of the

corium is realized within the boundaries of the under-reactor space of the concrete cavity. During the first 24 h after the accident under NPP blackout, localization and cooling of the corium is provided without the additional makeup of cooling water from outside the containment. To provide subsequent corium confinement in the device for corium localization, replenishment of the water inventory is necessary.

For severe accident management the following systems are also provided:

- Primary circuit pressure suppression system with the help of PRZ pilot operated relieve valve (PORV);
- Emergency gas removal system from the primary equipment.

3.2.5 Seismic Design

The RP V-428 design for “Tianwan” NPP is realized with regard for the seismic loads at safe shutdown earthquake (SSE) of magnitude 8 by scale of seismic impact classification (MSK) scale and the operating basis earthquake (OBE) of magnitude 7. In the SSE case, ground horizontal acceleration amounts to -0.2 g and vertical acceleration is 0.1 g. For an operating basis earthquake, the acceleration limits are assumed two times lower than the SSE limit. RP V-320 design is realized for SSE up to magnitude 9.

The justification of the seismic stability of the reactor plant equipment of the VVER-1000 type was performed using calculation procedures and the results of experimental studies that are based on applying floor-response spectra and accelerograms. The strength calculations to check the equipment and pipeline viability are performed by considering the combination of the operational, accident, and seismic loads.

3.3 Operational Experience

As of 30.09.2009, there are 28 NPPs with VVER-1000 reactors in operation and a total operational experience of over 480 reactor-years has been accumulated.

A list of NPPs with VVER-1000 reactors is given in [▶ Table 19](#).

Nowadays, studies are under way to justify the power uprating of operating units, which are equipped with V-320 RP.

More detailed information on the design of reactor plants for NPP with VVER reactor is found in the following publications (in Russian):

4 Conclusion

VVER reactors are pressurized water reactors developed in the Soviet Union and the Russian Federation. Because of certain peculiarities (hexagonal reactor grid, horizontal steam generators, etc.) and historical reasons they are distinguished from Western PWRs. The development

of VVER reactors was started already in 1955 and the first VVER reactor of 210 MW power was commissioned at Novovoronezh in 1964. Since then, two generations of VVER-440 reactors and the family of VVER-1000 reactors were developed. In Russia and in several other countries, 32 VVER-440 units and 28 VVER-1000 units were put into operation and until now only some of them were decommissioned. Safety philosophy of VVER reactors has been gradually refined and by applying new solutions for the new reactors and also by the safety enhancement of the existing reactors the present safety level of VVER reactors is widely accepted.

Mainly due to the special alloy of fuel rod claddings, the VVER fuel has an extremely good reputation. The conservative power density of VVER-440 reactors allow for power uprating whenever appropriate fuel (higher enrichment, burnable absorber) is introduced. Selection of structural materials and the applied water chemistry generally ensure the long-term operation of the VVER units.

Application of horizontal steam generators is a further specific feature of VVER-type reactors. They ensure very acceptable conditions even in complex cases. On the other hand, the horizontal arrangement of steam generators leads to a large containment.

1 Motivations for Fast Neutron Systems

1.1 Basic Principles and Consequences

In any nuclear reactor, there is both fissile material destroyed (FD)

and produced by conversion of the fertile material (FP):

The degree of conversion that occurs in a reactor is denoted by the general term of conversion ratio, CR, which is defined as $\text{CR} = \text{FP}/\text{FD}$. If this conversion ratio is greater than 1, it is called breeding ratio, **BR**.

1.1.1 Conditions for Breeding

A nuclear reactor can be a breeder in broad neutron energy spectrum, but adequate breeding ratios can be achieved only by selecting the appropriate fertile and fissile isotopes for that spectrum.

Starting from the fission process, if

- ν is the number of neutrons produced per fission
- η is the number of neutrons produced per neutron absorbed
- α is the ratio capture/fission (σ_c/σ_f),

these parameters are related by $\eta = \nu/(1 + \alpha)$.

The necessary condition for breeding is $\eta > 2$:

- One neutron for a new fission
- One neutron for a new conversion
- x for leakages or parasitic captures

► *Figure 1* shows that for U–Pu fuel, a sufficient value of η can be obtained only with a fast neutron spectrum.

One notices that the condition for breeding is well fulfilled in fast spectrum reactor in particular for ^{239}Pu for which the value of η averaged is about 2.3.

The ► *Table 1* below provides for U5 and Pu9 compared parameters in thermal and fast spectrum.

In a fast neutron reactor, the neutrons available for conversion are 1.3 or more. In such a reactor, there is net production of fissile material that can be used to fuel another reactor. This is “breeding,” fundamental characteristic of fast neutron reactors. To understand how breeding is possible in a FR and not in a PWR, it is worthwhile to compare the balance sheet neutron as depicted in ► *Fig. 2*.

Figure 1
Neutron yield (From Waltar and Reynolds)

Table 1
Fissile isotopes comparison

Isotope Spectrum	^{235}U		^{239}Pu	
	Thermal	Fast	Thermal	Fast
α	0.17	0.29	0.36	0.26
ν	2.42	2.43	2.87	2.94
η	2.07	1.88	2.11	2.33

1.1.2 Simplified Neutronic Balance in a PWR

This assessment is presented very schematically in Fig. 2 for a conventional PWR of about 1,000 MWe, assuming that the only fissile material is ^{235}U . The numbers given must be understood as orders of magnitude. One hundred fissions of ^{235}U release about 240 neutrons, and these neutrons give rise to the following reactions:

- 100 neutrons cause 100 new fissions, maintaining the chain reaction and consuming 100 fissile nuclei,
- 70 neutrons are absorbed by capture in fertile material (^{238}U), converting them into fissile nuclei (^{239}Pu),
- 45 neutrons are absorbed by sterile capture, of which 17 are by fissile nuclei,
- 60 neutrons leaking outside the core (and will be captured by the neutron shielding).

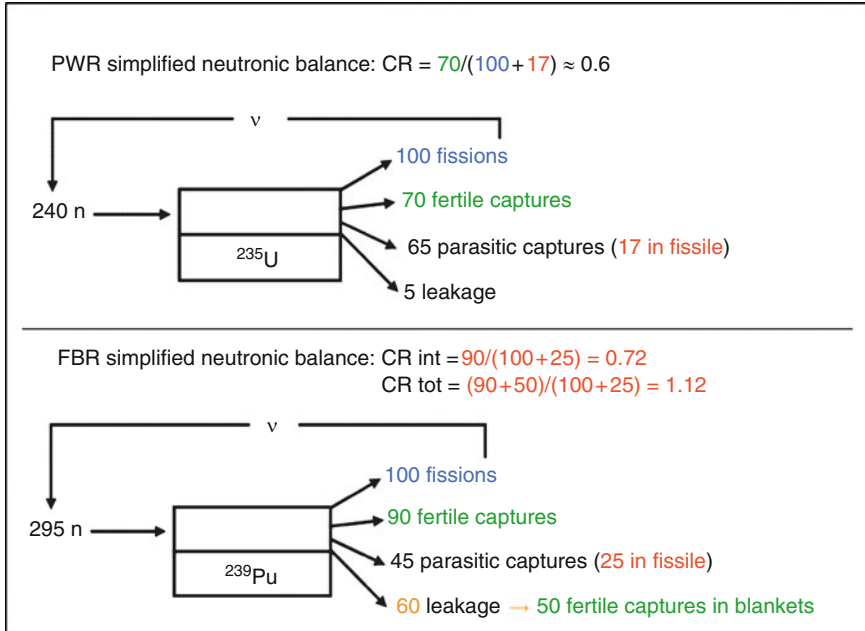

Figure 2

Comparison of neutron balance between PWR and FBR systems

1.1.3 Simplified Neutronic Balance in a FBR

This assessment is presented very schematically in [Fig. 2](#) for a FBR having power close to 1,000 MWe, very schematic, assuming that the only fissile material is ^{239}Pu .

One hundred fissions of ^{239}Pu release nearly 300 neutrons. These neutrons will yield the following reactions:

- 100 neutrons cause 100 new fissions, maintaining the chain reaction and consuming 100 fissile nuclei of ^{239}Pu
- 90 neutrons are absorbed by capture in fertile material (^{238}U) in the core of the reactor, converting them into fissile nuclei (^{239}Pu)
- 45 neutrons are absorbed by sterile capture, 25 of which are by fissile nuclei
- 60 neutrons leaking outside the core itself to the blankets, where they are, for the most part (~ 50 neutrons), absorbed by capture in fertile material (^{238}U), converting them into fissile nuclei (^{239}Pu); other neutrons (~ 10) are absorbed by sterile capture in blankets or in the neutron shielding.

1.1.4 Balances Comparison

It is in the large number of neutrons leaking out of the core to be captured by the nuclei of ^{238}U in the blankets that we find the possibility of breeding in the FBR.

That is demonstrated by calculating the conversion rate (or regeneration) in the two preceding examples which, despite their schematic nature, are sufficiently representative of orders of magnitude.

It is easy to find

- $CR = 70/(100 + 17) \approx 0.6$ in PWR
- $CR \text{ (internal)} = 90/(100 + 25) = 0.72$ in FBR core only
- $CR \text{ (total)} = (90 + 50)/(100 + 25) = 1.12$ in FBR core and blankets

We may therefore conclude that

- The rate of regeneration of the core itself a FR is certainly higher than the conversion ratio of a PWR of equivalent power but it remains less than 1 in this example.
- It is thanks to the blankets that a FR can breed.

In relation to these conclusions, two points must be underlined:

- Surrounding the core of a PWR with a blanket does not significantly change its conversion ratio due to the low number of neutrons leaking out of the core.
- It is relatively easy to modulate the breeding ratio of a FBR, for example, by changing the thickness of the blankets and therefore, the number of neutrons that are captured, to modulate the breeding ratio of a FBR.

1.2 Effective Utilization of Resources

The Nuclear Energy Agency has published the state of reserves and resources of uranium with different levels of cost and certainty (► [Table 2](#)). However, there is a slight confusion on the quantity of reserves (some resources) and resources (which are assumed or very possible). However, the “proven” reserves announced by the NEA can increase or decrease substantially depending on the year.

■ **Table 2**

State of reserves and resources of uranium

Reserves and resources in 2006	Uranium cost	Uranium quantity (kt U)	Amount (kt U)
RAR: Resources reasonably assured (reserves)	<40 \$/kg U	1,947	1,947
	40–80 \$/kg U	696	2,643
	80–130 \$/kg U	654	3,297
Inferred resources	<40 \$/kg U	799	4,096
	40–80 \$/kg U	362	4,458
	80–130 \$/kg U	285	4,743
To discover, predicted	<80 \$/kg U	1,700	6,443
	80–130 \$/kg U	819	7,262
To discover, speculative	<130 \$/kg U	4,557	11,819
	Unknown cost	2,979	14,798

Uranium world reserves (3.3 Mt) and resources (11.5 Mt) are estimated to be about 15 Mt or about 150 Gtoe. At the rate of current global consumption (0.6 Gtoe/year) and assuming the use of water reactor cycles opened, reserves and resources represent about 250 years of production.

The major trend that emerges by 2050 in terms of primary energy needs is a strong growth in primary energy needs that could rise from 9.8 Gtoe in 2000 to almost 15 Gtoe in 2020. Afterward, there is more uncertainty, but then, it might rise from 18 to 40 Gtoe in 2050 (which would mean doubling or quadrupling).

A possible scenario of the contribution of various energy sources to world consumption of commercial primary energy fits in perfectly with the WEC 98 projections for the years of 2000/2100, corresponding to the median doubling of world commercial energy consumption (~20 Gtep). The assumption was made that

- Growth in energy demand will be linear between 2010 and 2050.
- Nuclear power should contribute to the adjustment in the application, leading to increased production of nuclear power from 0.6 to 4 Gtoe/years between 2000 and 2050.

In this context, the pressure resulting from a growing demand and linked to strong constraints on fossil fuels (USA and China's heavy dependence on coal; USA and Europe's dependence on oil and gas) should lead to the relaunching of nuclear plant construction in countries possessing nuclear technology and to the development of this same technology in others.

The unavoidable steady reduction of economically exploitable resources of natural uranium will contribute to reliance on nuclear energy for sustainable development and cause nuclear energy to play a heightened role in the future, a point of view which is feasible on a more or less long-term basis. Only through the exploitation of fertile material and, therefore, through the use of fast neutron reactors can this be implemented. With fast neutron reactors, the only reserves ^{238}U , currently stored as tails (tails represent the depleted ^{238}U , which remains after completion of the enrichment process) from enrichment plants, allows for increased energy reserves up to a factor of about 50 in comparison to the current light water reactor technology. Therefore, fast reactors are the key to an efficient use of uranium resources.

1.2.1 Uranium Resources and Breeding

While these long-term considerations are rather clear, the near-term considerations that govern the timing for the introduction of a commercial FBR and the ensuing strategies are more complex for the transition to that FBR or to an FBR-LWR mix. Since fast reactors have to be loaded initially with plutonium produced by light water reactors of current technology, the availability of plutonium determines the maximum rate at which fast reactors can be introduced and the nuclear energy that can be provided.

An initial assessment of energy production has been formulated with the following assumptions:

- All uranium is used in LWRs
- LWRs have a lifespan of 60 years,
- Plutonium produced by LWRs is used in FBRs

To maximize the nuclear contribution, the use of FBRs is necessary. For example, an assessment with the optimistic assumption of a breeding gain of 0.2 and a doubling time of 50 years would lead to a power greater than 6 Gtoe/year in 2050.

1.3 Flexible Use of Actinides

Fast reactors play a unique role in the actinide management mission because they operate with high energy neutrons that are more effective in fissioning transuranic actinides. In contrast, thermal reactors extract energy primarily from fissile isotopes; a thermal spectrum also leads to the generation of higher actinides that complicate subsequent recycling. Fast reactors can operate in three distinct fuel cycle roles. A conversion ratio (the conversion ratio is defined as the ratio of the transuranics production rate to the transuranics destruction rate, whereas the breeding ratio is a similar ratio for the fissile material) less than 1 (“transmuter” mode) means that there is a net consumption of transuranics. Here, “transmute” means to convert transuranics into shorter-lived isotopes in order to reduce long-term waste management burdens. A conversion ratio close to 1 (“converter mode”) provides a balance in transuranic production and consumption. This mode results in low reactivity loss rates with associated control benefits. A conversion ratio greater than 1 (“breeder mode”) means that there is a net creation of transuranics. This approach allows the creation of additional fissile materials, but requires the inclusion of extra uranium in the SFR and fuel cycle. An appropriately designed fast reactor has the flexibility to shift between these operating modes and the desired actinide management strategy will depend on a balance of waste management and resource extension considerations.

1.4 Waste Minimization

Owing to their high level of neutron flux (10 times higher than that of a PWR) and to the ratios of capture cross sections on fission cross sections of major actinides more favorable in the fast spectrum (by a factor of 10), FBRs are the best tool for the transmutation of actinides in reactor.

Two modes of waste incineration have been considered:

- The homogeneous mode wherein actinides to be transmuted (Np, Am, Cm) are mixed with standard fuel in limited quantities (a few percent), thereby “diluting” the impact on the reactor and the fuel cycle facilities.
- The mixed mode in which the elements are separated from the fuel and placed in a limited number of devices is known as “targets.” The impact on all posts in the fuel cycle is then increased substantially but for a reduced flow of materials.

In order to establish the scientific feasibility of these different modes, radiation experiments are now being carried out in France in the PHENIX reactor. In conjunction with the actinide management, the SFR technology offers the means to reduce waste generation by features such as improved thermal efficiency, greater use of fuel resources, and the development of superior waste forms for the SFR closed fuel cycle. It is also obvious that SFR nuclear power contributes to the reduction of the greenhouse effect (CO₂ emissions) compared to electricity generation using fossil fuels. Efforts will also be made to achieve reductions in the amount of waste generated from the operations and maintenance and the decommissioning of system facilities and the amount of waste migrating into the environment.

There are potential benefits of a closed fuel cycle based on fast reactors for waste management. It is easier to transmute TRU or MA in a fast reactor core, and there is less impact on the fuel cycle (e.g., at fuel fabrication). It is then possible to have a sustainable close cycle, with reduced burden on a deep geological storage (🔍 Fig. 3). Certain elements (plutonium, americium, cesium, strontium, and curium) are primarily responsible for the decay heat that can cause repository temperature limits to be reached. Large gains in repository space are possible

Figure 3
Repository space requirements

Figure 4
Benefits of closed fuel cycle

by processing spent nuclear fuel to remove those elements (► Fig. 4). Related to treatment of recovered elements, cesium and strontium can be stored separately for 200–300 years and plutonium, americium, and curium can be recycled for transmutation and/or fission by irradiation in fast reactors. These advantages had been envisaged as early as in 1946 by Enrico Fermi, who demonstrated the breeding principle and stated that “the people who will develop SFR technology will lead the world in the future.” Further, in 1951, the world’s first nuclear-generated electricity is EBR-1. In 1964, at the third Geneva Conference, it was stated that “full-sized SFR stations will probably be commissioned in the early 1970s.” Against this backdrop, it is an unfortunate scenario that the SFR development has gone to standstill for many years. It is comforting now that the importance of SFRs is being felt by various countries and systematic plan of actions for the future growth have been formulated.

2 SFR History and Current Projects

2.1 Overview

Ever since the early research on nuclear energy in the 1940s and the 1950s, thermal neutron reactors and fast neutron reactors were studied and experimented at the same time. The first electricity generation produced by a nuclear reactor occurred in 1951 and it was achieved by EBR1, a fast neutron reactor. Even as far back as these times, scientists (In 1945 Enrico Fermi said, “The country that first develops a breeder reactor will have a great competitive advantage in atomic energy.) and even politicians understood that breeding could provide humanity, at least partially, with a solution to the energy problem, a solution that now in the perspective of the Generation IV reactor, we call “sustainable.”

FBRs have been built and operated in USA, UK, France, the former USSR, India, and Japan. An experimental FBR in Germany was built but never operated. As of now, three SFRs are under construction in China, one in India, and one in Russia.

But even if, as we have seen, research on fast neutron reactors and on thermal neutron reactors started at the same time, it must be pointed out that only a dozen fast neutron reactors have been built in the world as compared to hundreds of thermal neutron reactors. This is due, of course, to the fact that the long-term benefit of FBRs associated with the economy of resources is counterbalanced by the short-term additional costs involved in the use of a sodium coolant, which requires a more robust technology.

The development of FBRs could be considered only through different stages: first, the attainment of purely technical targets (the mastery of plutonium and sodium) and afterward, the validation of design options that will lead to industrial and economic solutions. The same steps have been observed in the various countries involved in the development of FBRs. Basically, they can be summarized in the following sequence:

- A preliminary step aimed at demonstrating its physical feasibility.
- A stage involving the building of experimental reactors to solve basic technical problems.
- A stage consisting of the construction of a demonstration reactor for testing designs.
- A final stage involving the creation of prototype power reactors.

The preliminary step includes the Clementine reactor in USA and BR2 in USSR, both are very low power and mercury-cooled and then, the first piles representing the technology of fast neutron reactors: the EBR1 in USA in 1951 and the BR5 in USSR in 1958. The next step, that of experimental reactors of significant size, included a set of achievements that runs from the DFR (70 MW) begun in 1959 in UK to the CEFR in China whose divergence is scheduled for 2010. ➤ [Table 3](#) below lists these existing reactors in the world.

These reactors had essentially twofold aims: On the one hand, their purpose was to provide experience in the operation of sodium-cooled reactors on a sufficient scale, and on the other, they were designed to allow the development of a fuel element capable of withstanding high burnup.

The next phase is that of demonstration reactors. These reactors are electricity generators with a power ranging between 100 and 600 MWe, and their purpose is to prepare for the introduction of high-power reactors by validating their concepts. ➤ [Table 4](#) lists these types of reactors in the world.

■ Table 3

Small reactor in the world

	Name	Thermal power (MW)	Criticality	Country	Status
Prelim.	Clementine	0.02	1946	USA	Stopped 1952
	EBR-I	1.4	1951	USA	Stopped 1963
	BR 1		1955	Russia	
	BR 2	0.2	1956	Russia	Stopped 1957
	BR 5–BR 10	5/10	1958/1973	Russia	Stopped 2002
	LAMPRE	1	1961	USA	Stopped 1965
Experimental	DFR	75	1959	UK	Stopped 1977
	EBR-II	60	1963	USA	Stopped 1993
	EFFBR	200	1963	USA	Stopped 1972
	RAPSODIE	24/40	1967/1970	France	Stopped 1983
	BOR 60	60	1968	Russia	Running
	SEFOR	20	1969	USA	Stopped 1972
	KNK1–KNK2	60	1972/1977	Germany	Stopped 1991
	JOYO	50	1977	Japan	Running
	FFTF	400	1980	USA	Stopped 1992
	FBTR	40	1985	India	Running
	PEC	120		Italy	Given up
	CEFR	60	2010	China	Under construction

■ Table 4

Medium size reactors in the world

Name	Electrical power (MWe)	Criticality	Country	Status
EFFBR	100	1963	USA	Stopped 1972
BN 350	150	1972	Kazakhstan	Stopped 1993
Phenix	250	1973	France	Stopped 2009
PFR	250	1974	UK	Stopped 1994
BN 600	600	1980	Russia	Running
SNR 300	300		Germany	Given up
Monju	280	1992	Japan	To restart
CRBR	350		USA	Given up
PFBR	500	2011	India	Under construction

The last phase involves the construction of high-power prototype reactors, between 750 and 1,500 MW, in order to achieve economic competitiveness. The first such project was the Super-Phenix reactor designed and built by a European consortium composed of France, Germany, and Italy. The reactor was connected to the grid in 1985 and shut down in 1998; the operation history of this reactor is detailed in the specific paragraph pertaining to Europe.

Other projects undertaken include the DFBR in Japan, the ALMR in USA, the SNR2 in Germany, the CDFR in UK, and then the EFR again within the framework of a European consortium, but these projects have all been abandoned. The reasons for that are not technical, but they are mainly due to a rise of hostility to nuclear energy rise in western nations and a lack of economic competitiveness demanding the development of fast reactor technology.

Today only the BN800, in Russia, is under construction but in recent years we have witnessed a renewed interest in nuclear reactors for the sake of saving natural resources. This corresponds to the launching of the Generation-4 International Forum. Such an event has led several countries to boost research on fast reactors, not only in USA, Japan, and France but also in Europe under the aegis of the European Commission, in Korea, and in China. It should be noted that in India, this technology has never been abandoned.

2.2 USA

On December 20, 1951, the fast reactor, EBR-I (Experimental Breeder Reactor-1) at the Idaho National Laboratory in Idaho Falls, produced enough electricity to power four light bulbs and the next day it produced enough power to run the entire EBR-I building. This was a milestone in the development of nuclear power reactors. The next generation experimental breeder was EBR-II (Experimental Breeder Reactor-2), which went into operation in 1964 and operated until 1994. It was designed to be an “integral” nuclear plant, equipped to handle fuel recycling onsite. It typically operated at 20 MW out of its 62.5 MW maximum design power and provided the bulk of heat and electricity to the surrounding facilities. The world’s first commercial LMFBR and the only one ever built in USA was the 94 MW Unit 1 at the Enrico Fermi Nuclear Generating Station. It was designed by Dow Chemical and Detroit Edison in a joint effort as part of the Atomic Power Development Association consortium. Groundbreaking began in Lagoona Beach, Michigan (near Monroe, Michigan) in 1956. The plant went into operation in 1963. However, it was shut down on October 5, 1966 due to high temperatures caused by a loose piece of zirconium that was blocking the molten sodium coolant nozzles. Partial melting damage to six subassemblies within the core was eventually found. (This incident provided the basis for a controversial book written by investigative reporter John G. Fuller entitled *We Almost Lost Detroit.*) The zirconium blockage was removed in April 1968, and the plant was ready to resume operation by May 1970, but a sodium coolant fire delayed its restart until July. It subsequently ran until August 1972 when its operating license renewal was denied.

The Clinch River Breeder Reactor Project was announced in January 1972. A government/business cooperative effort, construction proceeded fitfully. Funding for this project was halted by Congress on October 26, 1983. The Fast Flux Test Facility, first critical in 1980, is not a breeder but is a sodium-cooled fast reactor, which is in cold standby, with the possibility of restarting it for use in an international framework, currently under discussion (GNEP, GEN-IV).

2.3 Russia

The Soviet Union built a series of fast reactors, the first being mercury-cooled and fuelled with plutonium metal. Later plants were sodium cooled and fuelled with plutonium oxide.

BR-1 (1955) in Obninsk was 100 W (thermal) and fuelled with plutonium metal. It was upgraded in 1956 and renamed BR-2 at 100 kW. BR-2 was then replaced by BR-5 (5 MW) which attained criticality in 1958. It was the first reactor in the world to be fuelled with plutonium oxide. This reactor was operated until 1964 and then reloaded with a uranium carbide core. In 1972 the reactor was upgraded again and renamed BR-10 as 10 MW reactor fuelled with plutonium oxide. This reactor was shutdown in 2002.

BOR-60 (first criticality 1969) was a 60 MW reactor and its construction started in 1965 in Dimitrovgrad. This reactor was initially built as a Material Test reactor (MTR), but steam generators were added in 1970 and 1973 in order to provide 12 MW of electric power.

BN-350 (1973) was the first full-scale Soviet FBR. Constructed in Chevtchenko on the Mangyshlak Peninsula in Kazakhstan and on the shores of the Caspian Sea, it supplied 130 MW of electricity plus 80,000 tons/day of desalinated fresh water to the city of Aktau. Its total output was regarded as the equivalent of 350 MW, hence the designation. This loop-type reactor was fuelled with UO_2 .

The construction of the pool-type reactor BN-600 was completed in 1979 and criticality was achieved in 1980. This is a 1,470/600 MW reactor with a uranium core that is still in operation today.

Today, a larger plant, BN-800 (800 MW) is under construction at Beloyarsk.

2.4 Europe

2.4.1 France

In France, the first chapter in the history of fast reactors was the construction of the “Rapsodie” reactor (1962–1966) that used sodium as a coolant and mixed oxide fuel. The operation of Rapsodie was excellent from 1967 to 1978 (initially at 24 MW, it was upgraded to 40 MW in 1971). Rapsodie was an outstanding irradiation tool, allowing the demonstration of oxide fuel capabilities and an initial screening of the core structural material. However, from 1978 to 1982, the detection of primary sodium aerosols in areas surrounding the primary circuit hampered its operation. The reactor was finally shut down in April 1983, after several end-of-life tests; since 1983, the reactor has been undergoing decommissioning. The present strategy, defined in 2004 consists of two main steps: a cleansing period from 2004 to 2008 followed by a dismantling period lasting from 2008 to 2013.

The prototype fast reactor, Phenix (a pool-type reactor, 250 MW) went into commercial operation in 1974. Fifty one cycles were run, and more than 20 billion kWh were produced. Since the initial design life of the reactor was 20 years, the reactor should have been shut down in 1994, but in the mid-1990s, the role of the reactor changed: it was to be used as an irradiation tool acting as a support to the R&D transmutation programme of the CEA within the framework of the 1991 French law relating to long-lived radioactive waste management. This new objective required an extension of the planned reactor lifetime. A large refurbishment programme was defined and carried out in two phases within 6 years: the first phase lasting from 1994 to 1997

and the second from 1999 to 2003. These two phases were separated by one operating cycle and the plant resumed power at the end of 2003 and operated at its nominal power throughout 2004 and 2005. Five operating cycles (representing 600 EFPD) have been scheduled to carry out the experimental irradiation programme until the final shutdown of the plant in 2009. Preliminary studies on one end-of-life test and expertise programmes were performed and proposed to the international scientific community in the prospect of SFR development.

Construction of the SuperPhenix plant, in cooperation with Germany and Italy, lasted from 1977 to 1985. Full power was reached in 1986 and until the end of 1996, the plant operated for 4.5 years at different levels of power, with scheduled periods of maintenance and tests. It remained shutdown for 4.5 years, although still in an operational state, due to administrative procedures underway and a little more than 2 years went by following technical incidents and repairs. The last operating year was remarkable; the complete programme of overall qualification by successive stages of 30%, 60%, and 90% nominal power progressed without difficulty. After an interruption of activity of more than 5 years, all the parameters were found to be normal. Following the declaration made to the French National Assembly on June 19, 1997, the French government decided on February 2, 1998, to shut down the SuperPhenix plant permanently. The decree of December 31, 1998 finalized the immediate and permanent shutdown of the plant.

2.4.2 UK

The UK fast reactor programme was conducted at Dounreay, Scotland from 1957 until the programme was cancelled in 1994. Two fast reactors were built along with fabrication and reprocessing facilities for fuel, also collocated. The Dounreay Fast Reactor (DFR) achieved its first criticality in 1959 with uranium metal fuel. It used NaK coolant and produced 14 MW of electricity. This was followed by the sodium-cooled 250 MWe Prototype Fast Reactor (PFR) in the 1970s. The PFR, which was the first reactor with a $\text{UO}_2\text{-PuO}_2$ core, was shut down in 1994 as the British government withdrew major financial support for nuclear energy development.

2.4.3 Germany

Germany built two FBRs, but both were closed in 1991 without the larger of the two ever having achieved criticality. The KNK-II was converted from a thermal reactor, called KNK-I, which had been used to study aspects related to technology of sodium cooling. KNK-II first achieved criticality as a fast reactor in 1977 and produced 20 MWe. The outer driver core was uranium oxide, and the central test section was loaded with mixed oxide fuel.

Construction of the prototype plant 300 MWe SNR-300 at Kalkar in North Rhine-Westphalia was completed in 1985, but owing to political pressure, it was never operated. The plant was maintained and staffed until a decision to close it was finally made in 1990. It has since been decommissioned. Today, it houses an amusement park (Wunderland Kalkar).

SNR2 was a power reactor project of 1,300 MWe, which, of course, was abandoned as was the case of SNR-300.

2.4.4 Italy

In Italy, the PEC reactor (“Prova Elementi di Combustibile,” i.e., Fuel Element Test Facility) was an experimental, sodium-cooled fast reactor specially designed to study the behavior of fuel elements under thermal and neutronic conditions comparable to those expected in commercial power plants. The plant was erected at Brasimone, an ENEA (Since 1983, CNEN changed its name in ENEA.) research center located about 60 km from the city of Bologna. The first design studies, which began in 1964, were performed by the CNEN (Comitato Nazionale dell’Energia Nucleare). In 1973, the project progressed considerably, thanks to different agreements (Agreement between the CEA and CNEN on fast reactor R&D; the setting up of the NERSA Company with the participation of ENEL, the public Italian Utility; an agreement between NOVATOME and NIRA for the design and construction of SPX1, etc.). However, after the Chernobyl incident, the development of the PEC reactor was dropped, even if the state of the work was equal to 70% completion with an investment of about 1.5 billion euros. At the same time, Italy was working in fast reactor component development under a cooperative agreement signed with France and Germany for the SuperPhenix design and construction.

2.4.5 Belgium, Netherland

Belgium and the Netherlands have joined with Germany in a series of FBR development projects, namely, the SNR-300 and the SNR-2.

2.4.6 Multinational Project: EFR

In Europe, the construction of fast reactors of increasing size under the national development programs in France, Germany, and the UK secured a solid foundation on which to base the development of the combined European expertise on fast reactor technology.

The EFR program was based on the solid expertise in Europe on fast reactor technology and on the wide knowledge developed by the associated R&D. The main milestones concerning the fast reactors development and construction in Europe are recalled:

- Experimental reactors: DFR in the UK, Rapsodie in France, KNK II in Germany
- Prototype power plants (250–300 Mwe): Phénix in France, PFR in the UK, SNR 300 in Germany
- Industrial power plant (1,200 Mwe): Superphénix

The initial major objectives for initiating a new industrial concept were based on:

- An up-to-date safety level comparable with that of future LWR, leading to make easier licensability without significant design changes
- Potentially competitive electricity, generating costs compared to future LWR

Taking into account on one hand, the high flexibility of fast reactors regarding to the fuel utilization (breeding, self-sustaining, transmutation, or incinerating) and on the other hand, the important feedback (safety and economics) of the Superphénix operating experience, three

other objectives were added in order to furthermore enhance competitiveness as regard to nuclear acceptance and proliferation risk minimization:

- Demonstration that a high load factor and increased lifetime (60 years) could be achieved with up-to-date operating and safety standards, notably as regard to severe accidents
- Progress concerning the capabilities for In-Service Inspection and Repair
- Flexibility related to the fuel cycle and notably possible integration of Plutonium burner core designs or high-level radioactive wastes incineration

The whole project was spread in three phases over 10 years: conceptual (technical and economical) design, concept validation (design support by R&D, leading to improvements for safety or economics), and design consolidation (consistent design).

2.5 Japan

Nuclear power accounts for about 30% of the electricity generated. From 1961 to 1994, there was a strong commitment to FBRs, but in 1994, the FBR commercial deployment was set out to 2030, and presently, commercial FBRs are envisaged by 2050.

2.5.1 Joyo

Japan's first experimental FBR, Joyo is located at Japan Atomic Energy Agency's O-arai Research and Development Centre. It became critical in 1977 with the MK-I breeder core. The objective of the reactor is to conduct irradiation tests on fuel and materials, carry out experiments, gain operating experience, and validation of innovative technology for development of future FBR. The Joyo has been supporting the development of sodium-cooled fast reactors by providing valuable irradiation testing of advanced fuels and materials, and improvements in fast reactor safety and operation. The first major upgrade of Joyo to the 100 MWt MK-II irradiation test bed was successfully operated from 1982 to 2000. Work began in 2000 on the 140 MWt MK-III program, which was the second major upgrade to improve the irradiation capability of Joyo. Start-up test of the MK-III core was conducted from June to October 2003. The rated power operational cycle of MK-III core was started in May 2004. The Joyo MK-III core is going to serve as a powerful irradiation test facility for the fast reactor development needs of Japan and the world.

2.5.2 Monju

Monju is a prototype reactor designed to generate 280 MWe (714 MWt), fueled with Pu-U mixed oxide and cooled by liquid sodium (3 loops), with a rated capacity of 714 MWt/280 MWe. It is located in Tsuruga, Fukui Prefecture. The core of Monju and its sodium equipments were designed based on experience in Joyo as well as R&D results which had been obtained mainly at the O-arai Research and Development Center. The objectives of the development of Monju are to demonstrate the performance, reliability, and safety of an FR power plant; to establish the sodium handling technology during its design, fabrication, construction, operation, and

maintenance of the plant; and to contribute to technology development for commercialized FR cycle systems in Japan and world-wide. Monju successfully achieved its first criticality in April 1994 and supplied electricity to the grid initially in August 1995. However, the preoperational test of the plant was abruptly interrupted by a sodium leak accident in the secondary heat transport system in December 1995 during a 40% power operation test. After carrying out the investigation and the comprehensive safety review for 2 years and the necessary licensing procedure, the permit for plant modification (countermeasure against potential sodium leak, etc.) was issued in December 2002 by the Ministry of Economy, Trade, and Industry (METI). JAEA have started preparatory work for modification, after given prior approval by the local governor of Fukui in February 2005, and the main modification work is in progress since September 2005. The function test for modified systems has been in progress since December 2006. Sequentially the comprehensive system function test, considering the long period of plant shutdown, is scheduled in the near future. The restart (criticality) is expected to be achieved in 2010.

2.5.3 Rapid-L

A small-scale design developed by Toshiba Corporation in cooperation with Japan's Central Research Institute of Electric Power Industry (CRIEPI) and funded by the Japan Atomic Energy Research Institute (JAERI) is the 5 MWe, 200 kWe Rapid-L, using lithium-6 (a liquid neutron poison) as control medium. It has 2,700 fuel pins of 40–50% enriched uranium nitride integrated into a disposable cartridge. The reactivity control system is passive, using lithium expansion modules (LEM), which give burnup compensation, partial load operation, as well as negative reactivity feedback. As the reactor temperature rises, the lithium expands into the core, displacing an inert gas. Other kinds of lithium modules are also integrated into the fuel cartridge, to facilitate shut down and start up of the reactor. Cooling is by molten sodium, and with the LEM control system, reactor power is proportional to primary coolant flow rate. Refuelling would be carried out every 10 years in an inert gas environment. Operation would require no skill, due to the inherent safety design features.

2.5.4 L-4S “Nuclear Battery”

The Super-Safe, Small & Simple – 4S “nuclear battery” system is being developed by Toshiba and CRIEPI in Japan in collaboration with STAR work in USA. It is Pb–Bi cooled version of 4S conceived under GEN IV systems. It uses sodium as coolant (with electromagnetic pumps) and has passive safety features, notably negative temperature and void reactivity. The whole unit would be factory-built, transported to site, installed below ground level, and would drive a steam cycle. It is capable of 3 decades of continuous operation without refuelling. Metallic fuel (169 pins, 10 mm diameter) is uranium–zirconium or U–Pu–Zr alloy enriched to less than 20%. Steady power output over the core lifetime is achieved by progressively moving upward an annular reflector around the slender core (0.68 m diameter, 2 m high). After 14 years, a neutron absorber at the center of the core is removed and the reflector repeats its slow movement up the core for 16 more years. In the event of power loss, the reflector falls to the bottom of the reactor vessel, slowing the reaction, and external air circulation gives decay heat removal. Both 10 and 50 MWe versions of 4S are designed to automatically maintain an outlet coolant temperature of

510 °C – suitable for power generation with high temperature electrolytic hydrogen production. The design has gained considerable support in Alaska and toward the end of 2004, the town of Galena granted initial approval for Toshiba to build a 4S reactor in that remote location. A pre-application NRC review is being sought with a view to a demonstration unit operating by 2012.

2.5.5 Commercial Fast Reactor Development Program

The feasibility study on commercialized fast reactor (FR) cycle systems was initiated in July, 1999 with an initial two-year period of study (Phase I), and followed by a five-year period of study (Phase II). The Phase II final report was compiled in March, 2006, and the feasibility study was finalized at the end of March, 2006. A wide range of technical options have been evaluated to select several promising concepts as candidates for the commercialization. JAEA focuses on the R&D for commercialization as “Fast Reactor Cycle Technology Development” (FaCT) project and accelerate the R&D of FBR Cycle. According to current knowledge, sodium-cooled fast breeder reactor (MOX fuel) + advanced aqueous reprocessing + simplified pelletizing fuel fabrication were considered as the main concept to be implemented in the future because these were the most viable for commercialization facility. The sodium-cooled fast breeder reactor (metallic fuel) + metal electrorefining reprocessing + injection casting fuel fabrication were secondary concept because these were viable for commercialization facility but relatively uncertain in terms of social and technical aspects. JAEA aims at getting the conceptual design to meet the development goal and design requirement by concretizing conceptual design to judge the viability of the innovative technology of main concept by 2015.

In order to satisfy the high design requirements mentioned above, JSFR of 1,500 MWe with advanced loop type MOX fueled core has been conceived. Totally 13 innovative technologies were identified and included in the current design. The roadmaps of their R&D have been developed. They are categorized into three areas: for economic competitiveness, enhancement of reliability, and enhancement of safety. Advanced loop type design has a higher potential for drastic reduction of the plant materials compared with pool-type design. The 10 m diameter reactor vessel with 1,500 MWe core and simple and large capacity two-loop heat transport system are considered as major contributors for the reduction of the material amount. R&D items unique to the advanced loop type design are four: two-loop piping system, high chromium ferritic steel, pump-integrated IHX, and hot vessel. Technical feasibility has been already obtained for these items and activities related to validation of the technologies are in progress. The current and future SFRs in the Japanese program are shown in  Fig. 5 and technical data are given in  Table 5.

2.6 India

A survey by the Department of Atomic Energy forecasts electricity growth rate of 6.3%/y till the year 2020 and about 4.0%/y from 2020 to 2050. Nuclear share is planned to be about 25% by 2050. The growing energy demand would have to be met through fast breeder reactors and thorium fuelled reactors, in combination with other energy resources, taking into account sustainability and environmental issues. To achieve this, three stage programme is being followed ( Fig. 6). In the first stage, Pressurized Heavy Water Reactors (PHWRs) are employed which

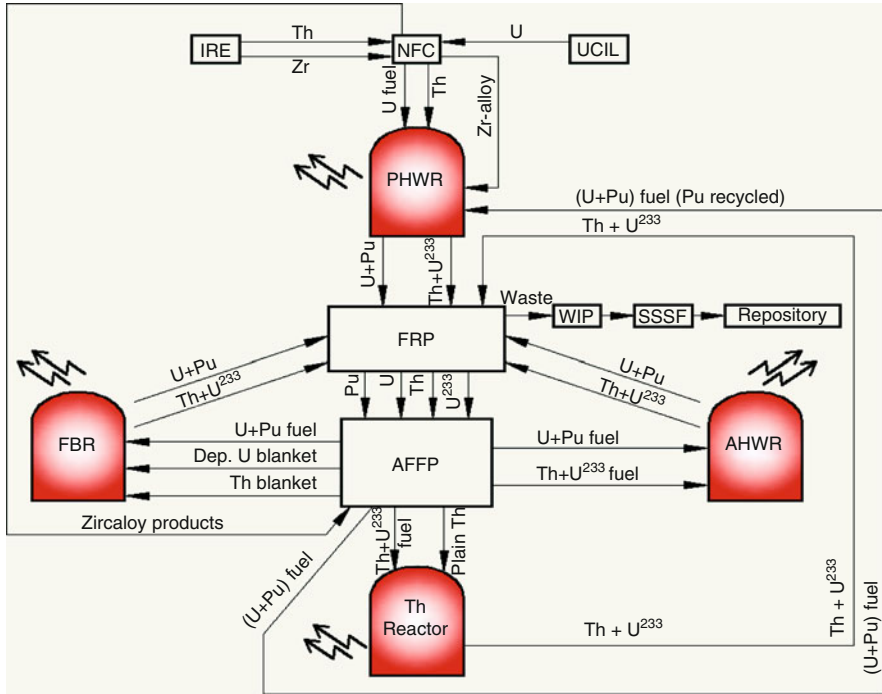

■ **Figure 5**
Fast reactor in Japanese program

Technical data on the current and future SFRs in Japan

	Monju	DFBR	JSFR
Output power	280 MWe/714 MWt	670 MWe/1,600 MWt	1,500 MWe/3,570 MWt
Number of loops	3	3	2
Primary coolant temperature (°C)	529/397	550/395	550/395
Secondary coolant temperature (°C)	505/325	520/335	520/335
Main steam temperature/pressure (°C/MPa)	483/12	495/17	495/19
Core fuel	MOX	MOX	MOX
Burn up (driver fuel discharge average) (GWd/t)	80	90	150
Breeding ratio	1.2	1.05–1.2	1.03–1.1
Cycle length (months)	6	15	26

will use natural uranium resource. PHWR is currently in commercial phase with 17 PHWRs in operation including 2 Boiling Water Reactors (BWRs), generating 4,120 MWe. Five reactors are under construction, which includes 2 VVERs. Liquid sodium cooled fast breeder reactors (FBRs) form the second stage of the nuclear power programme. Plutonium (Pu) generated from PHWRs would be used as the fuel with a closed fuel cycle programme. Subsequently, thorium resource will be utilized in the third stage reactors which will be either thermal or fast breeders.

The seed for fast reactor programme in India was sown through the establishment of a research center (then called Reactor Research Centre) in 1972 dedicated to the development of fast reactor technology and the decision to construct Fast Breeder Test Reactor (FBTR) at Kalpakkam. The experience gained in the construction, commissioning, and operation of FBTR as well as 390 reactor-years worldwide FBR operational experience, rich experience with

FBR : Fast breeder reactor

 NFC : Nuclear fuel complex
 UCIL : Uranium corp. of India ltd.
 WIP : Waste immobilisation plant

PHWR : Pressurised heavy water reactor
 FRP : Fuel reprocessing plants
 AFFP : Advanced fuel fabrication plants
 AHWR : Advanced heavy water reactor
 SSSF : Solid storage surveillance facility

■ **Figure 6**
Roadmap for Indian Nuclear Programme

MOX fuel, 30 years of focused R&D programme involving extensive testing and validation, material and manufacturing technology development and demonstration, peer reviews, and synergism among DAE, R&D Institutions and Industries, have provided the necessary confidence to launch a Prototype FBR of 500 MW capacity (PFBR). The reactor construction was started in 2003 and the reactor is scheduled to be commissioned by 2010. As a follow-up to PFBR, it is planned to construct two twin units of 500 MW reactors, with improved economy and safety during 2010–2020. Various elements of reactor design are being carefully analyzed with the aim of introducing innovative features toward further reduction in unit energy cost and enhancing safety in these reactors. Clear strategies have been identified to simplify the design, reduce construction time, enhance the burnup and close the fuel cycle with minimum cooling, and out-of-pile inventory, without sacrificing over all safety during entire process. It is targeted to bring down the unit energy cost by ~25%. Further, with advanced structural materials for clad and wrapper, a burnup of 25 at.% is envisaged for mixed oxide fuels.

It has been realized that for enhanced growth of fast reactors in the country, it is imperative to develop metallic fuelled FBRs, which promise a much higher breeding. A comprehensive

programme on development of metal fuelled reactor and its fuel cycle has been undertaken with the aim of introducing metal fuel in commercial FBRs by 2020. Fabrication of test fuels for irradiation in FBTR and pilot plant for pyrochemical reprocessing are the firm action plans under implementation. Directed research to develop metallic fuels for achieving high breeding ratio (1.45) and high burn up of ~25 at % is the target; based on which a spectrum of activities with synergism have been undertaken in the Department of Atomic Energy.

Figure 7
FBTR flowsheet

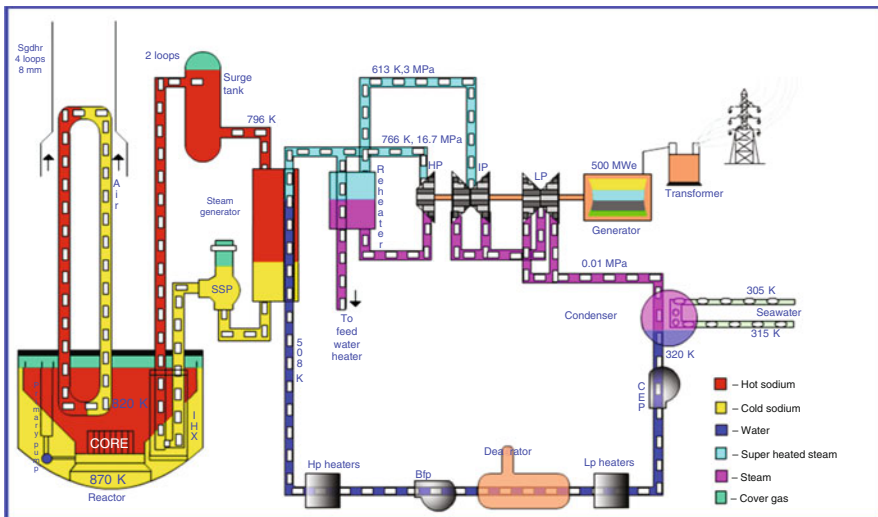

Figure 8
PFBR flowsheet

2.6.1 FBTR

FBTR is a sodium cooled loop type 40 MWt/13.2 MWe experimental reactor operating at Kalpakkam. FBTR has two primary and two secondary sodium loops and each secondary loop has two once-through, serpentine type Steam Generators (SG). The schematic sketch is shown in  Fig. 7. All the four SG modules are connected to a common steam–water circuit having a Turbo-Generator (TG) and a 100% steam Dump Condenser (DC). The first criticality was achieved in October 1985 with a small core of 22 fuel subassemblies (SA) of MK-I composition (70% PuC + 30% UC), with a design power of 10.6 MWt and peak linear heat rating (LHR) of 250 W/cm. Progressively, the core was expanded by adding subassemblies at peripheral locations. Toward increasing the core size and hence the reactor power, carbide fuel of MK-II composition (55% PuC + 45% UC) was inducted in the peripheral locations in 1996. MK-I carbide fuel has so far seen a burnup of 165 GWd/t without any pin failure. TG was synchronized to the grid for the first time in July 1997. The reactor has so far been operated up to a power level of 17.4 MWt by raising the LHR of MK-I fuel to 400 W/cm in 2002. During the recent campaign, Delayed Neutron Detector calibration experiments were carried out. Also, experiments are under way for mapping of flux at the grid plate location, accelerated irradiation of grid plate material as a part of its residual life assessment, short-term irradiation of a single pin of PFBR fuel for studying the initial restructuring and irradiation of core structural materials. PFBR test fuel irradiation would be continued to attain its target burn-up. Further, the reactor life is to be extended by 20 years to serve as an irradiation facility for the development of future fuels and core.

2.6.2 PFBR

Toward techno-economic demonstration of fast breeder reactor technology, based on the experiences gained with international FBRs, including FBTR, and comprehensive research and technology development programme in collaboration with a large number of academic and industrial organizations, a 500 MWe capacity Prototype Fast Breeder reactor (PFBR) is being established at Kalpakkam. It is a pool type reactor with two primary and two secondary loops with four steam generators per loop ( Fig. 8). It uses mixed oxide fuel with two enrichment zones (21% and 28% PuO₂), with a target burnup of 100 GWd/t, which is aimed to be increased to 150 GWd/t subsequently. Twenty percent cold worked D9 material (15% Cr–15% Ni with nano size TiC precipitates) is used for the core. SS 316 LN is the major structural material for the sodium components and modified 9 Cr–1 Mo is the material for steam generators. The sodium temperatures are 820 and 670 K for hot and cold pools, respectively. The design plant life is 40 years, with at least 75% load factor to be successively enhanced to 85%. The construction of PFBR in Kalpakkam has been started, and the reactor is planned to be commissioned in 2011. All the nuclear steam supply system components are being manufactured by the Indian Industries, based on the technology development, including in-sodium testing of relevant components over the last 2 decades.

In order to ensure comprehensive performance assessment of the components, an elaborate technology development program was carried out in which critical components such as absorber rod drive mechanisms, steam generator, and transfer arm were manufactured on a full

scale and tested in sodium. Few important reactor assembly components went through a manufacturing technology development program. The technology for the production of enriched boron carbide for use in control rods, as well as the MOX fuel has been established.

To close the fuel cycle of PFBR, a dedicated Fast Reactor Fuel Cycle Facility (FRFCF) is also being established at Kalpakkam. This facility would be operational by 2012 and will comprise a fuel fabrication plant, a fuel reprocessing plant, a waste management plant, as well as a plant for processing reprocessed uranium oxide. The colocation of these facilities with sharing of common facilities is a significant step toward the reduction of the fuel cycle cost for PFBR.

It is planned to construct a series of 500 MWe reactors similar to PFBR with improved economy and safety during 2010–2020. From the point of view of economy and experience gained/to be gained in construction and operation, it is planned to go in for a larger reactor (500, 1,000 MWe), rather than smaller sized modular type reactors. The next four reactors to be constructed after PFBR would also use mixed oxide as the fuel. Sodium will be used as the coolant. These reactors would be designed in such a way as to enable introduction of metallic fuels in a part of the core. Two of these reactors would be constructed at Kalpakkam site and the remaining at a suitable alternate site. The reactors to be built subsequently will use metallic fuel. The choice of metallic fuel is based on its good breeding characteristics and the possibility of realizing a fuel cycle based on pyrochemical reprocessing of the fuel, which would ensure reprocessing of fuel after a high burn-up and with short cooling. Thus, the choice of metallic fuel is an essential ingredient of the plans for the rapid growth of fast reactors in India. Beyond 2020, a series of large size reactors (1,000 MWe) with metallic fuel will be constructed. Emphasis would be placed on innovation, scientific break throughs, development of quality human resources, and robust technologies through academy–research–industry synergy.

Thorium would be irradiated in the second stage FBRs with the objective of generating U-233 which will form the fuel for the third stage reactors. Toward this direction, Advanced Heavy Water Reactors (AHWRs) are planned to demonstrate the technology of innovative thorium-based reactors and fuel cycle, and the design is under regulatory review presently. Clearance for construction is expected in a few years.

2.7 China

China began work in fast neutron breeder reactors in the late 1960s. During the initial period from 1965 to 1987, the works were focused on fast reactor physics, thermodynamics, sodium technology, and development of small sodium facilities. Further, about 12 experimental setups were established, and one sodium loop was constructed. This included a 50 kg U-235 zero-power neutron setup, which achieved criticality in June 1970. The engineering goal for the applied research phase program (1987–1993) was to construct a 65 MWt (25 MWe) experimental fast reactor. Further developments were made in sodium technology, fuel and materials, fast reactor safety, and reactor design. A preliminary foundation for a fast reactor design was established, and approximately 20 experimental setups and sodium loops were built. Currently, the experimental validation phase focuses on sodium loop technology. Two sodium loops were imported from Italy: ESPRESSO (sodium flow rate $110 \text{ m}^3/\text{h}$, maximum sodium temperature 650°C) and CEDI (sodium flow rate $320 \text{ m}^3/\text{h}$, maximum sodium temperature 650°C). The primary conceptual design was completed in 1992 and the final design was completed in 1994. To test the concept of the design, a zero-power simulation experiment was conducted at the

Physics and Dynamics Engineering Institute in Russia. It was not until January 1998 that construction work began on the country's first fast neutron reactor. The China Institute of Atomic Energy (CIAE), in cooperation with the Beijing Institute of Nuclear Engineering, is constructing the FBR with Russian technical assistance.

The strategy of fast reactor development is divided into three steps of experimental, prototype, and demonstration stages as outlined in [Table 6](#).

In the framework of the National High-Tech Program, China Experimental Fast Reactor (CEFR) project has been executed since 1990. The power tests including electricity generation test is planned in 2009. The CEFR is a sodium cooled 65 MWt experimental fast reactor with (Pu,U)O₂ as fuel, but UO₂ as the first loading, Cr–Ni austenitic stainless steel as fuel cladding and reactor block structure material, bottom supported pool type, two main pumps, and two loops for primary and secondary circuits, respectively. The water–steam tertiary circuit is also two loops, but the superheat steam is incorporated into one pipe, which is connected with a turbine. Design work was started in 1990 and preliminary safety analysis report review was carried out during 1998–2000.

The CEFR block shown in [Fig. 9](#) is composed of main vessel and guard vessel supported from bottom on the floor of reactor pit with the diameter 10 m and height 12 m. The reactor core is composed of 81 fuel subassemblies and is supported on lower internal structures. Three safety subassemblies, three compensation subassemblies and two regulation subassemblies, then 336 stainless steel reflector subassemblies, and 230 shielding subassemblies and in addition 56 positions for primary storage of spent fuel subassemblies are included. Two main pumps and four intermediate heat exchangers are supported on upper internal structures. These two structures are mounted on the main vessel. Two DHR heat exchangers are hung from the shoulder of main vessel. The double rotating plugs on which control rod driving mechanisms, fuel handling machine and some instrumentation structures are mounted, are supported on the main vessel top.

CEFR right now is under installation. About 450 bigger components have been pre-installed and 80% non-sodium system and 30% sodium systems have been installed. Main vessel installation was started in August 2005. Preoperation testing of auxiliary systems is under way. Eighty five tons of nuclear grade sodium has been stored in the storage tanks. In order to validate the design, a number of demonstration loops and facilities were built during 1995–2006, such as sodium component cleaning, sodium purification system, sodium fire testing lab, fixed expansion graphite extinguishing facility, sodium fire detection system, sodium sol–gel purification

Table 6
China FBR development strategy

Reactor	Power (MWe)	Beginning of design	Commissioning schedule
CEFR	20	1990	2008
CPFR	600	2009	2020
CMFR	$n \times 300$	If needed	
CDFR	1,000–1,500	2015	2025
CCFR	1,000–1,500	2020	2030–2035

■ Figure 9
CEFR reactor block

and filtration facility, sodium testing loop, water testing loop, reactor vessel water natural convection simulation, sodium siphon testing facility, over-pressure protection test facility, sodium valve testing loop, fuel handling system summing-up demonstration.

The government also proposes design and development of China prototype fast reactor (CPFR), during the Eleventh Five Year Plan (2006–2010) with the target to complete its construction in 2020. After CPFR, two possibilities are foreseen: (1) CPFR could be deployed in a manner of one-site multi-reactors (CMFR-B) around 2030, which should be still as a breeder in case the uranium resource is not sufficient to support PWRs development and (2) to deploy fast burners of 600 MWe size around 2030 in the same manner as breeder reactors if experience is enough on the partitioning technology, Minor Actinides (MAs) fuel fabrication and transmutation in fast reactor for MAs and long lived fission products (LLFP). In order to shorten the fast reactor engineering development period from CEFR to China demonstration fast reactor (CDFR) and to decrease technical-economic risks and for their follow-up, maximum continuity will be emphasized in the main technical selections for these reactors, such as coolant, primary circuit structure, decay heat removal system, fuel handling systems, etc.

2.8 Korea

A draft long-term SFR development action plan has been prepared with milestones of standard design approval by 2020 and construction of demonstration SFR by 2028 as shown in [Fig. 10](#). Process for the finalization of the draft action plan is in-progress.

Korea Atomic Energy Research Institute (KAERI) is developing 600 MWe capacity liquid metal fast reactor KALIMER-600, which can satisfy the Gen-IV technology goals of sustainability, safety and reliability, and economics and proliferation resistance. With a strong emphasis on proliferation resistance, the core design of KALIMER-600 is evolved to have a single enrichment zone without any blanket. KALIMER-600 is a pool-type sodium-cooled reactor with a fast spectrum neutron reactor core. The passive safety mechanism with an inherent safety is highly emphasized to realize the KALIMER-600 design targets. A reliable decay heat removal system is also employed as a passive safety-grade decay heat removal method. The investment protection and the achievement of a high plant performance are the other important aspects of the KALIMER-600 design. The net plant efficiency of 39.4% is much higher than that of the nuclear plants currently under operation in Korea. This high efficiency would enable us to utilize the nuclear fuel more effectively and mitigate the thermal load on the environment. The design life time is set to 60 years which is evaluated to be long enough to provide the role imposed on it without any degradation of the plant efficiency. The heat transport system of KALIMER-600 consists of primary heat transport system (PHTS), intermediate heat transport system (IHTS), residual heat removal system (RHRS), and steam generating system (SGS). They are configured in series and located on a bed seismically from the ground.

The PHTS of KALIMER-600 is constructed in a large sodium pool. This design feature eliminates the possibility of a coolant loss by a pipe break and it also provides a large thermal damping of the system which yields a slower transient, longer grace time at an accident condition, and eventually increases plant safety. The IHTS consists of two identical loops and this feature contributes to the flexibility of the plant operation and increases the reliability of the decay heat removal by the normal procedures. KALIMER-600 has 3-layered RHRS such as PDRC (passive decay-heat removal circuit), intermediate reactor auxiliary cooling system

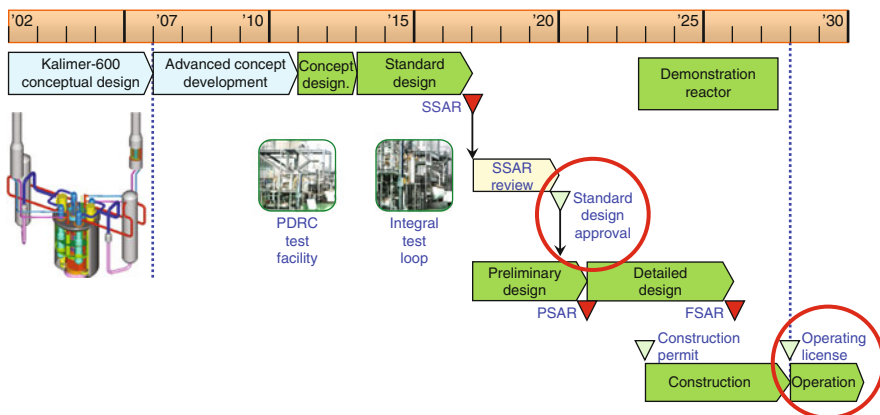

Figure 10
Draft action plan for SFR development in Korea

■ **Table 7**
Candidate concepts for an advanced SFR system

		KALIMER-600	Candidate concepts	Advanced concept
Reactor	Power (MWe)	600	600/900/1,200	To be decided
	Conversion ratio	1.0	0.5–0.8, 1.0	0.5–0.8, 1.0
	Core exit T (°C)	545	510–550	To be decided
	Cladding material	Mod.HT9	Mod.HT9/FMS	To be decided
	Fuel type	U-TRU-Zr	U-TRU-Zr	U-TRU-Zr
NSSS	No. of loops	2	2, 3	To be decided

(IRACS), and steam/feed water system to enhance the safety of the system. The PDRC is a pure passive system without any operator action and active components. The heat removal by PDRC relies exclusively on a natural convection heat transfer. The PDRC system comprises of two independent heat removal loops, and each loop is equipped with single sodium–sodium decay heat exchanger (DHX), one sodium–air heat exchanger (AHX) and the heat removing sodium piping connecting DHX with AHX.

Based upon the experiences gained during the development of the conceptual designs for KALIMER, KAERI is developing key SFR technologies. There are three categories of activities under way: (1) advanced concept design studies, (2) development of advanced SFR technologies necessary for its commercialization, and (3) development of basic technologies. For advanced concept design studies, various candidate concepts and options are under consideration and feasibilities of these concepts are being studied. ▶ [Table 7](#) shows a comparison of KALIMER-600 and candidate concepts.

3 Basic Design Choices

3.1 Sodium as Coolant

The sodium fast reactor (SFR) is a very promising candidate for the development of fast neutron reactors. It is well known owing to its wide development since the 1950s, throughout all countries involved in the development of nuclear power plants. The development of sodium-cooled fast neutron reactors is possible, thanks to the very attractive nuclear, physical, and even some of chemical properties of sodium. Sodium is the most common of the alkali metals. It is widespread in nature but only in the form of compounds (sea salt, rock salt, carbonates, nitrates), and it is the sixth most abundant element in the earth's crust (about 2.8% of terrestrial rock and present in great quantities in sea water as sodium chloride).

Sodium has been known since the early antiquity. The etymology of the word “sodium” and the symbol “Na” stretches back across history. The word “neter” is found in the bible, the word “natrium” is found in Latin, and the word “natron” in ancient Egyptian, where it was used to designate sodium carbonate decahydrate, a compound used to conserve mummies. Moreover, the word “natron” persisted into the middle ages; the word “natrium” is still used to designate

sodium in German, and in the present day, we still use the chemical symbol Na to designate sodium.

Sodium in its metallic form can be used to refine some reactive metals, such as zirconium and potassium, from their compounds. Other uses are for medicine, sodium vapor lamps, and chemistry as a reducing agent (i.e., styrene purification, methylate preparation. . .) and as a coolant in sodium fast reactors or in previous solar plants.

Sodium is a soft, silvery white alkali metal. A sodium atom has the symbol ${}_{11}^{23}\text{Na}$, which signifies that it consists of the following:

- A nucleus with 11 protons and 12 neutrons,
- Surrounded by 11 electrons distributed according to the formula $1s^2 2s^2 2p^6 3s^1$, which can also be written $(\text{Ne}) 3s^1$, which makes explicit reference to neon, the rare gas whose electron structure is most similar to sodium.

The atomic mass of sodium, for which the only naturally occurring isotope is ${}_{11}^{23}\text{Na}$, is 22.99 g. Like all the other alkali metals, sodium is a very reactive element (reducer), which easily loses its outer electron (singlet). In the majority of its compounds, it is found in the form of the cation Na^+ , which is clearly its most stable configuration.

Because of its very high reactivity, sodium does not exist in nature as a pure metallic element. Sodium salts are the most commonly used mineral salts due to their high solubility and their moderate price. Some exist in nature. Most of the others, including sodium hydroxide, the principle chemical base, can be prepared without returning to the metallic state. The metal itself, which is a strong reducer, is very difficult to obtain by chemical means; indeed, Humphrey Davy, the British chemist and physicist, first isolated it in 1807 by electrolysis of molten sodium hydroxide. Sodium is now produced commercially through the electrolysis of liquid sodium chloride: it is prepared in an electrolysis cell in which the NaCl (40%) is mixed with calcium chloride (60%) to lower the melting point down to 580 °C. The Na^+ ions are attracted to the cathode, and sodium is formed there. As calcium is less electropositive than sodium, no calcium will be formed at the anode.

3.1.1 Physical Properties

For the heat transfer calculations and thermalhydraulic analysis, the sodium properties are essential input data. Some of the important properties are given below. For each physical property, the references, from which the physical properties of liquid sodium have been taken, are given. There is not, in the thermodynamic sense, a coherent database for sodium within SFR community. By “reference database,” we mean a database having been the subject of a coherent internal thermodynamic study. We recommend that this activity be carried out within the framework of an International Organization (IAEA, OECD-NEA. . .).

Due to difference of structure and inter-atomic distances, most of the characteristics of sodium exhibit a discontinuity when passing from the solid to the liquid state; thus we give some different equations for each state, that is, solid and liquid, but clearly the characteristics of the liquid are of greater relevance to SFR.

At the atmospheric pressure, sodium is a liquid from its melting point, 371 K, to its boiling point, 1,156 K (➔ Sect. 3.1). This important range in the liquid state at atmospheric pressure is crucial when compared to the thermal inertia of the whole system for safety.

The critical temperature is relatively high which varies between 2,846 and 3,006 K (➤ Sect. 3.2).

The density of sodium decreases as the temperature increases (➤ Sect. 3.3):

$$\rho = 950.0483 - 0.2298 (T - 273.15) - 14.6045 \times 10^{-6} (T - 273.15)^2 + 5.6377 \times 10^{-9} (T - 273.15)^3 \quad (1)$$

with ρ in kg/m^3 , T in Kelvin.

It is always less than that of water. It has a value of around 850 kg/m^3 at 673 K. The density of liquid phase is higher than the solid phase's one (volume expansion is about 2.7%): due to this characteristic, it is necessary to foresee specific procedures for melting sodium in storage tanks or any other containment.

The viscosity of sodium at 673 K (➤ Sect. 3.3) is of the same order as the viscosity of water at 373 K, that is, 310 and 280 Pa s respectively.

$$\log_{10} \mu = -2.4892 + \frac{220.65}{T} - 0.4925 \log_{10} T \quad (2)$$

with μ in Pa s, T in Kelvin

Due to the similitude between sodium and water density and viscosity, it is possible to carry out some experimental thermohydraulic studies and code validation with water.

Wettability of structural material depends in a complex way on temperature, on the purity of the sodium, on the nature of the solid and on its surface state, as well as the possible presence of adsorbed gas and oxides, which are inevitably present on the surface, and which considerably modify the boundary conditions between sodium and the surface. Hence, the wetting characteristics of sodium on steel change as we go to temperatures higher than around 573 K, which corresponds to the dissolution of metallic oxides, inducing a very good contact between the sodium bulk and the structural material, which remains, after a period at raised temperatures (let us say around 24 h at 573 K), at lower temperatures, that is, 453 K.

Thermal conductivity of sodium is very high (➤ Sect. 3.3): about $76.6 \text{ W m}^{-1} \text{ K}^{-1}$ at 573.15 K. Comparatively, the conductivity of water varies from $0.6 \text{ W m}^{-1} \text{ K}^{-1}$ at 297 K to $0.465 \text{ W m}^{-1} \text{ K}^{-1}$ at 633 K (at a pressure of 150 bars), whereas the conductivity of sodium is between 100 and 150 times higher (and this of course at atmospheric pressure).

For solid sodium:

$$\lambda = 135.6 - 0.167 (T - 273.15) \quad (3)$$

For liquid sodium:

$$\lambda = 92.951 - 5.8087 \times 10^{-2} (T - 273.15) + 11.7274 \times 10^{-6} (T - 273.15)^2 \quad (4)$$

with λ in $\text{W m}^{-1} \text{ K}^{-1}$, T in Kelvin

Heat capacity of sodium is very attractive (➤ Sect. 3.3): at 673 K, that is, 1, 25 103 $\text{J kg}^{-1} \text{ K}^{-1}$ (water at 293 K: 4.18 103 $\text{J kg}^{-1} \text{ K}^{-1}$)

For solid sodium:

$$C_p = 1,199 + 6,491 \times 10^{-4} (T - 273.15) + 1,052.9 \times 10^{-5} (T - 273.15)^2 \quad (5)$$

For liquid sodium:

$$C_p = 1,436.715 - 0.5805 (T - 273.15) + 4.6273 \times 10^{-4} (T - 273.15)^2 \quad (6)$$

with C_p in $\text{J kg}^{-1} \text{K}^{-1}$, T in Kelvin

The fact that sodium has a very high boiling point (the boiling point is by definition the temperature at which the saturated vapor pressure is equal to the atmospheric pressure) leads one to expect that sodium is not very volatile.

The saturation vapor pressure is given by the following equation:

$$\ln P_s = 23.99 - 12,580 T^{-1} - 0.2241 \ln T + 1.712 \times 10^{-22} T^6 \quad (7)$$

with P_s in Pa and $371 < T < 2,573 \text{ K}$

The fact that sodium is not very volatile has several consequences:

- In normal operation, evaporation rapidly attains an equilibrium level (condensation = vaporization). Consequently, in the various gas plenums, and more particularly in the primary vessel, the mass transfer toward the colder roof of the slab is rather limited, particularly in the presence of argon, due to its low thermal conductivity. Nevertheless, the SFR operational feedback shows that there is a possibility of observing some sodium aerosols deposited in the upper structures or narrow gaps, and it is necessary to foresee vapor and aerosol traps in cover gas, to prevent any related issues.
- Vacuum distillation is not a very efficient cleaning technique, prior to inspection or repair. It should be pointed out, however, that evaporation, which depends only on the partial vapor pressure of the sodium, can occur at conditions away from boiling, for example, by flushing with hot gas.
- Due to this low volatility, the sodium flames are very short and the heat produced by the fire is rather low: thus, it is possible to extinguish the fire by spreading a powder, mixture of Na carbonate, Li carbonate, and graphite.

Sodium, like all metals, has a very low electrical resistivity:

$$\rho_e = 6.1405 \times 10^{-8} + 3.5047 \times 10^{-10} (T - 273.15) + 5.6885 \times 10^{-14} (T - 273.15)^2 + 1.66797 \times 10^{-17} (T - 273.15)^3 \quad (8)$$

with ρ_e in $\Omega \text{ m}$, T in Kelvin

These attractive conduction properties are widely used in sodium technology: instrumentation, level probes, flow measurements, electromagnetic pumps (➤ [Fig. 11](#)), and leak-detection (➤ [Fig. 12](#)).

The speed of sound in sodium varies little with temperature. It can be given by the relationship (➤ [Sect. 3.4](#)):

$$C = 2577.2 - 0.5234 (T - 273.15) \quad 373.15 < T < 643.15 \text{ K} \quad (9)$$

with C in m s^{-1} , T in Kelvin

■ Figure 11
Electro-magnetic pump (conduction pump-single phase current)

■ Figure 12
Insulated "sandwich" leak detection system (Courtesy of CEA)

This formula can be extrapolated up to 1,673 K.

Sound waves, therefore, propagate faster in sodium. This property is widely used in all the metrology and visualization techniques in sodium, and compensates the opacity in sodium for in service inspection operations (► [Fig. 13](#)). The influence of temperature remains weak; nevertheless, the temperature could also be deduced from the sound velocity in sodium. In order not to affect the accuracy of measurements and to avoid parasite echoes, it is necessary to make sure that the particulates and gas content in sodium are extremely low.

Figure 13

3.1.2 Chemical Properties

Since sodium has a tendency to lose its external electron, it will have very significant reducing characteristics, as do all the alkali metals. It reacts exothermically with water, and potentially with violence, as a function of local conditions. The reaction with water produces sodium hydroxide and hydrogen gas, inducing hazards to be analyzed when the sodium is used for chemistry or as a coolant. This reaction is strongly exothermic (162 kJ/mol Na) and extremely fast. For these reasons, sodium–water interaction which can occur in the Steam Generator Units is considered as an important issue and safety means are developed and implemented to mitigate this event.

Nevertheless, this reactivity with water is commonly used for the development of cleaning processes for structural material wetted with sodium, during handling operations and moreover for the conversion of the large amounts of sodium into sodium hydroxide, at the end of the reactor operation, during the decommissioning phase. Solid sodium quickly oxidizes in air and liquid sodium burns in air over melting point, that is, 370 K if it is spread out in air, and over 413 K, in other cases; it forms sodium peroxide Na_2O_2 , or with limited oxygen, the oxide Na_2O . If burned in oxygen under pressure, sodium super oxide NaO_2 will also be produced. Because of this high chemical reactivity, extreme care is required in handling elemental/metallic liquid or solid sodium: it must be stored or used in liquid phase in an inert (oxygen and moisture free) atmosphere such as nitrogen or argon. Specific means have been developed to reduce the occurrence of sodium leaks; for example, specific detection systems, based on insulated electrical wire: in case of sodium leak, sodium is put in contact with this wire inside the pipe and therefore generates a warning (🔍 Fig. 12).

For sodium fires, several approaches have been developed, based generally on the limitation of oxygen available for the combustion: specific catchers, dedicated volume portioning. Specific extinguishing powders have also been developed among the so-called “Marcalina” powder, made of sodium and lithium carbonate, mixed with graphite, spread out over the fire (🔍 Fig. 14) to insulate it from air.

Despite high care, with regard to the contact with air and water, thanks to protection devices and confinement, sodium contains various nonradioactive impurities either present from the start or introduced during operation.

■ **Figure 14**

Sodium fire extinguishing operation (Courtesy of Na School in CEA – Cadarache)

In the primary circuit, there is essentially

- One source of discontinuous contamination by oxygen and hydrogen at the start of the cycle and at the end of the handling of the assemblies
- One continuous source of hydrogen coming by permeation from the secondary circuit.

On the intermediate loops, there are essentially:

- One continuous source of hydrogen, mainly due to aqueous corrosion in Steam Generator Units, which produces magnetite Fe_3O_4 and native hydrogen.

In the event of a sodium–water reaction, there is one discontinuous source of hydrogen, sodium hydroxide, which is potentially decomposed over 593 K and produces Na_2O and NaH crystallized products, which dissolve if the sodium temperature is over its saturation temperatures, given by the respective solubility laws of oxygen and hydrogen in liquid sodium (see below). This is also the case after a contamination by air and moisture, following a handling operation.

Thus, oxygen and hydrogen constitute the major contaminants.

The respective solubilities of oxygen and hydrogen are very low; the solubility reaches a value around nul, near the melting temperature, that is, 371 K (this is property specific to sodium, in comparison with other liquid metals, used as coolants).

For oxygen, Noden law (➤ Sect. 3.5)

$$\log_{10} [\text{O}(\text{ppm})] = 6.250 - \frac{2,444.5}{T(\text{K})} \quad (10)$$

For hydrogen, Wittingham law (➤ Sect. 3.6)

$$\log_{10} [\text{H}(\text{ppm})] = 6.467 - \frac{3,023}{T(\text{K})} \quad (11)$$

Oxygen contributes to corrosion of steel (➤ Fig. 15), and the corroded activation products are transported from the core toward the components and mainly to the intermediate heat exchangers, leading to their contamination. All the elements that go to constitute steel (iron, Cr, Ni, Mn, C . . .)

■ **Figure 15**
General corrosion: formation of a ferrite film at the surface of sound austenite

are susceptible to being dissolved in sodium. Nevertheless, this phenomenon, which depends on diffusion near the interfaces, remains very weak because the diffusion coefficients of the components of steel are very low (► Sect. 3.9). General corrosion kinetics is a function of sodium physical parameters (temperature and flow rate) and sodium chemistry (mainly oxygen activity), and corrosion models have been established. Even if it is generally considered that corrosion is only significant for temperatures higher than 817 K and for oxygen contents of order 10 ppm, it is generally considered that a SFR requires to be operated with an oxygen content below 3 ppm, in normal operation, to limit the corrosion, consequently the contamination and associated dosimetry during handling or repair operations.

Some stress corrosion cracking phenomena can occur in the presence of aqueous soda, when the component, wetted by a residual film of sodium, is filled with air and moisture, which reacts with the film of sodium. Over 353 K for ferritic steels and over 383 K for austenitic steels, trans-granular cracking can occur. When preheating the facilities, prior to filling with sodium, such temperatures can be obtained. Therefore, it is necessary to avoid any presence of residual aqueous soda on components, gaps, by appropriate rinsing and drying processes.

Because steels tend to exchange nonmetallic elements such as carbon and nitrogen with the liquid metal, the effects of these elements have to be taken into account not only for the evaluation of the corrosion behavior of steels in liquid sodium and for mass transfer calculations but also for potential evolution of mechanical properties. At high temperatures, the diffusion rate of carbon in steel is fast enough to cause changes of carbon concentrations in cladding materials for instance. These evolutions have generally marginal effects on the corrosion behavior of steels at 873 K, but could be much more important at higher temperatures.

In the intermediate loops, hydrogen content has to be maintained as low as possible (<0.1 ppm), in order to allow a fast detection of water ingress. Moreover, some detrimental effects due to material embrittlement should be avoided, thanks to an efficient sodium purification campaign, after a sodium–water interaction, inducing a very high hydrogen content. The detection can be carried out with hydrogen-meters, diffusion type with Ni membrane (► Fig. 16), used in various countries and mass spectrometer or electrochemical cell, developed by IGCAR (India), implemented on PFBR.

■ **Figure 16**
Hydrogen-meter based on Ni diffusion

Two main sodium purification processes have been developed with regard to oxygen and hydrogen control:

- Cold trapping (➤ Sect. 3.7) by crystallization of Na_2O and NaH , by lowering the sodium temperature below the saturation temperature and thus creating the optimal conditions for Na_2O and/or NaH nucleation and growth on a steel packing distributed in an auxiliary cooled vessel. Cold trapping (➤ Fig. 17) is the process used worldwide for sodium purification in the sodium fast reactors, due to its undeniable advantages: the trapping of oxygen and hydrogen, which are the two most important impurities to trap in an SFR, in the same component, the easy reachability of lowest oxygen and hydrogen concentration due to the respective solubility laws, the highest efficiency and capacity obtained with optimized designs of cold traps, and the ability for the cold trap to be regenerated by extracting solely the packing or by *in situ* appropriate chemical process.
- Hot trapping or “getter” operation (➤ Sect. 3.8) based on the capacity of the chosen material (i.e., zirconium–titanium alloy for oxygen) to oxidize when it is placed in the presence of sodium containing some amount of oxygen. This last process is generally chosen for small sodium volumes to be purified and when the risk of Na_2O dissolution by loss of cooling function in the cold trap is unacceptable. As example, the $\text{Zr}_{0.87}\text{-Ti}_{0.13}$ alloy has been qualified for hot trapping in an irradiation loop for Phenix: kinetics and optimized operating conditions have been established for further use:

$$V = 41.26 \times 10^{-3} \times \exp(-40.3 \times 10^3 RT) [\text{O}] \text{ kg (O) h}^{-1} \text{ m}^{-2} \quad (12)$$

where V is the rate of oxygen trapping (mol h^{-1}), T designates the hot trap temperature (K), R is the Boltzman’s constant ($\text{J mol}^{-1} \text{ K}^{-1}$), and $[\text{O}]$ is the oxygen content in ppm.

For hydrogen trapping, “hydride” traps (i.e., yttrium) could also be set-up but, due to their very low potential capacity and reversibility, their application for large sodium volumes has never been foreseen. The monitoring of sodium quality can be performed by numerous on-line (plugging-meters, hydrogen-meter, and oxygen-meter) or off-line (sampling by dip sampler then analysis in laboratory: atomic absorption, distillation. . .).

■ **Figure 17**
Intermediate cold trap for SuperPhenix with NaH

3.1.3 Neutronic Properties

Sodium has only one stable isotope, namely, $^{23}_{11}\text{Na}$. The neutron flux leads to formation of radioactive isotopes: two other isotopes, with significant half life, are created: ^{24}Na (half life 14.98 h), inducing the necessity to wait for decay before some interventions on primary circuits and ^{22}Na (half life: 2.6 years), to be taken into account during decommissioning and sodium treatment. This low activation is also a very attractive property of sodium for nuclear use in SFR.

3.2 Fuel Design

3.2.1 Fuel Element

In most cases, the fuel element is a cylindrical solid of revolution. A circular section is the most adapted to allow the cladding to withstand the primary pressure stresses: for SFR application, the internal pressure of the fission gases released in operation outside the fuel.

Typical fuel element is shown in ► [Fig. 18](#). The fuel pin is mainly made up of the cladding containing the fuel pellets or rods and is closed by two welded end plugs, which results in a gastight assembly. In the top part of the pin, there is generally a spring, which maintains the fuel column in place and creates a gap (plenum) for fission gas expansion and fuel elongation. If the volume of fission gases released is very high, a large area at the bottom of the pin is also left.

Disks made of refractory materials (natural or depleted uranium oxide, alumina. . .) can be placed at the top and bottom parts of the fuel to insulate it from the metallic parts (plugs, spring. . .). The SFR fuel pin can include columns made of fertile material making up the axial blankets.

■ **Figure 18**

Illustration of fuel element: Phenix case

To improve heat transfer between fuel and cladding, the fuel element is filled with helium at atmospheric pressure. In the case of a fuel material that swells (metal alloy, carbide, nitride), a large gap is needed, and the thermal gradient increases in the gap. To reduce it, one can fill the pin with sodium (possible because of the good compatibility between these materials), in order to obtain very good heat transfer between fuel and cladding and thus take full advantage of the good thermal conductivity of the fuel. In this case, an alternative solution would be to have a fuel element with a vent, an opening equipped with a filter allowing the fission gases to be continuously released from the pin. We thus abandon the concept of a “clean reactor.” But the vented fuel has never really been used, except in the DFR experimental fast neutron reactor of Dounreay (UK).

A spacer wire, made of steel of the same nature as that of the cladding, is helically wrapped around each pin and attached to the end plugs. This solution

- Ensures regular spacing of the pins over the whole length
- Minimizes vibrations
- Ensures sodium mixing
- Allows some straining (by irradiation effect) of the pin cluster compared to the wrapper tube without any cooling perturbation

3.2.2 Fuel Subassembly

For the purpose of illustration, a typical fuel subassembly is shown in [Fig. 19](#). Fuel subassembly design, as far as the number, diameter, and arrangement of fuel elements is concerned, is mainly guided by thermomechanical, hydraulic, and neutronic considerations:

For a given power density (W/cm^3) to be evacuated, the temperature at the center of the fuel increases with its diameter (increase of the linear heat rate), which leads to fraction the fuel into several elements of small diameters so as to avoid reaching, at the center of the fuel, a

Figure 19
Illustration of fuel subassembly: Phenix case

temperature that would be incompatible with its limits of use (margin to fuel melting, thermal stability, chemical interactions. . .)

Another limit is given by the maximum surface heat flux (in W/cm^2), which the coolant is capable of extracting. For a given power density released by a fuel element, the surface heat flux decreases when the exchange surface increases, and therefore, when the diameter increases.

The bottom nozzle of the subassembly allows it to be positioned in a diagrid which is a cold sodium collector and supplies it with sodium several radial openings. It includes a pressure drop device used to adjust the sodium flow rate, as the fuel subassemblies are distributed over several flow rate areas, varying according to the radial (and axial) power distribution.

The median part includes the fuel pins contained in a steel hexagonal wrapper tube which has two functions: it forms the cooling channel, allowing sodium flow to be adjusted, and makes up, with the top and bottom nozzles to which it is connected by welding and crimping, the mechanical structure of the subassembly.

At about the same level as the top of the fuel, the wrapper tube includes spacer pads, which are dimples impressed on each face of the tube, with a small gap under cold conditions between two neighboring subassemblies, in order to obtain a compact core in normal operation under effect of thermal expansion.

The top nozzle, consisting of a steel hexagonal block with a circular central hole allowing circulation of sodium leaving the subassembly, is used both as neutron protection of the top components of the reactor and as the gripper head of the assembly for handling.

The FR fuel subassembly is characterized by:

- A high plutonium content (from 15 to 30% for example for the French FR)
- A fuel in the shape of solid or annular pellets of $(U,Pu)O_2$, $(U,Pu)N$, $(U,Pu)C$ or in the shape of rod of U–Pu–Zr metallic alloy

- Large plena (bottom and top)
- A spacing made by a wire helically wound around each of pins (even though different solutions, such as grid spacing have been tested)
- An hexagonal wrapper tube
- The use of austenitic, ferritic–martensitic steels or nickel alloys as materials for structural components

The previous paragraphs are a general description of the fuel element and the subassembly designed for the SFR and the Phenix design is chosen as an illustration.

The precise design of the subassembly (Fuel pin included) can continuously evolve because it depends on the objectives set and the state of knowledge achieved and can be changed during the life time of reactor. The cycle facilities have to be built to accept these evolutions (certainly very complicated if the nature of the fissile compound has to change). In the subassembly design of FR for new objectives such as Pu balance or minor actinides transmutation, different solutions can be taken into account, both during the study of new projects and during the definition of new reloads for operating reactors.

3.3 Pool/Loop and Modular Design

3.3.1 Features of the Primary Circuit Concepts

The primary circuit of the existing SFRs is based on two concepts:

- The pool concept
- The loop concept

The Pool concept is featured by nearly all the primary sodium coolant inside the reactor vessel. Therefore, this main reactor vessel encloses the primary pumps (PP) and intermediate heat exchangers (IHXs), in addition to the internal structures surrounding the core and devoted either to its feeding and supporting or separation of the various hydraulic plenums.

As opposed to the pool primary system, the loop concept is characterized by some major primary components outside the reactor vessel. Several variants of the loop concept exist. In the earlier existing loop-type SFRs, the primary pumps and the IHXs, without grouping, are located adjacent to reactor vessel and are connected together by inlet and outlet pipes through nozzles. Less conventional variants try to cope with the loop-type drawbacks, whereas the loop-type benefits are kept, and for this purpose:

- The nozzles, especially at the bottom part of the reactor vessel, are eliminated. The top-entry concept is typically a kind of solution with penetrations of the primary pipes through the reactor roof (either U-shape or L-shape pipes)
- Shortened primary pipes reducing the number of bends. This trend is illustrated by the Japanese reactor designs where the number and the length of primary pipes are strongly reduced.
- Primary pumps and IHXs can be located into dedicated component vessels or gathered in a single PP-IHX component.

In addition, some innovative conceptual designs try to combine the features of the pool and loop concepts in order to sum their own benefits and to remove their respective drawbacks. These variants can be considered as hybrid designs, but strictly speaking, they are variants of either pool or loop concept.

A detailed analysis of pool and loop concepts shows that the reactor unit power level can influence the choice of design variants. The possibility of components manufacturing in factory, and not on site, is considered by designers as an attractive option. In this respect, the modular plant concept characterized by several reactor power units coupled to a same power block (i.e., same balance of plant), complying with a commercial-size of power supply, is preferable. On the contrary, if the power units for the plant site are separated, in case of the large-size nuclear plant units, then, only possible size effects are preferred, but without common equipments for a given power block.

Generally speaking, modular concept can be applied to any component; for example, modular steam generator can be implemented on large-size power unit. The meaning of modular concept in the present case is particular to the reactor primary system.

An intermediate sodium system is usually added between the primary circuit and the energy conversion system for either pool or loop primary circuit concept (ECS), to prevent primary sodium–water interaction by means of two physical barriers (IHX and SG tubes). For the loop concept, the number of intermediate circuits has to be compatible with the number of primary loops, whereas for the pool concept the number of intermediate circuits is quite an open design option; it is based on reactor size.

Tentative of elimination of the intermediate system existed in the past from economic point of view, and it is considered again recently when alternative conversion systems (ECS without water–steam cycle) were proposed as concerns the sodium–water interaction risk. Feasibility of SFR without intermediate system is not yet demonstrated, but tentative designs are only based on loop concept (more suitable than the pool concept).

The advantages and drawbacks of each concept depend in practice on the design variants. However, one can notice some general trends allocated to each main concept but to be considered carefully based on the previous discussions. Some general trends are mentioned in the following paragraphs.

3.3.2 Pool Concept: Motivation and Challenges

The topics of motivation for a pool-type primary circuit can be perceived as opposed to the loop concept:

- There is no relevant accident scenario of loss of primary coolant. The primary sodium inventory is managed by safety provisions (e.g., guard vessel)
- The large thermal inertia of the reactor block contributes to slow down any transient loss of heat sink
- There is no risk to break the hydraulic loop from the core outlet toward the core inlet
- A very efficient natural circulation of the primary circuit is expected, as a flow backup at reactor shutdown state, in case of loss of the forced flow mode (e.g., pumps trip)
- There exists a cold sodium plenum at the pumps suction upstream, which acts as buffer against either thermal chocks or gas entrainment toward the core
- In practice, there is no risk of radioactive sodium fire, except for limiting events leading to a hypothetical core disruptive accident (HCDA)

- Good mechanical behavior of the primary containment against energetic HCDA
- Ease of radiation protection in normal operation.

On the other hand, matters on competitiveness and on flexible operational conditions remain as challenges:

- Limited access for inspection and repair of the under-sodium internal equipments
- Seismic behavior of sodium free-level and large structures
- Reactor-block compactness limitation due to integrated large components

3.3.3 Loop Concept: Motivation and Challenges

In the same way, motivation for loop concept and challenge as opposed to the pool concept can be perceived:

- Ease of access for maintenance and repair of those of the primary components located outside the reactor-block (e.g., IHX)
- Compactness of the reactor-block (e.g., vessel diameter) and reduction of the primary loops number
- Potential for further construction cost reduction and for innovative change of primary and intermediate equipment (e.g., pump design, integrated components, intermediate circuit change. . .)
- Any rotating pump-shaft is away from the core vicinity

In return, the designer has to solve some issues about:

- Prevention of loss of the primary coolant (e.g., pipe integrity) and provisions to keep a hydraulic loop through the core whatever the abnormal operating conditions are
- Potential consequences of a LOCA, inside (e.g., gas entrainment) and outside the primary circuit (e.g., active sodium fire)
- Provision against asymmetric operating faults (e.g., trip of one of the pumps leading to reverse flow)
- Suitable implementation of several decay heat removal (DHR) systems in order to cope with different accidental configurations of the primary circuit
- Additional provisions regarding the radiological protection

3.3.4 Modular Concept: Motivation and Challenges

The primary circuit of a reactor unit of the modular plant concept is equally a pool-type or a loop-type concept, and then the generic positive and negative features mentioned above remain applicable. Whatever the choice of primary circuit concept is (i.e., pool or loop), the search of variants is driven by size effect considerations. Therefore, topics of consideration depend on design variants. Some such topics connected to size effects are listed below:

- Improvement of the DHR safety function through a complete diversification of the redundant means, in particular with one of the means being a reactor vault auxiliary cooling system (RVACS), efficiency of which depending on size effects
- The largest components (internal structures, roof, core-support bottom structures, vessels. . .) *made in factory* which changes the fabrication modes and then the quality

(need of inspection in operation. . .); but this involves some limitations on the component dimensions for transport reason

- Potential for better availability rate as regards the electric power supply, in that only one reactor module is at shutdown state for some configurations
- Ease of safety demonstration, in particular to account for hypothetical core severe accidents and their consequences on the containment
- Validation at full scale for one first-of-kind seems sufficient, instead of validation (a demonstrator and a prototype) for the conventional high power reactor system
- Potential for easier repair (e.g., IHX handling) and end-of-life dismantling conditions

But generally speaking, the cost balance being more favorable when increasing the reactor power, the main challenge for the modular concept is then to reach competitiveness in terms of cost by a different way than the unit power. For this aim, the designer has to find technological thresholds in the reactor module design, thanks to size effects (e.g., use of electro-magnetic pump), in addition to the other saving items in the cost breakdown: production in series, reduced delay of the plant under construction, sharing of equipment (sized for one module scale) between the power units. . .

3.4 Main Components and Systems

The choice of design option is crucial at the start of conceptual design stage in order to meet the requirements for achieving safety and economy, concurrently. Hence, the concepts selected should be simple, mature, and robust and should be based on operating experiences, availability of relevant design criteria, analysis capability, operating experiences, international trends, availability of materials and constructability including transportation. Newer materials and concepts should be introduced carefully after detailed analysis and thorough validations for meeting both functional and safety requirements. Standard and proven concepts should be adopted wherever possible. The functions of each component should be defined comprehensively. The operating conditions, environments, safety classifications, design requirements and interfaces constraints should be identified clearly. While selecting the SFR components, whose design is largely governed by neutronics, complex pool hydraulics, structural mechanics, seismic design requirements, shielding requirements, etc., it is preferable to introduce judicious mix of flexibility and rigidity. From the point of long and reliable operation of the plant, needless redundancy and rigid geometrical constraints should be avoided. The geometrical features should be selected as far as possible to have complete access for inspection and to achieve reliable technology. The synergy and interplay of various governing performances need to be understood in a scientific manner with due regards to constraints in realization of technology.

In this part of the chapter, the important components in the heat transport circuits are introduced. The heat transport system of SFR, addressed in this chapter, has an intermediate circuit. Designs without intermediate circuits are found in literature, which are not covered. Accordingly, this chapter covers description of main heat transport system components, such as main vessel, grid plate, core support structure, inner vessel, primary sodium pump, control plug, and top shield, which belong to primary sodium circuit. Further main components of intermediate heat transport circuits such as intermediate heat exchangers, secondary sodium pump, and steam generators are covered subsequently. Finally, the components in the decay heat removal circuit are described. To start with, the overall heat transport circuit is briefly introduced. The major design choice for the reactor is the selection of number of primary and secondary loops and components, which is dealt in a comprehensive manner. The types of support arrangement

for the reactor block, also termed as reactor assembly, which is also an important design consideration, are brought out. Subsequently, design choices for each component are described in detail. While describing the design choices, the main functions and concepts adopted in various SFRs are brought out with schematic sketches. In this context, the international SFRs, mainly Fast Breeder Test Reactor (FBTR), Rapsodie, Phenix, SuperPhenix (SPX1), Prototype Fast Reactor (PFR), BN-350, BN-600, Monju, prototype fast breeder reactor (PFBR), BN-800, European Fast Reactor (EFR) and Commercial Demonstration fast reactor (CDFR) are referred. At the end of this chapter, certain innovative designs being conceived in advanced and future SFRs are also highlighted. For quantifying certain design parameters, where necessary, a typical 500 MWe pool type fast breeder (PFBR) is used as the reference case.

3.4.1 Description of Heat Transport Circuits and Components

The heat transport system consists of primary, secondary, and steam–water circuits. The purpose of primary circuit is to transport the heat energy, generated in the core to the intermediate heat exchangers (IHX), from which the heat is transported to the secondary circuit. The secondary circuit, in turn transfers the heat to the water circulating in steam generators, to generate steam. The steam–water circuit is the conventional electricity generating system, called as balance of plant (BoP). The main components in the primary circuit are main vessel (MV), also called reactor vessel (RV), which houses the core and contains the coolant, grid plate, primary sodium pumps (PSP), and top shield. The grid plate supports the core and facilitates circulating the sodium to the core subassemblies to remove the nuclear heat. The main vessel contains primary sodium and supports the grid plate. Primary pumps provide required pressure head to the sodium to flow through the core subassemblies. In the pool-type concept, there is a need of a vessel called inner vessel which separates the hot and cold sodium in the main vessel which houses the entire radioactive primary sodium circuit. Thus inner vessel ensures desired flow through IHX and targeted design temperatures in the hot and cold pools. The absence of inner vessel or a large leak in the inner vessel will result in higher stabilized overall temperatures of pool (which will exceed the structural temperature limits) in the process of heat removal by intermediate heat exchangers (IHX) from the mixed pool. The IHX, steam generators (SG), and secondary sodium pumps (SSP) are the main components in the secondary circuit. The heat transport circuit components of typical pool- and loop-type reactors are shown in  Fig. 20.

Apart from the above mentioned circuits, decay heat circuit consisting of dedicated heat exchangers immersed in hot pool (in the case of pool concept) and air heat exchangers to transport the heat to the atmosphere (ultimate heat sink) during decay heat removal operations are important systems from point of view of safety. Depending upon the system, this circuit consists of decay heat exchangers (DHR) and pumps. Compared to thermal reactors, SFR system operates with high operating temperature.  Table 8 provides the core outlet and steam temperatures in a few SFR power plants.

In view of higher steam temperatures, thermodynamic efficiency is around 40%, which implies less thermal pollution and less loss of nuclear heat. This is one of the main advantages of SFR power plants, compared to water reactors.

3.4.2 Primary Component Layout on the Top Shield

The layout of equipment depends upon the concept of the reactor system, namely, loop or pool type. In loop-type reactor system, the equipment such as primary coolant circulation pump,

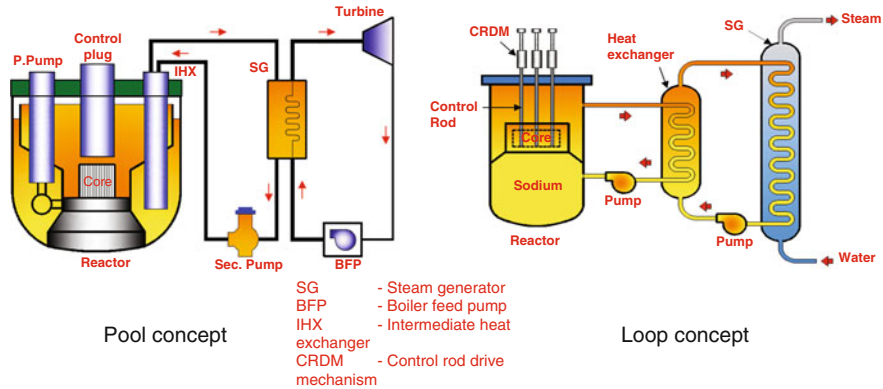

Figure 20
 Heat transport circuits of SFR power plant

Table 8
 Operating temperatures of FR power plants

Reactor	Thermal power (MW)	Electric power (MW)	Core outlet temperature – K (°C)	Steam temperature – K (°C)
BOR-60	55	12	803 (530)	703 (430)
FBTR	40	13	788 (515)	753 (480)
EBR-II	62.5	20	646 (473)	706 (433)
KNK-II	58	21	798 (525)	758 (485)
Phenix	563	250	833 (560)	785 (512)
PFR	650	270	833 (560)	788 (515)
Monju	714	280	802 (529)	756 (483)
BN 350	750	350	710 (437)	678 (405)
PFBR	1,250	500	820 (547)	766 (493)
BN 600	1,470	600	823 (550)	778 (505)
BN-800	2,000	800	820 (547)	763 (490)
SPX-1	3,000	1,240	818 (545)	763 (490)

intermediate heat exchanger, etc., are spread out and distinctly located outside reactor vault and hence does not influence the reactor block dimensions. On the other hand, in pool-type configuration, all these equipments are located within a single vessel, leading to close interplay of many parameters. This is broadly discussed in the following paragraphs.

As the reactor vessel in pool-type reactor is designed without any penetrations to assure highest reliability for the coolant boundary, all the equipment of primary coolant circuit, reactor control, and safety systems, etc., pass through the penetrations in the top cover of reactor vessel known as top shield. This brings the crucial issue of their layout over the top shield,

Figure 21
Radial/circumferential spaces in layout

which is one of the important factors in optimizing the overall dimensions of the reactor block. The overall dimension is governed by space requirements either in radial or circumferential directions (► Fig. 21). The core diameter and height are also governed by reactor physics considerations. The heat transport system components, such as primary pumps and IHXs should be positioned around the core. With more number of primary and secondary sodium loops (>2), the pitch circle diameter (PCD) of the component's layout on the top shield would be decided by the circumferential spacing. This is because of the large number of equipment to be arranged over the top shield, leading to a limiting value for the PCD beyond which it cannot be reduced. For lesser number of components, say for a typical two loop concept, PCD would be governed by radial spacing. These aspects are however linked to the size of the reactor. Generally, larger size reactors (say >600 MWe) are designed with more than two secondary sodium loops. On the other hand, medium size reactors (~500 MWe) are designed with two loops as it generally leads to optimum reactor block dimensions. However, for reactors with relatively lower number of loops, the reactor block dimensions are governed by radial considerations decided by the size of the equipment.

It is to be noted that the size of the pump and numbers would be decided with considerations of single/double suction option, flow, and temperature requirements based on the reactor power. Further, reducing their number beyond a value would not be practical from practical considerations. This is because, for removing the required amount of heat, certain minimum mass flow rate (m) is required as per equation: $Q = m C_p \Delta T$. The mass flow rate is decided by the number of pumps, which would increase in case the numbers are minimized. Further, safety considerations would demand minimum number of pumps to be not less than two.

Generally, in pool-type reactors, the ratio of the number of primary pumps to IHXs is maintained as 1:2. This is to take care of the loose coupling effect between the pump and IHX in pool-type configuration unlike in the loop-type configuration, where direct linkage is present between the pump and corresponding IHX. The ratio of 1 in a pool-type reactor ensures that if the situation so warrants, some flexibility for making finer adjustments in the outlet temperature

of IHXs is built into the system. This flexibility arises from the arrangement of one pump surrounded by IHX of the same secondary loop on either side. For a pool type, the basis for arriving at typical layout of equipment over the top shield based on various numbers of secondary loops and corresponding number of equipment is indicated in the following paragraphs, with reference to a typical 500 MWe pool-type fast reactor.

Estimation of Main Vessel and Top Shield Diameter: An Illustrative Example

The number of primary/secondary loops is varied from two to four. Accordingly, the number of pumps is varied from two to four, and IHX number is varied from four to eight, maintaining 1:2 ratios. The diameters of the pumps and IHX are assumed to respect the process requirements. With these assumptions, the main vessel/top shield diameter is calculated based on layout verification at core level and top shield level (👉 Fig. 22), both in radial and circumferential directions. In the radial direction, the diameter of the core, gap between core and inner vessel, stand pipe dimensions, radial clearances between various shells, and thickness of various shells decide the radius of main vessel at the core level. At the top shield level, diameters of various plugs and components and their layout, shielding and handling aspects would also control the radius of the main vessel. In the axial direction, core height, heat exchanger/pump heights, cover gas height, submergence requirements for inlet windows and pump impellers, and gap between the core top and bottom of above core structure would decide the height of the main vessel. This apart, the thickness of the top shield, the support skirt height should be added with main vessel height for arriving at the overall height of the reactor assembly. The diameter and height of the reactor assembly thus arrived at should be optimized through several iterations which is mainly due to diameter to height ratios of the intermediate heat exchanger and primary pump.

■ Figure 22

Reference levels in pool type SFR

Figure 23

Main vessel/top shield diameter vs. number of loops

Results for a Typical 500 MWe SFR

The diameter of main vessel/top shield is influenced by the number of equipment located over the top shield, which in turn depends on the number of loops and the size of primary loop components, which once again depends on the number of loops. Toward this, a study on minimum top shield/main vessel diameter with reference to the number of loops was made taking 500 MWe SFR design as a reference. The study indicates that for a typical 500 MWe reactor with two loops, the radial layout of equipment at both core/top shield level governs the size of main vessel/top shield where as the circumferential layout consideration governs the main vessel/top shield size, if the number of loops is increased. This is depicted in [Figure 23](#). Further, it can also be observed that the two loop design gives the optimum main vessel/top shield diameter. However, as indicated above, the diameter is also a strong function of primary loop equipment size, and hence, for reactors of different rating, similar study needs to be carried out. [Figure 24](#) shows the component layout over the top shield for the two, three, and four loop concepts.

3.4.3 Reactor Assembly Support Options

The other important decision is the option of supporting the reactor assembly either at the top or bottom. [Figures 25](#) and [26](#) show a few typical support arrangements adopted in the international loop and pool-type SFRs, respectively.

Both top support and bottom support arrangements have relative merits and demerits that require careful consideration. The top supported vessel is free to expand both in radial (except at the support location) and axial directions, leading to lower stress levels of thermal origin.

Figure 24
Component layout on the top shield vs. number of loops

Figure 25
Reactor assembly support arrangements for loop type reactors

Figure 26
Reactor assembly support arrangements for pool type reactors

On the other hand, the loss of this advantage, together with requirement of large diameter below for accommodating the axial thermal expansion between the support and the top cover, might weigh against the option of bottom supported vessel, especially, for larger power (>500–800 MWe) stations. However, the advantages of bottom supported vessel for seismic-induced loading is obvious in view of the possibility of bringing the support elevation in line with the mass center of the reactor assembly, and the overall weight of top shield could be reduced by transferring loads of the pumps and heat exchangers in the vicinity of the bottom support. In the bottom supported vessel design, the diameter of the top cover can be reduced (e.g., BN 600) by supporting the primary sodium equipment over the extended cantilever portion of reactor vault, thereby relieving the reactor vessel of such a function. In the loop-type design built so far, the top supported vessel designs have been predominantly favored except in BN 350, wherein a support closer to core level has been chosen. Generally, for both loop and pool designs, bottom supported option has been largely favored in Russian designs.

3.4.4 Basic Design Options of Primary Circuit Components

Reactor Vessel (Main Vessel)

The reactor vessel is one of the important components of reactor assembly as it forms a boundary for radioactive primary sodium and argon cover gas and is a part of core support path. In pool type, the vessel is generally made of a cylindrical shell with bottom dished head. The designs of various reactors vary in the kind of supports: bottom or top supports as discussed in [▶ Sect. 3.4.3](#), shape of the bottom dished head, and top shield arrangements ([▶ Figures 25 and 26](#)). The basic parameter that has high impact on the economy is the size of the vessel, that is, diameter and height. The vessel diameter of the main vessel for the pool-type concept has to be studied in a detailed manner. The basis of selecting diameter is dealt in [▶ Sect. 3.4.2](#). Owing to its size requirements and design loadings, the optimization of vessel geometry leads to a large diameter thin shell structure, whose design is largely governed by buckling considerations under seismic loading.

Apart from process parameters including core diameter, the main vessel cooling requirement and the form tolerances of the various vessels, such as main vessel, inner vessel, and thermal baffles, positioned coaxially, have high influence on the main vessel diameter: Experiences indicate that it is easier to achieve tight tolerances with smaller diameter, and large tolerances need to be specified relatively for the large dimensioned vessel. This calls for larger radial gaps between the shells to meet the functional requirements, which in turn results in larger diameter of the main vessel, due to the cascading effects. For example, the form tolerance targeted for Indian PFBR, whose main vessel diameter is 12.9 m, is less than its thickness in order to minimize the above effects. This has been achieved with considerable efforts put forth by the industry. An alternate could be machined main vessel, by which the vessel can have perfect geometrical shape that has high buckling resistance, which is one of proposals for the European Fast Reactor (EFR). Another aspect is main vessel cooling. The main vessel is designed with cooling by “cold sodium” (e.g., PFBR, BN 600, Phenix, SPX-1, etc.) to enhance the structural integrity by lowering the vessel temperature so as to minimize the formation of undesirable carbides and sigma phases in the austenitic stainless steel material and to maintain its temperature and temperature gradients (axial and circumferential) within acceptable limits (from creep and creep-fatigue aspects) during all operating conditions so that the dimensional limits for the

Figure 27
Main vessel cooling arrangements

main vessel are met over the design life. Figure 27 shows the cooling arrangements for a few international SFRs. The kind of cooling circuit concept adopted in these designs incorporates a weir shell over which cold sodium flows to cool the adjacent main vessel. The circuit generally consists of feeding collector (plenum adjacent to the main vessel), restitutions collector (plenum adjacent to feeding collector). The sodium after passing through these two collectors joins back to the cold pool. Apart from this, it also eliminates the possibility of sodium level and temperature fluctuations (responsible for thermal ratchetting and fatigue) on the surface of the main vessel. Hence, practically the vessel is subjected to insignificant creep-fatigue damage and ratchetting. In view of high incentive to design the vessel without cooling in terms of significant reduction of vessel diameter, it is worth putting efforts to eliminate the vessel without sacrificing the structural integrity and reliability requirements. This of course calls for many challenges to be addressed. However, with confidence gained through operating SFR and the advances in material development of high temperature design rules, it is possible to succeed in future reactors, which is one of means to make SFRs economically competitive.

Inner Vessel

The inner vessel is incorporated in pooltype reactors as a barrier between hot and cold pools of primary coolant. On the other hand, loop-type reactors do not require inner vessel. The geometry of inner vessel is designed with penetrations permitting passage of components passing through the vessels. Either single wall or double wall concept is adopted in the international SFRs. The single wall concept (Figure 28a) is generally a selfstanding vessel that carries both mechanical and thermal loads in an optimum way. On the contrary, in the double wall concept (Figure 28b), mechanical and thermal loads are separated out. In SPX1, the inner vessel, which is in contact with hot pool, absorbs thermal gradients in view of its flexibility and outer vessel, which is in contact with cold pool, carries the mechanical load due to the sodium pressure head and self weight including stand pipe. In BN series of reactors, the pumps are kept outside the inner vessel which is feasible for bottom support designs (Figure 29).

The other choice for the inner vessel is the kind of sealing system to be provided at the IHX stand pipes to minimize the leakage of hot sodium to cold sodium. In SPX1, an innovative system using argon pocket is employed. Though it has many advantages in terms of

■ Figure 28
(a) Single wall concept; (b) Double wall concept

■ Figure 29
Lobe type inner vessel concept adopted for BN-600

good leak tightness, construction simplicity, and ease of disassembly and assembly of IHX for maintenance, gradual loss of argon due to diffusion into the hot liquid sodium and consequent fear of argon entry into the core has led not to use this option for future reactors. Alternatively, mechanical seals are preferred, which can be designed to minimize the sodium leakage to insignificant level. ● Figure 30 shows argon and mechanical seal arrangements. Mechanical seals are employed in BN600 and PFBR.

The overall shape of the component is largely influenced by thermalhydraulics and structural mechanics considerations. Minimization of through-wall temperature gradients and thermal stratification in the hot pool are the main thermalhydraulics issues to be addressed.

Figure 30
Sealing arrangements used in inner vessel

From the structural mechanics point of view, buckling of torus portion of the vessel under mechanical loads combined with seismic-induced dynamic pressure, thermal gradients is the critical issue to confirm the shape of the vessel and thickness. Details of thermalhydraulics and structural analyses will be presented in the later chapters.

Grid Plate (Diagrid)

The grid plate supports the core subassemblies and acts as plenum for sodium coolant to pass through the core subassemblies. The coolant entry into grid plate is achieved through pipes. The salient features of grid plate: box-type structures with vertical sleeves connecting the top and bottom plates. The sleeves, apart from facilitating required flow to the various subassemblies, contribute to the rigidity of the structure. The grid plate should be very rigid so that the verticality of subassemblies will be ensured under all operating conditions including seismic events. Grid plate is generally supported on the strong back, which is also called the core support structure. Figure 31 shows the various possible support arrangements for the bottom of the grid plate. The support of grid plate can be through a peripheral ring (Figure 31a) or through multiple intermediate supports (Figure 31b). Generally, a combination of both is preferred (Figure 31c), as the ring provides sealing boundary at the periphery, and the multiple intermediate supports structurally connect both strong back and grid plate, which are beneficial for supporting the core with minimum deflection in grid plate. This also provides adequate rigidity under seismic loading.

Next issue is the connection of primary pipes, which delivers the coolant to the grid plate. A few potential layouts of pipes are depicted schematically in Figure 32. Conventionally, the pipes are connected to the grid plate so that there will be radial entry as in PFBR and SPX1. The plan of pipes can be in the horizontal or vertical plane. The entry can be axial for coolant as in CDFR (Figure 32c). The axial entry concept leads to larger diameter of grid plate compared to radial entry, wherein the nozzle size influences the height of the grid plate. It is desirable to keep the height of grid plate as minimum as possible as it affects the height of main vessel. Design with circular header, which provides multiple radial entries to the grid plate is also possible

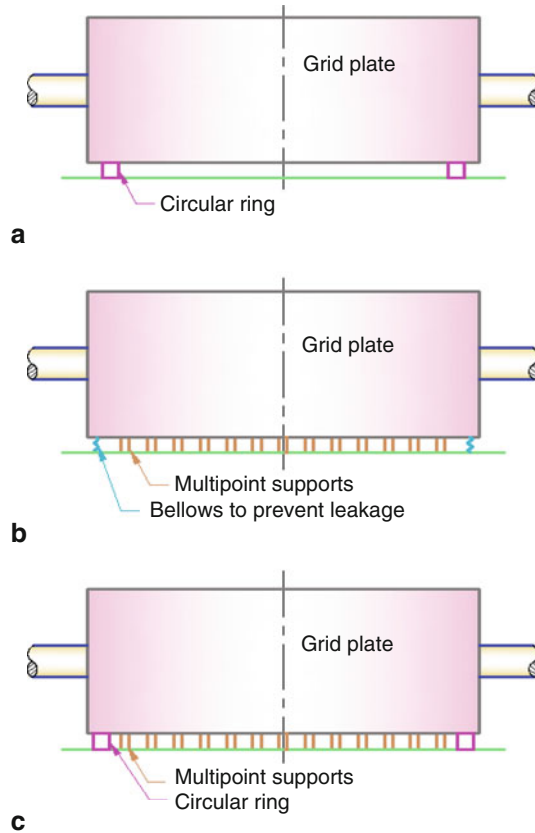

Figure 31

Various support arrangements for grid plate

as shown in ► [Fig. 32d](#). Any particular design selected should be based on available space, flexibility, nozzle junction stress considerations.

Another feature that requires careful evaluation is the type of construction of the grid plate, that is, bolted or welded. ► [Figure 33](#) shows the schematics of these options. The decision of choosing a particular option largely depends on the manufacturing capability. While bolted option is favorable from relatively ease of manufacture, welded option is preferable from totally avoiding coolant leakage from pressure plenum and significant economy.

Core Support Structure (Strong Back)

In pool-type reactors, the strong backup is structurally rigid passive structure providing support for grid plate and finally transmitting the loads to reactor vessel. The important functional requirement for core support structure (CSS) is to provide adequate rigidity to the grid plate. This should be achieved with possibly minimum weight. Hence, stiffened box-type structure is selected. The selection of stiffener configuration is an important design choice, which should be arrived at through comprehensive structural optimization studies. For EFR and PFBR, the

Figure 32
Primary pipe connections to grid plate

stiffener layout consists of a square grid pattern in the central zone with the radial stiffener at the periphery (► [Fig. 34](#)). This arrangement provides nearly uniform stiffness for the plate over the fuel subassembly zone, which minimizes “compaction” and “flowering” mode of core displacements, particularly during seismic events.

The CSS concepts adopted in SFRs are shown in ► [Figs. 35](#) and ► [36](#). The CSS adopted for CDFR has a unique feature that it is an integral with grid plate as shown in ► [Fig. 35](#). This would be advantageous for the spherical dished end concept adopted for CDFR. For the tori-spherical heads, this may not be an economical option from space utilization considerations. Concepts adopted for SPX1 and EFR (► [Fig. 36](#)) are preferred from structural reliability considerations.

Control Plug

Control plug is a part of top shield of reactor assembly and is in-line with reactor core. It accommodates the components/equipments related to safety of the reactor, such as absorber rod drive mechanisms (ARDMs), core monitoring thermocouples, neutron detectors, and failed fuel location systems. It is partially immersed in hot pool sodium. It promotes mixing of sodium

Various support arrangements for grid plate

exiting from the fuel subassemblies and reduces perturbation of sodium free level so as to prevent gas entrainment. As a part of top shield, it acts as biological and thermal shields. It absorbs significant mechanical energy release under core disruptive accident. The control plug forms a leak-tight barrier between RCB and reactor internals.

Generic Geometric and Design Features Control plug consists of many vertical tubes to provide passages for and to accommodate ARDMs, thermocouple sleeves, sodium sampling tubes, etc., which are positioned properly within a skirt assembly. The skirt assembly consists of perforated lattice plate, core cover plate, stay plates, etc. The diameter of the control plug is decided by the number of core (fuel/blanket) subassemblies, which are under temperature monitoring and would be roughly equal to the core diameter. ● *Figure 37* shows 3-D views of a typical control plug part. The height is decided by the level difference between the top shield and the top end of core subassemblies. The geometrical shape of the core cover plate, the gap between

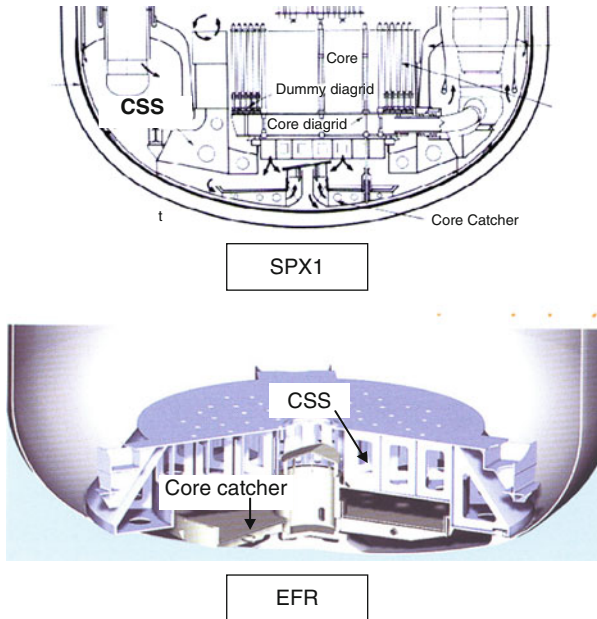

■ Figure 34
Square & radial grid stiffener configuration

■ Figure 35
Integral CSS and grid plate concept for CDFR

the core cover plate and the top end of core subassemblies, perforations in the skirt shell and perforations in the shroud tubes influence the hot pool hydraulics significantly. Thermal stratification in the hot pool, gas entrainment in the vicinity of sodium free level, and thermal loadings on the inner vessel are decided by control plug. The flow through control plug is a critical parameter. While higher flow is preferred to minimize thermal gradients in various parts of control plug under thermal transients, lower flow is better from flow induced-vibration and gas entrainment points of view. Hence, the flow into control plug should be optimized through detailed thermalhydraulics analysis supported by experimental validations to ensure

■ Figure 36
Isolated CSS concept of SPX1 and EFR

that thermal transient effects, gas entrainment, and flow-induced vibration risks are minimum and acceptable. Further, optimum gap has to be provided between the thermowells of core monitoring thermocouples and the head of subassemblies, so that free rotation of the plugs is possible during fuel handling operation.

The important design requirement is the slope at the support locations of absorber rod drive mechanisms due to self weight, and other loads should be minimum for ensuring smooth operation of ARDMs. Further its structural integrity should be ensured under all operating conditions. In view of its position just above the core, the bottom portion of the control plug is subjected to all thermal transients of core. The bottom end of skirt assembly experiences thermal striping because of differential temperature of sodium exiting from various core subassemblies. The skirt assembly in the vicinity of sodium free level is subjected to level fluctuations, thereby high cycle fatigue. The parts immersed in sodium may also be subjected to flow-induced vibrations. The perforated lattice plate provides guided passage for thermocouple tube sheath to avoid flow-induced vibration. The control plug is one of the critical components in the reactor assembly, which decides the design life of the reactor plant.

Many features are added to enhance the reliability of the plug. Stay plates provide structural rigidity to the shell and support the shroud tubes for absorber rod drive mechanisms. Thermal shields at the bottom of plug protect the core cover plate from thermal striping. The thickness of the shell and the plates are optimized by the detailed thermomechanical analysis during normal operation and seismic condition including fluid–structure interaction effects. Welding is avoided in the highly stressed locations and in the shell near the sodium free level.

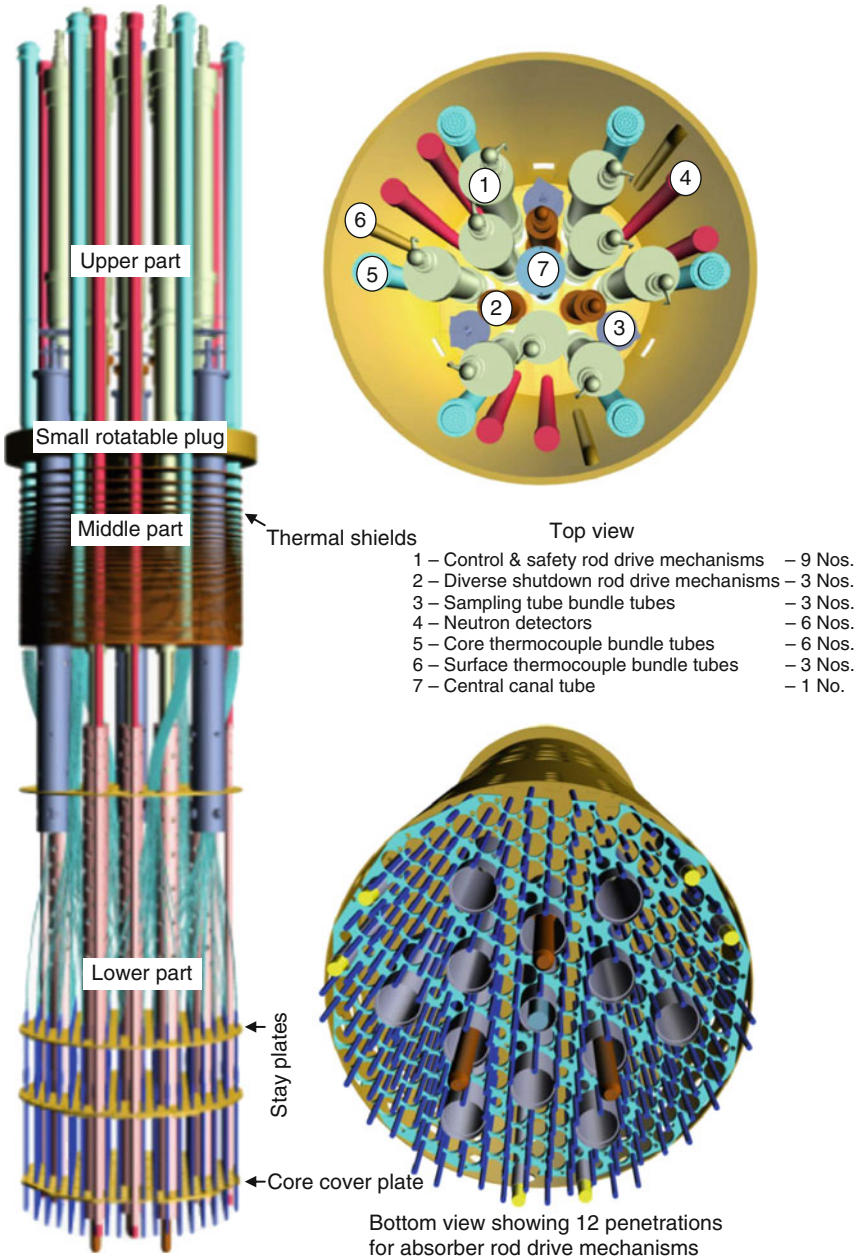

Figure 37
 Three-dimensional view of typical control plug parts

The middle assembly acts as thermal and biological shield. The purpose of shielding is to limit the radiation level over the control plug. Concrete is not considered as a shielding material, since the operating temperature is high. The possible alternatives are graphite, steel balls, and steel plates. It may be a single thick plate or multiple plates of same total thickness distributed over the plug height. The cellular convection in the annular gap between the middle assembly region of the shell and the housing shell produces circumferential temperature dissymmetry and may lead to shifting of core monitoring thermocouples due to tilting of the control plug. The Mechanism box assembly covers all the components, which are supported on the control plug.

Design Options/Trends ➤ *Figure 38* shows a few typical control plugs adopted in the international reactors. The control plug may be a separate or an integral part of the rotatable plug. Separate control plug is used in SPX-1 and PFBR and considered for SPX-2 and SNR-2, whereas PFR, SNR-300, and Phenix have integrated control plug with rotatable plug. The shape of the plug may be cylindrical or conical with tapering in or tapering out from top to bottom. A few variations of geometrical shapes of control plug is illustrated in ➤ *Fig. 39*, which are mainly in the shape, sizes, and perforations of the outer shell and shape of the bottom portion. Tapered shapes conceived for EFR and CDFR, curved shapes of the core cover plate (CCP) used in Russian reactors and Monju and cylindrical shapes with perforations used in SPX1, PFBR and PFR can be seen in ➤ *Fig. 39*.

All FBRs use a core cover plate. The shape of the core cover plate may be flat or curved. CRBRP uses a separate mixing chamber below the core cover plate. Other reactors do not use mixing chamber but allow sodium to mix in the pool. Core cover plate encompasses all the fuel subassemblies in most cases. BN-1600 has core cover plate size less than core size. Outlet temperature monitoring of individual fuel subassembly is done in all SFRs except in Russian reactors. Thermocouples are used in all the reactors. Monju, FFTF, and SNR-300 use miniature

Phenix

BN 600

Monju

■ **Figure 38**
Typical control plugs in SFRs

Figure 39
Geometrical variations of bottom portion of control plugs in SFRs

flow meters for each fuel subassembly. Acoustic detectors or wave guides are also used to detect boiling or acoustic noise in PFR, Phenix, and SPX-1. The location of core cover plate varies. PFR and SNR-300 provide this plate very near to free level of sodium. PFBR, SPX-1, SPX-2, and CDFR have indicated this about 1–1.5 m above the subassembly heads. PFR, SPX1, and PFBR have thermocouple tube sheaths located at about 100 mm over fuel subassemblies. In Rapsodie and FBTR, mobile core cover plate is used, and in other reactors, it is stationary. SS plates as insulation and shielding have been used in Phenix and SPX-1. Shroud tubes are provided around absorber rod drive mechanisms in all LMFBRs. Top plate temperature of SPX-1 control plug is 323 K and it is not cooled within and it is 383 K in PFBR.

In the recent innovative type of design of SFRs, control plug integral with small rotating plug (Fig. 40) and control plug with a slit to accommodate in-vessel fuel handling machine have been conceived (Fig. 41) for EFR and JSFR (Japanese concept), respectively. With the integral control plug adopted in EFR, the main vessel diameter can be reduced significantly. The option of split control plug as shown in Fig. 41 is being studied for JSFR to have compact reactor assembly by having the provision to lift the control plug above top shield during fuel handling operation to facilitate free access for the fuel transfer machine to handle the core subassemblies below the control plug region.

Top Shield

The top shield provides biological and thermal shielding in the top axial direction of the reactor and provides a leak tight barrier between cover gas and reactor containment building. It consists of stationary part (roof slab) and rotatable plugs. In the pool-type design, the stationary part supports the components, such as IHXs and primary sodium pumps. In the loop type, it forms the interface between the rotatable portion and reactor vessel. Depending upon the design concepts, there can be single or multiple rotatable plugs, which houses the mechanisms for the absorber rod drives and fuel handling machines. The components hanging from the top shield are generally very long, and thus, a small rotation of top shield parts would get amplified, resulting in large lateral displacements at the bottom locations, which

■ Figure 40
Integral control plug with small rotating plug (EFR)

■ Figure 41
Slit type control plug with in-vessel transfer machine (JSFR)

should be restricted so that the absorber rods, pumps, and IHX can be moved up and down without much mechanical constraints. This calls for very rigid design concepts (e.g., box-type design). The components, mounted on the top shield, penetrate it to enter the reactor and thus, annular spaces are unavoidable. Freezing of sodium in these annular spaces causes major problems during fuel handling and removal/replacement of the components for maintenance. To avoid freezing of sodium aerosols in the narrow annular gaps, it is preferred that the temperature of the top shield is maintained above sodium freezing point. To facilitate the plug rotations during fuel handling operations without any unacceptable leaks of radioactive cover gas to reactor containment building, proper seals should be provided. Thus, designing for high

rigidity, managing the sodium freezing problems, and sealing are the major challenges in the design and construction of top shield.

Regarding loadings, self weight along with the component weights supported on it are the main loads, under normal operation. Inertial forces generated during seismic events, weights of shielded flasks used for removal of components for maintenance, and transient forces due to sodium slug impact under core disruptive accident add additional major loads to the component, which decide the basic thickness requirements. It is preferable to keep the top shield temperatures low so that personnel access is possible for various maintenance operations. However, sodium freezing concern does not allow this, and hence minimum temperature of about 100 °C is always maintained. This is called warm roof concept. However, it is possible to maintain the structure at low temperature, by providing proper insulation, which is called “cold roof concept.” Thus, there are three types, namely, cold roof ($T = 40\text{--}60\text{ }^{\circ}\text{C}$), warm roof ($T = 100\text{--}120\text{ }^{\circ}\text{C}$), and hot roof ($T = 200\text{ }^{\circ}\text{C}$). US reactors have adopted the hot roof concept while French reactors initially adopted the cold roof and later switched over to warm roof. In cold roof, special insulation (as in SPX-1) is provided to keep the bottom and penetration inner surfaces hot to avoid sodium deposition. However, this is a very costly option. Among these three, warm roof concept is preferred in view of concerns of sodium freezing at the narrow annular penetrations. Further, irrespective of the concepts chosen, the temperature gradients across the height/thickness should be limited so that the tilting of components hanging from it would be within the acceptable values.

There are various options in the conceptual design of roof slab, which may be categorized based on (1) temperature of operation, (2) type of construction, (3) type of support, and (4) location of rotatable plugs. The roof slab can be constructed in different ways, namely, box type with radial/circumferential stiffeners and shielding material within the box structure or using thick plate. The box-type construction is a welded construction using plates and required structural strength is achieved by choosing proper combinations of height and number of radial and circumferential stiffeners. Concrete is generally filled as the shielding material within the box structure. Alternatively, top shield can be constructed by welding of thick plates and shielding is achieved by choosing appropriate plate thickness. Thus, the chosen plate thickness should meet both shielding as well as structural requirements. Cooling circuit can be embedded within the box structure to enable cooling of the structure and thus the absolute temperature as well as gradient can be controlled. In case of thick plate construction, adequate insulation should be provided at the bottom surface to ensure minimum heat transfer to the slab. The roof slab is connected to the reactor vessel by using a stepped construction at periphery. Generally, carbon steel is chosen as the structural material from economic reasons, there should be a dissimilar weld between reactor vessel and roof slab. The roof slab along with all the components is to be supported over the reactor vault. It can rest through either of rollers, screw jack, or welded skirt. The support should accommodate thermal expansion of the roof slab. The load distribution in the vault as well as roof slab shall be as uniform as possible. It should provide leak tightness between the concrete vault and the RCB atmosphere. The rotatable plugs facilitate the fuel handling operation and the location of the same can be concentric or eccentric with the core based on fuel handling option selected. The layout options of the components on the top shield are dealt in [Sect. 3.4.2](#).

A few typical concepts used in other SFRs are highlighted here. FFTF, CRBRP, and EBR-II have adopted a hot roof concept. In FFTF, thick plate concept is used and a combination of passive insulation system plus active head heating and cooling system is provided to maintain the temperature ([Fig. 42a](#)). The CRBRP reactor conceives a design similar to FFTF

(➤ *Fig. 42b*). In EBR-II, box-type construction filled with steel shots with provision of insulation and electrical heaters on top of the roof slab is used with no cooling provision (➤ *Fig. 42c* and ➤ *Figure 43*).

Features of Shaft The shaft transmits the torque from the drive motor to the impeller. The shaft of vertical sodium pumps are generally lengthy especially for pool-type reactors because of the submergence of the impeller, traverse of the reactor cover gas space, and radiation shielding requirements. To meet the simultaneous requirement of the torque and critical speed, it is made of composite construction with a hollow middle portion welded on either side to solid ends. A shaft based on critical speed alone would be uniformly hollow. However, in order to provide shielding against radiation, shaft is made solid at the top and bottom from hydraulic considerations. The diameters at the various sections are fixed based on torque and critical speed considerations. An important feature of the shaft fabrication is the stress relieving heat treatment to be carried out after the welding of the hollow and solid ends in a vertical furnace (to avoid the sagging of the long shaft) to remove the residual stress. If residual stresses are not removed, the shaft may distort during operation. The shaft is evacuated after the heat treatment to eliminate the convection currents inside the shaft. Precision manufacture and balancing of the pump assembly especially the rotor part should be done to have vibration characteristic to the desired level as problems of shaft vibration have been reported in BN-600.

Bearings in Sodium In order to avoid over hang in long shaft, bottom bearing is generally located underneath free sodium level closer to the impeller. Therefore, it becomes necessary

■ **Figure 42a**
Hot roof concept of FFTF (Thick plate)

■ **Figure 42b**
Hot roof concept of CRBRP (Thick plate)

that the bottom bearing be lubricated by sodium. Because of the rather low kinematic viscosity of the sodium at the operating temperature and the fact that maximum rotational speed is limited, the bearing used for this purpose is of hydrostatic type. These bearings get the sodium feed from the pump discharge itself. There is some flexibility in selecting the clearance for a hydrostatic bearing (hydrostatic bearing can permit more clearance). Higher clearance is required for sodium operated pumps to avoid any blocking due to impurities as compared to a hydrodynamic bearing, the only limitation being the permissible leakage flow. The top bearing is conventional as it is not immersed in sodium.

Seals Mechanical seals are used for sealing between the rotating shaft and the stationary parts of the pump to prevent escape of radioactive cover gas on the one hand and entry of air into the main vessel on the other hand. Stuffing box-type seals are not employed because of its leaking characteristic.

Materials The material selected should have (1) compatibility with liquid sodium, (2) good weldability, (3) good formability, (4) high temperature strength, etc. Based on these requirements, SS 304 LN is widely used as principal material for sodium pumps. Wherever metal to metal contact is inevitable, the surfaces are hard faced. The materials used for the major parts of the pumps operating at cold temperatures are listed in ► [Table 9](#).

Figure 42c

ISI device in annular gap between MV and SV (SPX1)

Figure 45
Fall of sodium levels due to postulated leak in the main vessel

of coolant from the main vessel, a safety vessel is provided surrounding the main vessel with optimum annular nominal gap so that the sodium level in the main vessel does not fall below the inlet windows of decay heat exchangers. Further, with the minimum gap between main vessel and safety vessel (MV–SV) selected, it should be possible to have full access for the periodic inspection of main vessel outer surface (➤ *Fig. 44*), after accounting for the possible deformations of vessel due to thermal ratchetting in particular. The gap is filled generally with nitrogen and is monitored for any sodium leak from the main vessel. The weight of the reactor internals including the core does not act on the safety vessel, even under an unlikely event of main vessel leak; only hydrostatic pressure of sodium would act on the safety vessel. Hence, the minimum nominal radial gap selected is 300 mm for PFBR and 700 mm for SPX1. Hence, the thickness of the vessel can be selected lower than that of the main vessel. The choice of the material can either be austenitic stainless steel 304 LN or even carbon steel for economic considerations. ➤ *Figure 45* shows the sodium level variations when main vessel leaks in case of a typical 500 MWe PFBR.

There is a need to minimize the heat loss from the hot pool and thereby reduce the heat load for the reactor vault cooling circuit. For achieving this, it is not preferred to mount thermal insulation on the main vessel surface, to avoid any difficulty of inspection. Alternatively, the outer surface of the safety vessel can be used for supporting thermal insulation panels. Thermal insulation panels should function reliably over the entire plant life of the reactor. Based on thorough analysis, thermal insulation panels constituted with specified numbers of thin polished stainless steel sheets arranged in parallel is found to be suitable for this important function. However, development, manufacture, and erection of such panels involve many challenges to be addressed. This has been successfully resolved for Indian PFBR. The safety vessel has been erected in the reactor pit precisely with the insulation panels mounted on it. ➤ *Figure 46* shows the vessel just before its introduction in to its location in the reactor pit for SPX1 and PFBR.

3.4.5 Design Improvements for Future SFRs

There are certain areas where we can apply new ideas from safety as well as from the economy point of view. This includes development of double suction pumps, which will reduce the size

■ **Figure 46**
Safety vessels of SPX1 and PFBR at the time of lowering into reactor pit

of the pump. Integration of intermediate heat exchangers with primary pump is an option to consider reducing the size of the reactor block. Leakage of oil from mechanical seals to primary system was reported in two reactors (PFR, BOR 60). Therefore, usage of oilless seals and bearings is being explored. Integration of the primary pump and IHX is another innovative design approach considered for Japanese SFR (JSFR). By integrating the primary pump and IHX, the primary heat transport system is remarkably simplified (➤ *Fig. 47*). The middle leg piping that connects IHX and pump is not necessary, and also the number of components is reduced by this design. In this design, a mechanical pump is selected. This is because the technological base accumulated through the development of the mechanical pumps for Joyo and Monju is available. Development of bearings for stabilization of the shaft and reduction of the vibration transfer to IHX tubes are major R&D issues.

The broad background on design options and other relevant details required for selection of the pump and also for carrying out detailed design has been highlighted in this chapter. Also, the design features of various PSPs of international SFRs are summarized in ➤ *Fig. 48* for information.

3.4.6 Intermediate Circuits and Steam Generator

The intermediate circuit is interposed between primary sodium circuit and tertiary steam–water system from considerations of reactor safety, in the sense that the primary sodium systems would be free from mechanical and chemical effects of sodium–water reaction, if it

■ **Figure 47**
Pump-integrated IHX (JSFR)

occurs in steam generator (SG). The overall reactor design incorporates provisions, for example, in vessel shielding around core, and the like, to render the secondary sodium circuit to be of nonradioactive type, thus making its components generally amenable for maintenance with adequate care. Provisions such as surge tanks/cover gas in SG are incorporated in the circuit to absorb the pressure surges during inadvertent sodium–water reaction. Apart from piping, the important components of the circuit are IHX, secondary sodium pump (SSP), and SG (● *Fig. 49*). From an economic consideration, there is incentive to minimize the overall length of piping and optimize the location of various equipments, thereby leading to compact circuit layout. Further, a detailed study is desirable to arrive at the number of loops in secondary sodium circuit. The operating experience of SFR worldwide has demonstrated the reliable operation of sodium pumps and IHXs (except in Phenix) as compared to steam generators, wherein maintenance operations on account of sodium–water reactions have led to prolonged shutdown of the respective plants. Therefore, plant availability considerations would desire incorporation of many SG modules, and hence, a

Figure 48
Summary of design features of various PSPs

detailed risk economic trade-off studies is to be carried out with due consideration to manufacturing and other infrastructure capabilities. A brief description and the salient features of important secondary sodium circuit components are highlighted in the following paragraphs.

Secondary Sodium Pump

In the case of pool-type reactors, the primary sodium pumps are always located in the cold pool. However, the secondary sodium pumps of both pool and loop-type reactors can be located in either the hot leg or the cold leg. Table 10 shows a number of PSPs and SSPs in the various

■ Figure 49
Schematic sketch of intermediate circuit

■ Table 10
Number of sodium pumps in various SFRs

	Rapsodie, KNK-II, PFBR	FFTF, Monju, PFR, Phenix, BN 600, BN 800	SPX-1, CDFR	EBR-II	EFR
No. of PSP	2	3	4	2	3
No. of SSP	2	3	4	1	6

reactors. It can be seen in the table that the numbers of PSPs and SSPs are generally equal. In EFR, more number of SSPs is adopted for having operational flexibility with nonavailability of SG module.

The secondary sodium pumps of all operating fast power reactors and most experimental reactors in the world are located in the cold leg at a higher elevation with respect to the steam generator. The design of secondary sodium pump is generally similar to that of primary sodium pump. The major differences are shorter shaft, absence of radiation shielding, and absence of the need for accommodating differential expansion. As the cover gas pressure in the secondary circuit can be higher than the primary circuit, the speed of operation of the

Figure 50
Typical secondary sodium pumps

secondary sodium pump (900–1,000 rpm) is more than PSP (500–700 rpm), thereby making the SSP more compact. Figure 50 shows two typical SSPs of PFBR and SPX1.

Steam Generators

Steam generator availability is recognized as the major factor for achieving good load factor, thereby commercial success of the SFR power plant. The reliability results not only from good design and fabrication practices but also from a proper selection of the structural material. A worldwide survey of fast reactor steam generators (SGs) in operation or under development shows considerable diversity in design and selection of materials. Many factors that are often difficult to quantify are involved, and considerable amount of judgment is required in assessing a steam generator design. The operating conditions of fast reactor SG are not severe compared to that of fossil fueled power plants; however, the tube leakage leading to severe sodium–water reaction affects the availability of the plant. No satisfactory design, which will ensure complete protection against the tube leakage, has been evolved. Due to this reason, no standard steam generator concept is available. Countries such as US, France, UK, Japan, and India have adopted diverse design for their fast reactor program.

The two different concepts generally followed for the steam generator design (Fig. 51) are

- Recirculation type
- Once-through type

The recirculation type consists of two units, namely, evaporator and super heater, which are connected through a steam drum. The water in the evaporator gets heated up to a certain quality

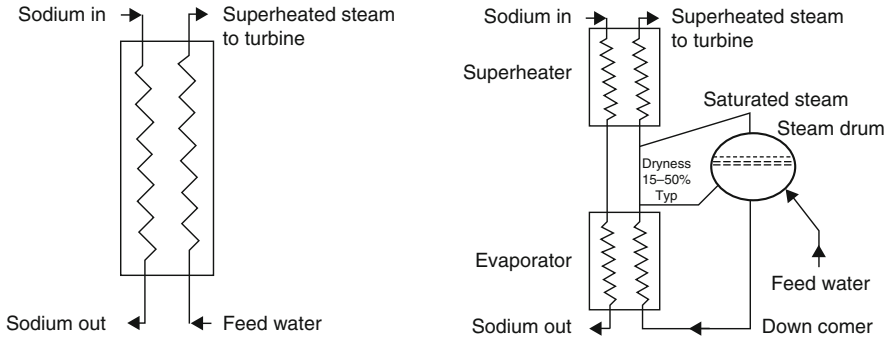

Figure 51
Once through and recirculation types of SG

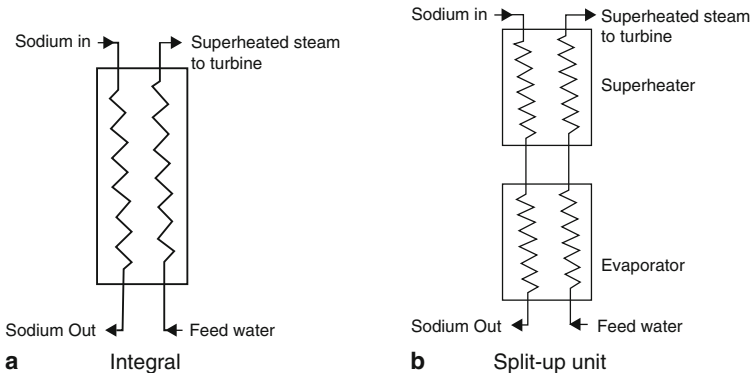

Figure 52
Types of once-through SG

and then the water–steam mixture gets discharged into steam drum. In the drum, the steam separators separate steam from the two phase mixture, and the steam goes to the super heater for super heating. In once-through type, the drum is absent, and the water entering the steam generator gets heated up to the super heat temperature passing through all heat transfer regimes. Once-through type steam generators have two variants, namely, integrated type and split up unit. In the integrated type, the evaporator and super heater are integrated in one unit, and water enters to the SG and come out as the super heated stem (Fig. 52a). In the split up type (Fig. 52b), the evaporator and super heater are separate units, and these two units are connected in series. Water enters to the evaporator and comes out as saturated steam, which enters to the super heater and come out as the super heated steam.

PFR, BN-350, EBR-I, EBR-II, and CRBRP have adopted the concept of recirculation type, while reactors such as Phenix, SPX1, Monju, and PFBR have once-through type SGs. All the new generation reactors have high power capacity and are now adopting once-through type SGs.

Design Options The SGs are shell and tube type, and different designs exist due to the different configurations of shell and tubes. Tube and shell configurations should be such that it must be able to accommodate the differential thermal expansion of the tube bundle and shell. The selection of the configuration is influenced by the following factors:

- Good tube bundle accessibility for inspection, maintenance and repair
- Relative freedom from sodium stratification
- Performance sensitivity with plugged tubes
- Ability to limit damage in the event of a sodium–water reaction

Based on the above requirements, different designs are evolved in different countries in which tube configuration may be either straight tube, helical, serpentine, or U tube. Tube may be either

■ Figure 53
Phenix SG

single wall tube or duplex wall tube. Among various choices available, each country adopted different designs in the early stages of the LMFBR reactor program.

Serpentine Type SGs of Phenix and FBTR fall under this category. The schematic of PHENIX steam generator (once-through integrated type) is shown in [Fig. 53](#). Similar type of SG is used in FBTR.

Figure 54
PFR SG

U Tube Type This design is adopted by older generation breeder reactors. This configuration provides reduced overall height and simplifies transportation and installation. The differential expansion between shell and tube bundle can be easily accommodated in this configuration. One of the examples of this design is the SG in PFR, UK, which was commissioned in 1975. PFR SG is a recirculation type with water in the tube and sodium in shell side (● Fig. 54). The tube bundle is removable. The evaporator, super heater, and reheater are using rigid shell with U-tubes. The SG in BN-350, which is a recirculating type, uses a bayonet tube for boiler–evaporator that is closed at bottom end (● Fig. 55). The evaporator is a shell and tube heat exchanger with U-tubes.

■ Figure 55
BN-350 SG

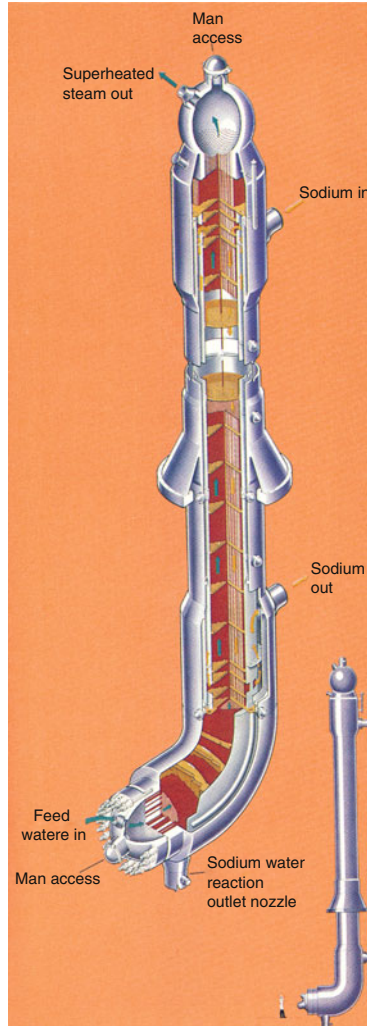

Figure 56
UK design CDFR

Hockey Stick or J-Tube Steam Generators This type of design evolved in the early 1970s for large plant applications. Development of these types of SG is taken up in USA for CRBRP and in UK for the CDFR. This type of design provides enough flexibility for high temperature operation due the bend in the tubes as well as in the shell. In this type of design, the horizontal leg can be either at the inlet or at the outlet of the SG. The UK design has the horizontal leg at the water inlet (► Fig. 56), while the US design for CRBRP has the horizontal leg at the steam outlet (► Fig. 57).

Helical Tube Type Helical coil SGs provide a compact unit thus simplifying transport and installation. This configuration is also good to take care of differential expansion between shell

■ Figure 57
US design CRBRP

and tube bundles and amongst the tubes. Helical tube design is adopted for SPX1 and Monju Reactors. The SG for SPX1 is shown in ► Fig. 58 and that of Monju, Japan, is shown in ► Fig. 59.

Straight Tube Designs Straight tube with bellows is used for BN-600 (► Fig. 60a) and EFR (► Fig. 60b), while shell and tubes with bend are used for PFBR SG (► Fig. 61). In the case of EBR-II, straight double walled tube with cold springing shell (shell was thermally elongated during the tube to tube sheet welding so that tubes were in compression at room temperature and hence relaxed stress state was achieved under operating conditions) (► Fig. 62).

Materials for Steam Generators Selection of good structural material for SG is an important step in the SG design. Material generally used for fast reactor steam generators are austenitic and

■ Figure 58
SPX1 SG

ferritic steels with exception of alloy-800 in SuperPhenix-1. The primary criteria for the selection of materials for SG are fabricability and resistance to stress corrosion cracking. The trend in first generation heat exchangers was to use austenitic stainless steel of type 321 or 316 for super heater and reheater and ferritic steel for evaporators. In PFR the material for evaporator was 2.25 Cr-1

Figure 59
Monju SG

Mo, and austenitic steel of type 316 for super heater and reheater. In the case of PHENIX reactor steam generator the evaporator is 2.25 Cr-1 Mo and the super heater and reheater are made of austenitic steel of type 321. Subsequent to severe damage in PFR reheater, no design has favored austenitic stainless steel for any portion. However, in BN 800, sodium/steam temperature has been lowered to mitigate the problem. The second generation breeder reactors in USA such as EBR-II, CRBRP Fermi, and HNPf used ferritic steels of 2.25 Cr-1 Mo for the SGs. Super-Phenix reactor in France used alloy-800 for tube and stainless steel of type 316 for shell. In UK, different materials were used for super heater and evaporator of PFR; but the same material ferritic 9 Cr-1 Mo was used in CDFR for both shell and tubes. The material used for PFBR steam generator which is an integrated type is modified 9 Cr-1 Mo for both shell and tubes. The first power generating fast reactor in Japan Monju has used 2.25 Cr-1 Mo for evaporator and material of SS-321 for super heater. ▶ [Table 11](#) gives the summary of SG designs used in various international SFRs.

Innovative Design for Future Reactors Elimination of intermediate piping is one of the steps to achieve economy. With this objective, French conceives a design, as shown in ▶ [Fig. 63](#), in

Figure 60
Straight tube SG with bend in shell

Figure 61
PFBR SG

Figure 62
EBR-II SG

which IHX and SG are combined. The primary sodium will enter through the top header and flow down through the tubes. The coupling fluid, which passes through the shell side, takes away heat from the primary sodium and transfers it to the water passing through the coils surrounding the shell side generating steam. This design the main problem facing the steam generator design, that is, the sodium–water reaction due the presence of the coupling fluid and reduce the heat loss due to the transport from IHX to steam generator.

JSFR conceives another concept, which uses a duplex straight tube concept with bellows in the shell side to take care of the differential thermal expansion (➤ Fig. 64). The SG uses a spherical tube sheet which enables different tube length reducing the differential expansion among the tubes. For the SGs, for future FBRs in India (CFBR), less number of SG modules, that is, the four/loop used in PFBR reduced to three with longer tube length of 30 m, is conceived to improve economy as well as enhance reliability through reduction of the number of welds (➤ Fig. 65).

■ **Table 11**
Details of SG designs in various international SFRs

Reactor	SG type	Configuration	Material
Phenix	One trough split type	Serpentine	2.25 Cr-1 Mo for evaporator and SS-TYPE 321 for super heater and evaporator
FBTR	One trough split type	Serpentine	2.25 Cr-1 Mo stabilized
PFR	Recirculation type	U tube	21/4 Cr-1 Mo for evaporator and SS-316 for super heater and evaporator
BN-350	Recirculation type	Bayonet tube for evaporator	2 Cr-1 Mo
EBR-1	Falling film type	Shell tube type with below in the outer shell	Tube of composite assembly of inner nickel middle copper and outer nickel and SS shell
EBR-II	Recirculation type, duplex tube	Straight tube with cold springing shell	21/4 Cr-1 Mo
SPX1	One through integrated	Helical coil tube	Alloy 800 for tube and SS-316 or 304 for shell
CRBRP	Recirculation type	Hockey stick	2.25 Cr-1 Mo
Monju	One trough split type	Helical coil tube	2.25 Cr-1 Mo for evaporator and SUS-321 for super heater
PFBR	Once through integrated	Shell and tube with bend	Modified 9 Cr-1 Mo
CDFR	Once through	J tube	9 Cr-1 Mo
EFR	Once through integrated	Straight tube with bellows in shell	Modified 9 Cr-1 Mo
BN-600	Once through	Straight tube with bellows in shell	2.25 Cr-1 Mo for evaporator & 304 SS for super heater
BN-800	Once through	Straight tube with bellows in shell	2.25 Cr-1 Mo for evaporator and super heater

Intermediate Heat Exchanger (IHX)

IHX transfers thermal energy from radioactive sodium on primary side to the nonradioactive sodium on the secondary side. IHX along with the steam-water circuit will be the normal decay heat removal path. In case of an on-site or off-site power failure, safety grade decay heat removal system is used to remove decay heat of the core. IHX is a shell and tube-type heat exchanger. In a loop-type fast reactor, the primary coolant is circulated through IHX external to the reactor tank (but within the biological shield owing to the presence of radioactive sodium-24 in the primary coolant). In a pool type fast reactor, IHX is immersed in the reactor tank.

Figure 63
Combined IHX and SG with a coupling fluid

Figure 64
SG for JSFR

Design Options For pool-type reactors, two IHXs per pump are preferred per secondary loop in order to better pool hydraulics with compactness. Moreover, same handling flask can be used for both primary sodium pump and IHX. However, in loop-type reactors, since this constraint does not exist, one IHX per loop is generally preferred though exceptions might exist. Figure 66 depicts the design options of a few typical loop-type SFRs. The IHX of BN 350 has a few unique features, namely, single shell accommodating three tube bundles (Figure 67), compared to other loop-type reactors, as depicted in Figure 66.

Figure 68 shows IHX concepts of a few typical pool-type SFRs. PFR, Phenix, BN-600, SuperPhenix, SNR-2, CDFR, PFBR, and PRISM have two IHXs per secondary loop. Of the

Figure 65
SG for CFBR

loop-type reactors, Monju, CRBRP, FFTF, and FBTR have one IHX per secondary loop though SNR-300 has three IHXs per secondary loop. The IHX thermal center is to be located above that of the core so as to promote natural circulation for ease of decay heat removal.

One of the options available for IHX is choosing the shell side sodium. Secondary sodium has been selected for the shell side in PFR, CDFR, and EPRI. In other reactors (Phenix, SPX-1, SPX-2, SNR-2, BN-600, PRISM, PFBR, FBTR, FFTF, CRBRP, Monju, SNR-300), primary sodium is put in the shell side. This issue is not of much concern in loop-type reactors where pressure drop restriction on the shell side is not a strong design parameter. Generally, the countries continued with the same option for the subsequent reactors.

In IHX tube bundle tubes can be either straight or with an expansion bend. Tube bundle with straight tubes has the advantages of lesser tube sheet thickness, ease of manufacture, less pressure drop, and low FIV due to the absence of bend. In some reactors (FBTR, PFR, BN-600, FFTF), tubes are provided with expansion bend to take care of differential thermal expansion among tubes, plugged tubes and other tubes, between central down-comer shell and tube bundle. The difference in temperature between the outer and inner rows of tubes due to the cross flow effects at inlet and outlet can be overcome by varying the secondary sodium flow with more flow in the outer rows by using a flow distribution plate at the bottom of the tube-sheet. By elimination of tube plugging, disadvantages of straight tube design can be further minimized.

The primary requirement of tube to tube-sheet joint is that it should be leak-tight and it should withstand pressure and temperature under various loading conditions. There are basically four options: internal bore welding (FFTF, PFR, and SNR), electron beam welding (alternative studies for Phenix), explosive welding (candidate choice for CDFR), and conventional rolled and welded (FBTR, Phenix). Internal bore welded joint offers advantage of crevice free joint and better inspectability, but it is more expensive. It has been reported and also can be interpreted from the operating experiences of Rapsodie and Phenix that crevice free joint is not a must for IHX. For CRBRP the front face fillet and explosively rolled weld was proposed instead of internal bore weld design of FFTF from economy consideration. Electron beam welding offers advantage of elimination of groove machining on tube-sheet and provided

Figure 66
IHX options for typical loop type SFRs

■ **Figure 67**
IHX of BN-350

better penetration. This technique calls for greater development and incidentally has not been reported to have utilized for any IHX. Explosive welding provides a potential for cost reduction. However, this welding technique is at an infancy stage in India. Good amount of knowledge has been generated on rolled and welded joint during the course of manufacture of FBTR IHX. Hence, the preferred choice for tube to tube-sheet joint is mechanically rolled and pulse TIG welded without filler wire.

The design of tube bundle support arrangement is important for the performance of any heat exchanger. Serious leaks have occurred in many heat exchangers due to fatigue failure caused by tube vibration or stress concentration by welded support arrangement. Tube bundle support arrangement choice is difficult because of conflicting requirements. Welded support arrangement is rejected as it is difficult for a closely spaced tube arrangement. No LMFBR IHX has adopted this design. The use of non-welded-type arrangement means that the risk of fretting under sodium has to be considered and such designs would need to be substantiated by experiments or adopted from proven designs. Hence, the preferred choice is tubes held by ferrules and anti-vibration belt. Such a design is used for Rapsodie, FBTR, Phenix, and SPX-1. Rapsodie IHXs had given satisfactory performance, and no problems have been reported yet on Phenix and FBTR because of tube bundle support design. 🔗 *Figure 69* shows a few options for tube bundle support, commonly used in SFR IHXs.

All intermediate heat exchangers in pool-type reactors admit fluid on the shell side through circumferential openings in the shell, called windows. Windows should provide minimum obstruction to flow. Since primary sodium pressure drop is very important from the perspective of main vessel and inner vessel sizes and as a result cost of the reactor, it is paramount to ensure minimal pressure drop through IHX. Various different options for window configurations are available. The shell of the heat exchanger can be rolled to full length and windows of required dimensions at appropriate elevations can be cut off. Perforations in the rolled shell at

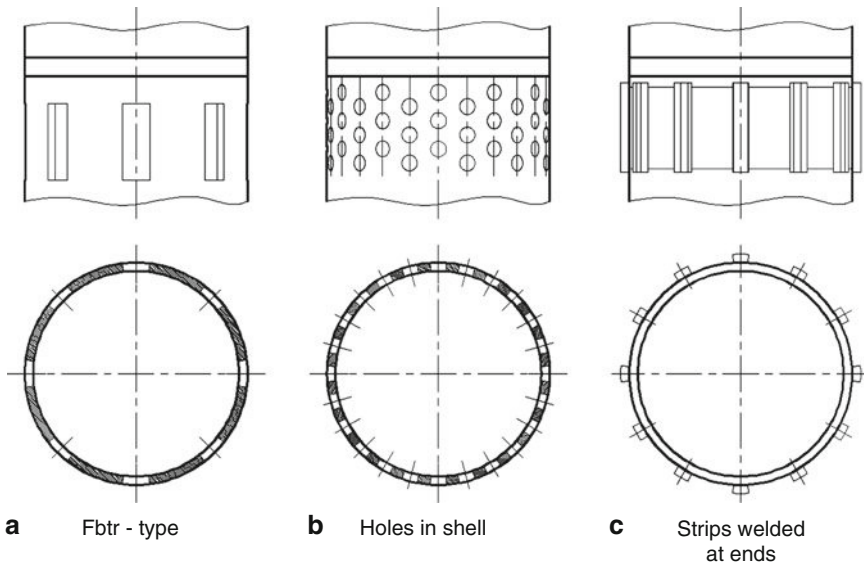

Figure 68
Design options used in typical pool type SFRs

■ Figure 69

Various options for the tube bundle supports

■ Figure 70

Options for primary sodium inlet/outlet windows

the inlet and outlet positions can also serve the purpose. Another option includes providing shells excluding the window locations and connecting them using small strips running across the height of the window.

The IHX principal support should allow easy removal of component for easy maintenance. At the same time, it should be sufficiently rigid to resist seismic loading and at the same time facilitating sufficient hold down force to prevent ejection of component during DBA. Its thermal expansion should not be constrained, and it should be easy to manufacture. In pool-type reactors the differential expansion between the IHX and the roof slab is accommodated by having adequately sized openings in the inner vessel where it penetrates.

For IHX biological shielding design, iron shots and stacked stainless steel (SS) plates are two options exercised in many reactors around the world. FBTR (India) uses iron shots for

shielding. However, the use of SS sheets is preferred and is used in most other reactors because it leads to a reduction of temperature differences between thermo siphon hot and cold legs. The annular space between secondary sodium outlet header and supporting shell is filled with thermal insulation to minimize heat loss from the sodium. Annular stainless steel plates are stacked enveloping the supporting shell.

Figure 71
CDFR IHX

Some IHX windows have isolation valves installed (SNR-2, CDFR, PFBR). They are often manually operated sleeve valves. These valves are provided in case the reactor has to be operated with a reduced number of loops. Most of the existing IHXs in the world are vertical in orientation, counter flow, shell, and tube heat exchangers. The tubes are basically straight, though expansion bends are provided in many models. However, there exists an important exception to this configuration. The primary side of IHX of Russian BN 350 fast reactor (Fig. 70) is horizontally oriented, its cross section being rectangular. Each of the horizontal IHXs are provided with three openings at the top through which U-tube bundles with rectangular cross sections are inserted, which serves as the secondary side. The tubes end in flat tube plates. Secondary sodium flows in series in the three tube bundles. Primary sodium enters in the horizontal shell from one side and exits from the other side. This configuration makes it a cross flow heat exchanger.

Materials Austenitic stainless steels are the principal materials preferred as structural material for IHX, owing to its superior high temperature behavior. SS316 and SS304 are the most preferred stainless steels. Variants of these steels obtained through small modifications with their constitution such as L, LN, etc. are often used for specific requirements. In some reactor, IHX SS321 was also used. SS316 is the principal material of construction in IHXs of FBTR, Phenix,

Figure 72
Kidney shaped IHX for PRISM

SNR 2, as also for primary inlet nozzle of CRBRP. PFR IHX uses SS 321 while SS 316L is used for Phenix IHX tubes as well as tubes of SuperPhenix. SS 304 is the chief structural material for FFTF, CRBRP, and PRISM. SPX1 uses SS 316LN.

Innovative Designs CDFR (United Kingdom), a pool-type reactor is one of the few reactors that has primary sodium on the tube side and the higher pressure secondary sodium on the shell side (also PFR). This particular feature allows easy integration of decay heat removal system with the IHX. Thus, in CDFR, DHX and IHX are integrated (➤ Fig. 71). PRISM (USA-GE) is another reactor with some novel features. Its IHX is noncircular in cross section (➤ Fig. 72). The shell of the IHX is kidney shaped, while the parts seeing secondary sodium are circular tubes. Also, the IHX is fitted with baffles on alternative sides. These baffles are perforated with the holes serving the purpose of holding tubes and for allowing some flow through. The flow hole sizes are controlled in order to control cross flow velocity.

3.4.7 Summary

Design options adopted for the primary components in various SFRs and innovative features are highlighted. The concepts are addressed with simple schematic sketches to bring out the convergence and variants among the designs. This background would certainly help to conceive new and innovative design options for future SFRs.

3.5 Fuel Handling

The term “fuel handling” refers to the operating sequences related to refuelling of the reactor. In SFRs, these operations are generally carried out in shutdown condition of the reactor. In this section, the functions of fuel handling system, its classification, reasons for performing fuel handling during reactor shut down, basic fuel handling scheme, safety/design requirements during handling, and basic design choices related to fuel handling are discussed. The choice of refuelling interval is linked to physics of core management. A batch of subassemblies is replaced at the end of each operational campaign fixed in terms of effective full power days (EFPD). The batch size may vary depending on number of replacement cycles of a full core. Additionally, a proportion of blanket subassemblies and control rods are also replaced depending on their cycle life.

The sodium temperature and cover gas pressure during fuel handling influence the design. The temperature of sodium is reduced to 423–553 K during fuel handling in order to reduce the influence of sodium aerosols on operation of fuel handling mechanisms. In this temperature range, the formation of sodium aerosols is very less and hence, this will lead to less deposition problems during rotation of rotatable plugs and movement of fuel handling machines. The temperature selected is also sufficiently high to avoid freezing of sodium at stagnant locations within the sodium pool. The pressure of cover gas during normal reactor operation is 10–50 kPa with respect to reactor containment building pressure. During fuel handling, it is reduced to few mbar with respect to reactor containment building pressure in order to reduce leakage through the dynamic seals of rotatable plugs.

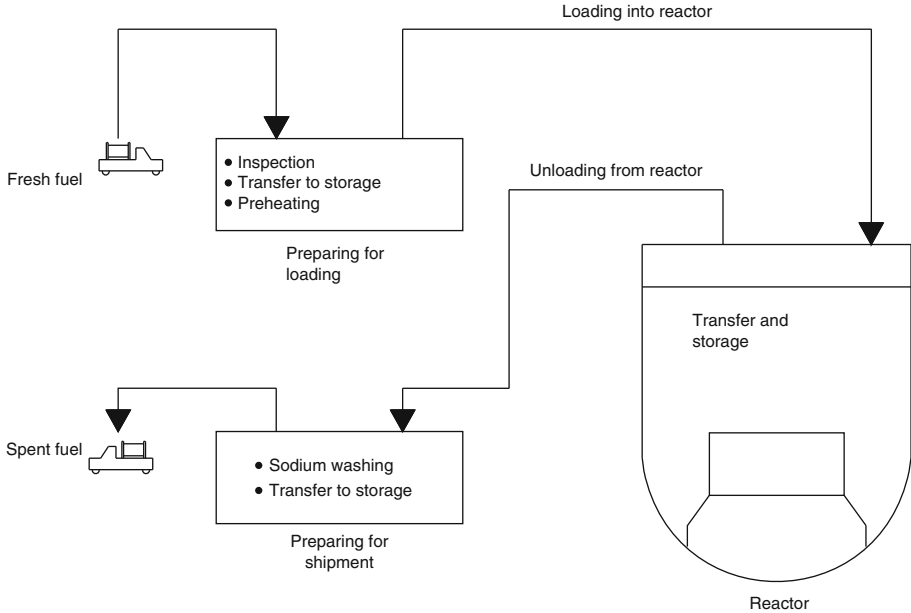

Figure 73
Functions of Fuel Handling System

3.5.1 Function

The functions of fuel handling system are:

- Receipt of fresh fuel from the fuel fabrication plant into the reactor plant
- Preparation of fresh fuel before loading into the reactor, which includes inspection, transfer to storage locations, and preheating prior to loading
- Transfer of fresh fuel into the reactor, shuffling of fresh/spent fuel within the reactor vessel, and transfer of spent fuel out of the reactor
- Storage of spent fuel to reduce the decay heat (in-vessel/ex-vessel)
- Washing of spent fuel to clean the sodium sticking to the fuel and storage of fuel for shipment to reprocessing plant
- Shipment of spent fuel to the reprocessing plant

The functions of fuel handling system are schematically shown in [Fig. 73](#)

3.5.2 Classification

The fuel handling is broadly classified as indicated below:

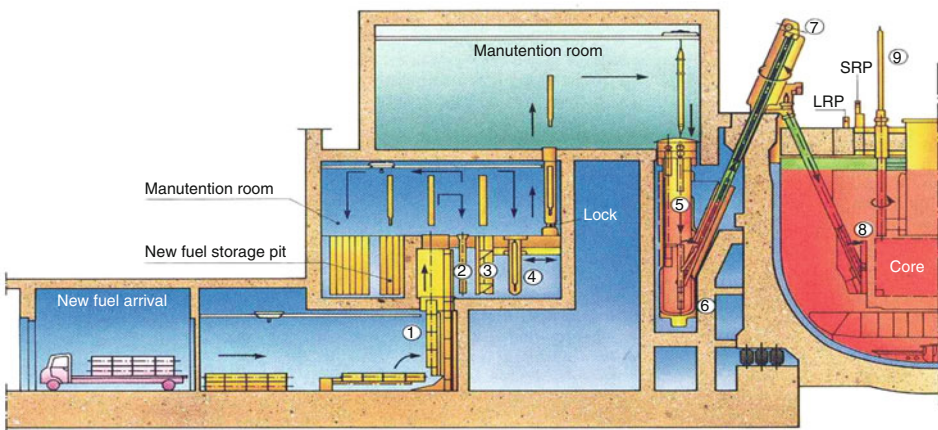

- State of reactor during refuelling: on-line and off-line refuelling
- Type of subassemblies being handled: fresh and spent subassembly handling
- Associativity with respect to reactor vessel: in-vessel and ex-vessel handling

3.5.3 On-Line Versus Off-Line Refuelling

SFR is characterized by a reactor core with high power density (~ 500 kW/L) and liquid sodium as the coolant with high heat transfer capability. The power density is obtained by a closely packed array of fissile material provided in the form of hexagonal subassemblies. The amount of reactivity associated with a single subassembly is considerable and reactivity changes due to subassembly loading/unloading, while the reactor is in power, would result in unsatisfactory reactor operation. SFR is generally refuelled in the shutdown condition of the reactor when all the control rods are fully inserted into the core and the core has sufficient negative reactivity. In addition, generally SFR has a vertical configuration of the reactor with the control rods along with their drive mechanisms housed in a control plug located above the core. The core is supported from the bottom of the reactor vessel. Since it is difficult to provide direct sealing for the high temperature and radioactive sodium present within the reactor vessel, an argon cover gas is used above the sodium level to provide an inert gas blanket for the sodium and to enable provision of sealing for the radioactive cover gas. Hence, the configuration of the reactor is such that, to gain access to the core subassemblies directly below the control plug, it becomes necessary to move the control plug away from the centerline of the core during fuel handling. This requires the control rods to be detached from their drive mechanisms resulting in need for reactor to be shut down. The time required for fuel handling more or less matches with the shutdown time required for other planned maintenance activities of the reactor and hence does not influence the availability of the reactor. Hence, off-line refuelling has been the choice in all SFRs.

3.5.4 Fresh Subassembly Handling

► *Figure 74* shows a typical fresh subassembly handling scheme as in SPX-2 reactor.

■ **Figure 74**
Fresh subassembly Handling scheme in SPX-2

The new or fresh subassemblies are brought to the reactor plant from the fuel fabrication plant inside a fuel transport cask. The new fuel has radioactivity due to gamma activity from residual fission products, low energy gamma rays from plutonium, and americium and neutron emissions largely from the (α,n) reactions from the oxide fuel. Hence, the fresh fuel subassembly requires moderate shielding. From the cask, the subassembly is transported to an inspection facility for checking of subassembly identification number, enrichment level, dimensional check, visual check, subassembly flow zone identification, and flow blockage test. After successful inspection, the subassembly is stored in a storage bay designed with adequate spacing to prevent criticality. Rejected subassembly, if any, is stored separately and returned back to the fuel fabrication plant. All the above operations are carried out with the subassembly in air. During a fuel handling campaign, the subassembly is loaded into the reactor which has argon as the cover gas. Hence, there is a need for change of contact of the medium in contact with the subassembly to an inert gas before loading into the reactor. This can be effected by transferring the subassembly through an inert gas filled cell and loading into the reactor through ex-vessel handling machine.

3.5.5 Spent Subassembly Handling

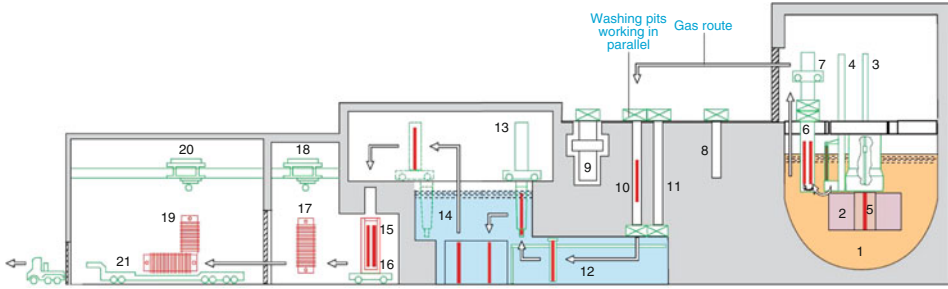

- *Figure 75* shows a typical spent subassembly handling scheme as in SPX-1 reactor.
- *Figure 76* shows the scheme adopted in EFR.

The main challenge in handling of a spent subassembly is its high decay heat shortly after reactor shut down and its high radioactivity. The decay heat is strongly dependent on the specific power (kW/kg of U+Pu) and cooling time (days after discharge from reactor) and is less dependent on burnup (MWd/t). This is illustrated in ➤ *Table 12* from published data (Noraiki Takahashi et al. 1989). The high decay heat leads to an increase in temperature of the fuel clad and if adequate heat sink is not provided during handling, it may lead to loss of integrity of the clad with resultant release of radioactivity into the working environment. While handling under

■ **Figure 75**

■ **Table 12**
Decay heat in kW for 100 kg fuel (U+Pu)

Sl. No	Fuel Burnup (MWd/t)	Specific Power (kW/kg)	Days after discharge from reactor		
			10	40	100
1	100,000	400	77	41	21
2	50,000	400	67	31	15
3	100,000	100	23	12	6
4	50,000	100	21	11	5.5

sodium, decay heats upto ~ 90 kW can be dissipated without loss of integrity of the clad (Blanks 1985). However, the spent subassembly has to be handled in an inert gas environment prior to its washing to remove the sodium sticking to SA.

This calls for storage of the spent subassembly either within the reactor vessel (in-vessel storage) or outside the reactor vessel (ex-vessel storage) in order to reduce its decay heat to a level compatible with handling in gaseous medium. The subassembly is then washed in washing pits to remove the sodium sticking to the SA. This is done to avoid the load of subassembly cleaning on the reprocessing plant. After sodium cleaning, the subassembly is stored temporarily to bring the decay heat to a level compatible with reprocessing plant requirements. The subassembly is then shipped to the reprocessing plant using a shipping cask.

3.5.6 In-Vessel/Ex-Vessel Storage to Reduce Decay Heat of Subassembly

In the case of in-vessel storage, the spent subassembly with high decay heat is stored in internal storage locations located on the periphery of the core. The subassembly is stored for one or more campaigns till the decay heat is reduced to a level suitable for subsequent handling. Initially, dummy subassembly is provided in these storage locations, which are progressively replaced with spent subassembly during successive fuel handling campaigns. In-vessel storage is provided in Phenix, PFBR, Superphenix-2, and EFR.

Figure 77
Storage drum in Phenix

Alternatively, the spent subassembly can be transferred for storage outside the reactor vessel and this is known as ex-vessel storage. This can be in the form of a vessel filled with sodium and with provisions to store subassembly vertically. Figure 77 shows the ex-vessel sodium storage drum in Phenix reactor. The vessel has provision for cooling to remove the decay heat transferred from the subassembly and a dedicated purification system to maintain purity of the sodium. The transfer of subassembly between the reactor and ex-vessel storage takes place in a sodium filled pot. By this method, subassembly having a large decay heat ($\sim 25\text{--}35$ kW) can be transferred out of the reactor vessel. Adequate number of storage locations are provided in the storage vessel to store fresh assemblies also prior to a fuel handling campaign. During a handling campaign, the spent subassembly is exchanged with a fresh subassembly between the reactor vessel and the storage vessel. The advantage of ex-vessel storage is shorter fuel handling time (subsequent transfers from the storage vessel to outside is done in parallel with reactor operation), capability to remove subassembly with large decay heats, and shortest time required for full core unloading, whenever the need arises. The disadvantages are that the storage vessel is a replica of reactor vessel with its own associated cover gas/cooling and purification systems,

large sodium inventory, and additional machines to transfer the fuel within the storage vessel resulting in high overall cost.

Ex-vessel storage in a large sodium vessel is adopted for Phenix and Superphenix-1. In Superphenix-1, there was a sodium leak due to failure in the welds of the storage vessel and ultimately, the sodium storage option was deleted. From economic considerations, the sodium vessel storage concept is not preferred though it offers great flexibility in fuel handling.

In-Vessel Handling

In-vessel handling or transfer of fuel within the reactor vessel is carried out using combined rotation of one or more rotatable plugs and using one or more in-vessel handling machines (IVHM). The principle of EFR in-vessel handling scheme using two rotatable plugs and two in-vessel handling machines is illustrated in [▶ Fig. 78](#). There are mainly three types of in-vessel handling machines: (i) straight pull, (ii) offset arm, and (iii) pantograph type. The three types of in-vessel handling machines differ in the location of gripper finger axis with respect to machine hoisting axis. For straight pull type, both the axes are coincident. For offset arm type, the hoisting axis is offset by a fixed distance from the gripper axis. In the pantograph type, the hoisting axis is offset but variable from the gripper axis. This is illustrated in [▶ Fig. 79](#).

[▶ Figure 80](#) shows three types of IVHM. FBTR, Superphenix –1, EFR, Joyo, DFBR, BN-350, BN-600, FFTF, and CRBRP have adopted the straight pull type; Phenix, PFBR, SPX-2,

■ Figure 78

In-vessel handling scheme in EFR

■ **Figure 79**
Working Principles of various types of IVHM

and Monju have adopted the offset arm type; and PFR, DFBR, and JSFR have adopted the pantograph type.

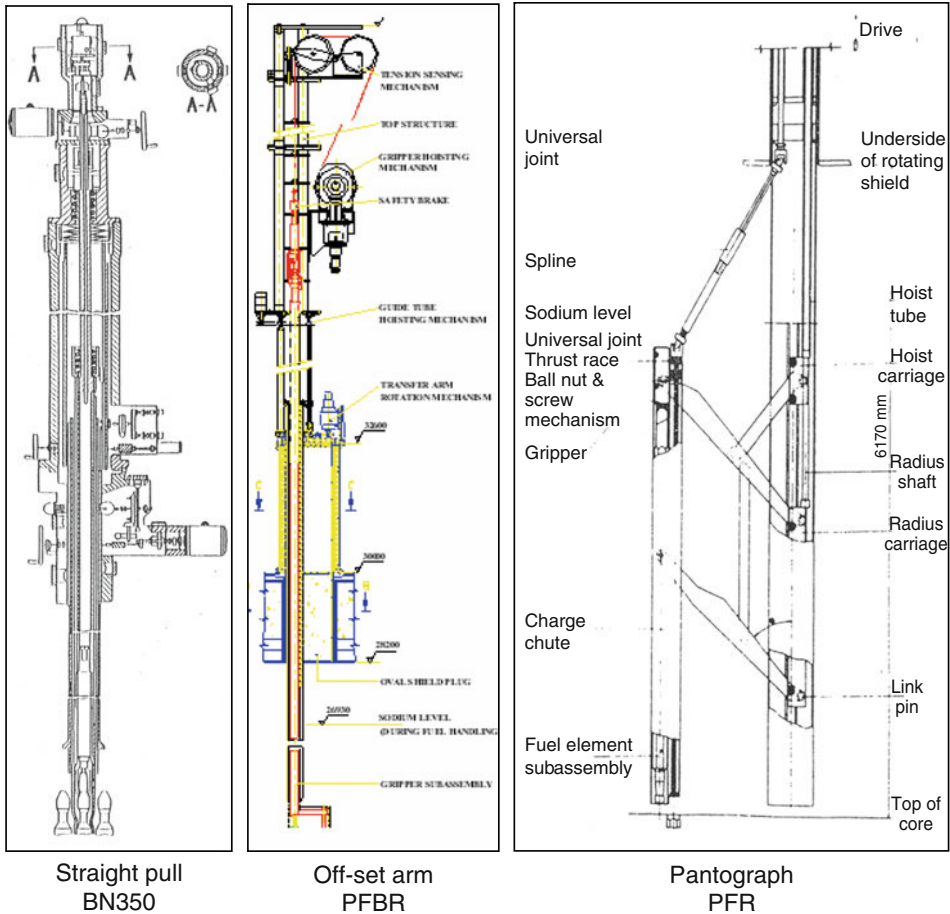

Straight pull type is the simplest and offers simplicity in design and operation. Offset arm and pantograph types have relatively complex loading due to eccentric application of load on gripper with respect to the hoisting function of the machine. However, all the three options have been designed and used in various reactors as indicated above and hence are technically feasible. Pantograph machine is the most complex among the three types but give great economical advantage of use of single rotatable plug and smallest LRP flange diameter as seen in recent innovative designs in Japanese reactors (JSFR).

Ex-Vessel Handling

Ex-vessel handling refers to the transfer of subassembly from IVTP (within the reactor vessel) to a location outside the reactor from where the subassembly is subsequently transferred by other machines for subsequent sodium cleaning and storage. The ex-vessel handling schemes is of two types namely, flask transfer and cell transfer.

The method of flask transfer is illustrated in ► [Fig. 81](#). In flask transfer, a leaktight argon filled flask is connected to a canal in the roof above IVTP and the subassembly is gripped and hoisted up into the flask. Leaktight valves, one on the roof and another on the flask, are provided. The valves are kept open for subassembly movement and are closed during transfer of subassembly to the washing pit. Before opening the flask and canal valves, the interspace between the valves is flushed with argon. The flask is handled by the building crane or moved on dedicated rails. The drawback of flask transfer is that it is a time-consuming process and leads to longer fuel handling time. There is also a limit to cooling during handling and subassembly with high decay heats cannot be handled.

In cell transfer, a dedicated cell is provided linking the canal in the reactor roof and a transfer location outside the reactor. The cell is filled with argon. The subassembly is transferred through the inert gas filled cell using a crane or a transfer machine. ► [Figure 82](#) shows the method of cell transfer. In another variant, a rotating transfer lock is provided between the reactor and outside. The lock has two inclined ramps through which the subassembly is hoisted up. The

■ **Figure 80**
Various types of in-vessel fuel handling machines

subassembly, after it is hoisted up, is either transferred to the other side of the ramp either by rotation or by swinging. This concept is adopted in PFBR, Phenix, Superphenix-1, and EFR. The cell transfer method is preferred due to reduction in fuel handling time and capability to transfer subassembly with larger decay heats.

The design choices adopted for fuel handling systems in various international SFRs are summarized in ► [Table 13](#).

3.5.7 Design Validation

The fuel handling machines have to be highly reliable to ensure higher reactor availability (due to off-line refuelling employed in fast reactors) and also to ensure safety during handling. In the

■ **Figure 81**
Flask Transfer Concept

design stage, higher reliability of the machine is achieved by providing a simple design, providing a high factor of safety in the design, adoption of single failure proof features in the load path to avoid load fall, and by extensive design validation by testing. To ensure reliability during operation, redundant and diverse instrumentation are provided with adequate interlocks between the various operations based on the feedback from the instruments provided. Extensive use of computers is used to assist the operator during fuel handling operations. A systematic maintenance schedule is also implemented in order to ensure smooth and trouble free operational performance of the machines.

The design of the critical in-vessel fuel handling machines is validated by extensive performance testing both in air and sodium. Generally, full-scale prototypes of the machines are manufactured and are performance tested with test cycles simulating the actual operations carried out. Testing is carried out first in air to study the behavior of the various moving parts and to take remedial action required, if any. Subsequent to this, testing is carried out in hot argon (few cycles) and in sodium under conditions identical to that in the reactor. Since it is difficult to simulate and maintain the required temperature distributions during hot argon testing, the number of cycles is kept limited. Sodium testing is carried out under conditions similar to both reactor operation and fuel handling simulated alternately as in the reactor. The effect of higher friction in sodium, sodium aerosol deposition in the annular gaps, behavior of material and material pairs in sodium, choice of hardfacing materials, and their behavior under actual loading in sodium are some of the key parameters which get qualified by testing in sodium. The fuel handling machines of Phenix, PFR, and Superphenix-1

a Using fixed cell

b Using rotating transfer lock

Figure 82
Cell transfer concepts

were qualified by testing in air/hot argon/sodium and similar approach is followed in PFBR also.

In addition, dedicated experimental setups/facilities were made to verify certain major influencing parameters/validation of computational codes. These include insertion/extraction forces of subassemblies using core mechanics experiments, experimental verification of decay heat of subassemblies, syphoning time of sodium from the sodium filled pot used in IFTM, time for sodium dripping from subassemblies prior to handling, efficiency of sodium cleaning

process for subassemblies, dimensional inspection of spent subassemblies after irradiation to high burnups, and inspection of fresh subassemblies prior to loading into the core.

3.5.8 Innovative Fuel Handling Concepts

With the accumulated experience of fuel handling system, it is recognized that scope exists for design simplification and use of innovative designs in order to reduce the cost of fuel handling system. This includes the provision of slit in control plug (or upper internal structure) along with use of a pantograph machine which will result in a compact rotatable plug arrangement thus leading to main vessel diameter reduction. This scheme is illustrated in [Fig. 83](#) as in JSFR and Gen IV sodium cooled fast reactor designs. Also a design which eliminates use of rotatable plug and which makes use of a fuel handling mobile crane for refuelling is shown in [Fig. 84](#). An inert cell is provided above the reactor into which the control plug is lifted to make way for the use of crane for refuelling. The objective is to achieve cost reduction of fuel handling system to have an overall economic design.

Crane type Fuel handling machine concept

3.6 Recent Evolution

For the Generation IV sodium fast reactor (SFR) systems, improvements are researched on safety approach and capital cost reduction. One of the main drawbacks to be solved by the standard SFR design is the proper management of the risk of leakage between the intermediate circuit filled with sodium and the energy conversion system using a water Rankine cycle. The limitation or reduction of this risk requires notably an early detection of water leakage to prevent a water–sodium reaction propagation and damages (i.e., to other tubes). Two innovative and alternative solutions to this problem can be proposed. They consist in the replacement of the sodium in the secondary loops by an alternative liquid fluid, less (or no) reactive with water,

either to the replacement of water to another nonreactive fluid (i.e., inert gas with a Brayton cycle). These two technological options are presented in the following sections.

3.6.1 Intermediate Coupling Fluid

This alternative fluid (AF) might also allow innovative designs, for example, intermediate heat exchanger (IHX) and steam generator (SG) grouped in the same component. For economical reasons, this fluid must be a liquid if a Rankine cycle is chosen. Many coolants have been tried or proposed in the past for fast reactors, but mostly for the primary circuit. The aim is now to evaluate the most interesting ones for the intermediate loop through a multi-criteria analysis in order to select the one or two most promising candidates which could be more thoroughly studied and envisaged as sodium substitute.

Fluid Preselection

The fluid must be compatible with a classical sodium reactor with a Rankine cycle. The temperature in the hot branch of the primary system is about 550°C and the one of the cold branch about 400°C. No fluid was selected or rejected a priori, but according to the following criteria:

- Melting point lower than 250°C (for easy cold trap operations)
- Boiling or complete decomposition point above 650°C
- Low corrosion rate allowing long-term use of the components
- Simple mixture (limited to ternary compounds) with consistent composition of each compound (more than 5 molar %) for chemistry control sake
- Compounds of reasonable cost and availability
- Reactivity with water and air significantly lower than sodium

The fluids were researched using simple elements and their mixtures, molten salts and hydroxides, and organic fluids. At the end, only six fluids fulfilled these preliminary required criteria. They are binary or ternary mixtures at eutectic composition. Their composition and melting point are given in [▶ Table 14](#).

Pb-Bi is well known as a fluid worldwide studied for the accelerator driven systems (ADS) and it has been experienced as a primary coolant in alpha class submarines. Two other bismuth alloys containing cadmium could be of interest due to their low melting point. Nitrate salts are of particular interest in solar application. The NaNO₃-KNO₃ mixture selected was used as coolant in the Solar2 Project. The hydroxides received the most attention in the 1950s, when they were tested as primary coolants for aeronautics applications.

Evaluation Method

It was decided to evaluate each of the selected fluids through a multi-criteria analysis known as “Kepner-Tregoe type” decision-making structured methodology. Eleven major criteria were defined and weighted according to their importance for the intermediary circuits (see [▶ Table 15](#)). The weights range from 10 (less important) to 50 (most important). For each of the nine first major criteria, sub-criteria with relative weights were also defined. Then a list of technical questions was established for each sub-criterion in order to rationalize the evaluation of the fluids through a consensual notation by experts ranging from 0 (very bad) to 40 (very good).

The two other major criteria, “confidence” and “availability and manageability of the reactor” are evaluated through the other nine major criteria, by giving also a notation for these criteria when the sub-criteria are evaluated. The analysis was applied to the six selected fluids of ► [Table 15](#). The sodium was also evaluated for sake of comparison. When all notations are completed, a weighted summation of the different criteria yields the final evaluation of the fluid (given as percentage of the maximum note). It was also thought that the best fluids should present equilibrate notation for each criterion: weak points should not be hindered by a good global note. It was decided to evaluate this quantitatively by calculating the average of the notation of major criteria dividing by the standard deviation between the notations. Practically, it yields an “equilibrium note” between 1 (bad unbalanced fluid) and about 10 (very good and balanced fluid).

Thermal Properties The ability of the fluid to transport and transfer the heat will directly impact the cost of investment by determining the size of the circuits and the exchangers surface.

Interaction with Structures The interactions between fluid and material lead to specific material choices. This item includes general corrosion (oxidation or dissolution), localized corrosion (grain boundary corrosion, liquid metal embrittlement, etc.), mass transfer (plugging, fouling), mechanical properties, and long-term behavior.

Interaction with Other Fluids The intermediate fluids can react with sodium, water, air, or other materials or fluids like concrete or oil (in case of abnormal situations). Thermodynamics, kinetics, and by-products of these reactions and their effects (corrosion, erosion, plugging, toxicity, etc.) must be considered to be compared with the case of sodium.

Chemistry Control, Operating Range Coolant can be operated in ranges of temperature, pressure, and chemistry (of the fluid or the gas phase) that have to be specified. The consequences

■ **Table 14**

Selected fluids for evaluation at SFR intermediate loops, molar composition, and melting point

Fluid	Pb-Bi	Bi-Cd	Pb-Bi-Cd	NaNO ₃ -KNO ₃	NaNO ₃ -LiNO ₃ -KNO ₃	NaOH-KOH
Composition (mol%)	Pb 45% Bi 55%	Cd 60% Bi 40%	Pb 38% Bi 48% Cd 14%	NaNO ₃ 64% KNO ₃ 36%	NaNO ₃ 17% LiNO ₃ 37% KNO ₃ 46%	NaOH 49% KOH 51%
Melting point	124°C	144°C	92°C	235°C	120°C	170°C

■ **Table 15**

Major criteria and their relative weight (10 – less important, 50 – most important)

Major criteria	Thermal properties	Interactions with structure	Interactions with fluids	Chemistry control	Safety, security environment	
Weight	30	50	50	30	50	
Major criteria	ISIR	Components and circuits	Cost	Level of use	Level of confidence	Availability and manageability
Weight	30	20	20	10	30	30

of out-of-range operation (temperature sudden rise, impurity ingress, etc.) must be evaluated. Measurement and control systems are evaluated through their reliability, sensibility, accuracy, robustness, efficiency, etc.

Safety, Security, and Environment Consequences of different types of leaks and reaction between fluids must be evaluated, by taking into account the risks of core plugging, gas bubbles in the core, exothermicity of reactions, risks of fire, etc.

In Service Inspection and Repair (ISIR) In operation, the following physical properties of the fluid must be measured: temperature, flow rate, and pressure. Leak of one fluid in another must also be detected. Maintenance of the components and the circuits is a periodical operation, while repair operations are not. But the related problems are globally the same: components must be cleaned (and decontaminated for the IHX) and requalified and strict procedures of start-up of the reactor must be followed. Experimental feedback from sodium fast reactors has revealed that difficulties arose mainly during start-up of the reactor after maintenance operations.

Components and Circuits The fabricability (including weldability) and approximate cost of the following components and circuits were evaluated: HX, SG, pumps, valves, main circuit, auxiliary circuit, chemistry control circuit, instrumentation.

Experience A fluid can be most confidently chosen if it has been already experienced as a coolant, especially in a nuclear context.

Cost The cost of a fluid (with purity specification) was estimated, as well as the availability of the component and the cost during operation.

Results

The final results of the evaluation are given in  [Fig. 85](#). The final notation of the fluid is given as a percentage of the maximum note, first (blue) bars. The “equilibrium notes” are the second (red) bars ($\times 10$ for easier comparison in the graph). The note of sodium is given for sake of comparison. The best note is obtained by Pb-Bi, 64%. It corresponds to a note between “average” and “good.” Pb-Bi is also the fluid with the best “equilibrium note”: 6.6. Another fluid has also good notes but its equilibrium note is much lower NaOH-KOH: 2.2. It is worth noting that a sensitivity analysis to the ponderations for the major criteria (in particular by giving less weight for the interaction with structure and a higher one to components and structure) has pointed out that the results stay globally unchanged in a reasonable extent.

In  [Fig. 86](#), a radar graph represents the notes of the major criteria for the most promising fluids: Pb-Bi. It can be seen that Pb-Bi does not suffer any weak point but at once does not present any good notation. NaOH-KOH has very good, but bad notes too, mainly in corrosion that disqualify it. In final today only Pb-Bi alloy can be considered as an alternative to sodium with a relative good maturity for nuclear application envisaged for a Gen IV reactor. Therefore, the major information regarding Pb-Bi alloy in this evaluation will be presented.

Key features for the Pb-Bi alloy

Thermal Properties Globally all fluids have good final notes for this criterion. Trivially liquid metals are good coolants.

Figure 85

Global (first bars) and equilibrium (second bars) notations of alternative fluids for the intermediate circuits of SFR

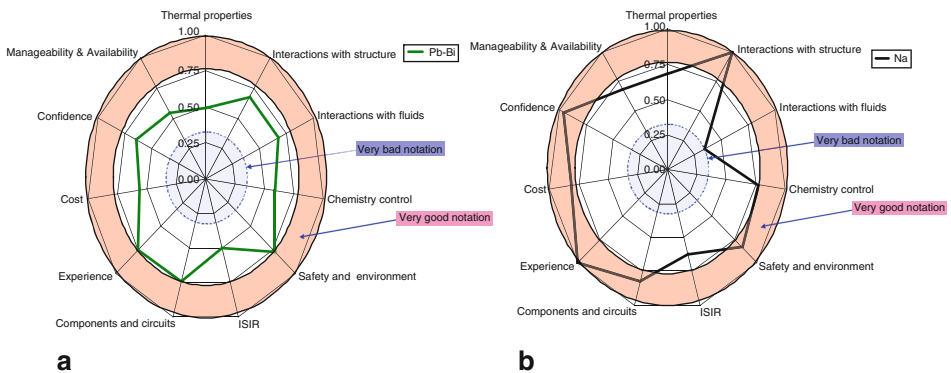

Figure 86

Radar graph of the evaluations of major criteria for (a) Pb-Bi and (b) sodium

Interactions with Structure It was calculated for Pb-Bi by using an oxidation model that T91 steel at 520°C and at the lowest acceptable level of oxygen (about 10^{-3} ppm) would develop an oxide layer of about 40 μm in 20 years. Mass transfer due to magnetite layer (half of the mixed chromium iron oxide layer) removal could be observed. For heavy liquid metal, significant gains could be obtained by operating at lower temperature or by using corrosion resistant steels (forming alumina or silica protective layers). Embrittlement by lead-bismuth is mostly observed in non-oxidizing conditions but would remain very low.

Interactions with Other Fluids HLM will react with Na above 400°C and forms solid phases as BiNa₃ and BiNa. The BiNa₃ formation is exothermic: $190 \text{ kJ}\cdot\text{mol}^{-1}$ from pure components.

Heavy BiNa_3 particles might settle and only those which diameter is smaller than $1 \mu\text{m}$ are transported by the sodium. Pb-Bi slightly reacts with air, the reaction being exothermic.

Chemistry Control, Operating Range Pb-Bi has a large liquid range ($125\text{--}1,670^\circ\text{C}$), a low vapor pressure (around 10^{-5} times lower than sodium at 520°C) but suffers from oxygen contamination. Oxygen content must be kept between two extreme values on the operating range: the upper limit corresponds to PbO formation (risk of plugging) and the lower value to the formation of protective oxide layers (Fe_3O_4) necessary for the protection against corrosion. Practically, the oxygen content should be fixed between $5 \cdot 10^{-4}$ and 10^{-2} ppm.

Safety and Environment For HLM, leaks in primary sodium could lead to safety hazards if the reaction products (BiNa_3 , etc.) has a probability to plug the assemblies.

ISIR The detection of HLM reactions with sodium could be performed by using two complementary methods: ultrasonic (US) measurement for BiNa_3 particles, and Laser Induced Breakdown Spectroscopy (LIBS) for elements dissolved in sodium (as Bi, Pb with a detection limit postulated to be around 1 ppm).

Components and Circuits For HLM, the materials should be T91 type (9 Cr) steels. Due to the high density of the liquids, short circuits are preferred (for seismic resistance purposes, etc.).

Experience Lead-bismuth is the only fluid that benefits from an experience as a coolant in nuclear facilities and international experimental facilities, in the framework of the ADS programs. But it should be underlined that the facilities do not address all problems arising when using these fluids in an SFR (in particular interaction with sodium).

Cost Lead and bismuth are rather low cost elements (maximum $10\$/\text{kg}$ for Bi), but the cost of the pure mixture could be one order of magnitude higher. This has to be compared to the estimated price of nuclear sodium, about $10 \$/\text{kg}$.

Availability and Manageability The notes of the fluid for this criterion are rather low, in particular in comparison with sodium, although it was expected that the elimination of the reactions with air and water would greatly improve this point. This is mostly due to the corrosion impact and the risks of the reaction with the primary sodium itself, and the instrumentation and safety approach which have to be implemented to detect it or prevent it.

Impact on Design

Some preliminary design calculations have been realized to validate these options using Pb-Bi as coupling fluid. The main parameters were the following:

- Selection of a loop type or hybrid SFR concept.
- Intermediate heat exchanger (IHX) and steam generator units (SGU) are in the same tank, thermally coupled with Pb-Bi coolant.

IHX/SGU component integration in a lead/bismuth filled tank is achieved with:

- A peripheral helical SGU
- A central straight tubes IHX
- A mechanical Pb/Bi circulating pump

■ Figure 87
IHX/SGU with Pb/Bi coupling

■ Figure 88
SFR hybrid concept with IHX/SGU option

The 600 MWth component is shown in [Fig. 87](#). The overall dimensions for 600 MWth components are a diameter of around 4 m and of height of 17 m. These components could be associated with a hybrid reactor block in which the primary pumps are installed in the reactor vessel ([Fig. 88](#)) or with a classical loop type reactor ([Fig. 89](#)).

■ Figure 89

SFR IHX/SGU option: four loops and four electromagnetic pumps (tertiary circuit is not represented)

Conclusions

Only one fluid seems to require attention considering its global notes: Pb-Bi. Indeed, Pb-Bi is a fluid with no major drawbacks (good equilibration note) and gets large benefits from an international research. Nevertheless this choice would imply heavy consequences and several technological breakthroughs remain to be solved. The gains in selecting Pb-Bi are mainly the suppression of the sodium/water reaction and the sodium fire hazards. But the Kepner Tregoe matrix has revealed that these gains are almost annulled (or compensated) by the existence of new specific risks: Na/Pb-Bi interactions, oxygen accurate monitoring, corrosion on metals, and long-term behavior. The replacement of Na by Pb-Bi in the intermediate loop is still an option under development that requires a complete rethinking of the SFR design and its safety approach in comparison with the existing and operating ones (i.e., such as Phenix). Thus, the difficult issue of the balance between advantages and drawbacks in the change of sodium to Pb-Bi is not completely settled. R&D improvement in the future will help to clear the debate. This is also the reason why today this option for GEN IV innovative SFR is not unique and an alternative approach remains the use of gas energy conversion system instead of water (see ► Sect. 3.6.2).

3.6.2 Advanced Energy Conversion System

Introduction

SFRs have traditionally employed a Rankine steam cycle for power conversion. For instance, the Superphenix plant was based on a Rankine steam cycle for power conversion allowing a 40% net efficiency with 545°C for the core outlet temperature. Although the Rankine cycle is a well-developed technology, the design and licensing safety evaluation must deal with the

sodium–water reaction and the secondary sodium fire issues. Potential sodium–water reactions which result in formation of combustible hydrogen gas and exothermic energy release can be eliminated by adopting a gas-based energy conversion system (ECS). Moreover, the interest for other cycles or architectures to extract power can be argued by costs reduction (efficiency improvement with the same core temperature, ECS design simplification, operability and maintenance and the potential of suppression or simplification of the intermediate loop).

Evaluations of an alternative power conversion system have to be carried out in three steps:

- The first step is the examination and assessment of the application to the SFR concept of such a cycle using a gas-based ECS. The thermodynamic efficiency of each cycle is investigated. The analysis considers parametrical studies. The cycle's efficiencies are compared to Rankine cycle.
- In a second step, the safety concerns related to each cycle must be investigated. Among the transients that must be considered, some must be assessed and the consequences have to be evaluated, for example, the depressurisation of the gas circuit.
- In a third step, the development of the main components must be considered, particularly the intermediate heat exchanger (IHX) design, taking into account Na–gas interaction risks and their consequences as well as monitoring and in-service inspection and reparability (ISIR) aspects.

This chapter will deal only with the first step. The first section describes numerical tools, in particular the Cyclop code. In the second section, design considerations for Brayton cycle will be presented and the main input data and the assumptions for the involved components will be provided (compressors, turbine, heat exchangers, etc.). Then, we will present the study done by the expert group from the viewpoints of thermodynamic analyses and cycle efficiency optimization for various types of gas and for indirect and indirect/combined cycles.

Design Consideration for Brayton Cycle

The Brayton cycle consists of an intermediate heat exchanger, a low pressure compressor, a high pressure compressor, a turbine, a pre-cooler, an intercooler, a recuperator, pipes, and a generator. Gas at relatively low pressure and temperature is brought by a low pressure compressor to an intermediate pressure; then it is cooled by the intercooler and brought by a high pressure compressor to a higher pressure; it is preheated by the recuperator before entering the intermediate heat exchanger. Downstream of the intermediate heat exchanger, the hot gas is expanded in a turbine to another state point. The turbine drives the two compressors and the three components are coupled on a single shaft. Downstream of the turbine, the gas is cooled in a recuperator which is a gas-to-gas heat exchanger after which it is further cooled in a pre-cooler: a gas-to-water heat exchanger.

➤ *Figure 90* illustrates a closed-cycle gas turbine applied to SFR and ➤ *Fig. 91* shows a schematic of the corresponding enthalpy–isentropy diagram.

The principal system parameters under the designers control are including:

- Turbine inlet temperature, T_3
- Recuperator effectiveness, ϵ
- Turbine and compressors efficiencies (low pressure compressor: LPC and high pressure compressor: HPC), $\eta_T, \eta_{LPC}, \eta_{HPC}$
- System pressure, P_x
- System $\Delta P/P_x$, where ΔP is the system pressure drop

Figure 90
Brayton cycle applied to SFR

Figure 91
Typical enthalpy-isentropy plot

The theoretical cycle efficiency is based on next expression:

$$\eta_{cycle} = \frac{w_{cycle}}{q_{cycle}} \tag{13}$$

where w_{cycle} is the work received by the turbine shaft and q_{cycle} is the heat energy exchanged through the IHX.

The turbine, compressors, and the generator components are coupled to a single shaft. The work received by the turbine shaft is:

$$w_{cycle} = w_T - w_{LPC} - w_{HPC} \tag{14}$$

The above equation can also be written using enthalpies H_i :

$$w_{cycle} = (H_3 - H_4) - (H_{1'} - H_1) - (H_2 - H_{1''}) \tag{15}$$

The heat exchanged by the IHX is given by:

$$q_{cycle} = (H_3 - H_x) \quad (16)$$

Turbine and compressors efficiencies are based on the following expressions:

$$\eta_T = \frac{(H_3 - H_4)}{(H_3 - H_{4,is})} \quad (17)$$

$$\eta_{LPC} = \frac{(H_{V,is} - H_1)}{(H_{V'} - H_1)} \quad (18)$$

$$\eta_{HPC} = \frac{(H_{2,is} - H_{V''})}{(H_2 - H_{V''})} \quad (19)$$

The recuperator effectiveness is given by the following expression:

$$\varepsilon = \max \left[\frac{(H_x - H_2)}{(H_4 - H_2)}; \frac{(H_4 - H_y)}{(H_4 - H_2)} \right] \quad (20)$$

Finally, the theoretical cycle efficiency is:

$$\eta_{cycle} = \frac{(H_3 - H_4) - (H_{V'} - H_1) - (H_2 - H_{V''})}{(H_3 - H_x)} \quad (21)$$

The IHX inlet temperature (T_x) is a dependent variable that is determined by optimization of the turbine pressure ratio. However, in practical systems, T_x can be constrained by material considerations. Concerning the overall pressure ratio, this parameter can be constrained by manufacturing considerations. For instance, if the gas is helium, because of the high-specific heat, helium compressors and turbines have a relatively low adiabatic head per stage, hence a large number of stages. Consideration of the number of stages can limit the optimization range of the overall pressure ratio. Selection of each of the parameter values is constrained by cost and material considerations. It is assumed that the ECS cost optimization will be driven by efficiency gains on each ECS components. Thus, we can assume that ECS component designs are limited mainly by technology. ➤ [Table 16](#) shows the current values of each power cycle system parameter.

The individual effect of these parameters on system performance and the cumulative effect is illustrated in the next section. Quite clearly, changing the core outlet temperature has the major effect on variations of the overall global cycle. Changing the other parameters within the stated range is playing a lesser but still significant role. In the future, a compromise will be found between high values of components efficiency and technological options.

Classical Indirect Gas ECS

The model consists of a closed-loop primary circuit with sodium as liquid metal coolant (see ➤ [Fig. 92](#)). The intermediate circuit also uses sodium as coolant. The Brayton cycle consists of a closed-loop circuit with gas as coolant and two open-loop coolant circuit for the pre-cooler and the intercooler (water). The gas average pressure ranges between 30 and 250 bar.

Many sensitivity tests were performed on various parameters (gases, cycle arrangement, gas pressure, recuperator effectiveness, turbine and compressor efficiencies, core outlet temperature, IHX pinch point, cycle cold point) in order to analyze previous assumptions and conceptual choices. The overall cycle efficiency is currently used to compare cycles. Later on, a compromise between high values of overall cycle efficiency and economical/technological issues will have to be found.

Gases Various types of gas are considered (helium, nitrogen, argon, separately or mixed, air, sub or supercritical carbon dioxide). The interest of the mixture He–N₂ is a gas density near air which allows using existing turbo-machines technology jointly with a good thermal exchange efficiency. These Cyclop calculations are performed using 550°C for the core outlet temperature (520°C for the turbine temperature inlet: $TIT = T_3$) and 50 bar for the turbine pressure inlet. Cycle cold point (gas compressor inlet temperature) is taken to 21°C in this assessment.

■ Table 16

Main input data

Gas secondary circuit components	Reference value
Pressure: P_3	30–250 bar
<i>Turbines</i>	
Isentropic efficiency: η_T	91–93% in gas
<i>Compressors</i>	
Isentropic efficiency: η_{LPC}, η_{HPC}	87–88% (HPC) 88–89% (LPC)
<i>Heat exchangers</i>	
IHX pinch point	15–30 K for Na–Na 15–30 K for Na–gas
Recuperator effectiveness : ε	90–95%
<i>Generator</i>	
Electrical losses	2%
<i>Shaft</i>	
Mechanical losses	1.3%

■ Figure 92

Schematic layout of indirect cycle

■ **Table 17**

Gases (core outlet temperature: 550°C, TIT: 520°C, 50 bar, cycle cold point: 21°C, with intermediate loop)

Gas	$T_{in, core}$ (°C)	Π_T	Net η (%)
He	390	1.7	35.5
He-N ₂ (He mass percent: 20%)	392	1.9	36.1
N ₂	393	2.1	36.6
Air	394	2.1	36.3
Ar	381	1.7	34.7
subcritical CO ₂	403	2.8	37.4

By assumption, pressure drops first evaluations are 1.4 bar for IHX1 and IHX2 (sodium side), 0.4 bar for each exchanger of the secondary circuit (IHX2, recuperator, coolers), and 5 bar for the core (Superphenix value).

Previous values are then refined using an iterative optimization process.

Components pre-sizing is undertaken with Copernic tool. Pressure drop and heat transfer correlations are based on the geometrical and thermal hydraulic characteristics of each component. Then, a new Cyclop optimization is performed taking into account calculated pressure drops.

According to these Cyclop calculations (see ► [Table 17](#)), sub-critical CO₂ as coolant is the most efficient gas. But nitrogen at high pressure is also considered as a promising candidate; following coolants are, in order, air and He–N₂ mixture. Concerning sub critical CO₂, a test has been performed at 65 bar (pressure lower than critical pressure: 73.77 bar) at TIT = 530°C and without intermediate loop: the net plant efficiency is 38.5%; in this case, the analysis must be pursued with a chemical evaluation to achieve compromise between thermodynamic properties and chemical specificities.

Cycle Arrangement Right now, sodium drawbacks make necessary to use an intermediate loop in the reactor system between the core cooling and the power conversion (► [Fig. 93](#)). An intermediate circuit leads to eliminate potential introduction of Na–gas reaction products into the primary system, and the potential for gas transport to the core. The elimination of the intermediate loop leads to a gain of 1% in plant efficiency and to the removal of one pump. The elimination of the intermediate loop is promising for future SFR; nevertheless, consequences of the gas circuit depressurisation as well as IHX tube failure have to be evaluated.

Gas Pressure In this assessment, the influence of gas pressure has been performed using nitrogen as coolant, in a wide range: 30 < pressure < 250 bar. The net plant efficiency becomes constant between 180 and 250 bar (► [Fig. 94](#)).

This high pressure (250 bar) may lead to significant technical challenges for critical components (turbo-machine, heat exchangers) and strongly encourages to turn to a lower pressure at the turbine inlet. With intermediate loop, at 100 bar, the net plant efficiency is around 38%; this level of efficiency is very close to the value obtained at 180 bar:38.5%.

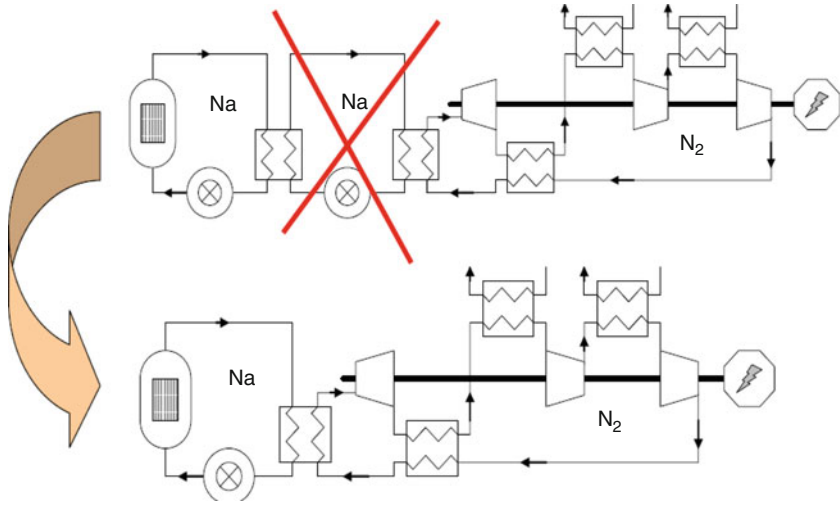

Figure 93
Cycles with and without intermediate loop

Figure 94
Overall cycle efficiency as a function of gas pressure (nitrogen, core outlet temperature: 550°C, TIT: 520°C, cycle cold point: 21°C, with intermediate loop)

Nitrogen cycle at high pressure (180 bar) and without intermediate loop appears very promising for SFR, with a potential of high net plant efficiency (39.5%). At the time of writing, cycle definition is in progress and gas pressure must be optimized to achieve compromise between technical challenges for critical components and plant efficiency.

Components Efficiency Sensitivity tests were performed on recuperator effectiveness and on compressors and turbine efficiencies:

- 2% on recuperator effectiveness leads to -1.6% on η_{cycle}
- 2% on compressors efficiency leads to -1% on η_{cycle}
- 2% on turbine efficiency leads to -1.1% on η_{cycle}

The heat exchanger effectiveness is a function of the heat exchange area and of the overall heat transfer coefficient and is therefore a design choice. Since the price of the recuperator increases with area, an efficiency of 95% seems to be a good compromise between performance and cost. This level of efficiency seems to be a maximal value; this key parameter will be assessed in the future. Concerning the turbo-machine, axial solution for turbine and compressors is privileged. According to experts, a value of 93% for the turbine, 89% for the low pressure compressor efficiency, and 88% for the high pressure compressor efficiency are maximal values for helium turbo-machines. In this assessment, the same values are taken for nitrogen turbo-machines.

Core Outlet Temperature With an increase of 25°C (550–575°C) at the core outlet, the net plant efficiency can be increased of 1.2% (see [Fig. 95](#)). This level of temperature should be assessed.

IHX Hot End Temperature Difference The cycle and plant efficiencies can be improved by increasing the turbine inlet temperature through the enhancing of IHX performance. Several technical solutions have been considered for the IHX: finned plates, printed circuit heat

■ Figure 95

Overall cycle efficiency as a function of core inlet and outlet temperature (nitrogen, 50 bar, cycle cold point: 21°C, with intermediate loop)

■ **Table 18**

Efficiency versus core outlet temperature (tertiary pressure: 180 bar)

Secondary pressure (bar)	$T_{out, core}$ (°C)	$T_{in, core}$ (°C)	$\eta_{secondary\ loop}$ (%)	Net η (%)
50	550	277	5	35.7
50	650	287	20	40
180	550	287	8,4	36.3

exchangers (PCHes). Heat exchangers evaluations and designs definition should be done for each specific cycle. IHX failure consequences have to be further studied on the safety point of view; in particular, in case of gas leakage into sodium, the separation of gas from liquid will be required (see Sect. VI.D. b).

The core outlet temperature is deliberately restricted to 545°C and a conservative IHX design is selected having a pinch point (primary sodium inlet temperature minus intermediate sodium outlet temperature) of 15°C. Decreasing the pinch point raises the cycle efficiency by decreasing the difference between the core outlet and TIT: 30°C \diamond net η = 38.7% and 15°C \diamond net η = 39.5%. Nevertheless, a pinch point of 15°C is considered as a weak value. In the future, this parameter must be optimized.

Cycle Cold Operating Point Cycle efficiency dependency upon temperature at the main compressor inlet is investigated. Decreasing the cycle cold point raises the cycle efficiency: 21°C \diamond net η = 39.5% and 27°C \diamond net η = 38.7%. Nevertheless, a cold point of 21°C is considered as a weak value. For future work, this parameter, depending on site location and cooling system technology, which is a key factor affecting the Brayton cycle efficiency should be known precisely.

Balance A compromise between a high overall cycle efficiency, technological, and chemical views leads to use nitrogen as the working fluid in an indirect Brayton cycle. The optimization iterative process, associated with 530°C and 180 bar respectively for the turbine inlet temperature and pressure, leads to a net plant efficiency of 39.5% for the nitrogen indirect Brayton cycle, without sodium intermediate loop. This evaluation considers maximal values for nitrogen turbo-machine and recuperator efficiencies and a low cycle cold operating point (21°C). The plant efficiency can be increased by increasing the core outlet temperature; in this case, significant material challenges for critical components will be necessary.

Indirect/Combined ECS

An alternative to the previous indirect cycle consists to use an indirect/combined cycle. The model consists of a closed-loop primary circuit with sodium as coolant. The second circuit uses helium–nitrogen mixture (He mass percent: 20%). The third circuit is a Rankine steam cycle for power conversion (see \blacktriangleright Fig. 96). The net plant efficiency is around 36.3%, at 180 bar for the secondary pressure. Sensitivity tests were performed on core outlet temperature and on the secondary pressure (\blacktriangleright Table 18). The secondary loop does not lead to a significant gain, in comparison with the Na–Na–H₂O cycle. According to this preliminary evaluation, indirect/combined cycle does not appear promising for SFR.

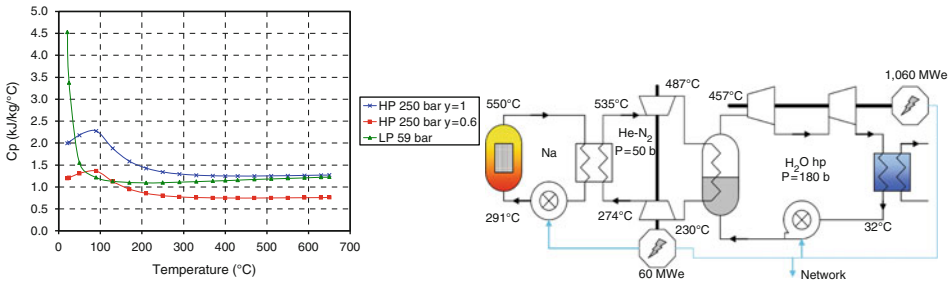

Figure 96
Schematic layout of indirect/combined cycle, with example of data

Supercritical Carbon Dioxide Indirect ECS

The supercritical carbon dioxide (S-CO₂) cycle was selected as the reference energy converter for the advanced burner test reactor (ABTR) pre-conceptual design developed at Argonne National Laboratory (ANL). The cycle is also under development for several years mainly in Japan, Korea, and France, because of:

1. The potential to reach high net plant efficiency
2. The elimination of potential sodium-water reactions
3. The potential for reduction in ECS costs from small turbo-machines having reduced costs

Supercritical CO₂ Properties S-CO₂ power conversion benefits rely on high supercritical CO₂ density and low work to compress S-CO₂ immediately above the critical point ($P_{crit} = 73.77$ bar, $T_{crit} = 30.98^\circ\text{C}$). S-CO₂ thermophysical properties exhibit strong variations, particularly in the vicinity of the CO₂ critical point. Rapid variation in thermophysical properties impacts cycle layout (flow split between heat rejection and direct recompression), compressor design, recuperator design, and cooler design. In this system, a partial cooling cycle is employed to compensate a difference in heat capacity for the high temperature-low pressure side and low temperature-high pressure side of the recuperators to achieve high cycle thermal efficiency (🔍 Fig. 97).

The thermal balance between low and high pressure legs can be written:

$$y \int C_p(T, HP) dT = \int C_p(T, LP) dT \quad (22)$$

where y is the part of the flow rate entering the main compressor, LP is the low pressure, and HP is the high pressure.

Cycle Description The preliminary reference S-CO₂ cycle is a recompression cycle with the turbine, compressors, and generator on a single shaft incorporating separate high temperature recuperator (HTR) and low temperature recuperator (LTR).

The flow from the low temperature recuperator is split such that $(1-y)\%$ of the CO₂ optimally rejects heat in the cooler and then enters the main compressor at a nominal inlet temperature; the remaining $y\%$ enters the by-pass recompressing compressor and is directly recompressed. Then, CO₂ enters the LTR, the HTR, and Na-to-CO₂ heat exchanger (see 🔍 Fig. 98).

Figure 97
Heat capacity versus temperature

Figure 98
Schematic layout of S-CO₂ ECS

Sensitivity Tests Tests were performed on various parameters (cycle arrangement, turbine inlet temperature, pressure losses and components efficiencies and cycle cold point) in order to analyze conceptual choices.

(a) **Cycle Arrangement** The preliminary adopted configuration consists of elimination of the intermediate circuit (► [Fig. 99](#)). The elimination of the intermediate loop leads to a gain of 1% in plant efficiency and the removal of one pump.

(b) **Turbine Inlet Temperature** ► [Figure 100](#) shows a comparison of cycle efficiency versus turbine inlet temperature for S-CO₂ cycle Brayton cycle and helium ideal gas Brayton cycle [6], [7]. Over the temperature range of interest to the SFR, the S-CO₂ cycle clearly provides a significantly greater efficiency.

(c) **Pressure Losses and Components Efficiencies** Sensitivity tests were performed on heat exchangers effectiveness and pressure losses (► [Table 19](#)). A cycle efficiency of 45.4% and a net plant efficiency of 43.6% can be obtained.

Figure 99
Schematic layout of S-CO₂ ECS without intermediate circuit

Figure 100
Efficiencies versus turbine inlet temperature for S-CO₂ Brayton cycle and traditional Helium Brayton cycle, without sodium intermediate loop

Table 19
Overall cycle efficiency (core inlet/outlet temperatures: 395°C/545°C, 250 bar, cycle cold point: 32°C, IHX pinch point: 15°C, without intermediate loop)

IHX pinch point (°C)	ε IHX (%)	ε HTR (%)	ε LTR (%)	ΔP IHX (bar)	ΔP HTR (bar)	ΔP LTR (bar)	ΔP cooler (bar)	net η (%)
30	85.7	88.2	90.1	1.4/1	0.4/0.4	0.4/0.4	0.4	42.2
15	92.2	92.5	92.5	0.2/1	0.5/0.5	0.5/0.5	0.5	44
15	92.2	92.5	92.5	0.2/1	1/1	1/1	0.5	43.6

(d) Cycle Cold Point There is incentive to cool carbon dioxide to as near the critical temperature as feasible. However, operation of the main compressor must remain stable over a sufficiently wide operating range near the critical point. Compressor work decreases when operating near the critical point. The low work of the compressor is the essential feature of the cycle that contributes to its improved efficiency over traditional gas Brayton cycles. In part, this is due to the high density of carbon dioxide immediately above the critical point ($P_{crit} = 73.77$ bar, $T_{crit} = 30.98^\circ\text{C}$).

32°C \diamond main compressor work: 77.47 MW, net $\eta = 43.6\%$

35°C \diamond main compressor work: 92.3 MW, net $\eta = 42.6\%$

Complementary Studies

(a) Sodium–Carbon Dioxide Interaction The supercritical carbon dioxide Brayton cycle option for the energy conversion has been considered because of its high thermodynamic efficiency and its potential compactness. Nevertheless, it assumes that the supercritical carbon dioxide–sodium interaction has less serious consequences than the water–sodium reaction or may be mitigated easily. Studies of the chemical interaction between sodium and CO_2 via calorimetric methods have been performed [8]; such methods are able to point out exothermic phenomena and to measure heat of chemical reactions. The view of reaction scheme is the following:

$T < 500^\circ\text{C}$

Complex scenario.

Kinetically controlled.

Carbonate and oxalate formation.

Na / oxalate and oxalate decomposition (CO release).

Na / CO reaction (induction time).

By-products: CO / Na_2CO_3 / $\text{Na}_2\text{C}_2\text{O}_4$ / C / Na_2O / NaCO / $\text{Na}_2\text{C}_6\text{O}_6$.

$T > 500^\circ\text{C}$

No more induction.

Fast global reaction: $2\text{Na} + 1.5\text{CO}_2 \diamond \text{Na}_2\text{CO}_3 + 0.5\text{C}$ (a)

From experiments, it seems that the interaction reactions Na- CO_2 and Na-CO are slow and become faster at high temperature ($>500^\circ\text{C}$). The kinetics would depend heavily on the contact mode between the sodium and the carbon dioxide and has to be extensively studied in view to control the global reactivity.

(b) Separation of Gas from Liquid The safety concerns related to gas cycle must be assessed and the consequences of some transients have to be evaluated, for instance the depressurisation of the gas circuit. In case of gas leakage into sodium, the separation of gas from liquid is required. The separator would be required for any Brayton cycle without intermediate loop (Sect. IV. B).

A schematic layout of a gas–liquid separator is proposed in  Fig. 101 as a preliminary solution. The fluid enters an inclined tangential inlet nozzle, sized to deliver a preconditioned flow stream into the separator vessel. The fluid momentum combined with the tangential inlet gener-

■ **Figure 101**
Schematic layout of a separator gas – liquid

ates a rotating liquid vortex with sufficient forces (centrifugal, gravity) to promote the separation of the dispersed gas from the carrying liquid. Finally, the gas exits at the top of the separator while the liquid exits at the bottom of the vessel. The separator is inserted in the sodium primary circuit between the IHX outlet and the pump.

Synthesis and Future Prospects of Advanced ECS

The gas Brayton cycle offers many solutions for nuclear power systems, in particular nitrogen at high pressure (between 100 and 180 bar). A net plant efficiency of 39.5% can be obtained with maximal values for cycle components efficiencies and with 395°C and 545°C respectively for the core temperature inlet and outlet. The individual effect of system parameters on performance has been investigated and reported in this paper. Quite clearly, increasing the core temperature has the major effect on increasing the overall global cycle.

An alternative Brayton cycle that offers higher efficiency at a lower reactor coolant outlet temperature is the Brayton cycle using super-critical CO₂. The main reason of the high thermal efficiency is attributed to a reduced compressor work at the vicinity of critical point. The use of a supercritical carbon dioxide Brayton cycle would potentially reach a net plant efficiency of 43.6% with a peak coolant temperature of 545°C and for a compressor inlet temperature of 32°C.

The main future R&D works on gas-based ECS concerns: gas insertion in the core in the case of suppression of the sodium intermediate loop, components technology, cycle operation, and sodium–gas interaction. For gas insertion in the core, the use of an efficient separator must be investigated as a countermeasure system against leakage of gas into sodium.

Supercritical carbon dioxide cycle components technology is less well developed than that for the Rankine cycle. The main concern is compressor efficiency due to its very small blades. The determination of the most adapted compressor type must be investigated, in particular the relevance of a radial compressor instead of an axial. Moreover, in the near critical regime, the values of properties such as heat capacity, density, etc. vary sharply and nonlinearly dependent on pressure and temperature. To our knowledge, there was no such turbo-machine used in a critical regime. Then, turbo-machine experimental data are strongly needed. For supercritical carbon dioxide cycle operation, stability concern due to significant variations of physical properties close to critical point needs a dynamic code to be investigated.

Gas cycle is a credible alternative to the steam cycles if the safety demonstration can be obtained with a design remaining competitive. Problems related to safety are mainly linked to the gas ingress into the core in case of leak. Concerning sodium–CO₂ interaction, future R&D actions are still necessary mainly to get a better knowledge of:

- The interaction in more representative conditions
- The particles issue (carbonate): dissolution or trapping
- The reaction detection systems: efficiency and reliability

3.6.3 Plant Layout

Reactor Building

The reactor building is designed to accommodate the reactor and its associated auxiliary systems, along with the fuel and component handling equipment, fuel decontamination facilities and stores for new and spent fuel. Other major features for sizing the reactor building are the provision for flasking of reactor components above the polar table using the reactor building crane and provision for protection against aircraft crash. A rectangular shape has been adopted for the reactor building, which is constructed of unlined reinforced concrete and forms, together with part of the polar wall, the containment boundary. It is designed to prevent the release of radioactivity and to provide radiological shielding. It is also designed to withstand the pressure resulting from a sodium fire on the reactor roof, for which it is assisted by the polar table, which provides a partial (non-leaktight) closure of the above roof area (► Fig. 102).

This has the dual function of limiting the oxygen supply to the sodium fire and attenuating the pressure rise in the crane hall. It consists of a rotatable circular steel slab with two holes, one central and one offset, which allow access for reactor component handling. The holes have steel covers which are only removed for component handling operations. The reactor building together with the adjacent steam generator buildings, switchgear buildings, and auxiliary building are all on a common raft with bearing pads for effective isolation of horizontal earthquake-induced loads. The reactor vault is additionally separated from the raft by springs to reduce the vertical seismic loads. However, this last feature is optional and required only in sites of very high earthquake activity, which are not likely in Europe. The isolation assures an essentially common seismic resistant design for a range of site conditions. It is

possible to save the cost of the isolators where this is justified by the site conditions without jeopardising the common design concept. The reactor building is subdivided into four main areas.

Crane Hall

This is the volume occupied from the building roof level to the polar table level. This area is served by an overhead bridge crane equipped with a selection of component handling flasks which allow reactor components to be removed and posted into transfer flasks inside the reactor building. The components can then be transferred out of the reactor building, via an airlock, and into the maintenance building (6) using special transporters.

Above Roof Area

The volume above the reactor roof is bounded by a cylindrical, steel lined concrete polar wall, of similar diameter to the reactor vault, and the polar table. This area contains all the components which interface with the primary circuit through the reactor roof in addition to roof and component cooling systems, i.e., primary pumps, IHXs, DHXs, the secondary and DHR sodium pipework, primary sodium purification and cover gas circuit pipework, the rotating plugs and their associated equipment and penetrations plus the cable support system.

Reactor Service Area

This is the volume surrounding the reactor and vault to the ground level. It contains cooling and auxiliary plant rooms, for example, the cover gas systems, the primary sodium purification system, vault cooling, and roof cooling. The air conditioning and recirculation systems are also housed within this area.

Fuel and Component Handling Area

This occupies about half of the reactor building below the crane hall, and comprises: fuel handling facilities, new and spent fuel stores, fuel cask and component handling flask servicing facilities, an area for posting of components into transfer flasks, a large airlock for transfer of components into and out of the reactor building.

Steam Generator and DHR Buildings

The three steam generator buildings are arranged on three sides of the reactor building. The location of the steam generator buildings is dictated by the position of the reactor in the reactor building and the component arrangement on the reactor roof (IHX, DHX). Each steam generator building is separated into two steam generator compartments. Each steam generator compartment comprises one secondary loop, one direct reactor cooling (DRC) loop, and parts of one feedwater/steam piping system with their auxiliaries/ancillaries.

Plant Layout

The reactor building is a component of the plant layout. The general site is based on a river site with a cooling tower, or near the sea. Here, we show an example of general layout based on a river site (► [Fig. 103](#)). The center of the Nuclear Island is formed by the rectangular reactor building

■ **Figure 103**
General plant layout

(1). Adjacent to the reactor building are the three steam generator buildings (2). In addition the nuclear island incorporates the switchgear buildings (3) which house the essential and non-essential electrics, and the auxiliary building (4) housing the nuclear island component cooling system and the reactor building HVAC system. The turbine generator building (5) is connected to the steam generator buildings by feed water and main steam lines. Tunnels are used for cables and pipes to connect the different buildings.

4 Safety Principles

4.1 Introduction

This chapter proposes safety orientations for future sodium cooled fast neutron reactors (SFR). It is established based essentially on the position that is expressed by the French Advisory Group on Safety (GCFS 2007) to start the process that has to lead to the definition of the safety approach and then to the selection of the corresponding safety options for these reactors (GCFS). The content is also coherent with the position of the GIF (Generation IV International Forum)-Risk and safety Working Group (RSWG 2008).

➤ **Section 4.2** indicates the specificities due to the use of sodium as coolant.

As a preamble, the chapter exposes, within ➤ **Sect. 4.3**, the safety objectives and the general principles suggested for all the future reactors, for example, those studied within the framework of the GIF. These objectives and principles apply for an industrial SFR.

➤ **Section 4.4** briefly reminds the objectives and scope of the defense in depth.

➤ **Section 4.5** addresses the general principles for the treatment of severe accidents or, more generally, “severe plant conditions.” It considers the possibility of developing a concept allowing excluding the occurrence of generalized core degradation by limiting the considered

severe accident to limited core degradation but, waiting for the results of the engaged R&D, which hopefully will support this strategy, the contents of the section remain focused on the treatment of the situations with whole core melting.

➤ **Section 4.6** examines the themes for the safety improvement and its demonstration; its content is based on the feedback experience acquired by the design, the operation and the safety analysis of the Creys-Malville (SPX1) power plant and of the more recent projects: SPX2 and EFR (European Fast Reactor), as well as by their examination by the European and French safety Authorities. The section deals, in particular, with the consideration of severe plant conditions and with the need to take into account their consequences within the design.

➤ **Section 4.7** presents briefly the review of the needed R&D actions.

It has to be noted that aspects related to the proliferation resistance and physical protection, and those connected to the safety of the fuel cycle, are not addressed hereafter.

4.2 Safety Features Associated with Sodium

In view of high heat removal capability, light weight, excellent compatibility with structural materials once purity is maintained and good neutronic behavior, and vast experience accumulated over the years through test loops, experimental, and prototype reactors, sodium has been a universal choice for the coolant for SFR. However, there is a need to address a few disadvantages of sodium, mainly due to its violent chemical interactions with air and water. These aspects are addressed in this portion.

4.2.1 Physical Properties

Salient physical properties of sodium are given in ➤ **Table 20**, and corresponding properties of water are also given for comparison. Melting point of sodium is approximately 2 K below the boiling point of water, and the melting is accompanied by a volume increase of 2.17%. Molten sodium appears like mercury but is actually lighter than water. Because of its high boiling point, sodium has a large liquidus range (1,057 K), which is next only to that of lithium among other alkali metals. Its thermal conductivity (0.84 *J/cm/s/K*) is approximately two orders higher than

■ **Table 20**

Physical properties of sodium and water

Property	Sodium	Water
Melting point	370.8 K	273 K
Boiling point	1,155.9 K	373 K
Density	0.904 g/cm ³ at 473 K	0.99 g/cm ³ at 323 K
Latent heat of fusion	0.113 kJ/g	0.334 kJ/g
Latent heat of vaporization	4.31 kJ/g	2.28 kJ/g
Specific heat	1,383 J/kg K at 371 K	3,275 J/kg K at 371 K
Thermal conductivity	0.84 J/cm/s/°C at 473 K	0.0067 at 323 K
Viscosity	0.45 cps at 473 K	0.55 cps at 323 K
Vapor pressure	2 Pa at 573 K	101,325 Pa at 373 K

that of water, and its specific heat ($1,383 \text{ kJ/kgK}$) is 2.5 times less than that of water. As seen from the table, viscosities of sodium and water are not very different. Hence, operations such as pouring, mechanical pumping, stirring, and other general laboratory manipulations of molten sodium are very similar to those of water. Electrical resistivity of sodium is very low (in fact, among alkali metals, it has the lowest electrical resistivity), and this enables it to be efficiently pumped by electromagnetic principles.

4.2.2 Nuclear Properties

Liquid sodium has very low absorption cross section for fast neutrons. The absorption cross section of ^{23}Na is 0.87 mb for fast neutrons. The (n, γ) activation product is ^{24}Na , which is a strong beta-gamma emitter. Fortunately, it has a short half-life of 15 h. It is possible to approach the radioactive sodium coolant circuit for maintenance and repair after about ten half-life periods from reactor shutdown. However, during reactor operation, the activity level is in mCi/cm^3 . The other activation product of ^{23}Na is ^{22}Na by $(n, 2n)$ reaction. This has a rather long enough half-life of 2.7 years. However, it has a high absorption cross section for thermal neutron, which prevents it from building up above a few mCi/cm^3 levels. The (n, p) reaction product of ^{23}Na is ^{23}Ne , which has a very short half-life of 38 s. This is quantitatively released to the cover gas space. Sodium is sufficiently non-moderating and can preserve the hardness of the neutron spectrum. It has a moderating ratio of only 0.89 compared to 62 for water. One nuclear property of the coolant that is important for reactor safety is its reactivity coefficient for both sodium temperature and void.

The temperature and power coefficients of reactivity of any reactor should be negative so that temperature and power transients are self-limiting. Further, the time constant associated with them should be small so that the reactivity feedbacks are available promptly and the system is stable. Upon temperature rise in the sodium coolant, larger leakage of neutrons occurs, leading to negative reactivity changes. Increased fast fission from fertile materials leads to positive reactivity changes. Increase in " η ," (neutrons emitted per neutron absorbed) leads to positive reactivity changes. Loss in density of sodium leads to reduction in absorption of neutrons and hence the positive reactivity effect. However, this effect is negligibly small. Calculations that have been confirmed experimentally indicate that for small size reactors such as FBTR, the net coolant reactivity coefficient is negative, while for medium and large sized reactors such as SuperPhenix, it is positive. In case of PFBR, though coolant reactivity coefficients (both temperature and power) are positive, the net reactivity coefficient constituted by fuel, clad, and coolant is negative. The contribution of coolant temperature reactivity coefficient is only 20% of the total. In power coefficient, only 4% contribution comes from positive reactivity coefficient of sodium and the rest is from the fuel. Thus, any under-cooling transient or reactivity-initiated incidents are mainly arrested by fuel reactivity coefficient not by coolant reactivity coefficient. Also, the time constant associated with the fuel and coolant reactivity coefficients are small and so pose no stability problem.

4.2.3 Chemical Reactions

Being an alkali metal, sodium metal is highly reactive. On exposure to dry air, solid sodium first reacts with oxygen to form voluminous sodium oxide layer, which retards the rate of further reaction. Sodium does not react with nitrogen and does not form any stable nitride. It reacts

with humid air very fast, and the major reaction product is sodium hydroxide, which subsequently reacts with carbon dioxide in air to yield sodium carbonate. Since these reaction products are highly hygroscopic, uncontrolled exposure of sodium to moist air can lead the metal coming into contact with water (or water rich phases), resulting in explosive sodium–water reaction. Liquid sodium reacts instantaneously with gaseous oxygen. It burns in air to yield sodium oxide. Under oxygen deficient conditions, the product formed is sodium monoxide, Na_2O . When oxygen supply is unlimited and temperature is low, the product formed would be sodium peroxide, Na_2O_2 . Liquid sodium reacts with gaseous hydrogen and forms its hydride, NaH . Reaction rate with gaseous hydrogen is slow at temperatures below 523 K and is very fast at temperatures above 673 K. Na_2O and NaH dissolve in liquid sodium before precipitating as a separate phase. Solubility of these compounds in sodium increases with increase in temperature.

Liquid sodium is generally contained in austenitic and ferritic steel circuits. Sodium is quite compatible with them under pure conditions. Solubility of the steel constituents, namely, iron, chromium, nickel, manganese, molybdenum, etc., in sodium is low and is in ppm ranges only. However, higher oxygen contents in sodium (>5 ppm) would lead to enhanced corrosion and mass transport phenomenon. Carbon is an important interstitial alloying element in structural steels, and sodium can act as a medium for its transfer from one section of structural component to another. This can arise because of to the presence of temperature gradient in a sodium circuit with structural components made of single alloy and/or presence of multi-alloy components in that circuit. Carbon transport is kinetically slow at temperatures below 673 K and can become very significant above 873 K.

Reaction of sodium with water–steam is of special importance. Heat from secondary sodium is transferred to water across a ferritic steel tube wall in the steam generator of a fast reactor. In case of a steam leak into sodium circuit, sodium reacts instantaneously with steam–water forming sodium hydroxide and hydrogen. The exothermic nature of the sodium–water reaction and the caustic nature of the product can lead to tube material wastage and cause the steam leak to expand rapidly. In case, these leaks are not detected in time and remedial action not taken, the growing flame can cut the adjoining steam carrying tubes and lead to sodium–water explosions. Such a blowout in PFR resulted in the destruction of 40 steam tubes, and the one at BN-350 resulted in a long shutdown. However, these incidents did not lead to any catastrophe or nuclear release, and the events were completely manageable. Sodium hydroxide is stable in sodium only above 693 K. Sodium hydroxide in excess sodium decomposes to yield Na_2O and NaH below this temperature. Hydrogen formed in the sodium–water reaction can dissolve further in sodium, the slow kinetics of which has been mentioned earlier.

In the Creys-Malville plant and for the EFR, these risks are mostly minimized by secondary loops placed between the primary system and the steam generators. The consequences of sodium–water reactions are also minimized by measures put in place to detect and limit loads (detection of hydrogen in the sodium, acoustic detection, and ruptured membranes). One possible way of increasing safety is to find measures that would intrinsically limit loads, thereby limiting the sensitivity of the safety case to the way the accident in question is defined in terms of number of ruptured tubes. An example of how this could be achieved could be to limit the size of the steam generators (modular design).

Eliminating water by using another cycle (e.g., gas) would remove this problem. However, other specific risks would then have to be considered (potential source of gas injection into the core or shaking of the core).

4.2.4 Thermalhydraulics and Structural Mechanics Considerations

Being a liquid metal, it is an efficient coolant, having high heat transfer properties and high boiling point, by which it is possible to have large margin between operating temperature ($\sim 550^\circ\text{C}$) and boiling point of coolant (980°C). Hence, there is no need to pressurize the system, and all the disadvantages associated with the unforeseen depressurization of coolant are absent in FBR. High thermal conductivity, low viscosity, and large difference between the hot sodium and air coupled with significant variation of sodium density with temperature permit decay heat removal through natural convection modes. Sodium provides high thermal inertia, and hence, more time is available for the operator to act in case of exigencies without fear of any temperature rise followed by thermal transients, exceeding acceptable limits.

High thermal conductivity of sodium ($70\text{ W/m}\cdot\text{K}$ at 700 K) enhances its heat transfer property, which is not favorable from structural mechanics point of view, particularly under thermal transients. Any transient temperature change in the sodium following thermal transients (reactor scram, for example) would be transmitted to the adjoining structural wall surface without any attenuation, causing high skin stress. This is the main structural mechanics problem, particularly when the austenitic stainless steel is the structural material, which has low thermal conductivity and high thermal expansion coefficient. Some issues to be addressed are illustrated in  Sect. 8.

4.3 Safety Objectives and Principles Applicable for Future Reactors

As for the safety objectives applicable to future reactors, and especially to the SFR, it is considered that those applicable for the European pressurized reactor (EPR) are already very ambitious and guarantee a very high level of protection. Further, prescriptive reduction of the risk with regard to this level of safety, in particular in terms of probability, is not justified and could even be counterproductive. (Within the range of very low frequencies of occurrence, the quantitative level of safety is difficult to measure because of the uncertainties [due to, e.g., the not recognizable common modes]. This level can be used to compare the nuclear risks with the other risks in human activities, but it should not be used as an absolute value for the design and the safety demonstration. Actually, the strengthening of the safety objectives for highly improbable events would have a marginal impact on the safety, or even could go against this last one, for example, by increasing the complexity of the installation.) That is why analogous objectives are retained for all the future reactors. Safety improvements will nevertheless be looked for, especially in terms of qualitative safety and robustness of the safety demonstration. This can be achieved taking into account safety requirements since the early phases of the design, that is, achieving a safety “built in” rather than “added on.”

This ambitious level of safety is achieved for the EPR through, among others, a design domain that addresses the treatment of severe plant conditions, both from the viewpoint of the prevention and from that of the consequences’ management and minimization. For the EPR, the reference for the severe accident remains the whole core melting. For the future SFR, it is not excluded that design innovations will allow to practically eliminate the situations with generalized core damage by limiting the severe accident domain to limited core degradations. The search for such innovations represents a key subject of the current R&D effort  Sect. 4.4).

An essential contribution to the safety improvement will come via the capability to realize a robust safety demonstration. For that purpose, the approach has to be based on the feedback experience as well as on design options and R&D programs which will contribute to the reduction and the mastery of the uncertainties, the introduction of adequate margins and the rejection of any possible cliff edge effect.

The design approach will remain essentially deterministic, based on the defense in depth (🔍 Sect. 4.4) and conventional rules as, for example, the single failure criteria (when justified), and will take advantage of insights brought by probabilistic studies. In these conditions, the safety objectives will integrate acceptability criteria, both deterministic and probabilistic.

4.4 The Defense in Depth Principle

The safety approach remains based on the prevention and the mitigation of the abnormal situations, the objective being to make acceptable the risks for all the events susceptible to arise in the installation. For that purpose, the approach leans on the full implementation of the concept of defense in depth (DiD).

4.4.1 The Levels of the Defense in Depth

Following the IAEA/INSAG 10, measures relative to defense in depth are generally ranked in five levels of defense. The first four levels are oriented toward the protection of barriers and mitigation of releases; the last level relates to off-site emergency measures to protect the public in the event of a significant release.

Level 1: Prevention of abnormal operation and failures

Measures at Level 1 include a broad range of conservative provisions in design, from siting through to the end of plant life, aimed at confining radioactive material and minimizing deviations from normal operating conditions (including transient conditions and plant shutdown states). The safety provisions at Level 1 are taken through the choice of site, design, manufacturing, construction, commissioning, operating, and maintenance requirements.

Furthermore, Level 1 provides the initial basis for protection against external and internal hazards, even though some additional protection may be required at higher levels of defense.

Level 2: Control of abnormal operation and detection of failures

Level 2 incorporates inherent plant features, such as core stability and thermal inertia, and systems to control abnormal operation (anticipated operational occurrences), with account taken of phenomena capable of causing further deterioration in the plant status. The systems to mitigate the consequences of such operating occurrences are designed according to specific criteria (such as redundancy, layout, and qualification). The objective is to bring the plant back to normal operating conditions as soon as possible.

Level 3: Control of accidents within the design basis

In spite of provisions for prevention, accident conditions may occur. Engineered safety features and protection systems are provided to prevent evolution toward severe plant conditions and also to confine radioactive materials within the containment system. The measures taken at this level are aimed at preventing core damage in particular.

To ensure a high reliability of the engineered safety systems, design principles are adhered to such as: redundancy; prevention of common mode failure by physical or spatial separation, and

structural protection, by diversity or functional redundancy; automation to reduce vulnerability to human failure; testability to provide clear evidence of system availability and performance; qualification of systems, components, and structures for specific environmental conditions that may result from an accident or an external hazard.

Level 4: Control of severe conditions including prevention of accident progression and mitigation of the consequences of a severe accident

For the concept of defense in depth as applied to currently operating plants, it is assumed that the measures considered at the first three levels will ensure maintenance of the structural integrity of the core and limit potential radiation hazards for members of the public. Nevertheless, additional efforts are made in order to further reduce the risks. The broad aim of the fourth level of defense is to ensure that the likelihood of an accident entailing severe core damage, and the magnitude of radioactive releases in the unlikely event that a severe plant condition occur, are both kept as low as reasonably achievable, economic and social factors being taken into account.

The most important objective for mitigation of the consequences of an accident in Level 4 is the protection of the confinement.

It has to be pointed out that accident management may not be used to excuse design deficiencies at prior levels.

Level 5: Mitigation of the radiological consequences of significant external releases of radioactive materials

Even if the efforts described in the foregoing are expected to be effective in limiting the consequences of severe accidents, it would be inconsistent with defense in depth to dismiss off-site emergency plans. These plans cover the functions of collecting and assessing information about the levels of exposures expected to occur in such very unlikely conditions, and the short- and long-term protective actions that constitute intervention. The responsible authorities take the corresponding actions on the advice of the operating organization and the regulatory body.

4.4.2 Objectives and Scope of Defense in Depth

Defense in depth is a rational response to uncertainties associated with the design construction and operation of a nuclear power plant.

Since nuclear power plant accidents are extremely rare events, empirical uncertainties exist about how the plant and its safety architecture will actually respond to certain challenges. In part, because of those uncertainties, overlapping levels of safety intentionally provide margin in addition to that which is likely to be needed to respond to a plant upset. In some respects, Generation IV designs will present significant new uncertainties that, from both a design and a regulatory point of view, will require defense in depth that will be set up in ways that have not been seen before.

In this context, one specific challenge for Generation IV systems is to develop an approach to defense in depth that is both consistent with the successful practices that have been used in operating reactors and that makes use of the improved analytical methods that have come to be available, the objective being the identification and the sizing of design provisions in such a way as to cost-effectively optimize the value of that defense in depth. For Generation IV systems, the goal will be to apply defense in depth in a manner that explicitly takes into consideration uncertainties based on their systematic assessment. The ideal outcome will be a design that optimizes both capital costs and safety by applying defense in depth where it will have the desired effect, but not to “over-design” in a way that adds cost but not safety.

The deterministic and probabilistic considerations have to be integrated into the comprehensive implementation of defense in depth. The notions of “deterministic success criteria” and “probabilistic success criteria” are suggested to help in correctly designing the provisions while fulfilling the requested missions for each DiD level. The performances of these provisions have to be defined in terms of physical performances and required reliability; following these requested performances the provisions have to be – if needed/justified – adequately safety classified. The final goal of this process is the optimization of the whole safety architecture in terms of performances, reliability, and costs.

Other complementary and essential characteristics that help improving the whole safety level, ensuring the effectiveness of the defense-in-depth concept, optimizing the risk-informed implementation, and easing the safety demonstration are as follows:

- An exhaustive defense, that is, the identification of the risks, which leans on the fundamental safety functions, should look for exhaustiveness; the identification of the corresponding scenarios to be retained to design and size of the safety architecture provisions must be as exhaustive as possible.
- A graduated, progressive defense; without that, “short” sequences can happen for which, downstream from the initiator, the failure of a particular provision entails a major increase, in terms of consequences, without any possibility of restoring safe conditions at an intermediate stage. (It is worth noting that graduate and progressive defense is an efficient means for investment protection.)
- A tolerant defense: no small deviation of the physical parameters outside the expected ranges can lead to severe consequences (i.e., rejection of “cliff edge effects”).
- A forgiving defense, which guarantee the availability of a sufficient grace period and the possibility of repair during accidental situations.
- A balanced or homogeneous defense, that is, no sequence participates in an excessive and unbalanced manner to the global frequency of the damaged plant states.

The application of these principles has to lead to an architecture leaning, as much as possible, on a “simple” design and uncomplicated conditions of exploitation (operation and maintenance) in normal and accidental situations.

4.5 Safety Approach for the SFR to Address the Severe Plant Conditions

Coherently, with the requirements related, in general, to the defense in depth and, in particular, to the fourth level of the DiD, this section addresses the consideration of the severe plant conditions, for this has a major impact on the reactor design. In these conditions, two safety strategies are possible to address the treatment of these conditions:

- The first strategy tries to use and develop the favorable characteristics of the SFR (e.g., large thermal inertia) to “practically eliminate” the occurrence of scenarios leading to the generalized core melting. For that purpose, it is necessary to provide a robust demonstration of such elimination. This demonstration should allow balancing the lack of feedback experience by the rigorous consideration of the principles of defense in depth with, in particular and nevertheless, the consideration of severe plant conditions characterized by situations with core degradation of lower amplitude.

- If it is impossible to develop a design allowing to eliminate all the situations that can lead to the generalized core damage, coherently with the fourth level of the defense in depth, a certain number of representative sequences leading to degraded states that can go until generalized core melting will be identified to design, size, and implement provisions allowing to master and mitigate the consequences.

The design studies and the current R&D are realized according to these two strategies (including the search for cores design with intrinsically favorable safety characteristics). Their results will allow determining which strategy is the best adapted and compatible with the implementation of the envisaged technical solutions.

It is indeed necessary to consider, from the early phases of the reactor design, if the SFR has to be conceived by taking into account the consequences of situations with whole core degradation, or if it is feasible to envisage a design allowing not having to consider the consequences of such whole core melting situations.

It is worth noting that the second strategy, with the consideration of whole core degradation, is coherent with the fundamental principles which have been the base of the safety approach retained for the EPR; the design of the latter, as a supplement to a substantial effort for the prevention of the accidental situations, takes conventionally into account severe plant conditions with the whole core melting. The strategy is also coherent with the feedback experience of the SPX2 project, for which the improvement of the prevention effort did not allow not to have to consider such situations.

Having said that, one can conclude that the success of the first strategy (i.e., practical elimination of the whole core melting) supposes an effort of prevention larger than those implemented for the SPX2 and EFR (and formally, higher of the one implemented for the EPR), and this as well as regards the selection of technical options, and as regards the robustness of the demonstrations that validate the implementation of these options.

For the moment, awaiting the results of the engaged R&D, it is the strategy that supposes the generalized core melting, which is retained and developed hereafter.

Besides, independent of the selected strategy (i.e., taken into account or not the situations of whole core melting), for a limited number of initiating events, sequences, or situations, whose consequences cannot realistically be covered by the design, the demonstration of their “practical elimination” will be brought by a specific method, appropriate to each single selected situation (➤ Sect. 4.5.3).

4.6 SFR: Safety Demonstration vis-à-vis of the Whole Core Melting

This section addresses the details of the strategy that consider the whole core melting.

The approach to address such accident leans on both the robustness of the prevention, the management, and the mitigation of its consequences, and especially on the efficiency of the confinement of dangerous materials. It is useless to say that the consequences’ management and mitigation rest on the mastery of complex phenomena in particular for the first phases of the accident.

The improvement of the safety demonstration with regard to the SFR of the previous generation (Creys-Malville and EFR essentially) is thus based on:

- The consideration of the feedback experience from the previous SFR, for example, for the identification of significant initiators and sequences, and from the improvements already achieved on other types of reactor, notably on the EPR.

- A significant effort to reinforce the prevention of the occurrence of whole core melting situations. The approach adopted for the EFR (e.g., third level of shutdown) is kept for the SFR with ways of progress detailed in ➤ Sect. 4.5.1.
- The consideration, coherently with the defense in depth, of severe plant conditions with generalized core degradation. The important way of progress with regard to the EFR is an improved mastery of the consequences through the development of a design aiming simultaneously at the decrease of the mechanical energy released during the accident and favoring the control of the uncertainties associated with the complex phenomenology which characterize the accident progression (➤ Sect. 4.5.2).
- The practical elimination of initiators, sequences, or situations by means of an adequate design and demonstration (➤ Sect. 4.5.3).

The safety demonstration for the SFR will benefit from positive aspects of the technology such as the capability to evacuate the produced heat by natural convection, the significant margin with regard to the sodium boiling, the favorable character of the concept toward the radioprotection concerns, the low pressure within the primary circuit and, in particular for the concept of pool reactor, the important thermal inertia, etc.

The selection of innovative options will have to take into account the specific issues related to the fast reactor technology in general or specifically related to the use of sodium as primary coolant. According to the feedback experience, several issues deserve a particular attention:

- The core is not in its most reactive geometry.
- The draining of primary coolant from the core (i.e., the sodium voiding) can lead to the introduction of positive reactivity (it is the same in case of disappearance of the core structural materials).
- Some safety characteristics are degraded if the fuel is strongly loaded with minor actinides.
- The power density could be high.
- The core is sensitive to certain types of external hazards (shakings).
- The sodium reacts with the water and the air; the reaction leads to releases of energy which can be violent, as well as a production of hydrogen during the reaction with the water. Besides, in case of fire, the created sodium aerosols present a risk of chemical toxicity and can make difficult the interventions (loss of visibility).
- The opaqueness and the temperature of the liquid sodium make difficult the inspection of the internal structures.
- Although for certain components the design can anticipate and ease the maintenance/repair intervention (for example, certain components can be drained away), the interventions or the palliatives measures on sodium circuits and components in postaccidental situation remain difficult,
- The duration of the fuel subassemblies downloading is longer than on a LWR, and this can have an impact on the management of certain accidental situations.

These specificities have to be considered for both the pool and the loop reactor types.

The human factor will be considered so as to minimize by design its possible impact, as well from the viewpoint of the risks of initiating an accident and during the accident progression.

4.6.1 Prevention of Whole Core Melting Situations

The objective is to set up a set of provisions to assure a very high level of prevention of sequences susceptible to degenerate into situation of whole core melting. The application of the principles of the defense in depth drives the approach for the definition and the implementation of these provisions. Probability studies will come to confirm the meeting of the requested level of prevention.

Quantitative Probability Objectives

For the SFR, within the framework of the strategy with consideration of the whole core melting, the objective for the core melt frequency (CMF) is roughly 10^{-6} (x reactor year) for the risks related to the internal events (same objective as for the EFR project).

Implementation of the Provisions for the Accident Prevention

Each of the sequences which can lead to a situation of whole core melting shall be made extremely unlikely. Besides, one should look for a level of balanced risk, reducing and equilibrating the worth of the dominant sequences.

Beyond the necessary measures, to meet the probability objective (10^{-6} x reactor year, for internal events), additional measures should be looked for and selected, based on an objective of reasonable and homogeneous minimization of the risk (ALARP).

To complete the demonstration of prevention, and according to the practices of the safety analysis, a set of envelope situations will be considered, independent of their expected frequency of occurrence.

Among these envelope situations, for example, for the EFR, there is the total loss of the offsite power, some unprotected sequences for which the failure of the shutdown system is arbitrarily postulated, the subassembly melting (resulting, for example, from a blockage) and the sodium leakages, even if they are prevented by specific design options (as, for example, the double envelope design).

This has to be translated into requirements and criteria in terms of allowable kinetics and amplitude for the transients and phenomena susceptible to tackle the safety functions, which have to be considered.

Axes of Improvement

With regard to the EFR, the possibilities of improving the prevention has to be examined, in particular as regards: the covered domain, which has to be as exhaustive as reasonably feasible, the improvement in mastering the uncertainties, the check of the existence of sufficient margins toward cliff edge effects, and the minimization of potential for common modes.

The evaluation of the options selected for the prevention has to systematically consider their global impact on the installation. In particular the designer has to privilege

- The solutions that would be independent, as much as feasible, from the scenarios.
- The forgiving solutions, in particular, those favoring the design which offers grace periods for possible corrective actions and which leave possibilities of repair.

4.6.2 Whole Core Melt Situations: Consequences' Control and Mitigation

A limited number of situations with whole core melting are considered to conceive and size the provisions needed to control and mitigate the corresponding consequences.

Implementation of Provisions Allowing Mastering the Consequences of the Whole Core Accident

With regard to the previous SFR, the important way of progress, resulting from the improvement of the knowledge and the experience feedback, lies on the implementation of provisions allowing to better control and mitigate the consequences of selected situations with generalized core degradation, and to provide a robust safety demonstration of their effectiveness. The innovation in this domain could go up to the partial or total suppression of some of the unfavorable characteristics of the SFR cores.

For that purpose, the designer should identify, as exhaustively as feasible, the sequences which can lead to the core degradation and the corresponding phenomena. Once the sequences are identified, adequate provisions have to be set up to guarantee that the corresponding consequences are correctly controlled and mitigated. For these situations, the designer should try to reduce the possible release of mechanical energy, on one hand, by reducing the risk of sharp insertion of reactivity and, on the other hand, by improving the control and the management – as far as feasible – of the interaction between the liquid-sodium and the melted fuel.

The structures which guarantee the confinement of dangerous materials, and the specific systems which achieve the safety functions during the selected situations, will be sized not only to cope with the loads inferred by these situations, but also for more severe loads, searching for possible threshold effects and trying to identify and correct – as far as feasible – residual weakness.

The approach consists then in:

- Identifying the phenomena involved by the accidents (in particular, those who are going to affect the amplitude and the kinetics of the reactivity effects/insertions) and to adapt the design so that, in an intrinsic way, their consequences are minimized and any cliff edge effects avoided.
- Acquire a detailed knowledge of the scenarios and the involved phenomena. This will, in particular, allow to control and minimize the mechanical energy susceptible to be released.
- Conceive the confinement by making it as robust as feasible and by identifying and correcting the weak points (notion of “homogeneous confinement”).
- Set up provisions allowing guaranteeing the long-term confinement and cooling of the melted core.

Main Phenomena Which Can Lead the Release of Mechanical Energy

The release of mechanical energy, the consequences of which should be minimized, result from phenomena susceptible to sharply insert positive reactivity, namely

- The draining of the sodium from the core region (sodium voiding). This insertion of positive reactivity is compensated during the accident by other effects: thermal counter reactions (for example, the Doppler effect linked to the fuel temperature increase, the expansion of the structures, etc.) followed, if the fuel melt happens (linked to the kinetics and the amplitude of the reactivity insertion) by the counter reaction related to the fuel dispersal.
- The movements of the fuel when it begins to melt. According to the scenario of the accident, these movements can occur inside and/or outside the fuel elements, before and/or after the

clad rupture/melting. The fuel design has to look for the reduction of the risk of centripetal movements of the fuel leading to its compaction and, on the contrary, has to favor the fuel dispersal.

- The movements of the melted steel from the core structures away from the core region. This effect (positive reactivity insertion), which can be very important and significantly higher than the sodium voiding effect, happen during the accident. The core and fuel element's design has to favor the heterogeneous behavior of the melted structures both from spatial and temporal point of view in order to "dilute" the reactivity injection
- The gravitational compaction of the melted core. As recommended for the management of the melted steel movements, the core and fuel element design has to favor a heterogeneous behavior and movements of the melted core both from spatial and temporal point of view. More generally, the designer should look for provisions allowing guaranteeing the quick and controlled core relocation and the achievement and the preservation of subcritical configurations for the melted core.

As already indicated, during the accident progression, a mechanical energy release can also result from the interaction between the liquid sodium and the melted fuel.

A particular attention has to be paid for the case of core bearing minor actinides for which some parameters which have an impact on the progress of the accident could be degraded.

Radiological Consequences

For the whole core melt situations, the objective for the SFR should at least be equivalent to that of the EPR for which, for these situations, *"the associated maximal conceivable releases require only protective measures of the populations very limited in terms of affected area and of duration."*

4.6.3 Initiating Events, Sequences, and Situations "Practically Eliminated"

When the risk associated to an initiating event, a sequence, or a situation is considered as unacceptable, provisions have to be implemented to make this risk acceptable. This is realized:

- First and foremost, by the implementation of provisions allowing to handle the initiator, the sequence, or the situation coherently with the design requirements and to guarantee the consequences management and mitigation (i.e., bringing the initiator, the sequence, or the situation within the extended design domain).
- If this is not feasible and if it is considered that it is not reasonable to look for the consequences management and mitigation, the designer should implement provisions for which the requirements are defined on a case by case basis, and which shall allow guaranteeing their "practical elimination." The demonstration of the "practical elimination" of the initiator, the sequence, or the situation shall be sufficiently robust to justify the fact that their consequences management and mitigation are not addressed by the design. The approach justification can lean on strategies similar to those used for the EPR, in comparable cases

Among the situations not covered by those retained by the design, and for which the experience feedback allows to envisage their "practical elimination," one can find, for example, the collapse of the core support structures, the sharp core draining due to the passage of a large bubble of gas of large volume, and the excessive compaction of the core. For these situations, the justification "practical elimination" will lean first and foremost on particular measures of prevention taken in the design (including the necessary measures for the plant operation).

These initiators, sequences, and situations will be identified as exhaustively as feasible since the early phases of the design and the corresponding measures to guarantee their “practical elimination,” immediately defined.

4.6.4 Control and Management of the Safety Functions

Below, some guidelines are given to exploit at best the experience feedback from previous studies and realizations. These guidelines should allow to define the technical options to be selected to realize the main safety functions, on one hand to prevent the occurrence of situations of whole core melting and, on the other hand, to control and mitigate the consequences.

Reactivity Control

Among the means allowing guaranteeing the reactivity control, one can quote:

- Shutdown systems. These systems will be conceived so as to assure their mission, with the due reliability, without requiring any source of power. In particular, in case of confirmed loss of power (some seconds), the shutdown of the reactor will be achieved in an intrinsic way by gravitational insertion of the absorber elements.
- Globally negative coefficients of counter reaction.
- Provisions allowing the “practical elimination” of initiating events, sequences, or situations that will lead reactivity insertion, for which the shutdown systems, and/or the counter reaction coefficients, would be insufficient to avoid unbearable releases of mechanical energy vis-à-vis of the confinement barriers.

In the Creys-Malville plant and for the EFR, two redundant and diversified shutdown systems were set up. Whenever an emergency shutdown was necessary, it was generally initiated by the detection of two distinct characteristics that typify the feared event (e.g., in the event of an LOF, a reduction of primary coolant flow and an increase in sodium temperature at the fuel assembly outlet). Further diversification was also provided by passive measures (or active measures if these are effective, yet diversified and reliable) that amplify natural counterreactions (e.g., for the EFR, measures identified as part of the “third-level shutdown” concept, such as those conducive to control rod expansion, etc.).

Further reinforcement is possible at this level, essentially to improve the reliability of the measures used to detect abnormal states. This should be achieved by finding systems that are capable of detecting variations in parameters that typify damage to the installation, rather than variations in parameters related to a given accident scenario. For example, one need to find a reliable and high-performance system that can detect sodium boiling, should it occur.

In the event of core meltdown, reactivity is controlled by fuel dispersion and relocation and a core geometry that keeps it subcritical. This implies that the structure that will receive the molten core in the long term is designed to ensure it remains subcritical (sufficient spreading and dilution of the molten core catcher). It is also essential that the entire route taken by the fuel, from the initial position to the final position, does not enable it to reach any critical status that might lead to a major release of mechanical energy.

Decay Heat Removal

The decay heat removal has to be assured in all the plant conditions, to avoid the occurrence of situations of core melting and, if this happen, to guarantee the cooling and the stabilization of

the degraded core. This mission has to be guaranteed over a lapse of time compatible with the needs to preserve safe configurations.

The accidents that could lead to the prolonged total loss of this function should be “practically eliminated.” This will lean in particular on the capability of circuits, including primary circuit, to evacuate the residual power in natural convection, as well as on the minimization of the risk of common mode failure of the provisions which realize the function.

In large-scale reactors such as that of the Creys-Malville plant and the EFR, decay heat is essentially removed by way of sodium loops. Despite the wide range of systems, their high level of redundancy and their capacity to operate in natural convection mode, improvements remain possible especially considering that:

- Few corrective actions can be carried out to counter any failure or human error – the systems are difficult to repair in accident situations and there are few ways of limiting damage other than those repairing faulty systems and refilling with sodium.
- There is a potential for common mode failure, given the fact that the systems lead into the vessel and exit it via the slab to release heat into the atmosphere. Therefore, any fault in the slab may have a knock-on effect to the systems. In the same way, a core meltdown accident could damage all of those parts of the various systems that pass through the reactor vessel.

Improvements that would address these items will make the function more robust and the corresponding safety case, therefore, more convincing, for example, by developing decay heat removal systems that use a fluid that is easier to handle than sodium and that minimize the risks of common modes in certain areas. (Finding an alternative fluid to sodium to evacuate residual power is particularly important, given how long the corresponding systems are in operation for (several months in the case of the EFR). The objective is to significantly increase the reliability of the system, with greater scope for repairs.)

The possibility must also be examined of setting up an entirely diversified system for the long-term cooling of a molten core.

The efficiency of the provisions will also be verified for minor actinides bearing cores which have a higher residual power.

Confinement of Radioactive and Harmful Materials

The confinement of the radioactive materials, and more generally harmful materials, is assured during all the normal and accidental situations, considering the possible failure of the implemented barriers.

Concerning the guidelines for the confinement (limitation, control of the radiological releases, protection of the safety functions against internal and external hazards), the strategy is to retain the same objectives as for the EPR. Accident sequences involving core damage and spurious containment bypass must be “practically eliminated.”

In order to avoid weaknesses, the possibility must be examined of setting up a double containment barrier system, whereby the second barrier would catch any leaks from the first barrier in the event of a core meltdown accident. Such a system would be all the more appreciable given that the first of the two barriers could, in an accident scenario, be exposed to high loads.

For the situations with whole core melting, measures of confinement will allow to avoid unacceptable radiological releases in order to guarantee the need for “*protective measures of the populations very limited in terms of affected area and duration.*”

4.6.5 Other Specific Risks

Sodium Fires

The risks of sodium leakages and the consecutive fires shall be taken into account in the design.

The risks, in case of sodium leakage, concern mainly the aggression of the confinement: pressure and temperature increase due to the fire and production of hydrogen in the presence of water (steam released by the concrete). The risk of aggression for the systems which achieve the other safety functions should also be considered; the consequences' control and mitigation will be guaranteed by the redundancy and the physical separation of the concerned systems.

In the Creys-Malville plant and for the EFR, minor fires in the sodium primary coolant are avoided by systematically using a second shroud containing an inert gas. For more severe accidents, sodium fires on the base slab are taken into account. Secondary cooling systems, however, are surrounded by a simple air shroud.

One possible way of improving safety would be to eliminate these risks by design, in all areas where they might affect safety functions, for example, by placing all critical systems in gas atmospheres that are inert in the presence of sodium, protecting the concrete and ruling out the presence of water in these areas. Having these systems in inert gas atmospheres would also make them harder to access during operation, thereby also minimizing the risk of malicious acts.

Finally, the sodium aerosols released during the fire could degrade the safety functions, in particular by making difficult post-accidental actions. They potentially represent an aggression for the operators, the environment, and the population. Provisions shall be implemented to minimize their impact.

4.6.6 Hazards

The main risks, in case of hazards, are the initiation of accidents and the unacceptable degradation of the provisions implemented to achieve the safety functions; the design of the reactor and the selection and sizing of these provisions should minimize their sensitivity vis-à-vis of these hazards.

The hazards will be defined and characterized according to an approach similar to that adopted for the EPR. The specific risks for the sodium technology (e.g., the potential for core compaction and the possible wave's effects at the free surfaces of sodium) shall be addressed.

4.7 R&D Organization

Given the analysis developed in the previous paragraphs, it is suggested that there be three main lines of R&D:

- Identification of the measures enabling integration of experience feedback on SFRs, with specific actions laid out for the various safety functions and acknowledgment of the risks inherent in sodium.
- Actions to strengthen core meltdown prevention, including the identification of measures that could make each sequence leading to this scenario highly unlikely. In particular, the aim

of these actions is to “practically eliminate” accidents that could lead to consequences that are difficult or impossible to control using the selected measures.

- Actions that give a stronger demonstration of the capacity to manage deteriorated core situations, and show robust containment as regards typical accidents (UTOP, ULOF) and their associated phenomena:
 - Identification of measures to “practically eliminate” those accident phases likely to lead to major releases of mechanical energy.
 - Simplify the safety case and improve robustness where necessary by suitable means (e.g., core and internals design, including the core catcher).
 - Check that the consequences of interaction between sodium and the molten fuel remain tolerable.
 - Optimize the design of those reactor structures that contribute to safety functions in degraded situations, finding and eliminating the potential weaknesses as regards mechanical energy releases and radioactive product containment.

4.8 Conclusions

The objective of this chapter is to set out the principles and objectives in terms of nuclear safety that would apply to a SFR of fourth generation.

The principles and the general objectives established for the EPR and the adoption and the application of the principle of the defense in depth guarantee a very high level of protection and are thus retained for the SFR.

The principles and objectives are set out focusing and dealing, as a matter of priority, with severe plant conditions which, coherently with the defense in depth, have to be considered by the design.

The chapter considers the possibility of developing a concept that practically allows eliminating the occurrence of a generalized core degradation by limiting the severe accident considered within the design to a limited core degradation, but, waiting for the results of the engaged R&D, its contents focus on the treatment of the whole core accident situations.

As for the safety demonstration, it will lean on the following:

- The consideration of the specificities related to sodium cooled fast neutrons reactor (taking into account the experience feedback and the risks specific to the technology).
- The prevention of occurrences such as the situations of whole core melting: the design will make highly improbable all the identified sequences that can lead to it.
- If the design innovations allow it: the elimination of the risk of severe and generalized core damage.
- Otherwise, the control and the mitigation of the consequences of initiators, sequences, or situations that lead to the whole core melting, and the implementation of a robust and homogeneous confinement. In this context, the designer should look for the possibility of designing innovative core with safety characteristics more favorable compared to those of the previous SFR.
- The “practical elimination” of initiators, sequences, or situations, the consequences of which are considered unacceptable.

The integration of these items within the SFR design effort is going to allow identifying and organizing the corresponding R&D effort.

5 The Materials

5.1 Fuel Materials

5.1.1 Oxide

Fuel Element Characteristics

The Fuel pin of a SFR is composed of several elements (► [Fig. 104](#)):

- A cylindrical cladding, closed at both ends by welded plugs, prevents direct contact between fissile material and sodium coolant. The cladding serves as a first safety barrier and was designed to keep its integrity in nominal and off-normal operations.
- A fissile column consists of a stack of fuel pellets whose outer diameter is chosen to provide an initial gap (a few hundreds of microns) between the fuel and the internal diameter of the cladding. The most widely used fuel is the mixed uranium–plutonium oxide: $(U, Pu)O_2$. Depending on the irradiation conditions, pellets are designed without initial central hole (case of Phénix) or as annular pellets (case of SuperPhénix).
- One or two axial fertile blankets are fabricated with depleted or natural uranium oxide UO_2 .
- Two free volumes (gas plenum) are located on both sides of the column and initially contain helium gas under 1 bar pressure. The main purpose of gas plena is to accumulate fission-gas products released during irradiation and limit the internal pressure below a few dozen bars,
- Other internal structures are added such as braces to support the fissile columns and a spring located in the upper plenum to keep the pellet in place before and early in the irradiation.

The main characteristics for Phénix and SPX1 fuel pins are provided in the following (► [Table 21](#)).

■ **Figure 104**
Typical SFR Fuel Pin

■ Table 21

Main characteristics for Phénix and SPX1 fuel pins

	Phénix (standard)	SuperPhénix
Outer cladding diameter (mm)	6.55	8.50
Cladding thickness (mm)	0.45	0.565
Cladding material	CW 15-15 Ti	CW 15-15 Ti
Outer pellet diameter (mm)	5.42	7.14
Inner pellet diameter (mm)	–	2
Plutonium enrichment: Pu/(U + Pu) (%)	20–28*	15–22*
O/M (M = U + Pu)	1.97 ± 0.02	≥1.96 < 2.00
Fuel fabrication density (%TD)	95.5	95.5
Fuel smear density (%TD)	88.1	82.5
Fissile column length (mm)	850	1,000
Lower fertile column length (mm)	300	300
Upper fertile column length (mm)	–	300
Fuel pin length (mm)	1,793	2,700

* Orders of magnitude for internal and external core.

TD: theoretical density.

Irradiation Conditions in Nominal Operation

The SFR core is characterized by a rather low height over diameter ratio (H/D) compared to PWR. Therefore, the axial profile for neutron flux, power density, and linear heat rate (LHR) is well pronounced with a $\Phi_{\max.}/\Phi_{\text{mean}}$ ratio of about 1.2–1.3.

The LHR depends on the radial position of the fuel subassembly in the core but also on the depletion of fissile material with the burnup. In standard SFR core, the fuel power roughly decreases continuously at constant neutron flux, with a rate depending on the initial plutonium enrichment. The cladding nominal temperature, on the top of the fissile column is between 893 and 923 K for an inlet sodium temperature in the assembly of about 663 K.

Temperatures in the Fuel Element

Thermal Conductivity of Mixed Oxide Fuel The thermal conductivity is a crucial property of a nuclear fuel and determines the temperatures when the linear heat rate and the surface temperature are known. Uranium–plutonium mixed oxide fuel, like most oxides ceramic, features a low thermal conductivity. Most of measurements carried out on mixed oxide with plutonium content between 15 and 30% do not exhibit a significant plutonium content dependence. In contrast, the thermal conductivity depends markedly on oxygen content O/M: a slight deviation from the stoichiometric composition (O/M = 2.00) leads to a major thermal conductivity decrease. Under irradiation, the evolution of fuel microstructure (cracks formation, porosity change, restructuring process, formation of a central hole, etc.) also tends to reduce the thermal conductivity. Accumulation of soluble fission products (in metallic or oxide phases) during irradiation affects thermal performance at high burnup.

■ **Figure 105**
Fuel temperatures prediction in a PHENIX fuel pin

Heat Transfers into the Fuel Element Heat generated in the oxide fuel by the slowing down of fission fragment is transferred by conduction in the fuel itself, by conduction and radiation in the fuel pellet/cladding gap and by conduction in the cladding thickness to be finally evacuated by the sodium coolant. ▶ *Figure 105* shows an example of radial temperature distribution in a PHENIX fuel element at the beginning of life (start-up – blue curve) and after fuel restructuring (after a few days – red curve). The importance of the thermal barrier constituted by the fuel pellet/cladding gap should be noted: at start-up, the temperature jump in the open gap filled with helium, can reach about 673 K.

Beginning of Life Phenomena

Phenomena Occurring During the First Rise to Power $(U, Pu)O_2$ ceramic has a brittle mechanical behavior at low temperature ($T < 0.5 T_{\text{melting}}$, i.e., up to 1,473–1,573 K) but becomes viscoplastic at higher temperature. Consequently, during the first power rise, axial and radial cracks are rapidly formed because of the strong temperature gradient.

Very quickly, equiaxed grains (size: $\sim 10 \mu\text{m}$) grow in the fuel area where the temperature is higher than $\sim 1,573$ K. In addition, it is observed a migration of the intragranular porosity and a coalescence of this porosity at grain boundaries. The resulting fuel swelling leads to a macroscopic expansion of the pellet fragments and contributes to reduce the fuel/cladding gap.

The most striking phenomenon in a SFR oxide fuel is the formation of elongated grains (columnar grains), which move toward the center of the fuel pin by the so-called sublimation–condensation process and form a large central hole. This mechanism occurs in the region where temperature exceeds $\sim 2,173$ K. Above that temperature, high values of vapor pressures of uranium and plutonium compounds play a major role in this restructuring process (▶ *Fig. 106*).

Lenticular pores will develop from the manufactured porosity but also from the voids created into the central area of the pellet by its initial cracking.

These lenticular pores, by migrating toward the centre, “sweep up” the porosity and leave behind elongated grains denser than the original ones.

■ Figure 106

Beginning of fuel restructuring – migration of the porosity toward the pellet centre

Lenticular pores will develop not only from the manufactured porosity but also from the voids created into the central area of the pellet by its initial cracking.

These lenticular pores, by migrating toward the center “sweep up” the porosity and leave behind elongated grains denser than the original ones.

Consequences of These Structural Changes In addition to the fuel microstructure modification, a radial redistribution of oxygen, uranium, and plutonium occurs.

- Oxygen, by thermodiffusion in solid and gas phases, is rapidly transferred from the hot center of the pellet to the cold periphery. Oxygen migration creates a radial distribution in the local oxygen potential and, of course, locally influences the thermal conductivity.
- At high temperature, a mixed oxide fuel with an O/M ratio greater than 1.92 is characterized by a gas phase more enriched in uranium (UO_3) than plutonium. As previously mentioned, the sublimation–condensation process in the enriched uranium vapor is responsible for the motion of lenticular pores. This process probably combined with a diffusion mechanism in the solid phase also contributes to significant plutonium enrichment in the hot part of the pellet, near the central void.

In the case of annular fuel (SuperPhénix manufacturing for example), the same mechanisms may occur. However, at comparable LHR, the maximum temperature in an annular fuel is smaller by 200–300 °C than in a solid fuel pellet. Thus, restructuring processes in an annular fuel is usually less pronounced and only cause a small increase of the initial hole radius.

The second effect of this fuel transformation is the fuel/cladding gap closure. The kinetics of this phenomenon is faster when the local power is high. Thus, the gap closure occurs in the first place at the axial position where the LHR is maximal and then gradually extends to both ends of the fissile column.

The main consequence of the previous mechanisms is an overall decrease of the fuel temperature; gap closure lowers the surface temperature of the fuel by roughly 200–300 °C, while fuel restructuring and associated geometric changes contribute to decrease the fuel center temperature and increase the margin to fuel melting (► [Fig. 107](#)).

■ Figure 107

Calculation, with the GERMINAL code, of the beginning of life fuel centre temperature and the central hole opening for a mixed oxide fuel for a PHENIX fuel element

Phenomena Occurring During the Life in Reactor

Generation of Fission Products The continuous accumulation of fission products (FPs) in a fast reactor fuel affects its physical and chemical properties. These are essentially the FP considered as stable throughout the duration of irradiation which will play an important role on the fuel behavior.

These FPs are customarily classified into five different families according to their chemical state:

- The noble gases (Kr and Xe) with a production yield of about 0.25 atom/fission in a fast reactor spectrum. They are chemically inert, thermodynamically not soluble in mixed oxide and thus, contribute to the fuel swelling
- The metallic inclusion (noble metals such as Ru, Pd, Rh, Tc. . .) which tends to accumulate in grain boundaries. Their total fission yield is about 0.5 atom/fission
- The oxide inclusions (Ba, Zr, Sr) with a production yield of about 0.1 atom/fission
- The fission product in solid solution (mainly the rare earth: Nd, Pm, Ce. . .) with a yield of about 0.5 atom/fission
- The so-called “volatile” FP such as Cs, Te, or I (0.27 atom/fission). During normal fuel pin operation, volatile FP can easily migrate under thermal radial and axial temperature gradients.

Chemical state of fission products primarily depends on the oxygen potential (ΔGO_2) imposed by the mixed oxide which increases during irradiation. The chemical state of molybdenum, for instance (0.21 atom Mo/fission), changes during irradiation: at low burn up, Mo is mostly transformed into metallic precipitates with ruthenium and palladium, while at high burn up (>10 at.%), it can be found in oxidized compounds such as caesium molybdate Cs_2MoO_4 .

The main effects of irradiation and fission-product accumulation on the fuel properties are the following:

- The melting temperature slightly decreases
- The thermal conductivity also decreases by the combined effects of composition change of the fuel and the accumulation of radiation damage in the lattice
- The oxygen potential tends to increase as demonstrated by measurements made on PHENIX irradiated fuels. This trend is related to the oxidative nature of plutonium fission. The O/M ratio also increases by nearly 0.003/at.%
- The fuel volume increases due to the solid and gaseous swelling

Fuel Swelling The fuel swelling rate versus burnup depends on the physical and chemical FP state. The SFR fuel, because of its very high thermal regime, releases a large proportion of fission gas into the pin free volumes. Fission gas atoms left in the fuel and closed pores are mainly located in the outer part of pellets and contribute to the total swelling. Fission products in oxide phases having usually a smaller density than the mixed oxide will also lower the average density. Thus, measurements on samples from irradiated fuel pins (► Fig. 108) show a regular decrease of the hydrostatic density with an average slope of 0.7/at.%.

Creep mechanisms can accommodate the fuel swelling as long as voids exist in the fuel section (fuel/cladding gap, cracks, porosity, central hole), even if the cladding deforms by swelling and irradiation creep. During operation at full power, mechanical interaction with the cladding (pellet-cladding mechanical interaction PCMI) is often negligible compared to the stress from the fission gas pressure (some MPa). Only in the case of fast power transients, the cladding can experience significant strain level. Experiments showed that the level of cladding stress rarely leads to a permanent plastic strain or a cladding failure.

■ Figure 108

Fuel density change with the burn up of some SFR mixed oxide fuels

Fission Gas Release The behavior of fission gas (FG) is complex. Given their very low solubility in mixed oxide fuel, fission gas atoms will tend to diffuse within the grains and precipitate as intragranular bubbles on structural defects. Then FG will accumulate at grain boundaries to form intergranular bubbles which will gradually interconnect and initiate a release in the open porosities. In nominal operating conditions, the average fuel temperature being high, a large majority of fission gas atoms will be quickly released (see Sect. Fuel Swelling).

The FG release rate (► Fig. 109) ranges from 30 to 50% at low burn up (<1–2 at.%) and commonly reaches 80–90% at high burnup. Up to about 6–8 at.%, the fuel temperature is the most sensitive parameter. At higher burnup (>8 at.%), the cold part of the pellet, which has accumulated large amount of fission gases, will experience a structural process similar to the high burn up structure (HBS) observed in PWR: the decrease of grain size will favor a thermal release. FG-retention measurements, performed by fuel sublimations and quantitative microprobe analysis in the burnup range 4–12 at.%, have highlighted this FG behavior occurring in the coldest part of the fuel.

Volatile Fission Products Behavior The high temperature of SFR fuel enhances the mobility of volatile fission products such as Cs, Rb, Te, Se, I, or Br. Like fission gases, volatile fission products usually leave the center of the restructured zone and condense in the colder outer area.

At low burnup (<7 at.%), the volatile FP compounds such as CsI, Cs₂Te, and Cs₂(U, Pu)O₄ (caesium-uranoplutonate) species are predominant. At higher burnup, with the increase of oxygen potential, caesium will gradually form caesium molybdate (Cs₂MoO₄).

O/M Ratio and Fuel Oxygen Potential Oxide fuel is chosen slightly under stoichiometric (O/M₀ ~1.97) to control the oxygen potential. However, during irradiation, with the oxidizing effect of fission products, the oxygen potential and O/M increase almost linearly to a value close to stoichiometry at a burnup between 5 and 8 at.%, depending on the initial O/M value.

At low burnup, the fission-product Mo is in metallic form, but, since the free energy of formation of MoO₂ is close to the oxygen potential of a stoichiometric fuel, Mo will gradually oxidize to MoO₂ and stabilize the O/M ratio to a nearly stoichiometric value. The evolution of

■ Figure 109

Fission gas release rate of standard PHENIX fuel pins according to average fuel burn up

O/M and oxygen potential plays a key role in two important phenomena encountered in the SFR irradiated pins at burnup (>68 at.%): the formation of a joint oxide gain in French (JOG) and the chemical reactions of the fuel with the cladding.

Joint Oxide Gain (JOG) Formation As said before, the high temperature of the SFR fuel favors the migration of volatile fission products such as cesium and tellurium not only from the hot central region of the fuel pellets to the periphery but also to the lower and upper ends of the fissile column. Postirradiation examinations with optical metallographic observations and more precise investigations with SEM and EPMA technique of fuel pins with burnup >7 at.% have identified between the periphery of the fuel pellet and the inner wall of the cladding a layer containing oxidized fission products such as Cs, Mo, Pd, Te, and Ba (➤ Fig. 110). The thickness of this layer, known as JOG, increases with burnup.

Inner Corrosion of the Cladding Most cladding materials tested in the SFR belongs to the family of “austenitic stainless steels” (AISI316 for instance) and nickel alloys. These alloys are characterized by chromium content greater than 12% to provide a chemical protective layer made of chromium oxide.

■ Figure 110
Microprobe analysis of JOG of PHENIX pin irradiated at 14 at.%

The increase of oxygen potential and the change in the chemical balance of fission product will favor chemical reactions of some FP such as caesium with chromium oxide. Simultaneously, other FP as volatile tellurium and iodine, made free by the association of caesium with chromium or molybdenum (see JOG Formation) can chemically react with the major components (Fe, Cr, Ni) of the cladding.

Fuel cladding chemical interaction (FCCI) usually takes place in the upper half of the column fissile where favorable thermodynamic conditions exist: high temperature and low cladding strain. This FCCI is seen as a localized attack (a few tens of millimeters in height) and affect a fraction or the entire inner wall of the cladding (➤ Fig. III). In other circumstances, FCCI can affect the cladding at the junction between the column fissile and fertile blanket. In these corroded areas, the sound cladding thickness can be significantly reduced (30–40%), and it constitutes an “Achilles’ heel” for the mechanical strength of the fuel pin in normal and accidental operations.

Behavior Under Irradiation of the Cladding The materials for subassembly structures and cladding for fuel pins experience two main kinds of damage during irradiation:

- The temperatures conditions between 673 and 923 K can lead to structural changes such as formation of destabilizing phases, producing a structural tightening with loss of ductility and toughness
- The important fast flux ($E > 0.1$ MeV) causes damages (dpa) in the atomic lattice of metallic materials. In the early stage of irradiation ($< \sim 10$ dpa), damages favor hardening effects (increase in yield strength) with significant losses of initial ductility. At high dose of irradiation (~ 100 dpa), a volume swelling due to the formation of stable cavities may lead to a complete embrittlement of the material (fracture toughness reduced to a few $\text{MPa}\sqrt{\text{m}}$).

The most frequently used cladding materials are the austenitic stainless steels, which have a very good structural stability in the operating range but are characterized by a fast swelling rate after an incubation period (which depends on the grade considered). The titanium stabilized cold

■ Figure 111
FCCI of PHENIX pin irradiated at a very high burn up (16 at.%)

worked steel such as the “CW 15-15 Ti” grade is today the reference cladding material in order to reach maximum doses of about 120–130 dpa with a swelling below 6%.

To reach higher doses and higher fuel burnup, investigations are focused on cubic-centered materials such as ferritic–martensitic steels reinforced by a dispersion of nano-oxides (oxide dispersion strengthened steels). They have a low sensitivity to swelling as it was demonstrated up to 130 dpa for a classical ferritic–martensitic steel (EM12 grade) in the PHENIX reactor. However, some grades may be weakened in the range of low temperatures, resulting in a too high increase of their ductile–fragile transition temperature (DBTT).

To prevent the risk of a cladding brittle fracture, the material needs to avoid excessive embrittlement by the combined effects of temperature and neutron dose, but it is also important to use design methodology that takes into account the evolution under irradiation of mechanical and all the loads that the cladding will experience in normal operating and incidental conditions. These considerations are reflected in the French design rules methodology, which is applied to embrittled materials by irradiation (RAMSES II).

Interaction with Sodium Fuel pins are designed to keep the probability of cladding failure as low as possible. The example of PHENIX reactor is therefore instructive, as the rate of failures requiring the unloading of the failed subassembly is only $5 \times 10^{-5}/(\text{pin} \cdot \text{year})$ despite the presence of many experimental subassemblies and capsules.

Nevertheless, cladding failures have to be properly managed because mixed oxide and sodium are not chemically compatible in a wide range of temperature and stoichiometry. Kinetics of reaction depends on many parameters such as sodium flow rate, oxygen diffusion, and burnup. The sodium-uranoplutonium compound has a lower density by almost a factor of 2 and a lower thermal conductivity compared to mixed oxide (factor of 4). These features are in favor of changing the initial cladding crack into a large breach, which has to be avoided.

In general, a cladding failure starts with a “primary failure” corresponding to a loss of sealing, which leads to a release of the fission gas under high pressure. This initial phase may be followed by a secondary one due to the development of the chemical reaction between the mixed oxide and the sodium (➤ *Fig. 112*). This second phase must be properly handled by means of gas and DDN (detection of delayed neutrons) detection systems because it would lead to FP and actinides severe pollution of the primary circuit.

Kinetics of formation of primary and secondary failures can be highly variable: from a few minutes to hundred days. However, the main factor that favors a rapid evolution of the breach is the embrittlement of the cladding material by an excessive void swelling or by an intrinsic weakening of the microstructure such as certain Ni alloys (Inconel 706).

Conclusion The numerous irradiation experiments carried out during 4 decades in the French sodium fast reactors Rapsodie and Phénix have significantly contributed to a better understanding of the mixed uranium–plutonium oxide fuel pin behavior in normal operating condition and in case of cladding failure. Despite some negative aspects, oxide fuels still remain the reference fuel for the Gen-IV sodium fast reactor.

5.1.2 Metal

Metal fuel is considered for future SFRs due to its high breeding potential owing to its high metal atom density and hard spectrum and ease of fuel fabrication. Metallic fuels are also amenable for

■ **Figure 112**
Macrograph of a failed fuel pin after the beginning of the second phase

■ **Table 22**
Salient properties of fuel materials

Fuel	Thermal conductivity (W/m-K)	Mass density (kg/m ³)	Breeding potential
Oxide	2–4	10,000–11,000	~1.1
Carbide	12–16	13,500–13,800	~1.2
Nitride	12–16	13,600–14,000	~1.3
Metal	30–35	19,000–20,000	~1.6

advanced reprocessing methods like pyrochemical reprocessing. Compared to oxide, carbide, and nitride fuels, metallic fuels have high mass density, high thermal conductivity, and breeding potential at typical operating conditions (► [Table 22](#)).

Generally, the composition of metallic fuel is a binary alloy of uranium metal and plutonium, the exact composition being decided by the reactor size. However, the melting point of such a binary alloy is lower and also it forms eutectic compounds with clad material at a lower temperature. To overcome this difficulty, normally Zr is added in small quantities either in the fuel matrix (U–Pu–Zr) or as a sacrificial liner around the fuel. The effects of Zr addition in a typical binary alloy are depicted in ► [Fig. 113](#). Also, zirconium improves the chemical compatibility between fuel and the austenitic stainless steel cladding material by suppressing the inter-diffusion of fuel and cladding components.

However, Zr addition reduces the breeding ratio marginally (◉ [Fig. 114](#)). The choice of binary (U–Pu) or ternary (U–Pu–Zr) or binary with a liner (U – Pu + Zr) depends upon the operating temperatures, linear power, and breeding requirements.

Figure 113
Melting point variation with Zr content

Figure 114
Breeding ratio as a function of Zr content

5.1.3 Properties of Metal Fuel for Design

Phase Diagram

The phase diagram of the U–Pu–Zr metallic fuel is given in [Fig. 115](#) as a function of Zr atom percent constituent. This will be useful in determining the various phase while deciding the fuel composition and their implications during its operating condition.

■ Figure 115
Binary (U-Pu)-Zr phase diagram (Pu at 19 wt%)

Density

Element	Density (ρ), g/cc	Atom fraction
U	19.1	$X_U = 1 - X_{Pu} - X_{Zr}$
Pu	19.816	X_{Pu}
Zr	6.5	X_{Zr}

Density of U-Pu-Zr = $X_U \cdot \rho_{U_r} + X_{Pu} \cdot \rho_{Pu} + X_{Zr} \cdot \rho_{Zr}$.

Thermal Conductivity of Fuel

Fig. 5.1.12 Binary (U-Pu)-Zr phase Diagram (Pu at 19 wt%)

Thermal conductivity of fuel for the calculation of fuel temperature is taken from the literature and is given below.

$$K(T) = a + bT + cT^2, \text{ W/m-K}$$

where

$$a = 17.5 \cdot ((1 - 2.23 \cdot W_{Zr}) / (1 + 1.61 \cdot W_{Zr}) - 2.62 \cdot W_{Pu})$$

$$b = 0.0154 \cdot ((1 + 0.061 \cdot W_{Zr}) / (1 + 1.61 \cdot W_{Zr}) + 0.9 \cdot W_{Pu})$$

$$c = 9.38 \cdot 10^{-6} \cdot (1 - 2.7 \cdot W_{Pu})$$

W_{Zr} , W_{Pu} , W_U are weight fractions of Zr, Pu, and U, respectively.

For U-15% Pu-6% Zr system,

$$K(T) = 6.945681 + 0.016174 T + 5.58 \times 10^{-6} T^2, \text{ W/m-K}$$

where T is in Kelvin.

For fuel with pores, porosity effect is considered in the fuel. Correction factor for porosity is, $f_{\text{pore}} = (1 - P)/(1 + 2.5P)$ where P is the porosity of the fuel.

$$K(T, P) = f_{\text{pore}} \times K(T, 100\% \text{ TD}).$$

Thermal Conductivity of Fuel with Burnup

With burnup, fuel swells which results in increase of pores and consequently in the reduction of thermal conductivity of fuel. Metallic fuel thermal conductivity comes down till a porosity of 0.23 is attained and from then onward sodium infiltrates into the porosity due to release of fission gases and thereby increasing the thermal conductivity of fuel. The factor, X, that minimizes thermal conductivity for an irradiated fuel has been evolved and is given by the equation

$$X = (1 - P_{\text{min}})^{(3/2)\epsilon}$$

where $P_{\text{min}} = 0.23$, $\epsilon = 1.75$ for metal fuel gas filled pores.

$$\text{Accordingly, } X = (1 - 0.23)^{1.5\epsilon} = 0.51$$

Thermal conductivity of metal fuel before sodium infiltration is $0.51 \times K_{\text{fuel}}$.

After this, fuel porosities become interconnected and sodium infiltrates into the pores, thereby improving the fuel thermal conductivity to the original value.

Coefficient of Thermal Expansion of Fuel

Coefficient of thermal expansion is given by the expression

$$\alpha_{\text{fuel}} \times 10^6 = 19.41 + 12.67 * C_{\text{Pu}} - 13.37 * C_{\text{Zr}} \text{ mm/mm-K}$$

where C_{Pu} and C_{Zr} are concentration of Pu and Zr in atom fraction, respectively.

Fission Gas Release

The fractional release rate, F_g , is dependent on burnup (Bu in at. %), porosity (P), temperature (T), and fuel swelling strain (ϵ_s) due to gas bubbles according to

$$F_g = [1 - \exp(-\alpha \text{Bu})] [1 + C_g (P - 0.1)P^{2/3}] R_g \exp(-Q_g/RT) + f(\epsilon_s - \epsilon_{s1}), s^{-1}$$

where $(P - 0.1) > 0$, $(\epsilon_s - \epsilon_{s1}) > 0$, and α , C_g , R_g , Q_g , f , and ϵ_{s1} are empirical parameters to be determined from in-reactor data. For example, the parameters used for U-Zr and U-Pu-Zr fuels are $\alpha = 1.0$, $C_g = 7.0$, $R_g = 1.14 \times 10^{-5}$, $Q_g/R = 5.6 \times 10^3 \text{ K}$, $f = 1 \times 10^{-2}$, and $\epsilon_{s1} = 0.3$. For $\epsilon_s > 0.3$, the second term is orders of magnitude larger than the first term in 8, giving rapid gas release for fuel regions with gas bubble swelling $>30\%$.

Hardness of Material – U-15 Wt% Pu-6.8 Wt% Zr

Hardness of material (VHN) is defined as follows for a typical load of 200 g:

$$\text{VHN} = 2e - 12Xt^6 - 8e - 9Xt^5 + 1.05e - 5Xt^4 - 0.0091Xt^3 + 3.9422Xt^2 - 898.5Xt + 84,536$$

where $t = T - 273$, T is temperature in Kelvin. ➤ [Figure 116](#) shows the variation of hardness.

■ Figure 116

Behavior under Irradiation

Importance of Smeared Density Under irradiation, the major concern is its high swelling. When metal fuel swells due to accumulation of fission gases, the fuel slug diameter and length increase

but the swelling is not isotropic. The length increase is consistently less than would be predicted from isotropic swelling. This difference was attributed to the difference in swelling behavior between the hotter center of the fuel and the colder periphery. The low smeared density (effective fuel cross section area/clad inside area) allows the fuel to swell to certain extent to enable the interconnection of pores which in turn facilitates the release of fission gases. If adequate free expansion is not allowed, the fuel slug creates strong fuel clad mechanical interaction (FCMI) forces, resulting in unacceptable stains. Many failures were reported in the earlier design of metallic fuel pins with high smear density due to high swelling and FCMI. Hence, a lower smeared density is essential for accommodating swelling. The smeared density effects are shown in **► Fig. 117**. The interconnection of porosities is reported to happen at $\sim 25\%$ volumetric swelling.

Fission Gas Release There is a need to provide adequate gas plenum at the top of the pin to accommodate the accumulated fission gas releases. The fission gas release is not a strong function of fuel composition and gets saturated at about 80%, as seen in **► Fig. 118**.

Radial Swelling Behavior **► Figure 119a** shows radial averaged swelling of 85% smeared density with U-19% Pu-10% Zr fuel plotted against burnup at the middle of the core. It is observed from **► Fig. 120a** that in the case of 85% smeared density, swelling due to the open pores is only $\sim 5\%$ at ~ 1 at. % burnup when the initial slug-cladding gap is filled with swollen slug. At a latter stage of irradiation, the open pore volume is replaced by the solid fission product (FP) swelling and cannot accommodate the solid FP swelling. FCMI stress continues to grow as seen from the **► Fig. 119b** for the same fuel composition and smeared density.

In the case of lower density fuel (75% smeared density), the open pore swelling amounts to about 20% and serves as a buffer to the solid FP swelling as seen from **► Fig. 120a**. As a result, there is no FCMI stress even at 2 at. % burnup as evident from **► Fig. 120b**. It is observed that fuel contacts with the clad around 3 at. % burnup and 75% smeared density fuel

► Figure 117
Influence of metallic fuel smeared density

■ Figure 118

Fission gas release for different metal alloy composition

a

Radial swelling

b

Pressure buildup

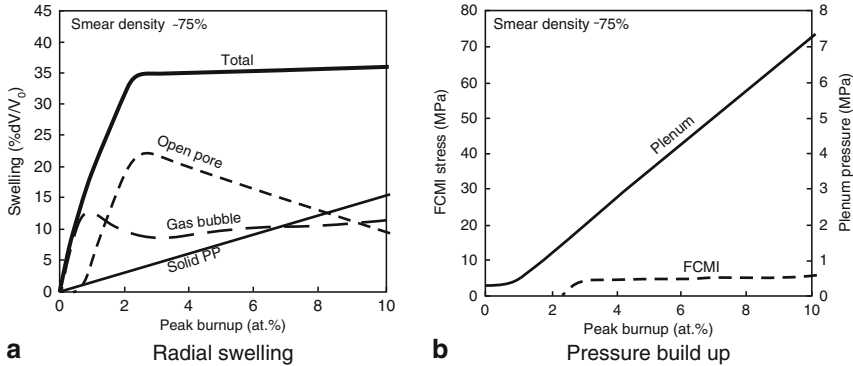

■ Figure 119

Swelling and pressure buildup with U-19%, Pu-10%, Zr (85% TD)

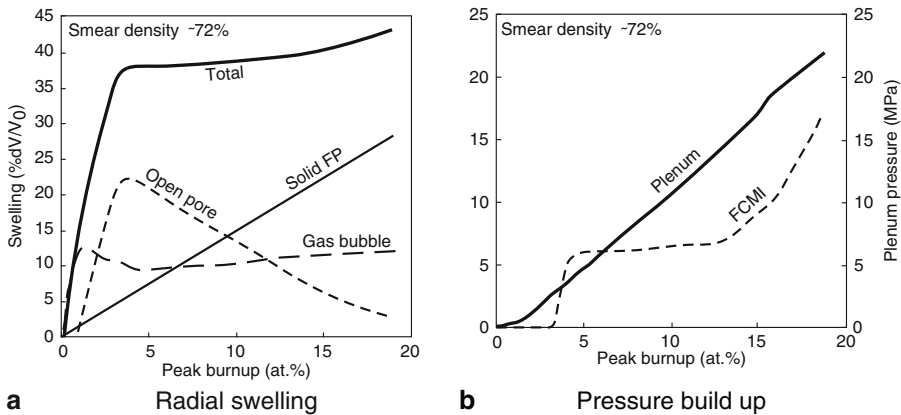

can accommodate about 35% swelling before it contacts the clad and remains constant beyond 3 at. % burnup. When the burnup becomes very high, significant FCMI can occur for even lower smeared density fuel slog, as seen from [Fig. 120a](#), because of the accumulation of the solid FP.

When the burnup becomes very high, significant FCMI can occur for even lower smeared density fuel slog, as seen from [Fig. 121a](#), due to the accumulation of the solid FP.

In this case, although the decrease in the open pore volume accommodates solid FP swelling until ~13 at. % burnup, the remaining volume of the open pores becomes too small at the higher burnup. It leads to significant increase in the FCMI stress as indicated in [Fig. 121b](#).

■ **Figure 120**
Swelling and pressure buildup with U-19%, Pu-10%, Zr (75% TD)

■ **Figure 121**
Swelling and pressure buildup with U-19%, Pu-10%, Zr (72% TD)

Based on the above discussions, it can be stated that swelling of fuel depends on the smeared density chosen for the fuel and burnup target.

Axial Swelling Behavior The axial fuel growth due to fission gas retention is expected to be around 2–4% as shown in the ► [Fig. 122](#) and is expected to be completed within 1–2 at. % burnup.

Safety Issues in Metallic Fuel Advantageous safety features of metal fuel are its high thermal conductivity, which results in less temperature, less temperature coefficient of reactivity and consequently less burnup reactivity swing, higher fuel axial expansion coefficient, and high negative reactivity feedback. However, sodium void worth is higher in metal fuelled core. Safety arising from low fuel temperature and strong axial expansion reactivity feedbacks make the metal fuelled core safe even though the sodium void worth is higher. Also, core reactivity does

■ Figure 122
Axial swelling for typical fuel compositions

not fall with burnup in such a core. Hence, the core size becomes more important in the physics design, and higher sodium void worth up to \$7 is permissible from the safety point of view. Low operating temperature, even though not favorable from the point of view of thermodynamic efficiency, leads to higher margin for sodium voiding. Other design measures that could be thought of toward minimizing the sodium void reactivity effect are use of sodium plenum in place of axial blanket and reduction of sodium volume fraction in the core.

One of the important safety issues to be addressed is redistribution of fuel constituents. Owing to interdiffusion of U, Pu and Zr within the fuel, Zr-depleted radial zones are created with lower solidus temperatures locally. Although it is not reported to be life limiting, it becomes important during transients as operational limits under incident conditions have to be determined. Another issue is fuel clad chemical interaction. When the metal fuel comes in contact with the cladding a situation involving multi-component diffusion transpires. In addition to fuel elements redistribution according to the phase relationships due to temperature gradient, the solid fission products participate in this radial diffusion process. So also the cladding elements. Three issues arise due to this complex interdiffusion process enhanced by the presence of lanthanide fission products with increased burnup. The effective cladding thickness could be uniformly thinned due to wastage. The cladding could be weakened due to grain boundary embrittlement. The combination of fuel and cladding elements could lead to an undesirable low melting alloy adjacent to the cladding. This may affect the clad integrity. In summary, low melting eutectic formation is one of the major issues in the case of metallic fuels.

High swelling and its non-isotropic characteristics have significant influence in design, especially while aiming for higher burnup, which would have to be handled by suitable design measures, choosing appropriate selection of smeared density, for example.

5.1.4 Carbide and Nitride

It has been demonstrated that mixed oxide behavior is satisfactory up to high burnup (15–20 at.%), and during the various steps in the fuel cycle (fabrication, storage, and reprocessing). Nevertheless, it has important drawbacks: a low heavy-atom density, a low thermal conductivity, and poor sodium compatibility. To overcome those current shortcomings, R&D organizations (CEA in particular) investigate potentially more effective fuels such as carbide and nitride ceramics as well as metal alloys (see ▶ Sect. 5.2 and ▶ Table 22).

Among these alternative fuels, most studies around the world have been focused on carbide, carbonitride, and nitride ceramics.

In the early days, the main reason for using dense uranium and plutonium fuel ceramics was to get a low doubling time (~15 years). Today, their main interests are the following:

- A good thermal conductivity leads to a low operating temperature at nominal power. Carbide and nitride can be considered as “cold” fuels with an important margin to fuel melting. This behavior improves core reactivity feedback coefficients. The Na-coolant Doppler ratio is also more favorable and provides a more satisfactory dynamic behavior and a good passive safety;
- High heavy atoms density favors a better breeding gain and therefore a smaller loss of core reactivity. Thus, longer irradiation cycles and/or a reduction of the number of control and shutdown (CSD) rods are possible;
- A very good chemical compatibility of these dense ceramics with liquid sodium enables, in case of clad failure, to continue the reactor operation with a broken fuel element until the next scheduled stop.

However, the design of carbide or nitride fuel element must take into account high swelling rates to ensure that the stress level in the cladding due to fuel cladding mechanical interaction (FCMI) remains acceptable at high burnup. Swelling behavior is certainly the most important drawback of these alternative fuels and will be discussed in the second part.

Properties of Dense Ceramic Fuels

This chapter examines not only the key physical properties of carbide and nitride fuels but also the most significant features concerning their behavior under irradiation.

A number of properties of (U,Pu)C and (U,Pu)N fuels, compared to oxide fuel (U, Pu)O₂ are provided in ▶ Table 23.

Chemical Properties Concerning the chemical properties of mixed carbide fuels, the phase diagram exhibits a very narrow C/M range for mono-uranium and plutonium carbide. After carbothermic manufacturing from mixed oxides, the monocarbide coexists with either a metallic phase or a higher carbide phase of type M₂C₃. The presence of a metallic phase should be avoided because it melts at low temperature (< 1,200 °C) and is chemically reactive with the cladding (eutectic phase formation).

Accordingly, manufactured carbides have usually a hyperstoichiometric composition with a major phase (U,Pu)C and a second phase (U, Pu)₂C₃. However, to avoid a chemical reaction of fuel with cladding steel (formation of Cr₂₃C₆ at grain boundaries of austenitic steel grades), the amount of M₂C₃ needs to be restricted to less than 15%.

For nitride fuel, manufacturing studies have shown that it was easier to control the amount of M₂N₃ by an adequate thermochemical treatment.

■ Table 23

Comparison of some properties of various ceramic fuels for FR (Pu/M = 20%)

	(U,Pu)O ₂	(U,Pu)C	(U,Pu)N
Theoretical density (TD) (kg/m ³)	11,000	13,600	14,300
Heavy atoms density (kg/m ³)	9,700	12,900	13,500
Density ratio (reference is oxide)	1	1.33	1.39
Heavy atoms density for a fixed smeared density (SD) (kg/m ³)	8,051 (SD = 83% TD)	9,675 (SD = 75% TD)	10,125 (SD = 75% TD)
Smeared density ratio (reference is oxide)	1	1.2	1.26
Thermal conductivity at 1,000 °C (W/m-K)*	2.0	12.0	13.2
Thermal expansion coefficient (20 ⇒ 1,000 °C)(10 ⁻⁶ /K)	11.5	12.1	9.5
Melting temperature (solidus) (°C)	2,740	2,325	2,720**
Compatibility with sodium	Poor	Good	Good
Compatibility with air	Good	Poor	Good
Compatibility with water	Good	Poor	Average

* For an hypostoichiometric oxide (O/M = 1.97) and a fabrication porosity respectively of 4% for the oxide and 17.5% for the dense ceramics.

** Above 2,000 K (1,723 °C), under helium atmosphere, a metallic phase (uranium and plutonium alloy) is formed by dissociation of mixed nitride: (U,Pu) N (s) ⇒ U (liq.) + Pu (liq.) + ½N₂ (g)

Nuclear Properties Nuclear reaction on carbon is not a serious issue for neutronics performance. A major problem during nitride-fuel irradiation is the formation of carbon-14 by (*n, p*) reaction on ¹⁴N and the production of ⁴He by (*n, α*) reaction. The occurrence of these nuclear reactions has three major impacts:

- It provides an additional gas production (He) estimated to at least 10% of the fission-gas production
- The production and release of ¹⁴CO₂ during reprocessing operations and during waste storage (the radioactive period of ¹⁴C is 5,600 years) needs to be handled
- The neutronics penalty can be balanced by an increase of the fuel plutonium enrichment with the negative effect of a reduction of the internal breeding gain

To limit ¹⁴C and He productions in nitride fuel, technical and economical feasibility of ¹⁵N enrichment have been assessed. At least two chemical processes could be developed: the NITROX and the chromatographic processes. The price range of the ¹⁵N produced by both techniques is about 8.2–12.2€/g, increasing the cost of the fuel assembly by about 10%. This additional cost could be, however, reduced if the ¹⁵N is recycled during the reprocessing stage.

■ Figure 123

Comparison of thermal conductivities of mixed oxide fuel (O/M = 1.97, P = 4%) and mixed carbide and nitride fuels (P = 17.5%)

Thermal Conductivity Carbide and nitride fuels have a higher thermal conductivity than the oxide fuel (see ► Table 22 and ► Fig. 123). Although these fuels need a strong manufacturing porosity (15–20%), which greatly penalizes thermal performance, the thermal conductivity of carbide and nitride remains much higher by a factor of 3–6 than oxide.

Mechanical Properties Among the various mechanical properties required to understand the fuel behavior under irradiation, creep properties are important for a reliable assessment of FCMI. In case of mechanical interaction between fuel and cladding, it is mainly the contribution of irradiation creep that allows the accommodation. Despite large scattered experimental data (see ► Fig. 124), carbide and nitride fuels have a similar irradiation-creep rate (ICR), which is an order of magnitude lower than oxide. This reduced irradiation creep for carbide and nitride fuels is a counterpart of their better thermal conductivity.

Fuel Swelling The main disadvantage of dense ceramic fuels is a high swelling rate under irradiation. Most of the experimental data have been obtained on carbide rather than nitride fuel. However, there is a general agreement in the open literature that nitride fuel does not swell as much as carbide (see ► Fig. 124).

Correlations drawn from fuel pin deformations (diameter deformation and elongation of the fissile column) as well as more accurate data such as density-pellets measurements or more rarely some image analysis on SEM or TEM led to the following conclusions:

- Below a critical temperature, athermal swelling occurs driven by the inclusion of solid-fission products (FPs) (typical value of ~0.5/at.%) and by fission-gas atoms in the crystal lattice or in nano-bubbles (<30 nm). The swelling rate is roughly a linear function of burnup: ~1.5–1.6/at.%,

■ Figure 124

Comparison of carbide, nitride and oxide irradiation creep rates

- Beyond this critical temperature, observations show that these nano-bubbles rapidly grow (30–400 nm) and increase the gaseous swelling. As shown in [Fig. 125](#), the critical temperature decreases with the increasing burnup. For a carbide fuel, the critical temperature is evaluated to 1,100 °C at the irradiation start-up, but only to 800 °C at 5 at.% burnup. [Fig. 125](#) illustrates the differences in the critical temperature between carbide and nitride and the influence of nitrogen content in carbonitrides. These data confirm the U.S. gas-swelling results obtained by density measurements (integrated swelling within the pellet fuel) showing a critical temperature of nitride higher by about 150 °C than carbide.

At high burnup, two effects limit the macroscopic fuel swelling:

- Saturation of gas swelling occurs through the interconnection of intergranular bubbles and interaction of this bubble population with the fuel microstructure: fabrication porosity and grain boundaries (it is estimated that the gaseous swelling cannot exceed 30–40%)
- When the fuel comes into mechanical interaction with the cladding (FCMI), effect of hydrostatic pressure on bubble behavior will limit the gas swelling

In conclusion, dense fuels tend to swell significantly at the beginning of life when the fuel/cladding gap is open (He-bonded concept) and when the pellets are above the critical temperature. Then, under the combined effects of gap closure, a possible power decrease and the FCMI, the swelling rate will decrease and stabilize at a level depending on various manufacturing and irradiation parameters.

Current swelling models ([Fig. 126](#)) for carbide and nitride in fuel behavior codes are usually simplified and include only few parameters such as fabrication porosity, irradiation temperature, and burnup.

A better description of situations encountered by a carbide or a nitride fuel during its normal irradiation and power transients will be possible if models include

Figure 125

Variation of critical temperature with fuel composition (From Ronchi et al., 1984)

Figure 126

Comparison of some empirical correlations for carbide fuel swelling

- Manufacturing parameters: porosity (open and close porosity and their repartition between grain and grain boundary), M_2C_3 content, oxygen content, grain size
- Irradiation parameters: time, BU, temperature, and mechanical loading history
- The development of such model requires a large and reliable experimental database for the selection of important physical mechanisms and for validation purpose.

Fission Gas Release The release of fission gas strongly depends on the fuel thermal regime but also on some fabrication parameters such as the nature of porosity: open and/or closed.

As previously said, the (n, α) reactions on nitrogen-14 lead to an extra production of gas (He) causing additional release (more important for nitride than carbide).

The results on helium-bonded carbide or nitride pins fabricated with a large amount of open porosity show that the fission-gas release remains always lower than in oxide fuel (irradiated in the same conditions) but still can reach values greater than 50% at high burnup.

Chemical Stability The chemical stability of (U,Pu)C and (U,Pu)N compounds depends on the temperature and on the gas confinement.

In carbide, the vapor pressure of plutonium in equilibrium with solid (U,Pu)C contributes almost exclusively to the total pressure. This strongly incongruent evaporation has consequences for fuel fabrication (possibility of plutonium losses) and performance when high level of temperature is reached ($> 1,650^\circ\text{C}$). The result is a plutonium enrichment observed in the peripheral region of the pellets and along the radial cracks.

In nitride:

- In helium atmosphere and above 2,000 K, loss of plutonium and nitrogen can be encountered. However, the rate of dissociation is rather slow; consequently, a brief temperature rise might not have a severe penalty on the fuel behavior in transients.
- Under nitrogen atmosphere, until 2,700 K, the decomposition of (U,Pu)N should not happen. However, recent investigations of nitride irradiations, carried out in the PHENIX and Joyo (Japan) fast reactors, have confirmed that nitride could exhibit signs of dissociation, with precipitation of plutonium-enriched metallic phase in the gap between fuel and cladding.
- In case of clad failure (open system), nitride could be dissociated for temperature as low as 2,000 K.

Physical Stability Drastic pellet geometric changes as observed in oxide fuel (columnar grains and central hole formation) are not possible for dense fuels in most situations.

However, given their high manufacturing porosity, these fuels may be subject to an in-pile densification if the operating temperature is close to the sintering temperature. A significant in-pile densification can increase the fuel/cladding gap and cause a fuel overheating. In addition, the fabrication porosity is chosen to accommodate the fuel swelling and its partial removal would have undesirable effects on FCMI.

Studies for optimizing a fuel manufacture with high-porosity content, thermally stable under irradiation, were carried out at CEA and at other research organization such as the *European Institute for Transuranium Elements* (ITU) and *Japan Atomic Energy Agency* (JAEA). All these processes use the carbothermic reduction from a mixture of oxides and graphite but differ in methods to obtain the thermally stable porosity:

- The thermal stable fuel proposed by JAEA involves the use of pore former and Ni powder additions as a sintering aid, leading to a high proportion of closed porosity.
- The method of direct pressing (DP method) proposed by ITU does not use any additives but achieves the carbothermic reduction stage on cylindrical clinkers directly into the required “green” pellets shape for sintering. A variant is the “granules” (G method) in which carbothermic reduction stage is performed on 0.5–1.25 mm granules of mixture ($\text{UO}_2 + \text{PuO}_2 + \text{C}$), which are directly pressed and sintered. These methods lead to a fuel with large proportion of open porosity.

Both ways provide a good thermal stability for dense fuel but, according to the nature of porosity: closed (JAEA) or open (ITU), irradiation phenomena such as fission gas release, gaseous swelling, and its accommodation can greatly differ.

Behavior of Fission Products For sake of simplicity, three categories of fission products (FPs) in irradiated carbide and nitride fuels can be considered:

- Rare earth FP (La. . .)
- Noble metal FP (Ru. . .)
- Volatile and gaseous FP (Cs, Xe. . .)

Regarding the first category, lanthanides are much more soluble in nitride than in carbide. For example, La and Nd are soluble in MN but only partially soluble in MC. According to Kleycamp, they can also form sesquicarbides such as La_2C_3 and Nd_2C_3 or dicarbides (LaC_2 and NdC_2).

In the second category, $\text{UFP}_3\text{C}_{1-x}$ carbide types have been observed by MET examinations. Intermetallic compounds, such as MFP_3 , are observed in nitride. Molybdenum also behaves differently in the two fuels: it tends to form MoC and Mo_2C in carbide.

Volatile FPs (Cs, Br, I, Te) behave chemically in the same manner in carbide, nitride, and oxide fuel. The solubility of rare gases is very low, forming an intragranular nano-bubbles network in the U, Pu matrix.

As a consequence, the C/M ratio will decrease during irradiation (existence of many FP carbides), while the N/M ratio tends to increase due to the strong solubility of lanthanides. These trends could be changed, especially for carbide fuel by the presence of a greater amount of residual oxygen after manufacture. In this case, FP such as Ba and Sr will preferentially oxidize rather than forming carbide compound and will slow down the C/M decrease.

Corrosion of the Cladding During irradiation, cladding austenitic steel carburization can occur through transfer of carbon coming from the M_2C_3 phase decomposition, which is less chemically stable than the chromium carbide (Cr_{23}C_6). A similar risk of nitriding exists for nitride fuel.

The kinetics of the process depends on factors such as the nature of fuel/cladding bonding (sodium or helium), the M_2C_3 content in carbide fuel, the linear heat rate (LHR), and of course the irradiation duration. It is generally for Na-bonded carbide fuel pins (► [Fig. 127](#)) that the highest carbon concentrations have been measured with values ranging from 0.4 (low LHR) to ~2 w% (high LHR > 1,000 W/cm). The extension of carburization can affect up to 2/3 of the initial clad thickness. However, carburization of He-bonded fuel elements may be also significant, because, after the closing of the fuel/cladding gap, a direct transfer of carbon by intergranular diffusion, with a kinetic similar to the Na-bonded concept, can take place.

The major outcome of this clad carburization is a significant embrittlement of the austenitic steel in the carburized region with the presence of numerous radial cracks. However, in most cases, cracks are confined in this zone without causing clad failure.

Design of Dense Ceramic Fuel Pins

Choice of Dense Fuel In the previous chapters, we have seen that carbide and nitride fuels had many things in common. Advantages and drawbacks can be compared on the following aspects: core performance, safety, fuel cycle, manufacturing, and past experience.

Previous considerations demonstrate that the carbide achieves the best performance, especially in terms of core volume and fissile material optimization. To get an equivalent level of

■ Figure 127

Carburization of the inner wall of an austenitic-steel cladding for a Na-bonded fuel pin irradiated at 3 at. %

performance, nitride would require nitrogen-15 enrichment to at least 50%. Without enrichment, helium generation from (n, α) reactions on ^{14}N has a direct consequence on decreasing the discharge burnup.

Another negative point for nitride is a worse chemical stability at high temperature during a core disruptive accident where the low partial pressure of nitrogen favors substantial nitride fuel dissociation.

Carbide, because of its instability in the presence of oxygen or water, has a much lower ignition threshold. For the same reasons, it is difficult to produce a carbide fuel without impurities, which may have a negative impact on in-reactor behavior. Handling carbide fuel, during the fuel fabrication stages, requires a perfect control of experimental conditions, which may be extremely difficult to achieve in an industrial context. In this respect, nitride would exhibit a greater tolerance.

Compared to existing fabrication processes, a technological gap is required. In the carbide case, the pyrophoricity and impurity issues must be overcome. For nitride fuel, technological improvements are also essential to attain adequate ^{15}N enrichment at a reasonable cost or to remove the ^{14}C from fuel.

The choice between carbide and nitride is not that obvious; it depends on the relative importance of key criteria (safety, manufacturing, irradiation performance. . .). Nevertheless, carbide, with a larger experimental feedback, a safer behavior in accidental situation, and despite a more complex manufacturing process, appears to be the best option at this time.

Choice of Fuel-Pin Concept Two different fuel-pin designs were investigated in detail: the sodium and the helium-bonded fuel/cladding gap. ▶ [Table 24](#) summarizes the positive and negative points for both types of fuel elements.

As ▶ [Table 24](#) shows, the main interest of Na-bonded concept is a relatively low-level operating fuel temperature (usually $< 1,000\text{ }^\circ\text{C}$), which remains constant during irradiation. This low-temperature regime causes a moderate fuel swelling rate and prevents the FCMI risk if the fuel/cladding Na gap is large enough. In addition, it guarantees a large margin to melting and a good safety Doppler coefficient.

■ Table 24

Comparison of dense fuel pin concepts

	Main advantages	Major drawbacks
Sodium-bonded fuel/cladding gap	Lower fuel temperature: Gain for Doppler coefficient, Rather low swelling rate, In principle, no severe FCMI	Fabrication and reprocessing, High risk of clad carburization, Risk in case of defective Na bonding in fabrication or during in-pile irradiation
Helium-bonded fuel/cladding gap	Conventional manufacturing, Lesser risk of clad carburization	Risk of thermal instability and high swelling rate before fuel cladding-gap closure, FCMI \Rightarrow difficulty to design fuel element for high BU rate

■ Figure 128

Comparison of temperature profiles for both Na and He-bonded concepts at 700 W/cm

Unfortunately, international experience pointed out serious flaws regarding the Na-concept:

- The fabrication at an industrial scale is difficult
- A large amount of contaminated sodium during reprocessing operations has to be handled

For He-bonded concept (► Fig. 128), we can observe a very different thermomechanical behavior. The necessity of having a large amount of preexisting voids (fabrication pores and fuel/cladding gap) leads to a poor heat transfer and implies that the fuel will perform at high temperatures. Thus, the fuel will swell significantly, leading to rapid closure of the fuel/cladding gap and to FCMI.

■ Figure 129

Macrograph of a He-bonded carbide fuel pin irradiated to 6 at.% in PHENIX reactor

FCMI can occur at the burnup of a few at.% as shown by numerous carbide and nitride fuel irradiations (see ► Fig. 129). Despite this predictable mechanical interaction, experiments carried out in various countries and involving He-bonded fuel elements have demonstrated that a well-suited design can handle FCMI situation without severe damage.

Nowadays, the choice for a dense fuel element clearly leans in favor of the He-bonded concept.

Optimized Design of a Carbide Fuel Element The performance of a carbide fuel pin depends on its design which has to ensure that the FCMI effects remain always acceptable in normal and incidental situations.

The first criterion is the choice of the smeared density (SD, see ► Table 23). It is a compromise between a better internal breeding gain and a limitation of the FCMI consequences. French and American experiences demonstrate the need to set the smeared density around 75–78% TD to reach a burnup of 15 at.%.

The voids in the fuel pin for a given smeared density may come from

- Fuel fabrication porosity
- Choice of a hollow pellet
- Fuel pellet/cladding gap

The balance between these contributions aims at maximizing the efficiency to accommodate the fuel swelling and minimize the cladding-stress level due to FCMI.

A central hole does not seem to be an efficient solution to accommodate the fuel swelling.

The use of a rather high fuel fabrication porosity (15–20%) associated with a reasonable fuel/cladding gap size is a good compromise to regulate the temperature level during the gap closure period and is more efficient to reduce the “constraint” swelling rate. In addition, experiments have shown that a too large gap may cause an important unrestrained relocation

of fuel fragments, leading to major cladding ovalizations. Thus, a good value of gap/diameter ratio seems to be around 3–4%.

Finally, the cladding material has also an essential role in the design of a dense fuel element. Most irradiation results on carbide fuel pins were obtained with conventional cladding materials such as austenitic stainless steels. These materials provide satisfactory mechanical properties at irradiated state (residual ductility and thermal creep behavior) and a good resistance to sodium corrosion. Its main weakness is a high swelling rate leading to significant cladding macroscopic deformations for neutron dose >130 dpa for the best grades.

There are only few experiments with materials resistant to swelling such as Nickel alloys or ferritic–martensitic steel grades. Nevertheless, the better dimensional stability of these alloys at high dose rate and a possibly worse ability to creep, could lead to additional difficulties for carbide fuel pin design.

Conclusion

This review of physical properties and design approach of carbide and nitride summarizes its strengths and weaknesses for use in SFRs. Today, the He-bonded concept of carbide fuel pin with an adequately smeared density of about 75–78% TD seems to be the best compromise to compete with the oxide reference. Nevertheless an experimental large-scale demonstration in a power reactor is still missing to validate this conclusion.

5.2 Structural Materials

5.3 Absorber Materials

5.3.1 Introduction

Most of the data presented here are obtained from IAEA reports (fast reactor data retrieval and knowledge preservation initiative) (IAEA-TECDOC-884 1996; IAEA-TECDOC-1083 1999). All the present or planned fast neutron reactors use boron carbide as a neutron absorber, which then appears as the reference material. This is due to the relatively good absorption cross section of ^{10}B in the fast neutron energy range, a smooth $\sigma(E)$ curve (no resonances) allowing easy efficiency calculations (➤ Fig. 130), nearly no long life wastes (except ^3H and impurities). However, most of the concepts require high ^{10}B enrichment, from the natural one (19.8 at.%) up to 90%. This leads to high elaboration costs. This drawback has been tentatively addressed by considering more complex absorber elements allowing a local moderation of the neutron spectrum. As a result, lower enriched boron carbide or even other material (hafnium) could be reconsidered. $^{11}\text{B}_4\text{C}$ has also been considered as a moderator, although with a lower efficiency than the hydrides.

The main features of the behaviour of boron carbide under neutron irradiation in a fast neutron reactor environment have been identified in the 1970s: cracking due to thermal gradients and swelling due to helium retention in highly pressurized bubbles (IAEA-TECDOC-1083 1999). Behavior laws have then been tentatively developed by most of the involved countries (mainly USA, GB, France, Japan, and USSR). However, the more recent available data have mainly been obtained in Japan, Russia, and France. Some of the most salient results are reported here. We then present a summary of the results obtained on boron carbide.

■ Figure 130

Macroscopic neutron absorption cross sections for some materials (90% density for B_4C), as deduced from the corresponding microscopic cross sections, from ENDF data base

Russia

The first design of B_4C control rods was sealed pins. They unfortunately have a too short lifetime (2–3 months) due to helium release and internal pressure increase leading to a quick recourse to vented pins. Costs reduction is obtained by reuse of irradiated boron carbide. Two processes are considered. First, non-damaged pellets can be directly reused in new rods. Second, damaged pellets are ground to powder then sintered to obtain new pellets. In both cases, a relatively low γ -activity is required.

BN-600 (Russia) and BN-350 (Kazakhstan) cumulate more than 20 years of operation. At the moment, the lifetime of the control rods (BN600) is around 500 epfd with a burnup around 19%.

Tests in BOR-60 in 1972–1973 of CrB_2 –Ta composites showed good radiation stability but too low efficiency as compared to B_4C . The most serious alternative to B_4C is Eu_2O_3 : this material shows a higher efficiency, no swelling, no gas release. The major drawback is the residual activity. Owing to the cost of highly enriched boron carbide, new designs have been tested to obtain better yields. A promising one consists in composite rods (so-called rod-traps) containing an absorber (Eu_2O_3 , B_4C) and a moderator (ZrH_2). Eu_2O_3/ZrH_2 rods are somewhat less efficient than B_4C/ZrH_2 ones. Different designs were tested in BN-350 and BN-600, for as long as 450 epfd. Other materials such as hafnium can then be considered leading to an improved use of B_4C .

France

Boron carbide was the only used neutron absorber in the French fast neutron reactors. From neutron economy considerations, it was soon considered that high density, high ^{10}B enriched materials were required. The first control rods used large pellets, resulting in very short lifetimes (clad cracking, recrystallization of the center of the B_4C pellets). Many improvements were then

successively introduced: lowering the pellets diameter, reducing the enrichment at the feet of the rods, introducing a contention shroud. As a result, a good overall behavior was obtained in the last experimental rods (SuperPhenix design), with high operating conditions (650 efpd, burnup up to $2.5 \times 10^{22} \text{ }^{10}\text{B/cm}^3$).

Further improvement routes were considered in the 1990s on an experimental level: further reducing the pellet diameter (thermal cracking reduction) and lowering the density instead of the enrichment (swelling reduction).

Japan

Experimental pins were irradiated in Joyo. A maximum burnup of $2.3 \times 10^{22}/\text{cm}^3$ was achieved, leading to one of the most comprehensive available data bases (IAEA-TECDOC-1083 1999). Swelling is determined at low burnups from volume measurements on non-cracked pellets and picnometry for the higher burnups. Helium release increases with temperature and appears close to the formation rate at the highest burnups and temperatures.

B_4C -Cu composites have been elaborated. As compared to similar French materials elaborated in the 1970s, a better Cu- B_4C bonding is obtained (IAEA-TECDOC-1083 1999). Control rods made of hafnium hydride are presently considered in which hydrogen is used as moderator to improve the absorption efficiency of hafnium (Basmajian et al. 1972).

Main Control Rods Characteristics

Some characteristics of the control rods of experimental or commercial reactors are reported in [Table 25](#). It appears that most of the absorber pins are now based on a double-vented concept, allowing efficient cooling of B_4C by sodium and helium release. Sealed pins have been developed, however leading to too short life-time (internal pressure increase due to helium release). Diving-bell concepts have also been considered (USA, China) with the major drawback that the B_4C temperature cannot be controlled due to high fluctuations of the internal sodium level related to helium bursts release.

5.3.2 Boron Carbide

Properties

Boron carbide is a light, brittle, very hard, refractory ceramic. It is most often obtained by carbothermal reduction at high temperature of purified boron oxide. The material has then to be ground to powder. In France, a magnesothermal process was used leading directly to micronic powders. In both cases, the powders are hot-pressed to obtain the cylindrical pellets constituting the absorber pins. In actual materials, the grain size usually ranges from 5 to 20 μm , and the density is around 80–95%. Industrial materials all have a composition very close to B_4C . Because of the bad behavior of graphite under irradiation (swelling, sodium intercalation), materials with as low as possible free carbon contents are required.

The thermal conductivity is mainly phonon-like, with a $1/T$ variation (for a 95% dense material, around 27 W/m-K at RT and ~ 12 W/m-K at 1,000 °C). The mechanical behaviour is purely brittle up to 1500 °C (for a 90% dense material at RT, $K_{1C} \sim 2.5 \text{ MPa}\sqrt{\text{m}}$, Young modulus ~ 250 GPa, yields ~ 400 MPa). Those properties decrease as the porosity increases.

Boron carbide has a complex crystal structure ([Fig. 131](#)) constituted of nearly regular icosahedra (mean composition B_{11}C) interconnected according a rhombohedral network. The

■ **Figure 131**
B₄C crystal structure

center of the cells is filled with a C–B–C chain allowing additional tight bondings between the icosahedra. It is then isostructural to some borides (e.g., B₆Si), mainly differing by the composition of the central element. Depending on the actual composition of the cell elements, boron carbide exists in a large composition range, from B₄C to approximately B₁₀C. Interatomic bondings are mainly covalent, this conferring its mechanical and thermal properties.

Behavior under Neutron Irradiation

Most of the damages observed in boron carbide directly flow from the main neutron absorption reaction:

Depending on the control rods' design and use, very high operation parameters can be reached, for example, a resulting volume power up to 400 W/cm³ and helium production up to 0.05 mol/cm³.

No clear effect of Li has ever been observed, but from diffusion coefficients as measured on B₄C irradiated in experimental reactor, it can be deduced that a high fraction of lithium is released in the temperature range in the absorber pins (IAEA-TECDOC-1083 1999). Even at the highest burnups (up to 2.5×10^{22} ¹⁰B/cm³, i.e., ~25% of total boron), the crystal structure is not modified. This can flow from the capacity of the structure of those borides to accommodate very large composition variations but also from very efficient (although unidentified) mechanisms for the healing of point defects. As compared to the stoichiometry limit formula “B₄C,” large excess carbon is produced during irradiation: no available study mentions the possible consequences of this composition variation. No reaction with sodium has been observed: the main effect seems to be a tearing of the surface grains due to the grain boundaries damage (► Fig. 132).

The first damage mechanism results from the high radial thermal gradients (up to 1,000 °C/cm) arising from the conjunction of the capture reaction energy and the low thermal conductivity of B₄C. This leads to thermal stresses, which exceed the yield of the material. This results in radial cracks at the very beginning of life in the most demanded parts of the control rods (feet of rods, high enrichment zones). This mechanism remains active as burnup increases, since the thermal conductivity of irradiated B₄C strongly decreases (► Fig. 134).

■ Figure 132

Tearing of B_4C grains (Phenix experimental control rod, $2.5 \times 10^{21}/cm^3$, 55 efpd)

Most of produced helium remains in B_4C at low burnups and low temperature. At the beginning of life, the retention rate is over 80% (► Fig. 133) with slight temperature dependence. This results in the second damage mechanism. In the grains, helium accumulates in a high density network (10^{15} – $10^{16}/cm^3$) of lenticular bubbles under high pressure (>5 GPa, IAEA-TECDOC-1083 1999) inducing high internal stresses. These bubbles are parallel to the (111) plane of the rhombohedral structure, inducing very anisotropic swelling and stresses (IAEA-TECDOC-1083 1999) and then high shear stresses between adjacent grains. Close to the grain boundaries, helium migrates and accumulates also in lenticular bubbles, here parallel to the boundaries. This results in depleted zones without helium bubbles at the periphery of the grains (thickness around 100–300 nm). Both mechanisms (shear stresses and grain boundary damage) induce intergranular cracking for burnups around 1×10^{21} $^{10}B/cm^3$. At higher burnups (threshold around 5×10^{21} $^{10}B/cm^3$), the stresses induced by the intragranular bubbles induce intragranular cracking. Both mechanisms (inter- and intra-granular cracking) induce an increase of helium release: for burnups over $1 \times 10^{22}/cm^3$ (and temperatures over 1,000 °C), Maruyama et al. (1997) have observed a helium release rate close to the formation rate. At high temperature (above 1,500 °C), the flat bubbles relax and transform to classical three-dimensional faceted ones, inducing an accelerated swelling and extensive grain boundary damage. As compared to other materials such as fuel, metals, or other borides, the intrinsic volume swelling of B_4C appears low, thanks to the high internal pressure in the bubbles. Most results show a nearly linear swelling as a function of burnup, with an apparent saturation for the highest burnups (over $1.5 \times 10^{22}/cm^3$), related to a higher release rate. The swelling values range around 0.15–0.2 volume percent for 10^{20} captures/ cm^3 . The macroscopic deformation in a given absorber rod section is somewhat different since it results from different mechanisms (swelling, cracking, and relocation of fragments). A high initial porosity leads to a lower and delayed geometric swelling. Relocation of fragments induces an anisotropic deformation (axial compaction, radial expansion). It is worth noting here that the so-called swelling is generally determined from the evolution of the density of irradiated fragments (e.g., by picnometry). As a result, it does not take into account the lithium and helium releases. The obtained values are then underestimated. Actual swelling values as determined from geometric measurements show significant discrepancy between swelling and density variation for the highest burnups (over $1.5 \times 10^{22}/cm^3$),

Figure 133

Helium retention as a function of burnup for some control rods. French data appear significantly different

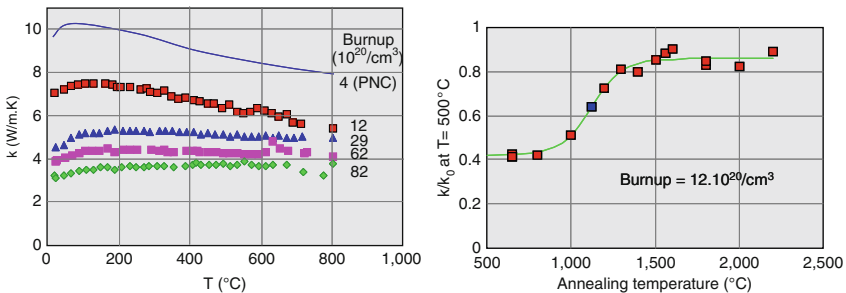

Figure 134

Left: thermal conductivity of irradiated B_4C (experimental Phenix control rod) as a function of burnup. Right: isochronal annealing ($1.2 \times 10^{21} \text{ B/cm}^3$)

evidencing a significant release of the fission products (He, Li) (Evaluated Nuclear Data File 2008).

The thermal conductivity strongly decreases during irradiation (► Fig. 134). This results from different mechanisms, helium bubbles formation, microcracking, internal stresses, and irradiation defects. Annealing above the BDT temperature allows the healing of the two latter damages but induces a strong swelling of the material due to the growth of the bubbles: the resulting conductivity is close to the one of an unirradiated material with a porosity equivalent to this swelling. Irradiation at lower temperature induces accelerated thermal conductivity damage.

Tritium is produced via a minor absorption reaction on ^{10}B with fast neutrons (depending on the actual local neutron spectrum, around $5 \text{ mCi}/10^{20} \text{ captures/cm}^3$) (► Fig. 135). The

Figure 135

Microscopic cross sections for the $^{10}\text{B}(n, \alpha)^7\text{Li}$ and $^{10}\text{B}(n, 2\alpha)^3\text{H}$ reactions

release rate is, however, high, over 50% in the hottest parts of the rod, that is, in the highest burnup sections. The use of locally moderated control rods would significantly lower this tritium formation.

On a general point of view, most data have been obtained on actual control rods or experimental pins: very few analytical results are available. As a result, the irradiation parameters are strongly dependant on the reactor operating conditions. As an example, the higher burnups are most often obtained thanks the high neutron flux at the feet of the rods, leading to the higher absorber temperatures. There is then a strong implicit coupling between temperature and burnup (Evaluated Nuclear Data File 2008); the time dependant parameters (e.g., diffusion) can then be hardly deduced.

5.3.3 Absorber Pins

The first limitation to the lifetime of the control rods is the damage of the cladding induced by interactions with the absorber. This results first from deformation induced by both the swelling of B_4C and the relocation of fragments (ACMI: absorber–clad mechanical interaction) and second from embrittlement due to chemical interaction (mainly carburization, ACCI: absorber–clad chemical interaction).

The mechanical interaction directly flows from the swelling of B_4C , higher than the metal's one. On classical rods, this interaction is anticipated due to the relocation of fragments (bevelled cracking) and filling of the gap with small ships, even with over-dimensioned clearance. Both effects limit the sodium flow in the gap, eventually allowing the formation of gas sections then inducing a strong increase of the B_4C temperature. The shrouded pins have shown an improved behavior: the shroud – even if extensively cracked – first efficiently contains the fragments and prevents their relocation and allows sodium to flow in the clad–shroud gap (Fig. 136). On the other hand, the cladding carburization is limited. This is clearly visible in Fig. 136: the absorber rod on the left shows first a clad failure but also very dense radial cracking. This may

■ Figure 136

Influence of the shroud on the absorber-cladding mechanical interaction (Phenix experimental pins). *Left:* 140 efpd, 1.4×10^{22} $^{10}\text{B}/\text{cm}^3$, $270 \text{ W}/\text{cm}^3$, showing gap filling with B_4C fragments and subsequent clad failure and extensive core damage (the hole at the center of the pellet results from post-irradiation machining). *Right:* 657 efpd, 2.5×10^{22} $^{10}\text{B}/\text{cm}^3$, $180 \text{ W}/\text{cm}^3$ showing shroud cracking but remaining gap

be attributed to clad–pellet gap closure leading to the formation of helium-filled gap sections inducing high temperatures in the core of the pellet, then an increased swelling of the core of the pellet.

Most of the postirradiation examinations (PIEs) have evidenced a strong carburization of the internal side of the clad, producing severe embrittlement. This shows that sodium is an efficient medium for carbon diffusion. A niobium coating has shown to efficiently prevent chemical interaction (Heuvel et al. 1985).

5.3.4 Developments

Major design modifications, based on numerous PIEs, have been performed, leading to strong improvements in the performances of the LMFNR absorber elements. However, the highest obtained life times, even for experimental control rods, remain lower than the fuel's one, which constitutes a major drawback for the reactor economy. Moreover, most of the behavior laws are only phenomenological ones: physically based laws are then clearly needed (e.g., fission products release).

From the results detailed here, a possible optimized (although classical) concept would have the following characteristics:

- B_4C absorber with
 - Density around 90% (optimum of mechanical properties, cheaper elaboration)
 - As small as possible (submicron) grain size (increased helium release)
- Small diameter pellets, reducing the thermal stresses
- Double ^{10}B enrichment, lower at the feet of the column (limitation of damage)
- Vented pins, allowing helium release and absorber cooling by sodium,
- Shrouded absorber column, preventing fragments relocation and sodium gap closure
- Niobium coating of the clad, limiting carburization

However, further improvements are necessary to reach the planned targets (lifetime in the range of 800–1200 efpd, corresponding to burnups around $2\text{--}3 \times 10^{22}$ captures/ cm^3). They would require the development of new concepts. In this frame, the design of moderated absorber

rods, as considered by Japan (hafnium hydride) and Russia (mixed zirconium hydride – B₄C/Hf rods), appears quite attractive.

5.4 Shield Materials

5.4.1 Vessel Shielding

This section deals with the shielding evaluation about neutron fluence and neutron dose on the SFR reactor vessel. The neutron fluence and DPA undergone by the vessel influence the plant lifetime. This evaluation is performed with TRIPOLI-4 Monte Carlo code (Lee and Hugot).

TRIPOLI-4 is a 3D Monte Carlo point-wise code developed by CEA. It is dedicated to radiation protection and shielding, criticality, and reactor core projects. It is used as a reference tool by CEA as well as its industrial or institutional partners, and in the NURESIM European project. It is available from the NEA and RSICC web sites.

The reactor is modeled from the core to the primary concrete. Assemblies, lateral reflectors, and neutron shields are homogenized. ➤ [Figure 137](#) shows a view of the reactor modeled using TRIPOLI-4 code.

Neutron sources are modeled in respect with the V2B configuration (Buiron 2009). They are homogenized for each assembly and are based on a common axial power distribution.

A preliminary shielding study was carried out to determine the lateral neutron shielding (LNS) thickness to respect the fluence and the DPA criterion (Bourganel).

The fluence and DPA criterion for RCGSC reactor are chosen as below:

- > 100 keV fluence criterion: $1.0 \times 10^{18} \text{ n cm}^{-2}$.
- > 1 MeV fluence criterion: $6.5 \times 10^{19} \text{ n cm}^{-2}$.
- DPA criterion: 0.1.
- The supposed load factor is 80%.

This study led to the necessity to use two LNP rows made of enriched boron carbide (B₄C).

A new reactor design is defined with a minor actinide charged blanket row (MACB) located between the reflector and the LNS, as shown in ➤ [Fig. 138](#).

■ **Figure 137**

Horizontal view of the SFR reactor

Figure 138
Horizontal view of the SFR reactor including a MACB row (green)

Table 26
MACB effect on fluence and DPA maximal values

Configurations	>1 MeV fluence	>100 keV fluence	DPA
V2B	$4.87E + 15n \times cm^{-2}$	$5.29E + 16n \times cm^{-2}$	2.96E-05
V2B with MACB	$2.86E + 15n \times cm^{-2}$	$3.75E + 16n \times cm^{-2}$	1.74E-05

The effect of this actinide row versus the fluence and DPA calculation is examined.

Table 26 gathers results.

In spite of the MACB row presence, representing an additional neutron source in the core, the fluence and DPA criterion is respected (Jasserand).

5.4.2 Sodium Activation

The sodium activation in the heat exchanger inside the reactor is calculated using a three-step calculation involving the TRIPOLI-4 code to calculate the neutron flux in the heat exchanger, the DARWIN/PEPIN2 activation/depletion code (Tsilanizara) to determine the sodium activation and the associated emitted gamma rays, and finally TRIPOLI-4 again to obtain the dose equivalent rate induced by these γ -rays around a sodium pipe outside the reactor.

Taking the French law into consideration (Arrêté 2006), the calculated dose equivalent rate when the reactor is working is low enough to allow a human presence if a special event requires it. However, a delay of 6 days after the reactor shutdown is required to reduce the dose equivalent rate corresponding to the regulated work area ($25 \mu Sv/h$).

6 Core Design

6.1 Performances Objectives and Design Criteria

The core design of sodium-cooled fast reactors is mainly driven by the enhancement of performances in terms of safety, competitiveness, and flexibility domains, compared to previous SFR projects. Performances objectives are:

- Improvement of safety features based on minimization of the burnup reactivity loss (to limit consequences of control rod withdrawal transients), a significant reduction of the sodium void effect, and a high resistance to core compaction, particularly with regard to earthquake risks. All these points aim to improve natural core behavior during transients and to exclude important mechanical energy release in case of severe core damage accidents.
- Flexible management of plutonium (optimization of uranium resources) and transmutation of minor actinides (environmental burden decrease).
- High burnup rates, high power density, low Pu core inventories.

6.1.1 Safety Objectives

According to the analysis of background of SuperPhenix reactor and EFR project, the major guidelines for core design are the following:

- Reduction of the burnup reactivity loss in order to limit consequences of control rods withdrawal accidents, in particular by reducing control rods neutronic weight. SFR cores with high internal breeding gain (internal breeding gain closed to 0) are particularly interesting because they minimize the BU reactivity loss. For instance, the BU reactivity loss by cycle is around $3\% \Delta k/kk'$, while for advanced SFR cores with $IBG = 0$, the BU reactivity loss is less than $0.5\% \Delta k/kk'$.
- Reduction of the sodium void effect in order to improve the natural core behavior during loss of flow accidents or gas core ingress accidents, limit the mechanical energy release in case of a core disruptive accident. The target for sodium void value is significantly less than \$6.
- Optimization of the Doppler Effect, knowing that increase of Doppler Effect is favorable for accidents of reactivity (such as control rod withdrawal), and decrease of the Doppler Effect is rather favorable for transient of flow.
- Reduction of the core pressure drop to facilitate the establishment of sodium natural convection during transients of loss of flow. The core ΔP was about 6 bar for EFR core; For the JSFR core, the core ΔP is about 2 bar.
- Decrease of plutonium enrichment which appears to be potentially favorable to limit consequences of CDA, in particular with regard to recriticality risks.

6.1.2 Flexibility SFR Cores

Depending on changes in the future in terms of natural resources, an important flexibility capability for plutonium management is needed for new SFR cores. It is essential for SFR cores to cover a wide range of breeding gain. The breeding gain (BG) represents the net production of

atoms of Pu (Pu-239 equivalent) by fission. The PHENIX reactor has a positive global breeding gain ($GR = +0.1$) because of the contribution of radial and axial blankets, and the internal breeding gain is clearly negative ($IBG = -0.5$). It is also the case for the EFR core, which has a slightly positive $BG = +0.02$ with blankets, with $IBG = -0.20$. It is understood that the design of SFR cores with IBG close to 0 is particularly favorable since it can reach high values of BG ($BG > 0.2$) by adding fertile blankets.

Also, new SFR cores have to recycle minor actinides (MA). Transmutation of MA is currently envisaged using two modes:

- The homogeneous mode for which minor actinides are mixed into the fuel
- The heterogeneous mode, for which minor actinides can be loaded in blankets subassemblies located in periphery of the core

Both options must be taken into account knowing that:

- Heterogeneous management of MA should not affect characteristics of the core,
- Homogeneous management of MA also should not significantly modify key physical parameters of the core (reactivity coefficients, IBG) if the quantity of MA in the fuel is not too large ($\approx 1\%$ of total heavy metal in the case of auto recycling, the limit being around 2.5–3% by mass).

6.1.3 Core Competitiveness

Reaching high fuel burnup ($BU > 100 \text{ GWd}/t_{HM}$) promotes the minimization of material fluxes in manufacturing and reprocessing plants, and therefore reduces the fuel cycle costs. To get high burnup, requirements are to have cladding materials and metallic structures, which are resistant to high neutron doses. Oxide dispersed steel are studied in many R&D programs because it could enable support of high level of neutron dose ($\approx 200 \text{ dpa}$).

For the deployment of a SFR reactors fleet, the core Pu inventory is an important parameter (with time off reactor) because it manages, for a given stock of plutonium, the total capacity of installed power. In this perspective, concepts of SFR cores which reduce plutonium inventories are interesting.

6.1.4 Design Criteria

Criteria for Fuel Design

The criteria are reported in the following [Table 27](#).

No Fuel Melting Criterion This criterion is based on an analysis of the uncertainties of calculating the fuel temperature and margins to take into account, the probability of fuel melting for each category of operation. For EFR project, the methodology for assessing the maximum linear power is based on the calculation of the no fuel melting probability considering a control rod withdrawal accident.

The maximum linear power usually varies between 350 and 450 W/cm for standard SFR cores.

No Sodium Boiling Criterion This criterion must be respected in all situations. It is usually “covered” by the criterion of no clad damage.

■ **Table 27**
Criteria for fuel design

Major criteria	Design criteria
No fuel melting	Max. linear power
	Max. fuel temperature
No sodium boiling	Clad nominal temperature
No damage on fuel cladding	Clad maximal temperature
	Maxi neutron dose
No mechanical fuel/clad at the end of life	Smeared density
	Central hole diameter of fuel pellet
Pressure strength of fuel rod	Gas expansion volume
	Clad thickness
	Limit of clad diameter deformation
	Limit of clad swelling

No Clad Material Damage Criterion This criterion indicates that for all the operating situations, the cladding material must keep intact and its structure must not be modified significantly. The maximal clad temperature corresponding to this criterion is 620 °C for stainless steel materials (type 316 Ti).

Criterion of No Mechanical Fuel–Clad Interaction

This criterion is essential to guarantee the fuel rod mechanical resistance to the end of life. The mechanical fuel–clad interaction is a result of the fuel swelling due to burnup. The initial available volumes: fuel porosity, initial gap between fuel and cladding, and presence of a central hole are gradually used by the fuel to accommodate its swelling. The background has shown that it is possible to achieve high burnup (15 at.%), with a smeared density around 88% Dth. Usually, fuel pins get a central hole with an internal diameter comprised between 1 and 2.5 mm.

Because the criterion of noninteraction is difficult to meet, it can use another criterion based on the reduction of the initial section of central hole, which appears to be a good indicator of an imminent risk of mechanical interaction, when it reaches about 50%.

Criterion of Strength for Fuel Rod Due to Internal Pressure

The increase of internal pressure due to fission gas production depends on the volumes of fission gas plena inside the fuel rod. These plena are located on both sides of the fissile column. The dimensions of the expansion volumes impact directly the primary stress and it is possible to respect criterion with adapted volumes of expansion plena.

Other Design Criteria

A limit for diameter deformation is imposed on the one hand, by the thermalhydraulics calculations that define a value beyond which the reduction of sodium channel generates excessive

temperature and the other by the mechanical behavior of the fuel bundle which does not lead to direct contacts between fuel rods. This limit is usually set to 6%.

Another limit concerns clad volumic swelling, which is used to prevent excessive weakness of the clad material. This swelling limit is set to 6% which corresponds to a clad diameter deformation of 3% (swelling + irradiation creep). It can be noticed that the limit swelling for ferritic–martensitic steels including the ODS is not known at this time.

Criteria for Wrapper Tube

The choice of thickness of the hexagonal tube and distance between assemblies must be compatible with the maximum allowable deflection of faces under creep irradiation and the maximum deformation by swelling.

The criterion of maximum deformation of the outer flat–flat wrapper tube is the absence of contact between faces of two neighbored wrapper tubes.

Moreover, the level of wrapper tube pads must be compact in normal operation: the outer flat–flat pads should be equal to the expanded pitch of wrapper tubes.

6.1.5 Core Shape Design

A reduced height for SFR cores enables to decrease the subassembly length (economic benefit), and the sodium void coefficient (safety benefit). However, it leads to a larger core radius which can be penalizing with regard to control for large cores. Usually, an active core height of 1 m is a convenient compromise and a minimum height/diameter ratio of ~ 0.2 is used for big size cores.

6.2 Core Neutronics

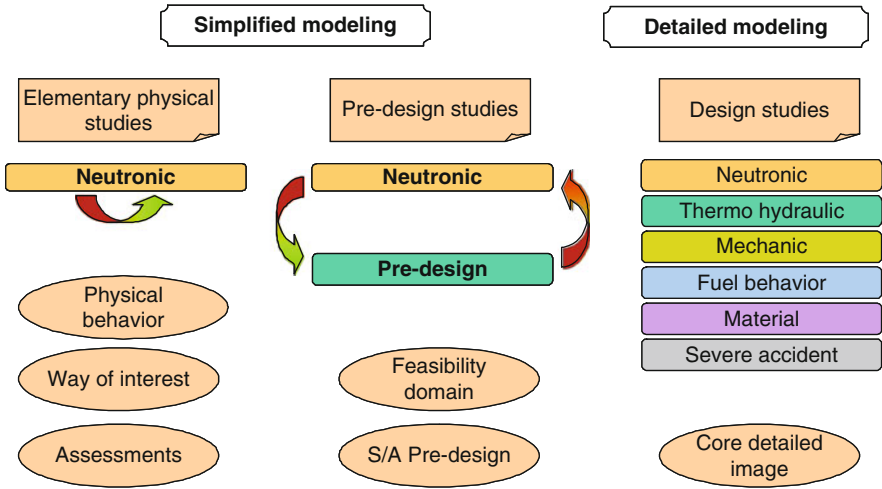

Neutronic core design studies can be grouped into three main families (➤ [Fig. 139](#)), within a classic design approach:

- Elementary physical analysis
- Pre-design studies
- Detailed design studies

In addition, analysis tools to quantify the effects, as the calculations of perturbations, and produce, in fine, high levels of uncertainty about the parameters required for full-end designers. The diagram below shows a simplified set of these studies and their purpose, as well as other scientific areas in liaison and interaction with purely neutronic studies.

6.2.1 Elementary Physical Analysis

To evaluate or design a core of a new reactor type, it is essential to master and understand the physics that governs, not only in order to master a high predictability on the system, but also to identify the first order parameters proceeding on it. Thus, it is possible to access both at the physical phenomenon and identify the way of progress and perform a first assessment. For that we need to have not only physical analysis tools, but also simplified and adaptable modeling.

■ Figure 139

Main families in neutronic core design

This type of study being strongly parametric, each elementary calculation should be done within a short time, both in the implementation and CPU time itself.

At this step of study we do not see strong linkages with other disciplines in the approach itself today. On the other side, the promising results obtained in this phase will be taken as an input for the pre-design studies.

Currently this type of evaluation is based:

Cell calculations in homogeneous description:

- Core calculation in 2D (R, Z) modeling, in diffusion approximation or in transport theory
- On sensitivity analysis based on perturbation theory

The analyzed parameters at this level are macroscopic type:

- The K_{eff}
- The average enrichment
- Core safety coefficients (Void effect, Doppler constant, delayed neutron fraction)
- The burnup
- The cycle length

For the core safety coefficient, calculation methods are given in [Sect. 6.5](#).

6.2.2 Pre-design Studies

The pre-design studies can be performed after preliminary physical analysis studies in order to evaluate a promising concept and also be used in the case of existing concepts adaptation or evaluation.

In the case of the design approach ([Figs. 140](#) and [141](#)), these studies are designed to resize a fuel element (pin for example) in the subassembly and adapt the core to reach the main objectives.

The objectives translation in term of neutronic core design could be converted in terms of area of feasibility as shown below.

This approach is iterative with other disciplines involved in subassembly design (thermohydraulic, thermomechanical, fuel physical chemistry. . .). The repetitive character of this approach requires simple models, near the one used in the previous step with robust methods, fast implementation, and short time calculations. And so, the calculation schemes are quite similar to the scheme used in the elementary physical analysis, but differ on the other hand by the type of results to be extracted here.

We need, at this stage, more comprehensive and detailed results not only for an access to new information but also to transfer data to other design disciplines involved in the holistic design approach.

The results are:

- The fissile enrichment values
- The equivalent plutonium W_i and associated W_i
- The heavy nuclide mass to reload
- The isotopic compositions of spent fuel
- The breeding gain
- Average and max burnup
- Average and max DPA
- Power and flux distribution
- The cycle length
- Average reactor safety coefficient (see drain effect, Doppler, proportion of delayed neutrons)
- An assessment of control rods total weight

The W_i value is defined by:

$$W_i = \frac{\sigma_i^+ - \sigma_{U-238}^+}{\sigma_{Pu-239}^+ - \sigma_{U-238}^+}$$

σ_i^+ is defined by:

$$\sigma_i^+ = \nu \sigma_{f,i} - \sigma_{a,i}$$

with

$\sigma_{f,i}$, equivalent fission cross section for the i nuclide (average on the core)

ν , the average number of neutrons by fission

$\sigma_{a,i}$, equivalent absorption cross section for the i nuclide (average on the core)

The total quantity of equivalent Pu-239 equivalent is defined by: $M_{Pu-239\acute{e}quiv} = \sum_i M_i W_i$.

6.2.3 Detailed Design Studies

These studies are carried out chronologically once the core design is roughly defined by previous studies. These studies are the full core design and could be corresponding to the phases of the feasibility report or detailed design of a design project. In terms of physic studies it is the maturity of the project which will see it will be in one phase or another. As against the code validation level and associated uncertainties will be refined as the project progressed and the needs of designers.

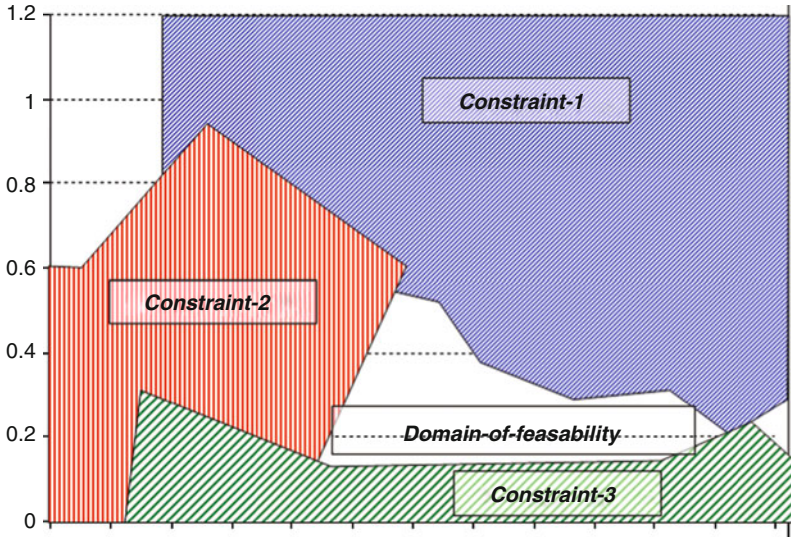

Figure 140
Example of feasibility domain

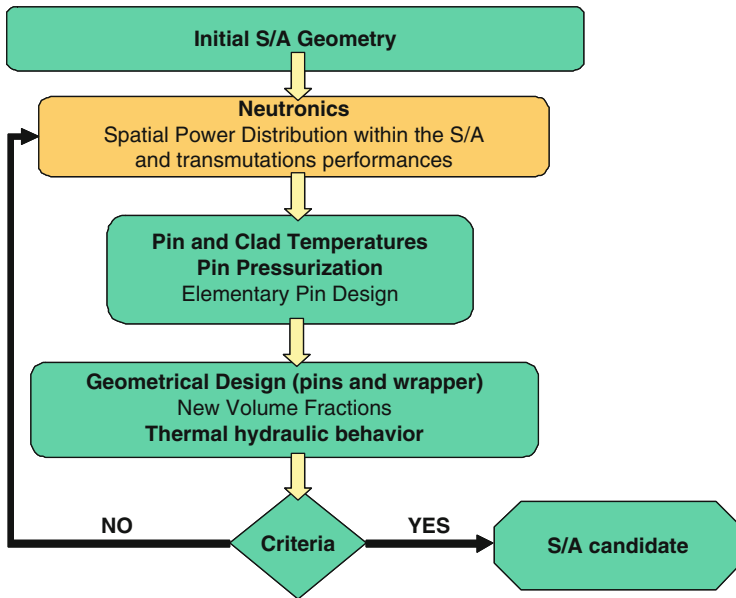

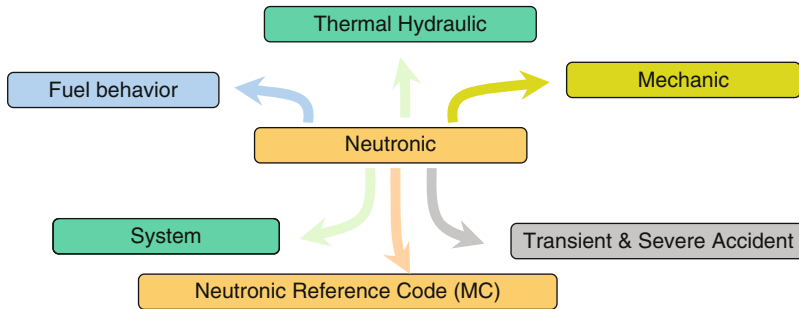

Figure 141
Design process

■ **Figure 142**
Synoptic scheme of needs between domain

For these studies, it is necessary to access on a very large number of parameters greater and more detailed than the previous stage and take into account more accurately the S/A and core geometry. The neighboring of the core will be also described as accurately as possible (fertile and/or radial reflector, radial and axial protection).

Geometric descriptions are three-dimensional and the mesh description is refined (as an example for a large core 350,000 meshes and 5,000 evolving medium. The subassemblies are axially subdivided into zones of independent evolution (10–15) and 1–19 volumes radially).

To reach the objective of an increase of the calculation accuracy it is necessary to perform best estimate calculations (with Monte Carlo Method and also with deterministic method using best validate schemes for cell and core calculations).

The needs in terms of result are quite similar to the previous step, but the uncertainty level could be associated with each result (► [Fig. 142](#)). During these detailed design studies, it is also necessary to transfer huge amounts of data to the other domain and associated codes.

6.2.4 Calculation Tool for Neutronic Core Design

The deterministic ERANOS neutronic system consists of data libraries, codes, and calculation procedures which have been developed within the European Collaboration on Fast Reactors over the past 20 years or so. The ERANOS code system was developed to answer the needs of both industrial and R&D organizations. A modular structure was adopted in ERANOS to allow the incorporation of the most recent research and development innovations.

This modular structure allows different modules to be linked together in procedures corresponding to recommended calculation routes ranging from fast running and moderately accurate “routine” procedures to slow running but highly accurate “reference” procedures.

The main features of ERANOS that are presented here are:

- Nuclear data libraries: several neutron cross section libraries, all derived from the JEFF-3.1, JENDL3.3, and ENDF/B-VII nuclear data evaluated files are available, each containing:
 - 1,968-groups library for the main resonant nuclides
 - 33-groups library for fast-spectrum applications
 - 175-groups library for shielding calculations
 - 172-groups library for thermal-spectrum applications

- The ECCO cell/lattice code prepares self-shielded cross sections and matrices by combining a slowing-down treatment in many groups (1,968 groups) with the subgroup method within each fine group and collision probabilities calculation for many types of geometries
- Core and shielding calculation codes:
 - Diffusion (1-D, 2-D, 3-D) codes
 - The BISTRO Sn transport 1-D or 2-D (X-Y, R-Z, R- θ) code
 - Variational Nodal Method transport 2-D and 3-D Cartesian and hexagonal, with “TGV/VARIANT code”

These codes solve both homogeneous and inhomogeneous (external source) equations and provide direct and adjoint solutions. A kinetics driver named KIN3D has been developed using the TGV/VARIANT module and is integrated into ERANOS.

6.3 Core Thermalhydraulics

A core design has a threefold objective:

- Guarantee the thermomechanical behavior of cladding in each subassembly (S/A) under nominal operating conditions
- Avoid the risk of compaction based on knowledge of the static mechanical equilibrium of the core
- Ensure fuel subassembly unloading

To achieve this threefold objective, it is essential to fully understand the thermal fields of the fuel (and breeder) assembly structures in the core (cladding and hexagonal wrapper tube or hex-can). The flow and temperature distributions in the coolant need to be calculated to determine these thermal fields. The temperature (structures and coolant) and flow calculations concern the field of core thermalhydraulic studies. The CEA has developed a core design method for its fast reactors, which is described below.

6.3.1 Core Flow Distribution

Objective

Calculating the core flow distribution is also a threefold process:

- The core outlet temperature must:
 - Be as high as possible to avoid affecting the reactor efficiency
 - Take into account the thermomechanical resistance of the reactor block structures
- Each subassembly (S/A) must be cooled correctly,
- The core outlet temperature map must be flattened to ensure resistance of the upper structures to temperature fluctuations (thermal stripping).

Method

The core design method involves meeting a given nominal clad temperature (NCT), defined as follows:

$$\text{NCT} = T_{\text{inlet}} + \Delta T_{\text{hsc}} + \Delta T_f + \Delta T_{1/2C}$$

where

T_{inlet} : Core inlet temperature,

ΔT_{hsc} : Heating of the hottest sub-channel,

ΔT_f : Temperature drop in the viscous sub-layer,

$\Delta T_{1/2C}$: Temperature drop in the cladding half-thickness (outside inward).

The NCT must remain below a criterion during the irradiation of the S/A in the core. It is therefore necessary to define a maximum power configuration for which the flow distribution is calculated. This envelope configuration is defined according to the maximum linear power of each S/A between the beginning and end of its residence in the reactor.

The solution chosen for the fast reactor technology involves classifying the fuel and breeder subassemblies into different flow zones. The subassemblies in the same flow zone share the same flow. This flow is determined by the subassembly with the hottest sub-channel, whereas the other subassemblies are slightly overcooled.

Once the envelope configuration has been calculated, it is necessary to determine the optimal number of:

- Flow zones, representing the first level of optimization,
- Subassemblies per flow zone, representing the second level of optimization.

Once this optimization process has been completed (by the SUPTHYL computer code), the flow of each subassembly classified into a flow zone is known. The following aspects must then be checked:

- Flattening of the core outlet temperature map
- Difference in outlet temperatures for two neighboring subassemblies at each moment of the cycle (start and end)

Mixing Coefficients

A thermohydraulic model for the subassembly is also required to obtain an optimal flow distribution in the core. This model must take into account:

- Geometry and orientation of the assembly
- Axial and radial power distribution in the bundle of pins
- Mixing effects due to the spacer wires (see chapter on “Modeling”)

The temperature map of a bundle cross section is defined by the parameter A as follows:

$$A_i = \left[\frac{T_i - T_{\text{inlet}}}{T_{\text{mean}} - T_{\text{inlet}}} \right]$$

where

T_{inlet} : Core inlet temperature

T_i : Sub-channel temperature i

T_{mean} : Mean temperature of the cross section

Axial Power Profile The parameter A is more or less independent of the axial power profile.

Radial Power Profile and Subassembly Orientation The orientation of a subassembly depends on the type of radial power gradient. There are two types of orientations:

- Side: when the most powerful pin is located in the middle of the side of a hexcan
- Angle: when the most powerful pin is located on an angle of a hexcan.

The power variation is assumed to be linear between two sides or two opposite angles. The radial power gradient depends on the (α_R , orientation) couple, with α_R being defined as such:

$$\alpha_R = \frac{P_{1 \max}}{P_{1 \min}}$$

where

$P_{1 \max}$: Maximum linear power of the most powerful pin

$P_{1 \min}$: Maximum linear power of the mean pin

Mixing Effects The effects of mixing due to the helical spacer wire are assessed with the CADET computer code on the basis of a sub-channel approach (see  Sect. 6.3.2). CADET is used to calculate two different temperature maps:

- A : A_i With mixing effects for each orientation and for different values of α_R . A is expressed as follows:

$$A(\alpha_R, \text{orientation}) = \left[\frac{T_{\text{hsc}} - T_{\text{inlet}}}{T_{\text{mean}} - T_{\text{inlet}}} \right]^{(\text{with_mixing})} = \left[\frac{\Delta T_{\text{hsc}}}{\Delta T_{\text{mean}}} \right]^{(\text{with_mixing})}$$

- F : A_i Without mixing effects for $\alpha_R = 1$. F is expressed as follows:

$$F = A(\alpha_R = 1) = \left[\frac{T_{\text{hsc}} - T_{\text{inlet}}}{T_{\text{mean}} - T_{\text{inlet}}} \right]^{(\text{no_mixing})} = \left[\frac{\Delta T_{\text{hsc}}}{\Delta T_{\text{mean}}} \right]^{(\text{no_mixing})}$$

ΔT_{hsc} : Heating of the hottest sub-channel with mixing effects (with_mixing) or without mixing (no_mixing),

ΔT_{mean} : Mean heating of the S/A in the hottest sub-channel with mixing effects (with_mixing) or no mixing (no_mixing).

The mixing coefficient C_m used for optimization purposes is defined as such:

$$C_m(\alpha_R, \text{orientation}) = \frac{A}{F\alpha_R}$$

6.3.2 Calculation of Fuel Assembly Thermalhydraulics

Introduction

The first objective of the CADET project code is to calculate the NCT, which requires both a global and local understanding of the fuel bundle thermalhydraulics. One of the main effects to be taken into account is coolant mixing due to the spacer wires. These wires impose local and global coupling in a bundle limited by a hexcan. The second objective is to calculate the above-mentioned mixing coefficients C_m .

The CADET computer code uses a sub-channel approach to achieve these objectives. Two different sub-channels are differentiated by a fictive boundary that is common to both and where thermalhydraulic coupling occurs. This approach requires physical models that are based on theoretical, analytical, and experimental data.

Thermal Balance Equation

CADET calculates the axial steps (Δz) for each sub-channel. The thermal balance for each sub-channel is as follows:

$$q_j(z) \cdot C_p \cdot [\theta_j(z + \Delta z) - \theta_j(z)] = W_j - \sum_a B_j^a [\bar{\theta}_j - \bar{\theta}_a] - B_j^r [\bar{\theta}_j - \bar{\theta}_r]$$

$$\bar{\theta} = \frac{\theta_j(z) + \theta_j(z + \Delta z)}{2}$$

where

q_j , sub-channel flow j

θ , temperature of sub-channel no. j (θ_j) or an adjacent sub-channel ($\bar{\theta}_a$) or a thermal boundary condition $\bar{\theta}_r$

B_j^a , equivalent thermal diffusivity modeling the transverse coupling between two sub-channels

B_j^r , equivalent thermal diffusivity modeling the thermal couple with a thermal limiting condition

W_j , dissipated power in the main sub-channel j

The thermal diffusivity B_j^a is equivalent to the sum of the three terms used to model the three radial thermal couplings:

- $B_j^{\prime a}$, thermal coupling due to deviated flow: $B_j^{\prime a} = q_j^a C_p \Delta z$ (Sect. Modeling Flow Deviated between Sub-Channels)
- $B_j^{\prime\prime a}$, thermal coupling by conduction in the coolant (Fourier's law)
- $B_j^{\prime\prime\prime a}$, thermal coupling due to eddy diffusion (correlation).

Bundle Flow Distribution

CADET assumes an isopressure for each planar coolant cross section of the bundle, which is a slightly conservative assumption. The flow is therefore constant per type of sub-channel.

Modeling Flow Deviated between Sub-Channels

Three types of sub-channels are defined: triangular, rectangular and corner. A by-passed flow law is required for each type of sub-channel. The incoming and outgoing flows at each mesh level are also assumed to be equivalent. The mass transfer occurs at the neck between two sub-channels in relation to the location and rotation of the spacer wire according to a sine function. This function is determined by equalizing the surface covered by the helical wire and the surface of the sine function. The by-passed flows per sub-channel type (over a half-pitch $h/2$ of the spacer wire) are expressed as follows:

- Two triangular channels (Δ):

$$q_{\Delta \rightarrow \Delta}^{(h/2)} = \text{COE1.0,6046 } d_{\text{wire}} (2D_{\text{pin}} - d_{\text{wire}}) q_{\Delta} / S_{\Delta}$$

- Two peripheral channels (\square):

$$q_{\square \rightarrow \square}^{(h)} = \text{COTRA} \pi d_{\text{neck}} (D_{\text{pin}} + d_{\text{neck}}) q_{\square} / S_{\square}$$

- A triangular sub-channel (Δ) and a rectangular sub-channel (\square):

$$q_{\Delta \rightarrow \square}^{h/2} = \text{COE2.0,6046 } d_{\text{wire}} (2D_{\text{pin}} - d_{\text{wire}}) q_{\Delta} / S_{\Delta}$$

where S represents the flow cross section; d or D are the diameters; and $COE1$, $COE2$, and $COTRA$ are coefficients adjusted according to the experimental results.

6.3.3 Assessment of Hexcan Temperatures

Safety studies require understanding the mechanical behavior of subassemblies for two main reasons: (1) verification of the level of stress on each wrapper with the reactor under nominal conditions, and (2) knowledge of strain in these same wrappers which, if too high, will prevent their unloading after reactor shutdown. These objectives necessitate:

- Understanding the irradiation conditions of subassemblies (neutron studies)
- Estimating the thermal loads of wrappers (thermohydraulic studies). These estimates are obtained by calculations.

Simplified Description of the Core Thermalhydraulics

Sodium flows into the core through the diaphragm. Most of this flow is distributed between the subassemblies in relation to their own pressure losses. This flow rises. At the core outlet, part of this flow hits the above-core structure (BCC in [Fig. 143](#)) and generates overpressure. This overpressure acts like a piston on the inter-wrapper flow which drops toward the bottom of the core and then rises to the core periphery ([Fig. 143](#)). The inter-assembly flow is also amplified by a leak in the sphere-cone bearing at the bottom part of the core ([Fig. 143](#)).

Figure 143

Simplified thermalhydraulic description

Figure 144
Schematic flow diagram

Calculation of Hexcan Temperatures

The coolant flowing into the subassemblies is heated by the full length of the pins in the bundle. This heating – for all fuel and breeder subassemblies – is calculated by the CADET computer code under thermal limiting conditions defined by the inter-wrapper flow. These thermal boundary conditions are calculated with the TRIO-VF finite-volume code. TRIO-VF predicts the thermalhydraulic behavior of the inter-wrapper flow under the thermal boundary conditions defined by the CADET calculations. At the end of the iterative calculation process, the temperatures of all six sides on each hexcan in the core are known, from the bottom to the top of the core and for different axial levels.

The TRANSCOEUR-2 code combines these calculations (► Fig. 144). This code also requires a geometrical description and a neutronic description (axial profiles and maximum linear powers) of each subassembly, as well as the core flow distribution.

TRIO-VF Thermalhydraulic Computer Code

The TRIO-VF finite-volume code can calculate complex laminar and turbulent flows under permanent or transient conditions. The fluids are assumed to be Newtonian, noncompressible and they are used to check the BOUSSINESQ approximation. The boundary conditions can be either DIRICHLET (imposed velocities or temperatures) or NEWMAN (imposed fluxes). The balance equations are averaged NAVIER–STOKES equations.

Core Modeling

The inter-wrapper space is described by an axisymmetrical geometry. The inter-wrapper flow model is based on a porous medium approach: obstacles in contact with sodium (subassemblies) are taken into account by porosity and pressure loss coefficients defined by:

- Radial porosity attributed to each ring, representing the inter-assembly distance divided by the pitch of the subassembly lattice
- Axial porosity equal to the ratio of the sum of the S/A hexagonal cross sections for the ring in question, divided by the surface of this ring

The subassemblies are classified by types (fuel, breeder, steel, neutron shielding) and integrated into the radial zones. Only the fuel and breeder zones are coupled with the internal temperature fields calculated with CADET (thermal boundary conditions). A power density can be attributed to the other subassemblies. The leak flow rate at the foot of the subassemblies and the overpressure gradient due to the above core structure are the hydraulic boundary conditions for the calculation.

6.4 Core Mechanics

Situated in a particularly hostile environment, SFR core subassemblies (S-As) undergo thermomechanical distortions, which induce S-As displacements that can be relatively large, and contacts between one another, which could be a cause of disturbance in the reactor operation.

A set of computer codes, named HARMONIE, has been created and developed by CEA in order to model the irradiated core static mechanical behavior as accurately as possible.

It is able to foresee the in-irradiation core static mechanical equilibrium evolution and to evaluate, while spending as little time and money as possible, the evolution of design changes.

6.4.1 Subassemblies Distortions

Steel wrapper tubes surrounding the fuel pins bundle are merged in the fast neutronic flux, which induces irradiation swelling and creep.

The permanent resulting distortions add to purely mechanical and thermic distortions and the total S-As distortions prove to be made up of lengthening, bowing, and cross section variation of wrapper tubes.

Broadly speaking, the core can be divided into three areas with respect to spatial distribution of neutronic flux and temperatures (► *Fig. 145*).

Almost constant in the central area where cross section variation of wrapper tubes can be observed, these fields are highly variable in the external fuel area where thermic and neutronic gradients induce centrifugal bowings.

The core external area, where small neutronic fluxes and smaller temperatures induce small distortions of the S-As wrapper tubes, generates a phenomenon of natural elastic hooping of the outward bowed S-As.

The S-As interactions mainly appear by the means of pads which are stamped on the wrapper tube, just above the axial fuel zone. By the way of thermal expansions these pads cancel the inter S-As gaps in full power reactor operation.

This resulting compact plane reduces the S-As vibrations due to the flowing sodium and plays an important part with respect to reactor safety.

6.4.2 Operating Considerations

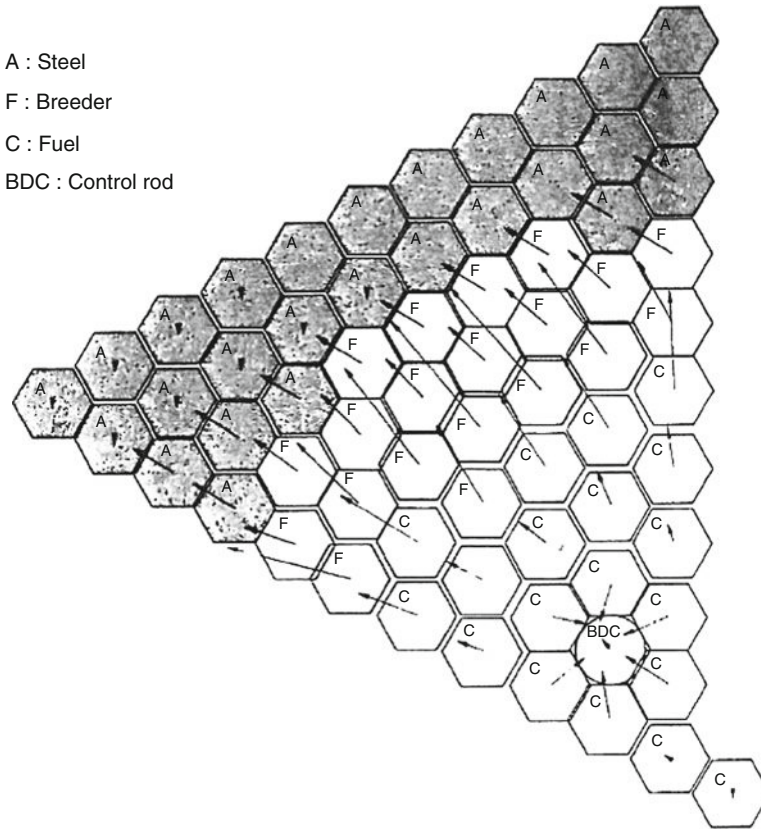

S-As Wrapper tubes large displacements could generate handling problems and difficulties in measuring exit sodium temperatures.

On the other hand, the S-As interaction forces must not be too large in order to handle and remove easily S-As in the core lattice. From this point of view the increase of the wrapper tubes cross section must not create an additional contact level in the fuel axial zone.

Safety Considerations

S-As Wrapper tubes large displacements could generate problems in operating down the in-core safety devices.

On the other hand, it is necessary to control the core reactivity evolution between two states of equilibrium. It can be a slow evolution over an operation cycle to adjust the control rods anti-reactivity. Moreover fast transient accidental situations are studied, such as the so-called “pad

■ **Figure 145**
S-As head displacement. See the control rod perturbation area

effect”: the pad temperature increase generates, by their cumulated thermal expansions, the outward expansion of the whole core, which induces a decrease of reactivity and consequently a decrease of reactor power.

In order to derive a benefit from this effect, which is favorable in consideration of safety, the core must be compact enough at the pads axial level.

Therefore, criteria with respect to main characteristic parameters are needed to operate the reactor with accuracy and safety. Meeting these requirements involves consequences concerning the core design and sizing.

For instance, the smaller the inter pad gaps are, the higher the handling friction forces are, but the tighter the bundle of core S-As is.

6.4.3 Modeling of the SFR Core Static Mechanical Behavior

The knowledge of physical phenomena occurring in the core while operating the reactor enables us to predict their evolutions through modeling, to emphasize the main parameters and determine their influence. Modifications of design are thus made possible.

HARMONIE is a set of computer programs successively describing, using precise 3D distributions of the neutronic flux and the temperature fields, the 3D distortions of each sub-assembly, the in-core interactions, the handling forces and the consequences of the whole core distortion with respect to reactivity:

- The calculation of distortions of each S-A, supposed to be alone in the core, is based upon the hypothesis, very classical with respect to the beam theory, that a cross section remains plane all through the S-A stretching. This plane is precisely the one which minimizes the internal energy of cross section distortion and its slope defines the local camber which, by integration over the height of the S-A, leads to the bend of the wrapper tube. On the other hand, at each vertical level, the expansion of the radial cross section is evaluated by means of the average value of each of the six side distortions. The increase of length is calculated by integration of the average axial distortion all over the height of the S-A. The individual history of each S-A is taken into account through the evolutions of its in-core position and orientation.
- The resulting state of mechanical equilibrium of the whole core, that is to say, the location of inter S-As contacts, the values of interaction forces, and resulting static displacements, is then determined.

The physical model consists of a bundle of beams, with an axial distribution of moments of inertia. The most probable levels of contact are selected (generally speaking pad level and S-A head level) and the elastic bending elementary matrix of the beam is only made consequently of the so-called Maxwell coefficients of the S-A, which are the horizontal displacements at each level due to a unit force put at the other one. Cross section distortions at the contact levels are taken into account through an elementary matrix of local flexibilities. Besides an elementary matrix of beam creep velocity is defined in a similar way (the evolution of creep bowings is supposed to be linear with respect to time). The bending potential energy of the bundle of S-As can be, therefore, expressed in a matricial way. The conditions of equilibrium of the core are determined by minimization of this energy with conditions of no overlapping of S-As with each other. As soon as the interaction forces are known, displacements all along the S-As can be calculated and other possible contact levels can be displayed (see  Fig. 146).

These efforts are also used to calculate stresses in the S-As wrapper tube and spike and besides, when the reactor is stopped and the core temperatures have decreased consequently, they are at last used to calculate the handling forces of the removed S-As through a friction coefficient.

It must be noticed that these handling forces can be calculated at different steps of the removal of the S-As.

Besides, a spatial distribution of neutronic coefficients describes the reactivity weight of the nuclear materials in the core. For a given state of equilibrium of the core, the reactivity variation – with respect to a reference state corresponding to a “new core in a cold state” – can be simply derived from the calculated displacements. Thus, it is possible to differentially assess the change of reactivity between any two equilibrium states, whatever.

6.4.4 Experimental Validation

In the past, three real scale experimental rigs in France, and another one in UK, have been designed and built, each of them made of a lattice equipped with a bundle of S-As (91 positions

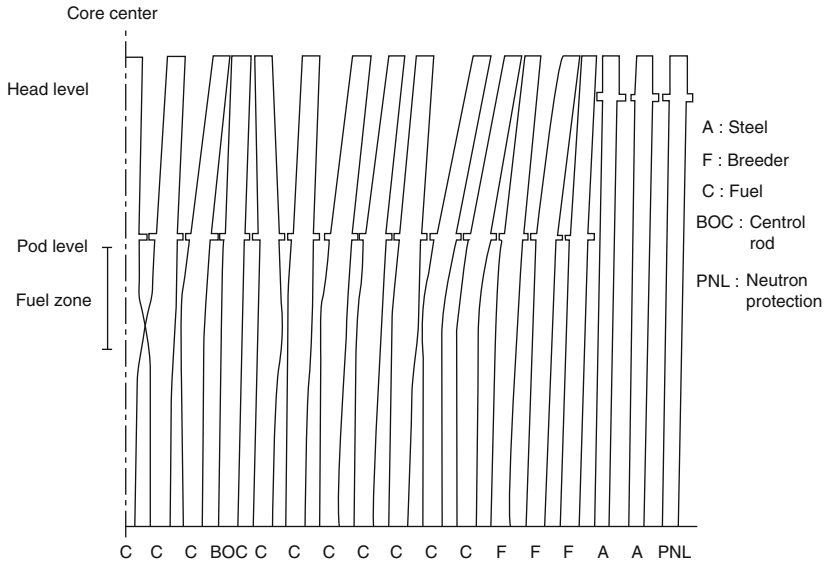

Figure 146
S-As bending and cross section expansion

for Rapsodie and Phenix simulations, and 106 positions for SuperPhenix simulations in the French rigs, 61–91 positions for EFR simulations in the UK-AEA rig).

Most part of HARMONIE validation has been realized with the 106 positions rig, operated at air temperature by the Italian ENEA and CEA (► *Fig. 147*).

A complete program consisted in distorting bundles of S-As by the use of jacks, with bent and/or expanded cross section S-As. Handling tests operating a SuperPhenix-like machine have also been made. Comparisons between measured and HARMONIE calculated results showed an almost complete consistency regarding contact positions and orientations of S-As displacements (► *Fig. 148*).

About 20% gap has been observed.

Besides, specific tests have been made to measure the pad rigidity at the air temperature or in hot temperature conditions. Transposition of these results to the real reactor operating conditions has been derived from sodium friction tests and the SuperPhenix handling machine qualification tests.

Moreover HARMONIE results have been compared to a great deal of Phenix irradiated S-As measures and handling forces measurements.

The strict HARMONIE validation is less easy in such cases because of the complex S-As managing and the great deal of experimental S-As in Phenix core. However theoretical S-As lifetime limitations have always proved to be less than the real lifetimes observed in Phenix.

This proves that HARMONIE overestimates the real physical values which are in favor of reactor operating safety.

Although the physical phenomena are very well known and correctly simulated with HARMONIE a 50% uncertainty coefficient is taken into account concerning most of the parameters,

Figure 147
Operating the CEA 106 E rig in Cadarache (handling test)

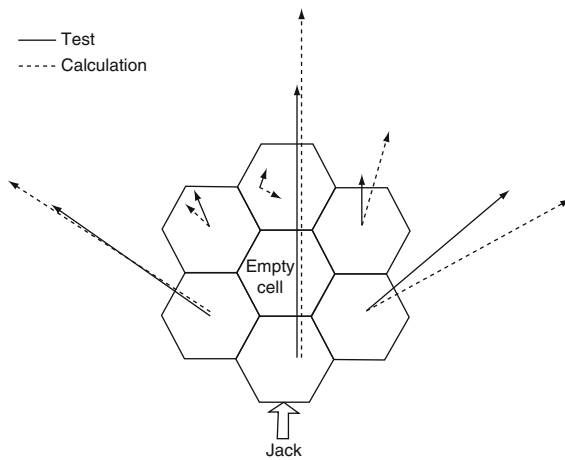

Figure 148
S-As handling has been simulated in distorted S-As bundles by the way of jacks. Qualitative consistency between tests and calculations is satisfactory

up to 95% concerning the friction handling forces. These coefficients stand for the irradiated wrapper tubes steel behavior laws and the various mathematical modelings all together.

6.4.5 Conclusion

Although mathematical models of HARMONIE be quite satisfactory, it would be of great interest to reduce uncertainties coefficients, in order to enhance SAs lifetime.

Complex phenomena such as inter-pad friction and lattice/S-As spike gaps could be therefore usefully studied.

6.5 Reactivity Effects

6.5.1 Description of the Feedback Effects

In this part, we will describe theoretically each feedback coefficient and the effect they have on the reactivity function of the temperature variation. The different effects are done for an increase of the considered temperature. The opposite effect (for a decrease of the temperature) is easily deduced.

Doppler Effect

An increase of the fuel temperature has for consequence a bigger thermal agitation provoking, for each isotope of the fuel, a broadening of the capture and fission resonances.

In fast reactors, the Doppler Effect coefficient is negative. Further, to an increase of the fuel temperature, the Doppler Effect involves a decrease of the reactivity, and conversely for a decrease of the temperature. This intrinsic effect is mainly due to the presence of the isotope U-238 and of its absorption resonances on the energy domain of 0.1–10 keV.

Sodium Expansion

The increase of the sodium temperature involves a decrease of its density, and so a decrease of the interactions between neutrons and coolant nucleus.

It involves a spectral effect (positive), an effect due to the leakages (negative) and an effect bound to the captures (positive):

- Spectral effect: due to the decrease of the coolant interactions, the spectrum becomes faster, and so in the case of a fast reactor, the reactivity increases. The increase or decrease of the reactivity depends on the fuel type; each isotope has its own distribution of cross section functions of the incoming neutrons energy.
- Effect bound to the leakages: as there are fewer interactions with the sodium, there are more available neutrons; on the other hand these are more energetic. Although the interaction and absorption probability function of the incoming neutrons energy depends on each isotope, it generally decreases with energy. And so it increases the leakages of the core.
- Capture effect: the decrease of the sodium interactions involves a decrease of the capture by the sodium and so an increase of the available neutrons. This positive effect is however weak.

The variation of the core reactivity depends on the competition between these three effects. In case of fast reactors, the global variation of the reactivity due to the sodium expansion is generally positive.

Clad Expansion

The clad expansion is subdivided into two effects.

- Axial expansion: the axial expansion of the clad involves a decrease of the steel concentration (geometry unchanged), and a decrease of the interactions between neutrons and steel nucleons. This effect is positive.
- Radial expansion: the radial expansion involves an increase of the clad volume chasing away an equivalent volume of sodium. This effect is similar to the decrease of the sodium density (previously described): it is a positive effect.

Wrapper Expansion

The wrapper expansion is subdivided into two effects like the clad expansion case: an axial and a radial expansion. This effect is positive.

Fuel Expansion

The fuel expansion is subdivided into two effects:

- Axial expansion:
 - Decrease of the fissile nucleons concentration in the fuel: negative effect on the reactivity
 - Increase of the fissile core height: positive effect
 - Increase of the sodium mass in the core due to the increase of the fissile core height. This effect corresponds to the effect of the increase of the sodium density (previously described): negative effect.
 - The axial expansion is taken as a whole negative.
- Radial expansion: the radial expansion of a cladding fuel does not change the sodium volume (unless there is a sodium gap). The radial expansion of the fuel is so without effects on the reactivity.

Grid Expansion

It concerns the increase of the core radius due to the grid expansion, provoked by an increase of the incoming sodium temperature. On one hand, the sodium volume inside core increases (effect previously described); on the other hand, the core volume increases (despite a constant fuel mass) and so the leakages increase. The global effect is negative.

Differential Expansion between Core, Vessel and Control Rods

This reactivity coefficient corresponds to three effects:

- An increase of the fuel temperature involves its axial expansion (it means in relative a control rod's insertion)
- An increase of the core out coming sodium temperature causes the axial expansion of the control rod's pipes, and so an insertion of these ones if their mechanism are fixed to the top of the vessel.
- An increase of the temperature of the cold sodium involves an axial expansion of the vessel to the bottom.

■ Figure 149

Differential expansion between core, vessel, and control rods in the case of an increase of the temperatures

The first two effects correspond to an insertion of the control rods in the core, and so a negative effect. It is the opposite effect for the third one. The global effect depends on the temperature variation of the incoming and out coming sodium and of the linear expansion coefficients of the different materials (vessel, fuel, control rods mechanisms). ► *Figure 149* explains this situation in the case of an increase of the temperatures compared to the nominal situation.

To notice: all these effects depend on different time constants, following the reactor conception.

The reactivity coefficient due to the grid expansion is related to the only variation of the incoming sodium and is bound to a time constant of several tens of seconds. So it does not appear in the slow transients.

The reactivity coefficient bound to the differential effect starts with the variation of the fuel height, then with the expansion of the control rod's pipes and endlessly with the vessel expansion. These last two effects are essential for the slow transients.

Pad Effect

It comes from the difference of radial expansion between the bottom of the subassemblies at the incoming sodium temperature and the top, at the pad level, at the out coming sodium temperature. But this effect is very low and will not appear in the calculation of the reactivity coefficients.

Summary of the Location of the Coefficient Calculation  [Table 28](#)

Table 28
This table sums up the location of the calculated reactivity coefficients

	Radial clad expansion	Radial wrapper expansion	Axial clad expansion	Axial wrapper expansion	Sodium expansion	Doppler constant	Axial fuel expansion	Grid expansion
Fissile	Yes	Yes	Yes	Yes	Yes	Yes	Yes ^b	Yes
Fertile ^a	Yes	Yes	Yes	Yes	Yes	Yes	Yes ^b	Yes
Bottom reflector	No	No	No	No	Yes	No	No	Yes
Plenum	No	No	No	No	Yes	No	No	Yes
Top reflector	No	No	No	No	Yes	No	No	Yes
Rod follower	No	No	No	No	No	No	No	Yes
Radial reflector	No	No	No	No	No	No	No	Yes

^a Axial and/or radial.

^b Linked or not.

Yes, if the coefficient is calculated on this region; No, if it is not.

6.5.2 Calculation Method

Main Principle

The principle is to use the perturbations method, available in the ERANOS code. The aim is to calculate the different reactivity coefficients within each region.

First, we have to generate the self-shielded cross sections and matrices of both the situations: standard and perturbed. Because of the thermal expansions, it has been chosen to decrease the concentrations of 1% to create the new cross sections. Second, equivalent temperature variations will be calculated with the corresponding expansion coefficient.

So, new cross sections, new concentrations, and new fluxes will be available for the perturbed situation at the corresponding “step.”

Cross Section Calculation Method

Doppler calculation: new cross sections have to be calculated at the new temperature: this one can be $T_{\text{standard}} + 30 \text{ K}$, or T_{fusion} , or . . .

Fuel, sodium, clad or wrapper calculation: new mediums and cross sections will be created: the density of the corresponding material will be multiplied by a constant of 0.99, simulating a decrease of the concentration of 1%.

Grid calculation:

- Homogeneous cell: the whole volume fractions change: except for sodium, each fraction is divided by a factor of $(1.01)^2$, simulating an increase of the core pitch of 1%. The sodium fraction is calculated to replace the created void by the new fractions.
- Heterogeneous cell: the cell pitch is multiplied by the 1.01 factor.

Flux and concentration calculation:

The evolution of each perturbed concentration is made with the nominal flux and in the standard geometry. At each step, nominal fluxes, adjoint fluxes of the nominal case are conserved.

For the sodium, clad, and wrapper expansions or for the Doppler Effect, perturbed flux calculations are done using perturbed cross sections and corresponding concentrations. Then, exact perturbation calculations are done to obtain a spatial decomposition of the variation:

$$\Delta\rho = \frac{\langle \Phi_1^*, (\lambda_2 \partial P_1 - \partial K_1) \Phi_2 \rangle}{\langle \Phi_1^*, P_1 \Phi_2 \rangle} \quad (24)$$

with

- Φ_1^* : standard adjoint flux
- Φ_2 : perturbed flux
- The whole terms with a subscript 1 correspond to the standard situation, the ones with a subscript 2 correspond to the perturbed situation. The associated terms correspond to the following Boltzmann equation for a critical reactor: $(\lambda P - K) \Phi = 0$ and the adjoint equation: $(\lambda P^+ - K^+) \Phi^+ = 0$.

For the grid expansion, a new geometry has to be created with the new core pitch (“standard one” $\times 1.01$). Then perturbed flux are calculated using perturbed cross sections, corresponding concentrations, and the perturbed geometry. The corresponding $\Delta\rho$ is calculated between the two direct flux calculations.

For the fuel expansion, a new geometry has to be created in order to conserve the fuel inventory of the core. The whole fissile and fertile height is increased by a factor 1.01. The perturbed

flux is calculated with the perturbed cross sections, the corresponding concentration and the “new” geometry. The corresponding $\Delta\rho$ is calculated between the two direct flux calculations.

However, to obtain a spatial decomposition of this effect, it is possible to do an exact perturbation calculation:

$$\Delta\rho = \frac{\langle \Phi_1^*, (\lambda_2 \partial P_1 - \partial K_1) \Phi_2 \rangle}{\langle \Phi_1^*, P_1 \Phi_2 \rangle} \quad (25)$$

But Φ_2 is not the perturbed flux calculated on the new geometry: the geometry has to be the same between the standard and the perturbed situation for a perturbation calculation. So, we calculate the perturbed flux with the perturbed cross sections, with the corresponding concentration but with the standard geometry. The obtained result will be normalized with the $\Delta\rho$ obtained from the direct flux calculations.

6.5.3 Return to a Temperature Variation

The last part consists in calculating the temperature variations corresponding to the expansions we made. In the whole following document, the variable i will refer to a subassembly, the variable j will refer to an axial mesh.

Sodium expansion: the equivalent temperature variation to a decrease of the sodium concentration of 1% is:

$$\Delta T_{\text{Na}} = \left[\sqrt[3]{1/0.99} - 1 \right] \cdot \frac{1}{\alpha_{\text{Na}}} \quad (26)$$

where α_{Na} is the linear expansion coefficient of the sodium at the calculation temperature of the material sodium. The corresponding coefficient is:

$$K_{\text{Na}}(i, j) = (\Delta\rho_{\text{Na}}(i, j)/\Delta T_{\text{Na}}) \text{ (pcm/K)}.$$

Axial clad and wrapper expansion: the equivalent temperature variation corresponds to a decrease of the concentration of 1%. However, this decrease can take place only on the axial direction. Then:

$$\Delta T_{\text{clad}} = \left[\frac{1}{0.99} - 1 \right] \cdot \frac{1}{\alpha_{\text{clad}}} \quad (27)$$

$$\Delta T_{\text{wrapper}} = \left[\frac{1}{0.99} - 1 \right] \cdot \frac{1}{\alpha_{\text{wrapper}}} \quad (28)$$

where α_{clad} and α_{wrapper} are the linear expansion coefficients of the clad and of the wrapper at the calculation temperature of the materials. The corresponding coefficient are: $K_{\text{clad}}^{\text{axial}}(i, j) = (\Delta\rho_{\text{clad}}(i, j)/\Delta T_{\text{clad}}) \text{ (pcm/K)}$ and $K_{\text{wrapper}}^{\text{axial}}(i, j) = (\Delta\rho_{\text{wrapper}}(i, j)/\Delta T_{\text{wrapper}}) \text{ (pcm/K)}$.

Radial clad and wrapper expansion: this coefficient does not come from a loss of the structural mass, but from a loss of the core sodium.

- Wrapper expansion: on each region of the core, we have the following coefficients $K_{\text{wrapper}}^{\text{radial}}(i, j) \text{ (pcm/K)}$, corresponding to the local variations $\Delta\rho_{\text{Na}}(i, j)$. The local reactivity coefficient is thus:

$$K_{\text{wrapper}}^{\text{radial}}(i, j) = \frac{\Delta\rho_{\text{Na}}(i, j)}{\Delta T_{\text{wrapper}}} \times 100 \times 0.02 \times \left(\frac{F_{\text{wrapper}}}{F_{\text{Na}}} \right) \text{ (pcm/K)}$$

where

- F_{wrapper} is the cell volume fraction of the wrapper
- F_{Na} is the cell volume fraction of the sodium
- $\Delta T_{\text{wrapper}}$ is calculated (18).

Clad expansion in the case of a sodium gap: just as it has been made for the radial wrapper expansion, we have the following coefficient.

$$K_{\text{clad}}^{\text{radial}}(i, j) = \frac{\Delta \rho_{\text{Na}}(i, j)}{\Delta T_{\text{clad}}} \times 100 \times 0.02 \times \left(\frac{F_{\text{clad}}}{F_{\text{Na}}} \right) \quad (\text{pcm/K})$$

where

- F_{clad} is the cell volume fraction of the clad
- F_{Na} is the cell volume fraction of the sodium
- ΔT_{clad} is calculated at (17).

The term $(1 - F_{\text{wrapper}} - F_{\text{Na}})$ corresponds to the pin volume fraction in the cell.

Fuel expansion: The temperature variation to expand the fuel in an axial direction (without a loss of fuel mass) depends if this last one is linked or not to the clad.

$$\Delta T_{\text{fuel}} = \left[\frac{1}{0.99} - 1 \right] \cdot \frac{1}{\alpha_X} \quad (29)$$

where

- $\alpha_X = \alpha_{\text{fuel}}$ if the fuel is not linked to the clad
- $\alpha_X = \alpha_{\text{clad}}$ if the fuel is linked to the clad The global effect is obtained by doing the difference between the k-effective of both the direct calculations: $\Delta \rho_{\text{fuel}}$. The spatial distribution of this reactivity coefficient depends on the values of the perturbation calculation: $\delta \rho_{\text{fuel}}(i, j)$.

$$K_{\text{fuel}}(i, j) = \frac{\Delta \rho_{\text{fuel}}}{\Delta T_{\text{fuel}}} \times \frac{\delta \rho_{\text{fuel}}(i, j)}{\sum_{i, j} \delta \rho_{\text{fuel}}(i, j)} \quad (\text{pcm/K})$$

- Doppler constant: the Doppler constant is calculated on the entire fuel zone: fissile and fertile. As their temperatures are different, it is important to separate them.

$$K_{\text{Doppler}}^{\text{fissile}} = \frac{\Delta \rho_{\text{Doppler}}^{\text{fissile}}(i, j)}{\ln \left(\frac{T_{\text{Doppler}}^{\text{fissile}}}{T_{\text{nominal}}^{\text{fissile}}} \right)} \quad (\text{pcm})$$

$$K_{\text{Doppler}}^{\text{fertile}} = \frac{\Delta \rho_{\text{Doppler}}^{\text{fertile}}(i, j)}{\ln \left(\frac{T_{\text{Doppler}}^{\text{fertile}}}{T_{\text{nominal}}^{\text{fertile}}} \right)} \quad (\text{pcm})$$

The whole temperatures are calculated in Kelvin.

- Grid expansion: both the direct flux calculations involve the reactivity variation: $\Delta \rho_{\text{grid}}$. The temperature variation is:

$$\Delta T_{\text{grid}} = \left[\frac{1}{0.99} - 1 \right] \cdot \frac{1}{\alpha_{\text{grid}}} \quad (30)$$

Thus, the reactivity coefficient is:

$$K_{\text{grid}} = \frac{\Delta \rho_{\text{grid}}}{\Delta T_{\text{grid}}} \quad (\text{pcm/K})$$

6.5.4 Validity of These Coefficients

It's important to notice that all these coefficients are calculated at a fixed temperature. Thus, it would not be discerning to apply these to the calculation of transients on the core in a very different situation: beginning of fusion of the core, for example.

Furthermore, if these coefficients are used for the calculation of transients with important variations of temperature of the considered materials, it is important to update the calculated reactivity coefficients with the correct expansion coefficient. For example, if the sodium coefficient has been calculated at the temperature T_0 and during a transient, varies between the temperature T_1 and T_2 , the correct reactivity coefficient for this phase will be:

$$K_{\text{sodium}}(\bar{T}) = K(T_0) \times \frac{\bar{\alpha}}{\alpha(T_0)},$$

with

$$\bar{\alpha} = \frac{1}{T_2 - T_1} \int_{T_1}^{T_2} \alpha(T) dT$$

Finally, if it is not possible to do some perturbation calculations, and only direct flux calculations, it will be important to verify the uncertainties on the k -effectives, because of the small reactivity variations. If they are so important, a solution could be to increase the percentage of density variation. Consequently, the whole temperature variations would have to be changed.

7 Specific Thermalhydraulics Issues

7.1 Thermal Stratification

7.1.1 Phenomena

High boiling point implies that sodium remains in liquid state up to the temperature of 1,175 K at atmospheric pressure and excellent heat transfer characteristics bring many advantages for the sodium as coolant. Higher boiling point permits high operating temperature for the reactor, still ensuring sufficiently high margin to avoid boiling of the coolant under all the design basis events. Sodium remains in liquid state during operating conditions without calling for any pressurization and hence design pressure for components is nearly atmospheric, in turn requiring lower wall thickness for the structures. The excellent heat transfer properties provide high natural heat removal capability, particularly in the pool type concept. While pool type concept has many distinct advantages from the point of view of safety, there are certain critical structural mechanics issues, especially with the austenitic stainless steels, commonly used structural materials in view of its excellent compatibility with sodium and high strength at elevated temperatures. In the pool type concept, both hot sodium pool which is about 820 K and cold pool

■ Figure 150
Development of stratification

at about 670 K coexist, which imposes high ΔT (150 K-maximum) in sodium in the narrow transition regions of hot and cold pools, during operating as well as transient conditions. This is termed as “thermal stratification.” Further, such stratification is also caused due to different temperatures of sodium jets coming out from core subassemblies. The compact arrangement of fast reactor core comprises fuel, breeder, and internally stored spent fuel subassemblies, located in the same layout. In spite of the elaborate flow zoning provisions, the temperatures of sodium exiting from the fuel (850 K typical), breeder (750 K typical), and spent (680 K typical) subassemblies are vastly different. The lower part of the hot pool is also influenced by the presence of cold flow due to leakage from the feet of the subassemblies. The difference of temperature between the hot pool and the cold pool induces a thermal flux through the inner vessel structures. These thermal conditions prevailing in the pool coupled with large thermal expansion coefficient of sodium ($2.8 \times 10^{-4} \text{ K}^{-1}$) and large size of the reactor pool, the Richardson number in the pool is of the order of unity, indicating the inertial and buoyancy forces are of similar magnitudes. As a result of this, a stratification interface is developed as shown in ► Fig. 150.

7.1.2 Locations Prone to Stratification

In SFRs, the bottom part of the hot pool is a transition area between the hot and cold zones of the reactor. This region is annular and bounded laterally by the core periphery and the redan portion of the inner vessel. The thermal behavior of this zone is influenced by two conflicting phenomena viz. (1) cold boundary layer due to the heat flux across the redan shell and cold sodium flow from peripheral subassemblies of core which generates a stable cold layer and (2) the main sodium in hot pool which causes penetration of hot sodium into this area. This hot main sodium flow is the consequence of the recirculation created by the core outlet flow. The

equilibrium between these two effects causes mixed convection and stratified flow in this region as shown in  Fig. 150.

Stratification effects will also be observed in pools during transient conditions. The limiting transient states for a pool type reactor are emergency shutdowns or rapid shutdowns. During such transients, cold sodium jets will be injected into the hot sodium pool. The sodium temperature at the core outlet falls rapidly (reduction in the temperature of the order of 130 K at 20 K/s). During these transient conditions, depending on the operating strategy adopted for the reactor, the primary sodium flow rate may also vary. Hence, under these conditions coupled with the temperature difference effects, the flow reduction effects will add to the net buoyancy forces imposed on the main sodium flow in the hot pool. This can in turn produce considerable changes in the flow pattern in the hot plenum, and can even lead to the formation of a stratified hot layer above the inlet windows of the intermediate heat exchangers.

Similarly, stratification effects may also be caused in the cold pool during transient conditions. Changes in the flow pattern may be brought about by the influence of buoyancy forces caused due to the temperature difference between sodium streams at the outlet of intermediate heat exchanger coupled with flow changes under transient conditions. These effects can produce, depending on operating conditions, considerable changes of flow in the cold plenum and may even lead to the formation of a hot stratified layer above the lower part of the pump assembly. Apart from pool, thermal stratification can develop in sodium pipelines also, if the conditions are conducive.

7.1.3 Effect of Stratification

With the austenitic stainless steel as structural material that has low thermal conductivity and high coefficient of thermal expansion and the sodium with its inherently high heat transfer coefficient, the adjoining structural wall surface is subjected to high temperature gradient (ΔT), created in sodium without any significant film drop and time delay. This causes high thermal stress range ($\Delta\sigma$) in the structural wall. Further concern of thermal stratification is steady oscillations, relatively at lower frequencies (<1 Hz), which is one of the sources of high cycle thermal fatigue damage for the metal wall.

7.1.4 Numerical Simulation of Stratification

Thermal effects cannot be adequately represented by water model tests and the construction and operation of large size sodium experimental facilities are also prohibitively expensive and time consuming; computational fluid dynamics (CFD) analysis is an essential tool for the prediction of temperature distributions in the reactor structures. In the CFD computations, turbulence model is a critical issue, especially for stratified flow conditions. Most of the turbulence models have been developed mainly for the forced convective flows. Identification of suitable turbulence model for stratified flow (buoyancy dominated), geometrical regimes for the computation and establishing the optimum mesh (computational time, memory and desired accuracy) are challenges in the CFD analysis for SFR applications. More fundamental studies (Surle et al. 1993; Iritani et al. 1991) on thermal stratification show the capability of the computational approach to estimate the time average vertical temperature gradients and interface position

correctly, making use of classical $k-\epsilon$ turbulent models. Additionally, three-dimensional large eddy simulation modeling calculations have been shown (Surle et al. 1993) to provide simulations of turbulent fluctuations and global instabilities. In this field, more work is necessary to assess to what extent time-averaged gradient characteristics are representative of instantaneous conditions and to validate more precisely the prediction of the frequency and amplitude of temperature fluctuations.

7.1.5 Experimental Simulation of Stratification

Experimental studies play a role in the validation of the computational modeling methods and also to study certain specific problems concerning transient and multidimensional effects involved in the phenomena. In the experimental simulations of thermal stratification in the hot pool, certain nondimensional numbers should be respected between the model and prototype. The Richardson number (Ri), which represents the ratio between the buoyancy and inertia forces involved in the flow and Reynolds number to simulate the flow fluctuations are also important nondimensional numbers that need to be simulated correctly. Further, the ratio of heat transfer by convection to that by conduction should be preserved for which the Peclet number should be nearly equal. In particular, Richardson number is important for thermal process. This is justified in the following two situations, that is, steady state and transient conditions.

Under steady state conditions, there exists a critical Richardson number Ri_c , beyond which the form of the flow pattern in the hot plenum is modified in comparison with the pattern under nominal operating conditions (Tenchine et al. 1990; Roubin et al. 1988; Astegiano et al. 1981). This is illustrated in [Fig. 151](#). [Figure 151a](#) shows the flow configuration when $Ri < Ri_c$ (Ri_c is about 2.6) where the inertial effects are large compared to buoyancy effects. Hence, the sodium emerging from core is able to move upward to produce strong recirculation in the upper portion of hot pool as well as in the cavity between core and inner vessel, thus facilitating good mixing and hence there is no stratification. [Figure 151b](#) shows the flow pattern when $Ri > Ri_c$, that is, the buoyancy effects are dominant compared to inertial effects, where the cold

Figure 151

Stratification mechanisms in hot pool (PSP – primary sodium pump; ACS – above core structure)

■ Figure 152

Hot plenum stratification after a SCRAM at 23% nominal power in SPX1

sodium from the peripheral subassemblies separates from the hot sodium of fuel subassemblies and occupies the cavity. This leads to inadequate mixing, creating stratification.

The transient thermalhydraulic behavior of hot pool can also be characterized by means of a Richardson number (Ri). In the same way as for steady state conditions, fully turbulent flow in the model must be ensured by imposing a low Reynolds distortion. Comparative studies were performed in SPX1 geometry (🔍 Fig. 152) (Astegiano et al. 1981; Astegiano 1990) between mock-up test measurements and reactor measurements, to simulate the transient temperature evolutions at various locations in the hot pool following a reactor scram. Under this transient, the hot pool temperature in the vicinity of core top drops rapidly (location 4 in the figure) compared to the locations far from the core (location 1). This has been simulated correctly in the model studies where Richardson similitude is satisfied.

7.1.6 Design Guidelines for Stratification

The generally adopted design solution to avoid the thermal stratification effects during steady state operating conditions of the reactor is to provide some devices that are able to break the stratification interfaces. These devices offer good mixing amongst the varying temperature streams, before they reach IHX primary inlet windows in the hot pool. Detailed multidimensional CFD studies aid in arriving at the design configuration of such devices. One such device adopted in the design of PFBR, is a porous cylindrical skirt provided just below the control plug (Tenchine et al. 1990). The effect of this skirt is to increase the sodium velocity entering into the hot pool and thereby promoting good mixing and avoiding stratification as shown in 🔍 Fig. 153. However, provision of this skirt increases the pressure below the control plug bottom. This increased pressure increases the flow entering the control plug through the annular passages in the absorber rod mechanisms. Large flow in the control plug is of concern from

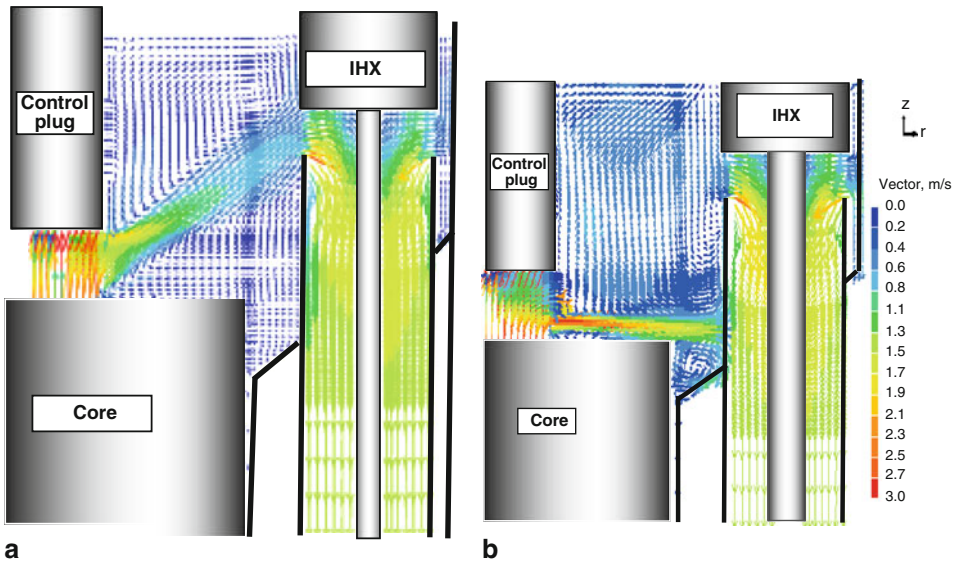

Figure 153
 (a) Stratified flow in hot pool; (b) Stratification eliminated by skirt

transient temperature (cold shock) seen by the control plug parts during a reactor SCRAM. Ideally, the flow entering the control plug has to be proportional to its volume in the hot pool. This can be achieved by choosing proper combination of annular clearances between the shroud tubes and respective absorber rods drive mechanisms and the perforations in the shroud tubes. However, care has to be exercised to ensure adequate clearances are available for facilitating smooth drop of absorber rods.

There are other detrimental effects due to the provision of the skirt. The skirt increases the radial velocity of sodium steam with which it enters the hot pool. This will result in increased velocity of sodium at the sodium free surface which can be harmful from gas entrainment considerations. The skirt diverts sodium flow exiting from various subassemblies in the radial direction. This causes the sodium streams exiting out of subassemblies located in the periphery of the core to be masked by the sodium stream from those located in the central region. Therefore, the positioning of thermocouples in the core temperature monitoring instrumentation should be very carefully decided to satisfy the subassembly plugging detection requirements. Another effect that is caused by the skirt is the nonuniform velocity profile of sodium at the entry to the intermediate heat exchangers, which is critical from flow-induced vibration of IHX tubes. Detailed experimental and theoretical studies have to be carried out in selecting the proper design configuration for the cylindrical skirt. Thus, the porosity of the skirt has to be optimized considering these factors. Typical porosity value of the skirt is 10%.

The skirt may not be effective in avoiding stratification in the pool at all power levels of operation of the reactor. If the low power operation is envisaged by reducing the flow (Q) proportionally to maintain the temperature rise across the core (ΔT), the Richardson number ($\Delta T/Q^2$) increases which promotes stratification. To avoid this, a strategy can be adopted

Figure 154

Thermal stripping phenomenon in the vicinity of core cover plate in SFR

wherein the flow can be reduced at the level so as to keep the Richardson number more or less unchanged; that is, the value of $(\Delta T/Q^2)$ remains nearly the same for all the power levels.

7.2 Thermal Stripping

7.2.1 Phenomenon of Stripping

Thermal stripping is a complex thermal hydraulics phenomenon, which generates random fast temperature fluctuations, originating from the incomplete mixing of hot and cold jets of fluid, sodium in the present context, in the vicinity of adjoining structural wall surface (► Fig. 154). The frequency of oscillations under thermal stripping is reported as 1–10 Hz. When the fluid temperature fluctuation amplitude and then thermal stress are large, structural integrity might be lost due to high cycle thermal fatigue. The amplitude and the frequency of the temperature fluctuations are important parameters on which the damage caused on the structures depends. The oscillating temperature phenomenon is basically caused due to the jet instability and turbulence.

7.2.2 Locations Prone to Thermal Stripping

Thermal stripping occurs at a few locations in the hot and cold sodium pools in the reactor assembly, predominantly on the core cover plate of control plug and at mixing “Tee” junctions in the secondary sodium pipelines. It is worth mentioning that apart from thermal stripping, oscillations of thermal stratification layers and sodium free level do cause temperature fluctuations in certain locations in the sodium pools. ► Figure 155 shows a few potential areas of level fluctuation, thermal stratifications, and thermal stripping. Another important location in the reactor which is prone to thermal stripping is the surge tank where, under specific transient conditions, mixing of sodium jets at different temperatures happens.

■ **Figure 155**
Zones of thermal fluctuations in SFR

The concerns of thermal fluctuations are also addressed comprehensively in Ohshime et al. (1994) and Gelineau and Sperandio (1994). There are a few reported failures, in the form of extensive cracking due to thermal striping in the operating reactors at: secondary sodium pump vessel in Phenix (Gelineau and Sperandio 1994), Tee junction of an auxiliary pipe of the secondary circuit in SPX (Gelineau and Sperandio 1994), control rod guide tube in PFR (Bettes et al. 1994), and primary cold trap in BN 600 (Sobolev and Kuzavkov 1994).

7.2.3 Effect of Striping

High thermal fatigue cycles are caused by thermal striping. The range of frequency of oscillations under thermal striping is reported as 1–10 Hz. Thermal striping occurs at a few locations in the hot and cold sodium pools in the reactor assembly, predominantly on the core cover plate of control plug and at mixing “Tee” junctions in the secondary sodium pipelines.

7.2.4 Prediction of Thermal Striping

Thermallydraulics of thermal striping phenomenon is governed by many physical phenomena, with each one having its own difficulties and limitations. There are difficulties with the experimental quantification and the modeling of turbulent mixing (temporal and spatial multi-scale phenomena). Since, thermal effects are associated with this phenomena the experimental simulation calls for sodium experiments. The oscillating temperature field in sodium is caused by

jet instabilities and turbulence. The size of turbulent eddies and their life depends on the velocity and hydraulic diameter of issuing jets. Therefore, the experimental simulation needs to be carried out on equal scale models with exact simulation of flow velocity. Meanwhile, on the theoretical modeling of this phenomenon, progress has been made with the advanced turbulence models, namely, large eddy simulation (LES), very large eddy simulation (VLES), and detached eddy simulation (DES). But these are still in the development and validation stages. The qualification of these models is extremely difficult as a result of measurement difficulties and uncertainty in the validation of the numerical and experimental results. The success of the numerical simulation of thermal striping depends on how accurately the turbulent scales responsible for the oscillating flow and temperature field are modeled. These methods require fine resolution of geometry to capture the formation and movement of eddies. Enormous computational resources are required for these calculations. Performing such calculations for the entire hot plenum of an LMFBR is very difficult. In this context, a localized analysis approach is a better alternative. However, presently there is a trend toward solving large numerical models that current computers can barely handle to simulate the entire range of fluctuations. On the heat transfer aspect, there are still difficulties in measuring and modeling the heat exchange between the fluid and the wall. In addition, there are theoretical problems associated with lack of understanding of the boundary layer phenomenon. Recent computational studies (Muramatsu 1993, 1994a, 1998a,b; Hu and Kazimi 2006; Menant and Villand 1994) have shown that simulations using high order accurate numerical schemes and advanced turbulence models (LES) are giving promising results in the prediction of distributions of the intensity and frequency of temperature fluctuations in liquid metal reactor systems. Menant and Villand (1994) have predicted the temperature fluctuations in a square section duct with T-junction (➤ Fig. 156) using the TRIO-VF code employing the LES model.

➤ Figure 157 shows the computed temperature fluctuations in the duct at various locations, for the temperature difference of 45 K in the fluid streams. The computed temperature fluctuation on the metal wall is found to be 20 °C, indicating an attenuation of about 50%.

Direct numerical simulation (DNS) on simplified and approximated two-dimensional geometries have also been attempted recently (➤ Fig. 158) for the prediction of temperature fluctuation in fluid due to jet instability effects.

In view of the difficulties associated with the complete modeling of the phenomena, the usual approach followed is a combination of numerical and experimental simulations.

■ Figure 156

Square section with Tee junction for numerical simulation

■ Figure 157

Temperature fluctuations in a typical T-junction predicted by TRIO-VF code at various nodes located 0.7D downstream of inlet

■ Figure 158

Transient flow and temperature profiles near the plate

Thermalhydraulics studies cover basic understanding of the phenomenon (Popiel and Trass 1991; Tokuhiro and Kimura 1999), establishing experimental simulation principles and assessments based on tests with water and air (Moriya et al. 1988) and attenuation characteristics of thermal striping on the metal wall (Muramatsu 1994b; Wakamatsu et al. 1995a). Experimental studies (Wakamatsu et al. 1995b) are generally performed for the validation of numerical models. International scenario in the understanding of thermal striping is very encouraging. Owing

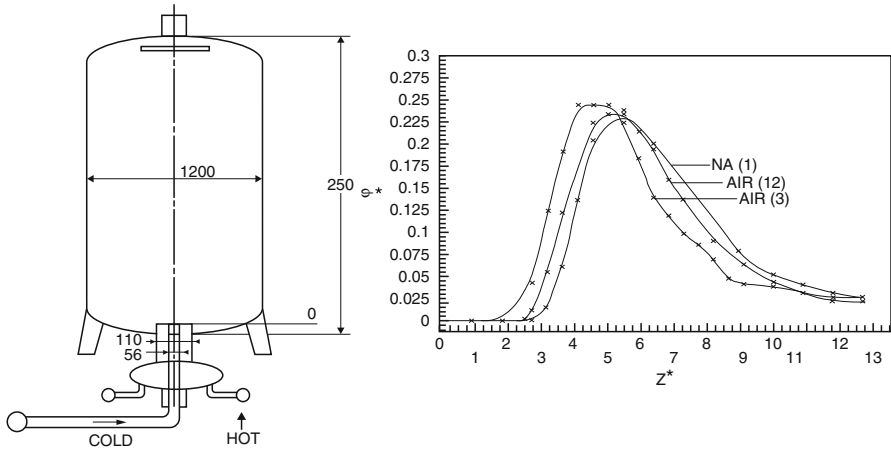

Figure 159

Sodium and air experiments on mixing of coaxial non-isothermal jets (left: experimental setup and right: variation of temperature fluctuation along the axis)

to vast experience gained in operation of fast reactors, France has reported many important observations related to thermal striping noticed in the operating plants, PHENIX and SPX-1 (Gelineau and Sperandio 1994). Tenchine and Moro (1999) carried out experiments in air and sodium (Fig. 159) to understand thermal striping during mixing of non-isothermal axisymmetric jets in a pool. They observed that the maximum amplitude of temperature fluctuation occurs at a nondimensional axial distance of ~ 5 .

In UK, Betts et al. (1983) carried out elaborate experimental research to understand if air or water could be used to simulate sodium in thermal striping studies. They found that air can be used to predict the temperature fluctuations in the fluid if the Reynolds number is of the order of 106 (Fig. 160). However, the boundary layer attenuation and the resulting temperature fluctuations in the structures cannot be predicted by air/water tests. This is because of the large difference in the heat transfer coefficient of sodium and air. To overcome this difficulty, Wakamatsu et al. (1995a) proposed an equivalent boundary layer model for the determination of boundary layer attenuation and the resultant temperature fluctuations in the structures (Fig. 161). Thermal striping phenomenon has been simulated in water tests through a dedicated test setup, developed at Indira Gandhi Centre for Atomic Research (IGCAR) (Fig. 162) (Chellapandi et al. in press). The setup simulates the situations of thermalhydraulics in the vicinity of core cover plate, placed on the control plug just above core. Temperatures and flow rates of hot and cold water are varied over wide ranges. A maximum ΔT of 90 K is possible in the setup. A few typical PSD generated from test data are also included in Fig. 162.

7.2.5 Design Guidelines for Striping

As the complete theoretical or experimental simulation of thermal striping phenomenon in a fast reactor system is difficult, the usual methodology followed in design is a combination of

■ Figure 160
Air model of PFR (1:5 scale)

simplified global and detailed local analysis approach. After a first step using global thermal-hydraulic models to identify the areas where thermal striping may occur, the characteristics of the fluctuation have generally been estimated from model tests using sodium as the working fluid. Based on global 3-D thermalhydraulic studies carried out for the primary sodium circuit, the localized zones prone to thermal striping identified in a pool type SFR are, namely, (1) fuel-breeder interface around the lattice plate, (2) fuel-breeder interface around the core cover plate, (3) bottom location of absorber rod drive mechanism where fuel-control subassembly sodium flows interact, and (4) main vessel near IHX outlet. These localized zones have to be further

Figure 161

Model to estimate boundary layer attenuation

Figure 162

Water test facility to simulate thermal stripping (IGCAR)

considered for the detailed prediction of flow and temperature oscillations. With the velocity and temperature values prescribed for the jet streams, the oscillations in the mixing layer region (interface) can be predicted at different locations. For conservatism, the influence of global flow field in the domain caused by other flow sources in the circuit can be neglected. Further, for a simplified numerical prediction of the fluctuating temperature phenomena, a method can be

Figure 163
Regions prone to thermal stripping in primary sodium

brought out by approximating the local geometry in each case to an equivalent two-dimensional domain and direct numerical simulation (DNS) calculation can be performed (Velusamy et al. 2005). The temporal oscillations and spectral distributions for each of the locations predicted for PFBR are summarized in [Fig. 163](#). Three-dimensional simulations would definitely lead to more accurate results compared to the two-dimensional predictions. The two-dimensional simulation is a compromise for the easy handling of the large geometrical domain of hot pool regions prone to thermal striping.

7.3 Free Level Fluctuations

7.3.1 Phenomenon

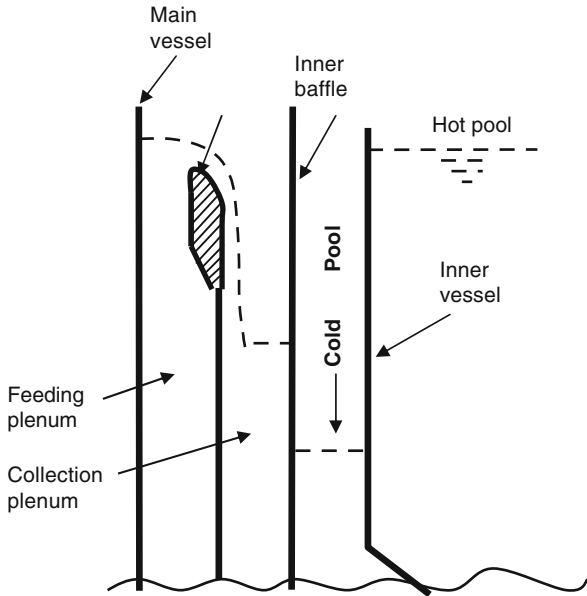

Argon cover gas is maintained above the sodium pools/tanks in the fast reactor. This is to accommodate volume changes in sodium as a result of temperature changes in sodium. The interface between the sodium top surface and argon cover gas is known as sodium free level. Some of the components in a fast reactor with sodium free levels are primary sodium hot and cold pools, surge tank, pump vessel and storage tank in the secondary sodium circuit, expansion tank in the safety grade decay heat removal (SGDHR) circuits, etc. These free levels are susceptible to fluctuations if, either the sodium has large velocities or the diameter of the vessel is large. The free level is a region of large axial temperature variation in the vessel walls as well as in structures partially immersed in sodium and partially exposed to argon. Normally, the sodium is at a higher temperature than the cover gas. The gas temperature reduces sharply from that of the sodium within a thin boundary layer of 20–30 mm over the sodium free surface. The heat transfer coefficient of sodium is very large ($\sim 104 \text{ W/m}^2\text{-K}$), due to its large thermal conductivity. Due to free level fluctuations, the components partially dipped in sodium will alternately see hot sodium and cooler argon (cover gas). These temperature fluctuations can lead to thermal

fatigue. Due to large heat transfer coefficient of sodium, the thermal attenuation in the wall boundary layer will be very low, leading to large amplitude of fluctuations in the structures.

When the amplitude of local sodium level fluctuations exceeds a critical value, it leads to entrainment of argon gas into the sodium. This entrained sodium is a source of concern, it enters the active core.

7.3.2 Locations of Concern

The level fluctuations in the expansion tank of safety grade decay heat removal (SGDHR) circuit are expected to be low, as the expected velocity levels in the tank as a result of buoyancy as well as the size of the tank are very small. In the case of storage in the secondary system, the sodium velocities are very less although the vessel diameter is significantly large. But in the case of hot pool, due to the interaction of sodium stream from the core with the free surface and cross flow-induced vortex shedding behind the immersed structures like pump, IHX, etc., the level fluctuation is critical. The components which would experience temperature fluctuation due to level fluctuations in the hot pool are inner vessel, IHX, DHX, control plug, level probes, etc.

Main vessel being the main load bearing member of the reactor assembly, in order to protect it from thermal fatigue effects due to free level fluctuations, a design that ensures constant level of sodium at free level is essential. This is achieved through the vessel cooling system designed to have an overflow weir, where sodium overflows from the feeding plenum to the collection plenum as shown in  Fig. 164.

 Figure 164

Main vessel cooling circuit with overflow weir system

7.3.3 Methods for Prediction of Level Fluctuations

The phenomenon of level fluctuation in the sodium pool is governed by inertial forces of the sodium flow and the gravitational forces of the fluctuating sodium free levels. The fluctuation is a random phenomenon of local nature. Prediction of the level fluctuation by computational fluid dynamics studies calls for 3-D, transient studies coupled with complex modeling features for predicting free surface profiles. Experimental simulation is the favored option. For the numerical prediction of these types of flows with moving gas–liquid interface, numerical methods such as height function method and volume of fluid (VOF) method (Harlow and Welch 1965; Hirt and Nichols 1981) have been developed and incorporated in commercial CFD computer codes. In order to capture the free level fluctuations of frequency less than 1 Hz, the simulations also have to be carried out with smaller time steps. The domain of our interest being a large pool, the number of computational cells will be large. Solving a three-dimensional transient problem of this nature is a computational challenge.

The free level fluctuations are governed by the balance between the inertial, gravitational, and frictional forces. The appropriate nondimensional number that governs the inertial force to gravitational force is Froude number (Fr) and the number that governs the inertial force to frictional force is Reynolds number (Re). These nondimensional numbers can be respected by water models. Since no heat transfer is involved, poor thermal conductivity of water is not a constraint. The effect of Re is secondary once the flow is well in the turbulent regime, and hence distortion in the Re can be permitted. Hence, water experiments, on geometrically similar scaled down models respecting Fr number similarity, are carried out and the measured free level fluctuations are extrapolated for the reactor.

The experimental studies on a $1/4$ model (Laxman et al. 2004) reveal that the free level fluctuations are not uniform throughout the hot pool and that the ripple height and the fluctuation frequency depend on the location in the pool. For nominal flow condition the maximum amplitude is about 82 mm in the vicinity of the control plug extrapolated to prototype conditions. The predominant frequencies of fluctuations for the reactor vary between 0.25 and 1.6 Hz. Using these data of frequency and amplitude of level fluctuations, the transient temperature fluctuations in partially submerged structures are determined by solving the transient heat conduction equation. It shall be highlighted that structural temperature fluctuations cannot be predicted by water experiments.

The free level fluctuations in the pool should be quantified for choosing the margins for avoiding the gas entrainments into the heat exchangers immersed in the hot pool. This apart, the free fluctuations cause special type of structural damage called “thermal ratchetting” on thin shells in the vicinity of level fluctuations, which is described in [► Sec. 8.1](#). Since the weir ensures maintaining the constant sodium free level in the vicinity of main vessel irrespective of the sodium flow rate, there is no possibility of level fluctuations in the main vessel ([► Fig. 165](#)).

7.4 Cellular Convection

7.4.1 Phenomenon

Natural convection of gases/liquids in vertical enclosures is a normal phenomenon, where the fluid absorbs heat from hot wall during its upward travel and deposits the heat on the cold wall during its downward travel. During these upward and downward movements, boundary

■ Figure 165

A schematic of weir flow system

layers develop over the hot and cold vertical walls. When the width of the annular space (e) reduces or the height of the enclosure (H) increases (i.e., as the aspect ratio, e/H reduces) the hot wall and cold wall boundary layers approach each other. At some specific value of aspect ratio, which depends upon the temperature for the given geometry, both the boundary layers would interact. This interaction is the condition for onset of the breakdown of symmetry in the flow structure leading to asymmetric convection. This phenomenon is termed as cellular convection (Goldstein et al. 1979). For example, the top shield penetrations face this phenomenon, which is depicted in Fig. 166. In this figure, the hot shell represents outer shell of IHX and cold shell represents the roof slab penetration shell, cooled by air. The annular space is filled with cover gas argon. In such conditions, the type of convection pattern formed in the annulus depends on many factors, namely, temperature difference between the source and sink, width of the annulus, ratio of length to height of the annulus and cooling conditions on the various boundary surfaces of the annulus.

Based on experimental studies performed, the geometric parameters of the cylindrical annuli where the convective flow turns out to be unsymmetric have been arrived. When the aspect ratio of the annulus is less than 0.21, unsymmetric pattern has been observed (Siegel and Norris 1957; Timo 1954), that is, $e/H < 0.21$. A more general relationship has been arrived at relating boundary layer thickness (δ) to the gap width as: $e/\delta < 3$.

The number of loops of convective flow formed depends on the ratio of the circumference (πd) and height of the annulus (H) (Mejane and Durin 1982). When this ratio is of the order

■ **Figure 166**
Condition for onset of cellular convection

of 2, the number of loops formed is one, that is, one hot leg and one cold leg. When this ratio is of the order of 4, the number of loops formed is two. However, a clear dependency relation has not yet been established. The vertical penetration depth of cellular convection depends strongly on e/H and cooling conditions. The convection is weak, if e/H is small and top shield cooling is strong.

7.4.2 Location of Cellular Convection

In an SFR, the primary sodium inside the vessel is blanketed by an inert cover gas, normally argon. The top shield forms a cover for the primary sodium pool with argon gas between its bottom and free level of sodium. Outside of the top shield is the ambient environment of the reactor containment building. The top shield has many penetrations for components like, IHX, decay heat exchanger (DHX), sodium pimps, control plug, rotating plugs, etc. These penetrations form narrow vertical cylindrical annuli open at the bottom. The temperature of sodium pool is $\sim 550^\circ\text{C}$ during nominal condition and the top shield is cooled to maintain its temperature at $\sim 120^\circ\text{C}$ (in the reactor adopting hot roof concept) and at $\sim 50^\circ\text{C}$ (in reactors adopting cold roof concept). The gap width of the annular penetrations has to be as narrow as possible to have compact top shield of small diameter and to reduce the heat load on the top shield. The height of the annular penetrations is typically 1.5–2.0 m. This large height is required from the considerations of biological shielding offered by the concrete that fills the box-type top shield. As a result of these, the bulk temperature of argon cover gas attains a value in between that of sodium and top shield. The gap width of the annular penetrations being very small ($\sim 10\text{--}25\text{ mm}$), compared to the height ($\sim 1.8\text{ m}$), the natural convection of argon taking place in the annuli is asymmetric as shown in [Fig. 167](#), because the hot argon enters the annulus at one circumferential location and leaves the gap at the opposite side. It is worth mentioning that if the gap would have been wide, both upward and downward flows occur within the annular gap resulting in symmetric flow pattern over the entire circumference.

■ Figure 167
Asymmetric convection of argon

7.4.3 Effects of Cellular Convection

Due to asymmetric nature of cellular convection, the hot argon enters the annulus at one circumferential segment of the penetration. It gets cooled along its vertical and circumferential travel in the annulus and then leaves the annulus in some other annular segment. As a result of this, the component wall becomes hot in one sector and cold in another sector. This leads to differential thermal expansion of the structures. As the components of SFR (namely, IHX, pump, control drive mechanisms, etc.) are thin and long structures (~10 m long). The long length of the structures amplifies the tilt and adverse interaction of the components with their mating parts inside the pool, as well stress. This tilt is very critical in components like control drive mechanisms.

When the number of loop is one, the maximum and minimum temperatures occur along the shell exactly at the opposite meridian lines, under which the component tilts without change of circularity (insignificant stresses). In the design maximum allowable tilting is specified for smooth functioning of mechanical seals in IHX and pump-pipe connections in the spherical header. When the number of loops is more, there would be multiple maxima and minima along the circumference, resulting changes of circular shapes (ovality), without causing significant tilting. However, the resulting ovality causes high hoop stresses, which are to be limited from thermal fatigue considerations. For very narrow annulus possible in the case of machined penetrations, flow through annulus is restricted and hence a stagnant region would be developed at the upper part of the annulus. Hence, the convective flow pattern would be restricted at the lower part of the annulus, which does not have any significance. Hence machined penetrations are preferred solution.

7.4.4 Methods for Prediction of Cellular Convection

As the cellular convection is a geometry-dependent and boundary condition-dependent phenomenon, involving radiative heat transfer in evaporation and condensation of sodium vapor and natural convection of sodium mist laden argon cover gas, the experimental studies have to be carried out on full scale models [Baldasari et al. 1984; Roux and Elie 1988; Lenoir et al. 1981]. The approach adopted in design is a combination of experimental and theoretical analyses.

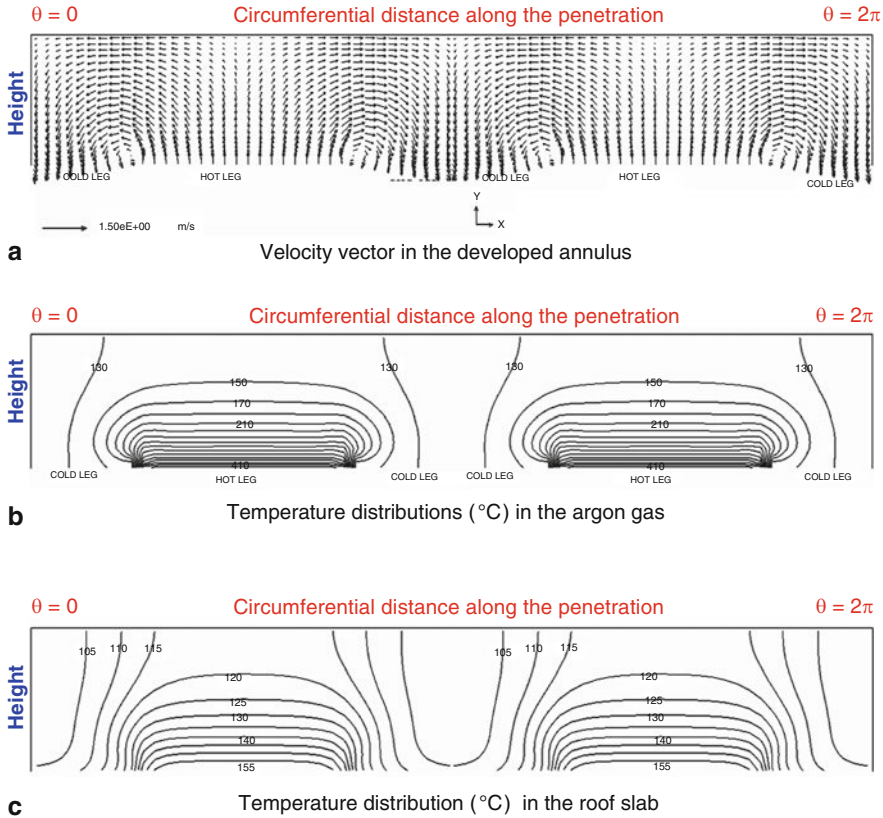

Figure 168

Important cellular convective parameters 1

Experimental studies are used for the validation of theoretical models and design predictions are made using the validated theoretical models (Yamakawa et al. 1986; Toda et al. 1990; Francois and Azarian 1989). Cellular convection in the penetrations and resulting asymmetric temperature distribution in the shells, have to be predicted by a conjugate thermalhydraulic model considering natural convection of argon, heat conduction in the multiple shells, radiative heat exchange among the shells, and forced convection cooling boundary conditions simultaneously (Silver et al.). Suitable turbulence models (depending on the Rayleigh number) with special approaches recommended for the simulation of natural convective flows have to be adopted in these predictions. The cellular convection velocity pattern and corresponding temperature pattern in the annulus predicted for a typical component penetration is shown in [Fig. 168](#).

7.4.5 Managing Cellular Convection

In FBTR, the cellular convection formed between the reactor vessel and the large rotating shield plug led to the uneven expansion and hence the tilting of reactor vessel (Vaidyanathan). In order

to overcome this problem, a comparatively lighter helium gas is being injected from the top of the penetration to suppress the cellular convection.

The tilting of components caused due to cellular convection has to be managed through proper care taken in the design. The tilting of control plug causes the thermocouples of the core temperature monitoring instrumentation to get offset with respect to the center of the sub-assembly. This needs to be considered in deciding the normal location of thermocouple with respect to the subassembly. The tilting of pump assembly due to cellular convection needs to be considered in the design of the spherical seat support. Wherever the cellular convection effects are unmanageable, proper design provisions have to be made for arresting the convection by the use of anti-convection barriers. Thus, cellular convection is an important aspect to be considered in the design to meet the functional requirements of various systems and mechanical design of various components.

7.5 Gas Entrainment

7.5.1 Phenomenon

In an SFR, argon gas blanket is maintained above the sodium free surface to accommodate volume changes of sodium as a result of its thermal expansion, due to various operating conditions of the reactor, as well as to avoid sodium–air contact through the numerous penetrations in the roof slab. Hence, a large sodium surface, which interfaces with argon, is formed as shown in [Fig. 169](#).

Reducing the size of the reactor vessel offers significant economic incentives. However, the reduction has a large impact on the thermohydraulics of the hot pool. One of the main problems in reducing the size of the vessel is the agitation of sodium free surface. The agitation of free surface due to large convective velocities can lead to entrapment of argon gas within high velocity sodium and its transportation to the intermediate heat exchangers (IHX). The mechanisms associated with various types of gas entrainment phenomenon are detailed below ([Fig. 170](#)):

Entrainment Due to Differential Dissolution of Argon

It may be mentioned that argon dissolves in sodium and its dissolution increases with temperature. The equilibrium concentration of argon in the hot pool, when the sodium temperature is 820 K is $\sim 7.5 \times 10^{-2} \text{ g/m}^3$ (Winterton 1972). Similarly, the equilibrium concentration of argon in the cold pool sodium, at 670 K, is $0.5 \times 10^{-2} \text{ g/m}^3$. Because of this, some quantity of argon is bound to be present in sodium. However, the dissolved argon is not expected to cause any reactivity perturbations in the core. But the argon bubbles, which are entrained by sodium that stays as separate phase has a potential to pass through the core sporadically.

Liquid Fall

One of the mechanisms, which can cause entrapment of gas in hot pool, is “liquid fall” (Kobus 1991). This is due to the fact that when the vertical velocity of liquid in the hot pool is large, the flow rises above the mean free surface forming a local hump. The flow, which rises above the free surface, falls back to the sodium surface as a liquid fall. The interaction between the falling liquid and the nearly stagnant pool causes entrainment of argon as shown in [Fig. 170a](#). The gas thus entrapped can be carried to the inlet window of intermediate heat exchangers, depending

■ Figure 169

Gas entrainment in SFR (IHX – intermediate heat exchanger; GP – grid plate; CSS – core support structure)

on the size of the gas bubble and the velocity of sodium, which decides the drag force: $F_d = C_d (\pi D^2/4)(\rho_{sod} V^2/2)$. The drag coefficient (C_d) for a spherical bubble of argon varies from 0.7 to 0.4 for range of Reynolds number (Re) between 200 and 105. ρ_{sod} is the density of sodium, D is the diameter of the argon bubble, and V is the upward velocity of the bubble as a result of buoyancy in a quiescent sodium liquid. The upward buoyancy force acting on the bubble (F_b) is given by, $F_b = (\rho_{sod} - \rho_{arg}) g (\pi D^3/6)$. ρ_{arg} is the density of argon and g is the acceleration due to gravity. Equating F_b and F_d , the terminal velocity of the bubble (also known as bubble rise velocity) can be calculated to vary as $\sim 5 \times D^{1/2}$. If the downward sodium velocity were larger than the terminal velocity of the bubble, the bubble would be carried along with the sodium. On the contrary, if the sodium velocity were less than the terminal velocity, then the bubble would escape to the free surface. It is estimated from the above that the terminal velocity of a bubble of 1 mm diameter is only ~ 0.18 m/s or a downward velocity of 0.5 m/s can successfully drag a spherical argon bubble of 10 mm diameter. For identical bubble sizes, the terminal velocity of bubble is slightly more in sodium than in water, due to the lower value of sodium viscosity.

Vortex Activated Entrainment

The sodium pool consists of many objects, which are partially immersed in sodium and partially exposed to argon gas. Horizontal sodium flows at the free surface past these structures lead to formation of vortices behind the structures. These rotating vortices have dimples of gas at the center as shown in [Fig. 170b](#). The vortices thus generated, travel along the liquid. If the vortices are strong, they take longer time to dissipate their energy. But, if they encounter strong vertical downward currents before their dissipation, it can lead to entrapment of gas in sodium.

■ **Figure 170**
Gas entrainment mechanisms in hot pool

The depth of the dimple is expected to be of the order of $V^2/2g$, where V is the horizontal velocity at the free surface of the pool. Typically, for a free surface velocity of 0.5 m/s, the depth of the dimple could be of the order of 1.25 cm. Generally, these vortices are generated at the periphery of the hot pool, close to the upper shell of inner vessel and get transported toward the control plug. If the free surface velocity is less, then the transit time of the vortices increases enhancing the possibility of dissipation of the vortices.

Drain-Type Vortex

The drain-type vortex, also known as “bathtub” vortex or “standing vortex,” occurs when the submergence level of inlet window, of heat exchangers for the given entry velocity of sodium to the heat exchanger is inadequate. In this type of entrainment, a long gas core is formed around the drain location starting from the free surface, as shown in  Fig. 170c. Presence of such a vortex can lead to transportation of large quantity of argon gas in IHX. Such drain-type vortices are not expected in decay heat exchangers as the associated natural convection velocity through them is of very low magnitude.

Shearing of Gas–Liquid Interface

When the free surface velocity is large, the shearing interface between sodium and argon gas becomes unstable leading to generation of surface waves as shown in  Fig. 170d. These waves can lead to gas entrainment near the free surface.

7.5.2 Potential Areas for Gas Entrainment

In the hot pool, IHX is the only source through with gas entrains. Other zones prone to gas entrainment risks in the primary sodium circuit are: (1) the free fall of main vessel cooling flow in the collection plenum and (2) the sodium free level around the rotating shaft of primary sodium pump. Gas entrainment is possible in the surge tanks of the secondary sodium circuit also. In the surge tank, secondary sodium from two or more IHX join and mix before branching to the steam generators, which are connected to the same secondary sodium pump. However, gas entrainment in surge tank does not pose any safety problem. Large-scale argon entrainment in surge tank is expected to affect the heat transfer in steam generators, due to poor heat transfer coefficient of argon laden sodium.

This has been explained in the previous section. In order to have a constant sodium level adjacent to the main vessel during all operating conditions of the reactor, the vessel cooling system is designed to have an overflow weir, where sodium overflows from the feeding plenum to the collection plenum. The overflowing sodium impinges on the sodium surface in the collection plenum. The impingement velocity depends on the flow rate, fall height, and shape of the weir. At the impingement point, it is possible that argon bubbles get entrained into sodium and this mechanism is the liquid fall entrainment described earlier.

The shaft of PSP is covered by a static pump vessel. Between the pump vessel and the shaft a sodium plenum is present. Due to the rotation of the shaft, the free surface of sodium between the shaft and vessel is expected to deform with a depression around the shaft as shown in  Fig. 171, similar to a drain-type vortex. The depth of this depression is a function of the rotational speed of the shaft, diameter of the shaft, and the radial gap between the shaft and the conical vessel. If the depression is very deep, argon entrainment and its passage to pump suction along with the hydro-static bearing flow are possible.

7.5.3 Effect of Gas Entrainment

The argon bubbles, thus entering the heat exchangers can reach the suction of the primary sodium pump, if they do not bubble out to the cover gas in the cold pool, which

■ Figure 171
Gas entrainment mechanism in pump vessel

depends on the velocity of sodium prevailing in the cold pool. The passage of argon through the core leads to reactivity oscillations. If the gas passes through the central part of the active core in medium/large size LMFBR, it leads to positive reactivity, while if it passes through the peripheral part of the active core, it leads to negative reactivity. Presence of large quantity of argon in sodium can lead to poor heat transfer in the core and heat exchangers.

7.5.4 Prediction of Gas Entrainment

The nondimensional numbers, which govern the flow distribution in the hot pool with undulated free surface, are the Froude number (Fr), the Reynolds number (Re), and the Weber number (We) (Guidez and Gognet 1990). The obvious choice of a simulant, which can be used to simulate sodium, is water due to the fact that it is transparent, cheap, and easy to handle. The kinematic viscosity of sodium ($3 \times 10^{-7} \text{ m}^2/\text{s}$) is half of that of the room temperature water ($6 \times 10^{-7} \text{ m}^2/\text{s}$). The surface tension force of sodium (0.16 N/m) is double that

of water (0.07 N/m). Due to these reasons, respecting all the three nondimensional numbers simultaneously is impossible in any scale size of the water model. However, the effect of Re is secondary, once the flow is in the turbulent regime, where flow pattern is not changing once $Re > 104$ and hence distortion in the Re can be permitted. Considering this, it can be shown that a scale of 0.59 is necessary to respect the Fr and We numbers exactly (Guidez and Gognet 1990). Thus the scale requirement is very large. Hence, chemicals such as sodium oleate have been proposed in literature which when added to water alter the surface tension of water. Alternatively, experiments can be carried out on a few small scale models and the results can be extrapolated for the full scale condition, based on the scale effect brought out by the study.

The mechanism of shearing gas–liquid interface depends on the horizontal velocity of sodium at the free surface. In scaled down models respecting Fr number, the velocity is always less than the prototypic value. Hence, it is essential to make sure that no entrainment takes place in the small-scale model even if the velocity is increased to the prototypic value. Based on such considerations, some researchers (Funada et al. 1991; Eguchi et al. 1994) propose equal velocity similitude (between the model and the prototype) for a conservative simulation of gas entrainment. On similar lines, Smith (1990) argues that the downward velocity level in the model should be more than the terminal velocity, if the prototypic downward velocity is more than the terminal velocity. Violation of this criterion is expected to distort the distribution of entrained bubble size. Another important aspect is that gas entrainment phenomenon is highly geometry dependent. Hence, experiments need to be carried out in models having exact geometric similarity with the prototype. The following are the major experimental findings related to gas entrainment in hot pool:

Small-scale experiments are nonconservative with respect to gas entrainment.

The nonconservatism stems from the fact that in Fr number similarity, which is normally adopted for a free surface flow, the model velocity is always less than that of the prototype. Hence, it appears that equal velocity simulation would yield realistic result.

No drain-type vortex entrainment has been observed in the model tests related to any reactor. Shearing of the interface between a liquid and gas requires large horizontal velocity at the free surface (>2 m/s) and hence this mechanism is also not expected to be present in hot pool.

Vortex-activated gas entrainment developed due to large horizontal velocities and liquid fall-induced gas entrainment developed due to large vertical velocities is the most probable mechanisms of gas entrainment in hot pool.

Established numerical methods are in vogue for the solution of Navier–Stokes equations, which govern distribution of single-phase three-dimensional flow. For the prediction of 3-D flows with deforming gas–liquid interface, numerical methods such as height function method and volume of fluid (VOF) method (Harlow and Welch 1965; Hirt and Nichols 1981) have been developed and incorporated in commercial computational fluid dynamic (CFD) computer codes. Typical diameter of spherical gas bubble, when entrainment takes place, is 0.5–10 mm. In order to capture these small gas bubbles in a computational mesh, the problem has to be solved in three-dimensions and the mesh size has to be at least one tenth of the bubble size. This results in a large number of mesh points, which is almost impossible to handle in the present day computers (Funada et al. 1991)]. To compound these difficulties, the three-dimensional numerical solution needs to be obtained in time domain to track the movement and breakup of the gas bubbles entrained. To circumvent these difficulties, the experimental approach or a combination of experimental and numerical approaches is being followed to study gas entrainment in sodium systems.

■ Figure 172

Devices to mitigate gas entrainment in hot pool

7.5.5 Design Provisions Against Gas Entrainment and Other Remarks

The free surface velocity estimated for the compact reactors SPX2, EFR, and PFBR is in the range of 0.6 m/s. Severe gas entrainment observed in the model tests of these reactors as well as that of DFBR IHX-plenum were overcome by simple solutions, like providing stiffeners and perforated plates. ➤ *Figure 172* shows a few practical options to mitigate the gas entrainments in hot pool.

The concept of purger subassemblies to vent out the gas pockets that are generated in the grid plate due to the accumulation of micro gas bubbles is well warranted to avoid the passage of the gas through the harmful regions of the core (➤ *Fig. 173*). A few purger subassemblies are positioned at the grid plate periphery, which are the preferential location for the gas segregation. After accumulation of a certain quantity, the gas escapes to the hot pool through the purger subassemblies bypassing the core. Hence, there would not be risk of reactivity effects in the core. Typically about six purger subassemblies are distributed around the outer periphery within the grid plate.

Suitable profiling of the weir-crest in the main vessel cooling system can avoid flow separation and minimizes gas entrainment.

Suitable vortex breakers have to be identified and installed in pump vessel to eliminate gas entrainment around the PSP shaft.

Figure 173
Purger subassembly to avoid gas entrainment problems in core

Hence, adequate care needs to be taken in the design to avoid any entrainment of argon, in terms of adequate submergence of heat exchanger primary inlet windows and lower levels of velocity close to the free surface.

7.6 Thermalhydraulic Design Criteria and Analysis Methods

7.6.1 Temperature Asymmetry in Cold Pool

During plant transients associated with one secondary loop, the temperature in the cold pool associated with the affected loop becomes hotter or colder than that of the unaffected loop. This leads to circumferential temperature difference in the cold pool structures, namely, main vessel, grid plate, etc. The flow coast down characteristics of the secondary sodium pump and cold pool capacity need to be arrived at such that the circumferential temperature difference (temperature asymmetry) is less than 30 K in the structures. Similarly, the flow in the main vessel cooling system is to be distributed to respect this temperature asymmetry limit.

7.6.2 Free Level Fluctuation

Due to large surface area ($>100 \text{ m}^2$) interfacing with argon, the hot pool free surface oscillates. The height of the inner vessel above mean hot pool sodium level should be adequate to avoid

overflow of hot pool sodium to cold pool. The amplitude of the fluctuation has to be minimum so that the height of the inner vessel can be minimum. The nominal temperature of hot pool is about 550 °C and that of argon cover gas is 430 °C. When the level fluctuates, structures partly immersed in hot pool and partly exposed to cover gas see alternating temperatures. From high cycle fatigue considerations, the amplitude of fluctuations has to be less than 50 mm.

7.6.3 Free Surface Velocity in the Pool

To avoid stratification risk in the pool, the velocity in the bottom part of the pool has to be high. At the same time, the velocity at the free surface has to be limited to 0.5 m/s to avoid gas entrainment. The entrainment of gas has to be limited to the extent that it does not cause any reactivity changes in the core. Continuous limited flow of argon through core is not any serious concern. But segregation of minute bubbles in grid plate to agglomerate into a larger bubble and its sudden movement into the core is to be avoided.

7.6.4 High-Cycle Temperature Fluctuation

The extent of stratification in the hot pool is a function of ratio of buoyancy forces to inertial forces. Stronger the inertial forces, the lower will be the axial temperature gradient. The stratification interface normally oscillates. Based on detailed structural mechanics calculations, it has been established that the gradient has to be limited to <300 K/m. From thermal striping considerations, the peak to peak temperature fluctuations on the structures has to be limited to 60 K for control plug and 40 K for main vessel and inner vessel.

7.6.5 Heat Loss to Top Shield

The heat loss to the top shield has to be minimum to minimize the heat load on the top shield cooling circuit. By the provision of thermal shield, the direct radiation heat load and argon convection heat load are reduced by ~50%. But this in turn increases the bulk temperature of argon cover gas. Increase in the bulk temperature will enhance cellular convection and the associated temperature asymmetry. The bulk cover gas temperature will also affect the axial temperature gradient in the structures. Cellular convection of argon in the narrow gap penetrations of the top shield has to be managed to have temperature asymmetry less than 30 K. The annular gap size and cooling conditions of the top shield are to be optimized to respect this limit.

7.6.6 Analysis Methods

The thermalhydraulic parameters can be predicted either by experimental simulations or by numerical simulations. Since sodium reacts in a strong manner with air and water with potential consequences, sodium experiments need to be designed with extra care for safety. Moreover, sodium is in liquid phase only above 98 °C. Hence, sodium experiments have to be performed at elevated temperatures. To compound these difficulties, sodium is opaque and hence flow visualization is difficult. Thus, large-scale experiments in sodium are costly and time consuming. Normal fluids like air and water cannot simulate sodium conditions for heat transfer, due to large difference in the values of their Prandtl numbers. But hydraulic conditions of sodium can

be nearly simulated by water models. Even for gases such as argon and nitrogen, the numerical simulation is cheaper and faster, especially when the number of parameters involved is large. But numerical models and the codes developed need to be validated by suitable experiments. For a successful design, a judicious combination of experimental and numerical approaches is a must. The method adopted in the design of SFR is based on performing many large-scale water experiments and limited sodium experiments to validate computer codes and then using these validated computer codes for numerical prediction of sodium flow and temperature distributions in the reactor.

The computational fluid dynamics-based approach calls for specific models for a particular phenomenon to be investigated. For example, for the prediction of gas entrainment in the pools, we need to adopt the VOF method, which is a 3-D transient simulation to predict the deformation of the free surface. For this simulation, we also need to take into account the surface tension effects. The number of grids or grid refinement has to match with the purpose of simulation. For example, to predict the deformation of the free surface, the grid need not be very fine. Coarser grid is adequate for the prediction of sodium level fluctuations that would be the input for thermal ratchetting phenomena. But to predict the onset of gas entrainment and tracking of the entrained gas bubble within the sodium, the grid has to be finer than the bubble size. Thermal striping arises due to jet instability. Conventional/standard turbulence models of $k-\epsilon$ family are adequate to predict the global features of turbulent flow. They cannot predict the intricacies of generation and decay of vortices around the jets. For a realistic simulation of thermal striping, direct numerical simulation (DNS) is essential. But to a large extent, the Large Eddy Simulation (LES) will be able to cater for the objective of thermal striping simulation. This is due to the fact that large eddies are associated with low frequency temperature fluctuations which are very critical in thermal striping. Fine eddies are associated with high frequency and low amplitude temperature fluctuations, which does not significantly alter the temperature of the structures. On the similar lines, the standard $k-\epsilon$ turbulence models have been developed and validated for forced convective regime. Application of this model for stratified sodium flow conditions requires detailed validation. Identification of suitable turbulence model for buoyancy dominated sodium flows is an on-going research in CFD.

Internationally, fast reactor pool hydraulics has been investigated successfully by many countries, especially, France, UK, USA, Japan, Russia, and India. All these countries have utilized a hybrid computational-cum-experimental approach. France has developed the TRIO-VF and TRIO-FE codes (Menant and Villand 1994). The former is based on finite volume method while the latter is based on finite element method. They have also developed the N3S code which is based on finite element method. These codes have been utilized for investigations of conventional pool hydraulics during steady and transient conditions and prediction of temperature history during thermal striping. Japan has developed many thermal hydraulic codes, namely, THERVIS-III (Yamakawa 1983) and AQUA (Muramatsu and Ninokata 1991) for pool thermal-hydraulics and DINUS-3 (Muramatsu 1993), which is a DNS code for the thermalhydraulic prediction of thermal striping.

UKAEA has developed the FLOW-3D code which has finally become the commercial CFX code (Presentation by AEA Technology – UK 1994) for the prediction of global thermalhydraulics of fast reactors. Simultaneously, academicians and consultants of UK have developed the two popular CFD tools, namely, PHOENICS (Cham Ltd.) (Farrar 1990) and STAR-CD (CD-Adapco). Russians have also developed many in-house CFD codes, of which TURBO-FLOW (Scherbakov 1994) is the notable one. India has also developed two CFD codes, namely, THYC-2D and THYC-3D for global thermal hydraulics of fast reactors.

8 Specific Structural Mechanics Issues

8.1 Introduction

Apart from excellent heat transfer properties, the use of sodium results in large margin between operating temperature and boiling point of coolant. Hence, there is no need to pressurize the system and all the disadvantages associated with the unforeseen depressurization of coolant are absent in SFR. High thermal conductivity, low viscosity, and large difference between the hot sodium and air coupled with significant variation of sodium density with temperature permit decayed heat removal through natural convection modes. It also provides high thermal inertia and hence, more time is available for the operator to act in case of exigencies without fear of any temperature raise exceeding acceptable limits.

Sodium has, however, certain disadvantages. It introduces challenging thermohydraulics and structural mechanics issues. High thermal stresses and thermal shocks are induced on the adjoining metal wall and also, the temperature fluctuations on the metal are to be considered due to sodium free level fluctuations. Temperature fluctuations are also created on the metal wall due to a special type of phenomenon called thermal striping which is caused due to lack of perfect mixing of sodium streams at different temperatures particularly in the sodium piping. The stainless steel parts when subjected to temperature fluctuations are subjected to high cycle fatigue damages. Seismic response analysis of thin walled vessels, pumps, and absorber rod mechanisms calls for complex numerical and experimental simulation techniques. These failure modes are presented comprehensively in [▶ Fig. 174](#).

8.2 High Cycle Thermal Fatigue: Thermal Striping and Stratification Instabilities

In the zones where hot and cold sodium flows meet, incomplete mixing (in spite of turbulent diffusion) can occur so that surrounding structures have to sustain temperature fluctuations on their surface. The consequence in fatigue damage (appearance of a network of cracks at the surface, [▶ Fig. 175](#)) is usually named as thermal striping. High frequency fluctuations of stratified zones if any result in similar consequences. The efficiency in rising stresses in the material is governed by

- Heat transfer at the surface of the structure,
- Thermal diffusion inside the wall of the structure.

Kasahara et al. (2002) have proposed analytic formulations of the bidimensional problem relying on a separation of these two effects and in the hypothesis of elasticity. They consider a sinusoidal fluctuation of the temperature of the fluid at the frequency f , applied to one side of a wall (the other side being in adiabatic conditions), of thickness L , thermal conductivity λ , and diffusivity a . This fluctuation will be transferred to the surface of the solid through a *heat transfer function* H , depending on this frequency f (or nondimensional frequency fL^2/a) and on the Biot number ($Bi = hL/\lambda$), h being the heat transfer coefficient.

The consequences in terms of stresses inside the material can be expressed as a stress function S of the nondimensional frequency fL^2/a , material data (thermal expansion factor, Young's modulus, Poisson's ratio), and a stress factor K determined from geometry and mechanical bounding conditions at the borders of the wall. It is worth noticing that the "gain" of the heat transfer function H decreases as the frequency increases and that the one of the stress function S

Figure 174
Failure modes for structural design

increases in the meantime. As a consequence, the resulting function $G = HS$ reflects the fact that there should exist a range of frequencies that has a maximal detrimental potential in fatigue. Figure 176 shows this effect with bending (only) constraint at the borders of the wall. A partition of the stress into different components such as membrane, bending, peak stress from this type of model was used in CEA to help fatigue analysis of complex cases (Chapuliot et al. 2005).

8.2.1 Experimental Evidence of Thermal Striping

In sodium, thermal striping has been obtained in laboratory in different dedicated loops: FAENA (Figure 177) in CEA, France, TIFSS (Figure 178) in JAEA, Japan (Lejeail and Kasahara 2005). Results are very useful for the verification of transfer functions discussed above, and check damage assessment methods discussed in Sect. 8.2.2.

FAENA used tubular (square cross section) specimens submitted to alternative hot and cold sodium injections. Mean flow rate could reach 700 l/h (velocity in the specimen 0.5 m/s), frequency range was 0.07–0.3 Hz, ΔT at the specimen inlet 398–553 K, (323–473 K at outlet), cycle numbers 10^4 to some 10^6 , surface roughness Ra 0.1–0.3 μm , and equivalent strain range at the level of the last crack initiated, 0.2–0.77%. These tests have concerned 316L and 316 LN austenitic

Figure 175
Thermal fatigue cracked surface

Figure 176
Thermal shock attenuation under thermal striping (From Kasahara et al. 2002)

grades and, to a smaller extent, 9Cr 1Mo mod martensitic steel. Some specimens were tested with successive different ranges in order to test damage accumulation rules.

In TIFSS, hot and cold sodium is alternatively fed into a nozzle and projected on a flat specimen as a vertical jet in the middle of a sodium pool. Temperature range at the nozzle is

■ Figure 177
FAENA facility

about 235°C (741–505 K), and frequencies are in the range 0.01–0.2 Hz. Specimens are 316 FR grade. In both experiments, the test specimens are fitted with thermocouples in the thickness that allow for adjustment of the temperature data, and interpretation.

Thermal striping has also been observed in reactor circuits, for instance in the PHENIX 250 MW sodium demonstration plant in France. A Tee junction of a small pipe ($T_{\text{Na}} = 700\text{ K}$, flow rate 7 kg/s) with a larger one ($T_{\text{Na}} = 610\text{ K}$, flow rate 800 kg/s) was affected by thermal striping at a location downstream from the tee, at a weld (geometrical/material discontinuity). This case was the opportunity to make an international benchmark on predictive methods (Gelineau et al. 1999), liable to be used at the design stage. Another case of mixing tee on a PWR unit has been detected and analyzed in depth from thermohydraulics, mechanics, and material science points of view (including some crack propagation aspects). The contribution of large scale flow

■ Figure 178
TIFSS facility

instability (such as pulsing) at low frequency was established, and the question of precluding such consequences at the design stage is pointed out (Chapuliot et al. 2005).

8.2.2 Assessment of Potential Damage by Thermal Stripping at the Design Stage

If fluid temperature ranges (ΔT_{fluid}) and associated frequencies (f) are known from the thermohydraulics studies (DNS, LES, $k-\epsilon-\theta^2$ methods, see “acronyms” below, experimental mock-ups), analytical solutions (such as Kasahara et al. 2002; Kasahara and Lejeail 2002) can be used. They allow for assessment of temperature and finally surface stress fields ($\Delta \sigma$ (f)) response, provided transposition of the model to more or less a complex structure (with peculiar

boundary conditions) remains relevant. It is worth noticing that this kind of method allows also for simplification of the problem by showing the most damageable frequency domain, and provided a service period is given, makes easy to get the input of the fatigue analysis as a set of $\Delta\sigma$ (N), where N is a cycle number during the said period.

An alternative case in design is to draw directly the mechanical response at the surface of the structure by chaining mechanical finite elements calculations of stresses with thermally-hydraulics. The information in terms of frequencies (cycle numbers) and stress ranges can be then derived from analysis of a time sequence long enough by some wave counting method, such as rainflow method (AFNOR 1996).

In both routes described above, stress ranges

- Are multiaxial and usually assessed according to the elastic behavior assumption for the material (so plasticity corrections are to be introduced if necessary).
- Have to be converted in strain ranges and expressed in terms of equivalent prior to enter (uniaxial) fatigue curves of the material.

For that purpose, the procedure of RCC-MR design code (2007i) for instance, for pure thermal fatigue (Additional plasticity corrections are to be applied if there is a possibility of elastic follow-up for instance, as are amplification factors related to discontinuities, if any.) is as follows. Equivalent strain variations are determined as

$$\overline{\Delta\varepsilon_t} = \frac{2}{3} \frac{1+\nu}{E} K_{vb} \overline{\Delta\sigma_{\varepsilon t}} \quad (31)$$

K_{vb} is a coefficient, which represents the difference of triaxiality between elastic and elastoplastic behavior; it depends on the elastic equivalent stress variation $\overline{\Delta\sigma_{\varepsilon t}}$, ν is Poisson's ratio, and E Young's modulus. The evaluated strain range $\overline{\Delta\varepsilon_t}$ predicts an allowable cycle number $N_f(\overline{\Delta\varepsilon_t})$ from fatigue curves of the material at the maximum temperature. Finally, Miner's rule evaluate fatigue damage factor D_f as:

$$D_f = \sum \frac{N(\overline{\Delta\varepsilon_t})}{N_f(\overline{\Delta\varepsilon_t})} \quad (32)$$

where $N(\overline{\Delta\varepsilon_t})$ is the applied cycle number of strain range $\overline{\Delta\varepsilon_t}$ and D_f is asked to remain lesser than one. This method and the one proposed by Japanese teams and their comparison versus FAENA tests can be found in Chapuliot et al. (2005).

8.2.3 Conclusion, Future Prospects

Coupled numeric simulation of thermallyhydraulics and mechanics problems offers now interesting prospect. Nevertheless, numerical simulation to predict the behavior covering the entire plant life is still costly in terms of CPU time. Extrapolation for the service duration should rely on statistical approaches that are an open field of work. Identification of damageable frequency range by simplified solutions can help to rationalize this approach.

Procedures for damage assessment exist in codes and standards. Nevertheless, establishing a safe limitation (making thermal striping analysis not mandatory) for max ΔT in design in between flows or zones of sodium at different temperatures would result in quite low values (some few tenth of degrees), which is not yet codified.

The other open topic is related to the question of consideration of a mean stress superimposed on thermal striping cycles (especially in case of small strain ranges). Most of the data and qualification of these procedures were obtained on austenitic steels. The trend in the new design of SFR is use of ferritic–martensitic steels, which appears at a first glance as favorable because of lesser thermal expansion and higher thermal conductivity of these steels with respect to austenitics. This needs confirmation by a limited number of tests in sodium. Nevertheless, more data and an in-depth analysis are desirable with water tests. A few tests have shown adverse results, raising the question of an environment effect and other considerations.

Acronyms:

DNS: Direct Navier–Stokes method,

LES: Large Eddy Simulation method,

$k-\varepsilon-\theta'^2$: Turbulent kinetic energy/rate of turbulent kinetic energy dissipation/temperature variance method.

8.3 Free Level, Stratification Level Fluctuations

SFR designs generally include the presence of a free level of sodium in some components. An inert gas (usually argon), at low pressure (max some bars), fills the space over the free level of sodium. These provisions allow for thermal expansion of sodium during temperature transients and guaranties inert chemical conditions above sodium.

Different vessels and tanks are concerned, whatever the type of concept (loop, pool):

- The main vessel itself
- The inner primary vessel that collects the hot sodium at the outlet of the core in case of pool type design
- According to the design, different baffle rings may exist (for instance, in case of design with dedicated circuit for cooling down the main primary vessel at the temperature of core inlet)
- The main primary pipes (hot, cold) in the loop type that may cross the free level in the main vessel. . .
- The dedicated expansion tanks and/or the main steam generator vessels in the secondary circuits that transfer the heat to the energy conversion system. . .

Stratifications can take place in cases of loss of forced convection trips, for instance. In both cases, axial thermal gradients are induced on the surrounding structures.

8.3.1 The Free Level Issues

They rely on the following facts:

- The projected part of shells has high-temperature inertia when compared with the part dipped in sodium, due to the very good heat transfer in sodium compared with gas.
- In the (theoretical) case of temperature step ΔT applied on a thin ($e \ll R$) shell, and with the assumption of linear behavior of the material, for instance, the stress system exhibits an axial bending maximum $\sigma_b \sim 0.3 \times E\alpha\Delta T$, and a hoop membrane stress $\sigma_h \sim 0.5 \times E\alpha\Delta T$,

the decay length along the shell affected by significant stress level being $\sim \pi/\beta$, with $\beta^2 = [3(1 - \gamma^2)]^{1/2}/e.R$

E: Young's modulus

α : thermal expansion coefficient of the material

ΔT : temperature step amplitude

γ : Poisson's ratio

e: shell's thickness

R: shell's radius

For stainless steel, 316L grade,

$R = 10$ m, $e = 2 \times 10^{-2}$ m, $T \sim 500$ °C, $\Delta T = 100$ °C, $\pi/\beta \sim 1$ m, $\sigma_b \sim 95$ MPa, $\sigma_h \sim 160$ MPa.

Furthermore, one can expect that the temperature gradient can vary and move along the shell (at free level: due to the thermal expansion of sodium associated with the transient, and/or variation of the pump speed depending on the trip considered, or in the hypothesis of stratification, by evolution of the level) as depicted by  Fig. 179.

Potential Thermomechanical Damages Associated With Free Level Issues

Their assessment requires considering the whole set of loads applied to free level zones. Nevertheless, loadings associated with mechanical loads (the so-called “primary stresses” that are not relaxable by the strain that they can yield), typically induced by inner pressure and weight, are very low in sodium fast reactors.

Basically, the thermal stresses induced by free level issues are prevailing and look like displacement controlled stresses (“secondary” stresses type in codes & standards). They must be assessed against fatigue and creep–fatigue damages, usually in the low/mean cycles (plastic) range (high frequency components come rather under  Sect. 8.1.).

In fact, such stresses are not to be considered as fully displacement controlled. The reason is that, due to temperature variation along the axis of the shell considered, the mechanical properties of the steel vary with temperature.

 Figure 179

Temperature gradients in the vessel near sodium free level

The “hot” zone exhibits a lesser yield stress with regard to the colder one. Furthermore, depending on the design and the component considered, the conditions can be such that they may be subjected to creep deformations.

As a result, both mechanisms will contribute to concentrate inelastic deformation in the hot part, while unloading the colder one: this situation is currently qualified as “elastic follow-up” in codes and standards. The potential consequences are as follows:

- Strain buildup at each cycle that can result in possible geometric increments (so-called ratchetting behavior) that may introduce functional disturbances (depending on the design)
- Effect on creep–fatigue damage because accumulation of strain that was shown to contribute to lifetime decreases if excessive; for this reason, accumulated strain has to be limited to a few percent, prior to entering fatigue–creep fatigue analysis
- Effect on creep–fatigue damage because of strain range enhancement by elastic follow up
- Risk of buckling associated with membrane compressive hoop stresses, and that may be emulated by geometric evolutions (interaction with geometric disturbances). Nevertheless, it is worth noticing that such a buckling would be limited because displacement is controlled.

Experimental Evidences of Damages Induced at Free Level

At the CEA (France), sodium experiments were made with the so-called VINIL device (➤ [Fig. 180](#)) on 316LN, on shells 800 mm in diameter, 1.2 mm in thickness, two different heights. ➤ [Figure 181](#) shows the loadings conditions and ➤ [Fig. 182](#) presents the displacements observed after 930 cycles. It is worth noticing that no buckling was observed. Other references with water devices are available (Wada et al. 1995). Japanese experiments with smaller samples (radius 76.5 mm, thickness 2 mm) on two 316 SS grades are also reported in Igari et al. (2002).

Assessment of Free level Problems at the Design Stage

Simplified Methods Early methods dedicated to this type of ratchetting (likely to occur in lack of significant primary stress, radically different of Bree type to this extent) have been proposed in Japan (Igari et al. 1993) for prediction of the strain increment by cycle. They rely on elastic/perfectly plastic material behavior, are based essentially on the membrane hoop stress, and are specific for travel of simple temperature profiles on cylinders. Refinements have been introduced later (Wada et al. 1995) for consideration of effects of axial bending stress, (low) primary stress, existence of work hardening in the material, and have been compared with small-scale water tests for 316 austenitic grades.

In France, following the VINIL tests, completed with COTHAA tests (double tubes with geometrical discontinuities, combination of thermal and primary loads, program undertaken in the frame of PWRs technology (Cabrilat et al. 1997)), a simplified assessment method was implemented in the French standard RCC-MR (2007a,b,c).

It consists, for those cycles that include membrane stresses (Q_m) induced by thermal effects, in considering that one part of this Q_m is to be combined with the membrane stresses induced by mechanical loads. The result of this combination is then used to determine the so-called “equivalent” primary stress (i.e., granted to yield the same strain as the whole set of loads) out of the “efficiency” diagram; the equivalent primary stress is finally used to check whether the strain limits are met or not. The application of both Japanese and French simplified methods to the VINIL experiments show quite a satisfactory result, with some conservatism.

■ Figure 180
VINIL test setup

Inelastic Analysis Different advanced models (i.e., beyond the elastic/perfectly plastic, isotropic hardening, and kinematic hardening bilinear models, which are disqualified intrinsically by the excessive simplicity of their description of plasticity effects) were tested against COTHAA tests ($T < 723\text{ K}$) results, in the frame of a benchmark by different teams in France in 1997 [3]. Most of these models are based on the use of non-linear laws for the evolution of the kinematic variable(s) and were used in elastic–plastic or elastic–viscoplastic formulations. The so-called “micro–macro” model that defines constitutive equations at a microscale was also tested.

■ Figure 181
Temperature variation

■ Figure 182
Displacement pattern variation

Igari et al. (2002) deals with a Japanese study, which also includes a set of models incorporating several types of kinematic hardening rules, creep being dealt with by superposition, except for the two so-called unified constitutive models.

The state of the art in the field of assessment of ratchetting on the basis of non linear, inelastic, materials behaviour models, is not yet in a position to allow for accurate results.

8.3.2 In Sodium Stratification Issues

It is clear that in sodium stratification resulting in steep temperature axial gradient in the surrounding structure, for instance, in the case of loss of flow, can lead to very similar situations and be dealt with by the same methods as free level issues.

8.3.3 Conclusion

Ratcheting induced by free level/stratification travels with negligible mechanical stress is a new area. A classical simplified method for ratcheting has been modified satisfactorily to deal with this case, and allows for conservative designs. A method specifically dedicated to the problems of thin shells at free level (short/long travels) has been shown to perform correctly compared to the experimental cases featuring the different hypothesis considered.

Further reduction of conservatism and generalization is still a matter of R&D, due to complexity of plasticity mechanisms and interactions with structures and loadings applied. To this extent, inelastic models keep a role to play.

The choice of materials too, is relevant to this problem, as differences are revealed out of simple tests, such as uniaxial stress–strain response. For instance, low carbon, nitrogen added, 316 grade stainless steel exhibits small ratcheting as compared to some others (304 grade for instance, [lgari])

It is worth mentioning that new materials considered for fast reactors, that is, ferritic–martensitic grades that exhibit softening in cyclic test, have to be studied from the point of view of the candidates for free level components.

8.4 Seismic-Induced Forces and Their Effects

8.4.1 Geologic Phenomena

Lithospheric displacements of the plates are carried out via motions along fault planes where concentrate the tectonic forces. The faults are breaks of the rigid terrestrial lithosphere accompanied by a relative displacement of the two compartments. There are basically two types of constraints or forces tectonic, which deform the rocks: compressive stresses and those of tension. In compression, the forces converge. In tension, the forces diverge and cause the material to stretch. The fault plane between two blocks is a “rough” zone on which the slip is not carried out easily. While the two blocks want to slip length one of the other, the fault is a surface of friction, which can block the motion.

The accumulation of the constraints continues until reaching a breaking value that the rocks cannot support any more. A brutal rupture then occurs. The rocks slacken: it is the earthquake. At the end of the earthquake, the constraints accumulate again along the fault until reaching a new threshold causing a new rupture: these successions of phase of activity and lull constitute the seismic cycle.

The power of an earthquake is quantified by its magnitude (magnitude of Richter is the most known scale). The magnitude is calculated starting from the various types of seismic waves

recorded by the seismographs. Richter magnitude is logarithmic scale: to increase the magnitude of one unit is equivalent to multiplying by 30 the energy released by the rupture. This scale also makes it possible to appreciate dimensions of the activated fault.

8.4.2 Seismic Risk

The seismic risk can be defined like the possibility for an area or a site to be exposed to an earthquake of given characteristics, expressed as much as possible in the form of parameters such as macro seismic intensity, acceleration, velocity, displacement, and spectrum of the temporal signal. The risk is characterized by the probability of occurrence of a given event and the vulnerability, which expresses the gravity of the effects or the consequences of the event supposed to be able to occur.

A seismic study of risk comprises three successive stages:

The first two relate to the identification of the seismic sources and the evaluation of the regional seismic motion according to a probabilistic or deterministic approach.

The third relates to the taking into account of the modifications of the seismic vibration with the geological and local topographic conditions.

The probabilistic evaluation of the seismic risk indicates, at any point of the territory, the level magnitude or acceleration of the ground (m/s^2) likely to be reached for one period of time given.

The deterministic evaluation is founded on the one hand on a detailed analysis of the various regional seismic sources and on the constraints governing the deformation and on the other hand on a precise study of the historical seismicity.

8.4.3 Site Effects of Seismic Forces

Seismic waves of the earthquake are amplified related to the topographic or geological configuration of the site. Site effects are as function of the structure and the nature of the ground: the mechanical characteristics (density, rigidity, and compressibility) and the geometry of the formations (stacking, basic filling of valley) can accentuate the effects of the seismic motion.

The seismic motion is a nonstationary, transitional, and unpredictable signal. However, it can mainly be characterized by

- The duration (ten seconds to several minutes).
- The frequency range (1–40 Hz).

The intensity characterizes the effects and local damage caused by the earthquake in a specified area. It is measured, thanks to seismometers. It is maximum plumb with the hearth of the earthquake. The scale most used in the world to measure the intensity is MSK scale (Medvedev, Sponheuer, Karnik, 1964). But EMS 1998 tends to scale replace it. (European Macro Seismic Scale). EMS 1998 Scale is adapted to current constructions. The seismic vibration can start motions of ground such as crumbling of underground cavities, cliff collapses, falls of blocks, and landslides (🕒 *Fig. 183*). Topographic effects of site: tops of hillock, lengthened peaks, and edges of plates and cliffs induce important amplification of the seismic motion.

Figure 183
Generation of seismic waves and their effects

In certain cases, the rupture of the fault plane is propagated to the surface of the ground, generating a rupture surfaces, some along the fault of a few centimeters to several meters of rejection. This propagation to the surface of the ground of the fault plane having broken depends on the initial depth of the seismic hearth (place of the fault plane where the rupture began) and magnitude of the earthquake (dissipated energy).

Temporary liquefaction of granular mediums (sandy or muddy horizons) gorged with water: seismic motion can produce a fast compression of the sediments and then the water contained in the sediments will be expelled with a brutal deconsolidation of material results: it is the phenomenon of liquefaction.

8.4.4 Effects of Seismic Forces on Structures

The physical damages due to earthquakes are depicted in [Fig. 184](#). Seismic excitation can be an important load to take under account during the design of structures. In many countries, the seismic risk is high and structures have to be designed using seismic codifications. For example, Europe recently created a codification, named Eurocode 8, dealing with seismic design of structures. Structure type has to be taken under account too; power plants have not the same design as standard building. Linear or nonlinear numerical methods can be used for the design. For example, an approximation of the structure response can be deduced from the linear response spectrum:

For a given earthquake excitation, the response spectrum is defined as the maximum displacement of a simple degree of freedom (1 DOF) structure with a damping ξ , and within a range of natural periods (or frequencies).

The maximum displacement for each frequency can be found from the computed displacement of the 1 DOF at this frequency. A plot of maximum displacement versus natural period is constructed, representing the deformation (or displacement) response spectrum.

From [Fig. 185](#), we can directly read the maximum relative displacement of any structure of natural period T (and a particular value of ξ , as damping). In order to cover the damping range of interest, it is common to perform the same calculations for $\xi = 0.0, 0.02, 0.05, 0.10$, and 0.20 . It is seen in the figure that the maximum response at short period (high frequency, stiff

Figure 184
Physical damages of earthquakes

Figure 185
Dynamic responses under seismic loadings

structure) is controlled by the ground acceleration. Low frequency (long period) is controlled by the ground displacement, and intermediate period by ground velocity. Many laboratories, over the world, are working to better understand the seismic behavior of components, equipments, and structures with experimental and numerical approaches. The objective is to reduce the consequences of earthquakes with improvement of standards and diagnosis of existing facilities.

8.4.5 Seismic Piping Behavior and Design Criteria

Context and Issues

Since the beginning of the 1980s, many R&D programs have been devoted to seismic design of piping systems. The reasons why there have been such activities on that subject are manifold:

- Piping systems do have good seismic behavior, as has been noted during real earthquakes as well as during laboratory experiments.
- Present design criteria are overly conservative.
- The application of these criteria leads to additional supports, which may be harmful from an economic and a safety point of view. Indeed, by limiting the piping system deformations, these supports can be harmful in regard to in-service loadings, such as thermal loadings.

A common objective of many of these R&D programs has been to reduce the present conservatism, but different means have been proposed to reach this goal, and none of these approaches has been totally convincing (Bertrand and Devictor 2006). So R&D programs have been pursued in order to reach sounder and more justified conclusions. The CEA R&D approach is based on the difference between the real behavior (or the best estimated computed one) with the codified methods. Criteria are applied on an elastically calculated behavior that can be significantly different from the real one: the effect of plasticity may be very meaningful, even with low incursion in the plastic domain. Moreover, and particularly in piping systems, the elastic follow-up effect affects stress distribution, for both seismic and thermal loads.

Experience feedback from seismic tests on piping has shown its ability to support very high levels of acceleration that are unacceptable under the current criterion (Farvacque et al. 2003).

Characterization of Nonlinear Behavior of Piping Systems under Seismic Loading

In piping system, the weakest parts are the elbows, where stress concentrations may be high. Under intense seismic loading, they are subjected to cyclic loads causing them to work in the plastic domain and resulting in consumption of a substantial amount of the kinetic energy of the piping. We therefore concentrated exclusively on these components to quantify the margins (the difference between the criterion and failure) inherent in the current criterion to establish a new one using the ductility of the piping.

A large number of static tests on elbows (➤ Fig. 186) and straight parts to the point of failure show that:

- Failure of elbows, under static conditions, is due to the plastic instability that appears when a certain angular threshold is reached (angle of closure).
- The limit angle depends weakly on the geometrical parameters of elbows, but more on the mode of bending of the elbow (in the plane or out of the plane), the internal pressure conditions, and the properties of the materials (tensile curve).
- A limit angle to avoid failure can be defined for a given material and a bending mode.
- Failure moment of straight parts is due to the buckling. This failure moment depends weakly on the geometrical parameters of straight parts but more on materials, and it does not depend on internal pressure conditions.

■ **Figure 186**
Actuator system for testing elbows

Seismic tests carried out on the Azalée shaking table (► [Fig. 187](#)) of the Tamaris facility (Blay et al. [1997a,b](#)) shows that:

- Pipe failure does not occur at the seismic levels that were reached during the tests (around 3 g in ZPA),
- Seismic failure is attributed to plastic instability, as under quasi-static conditions. This is not an oligocyclic fatigue problem, as around a thousand cycles would be required, which is not compatible with seismic excitation.
- The seismic response of the piping can be calculated with a linear kinematic strain hardening model for the plastic behavior.
- Calculations confirm that extremely high seismic levels are necessary for failure to occur.

The New Earthquake Design Basis Criterion

The new criterion proposed has the following form:

$$\sigma_{ref} = \left[\left(D_1 \frac{PD_e}{2h_c} \right)^2 + \sum_{i=1,2,3} \left(D_{2i} \frac{M_i}{Z} \right)^2 \right]^{1/2} \leq S_{adm} = k S_r \quad (33)$$

with

D_e , h_c , and Z geometrical parameters,

D_i stress intensity coefficients, depend on the component and the type of loading,

■ Figure 187
AZALEE shaking table

S_{adm} allowable stress taking into account margin k (corresponding of RCC-MR level) and failure stress S_r

P and M_i , the pressure and the elastic moments (response spectrum method for seismic load)

Moments M_i are elastic moments calculated in accordance with usual practice:

$$M_i = |M_i^p| + g_d \left(|M_i^d| + |M_i^{ds}| \right) + g_s |M_i^s| \quad (34)$$

M_i^p moment due to loading of the imposed force type (static accelerations, forces or weights, etc.).

M_i^d moment due to loading of the imposed displacement non-earthquake type (thermal expansion, etc.).

M_i^{ds} moment due to seismic differential displacement of the anchor points.

M_i^s moment due to the dynamic effects of the earthquake (inertial part) and other reversible dynamic loading.

g_d and g_s are reduction coefficients lower than 1 applied to elastic thermal and seismic moments.

The reduction coefficients is a way to take into account the elastoplastic behavior by Elastic Follow-Up method (extend Roche method).

8.5 Fluid Structure Interaction in the Fast Reactor Cores

The coupling between the movements of structures with fluid is called “Fluid Structure Interaction,” or “FSI.” Many different physical phenomena are concerned (Gibert 1988; Delangre 2001; Fritz 1972; www.cast3M.fr): the phenomena of interest in the Fast Reactors will only be considered here.

In the Fast Reactor cores, the fluid is the sodium. The excitation of the fluid–structure system may be an external loading (earthquake, impact) or, eventually, the fluid flow. Many different structures of the reactor are concerned. Important FSI R&D programs have been performed in the last decades, during the first generation of the Fast Reactors, for example, on the seismic behavior of the core (Buland 1995; Fontaine 1997): and to the stability of the vessels under fluid flow. The results of these programs have to be used in the Gen IV program.

It has to be noticed that, for many applications, the methods to take into account the FSI phenomena have been improved from the first studies on the Fast Reactors, in the understanding of the physical phenomena, in the numerical methods, and in the capacities of the computers. These new methods will allow, in the frame of the Gen IV program, to get a better understanding of the already studied phenomena (seismic behavior of the core, stability of the vessels), and to investigate new phenomena also. Here are presented:

- A short description of the mechanical structure of the reactor.
- Some elements on the methods to take into account FSI (modeling and numerical methods).
- Elements on the seismic behavior of the fast reactor cores: the movements of the assemblies lead to variations of the volume of the core with changes in the nuclear behavior of the core.
- Elements on possible vibrations of the vessels under the sodium fluid flow.
- Elements on new points to be investigated, using the now available FSI methods.

8.5.1 Short Description of the Structures of the Reactor

➤ *Figure 188* presents two schemes of the main vessel of a Fast Reactor: pool and loop configuration, and a mock-up of the core. In the “pool” reactors configurations, the vessels are very thin. It is necessary to control a possible buckling under thermal loading. In the analysis of the dynamic behavior, the vessel cannot be considered as a rigid boundary, and interactions could take place between the movements of the fluid and deformations of the vessel. Instabilities due to the fluid flow could take place. The core is constituted of beams (fuel assemblies, neutronic shields, etc.) immersed in the sodium. The confinement is high (thin space between two assemblies).

8.5.2 Methods to Take into Account FSI

It is necessary, in a FSI problem, to solve the coupled system constituted of the structure equations and the fluid equations (Gibert 1988; Delangre 2001; Axisa and Antunes; Fritz 1972). In the general case, the Navier–Stokes equations are used for the fluid. Depending on the

Figure 188
Fast reactor vessel, mock-up of a core

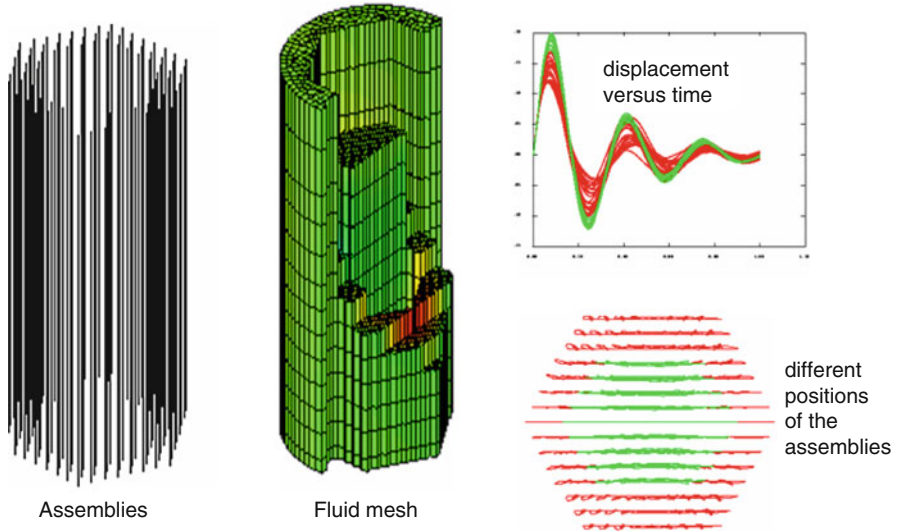

Figure 189
FSI phenomena in SFR core

conditions, simplifications can be made. In some cases, the Euler equations (more simple than the Navier–Stokes) may be used. Important improvements have been made in the methods to study FSI problems: in the understanding of the physical phenomena, in the numerical methods, and in the capacities of the computers. More accurate methods can be applied to the dynamic behavior of the Fast Reactors. For example, the use of homogenization methods for the dynamic behavior of tubes bundles immersed in a fluid will allow to perform simulations and analysis on a whole core (Sigrist and Broc 2007). The size of the mesh is strongly reduced

■ Figure 190

Three-dimensional modeling of the FSI in a fast reactor core (generic case)

as only one fluid element is needed for one beam in 2D calculations, or 20 fluid elements for a 20 elements 3D assembly beam.

8.5.3 Seismic Behavior of the Fast Reactor Cores

The main physical FSI phenomena in a SFR core are presented in ► [Fig. 189](#): the confinement is high (a). The space between two assemblies is thin and the fluid velocity may be much higher than the structured ones (a). Important FSI will take place, with inertial effects (with lower natural frequencies) and dissipative effects also (with higher damping). FSI will be higher for “breathing” modes (b, decrease of 60% of the frequencies) and lower for global movements (c, decrease of 15% of the frequencies). ► [Figure 190](#) presents an example of the calculations, which can be made now on a whole core, by using the homogenization methods.

8.5.4 Design Model for the Seismic Behavior of the Core

The design models for the seismic behavior of the Fast Reactor cores consider that the study may be reduced to the central row of the assemblies. So, the size of the problem is lower. Research programs (Buland 1995; Fontaine 1997) have shown that this hypothesis is not valid. Interactions take place, by the fluid, between the assemblies in the whole core. It is no more possible to reduce the study to the central row. A new design model has to be built.

■ **Figure 191**
Overflow instability in the SPX fast reactor

8.5.5 Overflow Instabilities

Weir instabilities could occur, in the SPX reactor, depending on the operating conditions, which is depicted in  *Fig. 191*. Such phenomena are due to the fact that the vessels are very thin, with a low stiffness.

8.5.6 New Fluid Structure Interaction Phenomena to be Investigated

Due to actual analysis of FSI methods, it is possible to get a better understanding of the phenomena in the Fast Reactor cores. It has been seen, for example, that the “one row” design model for the seismic behavior of the core is no more valid. A new model has to be built, taking into consideration the interaction between the assemblies in the whole core. Global investigation will have to be done to identify improvements of already identified phenomena or new phenomena as well (for example, coupling by the fluid between the vessels and the core).

8.6 Buckling of Thin Shells

It is well known that large diameter thin walled shell structures are prone to buckle under compressive stresses. In SFRs, pool type concept has such vessels, namely, main vessel, inner vessel, thermal baffles, and safety vessel, which have to be checked against this failure mode ( *Fig. 192*). Further, box type structures such as top shield, grid plate, and core support structure constituted by plates have buckling risks ( *Fig. 193*).

For these vessels/plates, generally lower wall thickness is selected due to (1) low design pressure at the operating temperatures (sodium coolant can remain in liquid state up to about 950 °C); (2) requirement of adequate flexibility under various operating conditions (550 °C for hot pool and 400 °C for cold pool under steady state, isothermal temperature of 220 °C

Figure 192
Thin shells/plates in SFR having risk of buckling

Integrated seismic forces concentrated at mass center

■ **Table 29**

Dimensions of main vessel and primary sodium masses of international SFRs

Parameter	Phenix	PFR	BN-600	SPX 1	PFBR	EFR
Diameter (m)	11.85	12.25	12.92	21	12.9	17.2
Thickness (mm)	15	25	30	24	25	35
Diameter/thickness	790	490	431	875	516	491
Primary Na mass (t)	800	850	770	3,200	1,150	2,200

during shutdown, and thermal transient of about 15 K/s during reactor scram); and (3) economic considerations, since the capital cost is directly linked to the steel consumption. The diameter to thickness ratios (D/h ratio) of main vessel of few international reactors is presented in ► [Table 29](#): the table indicates that D/h ratios lie in the range of 430–875; thus they are considered as slender.

The loads such as self weight, sodium pressure head, temperature, and thermal gradients are generally not critical under normal operating conditions. However, the forces generated under seismic events impose important loadings to the structures to cause buckling. The reasons for this are elaborated as follows.

The vessels, namely, main vessel, inner vessel, thermal baffles, and safety vessel are generally over hanging with “cantilever type” support arrangements as seen in ► [Fig. 192](#). For example, let us consider a top supported main vessel, carrying heavy liquid mass and dead load due to core and other internal structural mass (1,150 t of sodium with 700 t of other load acting at the vessel bottom for PFBR). This vessel would have natural frequency lying in the range 5–10 Hz where seismic force amplification is generally the maximum. Further, there exists relatively thin annulus of liquid between: (1) inner vessel to inner baffle, (2) inner baffle to outer baffle, (3) outer baffle to main vessel, and (4) main vessel to safety vessel under the event of main vessel leak. The radial annulus gap to diameter ratio lies around $\sim 1/100$ and the sodium confined in this space enhances added mass to the adjoining shells to reduce the natural frequencies, as well as generates high dynamic pressure during seismic events. The existence of large free fluid surfaces is the source of sloshing, which generates significant convective masses and forces under seismic events. Apart from seismic forces, stationary as well as cyclic loads do cause buckling, which are of different kinds in these shells. Nature of buckling of thin shells of SFR can be broadly classified as follows:

- *Shear buckling*: caused by shear stresses in plates and shells
- *Shell mode buckling*: constituted by circumferential waves caused by compressive membrane stress due to axial and bending stress in shells.
- *Localized shell mode buckling*: caused by local axial membrane compressive stress caused by axial thermal stress gradients, in shells near sodium free level.
- *Progressive buckling*: caused by combined steady axial stress of mechanical origin and cyclic variation of axial thermal stresses in shells.
- *Creep buckling*: caused by creep deformation of shells operating at high temperature.
- *Bowing mode*: created on plates subjected to compressive membrane stress.

The structural portions and associated buckling modes are presented in the ► [Table 30](#).

■ **Table 30**
Important buckling modes for various thin shells

Governing loads	Buckling mode
<i>Main vessel – cylindrical portion</i>	
Shear forces generated under seismic excitations	Shear mode
Cyclic axial temperature distribution in the vicinity of free level due to variation of levels	Progressive buckling
<i>Main vessel – bottom dished head</i>	
Combined effects of hydrostatic pressure of sodium and axial force acting at triple point under normal and seismic loading conditions	Shell mode
<i>Inner vessel – torus/redan portion</i>	
Combined mechanical and axial and through-wall temperature gradients	Creep buckling with shell mode
<i>Inner vessel – upper cylindrical portion</i>	
Cyclic axial temperature distribution in the vicinity of free level due to variation of levels	Progressive buckling
<i>Thermal baffles – top cylindrical portion</i>	
Cyclic axial temperature distribution in the vicinity of free level due to variation of levels	Progressive buckling
<i>Thermal baffles – bottom portion above the support</i>	
Combined effects of hydrostatic pressure of sodium under normal and seismic loading conditions	Shell mode
<i>Grid plate – top plate</i>	
Compressive stress developed under hot shock	Bowing
<i>Roof slab – top plate</i>	
Compressive stress developed due to self weight, weight of components mounted on it plus inertial forces generated under seismic events	Bowing
<i>Roof slab – stiffener plate</i>	
Shear force transmitted by stiffeners under normal and seismic loading conditions	Shear buckling
<i>Roof slab – bottom plate</i>	
Sodium slug impact pressure plus compressive stress developed under core disruptive accident	Bowing (concave upward)

8.6.1 Buckling Design Approach

In order to ensure that there is no risk of buckling, it is required to determine the critical loads at which buckling occurs in the first step by taking into account all the possible parameters which govern the phenomenon. The important parameters, apart from nominal geometrical and normal loading parameters, are geometrical deviations introduced during manufacturing, which are acceptable from functional point of view, elastoplastic behavior of structural material, thermal loads, seismic-induced forces, and dynamic pressure. Matured buckling design charts are presented for the standard symmetrical shells such as cylindrical, conical, spherical, and tori-spherical heads, subject to external pressure in design codes, namely, RCC-MR: Appendix A12 (RCC-MR 2007) and ASME Sec III Div 1 (2007). These aspects are not repeated here. In view of special geometrical features (mainly 3-D with stiffeners), presence of thermal loads which may be stationary or cyclic, concentrated loads at some selected locations, asymmetrical forces generated under seismic loadings, geometrical deviations to respect the functional limits and creep effects, the thin shells of reactor assembly call for special buckling analysis methods. The critical buckling loads/load combinations should be derived through detailed analysis. Simplified analysis methods are available to certain extent and presented in design code RCC-MR: Appendix A7 (2007). However, detailed analysis is inevitable in SFR design of thin shells, to determine the buckling loads realistically. Toward this, computer codes such as ABAQUS or CAST3M (CEA 2003) are used extensively. Since there are many uncertainties in buckling analysis of thin shells under the complex loading conditions, experimental validations are, however, essential to raise the confidence.

It should be ensured that the design loads specified for the components should be less than the critical buckling loads with appropriate factors of safety (FOS). Design codes specify the minimum FOS required. These factors of safety depend upon the various service loading conditions. As per the French design code RCC-MR, which is judged to be the most appropriate for FBR geometry and loading conditions, that is, for the normal, upset, and abnormal loads, categorized under “level-A loadings,” the highest FOS, equal to 2.5, is required. For emergency loading conditions, categorized under “level C loadings,” FOS specified is 2. For the faulted condition, the minimum FOS of 1.3 is sufficient. To respect these buckling design criteria, it is required to estimate the buckling loads either computed numerically or determined experimentally.

It is clear that the determination of critical buckling loads is essential for the buckling design. In SFR, thermal and seismic loadings are important to be considered. As far as thermal loads are concerned, both stationary and cyclic loadings should be seen. The seismic loadings involve combination of axial, bending, and shear forces, in association with dynamic pressure distributions on the shell surfaces. The determination of both mechanical and thermal loadings calls for detail analysis, which is not covered here. However, method of idealization of seismic forces is presented.

8.6.2 Simplified Analysis Method for Buckling of Shells Under Seismic Loadings

For applying simplified methods, the geometry and applied stresses should be idealized. The idealized geometry considered for main vessel is a cylindrical shell of mean radius R , height H , and wall thickness h , which is subjected to axial compressive stress σ_a , bending stress σ_b , and

shear stress τ . The height of vessel (H) is taken in the analysis as the sum of the actual height of the cylindrical portion and one third of the height of the dished head (RCC-MR 2007). The basic material properties are Young's modulus (E), average yield stress (S_y), and Poisson's ratio (ν).

Derivation of Idealized Stresses

Under normal operating conditions, the cylindrical portion of the main vessel sees only tensile stress due to dead loads, and hence, there is no risk of buckling. However, seismic event generates axial compression due to vertical excitations and bending moment and shear forces due to horizontal excitations. These forces are generally extracted from detailed seismic analysis of vessel and its internals including fluid–structure interaction effects, which are difficult to obtain by either hand calculations or simplified analysis.  Figure 193 depicts the peak forces and bending moment generated at the mass center of reactor assembly, which have been arrived at by integrating the appropriate stress distributions.

The distribution of various stresses as extracted from detailed analysis, do not vary uniformly in view of inertial local forces developed at the intermediate locations. Hence, for applying any simplified methodology to check the buckling strength, stresses are to be linearized, conserving the axial force, shear force, and bending moment generated, which are termed as σ_{a-cr} , σ_{b-cr} , and τ_{cr} . The distribution of various linearized stresses is depicted schematically in  Fig. 194.

Derivation of Allowable Buckling Strength for Main Vessel Straight Portion

Critical axial compressive, bending, and shear stresses (σ_{a-cr} , σ_{b-cr} , and τ_{cr}) are obtained through empirical correlations that have been recommended based on extensive testing and evaluations in Japanese design guidelines (Akiyama 1997).  Figure 195 depicts the static deformations created by these three stresses, and  Fig. 196 depicts corresponding buckled modes.

 Figure 194

Linearized stresses on the main vessel cylindrical portion

■ Figure 195
Unbuckled deformation modes created by linearized stresses

■ Figure 196
Critical buckling mode shapes

Critical axial compressive stress σ_{a-cr} :

$$\sigma_{a-cr}^e = 0.6 \times \left[1 - 0.901 \times \left\{ 1 - \exp \left(-\frac{1}{16} \sqrt{\frac{R}{h}} \right) \right\} \right] \cdot \frac{Eh}{R} \quad (35)$$

$$\sigma_{a-cr} = \sqrt{\frac{1}{(1/\sigma_{a-cr}^e)^2 + (1/S_y)^2}} \quad (36)$$

Critical bending stress σ_{b-cr} :

$$\sigma_{b-cr}^e = 0.6 \times \left[1 - 0.731 \times \left\{ 1 - \exp \left(-\frac{1}{16} \sqrt{\frac{R}{h}} \right) \right\} \right] \cdot \frac{Eh}{R} \quad (37)$$

$$\sigma_{b-cr}^p = \sqrt{\frac{1}{(1/\sigma_{b-cr}^e)^2 + (1/S_y)^2}} \quad (38)$$

Critical shear stress τ_{cr} :

$$\tau_{cr}^e = 0.8 \frac{4.82}{(H/\sqrt{Rh})^2} \cdot \sqrt{1 + 0.0239x \left(\frac{L}{\sqrt{Rh}} \right)^3} \cdot \frac{Eh}{R} \quad (39)$$

$$\tau_{cr}^p = \sqrt{\frac{1}{(1/\tau_{cr}^e)^2 + \sqrt{(3/S_y)^2}}} \quad (40)$$

Effects of Geometrical Imperfections

The geometrical imperfections are expressed as form tolerance, which is the maximum radial deviation (δ) achieved during the manufacturing stage (► Fig. 197). The maximum δ value assumed in the above equations (25–30) is $h/2$. This reflects the possible manufacturing deviations of the practical SFR components. If such imperfections should exceed the value, that is $\delta > h/2$, then, it shall be necessary to reduce the allowable strength obtained by a correction factor, computed from the following equation.

$$\eta = \frac{1}{(1 + 0.092(X - 1)^{0.9})} \quad (41)$$

■ Figure 197
Definition of form tolerance

Figure 198
Buckling strength reduction factors

where X is equal to $2\delta/h$ for shear force (applicable for main vessel undergoing shear buckling) and $4\delta/h$ for bending moment (applicable for inner vessel and thermal baffles, undergoing shell type of buckling). The formula recommended in (31) has been derived based on extensive tests conducted (Fig. 198) for establishing Japanese design code (Akiyama 1997). The critical buckling stress values arrived at through application of (26, 28, and 30) are to be multiplied by appropriate η values.

Effects of Interaction among Various Buckling Modes

Seismic forces are acting simultaneously, even though peak values may not occur at the same time. Hence, it is required to consider the effects of interaction among forces and moments. For quantifying the interaction, Japanese design procedure (Akiyama 1997) is followed, which is given in the following equations.

FOS for the individual cases are computed using the following (32):

$$\begin{aligned}\lambda_{\text{axial}} &= \sigma_a / \sigma_{a\text{-cr}}^p \\ \lambda_{\text{shear}} &= \tau / \tau^p \\ \lambda_{\text{bending}} &= \sigma_b / \sigma_{b\text{-cr}}^p\end{aligned}\quad (42)$$

The effective FOS, taking into account the interaction among axial, bending, and shear buckling modes (λ_{eff}), are obtained from the following (33), which has been derived based on empirical fitting of extensive experimental data.

$$1/\lambda_{\text{eff}}^5 = 1/\lambda_{\text{axial}}^5 + 1/\lambda_{\text{shear}}^5 + 1/\lambda_{\text{bending}}^5 \quad (43)$$

The λ_{eff} values are computed both for operating basis earthquake (OBE) as well as safe shutdown earthquake (SSE) and it should be ensured that they are higher than the appropriate minimum FOS, specified in the design code (25).

8.6.3 Thermal Buckling Due to Stationary Temperature Gradient

Thermal loading is defined by temperatures and temperature gradients. For the main vessel, inner vessel and thermal baffles, the locations in the vicinity of sodium free level are critical, due to high axial thermal stresses developed due to sharp temperature gradients. This apart, the inner vessel is subjected to large through-wall temperature gradient and axial temperature gradients in the redan portion. The effects of these thermal loads on the buckling behavior of shells should be seen critically.

A few experimental works are reported in Brochard et al. (1991) and the following are the experimental observations:

The tests on cylindrical shell subjected to external pressure indicate that the reduction of buckling load is marginal (<20%), which is mainly due to the reduced value of material properties, namely, Young's modulus and yield stress and also amplification of initial geometrical imperfections caused by thermal stresses. The amplification of imperfection depends upon the thermal gradients as shown in  Fig. 199 for a typical case of cylindrical shell subjected to external pressure.

Tests conducted on many thin shells (400 mm diameter and 0.8 mm thickness) with a large axial temperature gradients do not indicate any onset of buckling ( Fig. 200). Hence, it can be said that pure stationary thermal gradients do not cause buckling cause. However, thermal gradients cause large plastic strains in the form of local buckling due to thermal stresses developed in the vicinity of interfaces.

Tests on thin cylindrical shells subjected to axial tension and the axial gradient of temperature are reported in Combescure and Brochard (1991). The amplitude of the buckles is of about three or four times the thickness, when the cylinder is hot, but the residual buckle at room temperature is about one tenth of the thickness. A few experimental results are given in  Fig. 201 which shows that no buckling could be observed when there is no sufficient axial tension. Different load histories were also studied and one sees that the buckling is possible under tensile stress with the axial gradient of temperature ( Fig. 201).

 Figure 199

Amplification of geometrical deviation versus thermal load

■ **Figure 200**
Symmetric bulging of shell subjected to sharp axial thermal gradient

■ **Figure 201**
Effect of axial tension on thermal buckling

Theoretical analysis of critical buckling load under thermal loads is performed as follows (Brochard et al. 1991). First assuming that the structure is perfect, that is, there is no imperfection, elastic buckling analysis is performed with the applied mechanical and thermal loads and buckling mode is extracted. In the second phase, “large displacement elastoplastic analysis” is performed through incremental computation, introducing the geometrical deviations parallel to the buckling mode of the perfect structure, from which the ultimate load is calculated. The amplitude of deviations is chosen in two ways:

- Maximum deviation of the measured defect for 3-D buckling analysis.
- Amplitude of the measured deviation for a particular buckling mode harmonic, obtained by a Fourier decomposition of the deviations.

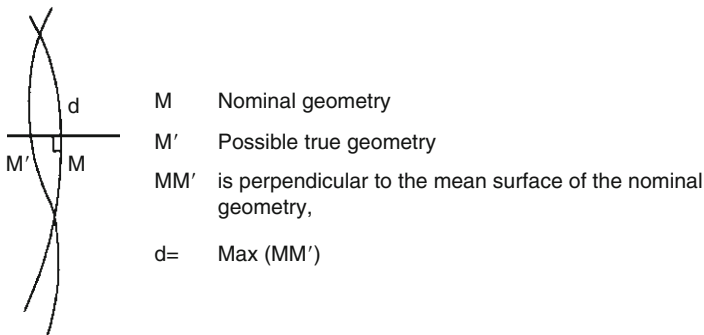

The above calculations can be performed with CAST3M, developed by CEA. A few benchmark analyses indicate that in the presence of thermal gradients, the computed critical buckling load is found to be too conservative in comparison with experimental results. In fact, it corresponds to the formation of a stable buckling mode, the amplitude of which is limited to a very small value (less than shell thickness). Hence, from an experimental point of view, it can be said that the structure does not buckle. The incremental computations on the imperfect structure give ultimate loads, which are in good agreement with the experimental results.

8.6.4 Progressive Buckling Due to Moving Temperature Gradients

When the axial temperature gradient is moving up and down along the cylindrical shell (🔍 Fig. 202), the shell develops wrinkles (indication of buckling), and the amplitude of wrinkles grows progressively as the number of thermal cycle increases. This is called progressive buckling. Typical buckled mode shape is included in 🔍 Fig. 203.

■ Figure 202
Buckled mode in the shell subjected to moving temperature gradient

■ Figure 203
Definition of "d"

Figure 204
Efficiency index diagram (RCC-MR, 2007)

Based on extensive testing and evaluation, the design rules have been proposed in Clement and Drubay (1991), which are highlighted below:

The basic parameters required are geometric deviation “ d ,” as illustrated in Fig. 203, primary membrane, and bending stress intensity ($P_m + P_b$) caused by mechanical load acting along the shell and stress intensity range created by cyclic variation of axial stress intensity (ΔQ). These apart, yield stress of material ($R_{0.2}$) is also required.

The first step is to determine the effective primary stress intensity ($P_{\text{eff}} = (P_m + P_b)/\nu$), and efficiency index “ ν ” is derived from efficiency index diagram as shown in Fig. 204, knowing the value of $\Delta Q/P_m$.

Second step is to determine the instability stress σ_I , which is derived from the interaction diagram presented in Fig. 205. Once the kind of buckling (elastic or plastic buckling) is defined and d value (here it is equal to deviation/diameter) is also known, “ x ” and “ y ” are extracted, from which σ_I (minimum value) is computed knowing S_y and P_{Euler} .

8.6.5 Creep Buckling

Creep buckling occurs on the shell, which is prone to buckle under compressive stress field, even though the applied stress is less than the critical stress, after a certain time period. The prediction of creep buckling is very difficult because of many uncertainties, particularly in the material parameters. The geometry of the structure and its deviations have to be well defined to have accurate prediction of failure loads. Hence, design rules have been developed (Combesure 1999), based on the case of shells subjected to external pressure axial compression. The instability of mechanism is the following: When the initially imperfect shell is loaded

■ Figure 205

Determination of instability stress

by the external P_0 , it undergoes a constant axial symmetric displacement (W_0), which produces a hoop membrane stress “ σ ,” as well as a circumferential mode “ m ” displacement field. The initial mode “ m ” imperfection amplitude ξ_0 increases to a value ξ_1 . If this does not lead to instantaneous failure by the formation of plastic hinge or elastic instability, then the creep buckling can take place. If a relatively high initial load is applied on a perfect structure, an elastic instability induced by evolution of the initial imperfection by creep is likely mechanism. This is also the case, when material is essentially elastic. If the initial imperfection is greater or the initial load P_0 is lower, it can be easily imagined that the instability will be of the plastic hinge type.

Design Rules for Creep Buckling as per RCC-MR (2007)

In the event of significant creep, the method described in the A75000 may be used to determine whether a structure subjected to thermomechanical loadings leading to primary stresses is prone to buckle at a lower loading level than the level that would cause instantaneous buckling, given the operating temperature and the holding time at this temperature. This method requires the calculation of both the critical Euler load and the load that causes the structure to start plastic flow. The method is limited to shells made of austenitic steel SS 316 LN. Where post bifurcation is unstable, steps shall be taken to ensure that the instantaneous critical load is virtually the same as would be obtained with the same structure if the post bifurcation was stable. The method comprises the following seven steps:

- Determine the operating temperature of the structure θ_m (maximum mean temperature in the thickness) and corresponding hold time t_m .

Figure 206

Typical design charts for assessing creep buckling in thin shells

- Calculate the critical Euler load at temperature θ_m ; this load P_E is obtained by an elastic buckling computation with no geometrical imperfection.
- Calculate the load at which the neutral fiber of the structure starts plastic flow. This load P_L is obtained with an elastic calculation of the structure, given the minimum yield strength $(R_{p0.2})_{\min}$ at temperature θ_m .
- Calculate the slenderness ratio for the structure P_E/P_L and select the diagram corresponding to the next largest P_E/P_L . It is also possible to select the diagrams that correspond to next largest and next smallest P_E/P_L ratios and then by linear interpolation, construct the instability curve corresponding to the instant t_m or both curves enclosing it. [Figure 206](#) shows two typical design charts.
- Calculate ratio $x = P/P_E$, where P is the nominal load multiplied by the margin coefficient for the specified condition of loading.
- Determine factor $\delta = d/h$ (ratio of geometrical imperfection over thickness).
- If point $M(x, \delta)$ lies beneath the instability curve at instant t_m , then buckling due to creep will not occur. On the selected diagram, the instability curve at instant t_m , could also be obtained by logarithmic interpolation.

8.6.6 An Integrated Buckling Analysis of Thin Vessels of Reactor Assembly

In [Sect. 8.5.3](#), simplified analysis method has been presented. In this section, detailed analysis procedure is described. The procedure consists of three broad steps: (1) natural frequency analysis, (2) seismic response analysis and (3) buckling analysis using established finite element computer codes. The natural vibration and seismic response analyses are performed for the reactor assembly components, including the essential internals and sodium. In case of axisymmetric analysis, Fourier option can be chosen, appropriately, to account for the circumferential variations of loads. Seismic analysis is to be carried out in time domain to determine the stresses at every discrete time steps involved. Subsequently elastic buckling analysis can be carried out at any time, knowing the stress distributions at the corresponding time step. Since the number of time steps required for the dynamic analysis (total duration of seismic event/minimum time steps for stable solution) is generally very large, carrying out buckling analysis at every time

step, covering the entire time steps, is computationally very expensive. Hence, it is appropriate to choose a few selected time steps, called “critical time steps” at which buckling analysis can be carried out, which provides lowest buckling loads. This should be based on a robust criterion. Critical time step is an instant during the earthquake at which the buckling load factor is possibly the minimum, for a particular vessel. The buckling load factor generally depends upon the magnitude of compressive stress field developed in the structure. In the complex structures where the compressive stress varies over the length, it is difficult to identify a particular value, which decides the buckling of the vessel. Hence, it is necessary to identify a global parameter. In this regard, the critical time steps are selected based on the integrated strain energy absorbed by the entire vessel or a few selected locations of vessel prone to buckle. As far as reactor assembly is concerned, the main vessel, inner vessel, and thermal baffles are the important shell structures, which are to be checked for buckling risks. Specifically, the cylindrical portion of the main vessel (prone to buckle under shear stress), the torus portion of the inner vessel (prone to buckle by meridional compressive stress), and the upper cylindrical portions of the thermal baffles (prone to buckle under hoop compressive stress) are the critical parts in the reactor assembly. Accordingly, the strain energies that are associated with shear, meridian, and hoop compressive stress distributions, respectively, in the critical portions of main vessel, inner vessel, and thermal baffles are computed at each time step, which forms part of seismic analysis. Subsequently, buckling analysis can be restricted only at these time steps, where strain energy is highest.

In order to account for the possible randomness on the applied support time histories, three time histories are artificially generated in each direction: (1) nominal time histories, (2) modified time histories by compressing the time scale by about 10%, and (3) modified time histories by expanding the time scale by about 10%. This implies that the above analysis should be repeated thrice and finally, the lowest buckling loads can be arrived at. More details of seismic analysis, such as generation of support time histories, idealization of geometries, boundary condition, kind of damping values to be applied, and practical application to the buckling analysis of PFBR vessels, are presented in Chellapandi et al. (2008). Some specific aspects to be applied and summary of the results are presented in the following paragraphs.

Geometrical Idealizations

The finite element model (FEM) generated with CAST3M, consists of structures (main vessel, inner vessel, outer and inner thermal baffles, CSS, grid plate, core, control plug, top shield, and support skirt), hot and cold sodium pools, sodium in the feeding and restitution collectors, sodium–shell interfaces, and sodium free level boundaries for predicting sloshing. The structures are modeled with “2-noded conical shell elements.” The sodium is modeled with “4-noded quadratic elements.” Special element called “RACC” is used for fluid–structure interaction effects at the sodium–shell interfaces. In order to simulate the sloshing behavior, five free level surfaces in (1) feeding collector, (2) restitution collector, (3) cold pool between inner vessel and inner thermal baffle, (4) hot pool, and (5) hot pool within control plug are considered. In the FEM, apart from the masses of core, grid plate, CSS, control plug, and top shield, the self-masses of main vessel (156.9 t), inner vessel (63 t), thermal baffles (68 t), and sodium (1,150 t) are automatically included. Thus, the total mass of reactor assembly including sodium (3,409.4 t) is preserved. The top edge of support skirt is fixed at which support excitations are applied. The FE mesh developed for the analysis is shown in  Fig. 207.

■ Figure 207
FE model

Natural Vibration Analysis

Analysis is performed to determine the natural frequencies up to 50 Hz. Three mode shapes depicting (1) rocking of inner vessel along with CSS, grid plate, and core about the triple point of the main vessel (1.23 Hz), (2) swaying of core along with inner vessel about grid plate (2.8 Hz), and (3) swaying of main vessel along with thermal baffles about the reactor assembly support (5.2 Hz) are shown in [Fig. 208](#). These modes have the dominant modal masses of 1,370 t, 534 t, and 1,785 t respectively. The modes having frequencies 1.23 Hz and 2.8 Hz can contribute significantly in generating high seismic forces on the inner vessel and the mode having 5.2 Hz has significance from the point of imposing forces on main vessel and thermal baffles, as seen from the respective modal displacements.

Seismic Response Analysis

Axisymmetric analysis is carried out for determining displacements, velocities, and accelerations with Fourier option assigning the harmonic wave number, equal to one applicable for the horizontal excitations and 4% damping value applicable for the mechanical components under safe shutdown earthquake (SSE). Totally, six analyses are carried out: three for X and three for Y directions by employing three support time histories (time scale compressed, nominal, and time scale expanded) for each direction. Analysis is carried out up to 20 s with the time step size of 0.001 s consistently for all the calculations.

■ **Figure 208**
Critical buckling mode shapes for the reactor assembly vessels

Strain Energy Distributions

The strain energies generated in the critical portions, namely, main vessel cylindrical portion due to shear stresses (U_{MV}), torus portion of inner vessel due to meridional compressive stresses (U_{IV}), and inner and outer baffles due to hoop compressive stresses (U_{IB} and U_{OB}) are computed using the following equations:

$$U_{MV} = \frac{1}{2} \sum_e \frac{\tau_e^2}{G \Delta V_e}, \quad e = 1, \quad n, \text{ number of elements in cylindrical portion} \quad (44)$$

$$U_{IV} = \frac{1}{2} \sum_e \frac{\sigma_{Ie}^2}{E \Delta V_e}, \quad e = 1, \quad n, \text{ number of elements in the toroidal portion} \quad (45)$$

$$U_{IB} = \frac{1}{2} \sum_e \frac{\sigma_{me}^2}{E \Delta V_e}, \quad e = 1, \quad n, \text{ number of elements in cylindrical portion} \quad (46)$$

$$U_{OB} = \frac{1}{2} \sum_e \frac{\sigma_{me}^2}{E \Delta V_e}, \quad e = 1, \quad n, \text{ number of elements in cylindrical portion} \quad (47)$$

where τ_e , σ_l , & σ_m are shear, meridional and hoop stresses, respectively, which are calculated from the associated stress resultants N divided by corresponding thickness, at the centroid of a particular element “e.” E and G are the Young’s modulus and shear modulus, respectively, of the structural steel of the vessels. ΔV_e is the volume of element “e” given by $2\pi R h \Delta L$ where R and h are radius and thickness at the centroid. ➤ [Figure 209](#) depicts a typical time variation of strain energy developed in the critical portion of the main vessel, which shows that the maximum strain energy is 300 kJ, which occurs at 5.3 s.

The values of strain energy are presented in ➤ [Table 31](#) for excitations X as well as Y directions including the variations considered in the time histories.

The critical time steps computed for the main vessel, inner vessel, and thermal baffles are shown in ➤ [Table 32](#).

Pressure Distributions on Vessels at Critical Time Steps

The dynamic pressure distributions generated over the vessel surfaces are responsible for buckling. The differential pressure distributions acting on the main vessel, inner vessel, and inner and

outer baffles are extracted at the specified critical time steps. In order to have a feel of distributions, a few typical distributions extracted from the seismic response analysis for the expanded time histories corresponding to the excitation in the X-direction, are also shown in Fig. 210. The inner and outer baffles are subjected to high dynamic pressures due to high added mass effects of the fluid confined in the narrow annular spaces between the shells.

■ Figure 210

Pressure distributions at the respective critical time steps

D Buckling Analysis

In order to obtain the lowest critical load factor in a single analysis including 3 D geometrical features, buckling analysis is performed on 3 D geometries. Toward this, the pressure/force distributions extracted from axisymmetric analysis, at the given critical time step, are translated to corresponding 3 D geometries.

Half-symmetric geometries are generated for the main vessel, inner vessel, and integrated geometry of inner and outer thermal baffles. Since the main vessel and thermal baffles are symmetric structures, 3 D geometries are generated by 180° rotation of the respective axisymmetric elements. For the inner vessel, three standpipes, one for primary sodium pump (PSPSP) and two for intermediate heat exchangers (IHXP1 & IHXP2), are included in the finite element model. Fixed boundary conditions (arresting all the displacements and rotations) are applied at the top edge for the main vessel, the bottom edge for the inner vessel, and the edge connected with the main vessel for the thermal baffle. The symmetric boundary conditions are applied all

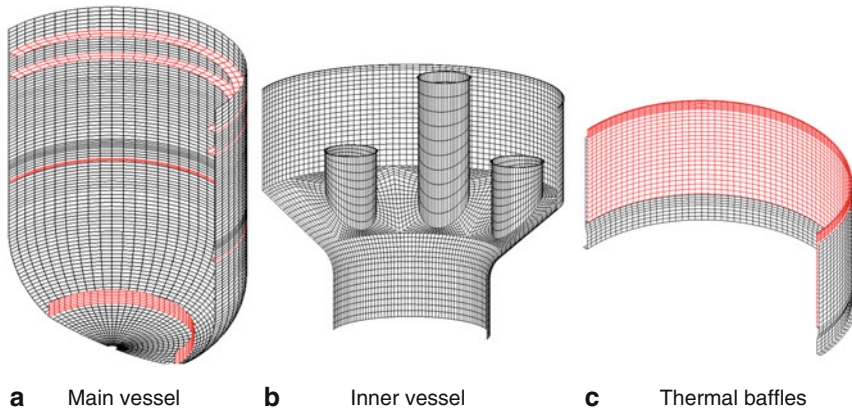

Figure 211

Three-dimensional finite element models of vessels

along the edges lying in the vertical symmetrical plane. The finite element models are shown in [Fig. 211](#).

Pressure Distributions on 3D Geometries

The hydrostatic pressure P_H acting on the surface that is in contact with sodium is symmetrically distributed. The pressure $P_{it}(\theta)$ generated in any node ‘ i ’ at the critical time step ‘ t ’ during horizontal excitation is superimposed as follows:

$$\text{Pressure : } P(\theta) = P_H + P_{it}(\theta) \quad (48)$$

$$P_H = \rho q H_i \quad \text{and} \quad P_{it}(\theta) = P_{ni}(t) \cos(\theta_i) \quad (49)$$

where ρ is density of sodium at operating temperature (880 kg/m^3), g is acceleration due to gravity (9.81 m/s^2), H_i is height of the node ‘ i ’ with reference to free level of sodium, θ_i is angle in radian of the node ‘ n ’ with respect to the X-axis, and $P_{ni}(t)$ is the pressure derived from the results of axisymmetric-Fourier analysis, at the specified time ‘ t ’ corresponding to the originating node ‘ n_i ’. The node ‘ n ’ and ‘ i ’ which lie in the same horizontal plane at the elevation H_i are indicated in [Fig. 212](#).

For the portions of inner vessel and thermal baffles which are in contact with sodium on both surfaces, $P_{ni}(t)$ is replaced by the differential pressure distribution $\Delta P_{ni}(t)$ which is derived directly from the axisymmetric analysis. However, for the main vessel which is in contact with sodium only on the inner surface and the portions of inner vessel and thermal baffles which are in contact with sodium either inner or the outer surface $P_{ni}(t)$ is directly applicable.

Force Distributions on 3D Geometries

In the FE model of main vessel, its connecting structures, namely, CSS, thermal baffles, and roof slab are not included. However, both static and seismic forces are applied appropriately along the edges at which these structures get isolated. The static and seismic forces acting on the CSS support skirt transmitted to the triple point are important for the buckling of the main vessel.

Figure 212
Position of nodes “n” and “i”

Figure 213
Distribution of forces acting on main vessel and inner vessel

The static loads applied at the triple point (W_{TP}) are 400 t for the half symmetric model. For the inner vessel, the static loads are 6.9 t on each IHX standpipe and 10.8 t for each pump standpipe, which are applied uniformly along the upper edges of standpipes. The distributions of static and seismic forces acting on the main vessel and inner vessel are indicated in [Fig. 213](#).

The seismic forces developed at triple point and standpipes are presented in [Table 33](#).

Elastoplastic Buckling Analysis

The minimum buckling factors thus obtained for various cases are summarized in [Table 34](#). The inner vessel, in virtue of high inertia imparted by the hot pool during safe shutdown earthquake (SSE) in conjunction with the pressure head, is the most critical component, that has the lowest buckling load factor of 1.9. The effect of randomness on time history is not significant on the buckling load factor of inner vessel and the effects are significant for the main vessel and

c – compressed time history, n – normal time history, and e – expanded time history.

thermal baffles. However, the load factors are higher than those seen for the inner vessel. From Table 34, the minimum buckling load factors are extracted: 3.2 for main vessel, 1.9 for inner vessel, 3.2 for inner baffle, and 3.0 for outer baffle.

The elastoplastic deformations and the buckled mode shapes for the main vessel, inner vessel, and thermal baffles, which have yielded the possibly lowest load factors, are shown in Figs. 215–217, respectively. Shear buckling mode shape of main vessel, asymmetrical shell buckling mode shapes of inner vessel, and thermal baffle can be seen clearly in these figures.

Design Check

The design code RCC-MR (2007) specifies a requirement of minimum 1.3 factor of safety on the computed critical buckling load, for the category D loadings. SSE is categorized as level D loading. This means that the minimum critical buckling load should be more than 1.3 times the imposed load under SSE. With the minimum load factors of 2.72, 1.52, 2.56, and 2.4 computed for the main vessel, inner vessel, inner, and outer thermal baffles, respectively, it is demonstrated that the critical vessels in the reactor assembly respect the buckling design criteria of RCC-MR.

Elastoplastic deformation and buckled mode shape of main vessel

8.6.7 Investigation of Buckling of Safety Vessel Subjected to Seismic Loading

In a pool type SFR, safety vessel is incorporated in the reactor assembly surrounding the main vessel, to collect the leaked sodium from main vessel, under unlikely event of main vessel leak. The annular gap between main vessel and safety vessel is chosen such that the sodium level in the hot pool will be maintained to the extent that sufficient sodium flow will take place in the decay heat exchangers immersed in hot pool. In this respect, it is preferred to have possibly lesser gap. However, some minimum gap has to be ensured for having free access of ISI equipment

■ Figure 216
Elasto-elastic deformation and buckled mode shape of inner vessel

■ Figure 217
Elasto-elastic deformation and buckled mode shape of outer baffle

which travels in the interspace for periodic in-service inspection. In finalizing gap, allowance should be given for the possible form tolerances for the main vessel and safety vessel achieved during the manufacturing processes. Typical gaps are 700 mm for SPX1 and 300 mm for PFBR. The level fall in the case of PFBR is shown in [Fig. 218](#).

Simultaneous occurrence of main vessel leak and a seismic event is a beyond design basis event (BDBE), for which the structural integrity of main vessel and safety vessel should be demonstrated. The main loading on the vessels is the dynamic pressure developed in the sodium filled in the inter-vessel space. This pressure acts on the outer surface of the main vessel and the inner surface of the safety vessel. Since the buckling strength of the main vessel is much higher than the safety vessel, the safety vessel is critical under this condition. The analysis methodology to ensure that the safety vessel does not buckle under this extreme loading situation is illustrated with reference to PFBR situation.

■ Figure 218

Fall of sodium levels due to postulated leak in the main vessel

■ Figure 219

Important natural frequencies of vessels under MV leaked condition

The first step in the analysis is finite element discretization of various geometries such as reactor assembly including reactor internals and sodium, sodium free levels and fluid–structure interactions, safety vessel, and reactor vault. The finite element mesh thus developed is shown in [Fig. 219](#). The second step is the determination of natural frequencies and mode shapes up to 50 Hz wherein the seismic excitations have significant energies. The analysis should identify two important additional modes of natural vibration, namely, in-plane and out-of-plane vibration of main vessel and safety vessel coupled by liquid sodium confined in the inter-vessel space. These modes are responsible for generating high inertia forces on the inner wall during SSE. The typical natural frequency values are 4.4 Hz (in-plane) and 7.7 Hz (out-of-plane) for PFBR case. The associated mode shapes are also shown in [Fig. 219](#).

The third step is seismic analysis to determine the dynamic pressure distributions on the safety vessel inner surface. The last step is buckling analysis of safety vessel under these pressures at every time step and determination of load factors. The lowest load factor should be more than 1.3 to respect the RCC-MR buckling design criteria (25). It has been found from analysis carried

■ **Figure 220**
Buckled mode shape of safety vessel

out for safety vessel of PFBR that the torispherical head portion develops many buckles under this situation (► [Fig. 220](#)). The design meets the buckling design criteria.

8.6.8 Investigation of Buckling of Top Shield Plates under CDA Loading

The cover gas pressure rise and subsequent impact of hot pool sodium at the bottom portion of top shield are the two important mechanical consequences of a core disruptive accident (CDA) in a SFR, for which the buckling of bottom plate of top shield has to be investigated. (► [Figure 221](#) shows the results of analysis carried out for PFBR, which depicts this scenario. (► [Figure 222](#) shows the cover gas pressure rise during CDA in PFBR.

The loading scenario is well explained in Breuil et al. (1991). The highlights are given below:

During the core bubble expansion, the cover gas pressure increases monotonically. Under this condition, the bottom plate of roof slab bows upward instantaneously since the natural frequency of the bottom plate is high (~100 Hz). Due to sodium slug impact, bowing of bottom plate increases sharply followed by global bending of (upward) top shield, whose natural frequency is about 5–10 Hz. These two consequent events cause the bottom plate to buckle. The buckling analysis calls for estimation of transient pressure history at the bottom plate and subsequently large displacement elastoplastic analysis. In order to limit the deformation of bottom plate, design provisions are kept in the top shield. The buckling analysis should take into account such provisions which call for nonlinearities caused by gaps between the plate and design provisions embedded in the top shield. A few highlights of experimental investigations carried out toward SPX2 (Breuil et al. 1991) are presented below:

The plate geometry simulating the dimension of bottom plate with the appropriate gap between the rigid rods which limit the displacements, provision of axial force, and distributed

Specimen simulating bottom plate

force (pressure) on the surface is considered (► Fig. 223). The pressure and in-plane forces are applied with a specified time delay as shown in ► Fig. 224. The nonlinear analysis methodology is validated with test data as seen in ► Fig. 225. After establishing the procedure and validating the computer code, optimum number of stoppers and corresponding locations are recommended as shown in ► Fig. 226.

8.6.9 Experimental Validations of Computer Codes

Validation of CAST3M

Since the buckling is a very complex phenomenon and numerical prediction of buckling loads and mode shapes involves very sophisticated analytical techniques, a few important predictions

■ **Figure 227**
Buckled MV models under shear

■ **Figure 228**
Buckled shells (1/18th model of main vessel) vessels under shear

by CAST3M code developed by CEA, France are validated by experimental data to raise the confidence. With this objective, a series of simulated buckling tests have been conducted at IGCAR (India) on various scaled down models of main vessel and inner vessel (Athiannan 2002; Bose 2001). Buckling tests on 1/18th scaled down models of main vessel made of SS 304 were completed under shear plus bending moments. For conducting these tests, a 100 t capacity loading frame and an automatic vessel profile measurement system were specially designed and constructed at IGCAR. ➤ *Figure 227* shows test setup for shear buckling experiments.

Totally 12 tests were conducted for validating shear buckling results and buckled vessels are shown in ➤ *Fig. 228*.

In order to validate CAST3M, large displacement elastoplastic analysis has been completed based on incremental theory and results are stored at every time step. Subsequently, buckling analysis is performed at every time step. The results are presented for three thicknesses in ➤ *Fig. 229*. The results are summarized in ➤ *Table 35*, which indicates that CAST3M are able to predict the buckling loads satisfactorily. The prediction of buckled mode shape is also found to be very good (➤ *Fig. 230*).

The buckling of inner vessel under internal pressure and loads through stand pipes has been simulated on 1/13th scaled models. Six tests were conducted and the vessel buckles at the torus

portion as seen in [Fig. 231](#). The results are summarized in [Table 36](#), which demonstrates that the CAST3M predictions are satisfactory.

The buckled mode shape predicted by CAST3M is shown in [Fig. 232](#), which demonstrates clearly the capability of CAST3M code.

■ **Figure 233**
Prediction of buckled mode shape of shells under shear force

Validation of ABAQUS Code

Many tests have been conducted at CREPI Laboratory, Japan to validate ABAQUS code (Matsuura and Nakamura 1997). Two sets of results are presented here: one set on shear buckling and another on the buckling of shells subjected to bending moment, both are representative loads developed under seismic event. ➤ *Figure 233* depicts a few predictions of mode shape by ABAQUS code.

➤ *Figure 234* shows the comparison of predictions of shear buckling loads by ABAQUS which lies within 20% deviation.

For the case of shells subjected to bending moment, ABAQUS predicts within 20% deviations, as seen in ➤ *Fig. 235*.

From the above two benchmark exercise, it is clear that the buckling loads can be predicted by matured computer codes within 20% error.

8.6.10 Summary

In this portion of the chapter, various critical portions of reactor assembly shells, which are prone to buckle, are listed out along with respective buckling modes. Design criteria and methodologies are brought out clearly. Analysis procedures for the nonclassical buckling modes for nonstandard geometries are highlighted. This includes buckling of thin shells subjected to seismic-induced forces and moments, thermal buckling, progressive buckling, and creep buckling. An integrated analysis approach is presented with reference to investigations carried

Figure 234

Prediction of shear buckling loads by ABAQUS

12 elements wrinkle

Figure 235

Prediction of buckling of shells under bending moment by ABAQUS

out for reactor assembly of typical pool type fast reactor (PFBR). As per this approach, the seismic analysis and subsequent buckling analysis are performed with careful translation of data from one stage to other stage. Experimental validation aspects of buckling of thin FBR shells are highlighted and buckling loads can be predicted within 20% error by matured codes such as CAST3M and ABAQUS. With these information and data, a design engineer can carry out the buckling design of FBR shells comprehensively.

8.7 Design Criteria and Analysis Method

Mechanical design of FBR components generally follows “design by analysis” method. American code ASME Section III, division 1 (2001) and French code RCC-MR (2002) are

■ **Figure 236**
Creep crossover curve for SS 316 LN as per RCC-MR

commonly used for the design. These codes identify the possible failure modes under creep and non-creep regimes, which depend upon the temperature and time duration that a particular component is subjected to. One broad guideline specified in ASME Section III: Subsection NB is the temperature limit, i.e., for austenitic stainless components, temperature above which creep is significant is 427°C . For ferritic steels, this value is 370°C . However, significant creep is possible at any high temperature, only if the component is exposed for sufficiently long time depending upon the temperature itself. Based on this fact, the French code RCC-MR specifies the rational criteria in the form of creep crossover curve to identify the combination of temperature and time which can cause significant creep effects. A typical creep crossover curve recommended in RCC-MR for austenitic stainless steel SS 316 LN is reproduced in

► [Fig. 236](#).

The failure modes addressed in the non-creep regime are the following:

- Gross deformation due to gross yielding
- Ductile rupture from short-term loading
- Incremental collapse and ratcheting
- Fatigue damage
- Buckling due to short-term loading

In the creep regime, the following additional failure modes are considered:

- Gross deformation due to creep deformation
- Time-dependent progressive deformation
- Creep rupture from long-term loadings
- Creep-fatigue interaction
- Creep buckling due to long-term loadings

■ **Table 37**

Permissible base materials for structures other than bolting

Material	304 SS	316 SS	Alloy 800H	2¼Cr-1Mo	9Cr-1Mo-V
Maximum temperature	815°C	815°C	760°C	650°C	650°C

While RCC-MR provided design rules concurrently, ASME provides similar rules in a dedicated subsection called “NH.” The design criteria specified in the codes are applicable for the materials specified in the code along with the maximum specified temperature. A few typical materials specified in ASME Sec. III Subsection NH are shown in ▶ [Table 37](#).

Further, specific design rules are called for the heat exchanger tubesheets, bolted joints, dished heads in the non-mandatory appendices, for example, RCC-MR Section I: Subsection Z.

8.7.1 Loadings

There are four service loadings specified in codes, namely design, Level A, Level B, Level C, and Level D. Design loadings are used to arrive at the reference thickness. Subsequently, adequacy of thickness needs to be confirmed for all the service loadings by respecting the primary stress limits specified below.

Design loadings shall equal or exceed those of the most severe combinations of coincidence pressure, temperature, and load forces specified under events, which cause service Level A loadings for the same zone of the component. Apart from these, it is required to specify the design life “*t*” in hours. For example, for a typical fast reactor, the design life is 40 years with a load factor of 75%. This yields a value for *t* equal to 2.63×10^5 h ($40 \times 0.75 \times 365 \times 24$).

Level A Service Loadings

Level A service loadings are any loadings arising from system startup, operation in the design power range, hot standby, and system shutdown, and excepting only those loadings covered by Level B, C, and D service loadings or test loading.

Level B Service Loadings

These loadings arise from the incidents of moderate frequency. These are deviations from Level A service loadings that are anticipated to occur often enough that design should include a capability to withstand the loadings without operational impairment. The events, which cause Level B service loadings, include those transients that result from any single operator error or control malfunction, transients caused by a fault in a system component requiring its isolation from the system, and transients due to loss of load or power. These events include any abnormal incidents not resulting in a forced outage and also forced outages for which the corrective action does not include any repair of mechanical damage. The estimated duration of a Level B service loading shall be included in the design specifications.

Level C Service Loadings

These loadings arise from infrequent incidents. These are deviations from Level A service loadings, which require shutdown for correction of the loadings or repair of damage in the system. The conditions have a low probability of occurrence, but are included to provide assurance that no gross loss of structural integrity will result as a concomitant effect of any damage developed in the system. The total number of postulated occurrences for such events may not exceed 25. If more than 25 are expected, then some types of events must be evaluated by the more stringent requirements of the Level B service limits. For a nuclear plant, a moderate earthquake, called operating basis earthquake (OBE), is considered under this category.

Level D Service Loadings

These loadings arise from limiting faults. These are combinations of loadings associated with extremely low probability, postulated events whose consequences are such that the integrity and operability of the nuclear energy system may be impaired to the extent that only considerations of public health and safety are involved. In the seismic design of fast reactor components, design basis earthquake, called safe shutdown earthquake (SSE), is considered under this category.

8.7.2 Design Limits

The important feature of the design codes is the classification of stresses, as primary and secondary. While primary stresses generated in the structure to maintain the equilibrium under externally applied mechanical loads such as dead loads and pressure, can cause failures (gross deformation or tensile rupture) upon single applications, secondary stresses, generated in the structures to conserve the continuity or compatibility conditions, can cause failure only after application of repeated loading cycles (e.g., ratcheting). The primary stresses are limited by appropriate stress intensities expressed in terms of “basic allowable stress intensity (S_m)” for non-creep regime and S_t for creep regime.

S_m : Smaller of the following quantities

- Two third of minimum yield stress other than austenitic stainless steels. For austenitic stainless steels, it is 90 % of minimum yield stress ($\sigma_{0.2}$) in view of its high strain hardening contribution.
- One third of minimum tensile stress.

S_t : Smaller of the following quantities

- Hundred percent of average stress required to obtain a total (elastic, plastic, primary, and secondary creep) strain of 1% at the specified time t .
- Eighty percent of minimum stress to cause initiation of tertiary creep at “ t .”
- Sixty-seven percent of the minimum stress to cause rupture at “ t .”

S_{mt} : Lower of S_m and S_t

Depending upon different loading condition, different factor of safety is used. For example, the primary membrane stress intensity is limited by S_m for Level A and Level B, $1.2S_m$ for Level C, and $2.4S_m$ for the Level D loading conditions.

The secondary stresses are controlled by limiting the accumulated strains. These apart, the component life would be limited by the accumulated creep-fatigue damages. These are illustrated in the following paragraphs.

Strain Limits

The principle strain components, namely, maximum positive membrane strain (ϵ_m), positive bending strain (ϵ_b) and positive local strain (ϵ_L) are to be limited as follows:

$$\epsilon_m \leq 1\%, \epsilon_m + \epsilon_b \leq 2\%, \text{ and } \epsilon_m + \epsilon_b + \epsilon_L \leq 5\% \text{ for base metal.}$$

For welds, 50% of these values should be applied. Since the ratcheting induces rapid strain growth, effect of ratcheting has to be considered in the computation of strains.

Creep Damage

Creep damage defined by Robinson's rule as $D_c = t/T_d$ should be less than 1. Where t is the total duration of a given stress (σ_{eff}) at maximum temperature θ . T_d is allowable time duration determined from stress-to-rupture curves for the stress (σ_{eff}) at temperature θ . The computation of σ_{eff} from the individual stress components depends upon the kind of multiaxial rule followed for creep damage estimation. Giving due consideration for the role of hydrostatic component in influencing the creep damage in addition to the Von Mises component, RCC-MR defines the effective stress as:

$$\begin{aligned} \sigma_{\text{eff}} &= 0.867\sigma_{\text{VM}} + 0.4\sigma_{\text{H}} \\ \sigma_{\text{VM}} &= 1/\sqrt{2}[(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2]^{1/2} \quad \sigma_{\text{H}} = [\sigma_1 + \sigma_2 + \sigma_3]/3 \end{aligned}$$

where σ_i are the principal stresses.

The criteria adopted in ASME-NH, which is given below:

$$\begin{aligned} \sigma_{\text{eff}} &= \bar{\sigma} \exp \left[C \left(\frac{J_1}{S_s} - 1 \right) \right] \\ J_1 &= \sigma_1 + \sigma_2 + \sigma_3 \\ S_s &= [\sigma_1^2 + \sigma_2^2 + \sigma_3^2] \\ \bar{\sigma} &= \frac{1}{\sqrt{2}} [(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2] \end{aligned}$$

where σ_i are the principal stresses. The constant C is defined as follows:

- For Types 304 and 316 stainless steels, $C = 0.24$.
- For Alloy 800R, $C = 0$.
- For $2^{1/4}\text{Cr-1Mo}$ and 9Cr-1Mo-V : 0.16 if $J_1/S_s \geq 1.0$ and = 0 if $J_1/S_s < 1.0$.

There is a need to apply a factor of safety K' by dividing the σ_{eff} before entering in to creep rupture curve. K' values are 1/0.9 for ASS.

■ **Figure 237**
Creep-fatigue ine

Fatigue Damage

At any material point, fatigue crack initiation occurs if fatigue damage (D_f) defined by: $D_f = n/N_d$ exceeds unity. Where n is applied number of strain cycles with the strain range of $\Delta\epsilon$ at temperature θ . N_d is permissible number of cycles determined from design fatigue curve. The design fatigue curves were determined from completely reversed loading conditions at appropriate strain rates. These curves have a factor of safety 20 on life and 2 on strain range.

Creep-Fatigue Interaction

When both creep and fatigue damages occur together, there can be a strong interaction, which reduces the life significantly. Accordingly, the sum of creep and fatigue damages should be limited to a specified value D follows:

$$D_c + D_f \leq D$$

As shown in  Fig. 237, the values of D are expressed as a function of either D_c or D_f .

8.7.3 Analysis Methods

Simplified Methods

The primary stress intensities are computed from the results of elastic stress analysis. However, for computing the stresses and strains accurately to check the strain, creep, and fatigue damage limits, inelastic analysis methods are preferred. However, considering the complexities, requirement of high level of expertise and sophisticated material data and high computational cost involved in the inelastic analysis, the codes provide robust and conservative simplified method to evaluate inelastic stress and strains based on elastically computed stresses and

strains. However, before applying these simplified procedures, certain restrictions on accumulated strains need to be respected. Accordingly, the first step is estimation of strains based on simplified methods as described in AFCEN (2002) and Roche and Nouailhas (1989). In the computation of inelastic strains, creep strains and cumulative strains accumulated due to cyclic thermal loadings in conjunction with primary stress (ratcheting) are computed by the simplified methodologies proposed in the code. Methodology recommended in ASME-NH is based on O'Donnell and Porowski diagram and that recommended in RCC-MR is based "efficiency index diagram." These diagrams are shown in [▶ Figs. 238](#) and [▶ 239](#) respectively. Additional details and systematic procedures are provided in both RCC-MR and ASME-NH for computing strain range and sustained stresses for estimating fatigue and creep damages. These procedures call for determination of maximum stress range ($\Delta\sigma_{\max}$) from elastically calculated stresses.

Inelastic Analysis

Inelastic analysis is essential for predicting accurately the stress and strain history in the components subjected to mechanical and thermal loadings and thereby for the accurate estimation of ratcheting, creep, and fatigue damages. This calls for use of realistic material constitutive models to be employed in the numerical prediction of stress-strain history at all the critical locations. The constitutive model should be able to simulate accurately the complex material behavior caused by monotonic and cyclic, mechanical and thermal loadings at high temperature. Apart from creep and creep relaxation, the material hardening behavior by which the instantaneous yield stress and strain hardening behavior changes continuously in stress or strain cycling is an important aspect need to be modeled. ASS exhibits cyclic hardening behavior. Further, depending upon the values of primary and secondary stress ranges, the material point exhibits many complex behaviors, namely, elastic cycling, shake down, and ratcheting. Under various cyclic loading as illustrated in [▶ Fig. 240](#), there is no permanent strain at end of each elastic cycling ([▶ Fig. 240a](#)). Under shakedown, there is no accumulation of strains except strain cycling with a fixed magnitude ([▶ Fig. 240b](#)). Under very high strain cycling (ratcheting), there is a possibility of progressive growth of strain, cycle by cycle, which can lead to development of unacceptable strains after application of a few number of load cycles ([▶ Fig. 240c](#)).

The behavior model to be considered will depend on the physical phenomenon and on the collapse mode to be analyzed. [▶ Table 38](#) gives a guideline for cyclic hardening materials and this table should be used with care when dealing with cyclic softening materials. Roche and Nouailhas (1989) can be consulted for further details about the viscoplastic constitutive model commonly used for numerical simulation of austenitic stainless steels.

8.7.4 Buckling Design

Time Independent Buckling

In the non-creep temperature range for structures, buckling occurs instantaneously. The critical buckling load can be determined by stability analysis. Normally the analysis is directed against

Combined hardening (Chaboche viscoplastic, etc.)	Suitable 	Use with care 	Suitable 

snap-through or bifurcation instability, taking into account time-independent elastoplastic material behavior. Calculation schemes are given to design against such buckling phenomena. After determining critical buckling load (P_{cr}), the allowable buckling load is established by applying required factor of safety (FOS). In case of buckling under mechanical loads such as pressure or dead load, minimum FOS required is 3. In case buckling occurs under strain-controlled loading such as thermal loadings, minimum FOS required is 1.67. These factors are applicable for design, Level A and Level B loadings. The corresponding factors for Level C are 2.5 and 1.4 and for Level D are 1.5 and 1.1 for load-controlled buckling and strain-controlled buckling.

In the determination of buckling loads, the effects of initial geometrical imperfection (which is very critical for axial compression and external pressure) and plasticity should be included carefully. To simplify the designers work, for the cylindrical and spherical shells under external pressure and cylindrical shell under axial compression, design charts are given in NB for checking that design pressure is less than the critical buckling pressure including effects of imperfection and plasticity.

Time-Dependent Buckling Design

At high temperatures, the creep buckling is a time-dependent phenomenon. It develops mostly as follows: at first deformations occur very slowly, but they change the shape in a disadvantageous manner. So it seems that two phases exist. Firstly, a slow deformation process, and then rapid deformations determined by strongly accelerated creep processes in some

■ Figure 241
Concept of creep buckling

sensitive regions of the structure. Creep buckling phenomenon for a typical heat exchanger tube subjected to external pressure is illustrated in [Fig. 241](#).

Design charts are provided in the codes that can be used provided the temperature and time combinations lie in the non-creep regime of charts, for the cylindrical and spherical shells both in ASME and RCC-MR. For the special types of geometries, buckling analysis is to be done either using bifurcation type or large displacement elastoplastic-creep analysis. After determining the load, for which the structure becomes unstable at the end of specified design life, factor of safety is applied appropriately as 1.5 for the Level A, Level B, and Level C loadings and 1.25 for Level D loading.

9 Plant Dynamics

A comprehensive list of conditions and its classification following their frequency of occurrence is an essential basic element for design safety analyses and afterward validation of the facility project. The demonstration of the adequacy of the design with the safety objectives is made through the analysis of three kinds of conditions:

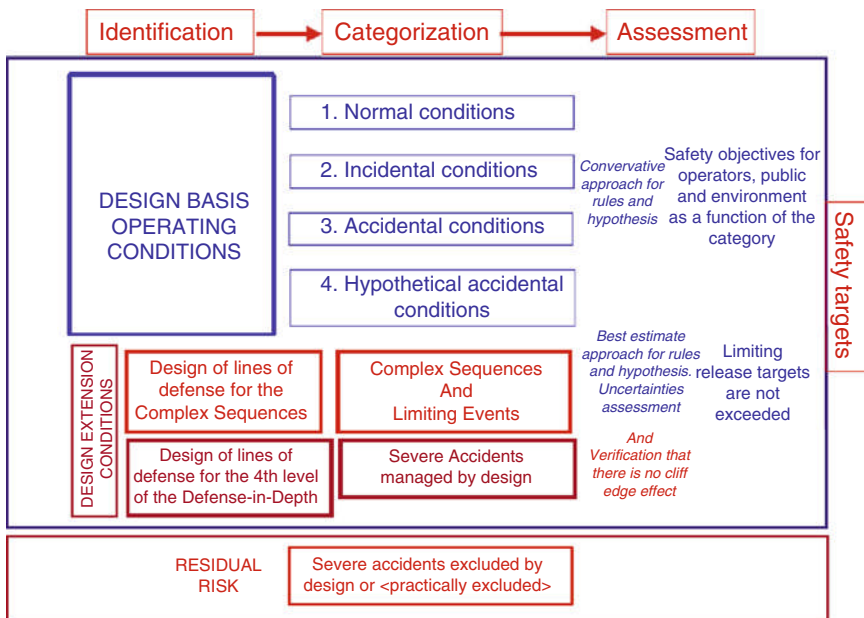

- **The design basis conditions.** The safety design of the plant mainly results from the analysis of these conditions. It must be shown that the consequences of accidents occurring in the previous situations are matching the objectives targeted in terms of radiological releases and radiation protection. Moreover, the estimated frequencies of incidents and accidents determine the acceptable consequences for each situation postulated. And it must be checked that the risk of whole core degradation initiated by the initiating events (IE) is very low.
- **Design extension conditions.** Complex sequences, limiting events, and severe accidents are evaluated despite their low occurrence frequency. The consequences of these accidents are

analyzed, and their consequences in the environment have to be demonstrated to be lower than the limiting release targets.

- **Residual risk situations.** The consequences of these situations are not analyzed. If these situations are not demonstrated to be physically impossible, the prevention measures regarding their occurrence have to be demonstrated to be sufficient to “practically eliminate” them.

► *Figure 242* describes the approach apply for a new design in order to determine and analyze its relevant operating conditions.

The objective of this chapter is to give examples of design basis events and safety criteria, then to explain analysis methods for such situation. Finally, examples of SFRs behavior in typical transient situations are described. If all this information is strongly dependent on the design (oxide or metal or carbide fuel, loop, pool or modular reactor with water or gas energy conversion system. . .), then the following information could not be considered as completed. At the end of the chapter are presented some anticipated transients without SCRAM (ATWS) as they are representative of the inherent behavior of the SFRs. Examples are given only as examples. The following references (Bertrand and Devictor 2006; GenIV GIF; IAEA 1996, 1999, 2000, 2005, 2007; Justin et al. 1985; Libman 1996; Waltar and Reynolds 1981) provide more details and examples.

■ **Figure 242**
General approach for the safety-related design and assessment

9.1 About the Design Basis Conditions, the Design Extension Conditions and the Residual Risk

A design basis condition is a plant condition resulting from the combination of a normal operating condition (category 1, see hereafter) and of an initiating event belonging to the design basis area, that is, classified from category 2 to category 4 (according to its probability, see definition hereafter). Initiating events may arise due to component failure, operator errors, internal, or external hazards. Their consequences affect the plant behavior. The design basis conditions are grouped in four categories on the basis of the expected occurrence frequency of the corresponding initiating events. Definition of the categories, referring to EFR, is as follows:

- **Normal operating conditions** are plant conditions planned and required. They include special conditions such as tests during commissioning and start-up, partial loading, shutdown states, handling states, partial unavailability for inspection, test, maintenance, and repair. The decommissioning conditions are not included in the safety analysis of the operating plant; they will be specifically analyzed in good time. Nevertheless, considerations concerning the decommissioning have to be made. The goal of the safety analysis of normal operating conditions is to verify that their consequences on the staff and the public are ALARA and in any case lower than the corresponding release criteria.
- **Category 2 operating conditions** are operating conditions not planned but expected to occur one or more times during the life of the plant (mean occurrence frequency estimated greater than 10^{-2} per year). Plant shall be able to return to power in short term after fault rectification. The goal of the safety analysis of category 2 operating conditions is to verify that their consequences on the staff and the public are ALARA and in any case lower than the corresponding release criteria.
- **Category 3 operating conditions** are operating conditions not expected to occur during the life of the plant (mean occurrence frequency between 10^{-4} per year and 10^{-2} per year) but after which plant restarting, by possible repair, is required for investment cost guarantee. The goal of the safety analysis of category 3 operating conditions is to verify that their consequences on the public are lower than the corresponding release targets.
- **Category 4 operating conditions** are operating conditions after which plant restart is not required because there is no expectation of occurrence during the plant life. The consequences of an operating condition must not exceed category 4 limits with a mean value of their frequency higher than 10^{-7} per year. The goal of the safety analysis of category 4 operating conditions is to verify that their consequences on the public are lower than the corresponding release targets.

Referring to the EFR categorization, the **Design Extension Conditions (DEC)** are not defined on the basis of their occurrence frequency, but they are postulated to be bounding cases resulting from risks specific to the design or the process. Two kinds of design extension conditions are considered: the situations for which the consequences have to be demonstrated to be limited and the severe accidents. The goal of the safety analysis of DEC is to verify that their consequences on the public are lower than the limiting release targets. In the safety approach developed in the European Utility Requirements (EUR), *complex sequences* are design extension conditions which are not covered by the safety analysis of category 2, 3, and 4 operating

conditions, but the occurrence frequency of which is not demonstrated to be sufficiently low (i.e., well below the mean value of 10^{-7} /sequence/year/plant). In the EFR safety approach, the complex sequences are complemented by limiting events defined for licensing purposes. They are bounding cases resulting from risks specific to the design or the process. The consequences of complex sequences and limiting events are investigated. This can lead to enhance the design in order to show that core damage is prevented, and then that the limiting release targets are not exceeded. *Severe accidents* are considered in order to verify that there is no “cliff edge” effect on the consequences even for very hypothetical conditions. The goal of the analysis of severe accidents is to prove the efficiency of the containment measures for limiting the consequences of core damage accidents. The radiological consequences shall be lower than the limiting release targets.

Residual Risk (RR) situations are accident conditions for which the prevention regarding their occurrence is such that the analysis of their consequences is not required by the safety demonstration. On the other hand, the adequacy of the prevention of these accident conditions has to be demonstrated. Such a demonstration may be performed using probabilistic assessment. In this case, the goal is to show that accident conditions which the consequences may exceed the limiting release targets have a mean frequency well below to a threshold, as for example 10^{-7} event/year/plant.

Hazards must be considered in order to add provisions aiming to avoid that they provoke an accident and to protect the systems permitting to control the facility conditions. The hazards to consider in the design of a plant could result from internal causes or external ones and are qualified as internal hazards and external hazards. A typical list of internal hazards to be taken into account is internal flooding, internal fire, electromagnetic perturbations (possibly externally caused, like lightning, but having an effect on control system of the plant), internal explosion, and missile projection. The following external hazards are usually considered: earthquake, extreme weather conditions, aircraft crashes, industrial environment (explosion, fire, . . .), external fire, and external flooding. For SFRs, specific hazards from the use of sodium are studied due to fire or leak, or gel of sodium.

The analysis of the causes of safety function losses by means of decoupling criteria leads to a set of typical families of initiating events: untripped or protected loss of flow (ULOF or LOF), untripped or protected loss of heat sink (ULOHS or LOHS), untripped or protected transient of power (UTOP or TOP), untripped or protected loss of power (including ULOSSP or LOSSP for the loss of station service power), loading error, local assembly fault, leak or sodium fire, sodium–water reaction or sodium–water–air reaction, internal and external hazard.

Their ranging in the previous categories depends on the design options, and then no categorization is proposed in the following sections. For some families, progressiveness in the severity is applied and the events are ranged in different categories. Examples of progressiveness are:

- The origin of a pump failure could be a speed reduction or a triggering or a jamming.
- For the sodium–water reaction, different quantities of broken tubes are considered.
- The duration of the loss of station service power affects the range, as for example for EFR project in Category 2 for a duration less than 1h, and in Category 3 for a longer duration.

The following list gives typical situations usually studied in the design basis:

- Spurious reactor trip,
- Pin failure leading to DND signal.
- Inadvertent withdrawal of an absorber rod.
- Internal and external flooding.
- Extreme weather conditions.
- Large leak (IXH secondary circuits or DRC circuits).
- Multiple faults in fuel transfer and storage systems.
- Conventional fire.
- Subassembly drop.
- Local subassembly cooling disturbances.
- Primary and secondary pump faults.
- Leakage or rupture of primary pump diaphragm connection of internal structures.
- Primary sodium vessel leak.
- Loading error.
- Large leak of cover gas.
- Abnormal passage of gas through the core.
- Large steam generator leak.
- Primary sodium circuit leakage in the secondary containment.
- Dropped loads.
- Earthquake.

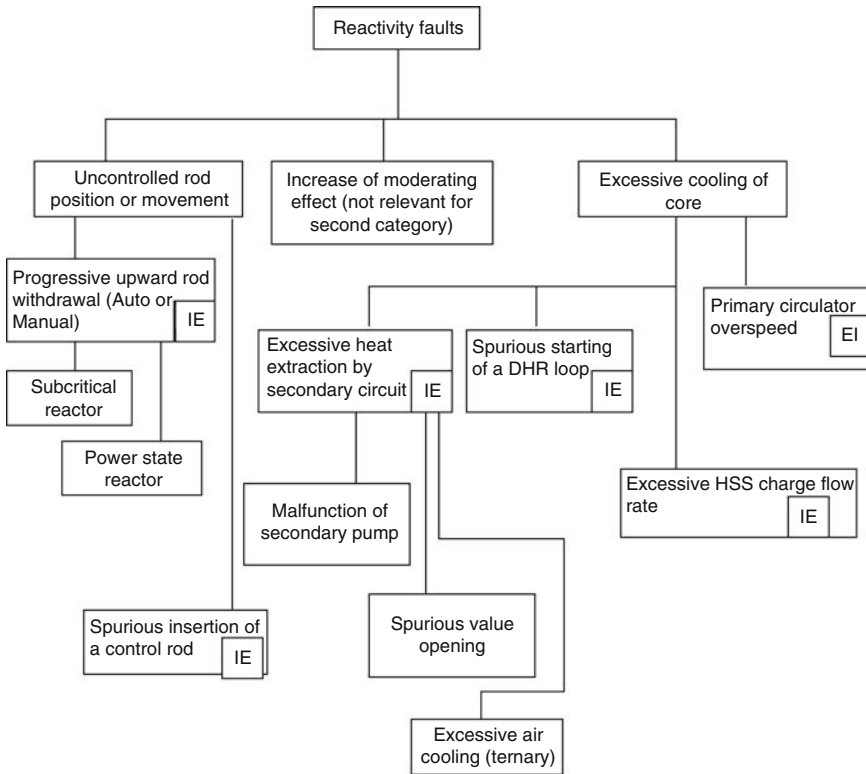

A list of typical DEC is:

- Leakage of main and safety vessels.
- Fuel subassembly meltdown.
- Sodium–water–air reaction in a steam generator building.
- Large sodium–water reaction in a steam generator (larger than design basis event).
- Large sodium leak on the reactor roof.
- Large sodium leak outside the secondary containment up to guillotine failure of a main sodium pipe.

Furthermore, in case of accidental sequences possible to quantify, probabilistic approach postulating failure of various safety systems and components could help in the identification of the sequences to consider in the DEC, thanks to a more realistic methodology than engineer judgement usually adopted. In particular, the identification of pertinent complex sequences postulating the failure of one or several mitigating means will be improved with probabilistic approach.

Some events needing the demonstration of classification as residual risk are

- Large reactivity insertion (HCDAs) due to core support failure, core compaction, voiding, large loading errors or ejection of control rod.
- Loss of all decay heat removal systems.
- Dropped large load causing failure of primary coolant system.
- Primary pump flywheel failures.
- Primary vessel buckling due to external overpressure Ingress of water into primary circuit.
- Large aircraft crash (could be classified in limiting events according to some national requirements).
- Large gas cloud explosion (could be classified in limiting events according to some national requirements).

▣ **Figure 243**
Example of a logic diagram for IEs resulting from category 2 reactivity faults

In case of innovative design, a possible approach for identifying new initiating events relies on the assessment of mechanisms to control in order to fulfil the main safety functions of the reactor. Once these mechanisms have been identified, cause–consequences diagram (inspired by Master Logic Diagram methodology, Papazoglou and Aneziris 2003) could be built in order to identify initiating events leading to induce the mechanisms presented as the top level of the diagrams. In other terms, the initiating events identification of the design basis area has been performed by looking for the physical phenomena able to disturb the physics of the reactor regarding each of the main safety function. An example of such a diagram is presented in [► Fig. 243](#).

9.2 Safety Criteria

According to the objective of progressiveness, targets of radiological dose to public are established as function of occurrence category. An illustration is given in [► Table 39](#), showing an ALARA approach from SPX to EFR. Some intermediate design criteria that ensure in particular

Table 39
Examples of plant and safety criteria

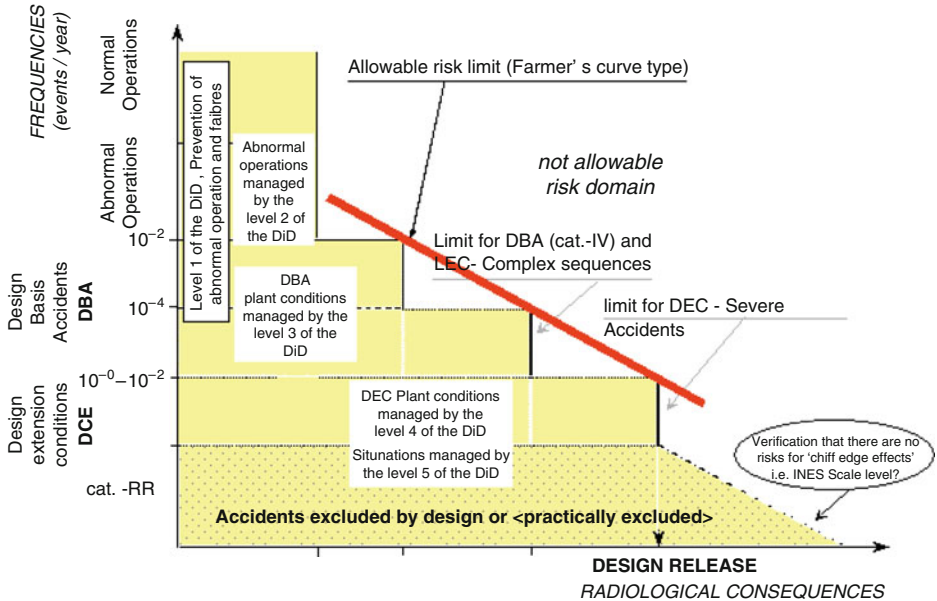

Category of conditions	Event frequency	Plant criteria	Safety criteria	Radiological criteria	
				EFR	SPX
1. Normal	$>1/\text{year}$	High availability	Radiological release ALARA	50 $\mu\text{Sv}/\text{year}$	To meet authorized release limits
2. Incidental	$>10^{-2}/\text{year}$	Able to return to power at short term after rectification	Radiological release lower than the limit	50 $\mu\text{Sv}/\text{year}$	
3. Accidental	$>10^{-4}/\text{year}$	Able to restart after inspection, repair, requalification	Radiological release lower than the limit	1 mSv/year	5 mSv/year (body)
					15 mSv/year (thyroid)
4. Hypothetical	$>10^{-6}/\text{year}$	Plant restart not required	To maintain core coolability, limited change of core geometry	50 mSv/year	150 mSv/year (at site boundary)
DEC	$>10^{-7}/\text{year}$	(Loss of plant investment)	Releases lower than the targets (no need off-site provisions)		250 mSv/event (30 days at 15 km)
Residual Risk	$<10^{-7}/\text{year}$	–	(No “cliff edge” effect)		

■ Table 40

Examples of design criteria for the core integrity, the core support, and the reactor block integrity (should be adapted to the design options)

Category of conditions	Cladding limits (MCT = maximum clad temperature for an oxide fuel)	Fuel limits	Primary boundary – cold structure	Primary boundary – hot structure
1. Normal	Non-open clad failure	No melting	Max. T° core inlet	<545 °C
	MCT < 700 °C			
2. Incidental	No clad failure, except due to random effect. MCT <700 °C and 700 °C < MCT < 740 °C during 2 h and 740 °C < MCT < 780 °C during 10 min	No melting	<520 °C	<545 °C
3. Accidental	No systematic (i.e., large number of) pin failures nor large increase of leak rate.	No melting	<530 °C	<545 °C
4. Hypothetical	“Reversible local sodium boiling” criteria.	Any predictable local fuel melting to be shown acceptable (simultaneous clad failure and fuel melting of the same pin excluded).	<630 °C	<880 °C
DEC	Coolability of damaged core; propagation of a pin bundle blockage must be prevented	Severe accident admitted complying with the containment measures; no recriticality.	<630 °C	
Residual Risk	Core collapse excluded by design	Energetic severe accident excluded by design	–	–

that the radiological limits are not exceeded are defined through the application of the defense-in-depth principle. Design criteria related to the design basis operating conditions (► [Table 39](#)) are then established as concerns the plant availability, integrity of the fuel elements, and of the mechanical reactor components(► [Table 40](#)). The safety demonstration requires not only

■ **Figure 244**
Relationship between categories and safety targets

to meet the design criteria during the transient (e.g., maximum temperature at the transient peak), but also to meet safe shutdown state criteria just after the event transient. Analysis of the scheduled shutdown states as normal operating conditions and of the transient operating conditions are both important. This analysis requires specific design criteria impacting the negative reactivity margins of each control rods system. The design criteria are generally as follows:

- To keep reactor cold state (180°C) by each shutdown system minus the most reactive rod ($n - 1$).
- To keep reactor cold state by the two shutdown systems minus one rod, in case of fuel handling mistake (one control rod replaced by one fuel assembly).
- To reach reactor hot state (330°C) by only the complementary emergency shutdown system.

➤ *Figure 244* shows the relationship between the categories described in the previous section and the safety targets.

9.3 Analysis Methods

These rules and methods depend on the conditions considered among the design basis operating conditions, the design extension conditions, and the residual risk situations.

9.3.1 Rules for the Different Conditions

For the **normal operating conditions (Category 1)**, the definition and the studies of these conditions are aimed to specify the variation range of the main physical parameters featuring the reactor operation. These parameters deal mainly with the protection of the physical barriers and also permit to check the integrity of the barriers (measurement of radio contamination, tightness of barriers. . .). These conditions include the different states of the reactors and the definition of the transients permitting to switch from one state to the other. The definition of these conditions is a starting point for the elaboration of the operating procedures (instrumentation and control system and human actions) and for the sizing of the threshold triggering the limitation actions permitting to maintain the reactor in normal operation. Moreover, the transient studies in normal operating conditions permit to assess the performance of the reactor and the sizing of the components regarding cyclic loadings. Finally, the systematic investigation of normal operating conditions permits to identify the enveloping situations to retain as an initial state to combine with an IE for the building of the operating situations. Considering each IE, the most unfavorable state must be retained.

For the **incidental and accidental operating conditions (Categories 2–4)**, the study of those conditions or, more precisely, of their representative enveloping situations is aimed to size the systems permitting their control and to avoid that they lead to nonacceptable consequences toward the facility and the surrounding. The acceptability criteria of the consequences deal with general safety objectives and more practically, they deal with the decoupling criteria. Actually, these criteria permit to uncouple and to perform separately the thermalhydraulic and neutronic transient calculations from the release calculations. Decoupling criteria will be elaborated for each category of operating situations. They deal generally with maximal admissible loadings (thermal, mechanical, power density) of the fuel and of the two first safety barriers. These criteria are defined to bring out a margin up to the physical resistance of the fuel and of the barriers or at least (for the highest category) to limited damages.

Once the various situations have been defined, the transient calculations of the sequences corresponding to the operating situations will be performed considering conservative assumptions that are supposed to lead to appropriate design margins. The deterministic approach relies on the pertinent selection of the conservative assumptions in order to cover the various uncertainties and the possible lack of exhaustivity of the analysis. Prior to applying the penalizing value on the key physical parameters in the calculation, those parameters are supposed to be identified properly. Moreover, an aggravating failure will be taken into account in the studies of the operating situations. Finally, the end of the incidental and accidental sequences investigated must correspond to a safe final state, which is either a controlled state or the safe shutdown state.

For the **Design Extension Conditions**, it should be remembered that these conditions include the complex sequences, the limiting events, and the managed severe accidents. The study of these conditions must show that the release target of the fourth category of the design basis situations is reached. These situations are built without respect with the rules applied for the definition of the design basis situations. The study of such situations relies on realistic hypothesis. More precisely,

- The initial state of the reactor is the nominal state.
- All the systems are available except those postulated unavailable due to the accident considered.
- The instrumentation and control system operates correctly.

- The physical calculations are performed with realistic hypothesis (best-estimate calculations plus uncertainties assessment).
- No additional aggravating failure is considered.

However, the uncertainties on physical parameters able to induce “cliff edge” effects will be assessed with a particular attention. The final state of the accident must correspond to a safe state insuring durably the core subcriticality, the decay heat removal, and radiological releases, fulfilling the acceptance criteria.

For the **residual risk situations**, the practical elimination of such situations must be shown according to a case-by-case analysis on the basis of the physical impossibility to obtain the situations considered, taking into account the design and safety provisions including ultimate systems, or by a combination of deterministic and probabilistic arguments.

The adequacy of the redundancy level of the systems fulfilling safety functions and more generally of the robustness of the safety design will be analyzed using when helpful.

- The aggravating failure assumption for the safety analysis of the design basis operating conditions
- The combination of initiating events according to a cause–effect reasoning
- The single failure criterion

Aggravating failure

When performing the study of design basis operating conditions, an aggravating failure on one of the system required to mitigate the IE is combined with this event. This failure must be independent of the IE causing the accident. The aim of this combination is to show that the consequences of the operating conditions remain lower than the limit allowed for the category of the initial initiating event. However, the combination of the initiating event with the aggravating failure may be classified in a higher category, thanks to a probabilistic assessment, the corresponding consequences being allowed to be larger. In order to simplify the approach and the number of combination investigated, the considered aggravating failure must induce the largest adverse effect. When the operating procedures are available, an operator error could be taken as an aggravating failure.

Examples of combination of IEs

Each design basis initiating fault must be analyzed in combination with a loss of station service power (LOSSP) of long or short duration, if it has an adverse effect. Combination with LOSSP is made at the most unfavorable time of the event. The combination of the initiating fault with LOSSP is considered to be a design basis operating condition (category 3 or 4 according to the category of the initiating event and the duration of the LOSSP). And combination of LOSSP with design extension conditions has to be examined on a case-by-case basis.

Earthquakes

Earthquakes are special initiating events because they affect at the same moment all the components of the plant and some systems outside the site, as the grid, for example, and then specific rules are used in practice. For example, for EFR project, the following rules have been proposed. Two kinds of earthquakes are defined in the design basis:

- An operational earthquake is defined in Category 3 mainly for the plant availability: the plant has to restart after such an earthquake.
- A safe shutdown earthquake is defined as an envelop of highly unlikely but most dangerous earthquake and is classified in Category 4.

Due to the possible consequences of the earthquakes (for example, multiple failures for the structures, multiple and simultaneous pin failures), an automatic trip initiated by specific seismic instrumentation is provided. The trip system response time and the absorber rod drop duration are taken into account in the analysis. These failures lead to plant transients, which are analyzed by taking into account all these consequential failures, an aggravating failure. Because the grid is not seismically qualified, these transients are combined with a consequential long-term LOSSP of 192 h.

The combination of earthquakes with initial states of the plant (part load, shutdown states, handling states, partial unavailability) depends on the estimated duration of these normal operating conditions, as for example EFR.

- In Category 3, the operational earthquake is combined with initial states which have a duration higher than 1,000 h per year.
- In Category 4, the operational earthquake is combined with initial states which have a duration higher than 1 h per year, but less than 1,000 h per year;
- In Category 4, the safe shutdown earthquake is combined with initial states which have a duration higher than 10 h per year.

Only for the safe shutdown earthquake, combinations of the failure of seismically qualified components are considered beyond the design, in DEC.

Single Failure Criterion

The single failure criterion (SFC) states that a system performing a safety function is able to fulfil its mission even if a single component of this system fails. It can be noticed that a system directly performing a safety function (reactor shutdown, decay heat removal, and containment) is usually designed according to the SFC (a safety function is indispensable to meet radiological limits imposed for any design basis operating condition). It is proposed as a design criterion for safety systems.

Basically, the single failure considered is different for passive systems (for instance, a leak) and for active systems (for instance, failure of a pump when functioning is required or spurious starting when it has an adverse effect). Regarding electric systems, all kinds of failure have to be considered. When applying SFC, the fulfilment of the mission of a system is not necessarily be obtained by the redundancy of an equipment, but can also be achieved by a functional redundancy. For instance, a DHR loop can operate in forced convection regime and in some situations in natural convection regime.

9.3.2 Line of Protection Analysis

The line of protection (LOP) method derived from the line of defense method is officially used since the RNR-1500 project has the advantage to gather the main components of the deterministic safety approach and to translate them into a single analysis method applicable for safety conceptual design as well as for safety assessments and analyses. The deterministic-based LOP method is semiquantitative, incorporating probabilistic notions. Any safety provision is conventionally agreed.

- Either as a strong line (“a”), when considering a material or system safety graded and, therefore, complying with the criteria of conception (e.g., “single failure” criterion), design (e.g., margins), fabrication (e.g., modes), surveillance, maintenance. . . ; in particular high

quality active system with internal redundancy (typical example: each shutdown system), high quality passive component or inherent behavior that allows long delays for fault rectifications could be considered as a strong line;

- Or as a medium line (“**b**”), when considering a material reliable but not safety graded or a human provision (e.g., in- or off-site procedure).

A conventional rate of reliability is assigned to each type of line of protection, based on experience (expert advice): one strong line (**a**-type) has an expected failure rate of about 10^{-3} to 10^{-4} per demand, and one medium line (**b**-type) has an expected failure rate of about 10^{-1} to 10^{-2} per demand. The respective reliabilities of successive lines of protection, implemented against a given risk, can be cumulated provided these lines are independent (common mode failures not possible). As a global objective, total loss of each main safety function must be equivalent to failures of at least two strong plus one medium lines: $2\mathbf{a}+\mathbf{b}$ (i.e., $< 10^{-7}$ /year/function). Then, from application of the LOP method, it is possible to check and justify the classification of the operating conditions and events and to classify any combination of several events, as shown in **Table 41**. The reliability of different LOP will depend on the redundancy (that provides protection against single failures), the diversity (that provides protection against common mode failures), and the independence (that provides protection against potential failure of common support systems, such as power supply).

■ **Table 41**

Theoretical relationship between LOP and operating conditions

Category of resulting event sequence	Category of initiating event or event sequence			
	2	3	4	DEC
3	b			
4	a	b		
DEC	2a	a + b	a	
Residual Risk	2a + b	2a	a + b	b

■ **Table 42**

Rule for analysis of LOP failure combined with operating situations

Initiating event	Failure of line of protection	Limits to be respected
Category 2	b	Category 3
Category 2	a	Category 4
Category 2	2a	Prevention of severe accident (DEC)
Category 3	a or b	Category 4
Category 3	a + b	Prevention of severe accident (DEC)
Category 4	a	Prevention of severe accident (DEC)

Additional LOP can be provided to minimize risk, but this should be considered based on the ALARP principle. Moreover, according to the categorization of operating conditions, combination of operating conditions with LOP failure can be analyzed following the requirements presented in the  [Table 42](#).

9.3.3 Method for Safety Classification of Reactor Components

The purpose of ranking safety functions into safety classes is to provide a basis upon which it is possible to establish adequate design and construction requirements for components performing the safety functions. Classification of the safety functions is based on the consequences of the safety function failure and the probability that the safety function would be required. The consequences are ranked by comparing with the release targets, and the probabilities are ranked by comparing the frequencies of the events requiring the safety function with the event classification used in the safety analysis.

Using these basic criteria, the method for classification of the safety functions should be in accordance with the rules defined in the selected design code. The methodology developed for the EFR project is not plant specific and could be used with simple adaptation for any plant provided it is designed using the standard European design code. On this basis, the consequences of the failure of the function are compared with the dose limits for the normal and category 2 operating conditions. If the releases are lower, the function is not safety classified, and the limiting release targets. If the consequences are higher, the function is fundamental for the protection of the public and the environment, and if the consequences are lower, the function allows minimizing the consequences.

The probability that the safety function would be required is compared with the expected occurrence frequency of the frequent events (normal and category 2 initiating faults), the infrequent events (category 3 and 4 initiating faults), the frequency of incredible events (design extension conditions). Thus, combining these comparison criteria, three safety classes can be defined as indicated in  [Table 43](#).

Components and parts of components are classified in design and construction classes in accordance with the safety functions they perform. The correspondence between the safety functions and the design and construction classes for the components is based on the class of the safety function performed by the component, and the reliability of the component to perform the safety function when required. The reliability is assessed taking into account the redundancy and the diversity with other components performing the same safety function in the same conditions, the degree of passivity of the component, and the delay before reaching unacceptable consequences after the failure of the component when required, and possibilities for corrective measures during this delay. Assuming the utilization of the European design and construction code (RCC-MR 2007), used for EFR, the correspondence between the safety functions and the design and construction classes of the mechanical components is indicated in  [Table 44](#). For electrical components, ranked as active components, the classical European codes generally consider two safety classes. The classification uses the same principle.

Additional requirements have to be considered. In order to exclude beyond the category 4 a double-ended pipe rupture, the leak-before-break approach (LBB) can be used. For this purpose, the concerned pipes and vessels have to be safety class 2 at least, independently of the safety function they perform. Concerning the earthquake, specific requirements are related to the

■ **Table 43**

Example of classification of safety functions

Safety functions	Classification
Function indispensable to meet the limiting releases in normal operating conditions or during a category 2 operating condition.	1
Function indispensable to meet the limiting releases during a category 3 or 4 operating condition.	2
Function indispensable to meet the limiting releases during a design extension condition.	3
Function allowing to meet the doses limits for normal and category 2 operating conditions.	3
Function allowing to meet the dose limits of category 2 during a category 3 or 4 operating condition (minimization).	3
Function not necessary to meet the dose limits for normal and category 2 operating conditions.	Not safety classified

components if they have to ensure their safety function during or after earthquake. Generally, components performing safety class 1 and 2 functions are seismically qualified. Components performing safety class 3 functions or non-safety functions may be seismically qualified if their failure during the earthquake leads to the failure of safety class 1 or 2 components.

9.3.4 Probabilistic Safety Assessment

The use of PSA for safety analysis and in support to design (see [Fig. 245](#)) is recognized under the framework of the risk-informed methodology. Several applications take profit of their use, as the checking of safety criteria associated to the core damage frequency or the plant damage states the definition of the design basis events and the critical SSCs (“systems, structures, and components”), and the maintenance in order to optimize the availability, and the choice among several options or among several optimizations of the architecture. . . (Bertrand and Devictor 2006; GenIV GIF; IAEA 2007; Kotake et al. 1993; Rasmussen 1975).

9.4 Illustration of SFRs Behavior in Typical Transient Situations

Reactor behavior depends on the characteristics of the core (sodium void, reactivity feedback coefficients. . .) and its inherent characteristics, for example, the quantities of sodium, the ratio of sodium quantities between the cold plenum and the hot plenum, the primary pump power supply. . . The behavior of a sodium fast cooled reactor under representative conditions is described in this chapter. The values given in the following figures are approximated results in support to the intention of the chapter, but are not related to an existing reactor. These examples have been obtained with an oxide core. The protection system of the reactor would be actuated

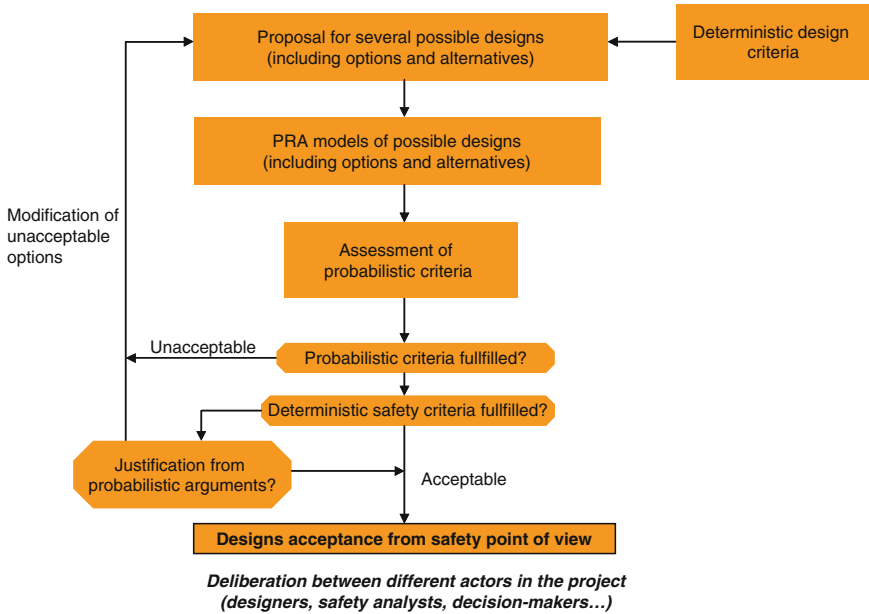

■ Table 44

Example of mechanical component classification

Classification of the function performed by the mechanical component	Characteristics of the mechanical component	Mechanical RCC-MR design and construction class
1 or 2	Active component needed before corrective measures can be implemented	1
1 or 2	Active component only needed after a delay which allows corrective measures to be implemented	2
1	Passive mechanical component with no redundancy provided	1
1	Passive mechanical component with redundancy provided	2
2	Passive mechanical component	2

from protection or safety signals. A noncomprehensive list of continuously monitored signals is given thereafter: the individual subassembly outlet temperature, the core outlet temperature, the core inlet temperature, the neutron power/core flow ratio, the absolute and relative neutron flux, the delayed neutrons fraction, the primary and secondary pump speeds, the feed flows, the steam generator outlet temperature, the steam generator leak... ➤ [Table 45](#) explains their use related to some possible events.

One of the objectives of thermalhydraulic studies is to foresee the thermal loads on the internal structures during different reactor operating conditions. To obtain these thermal loads, the detailed thermalhydraulic behavior of the reactor block should be known. The different results of thermalhydraulic studies are mainly the knowledge of velocity and temperature fields in the vicinity of the reactor block structure and around the core for nominal and partial-load steady state or transient operating conditions, heat and mass transfer in the cover gas, gas entrainment at the free surface, thermal striping. A general remark is that the various thermalhydraulic problems which occur in the primary circuit are connected. Thus their analyses require the use of system codes, as for example CATHARE (Farvacque et al. 2003) or RELAP (INEEL 2001), coupled with representative mock-ups; CATHARE v2 has been used for the examples in the ➤ [Sects. 9.4](#) and ➤ [9.5](#).

■ Figure 245

Example of a risk-informed methodology for design

For the analysis of the hot plenum, representative transients are emergency shutdowns or rapid shutdowns. During these transient conditions, the sodium temperature at the core outlet falls rapidly (► Fig. 246). Moreover, depending on operating choices, the primary flow rate can also vary. When these transients occur, two problems must be examined: the evaluation of the thermal shock on the structure (the above core structure in particular) induced by the rapid change in core outlet temperature, and the evaluation of the flow changes generated by the influence of buoyancy forces (core ΔT , minimal flow rate); depending on the operating conditions, which can, in fact, produce considerable flow changes in the hot plenum, and can even lead to the formation of a stratified hot layer above the inlet windows of the intermediate exchangers.

For the cold plenum, thermalhydraulics studies are used to study the thermal stresses in the structures (in particular the main vessel and the internal vessel), and the hydraulic supply to the primary pumps to be ensured. Transients of interest are, for example, asymmetrical transients with a secondary circuit out of operation, the variation of the primary flow, according to operating options. ► Figure 247 describes an example of a drying up of a steam generator. It implies a large hot shock in the diagrid, and a convergence of the inlet and outlet temperature of the intermediate heat exchanger (IHX). The questions to be risen are to know the effect of the temperature difference at the intermediate heat exchanger outlets in the vicinity of the structures (main vessel and internal vessel), both in terms of mean temperature and fluctuations, and the influence on the cold plenum thermalhydraulics of the difference of temperature between the hot plenum and the cold plenum that will induce a thermal flux through the internal structures.

Other interesting transients representative of the inherent behavior of a plant are transients of natural convection, as for example protected loss of station service power (PLOSSP). ► Figure 248 shows the evolution of the core inlet and core outlet temperatures during this

transient. At 1,000s, primary and secondary pumps are fully turned off on their inertia. Shutdown system is actuated. One DRACS, which is able to remove 100% of the residual power, starts within a delay of 30 min after the triggering of the pumps. The IHX and the DRACS have been designed to fulfil a constraint on the maximal temperature in the pool ($700\text{ }^{\circ}\text{C}$); we can observe that after the starting of the DRACS the temperatures reach a maximum value below $700\text{ }^{\circ}\text{C}$ and thus decrease.

9.5 Anticipated Transients Without SCRAM

Three anticipated transients without SCRAM (ATWS) are studied in order to contribute to the assessment of the robustness of a reactor:

- Loss of coolant flow without scram, also known as untripped loss of flow (ULOF), due to a loss of power to the coolant pumps, causing a flow coastdown and a large mismatch in core power and coolant flow (P/F ratio).

- Loss of main heat sink without scram (ULOHS), characterized by the loss of the ability to reject heat at the steam generator, such as sudden loss of generator load, increasing core inlet temperature.
- Uncontrolled fast transient of overpower due, for example, to a gas passage in the core (fast transient) or to an uncontrolled withdrawal of a reactor control rod, causing a slow transient overpower condition (UTOP).

The values given in the following figures are approximated results in support of the illustrative objective of the chapter, but are not related to an existing reactor. These examples have been obtained with an oxide core.

The **untripped loss of flow (ULOF)** accident is a challenging accident if only a passively safe response is expected, due to the severity of the conditions. The accident is initiated from nominal full power steady state conditions, and at the start of the accident, all power is lost to the coolant pumps, and the scram failed. The result of this accident is a coastdown of the forced flow through the reactor, governed by the stored inertia in the pumps (typical flow-halving time of about 10 s as for EFR project or 30 s for SuperPhenix). However, since the reactor is still operating at full power, this results in a rapid heating of the coolant. Depending on the timing and magnitude of the reactivity feedback, the reduction in power could be sufficient to prevent excessive temperatures and a coolant boiling. ➤ [Figure 249](#) describes the typical behavior of the

■ **Figure 249**
Example of an ULOF

temperatures in the hot plenum and the core inlet and outlet temperatures, and the influences of the different reactivity feedback; in this example primary pump power supply is actuated at a 28% of nominal flow. The Doppler is the first reactivity feedback opposing the effect of the decrease of the sodium coolant density. After a few minutes, this Doppler reactivity feedback is positive because of the power decrease, and the reactivity feedback due to the fuel, the structures, and the control rods expansion counterbalance the sodium void and the other positive reactivity feedback. Consequently the occurrence of a coolant boiling depends on the design choice for the architecture (for example, via the inertia of the pumps. . .) and the core reactivity feedback coefficients.

The occurrence of an **untripped loss of heat sink (ULOHS)** implies a rise of the core inlet temperature that yields a negative reactivity feedback. The main challenge is to avoid high temperature for the structures over the authorized time period, in order to avoid too important thermomechanical damages.

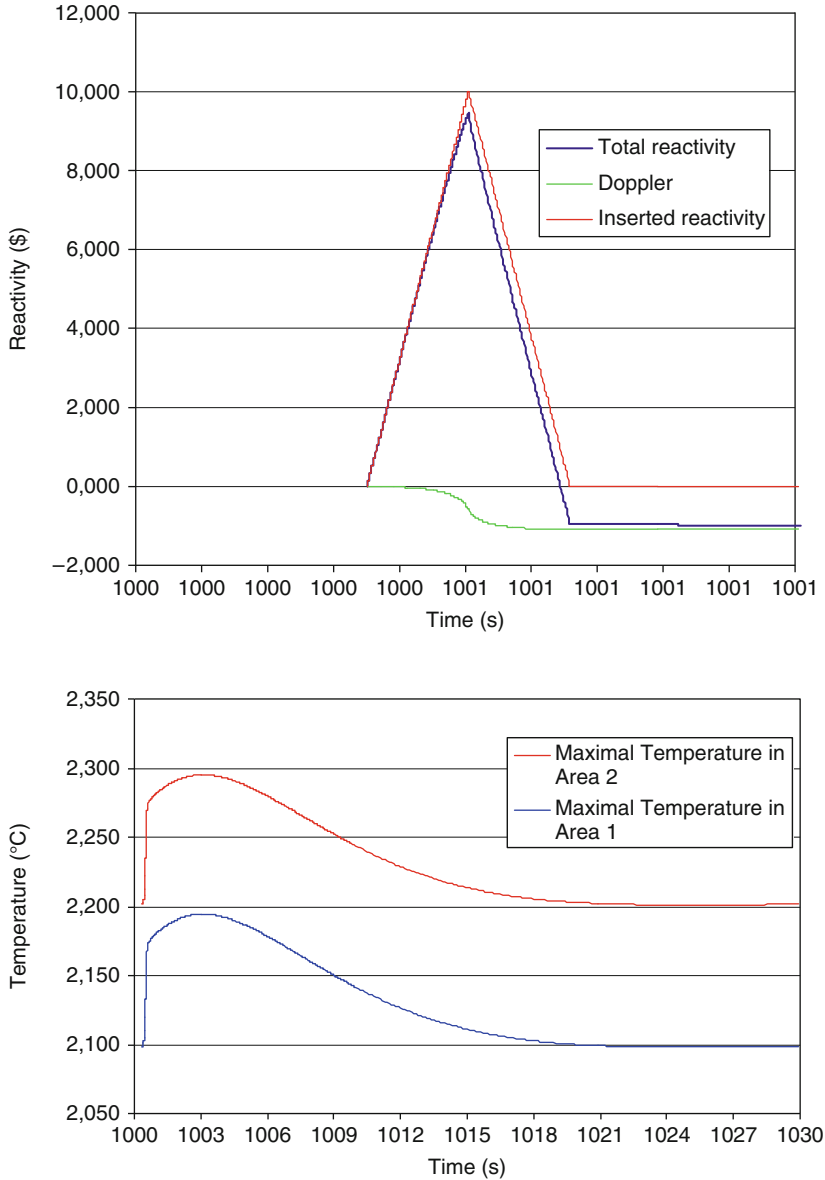

An **untripped transient of overpower (UTOP)** is a transient of a reactivity insertion, leading to power increase. For fast UTOP only the Doppler feedback could be efficient to counterbalance this insertion. ➤ *Figure 250* shows the consequence of a gas bubble leading to an insertion of 1\$ in 0.15 s then a back to normal into 0.15 s on the maximal temperatures in two areas of the studied core and the variation of the different components of the reactivity.

10 Severe Accidents

10.1 Introduction

In the water reactor, the core is in its most reactive configuration and hence, any phenomenon that results in disintegration of core makes the reactor, generally, to shutdown automatically. This is not the case with SFR. The disintegration of core in SFR (fuel slumping, for example) may lead to power excursion, resulting in an accident. The core has high density of power, which can have a positive voiding effect. The physicochemical characteristics of sodium pose sodium–water reaction and chemical toxicity challenges. There is a need for development of specific and innovative technologies for in-service inspection of the structures under sodium due to opaqueness of sodium. Repairing circuits and components in postaccidental situation call for sophisticated and specific technologies. The SFR components, i.e., large size thin walled shell structures, are also sensitive to earthquake loadings. The requirement of high breeding ratio, burning of minor actinides in suitable matrices and enhanced safety with improved economy needs advanced materials and technologies which call for extensive experimental, modeling and simulation technologies. High burnup targeted for the future reactors and near complete burning of minor actinides and long lived fission products introduce higher levels of radioactivity during fuel handling and fuel reprocessing.

Fast reactors are designed to be stable, and experiences accumulated so far have demonstrated the attainability of such behavior. Though the potential for radiation release to the atmosphere exists, there are numerous inherent and engineered safety features to inhibit such release. Robust design philosophy is commonly applied for the core and coolant circuits by way of choosing high quality materials, adopting matured design, construction and inspection

■ **Figure 250**
Example for a fast UTOP

standards, guides and methodologies, with the ultimate objective of minimizing/eliminating the initiators, which lead to partial and whole core accident. Design provisions, such as diversity in shutdown and decay heat removal systems are introduced to meet the safety limits with adequate margins for the design basis events, so as to prevent beyond design basis

accidents. Advanced design features such as recriticality in molten core, effective core catcher, and containment are introduced for the management of beyond design basis accidents.

In order to demonstrate the safety, analysis is performed by postulating various scenarios of high probability to very low probability. The events that result in the highest damage are commonly labeled beyond design basis accident (BDBA). Beyond the DBA, there lies a domain of accident consequences which are less probable and in order for such accident to take place, at least two or more low probability failures must take place in sequence, e.g., a large reactivity insertion event coupled with complete failure of the plant protection system. Those BDBA which involve degradation/melting of whole core is termed as core disruptive accident (CDA) or severe accidents.

In this chapter, the history of CDA, various phases of accident scenarios, mechanical and thermal consequences and post accident heat removal conditions, and computer codes used for the safety studies are described. Finally, various international computer codes used for the CDA analysis are highlighted.

10.2 History

From early days (1950s), the perspective on severe accident in SFR has been influenced greatly by the fact that core compaction in SFR results in increase of reactivity, in contrast to thermal reactor systems. Also, the low value of delayed neutron fraction and prompt neutron lifetime, raises concerns that a core melt down may rapidly lead to a prompt critical condition and that the power rises beyond that point could be extremely rapid. A mismatch between heat generation and heat removal in the core can lead to fuel melting and ultimately to a CDA, if the reactor shutdown system fails on demand. Although fuel vaporization, an inherent shutdown mechanism, would ultimately limit the energy generated by physically moving the core apart, the concern has been visualized that potential work energy released might be larger than practically containable (Walter and Reynold 1981). Initial analysis led to conservative and very high values of energy release in CDA, like the one proposed by Bethe and Tait, which assumes a gravity-driven collapse of the core and a hydrodynamic core disassembly. It also assumed no Doppler feedback and no delayed neutrons. During early 1960s, the safety analyses of EBR-II were performed considering reactivity feed backs and simplified but conservative core slumping models after onset of fuel melting (Graham 1971). During 1970s and 1980s, with experimental knowledge from primarily TREAT, ACRR, CABRI, and SCARABEE test reactors used for validation, safety analysis codes SAS3D and SIMMER-II were integrated for CDA analysis in 2-D. It was shown that the energy production in the initiating phase decreased drastically (Nonaka and Sato 1992). In 1990s with more experiments, the understanding of the phenomenon improved considerably and validation of SAS4A and SIMMER-III led to further reduction of energy release values (Tobita et al. 1999). During 2000s, the analysis capabilities have further improved with the development of SIMMER-IV for 3-D modeling (Yamano et al. 2008). In [Fig. 251](#) and [Table 46](#), the trend of energy release predictions from examples of various reactors is depicted, which reflects the reducing value of the ratio of CDA energy release (MJ) to reactor power (MWt). Even, near zero energy release has been computed in CDA as indicated for EFR with in-pin fuel motion with intact clad. Thermal energy release and its consequences are being studied in depth internationally.

Figure 251

Trend of mechanical energy release in various reactors

Table 46

CDA energy release for reactors

Reactor	Power – P (MWt)	Mechanical energy – W (MJ)	Ratio – W/P
SPX1	3,000	800	0.270
SPX2	3,500	110	0.030
BN 800	2,100	50	0.024
DFBR	1,600	50	0.031
EFR	3,600	150	0.040
PFBR	1,250	100	0.080

10.2.1 Instances of Severe Accidents in Fast Reactors

Core melt down accidents have occurred in EBR-I and Enrico Fermi Fast Breeder Reactor. These accidents were severe accidents, though there was no whole core disruption subsequent to core melt down.

EBR-I reactor was metal fuelled (highly enriched uranium), NaK cooled low power (1 MWt) reactor. A core melt down accident occurred in EBR-I in November 1955 (Thomson and Beekery 1964). Tests were being run involving reactivity ramps at low flows. As the power neared the safety limit, a slow shutdown was initiated by mistake, instead of a scram. Temperatures at the center of the core exceeded the NaK coolant boiling point. Then the fuel also melted. The boiling NaK forced molten fuel material outward, both above and below the core. The channels were then blocked by freezing of the core material that formed a cup into which further fuel material fell. Fission products were released as gas bubbles, forming a porous fuel mass when the fuel froze. Forty to fifty percent of the fuel of the core melted before shutdown occurred. The EBR-I had a small core 20 cm in diameter. The consequences of this event are perhaps not representative of a CDA that would occur in a large core. Nevertheless, the quick progression

of the accident (less than few seconds) gave strong indication that such accidents, even when they occur in large cores, will happen within a short duration.

Enrico Fermi reactor was a 200 MWt/65 MWe, U metal fuelled, SFR. The reactor became critical in 1963. A core melt down accident occurred in October 5, 1966 (Anderson 1978). There was earlier history of unexplained subassembly outlet temperature rise ($>30^{\circ}\text{F}$) over the earlier 3 months. This was observed even after relocating the subassemblies. On the day of the incident, the absorber rods had to be withdrawn to higher level than previous values at 30 MWt. The operator got alerted and suspected unaccounted negative reactivity. The radiation detectors in containment building gave alarm from radioactivity of the cover gas and containment was isolated. Subsequently, the reactor was manually shut down by which time gamma monitors in fuel building also gave alarm. It was understood that heating and voiding of the four subassemblies due to reduced coolant flow was the source of negative reactivity, which resulted in the higher absorber rod level. Trip on rate of power reduction had been introduced earlier (6 MWt/s) against sudden insertion of negative reactivity. It was diagnosed that partial flow blockage had been caused by segments of zirconium plates relocated from above the core. Earlier noted higher subassembly outlet temperatures were due to this partial blockage. The accident caused by flow reduction of about 97%, resulted in melting in 2 subassemblies.

10.3 Defense in Depth

Application of the concept of defense in depth (INSAG-10 1996) throughout design and operation provides a graded protection against a wide variety of transients, anticipated operational occurrences and accidents, including those resulting from equipment failure or human action within the plant, and events that originate outside the plant. The following five levels of defense (inherent features, equipment, and procedures), aimed at preventing accidents and ensuring appropriate protection in the event that prevention fails, have been listed in IAEA safety standard (IAEA 2000).

Level-1

The aim of the first level of defense is to prevent deviations from normal operation, and to prevent system failures. This leads to the requirement that the plant be designed with sufficient safety margins, comprehensively addressing the possible failure modes and operating experiences, constructed and operated in accordance with high quality levels and engineering practices, such as the application of redundancy, independence, and diversity. To meet this objective, careful attention is paid to the selection of appropriate design codes and materials, and to the control of fabrication of components and of plant construction. Design options that can contribute to reducing the potential for internal hazards, e.g., controlling the response to a postulated initiating event (PIE), to reducing the consequences of a given PIE, or to reducing the likely release source term following an accident sequence, contribute at this level of defense. Attention is also paid to the robust procedures involved in the in-service inspection and maintenance. This whole process is supported by a detailed analysis, testing, validations, and peer reviews.

Level-2

The aim of the second level of defense is to detect and intercept deviations from normal operational states in order to prevent anticipated operational occurrences from escalating to accident conditions. This is in recognition of the fact that some PIEs, such as power failure and pump trips, are likely to occur over the service lifetime of a nuclear power plant, despite the care taken

to prevent them. This level necessitates the provision of specific systems as determined in the safety analysis and the definition of operating procedures to prevent or minimize damage from such PIEs.

Level-3

For the third level of defense, it is assumed that, although very unlikely, the escalation of certain anticipated operational occurrences or PIEs may not be arrested by a preceding level and a more serious event may develop. These unlikely events are anticipated in the design basis for the plant, and inherent safety features, fail-safe design, additional equipment, and procedures are provided to control their consequences and to achieve stable and acceptable plant states following such events. This leads to the requirement that engineered safety features be provided that are capable of leading the plant first to a controlled state, and subsequently to a safe shutdown state, and maintaining at least one barrier for the confinement of radioactive material.

Level-4

The aim of the fourth level of defense is to address severe accidents in which the design basis may be exceeded and to ensure that radioactive releases are kept as low as practicable. The most important objective of this level is the protection of the confinement function. This may be achieved by complementary measures and procedures to prevent accident progression, and by mitigation of the consequences of selected severe accidents, in addition to accident management procedures. The protection provided by the confinement may be demonstrated using best-estimate methods.

Level-5

The fifth and final level of defense is aimed at mitigation of the radiological consequences of potential releases of radioactive materials that may result from accident conditions. This requires the provision of an adequately equipped emergency control center, and plans for the on-site and off-site emergency response.

10.3.1 Physical Barriers

A relevant aspect of the implementation of defense in depth is the provision of a series of physical barriers to confine the radioactive material at specified locations. Three barriers exist within a reactor to physically prevent the release of fission products to the outside environment. These include (1) the fuel matrix itself, (2) the fuel pin cladding, and (3) the primary coolant system. A fourth barrier, the outer containment, represents an engineered safeguard.

The fuel matrix, normally a ceramic material, has considerable capability for retaining solid fission products, as well as gaseous fission products in the unrestrained region. Fission gas, which is released during irradiation, is normally contained in a fission gas plenum, in order to prevent contamination of coolant. However, reactors are designed to operate with a small fraction of failed fuel. All large reactors have a radioactive waste removal system built in as part of the cover gas system, and small amounts of radioactive debris in the primary sodium can be removed in a routine manner using cold traps.

To provide framework for establishing a defense-in-approach, it is necessary to recognize the relationship between the anticipated frequencies of occurrence for various accidents versus the accident severity levels, which could be accepted for each event. Such a relationship should

certainly indicate little or no damage to the reactor system for high frequency events, whereas relatively higher levels of damage could be tolerated for lower frequency events. Appropriate engineering features, such as an effective plant protection system (PPS) should be available to ensure such a characteristic.

10.4 CDA: Phenomenology

A mismatch between heat generation and heat removal in the core can occur if either heat generated is more than heat removal, or heat removal is less than heat generated. The former situation will arise if there is uncontrolled reactivity addition in the core, and corresponding power increase. The later situation will arise if there is coolant flow starvation and reduced heat removal. With an accompanying shutdown system failure, the former situation can lead to a unprotected transient overpower accident (UTOPA) and the later situation to a unprotected loss of flow accident (ULOFA). Apart from this, if there is failure in decay heat removal in shutdown reactor, it can potentially lead to protected loss of heat sink accident (PLOHSA) resembling a gradual LOFA. But probability for such an accident is still lower and this is presently considered under the category of residual risk due to the highly reliable and passive decay heat removal systems. In case of UTOPA, fuel melts initially. This results in in-pin fuel motion (Porten et al. 1981), which can act as a shutdown mechanism. If the positive reactivity excursion continues, the clad failure, Na voiding, and then core collapse are possible. In ULOFA, initially coolant voids were followed by clad failure and then, fuel slumping. Core collapse or slumping can introduce positive reactivity and produce CDA where a lot of thermal energy is released due to the neutronic power excursion. Subsequent core dispersal reduces core reactivity and terminates the highly energetic phase of the accident.

Uncontrolled reactivity addition leading to UTOPA can occur due to (1) uncontrolled withdrawal of control rods, (2) passage of large bubble in core, and (3) collapse of core support structure leading to core compaction. Uncontrolled withdrawal of control rods is a PIE, even though control rods are usually moved for a preplanned distance. If the worth of the rod is high enough or more than one rod is involved, it can lead to high reactivity addition and, consequently, large power increase. Uncontrolled reactivity addition can also occur due to passage of large gas bubble in the core. Passage of such a large gas bubble in the core is very highly unlikely, and the reactivity that can be inserted in present designs (with low coolant void reactivity effect) is low. Small gas bubbles result in very negligible reactivity addition. UTOPA can perhaps occur due to sudden structural failure of core support structure which is again considered as residual risk at present. The core support structure is a safety class 1 component with a box type structure and random failures or stiffeners do not degrade its performance. Structural vibrations caused by seismic excitations can give rise to only reactivity oscillations, which are small in magnitude (less than 0.5\$, which a peak pulse), and further there is damping due to negative reactivity feedbacks and which can be shown to result in only a small increase in reactor power (Srinivasan 2002). Hence, the uncontrolled withdrawal of control rod is the only initiator considered for UTOPA and possible CDA.

The coolant flow starvation can be initiator for ULOFA, caused by failure of primary pump or seizure of primary pump or pipe rupture or total instantaneous blockage in subassembly. The failure of primary pump due to loss of power supply can be an initiator for CDA. The loss of power supply leads to flow coastdown (with flow-halving time of about 8–10 s) and reduced heat removal, leading to mismatch in heat balance. The pipe rupture does not lead to total flow

starvation. Total instantaneous blockage is prevented by having multiple holes for coolant entry in the foot of the subassembly, and an adapter at the top of the subassembly gives an alternate flow path. Pump seizure can lead to a CDA, if it does not recover operation within a few tens of seconds. Thus, the pump seizure or stoppage of primary pump due to loss of power supply is the only main initiator for ULOFA and possible CDA.

10.4.1 Different Phases of a CDA

Analysis of CDA is carried out in a rigorous manner from early stage, starting with the initiating event, through various stages, until the estimation of mechanical energy release, and the response of the main vessel and top shield to the mechanical energy release. Different physical phenomena are dominant at various stages of the accident and also the time scales involved are different. Therefore, the accident progression is analyzed deterministically in different phases using cause and effect phenomenology and adopting a conservative approach where deterministic analysis is not possible. The phases of accident analysis are discussed below.

Pre-disassembly Phase

This phase of analysis deals with the transient response from accident initiation to the point of (1) neutronic shutdown with essentially intact geometry, (2) a gradual core melt down where the computational models needed for tracking the accident further must be significantly modified, or (3) the onset of conditions for hydrodynamic core disassembly due to generation of high internal pressures from vaporized core materials. Calculations are performed deterministically for core neutronics, reactivity feedbacks, thermohydraulics, sodium boiling, fuel pin failure, cladding and fuel slumping, and their relocation and fuel coolant interaction.

Transition Phase

At the end of the pre-disassembly phase, the reactor can become subcritical if there are sufficient negative reactivity feedbacks. Then the accident gets terminated. If the negative reactivity feedbacks are insufficient, the fuel and clad can melt and form a molten pool. This is the called transition phase, since the fuel attains gradual transition from solid to liquid phase, and since this phase is sandwiched between the pre-disassembly and disassembly phase. The core can boil and then cool – subcritical configuration could be established or criticality conditions can recur.

Disassembly Phase

Once the fuel starts dispersing, fuel displacement feedback dominates, time scales are short (of the order of milliseconds) and all other reactivity feedbacks except the Doppler can be ignored. The core loses its integrity. The core neutronics and core hydrodynamics calculations are performed for the dispersing core. This phase lasts till the reactor attains subcriticality due to fuel dispersal.

Mechanical and Thermal Consequences of CDA

The various phases of CDA are illustrated in  Fig. 252. In the pre-disassembly phase, the heat is generated due to power excursion that could melt the core, to the extent of saturated liquid state. Subsequent heating generates vapor phase, which is having high potential to do mechanical

Figure 252
Mechanical and thermalhydraulics consequences of CDA

work, in view of its high temperature and high pressure (► Fig. 252a). The mechanical energy release is due to expansion of vapor phase from initial pressure (P_0) which is at saturated condition to the final pressure (P_f) equal to ambient condition prevailing in the reactor. During this rapid expansion of core bubble in the liquid sodium environment which is considered as isentropic, the pressure/shock waves are generated, which deform the shell structures surrounding the core (► Fig. 252b). Subsequent to completion of mechanical work, the vapor phase which is at $\sim 5,000$ K, condenses due to cooling of sodium pool, which is at 855 K and starts moving downward melting the support structures, such as grid plate and core support structure (► Fig. 252c). Finally, the liquid settles on the core catcher and subsequently will be cooled by natural convection (► Fig. 252d).

10.5 Analysis for Mechanical Consequences

10.5.1 Idealization of Molten Core Expansion Behavior

The mechanical consequences are described based on the energy stored in the core at the end of the neutronic event. The mechanical energy release (W) is the expansion work that can be delivered by the molten core while expanding from its initial state (high pressure and high temperature) to the state of ambient pressure (~ 1 bar). The W depends on the equation of state of molten core. The molten core would be in the form of saturated liquid and vaporizes sequentially in the process of expansion. Hence, for the analysis of mechanical consequences, equation of the state of core bubble has to be established first. Since temperatures of core are different at different locations, the integrated effect of the core bubble should be established correctly. For this, the core is divided into number of cells in the reactor physics computation. The average temperatures are extracted at the center of each cell. From the individual cell temperatures (T_i) and cell mass (M_i), the average temperature and mass of homogenized molten core are computed as: $M_o = \sum M_i$ and $T_o = \sum M_i T_i / M_o$. Further, assuming conservatively that the entire homogenized core is at its saturated liquid state, the following steps are adopted to derive the equation of state:

Knowing to, the initial state of saturated liquid is identified in the “T-s” diagram and path of the various states in the course of adiabatic expansion are shown in ► Fig. 253. Then, initial

■ Figure 253

Adiabatic expansion of core bubble

enthalpy h_0 , equal to cpT_0 and entropy s_0 from thermodynamic property tables and pressure P_0 are computed from the following equation of state (Srinivasan 2002):

$$P_0 = e^{(A+B/T_0+C \log_e T_0)} \quad (50)$$

where $A = 68.3$; $B = -8.0541 \times 10^4$; $C = -5.641$.

Assuming a small value for V_0 in the first iteration, the starting point (P_0 and V_0) is fixed in the P versus V diagram. Subsequent points are arrived at by adopting the following steps.

- Step-1: Assume a small drop of temperature from T_0 to T
 - Step-2: From T , extract hL and hLg and sL and sLg from thermodynamic data for oxide fuel
 - Step-3: Compute vapor mass fraction: $x = M_v/M_o = (s_0 - sL)/sfg$ for the isentropic expansion
 - Step-4: Compute $h = (1 - x)hL + x hLg$
 - Step-5: Compute $\Delta W = M_o(h_0 - h)$
 - Step-6: Compute $\Delta V = \Delta W/P_0$ (assuming pressure is constant for a small volume change)
 - Step-7: Compute $V = V_0 + \Delta V$
 - Step-8: Thus the next point in P vs. V diagram is arrived at.
- The above 8 steps are repeated sequentially by updating pressure ($P_0 = P$) and volume ($V_0 = V$), till P is equal to ambient pressure P_a of 0.1 MPa.
- Step-9: Plot the $\log P$ versus $\log V$ diagram
 - Step-10: Draw the trend line and the slope of the curve is the exponent " γ " for the equation of state for homogenized core gas bubble: $PV^\gamma = \text{constant}$

Following the above methodology, the equation of state has been derived for a typical 500 MWe SFR as depicted in [Fig. 254](#), wherein the γ value is found to be 0.72, yielding 100 MJ of mechanical energy.

■ Figure 254

Determination of exponent of equation of state: $PV^\gamma = \text{constant}$

10.5.2 Analysis for Vessel and Roof Mechanical Loading

The core bubble containing highly pressured mixture vapor phase can generate pressure/shock waves. An immediate effect of such waves is plastic deformation of surrounding structures, which offers resistance for the propagation of pressure waves. Due to the presence of cover gas space above the sodium free level, there is less resistance for the movements of liquid in the upward direction and hence, a portion of sodium above the bubble is accelerated upward. Hence, a net force develops in the downward direction due to which, the main vessel is pulled down. This in turn produces compressive force on the reactor vault. This force is termed as “pull-down force.” The accelerated sodium continues to move upward for a certain period (50 ms typical) during which, there is no significant mechanical deformations, till sodium impacts on the top shield. Once the sodium impacts on the top shield, which is termed as “sodium slug impact,” the kinetic energy of the moving sodium is converted into pressure energy. Consequently, the pressure in the cover gas as well as in the sodium increases steeply, producing (1) further overall plastic deformation on the main vessel, (2) large local deformation on the main vessel near top shield junction in the form of bulging, and (3) impact force on the top shield in the upward direction. The slug impact phenomenon (from the start of impact till stabilization of vessel deformation) occurs during 100–150 ms (typical).

The two important phases of the accident, where the vault is subjected to forces, are: (1) the reactor vault is pulled down by the main vessel through support shell, due to net unbalanced pressure force acting on the bottom portion, and (2) it is subjected to upward force through top shield due to sodium slug impact. The force acting on the support shell, which in turn transmits to the reactor vault, is the net effect of these two forces. During the slug impact, the bolts of top shield components elongate and the seals in the annular gaps of the top shield may fail; as a result of this, sodium may fill the top shield penetrations. Subsequently, sodium

Figure 255

Mechanical consequences of CDA

leaks to reactor RCB. In the quasi-static condition when the sodium leak phenomenon occurs, the core bubble pressure drops. This is mainly due to the cooling of the bubble by the surrounding subcooled sodium, which has high heat capacity, while the volume of the core bubble remains unchanged. The quasi-static condition prevails during 150–900 ms (typical). The leaked sodium will catch fire and cause temperature and pressure rise in the reactor containment building (RCB). The RCB is designed for this pressure. Figure 255 depicts the above mentioned scenarios. Beyond 900 ms, the mechanical consequences are terminated except creep of high-temperature components, which depends upon the heat removal provisions made in the design.

Theoretical Predictions

Analysis is generally carried out using either finite element or finite difference method-based codes. These codes solve a set of governing differential equations of fluid, structure, and fluid–structure interaction dynamics, written in Lagrangian, Eulerian, or Mixed Lagrangian–Eulerian (ALE) coordinate systems. The generic form of equations is as follows:

Mass balance

$$\frac{dM}{dt} = \frac{d}{dt} \int_{V(t)} \rho dV = \oint_{S(t)} \rho \left(\overrightarrow{W} - \vec{V} \right) \cdot \vec{n} dS$$

Energy balance

$$\frac{dE}{dt} = \frac{d}{dt} \int_{V(t)} \rho e dV = \oint_{S(t)} \rho e \left(\overrightarrow{W} - \vec{V} \right) \cdot \vec{n} dS - \oint_{S(t)} p \vec{V} \cdot \vec{n} dS + \int_{V(t)} \rho \vec{g} \cdot \vec{V} dV$$

Momentum balance

$$\frac{d\vec{Q}}{dt} = \frac{d}{dt} \int_{V(t)} \rho \vec{V} dV = \oint_{S(t)} \rho \vec{V} \left(\overrightarrow{W} - \vec{V} \right) \cdot \vec{n} dS - \int_{V(t)} \text{grad } p dV + \int_{V(t)} \rho \vec{g} dV$$

The complexities modeled in the code are large distortions in fluids, large displacements in structures, interactions of fluids with structures completely immersed as well as partly contact with fluid, treatment of solid–fluid and liquid–gas boundaries, sodium slug impact and shock wave propagation. An efficient numerical solution technique involving explicit algorithm to calculate initial values and subsequent implicit algorithm to get converged values

has to be incorporated to the resulting equations. The computer code should have an efficient automatic rezoning algorithm at the end of every time step. The code needs to be validated. REXCO (Chang and Gvildys 1975), SEURNUK (Cameron et al. 1978), EURDYN (Donea et al. 1980), PISCES (Cowler and Hancock 1979), SIRIUS (Blanchet et al. 1981), FUSTIN (Chellapandi 2000a), ICECO (Wang 1975) and Cassiopee (Graveleau and Louvet 1979) are the international codes developed for this purpose. For illustrating the numerical prediction capability of the computer codes, a few typical results obtained by FUSTIN for assessing the structural integrity assessment of the PFBR components are presented.

Experimental Validation of Computer Codes: Typical Case Study

One typical experimental validation relevant to the present problem is presented in this chapter (Chellapandi et al. 2007). The test problem deals with 1/30th scaled down model of PFBR main vessel with rigid top cover, subjected to low density explosive (LDE). The vessel is filled with water leaving an empty space at the bottom. The dimensional details are shown in ► Fig. 256. The LDE is produced from the basic chemical called PTN precipitated in foam to bring down the density from ~ 0.8 to ~ 0.14 g/cc (the targeted value) and placed at the center. Three tests were carried out to ensure the repeatability. The work potential and equation of the state of the LDE charge are established simultaneously from the tests on simple cylindrical shell with rigid top and bottom covers, completely filled with water. Post processing of the test data yields values for work potential of 2.3 kJ/g and equation of state: $P = P_0 (V_0/V)^{0.75}$ (MPa), where $P_0 = 40$ MPa and $V_0 =$ parameter (m^3). The mass of charge denoted for the tests is 2.2 kg which

■ Figure 256
Geometrical details of test vessel

yields mechanical energy release of about 5 kJ. The evolution of vessel deformations is captured by high speed photography. ▶ *Figure 257* shows a few frames that depict the vessel deformation scenario in which the numerical prediction is the same as predicted by FUSTIN code. The transient pressure distribution in the water during the process of loading is also superimposed in ▶ *Fig. 257* to understand the sequence of loading. The vessel is highly strained in two phases. During the first phase, which lasts about 1 ms, the bottom portion of the vessel undergoes radial bulging and downward motion, and the top portion is subjected to high axial tensile stress. This is due to the impact of direct pressure waves on the bottom portion of the vessel. It is worth noticing that the top portion shrinks slightly, while the bottom portion moves down due to Poisson's effect. During the subsequent phase (1–2.5 ms) the upper portion of the vessel undergoes local radial bulging due to water slug impact on the top cover and subsequent local pressurization in water in the process of conversion of kinetic energy into pressure energy. These scenarios are clearly depicted in ▶ *Fig. 257*.

The initial and final shapes of the vessel as seen in the test setup are shown in ▶ *Fig. 258*. The transient evolution of vessel deformations at various instants is shown in ▶ *Fig. 259*. The comparison is found to be excellent.

Structural Integrity Assessment under CDA: Two Case Studies

Theoretical Investigations For SPXI, the CDA has been analyzed for mechanical consequences on internal and main vessels for the energy release of 800 MJ energy (Bour et al.). The hydrodynamic and structural aspects are coupled for the whole reactor block, except for the roof slab, which were analyzed with a structural code, gravity loads not taken into account in the hydrodynamic analysis. The fluids are modeled as compressible medium. The structural material is austenitic stainless steel SS316 LN, which is treated as elastoplastic materials and best fit properties are used in all analyses. The hydrodynamic and structural calculations were carried out by 2D explicit Lagrangian code SIRIUS, developed by CEA, which uses finite difference discretization for the fluid and the thick structures and a finite element meshing for the shell structures. Subsequently, the mechanical calculations are carried out using INCA for roof, TRICO for dome, and TEDEL for IHX and secondary loops. [Figure 260](#) shows the deformation of main vessel bottom. The important results are the maximum displacements, strains, and stresses at critical locations in the reactor block, for 800 MJ energy release. The maximum deflection calculated at the roof is 35.2 mm. The maximum strain observed in the high part of the main vessel is 4.2% in the meridian direction (bulged area). Hence, there is no risk of a shock between main and safety vessels deduced from the calculated displacements.

For PFBR, analysis is carried out using the finite element code called “FUSTIN,” which uses Arbitrary Lagrangian–Eulerian coordinate system for describing fluid motions and convected coordinate system for modeling the geometrical nonlinearity of structures (Chellapandi et al. 2000b). Further, to overcome the limitations of the algorithm to handle the complicated core boundary movements with the presence of reactor internals, particularly the control plug, a “two phase fluid element” is developed and implemented in the code. With this element, the core bubble boundary nodes need not be purely Lagrangian. The code FUSTIN has been validated against many international experimental and theoretical problems. The equation of state for sodium is: $P = a_1\mu + a_2\mu|\mu| + E(b_1 + b_2\mu)$, where $\mu = \rho/\rho_0$; $\rho_0 = 832 \text{ kg/m}^3$, $\rho =$ instantaneous density, $E =$ internal energy per unit volume, $a_1 = 4.44 \times 10^9 \text{ Pa}$, $a_2 = 4.328 \times 10^9 \text{ Pa}$, $b_1 = b_2 = 1.218$. The equation of state for argon is $PV^\gamma = \text{constant} = P_0V_0^\gamma$, where $P_0 = 0.1 \text{ MPa}$, $V_0 = 104 \text{ m}^3$, and $\gamma = 1.67$. The true stress–strain curve for structural material SS 316 LN recommended by RCC-MR (2002) at metal average temperature 773 K is used. The initial volume and pressure

■ Figure 260
SPX1 main vessel deformation (U)

of core bubble are 2.56 m^3 and 4 MPa, respectively. The core bubble is considered as a spherical ball, governed by the equation of state: $PV^{0.72} = \text{constant}$.

The main vessel, core support structure, grid plate, control plug and top shield, and support skirt are included in the geometrical model. The vessel is filled with sodium with a cover gas gap of 800 mm. The masses of thermal baffles are lumped at a junction point on the main vessel. The masses of core, grid plate, and core support structure are distributed appropriately. With these added/distributed masses, the entire mass of reactor assembly is truly conserved. The geometry consists of core bubble, sodium, cover gas, and vessels with the interfaces between core bubble and sodium, sodium and cover gas, sodium to metal surface, cover gas and metal surface, and the core bubble to metal surface (in case the bubble interacts with the inner vessel and control plug). The shell structures are modeled with “2-noded conical shell element.” The structural nodes are Lagrangian. The sodium and core bubble are modeled by “quadralateral axisymmetric solid elements.” The interface between the structures and fluids are ALE since the fluid nodes, which are attached to the specific structural nodes, move with the corresponding structural nodes. The argon space is considered as a single homogeneous medium obeying the equation of state. The finite element model of various geometries is shown in [Fig. 261a](#).

From the analysis, the overall sequence of events is depicted clearly as shown in [Fig. 261](#). The sequence of events which are depicted is: upward bowing of core cover plate of control plug and bulging of inner vessel and downward displacement of main vessel bottom portion ([Fig. 261b](#)), core bubble crossing the control plug ([Fig. 261c,d](#)), sodium slug impact on the top shield, reflection of pressure waves from top shield and downward bowing of core cover plate and downward displacements of sodium free levels ([Fig. 261e](#)). Important observations are regularities of meshes till the end of the analysis, simulation of complicated motions of core bubble around the control plug, sequential immersion of inner vessel in the sodium pools, upward and downward bowing of plates in the control plug, high local straining of main vessel due to load transmitted at the triple point, sodium impact restricted to a small zone on the top

Figure 261
Evolution of core bubble behavior in PFBR reactor assembly during CDA

Figure 262
Evolution of energy distribution

shield around the control plug and no impact of sodium slug within the control plus on the top shield, and nearly uniform overall deformations of internals and main vessel.

The energy balance is shown in Figure 262. Due to constraints of main vessel and internals, the maximum energy released by core bubble is 60 MJ during transient condition. Under quasi-static condition when the kinetic energy is ignored, the energy released by core is fully absorbed by vessels and cover gas space. The total energy would be 45 MJ. The main vessel absorbs the energy in two phases: at about 25 ms due to initial impact of pressure waves propagated in sodium at about 25 ms subsequently, due to cover gas pressurization resulting due to sodium slug impact, which initiates at about 135 ms and completes at 145 ms. The cover gas absorbs 31 MJ (maximum) which is elastic in nature, responsible for free levels oscillations without any further staining of main vessel.

Figure 263 shows the evolution of displacements of various structures. The core cover plate oscillations, bending upward (~ 70 mm) and bowing downward (~ -110 mm) are seen clearly in the figure. The peak main vessel bottom displacement is 160 mm and the radial bulging is 103 mm. The triple point moves down by 36 mm (maximum).

■ Figure 263

Evolution of displacements of structures

The important strains are peak strains on the main vessel surface. There are two critical locations: one is triple point and another is the upper cylindrical portion above sodium free level. ▶ Figure 264 and ▶ Figure 265 show the strain evolution at these two critical locations. The peak strains are: 2.6% (longitudinal) and (−0.1% hoop) at the triple point and 1.53% (hoop) in ▶ Figure 264 and −0.1% (longitudinal) at the upper portion in ▶ Figure 265.

Experimental Approach For the early SFRs, the fraction of energy generated during disassembly that was assumed to be converted to mechanical work was based on conservative assumptions. Later research succeeded in reducing this conservatism to some extent, and there is research still underway to establish the degree to which additional physical phenomena may reduce this fraction still further. Early assessments of damage potential due to such energy release were based on equating this potentially available work energy to an equivalent charge of TNT, that is, 4.2 MJ ~ 1 kg of TNT. Hence, every MJ of work potential was assumed to represent the explosive potential of about 250 g of TNT. The principal reason for using this equivalence was that substantial experience existed. Any attempt to predict the actual mechanical response of an FBR system to a CDA excursion using the TNT energy equivalence model is ambiguous because the pressure–time characteristics of a TNT detonation are considerably different from those of a nuclear excursion. Mechanical damage from an explosion or pressure transient can be caused by both a shock wave, which is transmitted rapidly to a structure, and the more slowly expanding bubble of reaction products or vaporized material. Pressures in a TNT detonation build up on a microsecond time scale and reach the order of 5,000 MPa. Hypothesized energy releases from an HCDA excursion, on the other hand, built up over a millisecond time scale, and peak pressures are orders of magnitude lower. As a consequence, much of the damage potential of a TNT detonation to surrounding structures comes from shock wave effects, whereas longer-term bubble expansion would be the predominant damage mode for the slower time-scale pressure

Figure 264
Strains at MV triple point

Figure 265
Strains at upper portion of MV

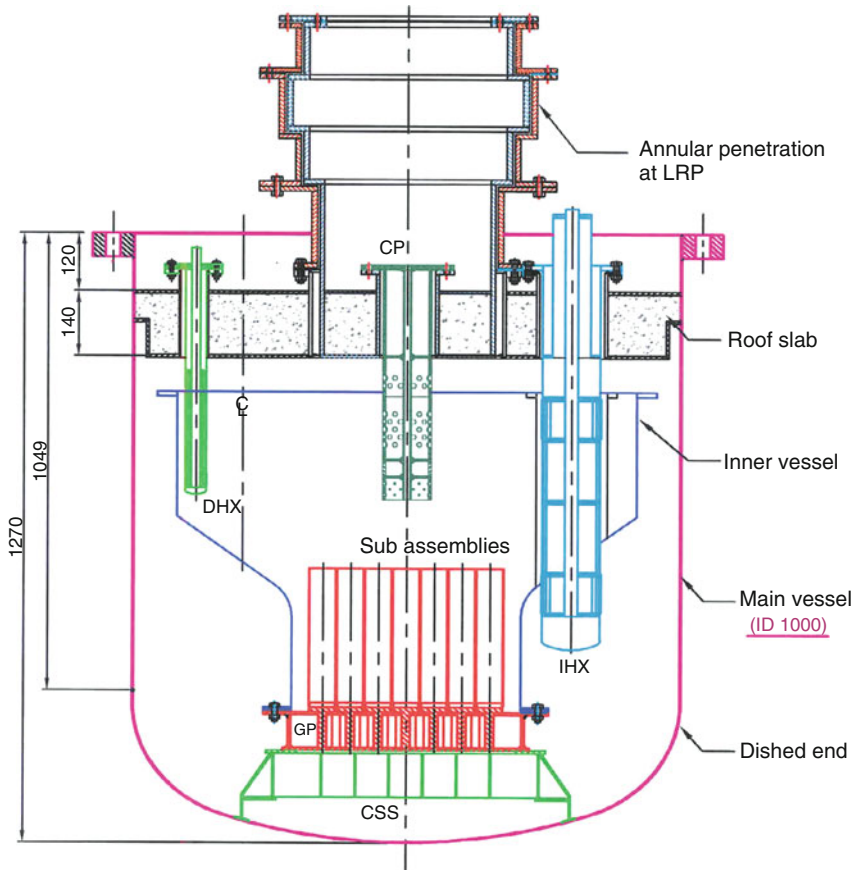

buildup of an FBR excursion. Hence, a considerable effort was expended to develop simulant explosives with a burning rate more compatible with the millisecond time frame. In addition to the vessel damage experiments referenced above, tests with simulant explosives under sodium have been conducted at Cadarache to study breach of the cover and sodium transport through the cover in an HCDA. Small scale in-pile tests involving fuel and/or sodium expansion and energy partitioning have been carried out at several transient test reactors, for example, TREAT, ACPR, and CABRI.

For SPX1, two series of experiments were carried out in the early 1980s: MARA program, based on 1/30th scale mock-up representing only the main vessel and coarsely the internal structures were undertaken in order to have accurate information about the roof and main vessel and also used for validation of SIRIUS (Louvet et al. 1987). More elaborated mock-up called MARS was built with representative inner components (1/20 scale). The most challenge in the definition of mock-up is appropriate simulation laws for loading, structural material, fluid, and explosive behavior. Water is used in place of sodium and 80 g of L54/16 explosive which can yield 800 MJ (equivalent) energy release is used for simulating nuclear excursion. The explosive has been qualified on MANON tests. Essential instrumentations were incorporated to measure the parameters related to the mechanical behavior and also to compare with calculations results. Tests indicated that there is no leakage observed, and welds were found to be safe. After transposition to the reactor scale, the maximum radial displacement in the bulge area is 240 mm and maximum deflection for the roof slab deduced is 110 mm. The main strains are 2.4% at the bulge level (hoop) and 1% at the vessel bottom (axial and hoop).

Toward assessing the structural integrity of PFBR components under CDA, the tests were carried out in three stages (Chellapandi et al. 2002). In the first stage under TRIG-I series, 17 tests were conducted in water filled cylindrical shells with rigid and fixed top and bottom plates of various dimensions to characterize the chemical charges (the energy conversion ratio, i.e., mechanical energy release per unit mass and the equation of state). In the second stage under TRIG-II series, tests were conducted in the main vessel models without any internals. Under this series, 30 tests on 1/30th scale models and 3 tests on 1/13th scale models were conducted. Sufficient data have been generated for validating the FUSTIN code and also for establishing acceptable strain limits for the vessels under simulated CDA loading conditions. In the last stage, under TRIG-III, tests were conducted on 1/13th scale mock-ups with the main purpose to demonstrate the structural integrity of IHX and DHX and also to estimate the sodium leak based on simulation principles. Totally 61 tests were completed during the period of 4 years.

► *Figure 266* shows a schematic of the mock-up. The entire core is simulated with 37 hexagonal core subassembly (CSA) models, which have matching rigidity characteristics as that of CSA in reactor. The top shield assembly consists of roof slab, rotating plugs, and control plug (CP). The roof slab is an annular box type structure having ten penetrations essentially to accommodate four pumps, two IHX, and four DHX models. The pumps are simulated by cylindrical tubes with appropriate thickness to represent the rigidity characteristics. The DHX and IHX models have all the essential parts of the prototype components including the required number of tubes. The annular leak paths in the top shield were modeled in detail incorporating all the geometrical characteristics to simulate the flow resistances. The entire mock-up is supported on the reactor vault through a cylindrical skirt. The reactor vault is represented by six steel columns embedded in the concrete, instead of continuous structure, to facilitate photography.

A low density explosive (LDE) has been specially developed which can simulate satisfactorily the rate of energy release including peak pressure, at TBRL using a technique of lowering the

■ **Figure 266**
1/13th scale mock-up of PFBR reactor assembly

density of PETN by precipitating it in the U foam, thereby reducing the charge density of PETN from ~ 0.8 to ~ 0.14 g/cc. This LDE is used for the PFBR mock-up trials. The overall dynamic displacements of main vessel, top shield, lifting of plugs, CP, DHX, and IHX are captured through two high-speed cameras: one is digital (3,000 pps) and another is conventional one (6,000 pps). Sufficient strain gauges are pasted at the critical locations in the main vessel, cylindrical support skirt, and reactor vault structures. Accelerometers are placed on the top shield to understand the inertial forces and pressure transducers are placed on the bottom of the top shield to measure the dynamic pressures due to slug impact. Five tests were conducted with 22 g LDE, which simulates 110 MJ of energy release in the reactor scale, which is the design requirement. It is noted from the tests that the main vessel, top shield, DHX, and IHX were integral with negligible deformations (🔍 Fig. 267). It is worth mentioning that the tests with increasing quantity of LDE (up to 220 g) indicate that the main vessel without internals is integral up to 1,200 MJ (🔍 Fig. 268). The maximum rupture strain is established as 30% for welded SS 316 plates at room temperature under simulated CDA loadings. However, a strain limit of 16% is considered

10.6 Post Accident Phase

10.6.1 Scenarios

The capability in achieving a stable coolable material configuration following the postulated accident is demonstrated by appropriate objective of post accident heat removal (PAHR) mechanisms. The distribution of heat sources following the accident is a controlling factor in the assessment of adequacy of PAHR. Because of the substantial differences in the accident scenario, the post accident dispersion behavior also varies. The PAHR analysis should therefore be prepared to cover a range of possible fuel distribution patterns. Analysis of the UTOPIA shows that the early sweep out of fragmented fuel may limit the damage in the core to few subassemblies. However, scenario following a ULOFA may result in gross whole core melt down. In such a case, sufficient steel and fuel vapor may be generated in the core to result in fuel removal from the core, within a two phase mixture of fuel and steel, thus leading to neutronic shutdown. The exact amount of fuel that will be driven into the cold plenum of the reactor vessel cannot be predicted. Therefore, to define the pattern of fuel dispersal following a CDA in an SFR, a semi-mechanistic approach is currently being pursued.

Upward relocation of fuel and steel will depend on the ease with which the mixture can penetrate through the pin bundle above the active core region of subassemblies. Ostensen et al. (1974) were the first to consider the fuel penetration behavior in the steel cladding structures. They assumed that fuel freezing will depend on reducing the average enthalpy in the leading edge of the flow to the enthalpy of solid fuel at its melting point. This condition of freezing has become known as bulk freezing. Their analysis seemed to be supported by experiments utilizing thermite generated molten fuel. Epstein et al. (1976) proposed that the bulk freezing is in fact due to steel melting, ablation, and mixing with flowing fuel. Therefore, the voids formed during the penetration process will have large impact on the freezing behavior. Downward relocation of fuel and steel may occur by two mechanisms, namely, (1) axial melting through the lower assembly structure and (2) streaming through the coolant channels in the lower assembly structure. Streaming is a much more rapid mechanism for relocation. Molten fuel may not penetrate far in the pin cladding structure without plugging, because of the small channel flow area/cladding surface area and due to significant potential for steel melting. However, large coolant paths existing below the active core region facilitate the steaming process. Studies carried out for CRBRP have shown that coolant streaming is possible within seconds. In summary, a significant portion of core materials may be redistributed to the cold plenum in a short time following a CDA. The molten core debris ejected in the cold plenum will be quenched in the subcooled sodium and converted into particles. The debris particles will then settle on the core catcher.

Heat Source Strength

The heat generation following CDA involves (1) transient heat generation associated with the decreasing fission process (immediately after neutronic shutdown), (2) decay heat of the activated fuel nuclides, (3) decay heat of fission products, and (4) decay heat due to stainless steel activation. The transient heat generation is significant only for very short duration (~ 10 s) after

attaining subcriticality. Analytical tool commonly adopted in the estimation of the heat load is RIBD code (Bunch and O'Dell 1969). In large power plants, considerable decay heat will be generated in the radial blanket subassemblies and such heat generation should also be included in the PAHR studies.

In-Place Fuel Retention

This concept involves retention of the fuel material in the core position. In the case of in-place cooling, the fuel material in the original core region is cooled by (1) cooling of the subassemblies that remain intact by liquid sodium flow, (2) survival of the partial voided assemblies due to coolant flow near the assembly walls, (3) recovery of voided assemblies due to cooling by neighboring intact assemblies, (4) cooling of particulate debris in blocked assemblies by sodium leakage through the debris, and (5) containment of the assemblies in the lower shielding section of the assemblies due to heat transfer to neighboring assemblies. Many of these mechanisms depend on the specific arrangement of core, the severity of the accident, and the resulting damage pattern.

Kazimi et al. (1977) have analyzed a specific situation for CRBR by considering the core region to be completely blocked while radial blanket and shielding assemblies remained undamaged. Part of the debris was assumed to lie in the upper and lower plena with some fraction still remaining in the core region. Considering complete loss of pumping power, they estimated coolant flow capability due to natural convection of sodium from the reactor vessel to intermediate heat exchangers. The results indicated that steady state natural convection is potentially capable of preventing gross sodium boiling in the vessel. However, if the fuel debris is localized, local sodium boiling may occur. Larger surface area available for debris cooling prevented sodium boiling. This can be achieved by selecting a large size of vessel.

Molten Fuel Relocation

Another scenario which is most probable is the formation of a particulate bed at the bottom of the reactor vessel. In the absence of adequate heat removal, the frozen core debris would remelt due to internal heat generation and may promote melting process of steel structures and move downward. It has been established from studies of fuel-coolant interactions that molten fuel and steel tend to fragment and form solid particulates upon quenching in sodium. The size distribution of these particles significantly affects the ultimate coolability of debris bed. In-pile tests in transient reactor test facility (TREAT) (Gabor et al. 1974) have shown that the particle size distribution is scattered as shown in  Fig. 269. The general indication is that the major fraction of debris (70–80%) has diameters <math><1,000\ \mu\text{m}</math>. The average fuel size of fuel particle is $\sim 200\ \mu\text{m}$ and that of steel particles is $\sim 400\ \mu\text{m}$. In all experiments, difference in appearance between metallic particles and UO_2 particles has been observed. The metal particles are generally rounded whereas UO_2 particles are irregular and of smaller size. The fragmentation is primarily due to thermal and mechanical interactions, including hydraulic forces and thermal stress cracking.

Core debris generated by quenching of molten core debris in sodium is expected to settle downward. Before the particles settle on the main vessel/core catcher, the debris has to cross lower axial blanket, grid plate, and core support structure. The debris may reach the foot of subassembly and are then collected between sleeves of the grid plate. If the mass of the debris is large enough, they might spread and deposit on the peripheral region of the grid plate. An analysis of downward streaming from the core and freezing of molten fuel/steel mixture indicated that at least one third of the fuel will reach the grid plate in a very short time period (several seconds) (Glueckler et al. 1982). This fraction would be higher if the flow through the control

■ **Figure 269**
Debris particle size distribution

rod channels is high or if the remaining fuel mass becomes critical and remelts the frozen fuel plug. A typical result of material penetration as a function of the driving pressure is shown in [Fig. 270](#). The debris could melt the lower plate of the grid plate or open a way through the sleeves of grid plate. French study (Le and Kayer 1979) for SPX-1 has indicated that if the debris is deposited on the grid plate 100 s after the accident, the time needed to melt the lower plate of grid plate would be 1,600 s. At the same time incipient sodium boiling below the grid plate is expected.

Gluekler et al. (1979) have conducted a study on the ability of the 50 mm thick lower plate of grid plate to retain the debris. In this study, the core debris was assumed to reach the inlet plenum 1 s after the neutronic shutdown and to consist of molten fuel and steel. The debris layer was assumed to have a maximum thickness of 140 mm. The time of complete melt through of the plate is shown in [Fig. 271](#). In this figure, fuel mass fraction refers to fraction of fuel, internal blanket, and steel materials in the active region plus all materials in the lower axial blanket. It has been indicated that the failure mode in most cases is expected to be by creep rupture prior to melt through. The fuel mass fractions greater than 25% would have a high probability for melt through within 100 s. This fuel mass fraction corresponds to a molten debris layer thickness greater than 70 mm. The result of this study has indicated that the grid plate has a considerable core debris retention capability even for the extremely pessimistic initial debris conditions and transport times. Once the grid plate structure fails, the core debris will be settled on the horizontal surface of the main vessel and form a core debris bed.

■ Figure 270

Material penetration under CDA

For the event of large accumulation of core debris (10–100%) at the bottom of main vessel, the bed would be in a molten state. If the steel and fuel separate due to density differences, then no steel boiling is expected. For a homogeneous mixture of fuel and steel, maximum layer temperature can be 3,200 K. Therefore, steel boiling may occur and this would increase upward heat transfer and sodium boiling leading to further pressurization of main vessel. The debris bed in contact with the bottom of the main vessel would penetrate through the wall. The vessel may fail due to structure melting and creep rupture. Characteristics failure time of 12–60 min have been reported for melt through failure if the heat removal from the bottom of the vessel is by thermal radiation only. High pressure exerted on the vessel would cause structural failure prior to melting. Conditions following failure of main vessel and safety vessel are very serious. It can lead to failure of liner resulting in chemical attack of concrete by core debris and sodium resulting in degradation of structure, hydrogen production, and pressurization of containment. In view of the above serious consequences, there is a need for accommodating the core debris in a safe manner.

10.6.2 Core Debris Accommodation

There are two approaches to debris accommodation. One approach is to retain the debris temporarily within the containment system followed by a controlled release, such as filtered vents. The second method is permanent retention either through inherent or engineered features. The retention may be achieved either in-vessel or ex-vessel. The concepts used various reactors for core debris accommodation is shown in  Table 47.

■ Figure 271
Grid plate melt through time

10.6.3 In-Vessel Debris Accommodation

Considerable improvement of retention capability within the main vessel can be accomplished by placing a core catcher for collection of debris in the sodium plenum under the core support structure. The core catcher with heat removal capability from the bottom could increase the coolability range to a value between 55 and 100% of the core fuel (Dufour 2007). The overall conclusion of the in-vessel retention study is that a partial core meltdown involving up to, approximately, 50% of the core can be accommodated within the main vessel provided a heat sink is available. One important advantage for a pool type SFR is that the cooling capabilities of the sodium inventories can still be used if the main vessel remains intact. The thermal capacity of the in-vessel sodium between normal operating temperature and sodium boiling point is substantial and provides a period of several hours before significant sodium boiling occurs. For a number of core melt accident sequences, the decay heat removal loop may still be functioning and this gives a scenario satisfactory mode of heat rejection. Natural convection occurs in internally heated molten pools, with hot fluid rising and colder fluid moving downward. The onset of motion in a fluid occurs when buoyancy forces caused by temperature gradients

■ Table 47

Core debris retention concepts adopted in various reactors

Reactor	Provisions
EBR-I & -II	None
FERMI-I	In-vessel: zirconium meltdown pan and ex-vessel: graphite crucible below vessel with primary shield tank
SEFOR	Ex-vessel: sodium catch tank 45 ft below vessel. Fuel dispersion cones below vessel and in catch tank
CRBRP	In-vessel: some small amount of debris cooling on reactor internal structures, but not special design provisions and ex-vessel: lined and insulated reactor cavity, vented pipe chase and ex-containment cooling–venting purge system
DFR	Fuel dispersion cone and melt tubes to bedrock
PFR	Single layer of trays within tank; capable of retaining seven assemblies
CDFR	Three layers of trays within tank; retention capacity for entire core
Rapsodie	None
Phenix	Externally cooled outer vessel
SPX-1	In-vessel catch trays, external cooling of safety vessel
SNR-300	In-vessel: catch trays in lower plenum

exceed the viscous forces. Inertial forces also affect the transport process after flow develops. According to the studies carried out in France for the SPX-1 on the postaccident situation, it is difficult to conceive that the non-molten subassemblies are not blocked by the debris ejected upwards (Gluekler et al. 1979). Consequently, the cooling of the non-molten subassemblies by natural convection cannot be ensured, which can lead to a slow fusion under residual power. The debris settlement behavior considered is shown in  Fig. 272.

Further PAHR study considers three different possible cases, namely, (1) the lower plenum remains closed after the passage of the debris, (2) the lower plenum is in communication with the upper plenum through a hole at the diagrid level (The total exchange coefficient between the two plena was estimated for a hole of 0.2 m diameter from the results obtained on LULU-II water mock-up.), and (3) the lower plenum is in communication with the upper plenum through a broad hole at the diagrid level (the total exchange coefficient between the two plena was assumed equal to ten times that of the case (2)). The transfers of heat by natural convection of sodium around the debris tray and under the support plate were evaluated in steady state operation from experimental correlations. LULU-II water mock-up tests were carried out to study the influence of the forms of the core catcher plate, chimney, and containment of the fluid on the heat transfer. The PAHR performance was evaluated based on the following three criteria, namely, (1) the damage on the triple point during the transient is within permissible limits, (2) the sodium temperature under the debris tray is below sodium boiling to avoid deterioration of heat transfers in the downward direction, and (3) sufficient mechanical resistance for the core catcher plates taking into account the mechanical loads and temperature reached. (at least several hundreds of seconds). Thus, the only possible evolution is the progression of molten materials

■ Figure 272
Debris settlement behavior considered for PAHR studies of SPX-1

■ Figure 273
In-vessel core catchers in international SFRs

to the bottom. The core debris penetrates the grid plate only after several thousands of seconds subsequent to the end of the power transient. Schematic sketches of in-vessel core catcher conceived in PFBR and EFR are shown in [Fig. 273](#).

10.6.4 Ex-Vessel Debris Accommodation

Broadly two concepts are adopted. The concepts under first category are designed to prevent failure of reactor containment by relying on somewhat involved engineered core retention systems. Such systems include a sacrificial bed of refractory materials, a multi-tray system cooled by natural convection and a single crucible cooled by forced convection. The concepts under second category allow for failure of reactor containment, but rely on either inherent capabilities

of the reactor building or simple solutions to sufficiently delay containment failure and hence keep radioactivity release within the regulated guidelines. The concept may include a concrete filled reactor cavity and/or special venting and filtering measures for containment.

10.7 Computer Codes and Validation

The accident propagates through various phases, namely, pre-disassembly phase, transition phase, disassembly phase, and mechanical energy release/system response phase. The computer code developments over the past 4 decades have gone through for all these phases, with thorough verifications both with in-pile and out-of-pile experiments.

For the pre-disassembly phase, the SAS series of codes were developed in the 1970s at the Argonne National Laboratory in USA. The first code in the series is SASIA (Carter et al. 1970) code. Subsequently, the SAS2A (Dunn et al. 1974), SAS2B, SAS3A (Stevenson et al. 1974), SAS3D (Cahalan et al. 1977), and SAS4A (Wider et al. 1982) were developed. The last version of the code is the SAS4A version, which was widely used in the US, Europe, and Japan. The SASIA code started with a single pin representation in a channel. The different coolant channels are not coupled thermohydraulically. It performs neutronics calculations by point kinetics model, taking into account reactivity feedbacks from Doppler, fuel and clad axial expansion feedback, coolant density feedback, and radial feedback. The sodium boiling model is a two phase slug ejection and single bubble model. An additional slumping reactivity feedback is also included. Fuel motion and clad deformation models are also included. All the calculations are done for the fresh pins only.

The next version of the SAS series code is SAS2A. This code is a multi-channel code, which can couple thermohydraulics between the different channels. Primary loop model is included in this version. The code was also improved to include transient fuel pin mechanics (fission gas pressure, effect of fission gases on clad deformation, etc.). The sodium boiling model is a two phase slip flow slug ejection multiple bubble mode. The SAS3 series of codes (SAS3A–SAS3D) were further improved to calculate fuel coolant interaction (FCI), FCI-driven fuel motion and voiding and primary and secondary loops for thermalhydraulics.

The last in the series is SAS4A version which was widely used in the recent past. In SAS4A code, new features were incorporated. A balance of force model was incorporated to calculate the fuel axial expansion. The clad motion and sodium boiling were coupled. The sodium boiling model was improved to treat a variable coolant flow cross section to couple with pin mechanics. A unified molten fuel motion model was also incorporated.

All the SAS series codes use point kinetics model for neutronics. The space time kinetics model may be required when there is a large scale fuel and clad motion. The recent SAS4A modeling includes (Cahalan and Wei 1990) extension of the boiling model to treat sudden fission gas release upon pin failure, fuel deformation to handle advanced cladding materials, and metallic fuel modeling capability to fuel relocation model.

A computer code system, KALDIS, is used for PFBR analysis (Harish 1999). For pre-disassembly phase, a computer code, PREDIS has been developed, and it forms part of KALDIS. The processes modeled in the code are: core neutronics, transient thermalhydraulics, reactivity feedbacks like Doppler, fuel and clad axial expansion, coolant expansion, spacer pad, grid plate, main vessel and differential control rod expansion, coolant boiling, and clad and fuel melting and slumping. For disassembly phase, VENUS-II code (Jackson and Nicholson 1972) developed

by ANL is commonly used. In this code, point kinetics is used for power calculations and using the 2D reactivity worth and Doppler coefficient distribution, the calculations of displacement and Doppler reactivity feedbacks are performed. Calculations are stopped once the multiplication factor of the reactor is 0.98 or 0.95 due to outward material movement of the core. The calculations of work energy potential of the thermal energy released in the disassembly phase is calculated using the straight forward methodology available for isentropic expansion of fuel vapor expansion up to one atmospheric pressure or up to the upper cover gas volume (Walter and Reynold 1981). This algorithm has been made a part of the VENUS-II code.

10.7.1 Validation of Codes: A Case Study

For ULOFA, the code is tested up to onset of boiling against BN-800 IAEA CRP Benchmark (🔗 [Table 48](#)) (Om Pal Singh and Harish 1998; Sathiyasheela et al. 1998). It is found that of boiling and its location, the sodium void reactivity, and net reactivity are predicted nearly same by all the countries, even though some differences are noted in Doppler reactivity.

10.8 Innovations Toward Enhanced Safety

10.8.1 Core

Improvement of the core behavior to achieve possibly lowest ratio of sodium void effect/Doppler effect, reduced sodium volume fraction, higher fuel volume fraction, reduction of height/diameter ratio, moderate core size, annular fuel pellet, use of metallic core, use of advanced cladding materials (15/15Ti, ODS, etc.) to gain higher margins for the cladding ruptures during transients and state-of-art core monitoring instrumentations are some of the innovations, being considered by international expert groups.

📌 **Table 48**

Results of onset of boiling

Parameter	Germany	France	Japan	Russia	India
Time (s)	17.96	18.93	18.96	16.72	17.60
Channel no.	5/1	5/1	5/1	5/1	5/1
Axial position from core bottom (cm)	84–90	95	87–94	85	84
Normalized power	0.66	0.63	0.63	0.71	0.71
Net reactivity (ρ)	-0.17	-0.183	-0.183	-0.135	-0.147
Doppler reactivity	0.026	-0.005	-0.004	+0.039	+0.027
Fuel axial expansion reactivity (ρ)	-0.003	+0.015	+0.014	+0.017	+0.020
Sodium reactivity (ρ)	-0.207	-0.205	-0.205	-0.188	-0.223

10.8.2 Sodium Fire and Sodium–Water Reactions

The main objective is to practically eliminate sodium fires and sodium–water reactions susceptible to degrade the safety functions in an unacceptable manner or to lead to unacceptable consequences in the environment. In order to achieve this, apart from the existing design features, reduction of welds in piping by reducing number of sodium loops, shortening of pipe with high chromium content, double wall piping, double wall steam generator tubes, integrated pump-IHX, and state-of-art inspection and repair systems are being considered. The passive systems for self-extinguishing of the sodium fires when sodium is leaking from the circuits: sodium discharge into a pan with hydrolock; sodium discharge into a tank blanketed by inert gas, sophisticated numerical simulation of sodium fire and sodium–water reactions coupled with extensive experimentation and validation are the few additional innovative features envisaged in the future designs.

10.8.3 Reliable and Diverse Shutdown Systems

A few innovations are introduced in the shutdown systems (► Fig. 274). In case of power excursion, automatic negative reactivity insertion devices (1) by way of enhanced expansion of the core and shutdown systems, (2) use of curie point electromagnets or magnet switches to de-energize the magnet holding the absorber rods, hydraulically suspended rods which would lower automatically into the core in case of any loss of flow due to pump seizure or primary

► Figure 274

Passive shutdown system concepts

pipe rupture, stroke limiting devices to arrest the uncontrolled withdrawal of absorber rods and self-actuating devices to shutdown the reactor directly under class 4 power supply failure, are considered for ensuring reactor shutdown. Details can be found in INPRO (2007).

10.8.4 Decay Heat Removal Systems

Pumps with high mass inertia to ensure heat removal before establishing adequate natural convection, introduction of reliable electromagnetic pumps in the decay heat removal circuit, passive decay heat removal features, like use of shape memory alloys for automatic opening of dampers, thermal valves which opens to enhance the flow paths during decay heat removal conditions are a few innovations being envisaged by the designers worldwide.

10.8.5 Core Catcher

Subsequent to partial or whole core melting of core subassemblies, the molten core (debris) would be settled at the bottom of the main vessel. This may cause the rupture of the vessel, if it is not protected. For this, the core catcher is placed with the objective of maintaining the core in stable conditions within the vessel. The core debris settled at the core catcher is called corium. Hence, the core catcher does very important safety function. The robust design of core catcher involves definition of scenarios for the core melt down relocation, settling behavior of debris within sodium, post accident heat removal of corium (pool thermalhydraulics, decay heat removal aspect) and design analysis to demonstrate integrity of the main vessel.

10.8.6 Breakthroughs for Future SFR

Certain breakthroughs are also considered for the future innovative reactors. In the core design, in order to eliminate the possibility of flow blockage and at the same time to achieve lower pressure drop, power flattening is achieved without gagging by the use of different core zones at identical Pu content with different pin sizes or adopting the design of subassemblies with perforated wrapper or without wrapper by use of advanced spacer concepts for pin bundle. Stable power shape with burnup, metal plate concept for metallic fuels in place of pellets, ultra long life core, fuel assembly design for enhancement of molten fuel discharge upon the unprotected core degradation (parallel path for molten fuel), and engineering for the stabilized sodium boiling in the upper part of the S/A without voiding the fissile part are some additional breakthrough reported. In the natural decay heat removal circuit, multiple flow paths in the pool to facilitate increased natural circulation (e.g., thermal valve in the inner vessel) are proposed.

For the shutdown system, fusible shutdown devices (FSD) are used placed above the upper fissile zone, which acts when a fusible threshold is reached. The core catcher would have features to achieve enhanced cooling of debris and to prevent recriticality. These can be achieved by incorporating enlarged coolant plenum for molten fuel quenching and pelletizing the debris, novel chimney for effective coolant circulations, multilayer debris tray debris for debris retention within limited height for cooling and subcritical state, well-defined paths for debris, sacrificial layers, etc. Alternate coolants and comprehensive ISI and repair strategy are also the breakthroughs being thought of for the future design.

Figure 275

Post accident heat removal mechanisms: French proposal

Enhanced safety concepts are being considered for future SFRs in France (Fig. 275) and Japan (Fig. 276) (TWG-FR 2008a,b). The ultimate objective of the French proposal is to make CDA, nonenergetic, that is, the mechanical consequences, such as loadings on the vessel and top shield and sodium release need not be considered, as illustrated in Fig. 277 (INPRO).

10.9 Summary

The severe accident scenarios which lead to core disruptive accident have been analyzed thoroughly by various countries. Several dedicated safety tests such as TREAT, CABRE, and SCRABE were conducted and advanced computer programs have been developed to get excellent insight to the problems. With these, it is time to consider elimination of such severe accidents in the reactor safety studies. International experts are proposing very elaborate R&D program, which should be executed through international collaborations. In spite of these developments, numerical and experimental simulations of severe accidents are challenging and provide high impetus to the advancements in wide spectrum of subjects, both in science and technology.

11 French Licensing Experience on SFR

11.1 Phenix

- The evolution of knowledge which results in improving the reliability of safety systems:
 - Better evaluation of residual power and natural convection: this led to an operation at a reduced power
 - Improvement of the redundancy of power supplies with the ultimate energy supply

Figure 276
Enhanced safety features: Japanese proposal

Figure 277
Elimination of mechanical consequences of CDA: French proposal

- Improvement of the diversification of reactor shutdown systems (complementary shutdown systems)
- Reevaluation of seism: reinforcement works
- Confirmation of proper behavior of the structures: extensive ISI program, including on the reactor internals
- Same as for SPX: pulverized sodium fires
- Reactor shutdown events resulting from a negative reactivity signal: the lessons learnt from a licensing point of view are that an event difficult to conceive or predict did occur and that it is thus necessary to target designs not very sensitive to specific SFR-related risks, even if one does not see a priori what would cause them
- Like in the case of SPX, one can also underline the confirmation of the favorable aspects, in particular the absence of any events due to the core (except for the RSNR) and the mastering of the water–sodium reactions

11.2 SPX-1

- The initial regulatory framework, all while reminding that there was no specific framework for the SFR, and that the standard regulatory process was applied (the same as that of the PWRs making up the fleet)
- The topic of severe accidents which resulted in a very detailed specification right from the creation decree of the reactor (definition of the core disruptive accident based on a mechanical energy level to be used for the containment design): the rationale being that the authorities fixed this energy level on the experts' judgement without awaiting the results of the studies. In parallel, studies and R&D (CABRI) were launched to demonstrate that the energy released during a CDA was below the fixed criteria. With the current EPR feedback, such an approach would turn out to be difficult today
- The SPX studies, R&D and operation showed that new situations were to be considered or to be considered differently. For example,
 - The control rod withdrawal which shows that licensing requires qualified tools to evaluate the fuel behavior
 - The external fuel storage vessel leak which highlighted the need for long-term accident management, and for fast neutron reactors, the problem of rapid core unloading and the difficulty of ISI on the internals
 - The air ingress event which shows on one hand, that situations, which seemed highly improbable, had occurred, and on the other hand that very limited effort would have been required to detect it at an early stage. The need for simple monitoring and clear procedures for the operator was also underlined
 - The taking into account of pulverized fires, which shows that it is necessary to account for, in the design, an evolution not necessarily compatible with commonly accepted and known scenarios
 - The goal is not to deal in this presentation with all the problems which occurred, but, rather, to focus on those which have had a significant impact on safety and licensing. One could also present the positive aspects of the fast neutron reactors confirmed by the SPX operation: No core incidents and no radio-protection problems were reported (the roof was a green zone); Good passive behavior (natural convection of primary and secondary circuits and of the DHR circuits), as well as negative reactivity feedbacks were demonstrated.

11.3 SPX-2

After recalling that its review by the Safety Authority was made at the time of the Chernobyl accident, and while the need for breeding in France was not topical, the presentation could focus on the failure of the severe accident exclusion strategy, the demonstration of which was based on semi-probabilistic objectives. In spite of that, the consequences of severe accidents had been taken into account based on the R&D carried out for SPX and by improving the SPX design. One could indicate that the results of SPX2 are included in the EFR project which did not undergo a licensing procedure, even if a very preliminary examination was made of it by the Safety Authority experts of the three countries involved in the project.

To help in the better understanding of the presentation, one could start with a brief description of the three reactors, at least of their safety functions.

12 Innovative Design Evolutions

12.1 In India

Selection of main options for a large FBR power plant is an important phase of the project as this gives a definite shape to the plant. The satisfactory plant operation depends on correct selection of the robust concepts. The concepts affect not only PFBR but also the future FBR program. The concepts are selected based on the energy situation in the country, economic competitiveness of the plant, design trends in other countries, operating experience of other fast reactors including FBTR, PHWR experience in India, industrial infrastructure, design and construction codes, available materials, O&M requirements, electric power grid, site characteristics, R&D requirements, safety and engineering judgment.

12.1.1 Pool Type Concept

The loop and pool concepts have been discussed qualitatively in several forums. Although many prefer pool concept, both types are in use. Pool concept is decided for PFBR due to the following advantages:

- Simple shape of reactor vessel without any nozzles, low neutron fluence and its easy in-service inspection results in high reliability.
- Large thermal inertia of the pool attenuates thermal shocks, results in slow temperature rise during decay heat removal and load throw conditions, and gives longer time for operator action.
- Capability to withstand higher work potential under core disruptive accident.
- Containment of radioactive components and fluids is easy.
- Compact primary sodium circuit layout. Russian and Japanese studies indicate that the pool type is less costly than loop type. Based on experience with loop (BN 350) and large pool (BN 600) reactors, Russians prefer pool type concept for plants with generation capacity more than 300–400 MWe.
- Preheating is simple
- Leakage in primary sodium circuit will not lead to LOCA and hence there exists high reliability of core cooling.

The pool type concept, however, calls for a few challenging aspects to be resolved successfully:

- Complex pool hydraulics: Specially developed computer codes and several scaled down water models have solved these problems successfully. Operation of EBR-II, PHENIX, PFR, BN600, and SPX has demonstrated the compliance with the predicted thermalhydraulic behavior.
- Complex seismic design of thin vessels with large mass of sodium: Robust analysis techniques developed and validated with experiments.
- There is more interdependence for overall optimization in component designs. The design of primary sodium pump, intermediate heat exchanger, inner vessel, and roof slab are closely interconnected. Few (~2–3) design iterations give good judgment for the design decisions.
- Large size of vessels need site assembly. The vessels are assembled at site workshop by welding with stringent tolerances specified.
- Difficulty in maintenance on the top of pile: Close layout of many components on reactor assembly resulting in space constraint can prolong maintenance works, thus affecting capacity factors. This has been taken care of by reducing the number of components and also making them compact. Thorough check on drawing boards toward avoiding interference and availability of adequate space for component handling and further full scale sector mock-up have been done to eliminate such problems.
- Measurement of neutron flux in start-up range and primary sodium flow require special instrumentation: Indigenous neutron flux monitoring systems have been developed.

12.1.2 Reactor Power

The following considerations lead to selection of 500 MWe capacity:

- Specific capital cost is lower for 500 MWe than for lower power, say 250 MWe (~30%).
- Medium size power is desirable for constructing more number of similar follow on plants, before a large commercial scale plant is built.
- Coal fired power plants and PHWR of 500 MWe capacities have been designed. The coal fired plants are in operation and PHWR are under construction. The conventional power equipment of this size, particularly TG set, is readily available.
- Design and development efforts for 250 and 500 MWe plants are comparable.
- Constructability of 500 MWe size components was assessed based on the experience of 220 and 500 MWe PHWR and FBTR. The Indian industries are equipped with necessary infrastructure.
- Large size pool type reactors have operated in other countries up to 1,240 MWe and basically there are no technological problems.

12.1.3 Core

Fuel

PuC-UC has been used as fuel for FBTR due to nonavailability of enriched uranium for mixed oxide option. For PFBR, enriched uranium is not required. Though carbide gives high breeding ratio, it raises safety problems in fabrication because of its pyrophorocity. Fabrication cost is also high. Fuel burnup is lower compared to oxide because of its high swelling rate. Reprocessing

on prototypic scale has not yet been done anywhere and this cost is also expected to be more. Being a large power plant, proven fuel cycle is essential. High breeding is not the objective for PFBR. As the design of the entire plant revolves around the fuel, a firm decision is essential.

Most of the large sized FBR use MOX fuel. This choice was natural since the technology of mixed oxide fuels is very similar to that of UO_2 , which is used in thermal reactors. MOX fuel has shown excellent performance in all FBR where it has been used, with respect to high burnup (up to 200,000 MWd/t on full size subassemblies) and has proven reprocessing technology. A large experimental data base with respect to satisfactory behavior under off-normal operating conditions is available. Extensive experience is also available in India from thermal reactors. Therefore, MOX is chosen as fuel for PFBR.

Core Layout

A conventional homogeneous type of layout is selected for the core and blankets. The core is provided with both radial and top and bottom axial blankets. Radial heterogeneous configuration, in spite of advantages of higher breeding ratio and reduced sodium void coefficient, is not considered due to increase in higher fissile inventory, larger core size, reduction in Doppler coefficient, requirement of increased thermal striping protection arrangements for the above core internal structures and possible difficulty in achieving optimum neutronic coupling between core zones without extensive experimental studies.

Core Height

Core height has an effect on both physics and engineering design parameters. These have been studied in detail. The advantages of small core heights are increased fuel volume fraction for the same coolant pressure drop, reduced subassembly length, easier fuel fabrication, and reduced sodium void coefficient. The disadvantages are increased fissile inventory, larger number of pins, and larger core radius. Based on the parametric study to limit the penalty on fissile inventory, an active core height of 1 m with height/diameter ratio of ~ 0.5 has been selected.

Pin and Subassembly Sizes

The choice of pin diameter significantly affects the fissile inventory, fuel cycle cost, and doubling time. Parametric studies made for doubling time and fuel cycle cost considerations for oxide fuel indicate that the optimum pin diameter is 8–9 mm depending on the out-of-pile time. In order to reduce Pu inventory, a small pin diameter of 6.6 mm has been selected. Pu inventory for 6.6 mm pin is lower by $\sim 15\%$ in comparison to optimum pin diameter range. Considering factors like, subassembly worth, decay heat of spent fuel, handling loads, number of positions on grid plate, core monitoring positions, core average burnup, handling time, fabrication cost, etc., 217 fuel pins per subassembly have been selected. The active core consists of 181 fuel subassemblies of which 85 are in the inner enrichment zone and 96 are in the outer enrichment zone. The core layout is shown in  Fig. 278.

12.1.4 Shutdown Systems

For the reactor shutdown, two diverse, redundant, and independent systems, namely, control and safety rods (CSR) and diverse safety rods (DSR) have been provided to increase the reliability of shutdown. Enriched B_4C pellets are used as neutron absorbing material in both CSR and DSR.

■ Figure 278
Core layout

12.1.5 Main Heat Transport System

Main heat transport system comprises primary sodium, secondary sodium, and steam–water circuits. Sea water is the ultimate heat sink. A secondary sodium circuit is interposed between primary and steam–water circuits from the consideration of safety. It avoids entry of moderating and corrosive material into the core during sodium–water reaction in SG. Further, this avoids radioactive contamination of SG and steam–water system.

It is worth noting that the investment cost is the major contributor (~75%) of unit energy cost in comparison with 15 and 10% for O&M and fuel cycle costs, respectively. Out of 75% investment cost, ~25% is contributed by sodium heat transport systems. This indicates that the major efforts should be directed toward reducing the capital cost and construction schedule which, in turn, calls for a less number of systems and components.

A study on 2/3/4 primary and secondary sodium loops was made. Due to adoption of design improvements, the increase in size of components, when the number of loops is decreased, is not large and the increased component dimensions are within the Indian industrial capability. The reduction in the number of components helps to reduce the capital cost, construction time, and the outage time due to generic design failure/inspection/repair of components. Hence, the capacity factor is expected to be marginally higher for the case with lower number of components/loops, except for SG where more units offer higher capacity factor as failure is linked to number of tube to tube sheet welds.

Reduction in number of loops also reduces instrumentation and control, electrical systems, and the space required for layout of components. Hence, the two-loop concept has been selected

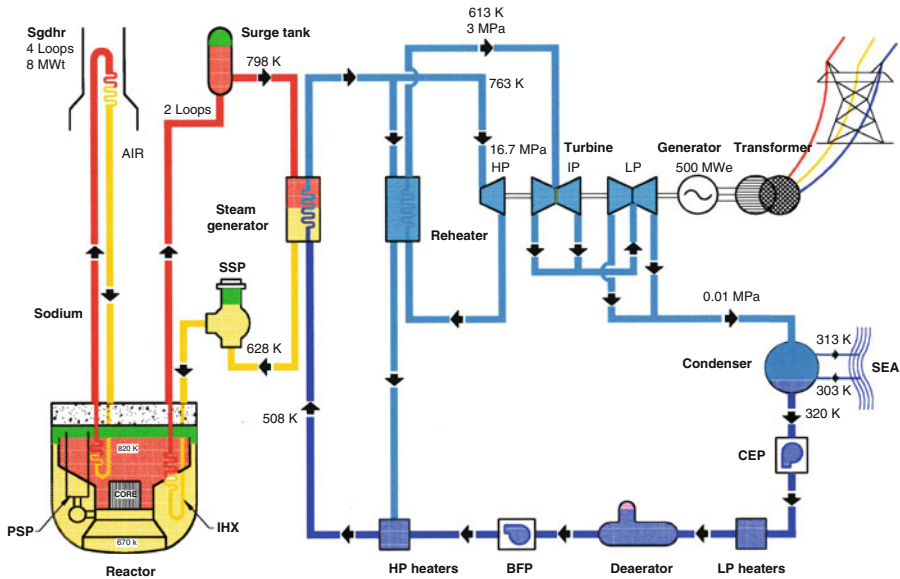

Figure 279
Main heat transport flow sheet

which results in two primary sodium pumps, four IHX, and two secondary sodium pumps. Each primary pump is flanked by two IHX as in other large pool reactors to optimize the main vessel size and economics.

Figure 279 shows the flow sheet of the main heat transport system. Liquid sodium is circulated through the core using two primary sodium pumps. The sodium enters the core at 397°C and leaves at 547°C .

The hot primary sodium is radioactive and is not used directly to produce steam. Instead, it transfers the heat to secondary sodium through four intermediate heat exchangers. The non-radioactive secondary sodium is circulated through two independent secondary loops, each having a sodium pump, two intermediate heat exchangers, and four steam generators. The choice of four steam generators per loop is based on overall optimization studies carried out considering capital cost, outage cost, and operation cost with three steam generators in the affected loop in case of a leak in one steam generator. The primary and secondary pumps are vertical, single stage, and single suction centrifugal type, with variable speed. AC drives are provided with flywheels to meet the flow coastdown requirements of 8 and 4 s, respectively. An AC pony motor of 30 kW rating is additionally provided for each of the primary pumps. The steam generator is a once through integrated type design using straight tubes and an expansion bend in each tube. The decay heat is removed using the operation grade decay heat removal system of maximum 20 MWt capacity in the steam–water system under normal conditions. In case of off-site power failure or nonavailability of steam–water system, the decay heat is removed by a passive safety grade decay heat removal circuit consisting of four independent loops. Each safety grade decay heat removal loop is rated for 8 MWt and consists of a decay heat exchanger immersed in the hot pool, one sodium/air heat exchanger, associated sodium piping, tanks, and

air dampers. Diversity is provided for decay heat exchanger, air heat exchanger, and dampers. The circulation of sodium and air is by natural convection.

Once through concept is selected for SG because of reduced water inventory, which minimizes the consequences of large sodium–water reaction and improves economics. Considering the advantages of simplification in design, manufacture, reduction in capital costs, construction schedule, operation, and availability of proven turbine, steam reheat cycle has been chosen. Most of the FBR designs use steam reheat concept to reduce the complexity. Saturation steam cycle does not permit the exploitation of higher steam temperatures possible in FBR. Hence, super heated steam cycle is adopted.

For SG, modular type concept, that is, more number of units/secondary loop, is opted, because of inherent advantages in design and construction of smaller units. In the modular concept, the tube sheet size is also relatively small. The choice of 4 SG module/loop has been arrived at based on optimization of capital cost and outage cost in case of a tube leak, with due consideration to construction schedule, while permitting $(n - 1)$ module operation. From economic considerations, integrated design, combining evaporator and superheater, is preferred over the split up units. Since steam pressure is high, the instability problem can be easily taken care of.

Finally, the combination of two PSP/four IHX/two secondary loop/four SG per loop is selected from both economic and availability considerations as compared to other combinations such as two PSP/four IHX/four secondary loop/eight SG per loop, 4 PSP/four IHX/four secondary loop/four SG module per loop, etc.

12.1.6 DHR System

Even after the reactor is shutdown, there is heat generation in the core due to radioactive decay of fission products. This heat, called decay heat, needs to be removed to prevent unacceptable temperature rise. When off-site power is available, the decay heat is removed through normal heat transfer path of primary sodium, secondary sodium, and steam–water circuits. Under loss of off-site power or nonavailability of secondary sodium circuit or steam–water circuit, the decay heat is removed through independent safety grade decay heat removal (SGDHRS).

Various options are available for SGDHRS. Main options are radiant vessel auxiliary cooling system (RVACS) wherein the heat is transferred from fuel to main vessel through natural convection and then, from main vessel by conduction, convection, and radiation (Phenix, SPX, PRISM), independent Na–air HX riding on the secondary sodium circuit with the primary and secondary sodium pumps having emergency power supply (SPX and Monju), direct reactor auxiliary cooling system (DRACS) wherein the decay heat is removed by sodium to sodium heat exchangers immersed in the hot pool, which in turn transfers the heat to sodium–air heat exchanger (SPX, EFR, DFBR, BN-600M). RVACS does not provide adequate heat transfer capabilities for the large pool type plants (>350 MWt). The function of DHR system attached with secondary sodium depends upon the availability of the latter and also requires safety grade design for the secondary sodium system. Hence, for PFBR, DRACS option is selected.

Four independent loops of 8 MWt capacity each have been selected in order to provide adequate redundancy. Even with one of these loops not being available on demand, it is possible to keep the temperatures within the acceptable values for upset conditions. Each of these loops comprises one sodium–sodium heat exchanger dipped in reactor hot pool, one sodium–air heat

exchanger, associated piping, and tanks. Except for the dampers on the air side, this system is entirely passive. In order to enhance the availability, dampers are motorized with the provision for manual operation. NaK which has low melting point is not considered as coolant in the loops of SGDHRs, because of its higher chemical affinity for air, inferior thermal properties, higher cost compared to sodium and possibility of NaK leaking into primary sodium. Sodium is used as the intermediate coolant. There is no risk of sodium freezing in SGDHRs as dampers are closed whenever the sodium temperature falls below 433 K.

12.1.7 Main Structural Materials

Twenty percent CW D9 material is selected for cladding and hexcan because of its improved resistance against swelling due to neutron irradiation, high strength at operating temperature, and good corrosion resistance against Na and fuel. Ferritic steel will be considered for hexcan of future cores. AISI 316M has been used in FBTR for sodium components except SG. There has been no problem with this material. It is decided to adopt the same grade with some improvements. SS 316 LN minimizes risk of sensitization during welding and avoids risk of IGSCC, while maintaining high-temperature strength. The embrittlement due to thermal ageing is also within acceptable limits and operating experience of other FBR has indicated satisfactory performance of this material. Hence it is selected for out-of-core sodium components. Use of SS 304 LN for cold leg is chosen except for parts where there is risk of mix up (e.g., sodium piping). Modified 9 Cr–1 Mo steel has been selected for SG because of its high mechanical strength, freedom from the risk of stress corrosion cracking (problem with stainless steels) and also decarburization (problem with 2.25 Cr–1 Mo). Based on economic considerations, A516 Gr 65/A 48 P2 (French AFNOR Std) type carbon steel is selected for top shield of the reactor because of low operating temperature, good impact strength, and compatibility with sodium vapor.

12.1.8 Operating Temperatures

High reactor outlet temperature is always preferred for achieving high thermodynamic efficiency. However, this is limited by fuel clad and component structural integrity considerations. In order to satisfy the allowable clad hotspot temperature of 973 K, the reactor outlet temperature can be as high as 833 K with 150 K ΔT across the core. As regards structural integrity of high-temperature components, with the recent advancements in high-temperature design codes and structural analyses methodology, the reactor outlet temperature is limited to 825 K. Detailed inelastic and viscoplastic analyses have been performed for control plug, inner vessel, and IHX using ORNL and Chaboche viscoplastic models. While the permissible reactor outlet temperature is about 770 K in order to satisfy the design rules of RCC-MR through “elastic” route, the viscoplastic analysis indicates that the acceptable temperature can be 825 K. Modified 9 Cr–1 Mo can permit up to 775 K steam temperature. The turbines used in conventional thermal power plants allow steam temperature of 811 K. The reactor inlet temperature and hot and cold temperatures of the sodium in the secondary sodium circuit are arrived at from overall cost optimization studies.

- Core inlet/outlet (T_{ri}/T_{ro}): 670/820 K
- Primary Na inlet/outlet to IHX: 817/667 K
- Secondary Na inlet/outlet to IHX: 628/798 K

12.1.9 Reactor Assembly

The primary sodium circuit is housed in a single vessel called main vessel (MV). This is closed at the top by top shield, which includes roof slab, large and small rotatable plugs (LRP & SRP), and control plug (CP). The roof slab supports the major components such as main vessel, rotatable plugs, two primary sodium pumps, four intermediate heat exchangers, four decay heat exchangers, eight delayed neutron detectors, etc. CP houses nine control and safety rod drive mechanisms (CSRDMs) and three diverse shutdown rod drive mechanisms (DSRDMs), core thermocouples, and three failed fuel localization modules (FFLM). The main vessel is surrounded by the safety vessel (SV) to ensure that the sodium level inside the reactor, even in the case of unlikely leak in the main vessel, will be sufficient to send the sodium into the IHX and DHX for the decay heat to get removed. To achieve this, a nominal gap of 300 mm is chosen between main vessel and safety vessel. It is ensured that the robotic ultrasonic inspection device developed for the inspection of the main and safety vessels has free access for the smooth operations.

The interspace between main and safety vessel is inerted with nitrogen. SV is supported directly on the reactor vault independent of the support for main vessel. On the outer surface of SV, metallic insulation is provided to limit the heat transfer to the vault. The core subassemblies are supported on grid plate and their combined load is transferred to main vessel through core support structure (CSS). The main vessel contains about 1,150 t of primary sodium. The sodium pool is divided into two parts, namely, hot pool and cold pool by the inner vessel. Argon is used as the cover gas above the sodium pool. The cover gas height is chosen as 0.8 m giving due considerations to thermomechanical behavior apart from other functional requirements. A core catcher is provided below the core support structure and prevents the core debris from coming in contact with the main vessel during the extremely unlikely event of CDA. Inner vessel is incorporated to separate the hot and cold pools of sodium. The assembly of main vessel and its internal and top shield along with safety vessel is called reactor assembly (► Fig. 280). The reactor vault which supports the reactor assembly consists of two walls: the inner wall supports the safety vessel and top shield carrying other components is supported on the outer wall.

The top shield is a box structure made from special carbon steel plates and is filled with heavy density concrete ($\rho = 3.500 \text{ kg/m}^3$) and provides thermal and biological shielding in the top axial direction. The principal material of construction is SS 316 LN for the vessels and boiler quality carbon steel for top shield. The biological shielding in the radial and bottom axial direction outside the main vessel is provided by the reactor vault concrete.

12.1.10 Component Handling

Fuel handling is done after 185 effective full power days with reactor in shutdown condition at a sodium temperature of 200°C . Two rotatable plugs and a transfer arm are provided for in-vessel handling of core subassemblies. For ex-vessel handling, an inclined fuel transfer machine and cell transfer machines are used. The preheated fresh subassemblies are transferred to the core using cell transfer machine and inclined fuel transfer machine. The spent fuel subassemblies are stored inside the main vessel for one campaign and then shifted to a demineralized water filled spent subassembly storage bay pool located in fuel building. Sodium sticking to subassembly is

■ Figure 280
Reactor assembly

washed in spent subassembly washing facility. Leak-tight shielded flasks are provided for special handling of components like primary sodium pumps, intermediate heat exchangers, decay heat exchangers, absorber rod drive mechanisms, and transfer arm. The components are decontaminated in a separate facility provided within reactor containment building before they are

taken for maintenance. After decontamination, the above components are shifted to a separate building for maintenance purposes.

12.1.11 Plant Layout

The plant layout is evolved on the basis of a single unit. The reactor assembly, primary sodium purification, primary argon cover gas system including its tanks and cover gas purification, and decontamination facility are housed in a rectangular reactor containment building. Each of the two steam generator buildings houses four steam generators and associated components and piping. The reactor containment building, steam generator building, and fuel building are connected and laid on a common base raft (► Fig. 281). This minimizes the differential movement in piping and facilitates satisfactory working of inclined fuel transfer machine. In addition, control building, two electrical buildings, and radwaste building are also laid on the common raft and connected to form a nuclear island, to reduce the magnitude of structural response under seismic loads and length of cables. The elevation of the raft is +12 m for reactor containment building and steam generator buildings and +14 m for the other buildings of nuclear island from functional, economic, and seismic considerations (finished floor elevation is +30 m). A service building is provided to cater to the needs of plant services. The turbine building layout is selected such that the turbine missile trajectory is outside the safety-related buildings. The finished floor levels of all safety-related structures are above the design basis flood level estimated for 1,000 year return period. The finished floor levels of non-safety-related structures is based on design basis flood level of 100 year, and these structures are located 1.5 m lower than the safety-related structures from cost considerations. The diesel generators are housed in two separate safety-related buildings. A 100 m tall stack is located close to the radwaste building.

12.2 In France

The reactor technologies deployed today use only a small part of the energetic potential of natural uranium. Internationally, the need to deploy at the appropriate time the fast reactor (FBR) that has the ability to extract about 100 times more energy from this resource is a consensus. The FBRs have also the ability to burn minor actinides, leading to a reduction in the amount and duration of life of final radioactive wastes.

In this context, the sodium-cooled fast breeder reactors (SFR) is the reference in France: It has already reached the industrial level in France and Russia. In France, more than 60 years of combined experience with Rapsodie, Phenix, and Superphenix has been accumulated. This feedback is particularly important in the field of materials (fuel, cladding and hexagonal tube, structural material of the primary circuit), the physic of the core, operation, and safety (building a very important base of experimental safety tests). However, some improvement tracks are still open:

- **Safety:** must be at least equivalent to that of GEN-III systems and be a differentiating factor compared to the past.
- **Economy:** will reduce the amount of investment and financial risk and increase availability, while reducing the operating costs. It will also extend the lifetime of the reactor to 60 years (or more).

The development of efficient techniques for in-service inspection and repair (ISIR) is a key contributor to these two areas for improvement.

The CEA and its French industrial partners, Areva and EDF, have elaborated in spring 2007 a program of work in four axes of research innovations:

- The development of an attractive and safe core, taking into account the specificities of the fast neutrons and sodium and also the ability to transmute minor actinides
- A better resistance to severe accidents and external hazards
- The search for an optimized energy conversion system, reducing the sodium risks
- The reexamination of the reactor and components design to improve the conditions of operation and the economic competitiveness

A first exploration phase of innovative options was conducted until late 2009.

12.2.1 A Core with Improved Safety Performances

This involves optimizing the core according to several criteria that are difficult to combine: improving prevention and control of accidents (reactivity insertion due to sodium voiding and minimization of the initial reactivity reserve of fuel), looking for efficient fuel, and possibility of minor actinides recycling.

An innovative core using oxide fuel was developed. It has safety features constituting a substantial step: it involves the use of large diameter fuel pins spaced by a small diameter wire, which maximizes the fuel content and thus reduces the enrichment, the reactivity margins, and the sodium voiding effect.

Such cores require a cladding material which does not swell under irradiation. Ferritic-martensitic steels strengthened by oxide dispersion (ODS) as reference, and enhanced austenitic

steels as an alternative, are candidate materials. Their development is the key of the concept. New grades of ODS have been developed in 2007 and were irradiated in the MATRIX 2 experiment in Phoenix from June 2008. A first ODS tube with the geometry considered in these new concepts of core has been successfully fabricated in late 2009.

New options for minor actinides recycling have been studied, including the heterogeneous recycling mode using blankets loaded with actinides and placed at the periphery of the core and it looks very attractive.

12.2.2 A Better Resistance to Severe Accidents and External Hazards

The R&D objectives in the field of safety are divided into two paths of study: practically eliminate by design the wool melting of core, or if not feasible, practically eliminate the accident sequences that would lead to an excessive energy release with, respect to the defense in depth, mitigation options (path, cooling, and containment melted core ["corium"]) took into account in the design of the reactor. More generally, the safety level referred to is equivalent to the EPR, with an emphasis on the robustness of the safety demonstration opposite to that of the previous SFR.

12.2.3 An Optimized Energy Conversion System Optimized to Reduce or Exclude the Risk of Sodium–Water Reaction

Various tracks have been explored to simplify the reactor design and reduce the sodium risks using a cycle of energy conversion with gas (nitrogen or carbon dioxide supercritical), development of a compact intermediate circuit using a low reactive with water and with sodium thermal coupling fluid, and design of a robust steam generator minimizing the consequences of sodium/water reactions.

For energy conversion by conventional gas, which is not the solution preferred by the industry, choosing to work with a high pressure gas is preferred to a temperature increase of sodium output. Regarding safety, the elimination of intermediate circuit seems to be not reasonable. For supercritical CO₂ option, the intermediate circuit is necessary because the fluid reacts chemically with the sodium. Attractive efficiency seems yet accessible.

For the energy conversion using a water–steam cycle, seven intermediate coupling fluids have been selected (liquid metals and molten salts) for a thorough evaluation. The Pb-Bi was finally chosen and a long-term program concerning the feasibility points of this alloy has been launched for 3 years beginning 2009. The design of an integrated intercooler/steam generator component with Pb/Bi as a coupling fluid has been studied in some depth.

Finally are proposed steam generator designs for confining the consequences of any sodium–water reaction (including limit scenarios of simultaneous failure of 100% of tubes of a SG module) that in this aim of a robust safety demonstration. SG modules with a capacity of 150 MW seem accessible. Studies on structural materials lead to consider the application of ferritic-martensitic 9% Cr steels to the steam generators, allowing a greater compactness.

Figure 282

Examples of pool reactors with cylindrical internal vessel and simplified core support structures

12.2.4 A Reexamination of the Reactor and Its Components Design

The work on reactor sketches aims to provide a report, comparing pool and loop designs and comparing between high-power units called “monolithic” and modular concepts. Studies on the pool reactor were particularly highlighting the potential interest of concepts with:

- Cylindrical internal vessel (an example is given in [Fig. 282](#)),
- Simplified and integrated support structures of the core
- Slab cooled by air

12.2.5 ASTRID Program

The ASTRID prototype (as for Advanced Sodium Technological Reactor for Industrial Demonstration) is seen as an industrial prototype prior to the first-of-a-kind, meaning that extrapolability of the technical options and of the safety demonstration is of utmost importance. The reactor will also provide some irradiation capacities especially in order to validate the expected properties for the new fuel (big pin and ODS clad) and the ability to burn Minor Actinides in an industrial way.

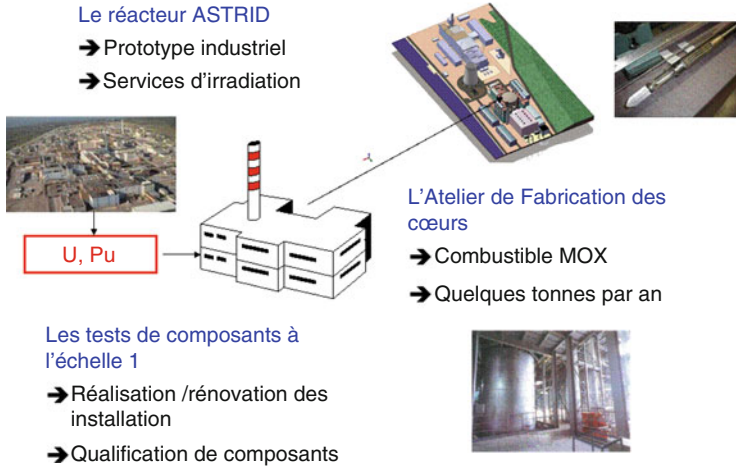

Figure 283
Components of the ASTRID program

The ASTRID program (► *Fig. 283*) defined by CEA also includes the facility to manufacture the fuel for the reactor, of limited capacity, from 5 to 10 t heavy metal per year. The refurbishment of existing testing facilities and the construction of new tools is part of the program as well.

ASTRID shall be coupled to the grid with an electrical power of about 600 MWe. It shall integrate operational feedback of past and current reactors. It is seen as a full Generation IV prototype reactor. Its safety level shall be at least as good as current third-generation reactors, with strong improvements on core- and sodium-related issues. After a learning period, the reactor shall have a high load factor (e.g., more than 80%). The reactor shall provide capability for demonstration of transmutation of minor actinides, at larger scale than previously done in Phénix. And of course, the investment costs of the prototype shall be kept to the lowest possible, with technical options compatible with later deployment on a commercial facility.

Abstract: This chapter describes the various families of reactors in which the primary fluid cooling the core is a gas, usually carbon dioxide or helium.

Early on, gas cooling was mostly used in graphite moderated reactors fueled with natural uranium, the British Magnox, and the French natural uranium graphite gas (NUGG). The availability of low enriched uranium fuel allowed the British to develop the advanced gas-cooled reactor as a successor to the Magnox.

In a world progressively dominated by the water cooled reactors, mostly PWR and BWR, gas cooling remained alive in the high temperature reactor families, prismatic, and pebble bed HTR, associated with graphite moderation. Both are based on the use of a very innovative fuel element, the coated particle.

The same fuel was used in a seldom known US program to develop nuclear propulsion for rockets: this NERVA story will be briefly recalled.

Still marginal, gas cooling is also present among the “Generation IV” concepts, through the very high temperature reactor system aimed at both electricity generation and hydrogen production and the GFR, gas cooled fast neutrons reactor.

1 Gas Cooling

If the very first man-made nuclear reactor, CP1, had no coolant at all, the second, X10, which achieved criticality in November 1943 at Oak Ridge, was cooled by a gas (air). But today, most nuclear reactors are water cooled (PWR, BWR, HWR, and RBMK, in that order).

Despite its name, the real task of a coolant is not to cool the fuel but to transport heat from the reactor core to the boilers to produce steam for electricity generation or to generate process heat. In that respect, gases exhibit interesting qualities, as described in Mc Farlane et al. (1992).

First, because the density of a gas is variable, its operating temperature can be chosen independently of the operating pressure. Thus, a high gas temperature can be used, limited only by the core and circuit materials, to give good steam conditions from the boiler and thus good conversion of heat to electrical energy through the resulting high turbine efficiency. The optimum pressure can be selected separately on considerations of safety and of the economies of pumping power and pressure circuit costs.

Gas has certain intrinsic safety advantages. It can undergo no phase change as a result of rising temperature or falling pressure, and so there cannot be any discontinuity in cooling under fault conditions, and flows and temperature can be predicted more simply and with greater confidence.

Continuity of fuel cooling for on-load refueling is more easily achieved with a gas. In addition with a gas, there is no risk of a fuel-coolant interaction of the kind that in certain circumstances could result from the dispersion of melted fuel in a liquid coolant. Finally, a gas carries a relatively low burden of activated corrosion products, gives low radiation levels for maintenance round the circuit, requires small active effluent plants, and gives rise to only low radiation doses to the operators.

Offsetting these virtues is the combination of low density and low specific heat of gases. Even with fairly high pressures, this requires comparatively large temperature differences to transfer the heat between the fuel and gas, and between the gas and the boiler surface. As a result core ratings are low and core and boilers need to be large. It also requires large volume flows to transport the heat, and therefore large circulator sizes and powers.

Table 1
Properties of some possible coolant gases

Gas	Molecular weight	Density at 1 bar (kg/m ³)	Specific heat at 1 bar (kJ/kg °C)	Absorption cross section (barn)
Air	29	0.60	1.0	1.9
Oxygen	32	0.67	1.0	0
Nitrogen	28	0.58	1.1	2.4
Hydrogen	2	0.04	14.7	0.4
Helium	4	0.08	5.2	0
CO ₂	44	0.92	1.1	0.003

The question of what gas to use is associated with the choice of moderator to slow the neutrons to thermal velocities. The first gas-cooled nuclear reactor above mentioned used graphite. The good moderating properties of graphite, combined with its low neutron capture cross-section, have led to it being used almost universally for gas-cooled reactors. Only a handful of experimental or demonstration reactors have been built with heavy water as moderator with pressure tubes containing the fuel and gas coolant, like the French 70 MWe EL4 at Brennilis. Indeed, graphite moderation has become almost synonymous with gas-cooled reactors. If gas-cooled fast breeders are developed, this couple will have to divorce.

The choice of coolant gas is influenced mainly by the thermodynamic, nuclear and chemical properties, and by its cost and supply. ▶ [Table 1](#) gives properties of some of the candidates at 300°C, a typical temperature of interest.

For good heat transfer and heat transport with low pumping power, a gas with high specific heat and high molecular weight, or density, is desirable. The coolant needs to have a low neutron absorption, to give good neutron economy and to avoid a rise in core reactivity if the reactor accidentally loses pressure. It also needs to be stable under irradiation, and preferably to have low neutron-induced radioactivity. Good chemical stability and low corrosion are obviously important. Of the many gases available the choice narrows quickly. Two gases stand out as candidates: carbon dioxide which is dense, cheap, but not chemically fully inert and helium which is inert, has a high specific heat, but is costly.

These two coolants have led to parallel lines of development in the family of gas-cooled reactors, sharing much common technology but with differing characteristics. The carbon dioxide reactors are characterized by relatively low specific core ratings, moderate temperatures, and large size – typically the natural uranium plants of the UK and France and the advanced gas-cooled reactors (AGRs). The helium reactors aim for high ratings, small size and high temperature: the family of high-temperature reactors, or HTRs.

2 Natural Uranium Fueled Reactors: Magnox and NUGG

Most “first generation” gas-cooled power plants were designed and built in the UK – the Magnox series – and in France – the NUGG. Both countries started their nuclear generation program in the early 1950s. Both had access to sufficient quantities of uranium ore, but no heavy water or

enrichment facilities, and this severely limited the choices available. Graphite has many advantages as a moderator as it absorbs few neutrons enabling the use of natural uranium as a fuel. The graphite industry was also a mature one as the material had been used for a long time in the electrochemical and electrometallurgical industries.

To use natural uranium in a graphite moderated reactor, the fuel must be in its metallic state in order to achieve a high enough density of fissile material. It must also be renewed at regular intervals to minimize the number of sterile captures by the fission products. The MAGNOX and NUGG reactors used bars of uranium clad in a magnesium alloy. These were inserted into channels in a massive graphite pile through which carbon dioxide was circulated under pressure. These reactors were built using fairly primitive technology – that available in France immediately after the war – but the poor slowing-down power of graphite meant that the size of the plants had to be large in order to achieve significant power levels, and this in turn led to a high capital cost. Their sensitivity to the xenon effect made them very inflexible in operation, but the ability to unload the fuel without having to shut down the reactor made it possible to produce almost pure ^{239}Pu for military applications by short irradiation.

Early “production” reactors, Windscale in the UK and G1 in France were cooled by air, but even before the 1957 fire of the Windscale reactor (due to the sudden release of the energy stored in the graphite by the “Wigner” effect during an attempt to anneal the pile), it was decided to turn to carbon dioxide as a coolant: This gas was readily available, cheap, and well known in industry. It has good heat transfer characteristics (for a gas) and good neutronic properties. It is also chemically compatible with the use of graphite as the moderator and with the cladding material and fuel used, provided certain precautions are observed. In addition to the series described below, two Magnox were exported by the British industry to Italy (Latina) and Japan (Tokai Mura), while a “sister ship” of the French St Laurent units was built in Spain (Vandellos).

2.1 The Magnox Family

The first nuclear electricity on the western side of the iron curtain was generated by dual purpose (weapon-grade plutonium production and power generation) Magnox plants located at Calder Hall, a station inaugurated by HM Queen Elizabeth II in October 1956. Eight 60 MWe reactors were built almost simultaneously by the UKAEA: 4 units at Calder Hall and 4 at Chapelcross, in Scotland. The Calder Hall design was simple and reliable but was not very efficient (22% thermal efficiency). The gas pressure was limited to 6.9 bar and the maximum outlet temperature was kept at 345°C. Refueling was carried out off-load at atmospheric pressure. All those units were shut down in 2003 and 2004, having operated over 45 years.

In 1955, Great Britain decided to embark on a significant program of nuclear power plants. The Magnox (magnesium non-oxidizing) alloy used to clad the uranium rods gave its name to the series. Nine commercial power stations with twin plants were eventually built in England, Scotland, and Wales, totaling 5,000 MWe (➤ [Table 2](#)).

The fuel was in form of metal rods, 28 or 29 mm diameter and between 48 and 128 cm length according to the model, clad with magnesium alloyed with a little beryllium and aluminum. The cladding is finned to improve the heat transfer to the gas. Gas outlet temperature was in the range 340–410°C and refueling was carried out on-load, to improve availability. That made it possible to unload immediately any failed fuel element without shutting the plant down.

Despite such a significant series, there was no standardization because the plants were designed and built by up to five different industrial consortia!

Table 2

Figure 1
The 300 MWe Magnox reactor Oldbury A1 (Marshall W 1981)

The Magnox reached their peak efficiency, 33.6%, in Oldbury A (Fig. 1), the general layout of which was to inspire the following AGR series. Once-through boilers were integrated around the core in the central cavity of a prestressed concrete vessel (Table 3).

Volumic power was low and, consequently, capital costs were high but fuel costs were low enough to make the stations economically competitive during the 1970s and 1980s. Toward the

■ **Table 3**

end of the Magnox construction program, in order to reduce the corrosion of mild steel by carbon dioxide, it was decided to restrict the outlet temperature below 360°C.

2.2 Natural Uranium Graphite Gas (NUGG) Reactors

Nine NUGG reactors were built in France. The first three reactors, at Marcoule, were used almost exclusively for the production of plutonium. The electrical power generation program began with the successive commissioning of Chinon 1 (1957), Chinon 2 (1958), and Chinon 3 (1961), with power capabilities of 70,200 and 480 MWe net respectively. There was no question of waiting for these reactors to go critical, even less of waiting for the first operational results, before starting work on the next design. These three reactors were prototypes, and each very different from the others. The next reactors were built at Saint Laurent des Eaux (1963 and 1966) and Bugey (1965). The Fifth Plan (1966–1970) included plans to build a total capacity of 2,500 MWe of NUGG reactors. The construction of a new unit at Fessenheim began in 1967, but was abandoned at the end of 1968. By that time, water-cooled reactors had become the favored option.

The characteristics of NUGG reactors are listed below, using Saint Laurent 2 as an example (see ► [Fig. 2](#) and ► [Table 4](#)).

The low specific power of the reactor meant that the core had to be very large. This core was enclosed in a vessel that also contained the coolant circuit and its heat exchanger. The vessel was a prestressed concrete structure, 33 m in diameter and 48 m high. The internal face of the vessel was lined with steel, 25 mm thick, in order to prevent any leakage of the CO₂ under a pressure of 29 bar.

The graphite pile in the reactor was in the form of a vertical cylinder 10.2 m high and 15.7 m in diameter. It consisted of a network of columns locked together by mortise and tenon joints. The pile weighed no less than 2,680 tons.

The four CO₂-steam heat exchangers were single tube cross circulation types. The water inlet was in the lower section, while the hot CO₂ entered the upper section. The total CO₂ flow rate was 8.6 tons/s, and the steam flow rate was 0.6 tons/s.

The fuel elements were replaced while the reactor was in operation, at a rate of around 2–3 channels per day, requiring the use of a sophisticated handling system.

■ Figure 2
St Laurent reactor layout

A system for detecting the presence of fission gasses in the coolant was used to detect and locate any breaks in the claddings.

The fuel elements used in the NUGG reactors were developed over time. In the latest versions, each element consisted of a metal tube of uranium alloyed with 0.07% aluminum and 0.03% iron, surrounding a graphite core. The borderline neutron balance of the NUGG reactors resulted in a fairly low fuel burnup rate of 6.5 GWd/tons. The maximum operating temperature of the reactor was determined by the maximum permissible temperature of the uranium. This was set at 650°C at the internal surface of the tube.

The last NUGG plant, 540 MWe Bugey 1 was shut down in 1994.

2.3 Safety of NUGG and MAGNOX Reactors

The containment of the fission products is provided by two barriers: the fuel element cladding and the prestressed concrete vessel. As the cladding is exposed to conditions close to its technological limits during operation, specific precautions must be taken in order to ensure that it remains within these limits. The core cooling is an essential factor in maintaining the integrity of the cladding. Four independent cooling systems are used.

The monitoring of the cladding integrity is also a crucial factor in maintaining the safety of NUGG and MAGNOX reactors. The monitoring system works by preventing the operation of

■ Table 4

Comparison of the characteristics of an AGR (Hinkley point B), a MAGNOX reactor (Wylfa) and a natural uranium graphite gas (NUGG) reactor (Saint Laurent 2)

	Units	AGR	MAGNOX	NUGG
Mass of U	Tons	114	395	430
Fuel		UO ₂ oxide Steel cladding	U metal Mg alloy cladding	U metal Mg alloy cladding
Power density	MW/m ³	3	~1	1
Enrichment	%	2.1–2.6%	Natural U	Natural U
Cladding		Stainless steel	Mg alloy	Mg–Zr alloy
Coolant gas pressure	Bar	41.9	27.6	29
Number of heat exchangers		12	4	4
Gas outlet temperature	°C	645	414	400
Maximum cladding temperature	°C	825	450	473
Mass of graphite pile	Tons	1,248	3,735	2,440
Net electrical power	MWe	625	590	480
Net efficiency	%	41.7	31.4	28.7
CO ₂ flow rate	tons/s	3.8	10.2	8.6
Burnup rate	GWd/tons	18	4	6.5

the reactor if any of the claddings are damaged. This is to avoid the oxidation of the metallic uranium by the CO₂ and to keep the coolant gas as clean as possible. In the event of a failure of the first barrier, the vessel is purged through filters trapping aerosols and radioactive iodides.

The Design Basis Accident for these reactors is a loss of pressure in the vessel via a fuel loading well or following a break in a gas pipe. A backup cooling system maintains the integrity of the barriers in the event of a total loss of the normal cooling systems. Studies of the radiological consequences of an accident do not indicate any major environmental risks. The addition of a further containment vessel was not considered necessary.

The only notable incidents occurring in this type of reactor were the meltdown of five fuel elements at Saint Laurent 1 and four fuel elements at Saint Laurent 2. Both had only minor consequences for the operating personnel, and the environmental impact was negligible.

The main components of the solid waste produced by these reactors are the graphite sleeves from the fuel elements. The annual volume produced by a 500 MWe NUGG or MAGNOX reactor is around 25 m³, equivalent to a mass of 45 tons.

The main problem with this type of reactor was the corrosion of structural components by oxidizing radicals produced by radiolysis of the carbon dioxide gas. The power levels of MAGNOX and NUGG reactors had to be reduced slightly in order to minimize this effect. For the same reason, the gas outlet temperature was limited to a maximum of 400°C. Other problems

associated with these old graphite-moderated gas-cooled reactors include friction wear, noise, and vibration.

Contrary to spent LWR fuel assemblies, spent Magnox and NUGG fuel elements could not be stored under water for long periods of time: For this spent fuel, early reprocessing was a necessity. Furthermore, at the time, breeder reactors were expected to be developed much sooner than they actually were: plutonium was considered on short supply. Here is the main reason why both British and French chose to reprocess their commercial spent fuel, making it an industrial success where the US industry failed.

3 Advanced Gas-Cooled Reactor (AGR)

The limitations inherent to the use of natural uranium were recognized from the start. In the mid-1950s, the British started studies of an improved design, based on low enriched uranium oxide fuel, manufactured in clusters of small diameter pins, with stainless steel cladding. This design was called AGR (► Fig. 3). The AGR is a direct descendent of the MAGNOX reactor and has only been built in Great Britain. After a small demonstration 30 MWe reactor commissioned at Windscale in 1962, a commercial AGR program of seven twin 600 MWe units was started (► Table 3). The power density is four times that of a MAGNOX reactor, and the volume of the heat exchangers is smaller. The chemical compatibility of UO_2 and CO_2 and refractory nature of the oxide make operation at higher temperatures possible. The coolant is at 650°C on leaving the core, giving the AGR an excellent electrical efficiency (42%). The first reactors

■ Figure 3
Cross-section of an advanced gas-cooled reactor (AGR) with single cavity vessel (Marshall W 1981)

suffered from a number of problems, partly due to failures in industrial organization, and partly due to a failure to control corrosion. Methane was added to the coolant gas in order to reduce radiolytic corrosion by CO and the oxidizing free radicals formed by the irradiation of the CO₂. Controlling the concentration of this gas proved to be difficult.

This first generation of gas-cooled reactors has an excellent operating record, generating electrical power continuously with no major accidents. However, these old NUGG, MAGNOX, and AGR designs are now obsolete for economic reasons. Graphite-moderated gas-cooled reactor technology has gradually been abandoned in France, Italy, Spain, and Japan, and only accounted for 4% of worldwide nuclear capacity in 2008. The British AGR and MAGNOX reactors are the only types still in operation. All of them should be decommissioned by 2020.

4 High Temperature Reactors HTR

High Temperature Reactors HTR, first developed during the 1970s and 1980s in Germany and the USA, may be doing a comeback based on their high thermal efficiency and their very high degree of “intrinsic” safety. These characteristics derive from the use of helium gas as coolant (Melese and Katz 1984), graphite as moderator, and, above all, a very unusual type of fuel.

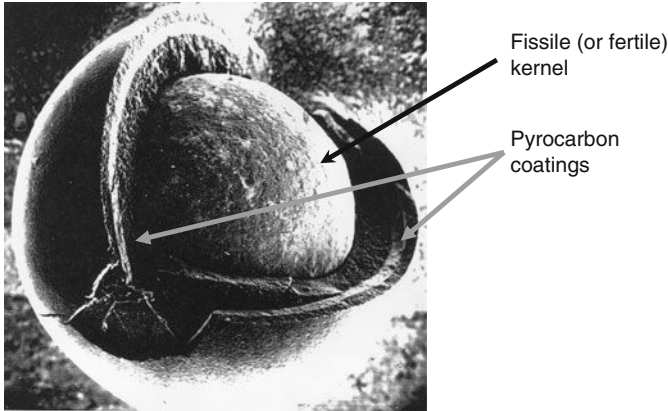

4.1 Particles, Pebbles and Prisms

What constitutes the specificity of the HTRs and gives them their qualities is their fuel. It was invented in Harwell, UK, during the mid-1950s. Wholly refractory and helium cooled, the core is made of tiny fissile particles, less than 1 mm diameter, dispersed within a graphite moderator.

The kernel of each individual particle is coated (🔍 Fig. 4) by catalytic cracking in fluidized bed, with a number of concentric layers, like the sugar coatings of the almond in a *dragée*: inner layers of pyrocarbon which protect a layer of silicon carbide SiC from the hot kernel and outer layers of dense pyrocarbon which can withstand the pressure of fission gases up to very high burnups. The SiC layer is a leaktight barrier to contain the fission products: it plays the role of the cladding in a conventional fuel pin. The outermost carbon layer facilitates the agglomeration of the particles inside “compacts” or pebbles (🔍 Fig. 5).

Extremely divided and fully refractory, this fuel enables the reactor to operate with very high coolant temperatures (we shall see how high later) and therefore with an excellent thermal efficiency while the center of the particle remains relatively cold. The coated particle is, indeed, a very special breed of fuel element:

- There are several tens of billion particles in a reactor core. It is therefore a mass produced object, whose quality can only be assessed by statistical tools (no fewer than 10¹¹ individual claddings constitute the first barrier against radioactivity dispersal, versus the 2×10⁵ pin claddings of a PWR).
- There is an almost unlimited flexibility in the core composition. You can freely select the nature (fissile, fertile, burnable poison, mixture) and dimension (i.e., self-protection) of the kernels. You can adjust the particle concentration within the graphite matrix of the compact or pebble, as well as their distribution by size (double heterogeneity). HTRs can therefore be adapted to any fuel cycle whatsoever.

■ Figure 4
Scanning electron micrography of a coated particle

■ Figure 5
The two families of fuel elements (compacts-in-prism and pebbles)

The actual flexibility offered to the designer can be illustrated by the two types of fuel elements used in the HTR prototypes, prisms in Fort Saint Vrain and pebbles in THTR, not to mention many other types tested in Dragon (annular, teledial, etc.).

4.2 HTR Demos: Dragon, AVR, Peach Bottom

4.2.1 Dragon

It is around 1956, while the UK was launching its big Magnox program, that the Harwell discovery was developed inside the Dragon Project, an ad hoc OECD enterprise located on the UKAEA Winfrith site. A demonstration facility was built and operated at Winfrith as soon as

■ **Table 5**
Characteristics of HTR demos

Characteristics	Dragon	Peach bottom	AVR
Criticality/shutdown	1964/1975	1966/1974	1966/1988
Thermal power (MWt)	20	115	46
Net electrical power (MWe)	–	40	15
Helium pressure (absolute bars)	20	24	11
Core inlet temperature (°C)	350	340	260
Core outlet temperature (°C)	750	715	950

Fuel cycle	Various	²³⁵ U/Th	²³⁵ U/Th

1964, and established successfully the HTR feasibility. In addition to building and operating the reactor, the 12-country Dragon team paved the way for future HTRs by exploring reactor designs and testing a number of fuel cycles (low enriched uranium LEU, thorium/²³⁵U, and plutonium, both with oxide or carbide kernels).

Being multinational, Dragon Project introduced the HTR to the whole Europe and triggered interest in the USA, then Japan (🔗 [Table 5](#)).

4.2.2 AVR

Dragon partner through Euratom, Germany developed HTRs as its first purely national design. As soon as 1967, the AVR, a very innovative demonstration reactor, began operation in Jülich, where it operated very successfully for more than 20 years.

Both core and steam generator were contained in a single steel double walled pressure vessel. The helium coolant was circulating upward, as its outlet temperature was increased from 750

■ **Figure 6**
HTR pebble

■ **Figure 7**
 The Jülich AVR

to 850°C , and then to 950°C during its last two years of operation. The temperature was even pushed to $1,050^{\circ}\text{C}$ in the last days before shutdown.

The main innovation of AVR was its spherical fuel element, the 6 cm diameter graphite “pebble” inside which coated particles were agglomerated (➤ [Fig. 6](#)). Hundred thousand pebbles are heaped inside a funnel shaped graphite cavity. The control rods move in channels within the graphite reflector (➤ [Fig. 7](#)).

Six hundred pebbles a day were continuously extracted from the bottom of the funnel, and tested for physical integrity and burnup. Ninety percent were recycled on top of the heap, with the required complement of fresh pebbles: an intact pebble traveled therefore ten times through the core before disposal. Each pebble contained on average 1 g of HEU and 6 g of thorium, in particles with a “BISO” all pyrocarbon coating. Burnups as high as 150 GWd/tons were routinely reached in AVR.

4.2.3 Peach Bottom

Fifty-three electricity producers, with support from the US government, very soon entered the HTR race and built a demonstration reactor at Peach Bottom (Pennsylvania), which reached its nominal 40 MWe power in 1967. The Peach Bottom fuel element is close to the Dragon design, a long hexagonal graphite prism with a pile of annular compacts inside. The core, surrounded by a graphite reflector, is located at the bottom of a steel pressure vessel. The first core was fabricated using particles with a coating still imperfect. It was soon replaced by a core with much improved fission products retention. Peach Bottom was decommissioned in 1974, just after the start-up of the Fort Saint Vrain prototype.

The very successful operation of these three demos gave great hopes concerning the future of the HTR families. Unfortunately, the performances of their immediate successors were less bright.

4.3 Fort St Vrain and THTR Prototypes

4.3.1 Fort St Vrain

In 1968, 1 year only after the start-up of Peach Bottom, general atomic started the construction on the Fort St Vrain site of a 330 MWe HTR prototype. The operator was to be Public Service of Colorado, a small utility without previous nuclear experience. Being a prototype, Fort Saint Vrain was built with federal support (👉 [Table 6](#)).

The general layout of the reactor (👉 [Fig. 8](#)) is strongly inspired by the 500 MWe St Laurent UNGG design but with a reactor cavity six times smaller.

The core is composed of 1,483 prismatic fuel elements (👉 [Fig. 9](#)) superposed on six layers. Each fuel element is a hexagonal graphite prism in which cylindrical blind channels are bored. Cylindrical compacts fill these channels, which are surrounded by coolant channels in which helium circulates downwards, under 48 bars pressure.

The compacts are fabricated by mixing two types of particles: fissile particles with a kernel of HEU dicarbide $^{235}\text{UC}_2$ with TRISO coating including one SiC layer and fertile particles ThC_2 with a BISO coating without silicon carbide. The core is axially and radially zoned, and it is reloaded by 1/6th at each annual outage.

Twelve once-through helical steam generator modules are located below the core.

Critical in 1974, Fort St Vrain was connected to the grid in 1976, to be decommissioned in 1989 with a cumulative load factor of 30%. The fuel behaved successfully, but the reactor's overall design was rather a failure.

At the very beginning of the 1970s, while Fort St Vrain was under construction and Peach Bottom still operating, a few US utilities ordered from General Atomic, then a subsidiary of

■ **Table 6**
Characteristics of HTR prototypes

Characteristics	Fort St Vrain	THTR 300
Criticality/shutdown	1974/1989	1983/1989

Fuel reload	Annual per 1/6th	Continuous

Gulf Oil (and soon of Shell as well), 8 large HTR rating 1,160 or 770 MWe, two very similar models with either three or two loops.

The general layout (➔ [Fig. 10](#)) is derived from the pods-type AGR, but with downward coolant circulation to protect the upper structures and control rod mechanisms from the hot helium. Prominent in this design stands the massive prestressed concrete reactor vessel (PCRV), with vertical tendons and circumferential wire wrappings. In the center of the PCRV, a main cavity contains the core while peripheral cavities (the “pods”) contain the helical SGs and the helium circulators. The core, extrapolated from Fort Saint Vrain, was supported by a forest of graphite pillars above a lower plenum connected to the pods by hot ducts with thermal insulation.

The 1974 oil shock triggered overnight a rash of nuclear project cancellations in the USA: latest ordered, most HTR projects were victims of this epidemic. The vendor itself canceled in 1975 the last two survivors. One must remember that there has been no surviving nuclear order in the USA since 1973.

4.3.2 The Schmehausen HTTR

In 1970, The German industry received an order for a 300 MWe prototype developed from AVR, to be built on the Schmehausen site.

The construction of THTR lasted 14 years, but the plant was operated only for four years before definitive shutdown. A number of technical difficulties, mostly due to the increase in size were met, but none appeared insolvable: the control rods had to be inserted in the stack of

Figure 8
Fort Saint Vrain reactor layout (Melese & Katz 1982)

Figure 9
HTR prism

pebbles instead of in the reflector, the mass flow of helium was too big to allow counter current circulation of helium and pebbles, fixation of the graphite to the wall of the core cavity above the level of the top of the pebbles heap proved to be uneasy (Fig. 11). But the real reasons of THTR premature shutdown were the context of a German public opinion becoming antinuclear, and power struggles between the Land and the Federal government about licensing issues.

The mediocre performances of Fort St Vrain did not convince utilities from other countries to order HTR plants, but General Atomic, well introduced in the US Congress, managed to get year after year enough money on the US DOE budget to keep alive a small but highly competent team of engineers and scientists. But the thorium cycle was abandoned because it needed highly enriched uranium HEU to start the cycle and as a complement to ^{233}U because HTR are not breeders. After 1974 and the Indian explosion, the civilian use of HEU became taboo for nonproliferation reasons. Today, one would likely use plutonium to start a thorium cycle.

1160MWe HTR Project (1973) (Melese & Katz 1982)

■ Figure 11
THTR schematics

4.4 Lessons Learned from the First HTR Units

Despite the abortion of the US and German programs, the results of this first part of the HTR saga were far from negligible.

On the plus side:

- This type of reactor can reach a high thermal efficiency, as good as that of the best gas turbines
- Cold fuel, refractory core, high thermal inertia, one-phase coolant chemically inert: all these elements result in a high level of safety and forgiveness of operator mistakes
- The particle-based fuel can accommodate any possible fuel cycle
- The first small demos have proven the concept feasibility (and the rocket program described below demonstrated the existence of huge margins)
- HTR is one of the very few concepts to offer real prospects of non electrical uses of fission (together with the Gas-cooled breeder, which exists only on paper)

On the minus side:

- The low core power density means a large vessel and therefore a high capital cost
- The GA 1160 Project did not have a secondary containment
- If core meltdown is beyond credibility (though the SiC layer begins to deteriorate when the particle temperature exceeds 1,600°C), a massive water ingress in the hot core might provoke a dangerous weakening by corrosion of the core support pillars
- The core itself is quite refractory, but the long-term behavior of the materials outside the core exposed to hot helium is of concern. This includes the concrete PCR/V
- Both prototypes did not meet with great success

On the “plus or minus” side:

For all its great qualities, the HTR fuel is not easily reprocessed – and reprocessing is indispensable if one wants the advantages of the thorium cycle. The process originally developed at the laboratory scale at Idaho Falls had the following stages:

- Crushing of the prismatic blocks to free the compacts. The graphite fragments would have been incinerated, with the corresponding ^{14}C release, which would no longer be acceptable today
- Burning of the compact matrix as well as the outer pyrocarbon layers. This operation bares the BISO kernels, while the TRISO keep their SiC shell
- Dissolution of the BISO kernels in nitric acid: the remaining thorium is separated from ^{233}U by solvents extraction, PUREX type, while TRISO particles remain solid
- Crushing of the TRISO SiC shell and burning of the inner pyrocarbon
- Dissolution of the uranium kernel to recover the residual ^{235}U , contaminated with ^{236}U but still valuable

This difficulty to reprocess was considered a weakness in 1970, within a thorium cycle vision. After switching to LEU (about 8% ^{235}U enriched), and taking into account the very high burnups achievable, the residual value of the remaining fissile materials is very low. Reprocessing is all the less desirable that the spent fuel, whose graphite resists corrosion quite well at moderate temperatures, appears to constitute a quite acceptable waste form for direct disposal. The low power density of the core becomes then an asset. The fact that reprocessing is difficult and not very attractive is now advertised as an advantage in terms of non-proliferation.

In retrospect, HTRs have suffered above all from a bad timing of introduction. Their story might have been quite different if a few of the – better designed – large reactors ordered in the 1970s had actually been built. Their performance might have erased the bad memory of Fort St Vrain.

Figure 12
HTTR core and fuel element (from JAEA)

4.5 Recent Japanese and Chinese Demos

While both USA and Germany were abandoning the HTR development, it was continued along both types of HTR, but in other countries.

Japan built the HTTR, a 30 MWt demo HTR, whose construction by JAERI started in 1990, which has been operating since 1998. The HTTR uses prismatic blocks but the fuel design is not identical to the US: annular compacts are piled within a cylindrical graphite sleeve, located in open channels of the graphite hexagonal prism (Figure 12). Helium flows in the annulus between the sleeve and its channel. HTTR is planned to be used to demonstrate hydrogen production using nuclear heat (see Sect. 6).

The Chinese have built a small 10 MWt pebble bed demo, which went critical in December 2000. This reactor can passively evacuate its decay heat and has carried out some interesting safety experiments.

4.6 GT-MHR and PBMR

Since the 1980s, a number of evolutions have triggered a renewed interest in HTRs, even from some PWR champions like AREVA-NP (formerly Framatome) or Westinghouse (at least when it was affiliated to BNFL).

1. To overcome the formidable economic “size effect” and attempt to remain competitive with plants adapted to the needs of emerging countries, i.e., much smaller than 1,600+ MWe EPR, many reactor vendors have considered in the 1980s “modular” concepts. A modular power plant would be built progressively by adding identical units, small enough to have a high degree of prefabrication in factory and, therefore, a minimum construction – or rather assembly – time on-site. The progressiveness allows the first unit to start generating power, hence cash flow, when later units are still under construction. Taking into account the weight of interests during construction IDC in the capital cost of a plant, both prefabrication and stepwise assembly offer the prospect to balance the size penalty.
2. Below a threshold in size, it becomes possible to remove the decay heat after shutdown through purely passive means: thermal conduction and convection. Of course, the pressure vessel must be metallic. The threshold comes from the surface/volume ratio, for a given power density. If the safety authorities accept the demonstration, one can get rid of expensive emergency core cooling systems – there again, to overcome the size penalty.
3. Taking advantage from the fallouts of the aerospace developments, gas turbines have achieved spectacular improvements, both in size and efficiency. This underlined the importance of thermal efficiency, one HTR strong point (➡ Fig. 13), and lent credibility to the feasibility of high power helium turbine, hence the direct cycle HTR.
4. Nuclear weapons reduction agreements between the USA and the Russian Federation after the end of the Cold War have “freed” huge quantities of weapon-grade plutonium, which must be “disposed of.” The best way is to burn this plutonium in power plants. With their wide fuel cycle flexibility, HTRs can be optimal plutonium burners (➡ Table 7).

■ Figure 13
Achievable thermal efficiencies

4.6.1 GT-MHR, Gas Turbine Modular High Temperature Reactor

As mentioned above, during the “lean cows” years, General Atomic still carried out some HTR development, federally funded. In 1993, this development was boosted in an American-Russian framework, to design a HTR optimized for weapon-grade plutonium burning. Framatome (now AREVA-NP) joined the project in 1995, followed by Fuji Electric.

The GT-MHR nuclear island has the following characteristics:

- Steel pressure vessel without thermal insulation to allow heat removal by radiation
- Prismatic “GA type” fuel elements constituting an annular core to maximize the surface-to-volume ratio (The center columns of the core, in pure graphite, add to the overall thermal inertia)
- Cooling panels inside the walls on the underground reactor containment building, operating in natural convection

The conventional island features:

- A direct cycle helium turbine, allowing for excellent thermal efficiency and eliminating the risk of water ingress in the core
- Magnetic bearings (water ingress through the bearings was an endemic plague in Fort St Vrain)

The core, on the one hand, and the single shaft turbo-alternator-compressors are located side by side in two separate steel vessels connected by a short duct. The whole layout is quite compact (► [Fig. 14](#)).

4.6.2 ESKOM PBMR Pebble Bed Modular Reactor

While GT-MHR was directly in line with the General Atomic family, PBMR, derives from the Jülich AVR, revisited by the South African utility ESKOM. Here were its original characteristics:

■ **Table 7**
PBMR and GT-MHR characteristics

Characteristics	PBMR	GT-MHR
Thermal power (MWt)	265	600
Net electric power (MWe)	116	285
Efficiency (%)	44	47,5
Core inlet/outlet temperatures (°C)	536/900	490/850
Helium mass flow (Kg/s)	140	320
Turbine inlet/outlet temperatures (°C)	751/554	850/510
Turbine inlet/outlet pressure (MPa)	7,0/4,3/2,6	7,0/2,6
Fuel element	Pebbles	Prismatic

■ Figure 14
GT-MHR's two "bottles" (from AREVA)

The PBMR is very simple and the fuel has been thoroughly qualified (but the German fabrication facilities have disappeared). On the other hand, construction time and cost initially quoted by ESKOM were not quite credible. Over the years, PBMR has increased its rating to 165 MWe and adopted an annular core design, and PBMR intends to build a high-temperature ($>1,000^{\circ}\text{C}$), high-pressure (90 bar) demonstration reactor at Koeberg. A Helium Test Facility (HTF) is already testing many components in a helium environment at Pelindaba in the North West province. The HTF has specifically been built to test helium at the very high temperatures and pressures that will be experienced in the Pebble Bed Modular Reactor. According to the PBMR website <http://www.pbmr.co.za/>, the latest design is as follows:

The PBMR essentially comprises a steel pressure vessel, which holds about 456,000 fuel spheres. The fuel consists of low enriched uranium triple-coated isotropic particles contained

in a molded graphite sphere. A coated particle consists of a kernel of uranium dioxide coated with silicon carbide and pyrolytic carbon. The particles are encased in graphite to form a fuel sphere or pebble about the size of a tennis ball. Helium is used as the coolant and energy transfer medium, to drive a closed cycle gas turbine and generator system.

The plant comprises a module building with the reactor pressure vessel (RPV) and the power conversion unit (PCU) (► Fig. 15).

The PBMR has a 27 m high vertical steel reactor pressure vessel (RPV) with an inner diameter of about 6.2 m. The RPV contains and supports a metallic core barrel. It is lined with a 1 m thick layer of graphite bricks, which serves as an outer reflector and a passive heat transfer medium. The geometry of the fuel region is annular and located around a central graphite column. The latter serves as an additional neutron reflector. The core barrel supports the annular pebble fuel core, which is located in the space between the graphite reflectors. Vertical borings in these reflectors are provided for the reactivity control elements. Two diverse reactivity control systems are provided for shutting the reactor down. One of the systems is 24 control rods in the outer reflector, while the other consists of small absorber spheres which are dropped into eight borings in the central reflector.

To remove the heat generated by the nuclear fission reaction, helium coolant enters the reactor vessel at a temperature of about 5,000°C and a pressure of nine MPa. The gas flows down between the hot fuel spheres, after which it leaves the bottom of the vessel having been heated to a temperature of about 900°C.

The hot gas then enters the turbine, which is mechanically connected to the generator through a speed-reduction gearbox on one side and the gas compressors on the other side.

► Figure 15
PBMR nuclear island

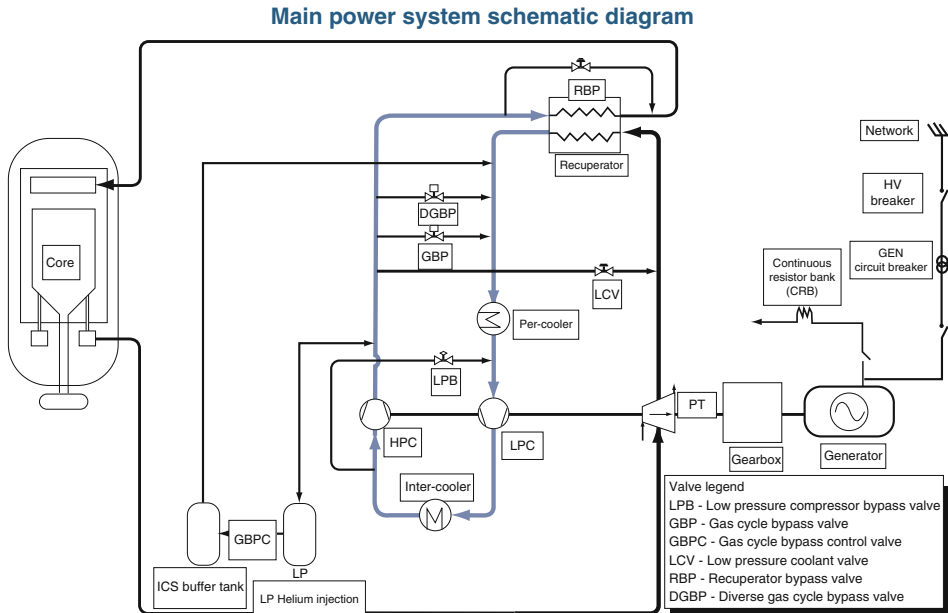

Figure 16
PBMR Flow Chart

The coolant leaves the turbine at about 500°C and 2.6 MPa, after which it is cooled, recompressed, reheated, and returned to the reactor vessel (🔍 Fig. 16).

The thermodynamic cycle used is a Brayton cycle with a water-cooled pre-cooler and inter-cooler. A high efficiency recuperator is used after the power turbine. The helium, cooled in the recuperator, is passed through the pre-cooler, low-pressure compressor, the inter-cooler, and high-pressure compressor before being returned through the recuperator to the reactor core.

The power taken up by the helium in the core and the power given off in the power turbine is proportional to the helium mass flow for the same temperatures in the system. The mass flow rate depends on the pressure, so the power can be adjusted by changing the pressure in the system. The high pressure and high temperature operation of the reactor in a relatively high thermal efficiency.

While a typical light water reactor has a thermal efficiency (electrical power output/thermal heat input) of approximately 33%, an efficiency of about 41% is anticipated in the basic PBMR design.

Online refueling is another key feature of the PBMR. Fresh fuel elements are added to the top of the reactor while used fuel is removed at the bottom while the reactor is at power. The aim is to operate uninterrupted for 6 years before the reactor is shut down for scheduled maintenance. For the demonstration module, however, a number of interim shutdowns will be required for planned evaluation of component and system performance.

Shutdown will be done by inserting the control rods. Start-up is effected by making the reactor critical, then using nuclear heat-up of the core and circulating the coolant by motoring the turbo-generator set. Heat is then removed by the pre-cooler and inter-cooler. At a specified temperature, the cycle becomes self sustaining.

4.6.3 PBMR Fuel Fabrication and Fuel Cycle

PBMR fuel is based on the proven, high-quality AVR fuel design consisting of low enriched uranium triple coated isotropic (LEU-TRISO) particles contained in a molded graphite sphere. A coated particle consists of a kernel of uranium dioxide surrounded by four coating layers. The uranium in the PBMR fuel is enriched to about 10% in ^{235}U .

In the fabrication process, a solution of uranyl nitrate is dropped from small nozzles to form microspheres, which are then gelled and calcined to produce uranium dioxide fuel “kernels.” The kernels are then run through a chemical vapor deposition (CVD) furnace in an argon environment at a temperature of $1,000^{\circ}\text{C}$, in which layers of specific chemicals can be added with extreme precision.

For PBMR fuel, the first layer deposited on the kernels is porous carbon. This is followed by a thin coating of pyrolytic carbon (a very dense form of carbon), a layer of silicon carbide (a strong refractory material), and finally, another layer of pyrolytic carbon. The porous carbon accommodates any mechanical deformation that the uranium dioxide kernel may undergo during the lifetime of the fuel, as well as gaseous fission products diffusing out of the kernel. The pyrolytic carbon and silicon carbide layers provide an impenetrable barrier designed to contain the fuel and fission products. Some 15,000 of these coated particles, now about a millimeter in diameter, are then mixed with graphite powder and a phenolic resin into 50 mm diameter spheres. A 5 mm thick layer of pure carbon is then added to form a “non-fuel” zone, and the resulting spheres are sintered and annealed to make them hard and durable. Finally, the spherical fuel “pebbles” are machined to a uniform diameter of 60 mm. Each fuel pebble contains about 9 g of uranium, i.e., ~ 1 g of ^{235}U . The total uranium in one fuel load is 4.1 metric tons, and the total mass of a fuel pebble is 210 g.

The reactor is continuously replenished with fresh or reusable fuel from the top, while used fuel is removed from the bottom. After each pass through the reactor core, the fuel pebbles are measured to determine the amount of fissionable material left. If a pebble still contains a usable amount of the fissile material, it is returned to the reactor at the top for a further cycle. Each cycle takes about 6 months. Each pebble passes through the reactor about six times and lasts about 3 years before it is spent, which means that a reactor will use 15 total fuel loads in its design lifetime of 40 years.

The PBMR fuel will be manufactured at the Necsa site at Pelindaba near Pretoria. The facility will have an initial capacity of 270,000 fuel spheres per year. A 165 MWe PBMR module will generate about 32 tons of spent fuel pebbles per annum, about 1 ton of which is uranium.

The storage of PBMR spent fuel should be easier than for fuel elements or rods from conventional nuclear reactors, as no safety graded cooling systems are needed to prevent fuel failure. The fuel is transported to the spent fuel storage facility in the reactor building by means of a pneumatic fuel handling system. The spent fuel storage consists of ten tanks, each with a diameter of 3.2 m and a height of 18 m. One tank can store 600,000 pebbles. There will be enough room for the spent fuel to be stored in dry storage tanks at the PBMR plant for the power station’s expected 40-year operational life, during which time no spent fuel will have to be removed from the site. After the plant has been shut down, the spent fuel can be safely stored on site for another 40 years before being sent to a final repository.

5 The NERVA Story (Simpson JW 1995)

Let us forget electricity for a while, and follow the HTR adventure in the wake of the famous APOLLO space program.

In parallel with their conventional program of chemical rockets development, during 20 years or so, the US developed a project of nuclear propulsion rocket of an incredible ambition, as seen today. The objective was to heat much above $2,000^{\circ}\text{C}$ and for several tens of minutes formerly liquid hydrogen, using the heat generated by a nuclear reactor. For the sake of comparison, the Vulcain motors powering the Ariane V rocket are qualified to operate during no more than 10 min. Only the particle-based HTR fuel could let one dream of such performances.

The most surprising is that, despite incredible technical difficulties, this project met a total success (➤ *Figs. 17* and ➤ *18*). From the tiny Kiwi to the big Phoebus, from 1959 to 1972, all records were consistently broken, as shown on the (➤ *Table 8*). The project was then completely dropped, as NASA never launched the APOLLO XVIII to XX though completely built: 3 years after the first Moon landing, space was no longer a national priority. Over those years, the complete Rover/NERVA program cost amounted to a total of \$ 1.5 billion. Since 2000, NASA and DOE have somehow revived a few nuclear space propulsion projects. Whatever their future may be – and it is too early to guess – the early space attempt has demonstrated the huge margins imbedded in the HTR fuel!

6 Gas Cooling in Generation IV (DEN 2006)

Much energy has been vested in international cooperation to define goals for the nuclear energy systems of the future, and also select the key technologies for achieving them. The effort has

been made primarily through the Generation IV International Forum (GIF) that the American Department of Energy (DOE) launched during the course of 2000. In 2009, GIF participants were Argentina, Brazil, Canada, China, the European Union, France, Japan, Russia, South Africa, South Korea, Switzerland, UK, and USA.

The GIF is a major initiative to identify and organize the R&D required to develop a new generation of nuclear energy systems due to go on stream around 2040. Each of the systems

comprises a nuclear reactor, an energy conversion system and the necessary fuel cycle, fuel manufacturing, spent fuel, and final waste management equipment.

GIF participants agreed on four major goal areas: aptitude for developing sustainable energy, economic competitiveness, more robust safety and reliability, and nuclear materials proliferation resistance along with physical protection for installations.

Twenty families of nuclear systems were initially presented by nuclear engineers and scientists. A one hundred-strong international expert panel evaluated the performances of each family against 24 metrics. Final selection of the systems also brought into play considerations such as the selection's completeness in terms of diversity of technologies, deployment lead times, the possibility of staged development and the ability to meet the identified needs of electricity production, hydrogen production, fissile material regeneration, and transmutation of long-lived waste for forthcoming decades.

The following six systems deemed the most promising at the end of this evaluation exercise were called on to rally Forum cooperation on development work starting from 2004:

- VHTR – very high temperature reactor system, over 1,000°C, helium-cooled, dedicated to hydrogen production or hydrogen/electricity cogeneration
- GFR – gas-cooled fast reactor system – helium-cooled fast reactor
- SFR – sodium-cooled fast reactor system
- SCWR – super critical water-cooled reactor system
- LFR – lead-cooled fast reactor system – lead or Pb-Bi alloy-cooled fast reactor
- MSR – molten salt reactor

The first two of the six selected systems are gas-cooled. VHTR offers the strengths of economics and safety in particular. Because an open cycle is used, its aptitude for sustainability is deemed to be similar to that of a second generation reactor. Likewise, the radiotoxicity and volume of VHTR waste are characteristically high.

GFR offers a different picture: its closed fuel cycle makes both waste and its aptitude for sustainability of positive strengths. On the other hand, it meets the economics and safety criteria less satisfactorily, and would need a much longer development time.

6.1 VHTR

The VHTR is one of the six concepts selected by the GIF as a candidate model for Generation IV. With respect to the other concepts, VHTR stands apart: it offers very little improvement in terms of sustainability (fissile material utilization and waste management), but it opens to nuclear fission a wide new range of applications, the most promising of which appears to be hydrogen production.

6.1.1 Electricity Production

As seen above, HTRs were developed in the 1970s. Reactors of this type were subsequently built and operated, and numerous test facilities were also built (e.g., to test the performance of direct-cycle gas turbines, the heat resistance of refractory concretes, or the oxidation resistance of graphite).

The pursuit of increased system performance led to the idea to increase the reactor operating temperature. According to the Carnot principle, the efficiency of a reversible thermodynamic system increases with temperature as follows:

$$\eta = 1 - \frac{T_2}{T_1},$$

where T_1 and T_2 are the absolute temperatures of the hot and cold source, respectively.

If technologically possible, increasing the core outlet temperature approximately 100° improves efficiency by several points. For example, under otherwise identical conditions, the electrical production efficiency of an industrial machine operating on a direct Brayton-cycle with helium as the working fluid increases from 50.5 to 56% when T_1 increases from 850 to 1,000°C (see  Fig. 19, dotted curve).

However, the technological constraints associated with the resistance of the reactor vessel steel limit the foreseeable increase, i.e., an increase in core outlet temperature is generally accompanied by an increase in helium return temperature near the reactor vessel. The best reactor vessel material currently being developed (chrome steel) does not withstand temperatures above 490°C. With a core outlet temperature of 1,000°C and a helium return temperature of 490°C, the electrical production efficiency is only 53% ( Fig. 19, poor efficiency curve). An increase in efficiency of 2.5 points amounts to a 5% decrease in production cost. Moreover, increasing the efficiency without modifying the fuel quantity used, which is the case when switching from an HTR to a VHTR, leads to a proportional decrease in the quantity of radioactive waste created per kilowatt-hour produced.

The benefits of higher temperatures are apparent, but also the difficulty of achieving them.

 Figure 19

Electrical production efficiency of a very high temperature reactor system (VHTR) using a direct helium cycle (Brayton), as a function of core outlet temperature and return temperature (T_e). Depending on the reactor vessel steel used, a low return temperature may be necessary to prevent embrittlement (in this case $T_e = 490^\circ\text{C}$ for chrome steel, poor efficiency curve), which produces a reduction in efficiency as compared to unconstrained conditions (dotted curve) (DEN 2006)

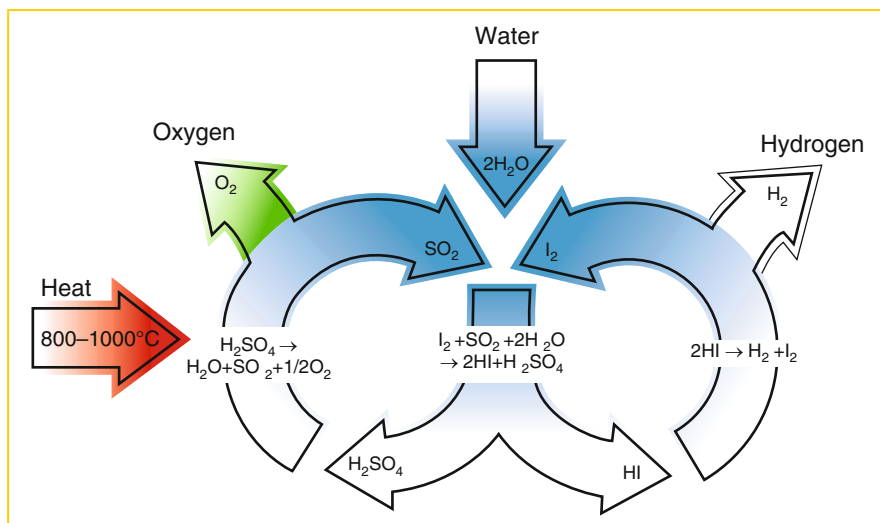

6.1.2 Hydrogen Production

Very high temperatures also allow the possibility of producing hydrogen directly via thermochemical cycles, without transforming heat into electricity. Hydrogen is a good substitute for hydrocarbon fuels because its combustion in air yields only water. It may even be more interesting as feedstock for synthetic liquid fuels, associated with coal or biomass. But hydrogen does not exist naturally in free state: it needs to be produced. Dissociating a water molecule is an attractive solution, as the water cycle (dissociation and combustion) constitutes a closed and clean cycle, but it is energetically costly. We currently know how to produce hydrogen by water electrolysis, but at a very high cost. Most of the industrial production of hydrogen is achieved by making light hydrocarbons react with high-temperature steam. For example, methane reformation with steam consists of the following reaction:

The reformation is performed at over 700°C , burning part of the methane to produce the heat required. This economic process consumes hydrocarbons and produces carbon dioxide contributing to the greenhouse effect. The concept of using nuclear heat as an energy source and water as a resource allows the possibility of industrial production without greenhouse gases.

In order to chemically dissociate a water molecule, various reaction methods can be considered. They involve intermediate steps with additional products that are recycled in the process, therefore acting as chemical catalysts. The most studied processes operate at very high temperatures, typically above 900°C , hence the interest of a heat source exceeding 950°C . For example, sulfur-based cycles use a sulfuric acid dissociation reaction that only works above 870°C and whose efficiency increases with temperature (see  Fig. 20).

 **Figure 20**
Hydrogen production by iodine-sulfur thermochemical cycle (DEN 2006)

■ Figure 21

Energy required to dissociate a water molecule by steam electrolysis, as a function of temperature. Below 600°C, electricity is partly lost heating the water. Above this temperature, the direct heating of the water reduces the electricity required (DEN 2006)

This cycle decomposes the water molecule using heat at over 870°C.

We can also dissociate a water molecule by steam electrolysis. Preheating the water vaporizes and superheats it, thereby decreasing the electrical energy required for its dissociation. The direct use of heat minimizes losses associated with the transformation of heat into electricity

(► Fig. 21).

As described above, the electrical transformation efficiency of an HTR is approximately 50% (as compared to only 30% for a PWR). Assuming an electrolyzer efficiency of 80% at 900°C, the global efficiency of the system is 40%. On the other hand, if part of the reactor's calorific energy is used to heat the electrolyzer and decrease the share of electricity required, the global efficiency can be increased by several points so as to approach 50%.

Again, as in the case of electricity production, the final criterion is the cost of the hydrogen produced, but good efficiency is essential no matter what method is used.

6.1.3 Water Desalination

Saltwater desalination at low cost is another interesting application of HTRs. The production of freshwater constitutes a major challenge for numerous countries in the years to come. Seawater desalination technologies are already available and industrially implemented throughout the world, but their cost is high. Water desalination processes require mechanical or heat energy, depending on the method used.

For example, we can vaporize saltwater and condense the steam obtained, which no longer contains salt. This process is efficient at temperatures above 120°C. HTR thermodynamic cycle optimization processes produce temperatures of 120–130°C, depending on the circuits used.

This heat is released to the exterior and it is perfectly possible to install a desalination circuit. In that case, only the cost of the desalination circuit needs to be considered. The heat is free (normally unused), thereby reducing desalination costs. Moreover, by increasing the hot temperature of a VHTR, we also increase the temperature of this heat energy by a few tens of degrees, making the desalination process even more attractive.

6.1.4 NGNP Project (USA)

Simultaneously with the international structuring of research on future reactor systems (GIF) in 2003, the US DOE announced the construction of a VHTR prototype in the near future. Referred to as the *next generation nuclear plant* (NGNP), this prototype should demonstrate high-efficiency electricity production and hydrogen production capacities.

The objective is twofold: to produce a prototype that can be marketed as such in an electronuclear fleet, and to promote associated research and development for innovation. The initial development plan was very ambitious (construction between 2011 and 2015). Subsequent innovation scheduling analyses showed the need for a transition period from recognized HTR technologies to the more ambitious VHTR technologies described above. In 2008, the NGNP was scheduled to begin operation in 2018.

The NGNP consists of a fourth generation VHTR prototype to be financed by the DOE and a consortium of US research centers and industrial partners. The NGNP will be built at the Idaho National Laboratory (INL). The main characteristics of this reactor are the following:

- Helium-cooled reactor
- Helium temperature at core outlet: 1,000°C
- Modular reactor with an output power of 300–600 MWth
- TRISO particle fuel
- Graphite core (prismatic or pebble bed)
- Hydrogen coproduction
- Attractive safety characteristics

The NGNP should produce electricity at an attractive cost. Its temperature of 1,000°C should allow for an efficiency of 50%.

Technologies suitable for operating at such temperatures will need to be developed based on the knowledge acquired in previous HTR projects. The core temperature increase of 150°C (under otherwise identical conditions) requires the confinement of fission products within multilayer particles. Metallurgists consider that the exposure of internal components and circuits to temperatures exceeding 950°C imposes a radical change in the choice of materials. Further research on energy conversion systems coupled to a direct helium cycle turbomachine will also be necessary.

Hydrogen production demonstrations will concern two processes. A high-temperature thermochemical cycle capable of directly using the heat produced will be tested using the iodine-sulfur cycle as the reference. It will be coupled to a production loop drawing 50 MWth from the NGNP. The resulting production will amount to approximately 500 kg/h of hydrogen, the equivalent of 40,000 l of gasoline per day. The second demonstration, to be conducted in parallel, will concern hydrogen production by high-temperature electrolysis with an equivalent

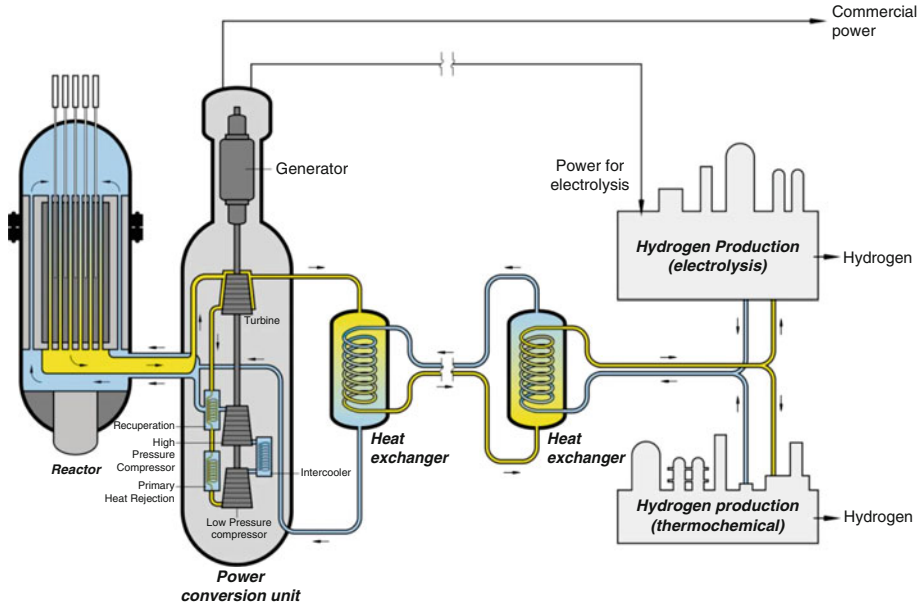

Figure 22

Basic diagram of the next generation nuclear plant (NGNP)

output power (i.e., 5 MWth and 20 MWe). A basic diagram of the NGNP concept is shown in (Fig. 22).

The choice of core type (prismatic or pebble bed) will be postponed until after the preproject phase, thus allowing the various engineering teams involved to defend their positions. The GIF is organizing R&D activities on the VHTR in support of this project.

To be in a position to answer a potential DOE bid, AREVA has developed the Antares conceptual design of a VHTR cogeneration demonstrator (Fig. 23). Leaving out the direct cycle helium turbine of the GT-MHR, judged still to be a technological uncertainty, the Antares reactor is coupled to the applications through an Intermediate gas-to-gas heat exchanger IHX. The high temperature calories can be used either to produce hydrogen or to generate electricity in a gas turbine (using an air-like mix of helium and nitrogen) and a bottoming conventional steam cycle generate additional electricity, like in a combined cycle gas turbine.

6.2 GFR

The Generation IV GFR project addresses a twofold challenge: combining high thermodynamic efficiency through high temperatures, and high neutronic efficiency (with significant economization of resources in the case of the uranium-plutonium cycle) through fast spectrum conditions. It has therefore been referred to as a “high-efficiency reactor,” constituting the second wave of modern GCRs (beyond HTRs).

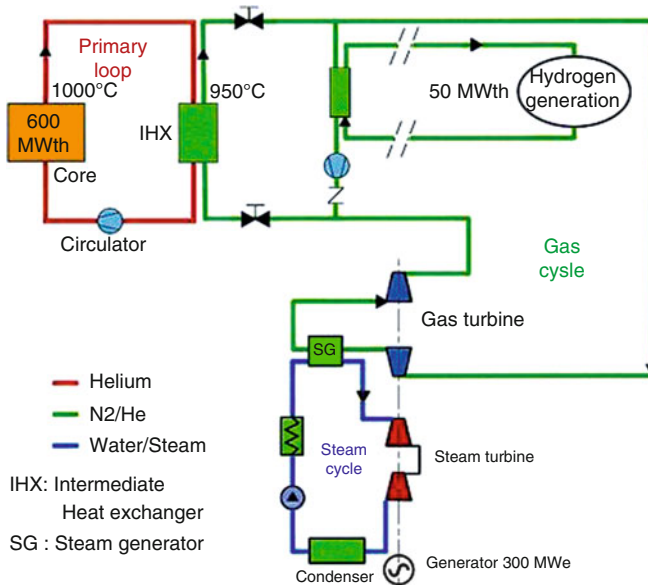

Figure 23
ANTARES flow chart (from AREVA)

The specific advantages of the GFR are the following: knowledge and operating experience acquired with GCRs, twofold concept allowing the nuclearization of high-performance modern technologies developed outside the nuclear field, and progressive transition via the HTR-type thermal GCR fleet that will precede it.

To address the twofold challenge of fast spectrum and high temperature conditions, the GFR possesses advantages inherited from modern HTR concepts, i.e., combination of a chemically inert coolant (helium) transparent to neutrons (no capture, little diffusion, no activation, even at pressures of several tens of bar) with a refractory and mechanically robust core using “cold” fuel and locally confining FPs at high temperatures.

This combination makes it possible to benefit from the decoupling of neutronics and thermal hydraulics, and thermomechanics and chemistry. The design of nuclear reactors is determined by the analysis of failure modes associated with couplings of neutronics, thermal hydraulics, material mechanics, and chemistry. The benefits of said decouplings, associated with a more efficient fuel, manifest themselves under both normal and accident operating conditions.

The helium flow path in the core can be modified beyond a minimum core volume without significant disturbance of spectrum, capture, and leak conditions. Together with the possibility of significant increases in core temperature, this property allows for reducing the pumping power under normal operating conditions and favors gas convection in decay heat evacuation situations.

The practical exclusion of recriticality accidents through the insertion of reactivity exceeding the delayed neutron fraction constitutes a significant advantage for the design of a fast neutron reactor concept subject to increased core sensitivity (namely due to the loading

dominated by plutonium, which reduces the delayed neutron fraction β_{eff} , and also due to the short lifetimes of prompt neutrons under fast spectrum conditions, i.e., approximately one microsecond). The increase in reactivity due to depressurization can be limited by design to a value less than β_{eff} .

The use of a chemically inert coolant makes it possible to benefit from the refractory and mechanical robustness qualities of the core. In severe accident situations, an additional margin of a few 100° is guaranteed beyond the fission gas containment limit (i.e., before extended core degradation leading to a loss of geometry inhibiting core cooling in the long term, or to a core collapse possibly resulting in a significant release of energy due to recriticality).

Helium is not activated under neutron flux. It is chemically inert and, if pure, does not contribute to structural corrosion or activation. This advantage has been confirmed in HTRs. Combined with the HTR fuel containment quality, it has led to very satisfactory operating experience in terms of doses. It is particularly advantageous in the hypothesis of reactors operating on a direct cycle with gas turbines.

It is therefore possible to benefit from the remarkable increases in efficiency and competitiveness achieved by fossil fuel plants over the past decades with conventional industrial coolants (gas and steam or supercritical water). This is particularly clear in the case of gas turbines.

The GFR system combines high thermodynamic and neutronic efficiency. It is a modern and competitive technology capable of following up on progress with fossil thermal systems (particularly as regards coal, a potential competitor in the long term). It guarantees a sustainable development of nuclear energy by maximizing the use of uranium resources through industrially optimized plutonium recycling.

6.2.1 Specific Problems Associated with the GFR

These problems are due to the above-mentioned twofold objective (high temperatures and fast spectra) and mainly concern the following: fuel and structural materials under flux, economic fuel reprocessing and fabrication, and evacuation of residual power under loss-of-pressure accident conditions. They can be overcome through a combination of technological innovation and optimized reactor design.

A steel-clad pellet-type fuel with large volumes of fission gas expansion outside the core, such as that developed for SFRs, can be adapted for a GFR core. However, it does not provide the second set of properties sought, characteristic of micro-confining, refractory (cold), and mechanically robust fuels such as the graphite matrix particle fuels tested up to very high burn-up fractions under thermal spectrum conditions in HTRs. Due to the damage associated with fast spectrum irradiation, and given the power density sought, these fuels are not usable as such in a GFR system.

In addition, imposing fission gas retention within the core volume leads to a diluted core and makes it more difficult to obtain a hard spectrum. Adapting such concepts, modifying the materials and ensuring competitive fuel reprocessing and fabrication is therefore one of the greatest challenges for the GFR. The same applies to the core structures and, more generally, the flux-exposed structures.

The need to evacuate residual power under loss-of-pressure accident conditions with loss of nominal forced gas convection contributes to the design of the backup systems. The combination of high specific power (aimed at minimizing the plutonium inventory required for a

given power output) and high concentration of fissile nuclei (aimed at hardening the spectrum) imposes a power density of between 50 and 100 MWth/m³. Correlatively, the thermal inertia of the core and structures (thermally coupled) is reduced as compared to HTR systems. As a result, the GFR cannot copy the solution implemented in HTR systems, which is primarily based on thermal inertia. It is necessary to use gas convection, maintaining a backup pressure capable of ensuring minimum thermal efficiency for the coolant.

In a high-power core, with moderate power density compared to that of conventional water-cooled reactors, increasing the core fraction reserved for the coolant has little impact on spectrum hardness and reactivity. We can therefore consider a “porous” core with low hydraulic resistance but still mechanically robust. Satisfactory gas convection for residual power evacuation as per admissible core outlet temperatures can be ensured for a core power of approximately one electric gigawatt through the use of backup systems pumping requiring approximately 100 kW, assisted by natural convection capable of taking over after a few hours.

6.2.2 The Advantages of the GFR System Have Two Main Origins

Firstly, the genealogy and operating experience of the series are very significant. In addition to the AGR, this particularly includes the AVR (pebble-bed HTR), which operated for approximately 20 years and sustainably achieved core outlet temperatures of 950°C. It also includes the reactors of the NERVA nuclear space propulsion program, which achieved exceptional performance in terms of hydrogen outlet temperature (2,500°C) and power density (4,000 MW/m³) due to the absence of industrial constraints regarding cost, lifetime, and safety. The most powerful reactor of the series had a total power output of 4.3 GWth, close to that of the EPR (and the largest ever built in the USA).

Secondly, significant scientific and technological progress has been achieved regarding high temperature and fluence materials, and also high-temperature mechanics. In addition, at the system level, the benefits of the twofold concept enable the exploitation of high-temperature technologies, particularly for gas turbines.

The GFR is still mostly a “paper-design,” which cannot be fairly compared to the Sodium-cooled SFR for instance. The fuel remains to be designed, even though some preliminary tests were carried out in the Phénix reactor during its very last years of operation. It is notably impossible to venture any comment about its future economics.

Its prospects will depend upon the magnitude of the so-called “Renaissance” expected to take place soon in nuclear power development, because this magnitude shall, through the fear of uranium scarcity, determine the timing of deployment of generation IV fast breeders. If this deployment starts around 2040, it will be too early for the GFR to have passed through the steps of demo plant and prototype and be ready for commercialization. If the renaissance is slower, then, maybe, the intrinsic qualities of the GFR will open opportunities for its deployment.

7 Conclusion

As we have seen, gas cooling was extensively used in the early days of nuclear power. For reasons completely independent of their technical characteristics, HTRs missed their commercial introduction in the late 1970s and are still today considered as “promising” designs. It is the

personal opinion of the author that as pure electricity producers they will not compete economically with LWRs, the dominant species in the nuclear “biotope.” Their future may be as co-generators of electricity and process heat, notably to produce hydrogen as feedstock for synthetic liquid fuels, which would provide the opportunity for nuclear power to enter significantly the transportation sector. They might, later on, share this “niche” with GFRs.

Abstract: The lead-cooled fast reactor (LFR) has both a long history and a currency of innovation. With early work related to the mission of submarine propulsion dating to the 1950s, Russian scientists pioneered the development of reactors cooled by heavy liquid metals (HLM). More recently, there has been substantial design interest in both critical and subcritical reactors cooled by lead (Pb) or lead–bismuth eutectic (LBE), not only in Russia, but also in Europe, Asia, and the USA. This chapter reviews the historical development of the LFR and provides detailed descriptions of the recent and current initiatives to design a variety of LFR concepts with several different missions in mind: accelerator-driven subcritical (ADS) systems for nuclear materials management, small modular systems for deployment in remote locations, and central station plants for integration into developed power grids. It describes design criteria and system specifications; features particular to the LFR in terms of neutronics, coolant properties, and material compatibility issues; approaches taken to core and reactor design; and considerations related to the balance of plant and plant layout.

1 Lead-Cooled Fast Reactor (LFR) Development

The idea of developing fast spectrum reactors with molten lead (or lead alloy) as a coolant is not a new one. Although initially considered in the West, in the 1950s, such technology was not pursued to completion because of the anticipated difficulties associated with the corrosive nature of these coolant materials. However, in the Soviet Union, such technology was actively pursued during the same time frame (1950s through the 1980s) for the specialized role of submarine propulsion. More recently, there has been a renewal of interest in the West for such technology, for critical as well as for accelerator-driven subcritical (ADS) systems. Meanwhile, interest in the former Soviet Union, primarily Russia, has remained strong and has expanded well beyond the original limited mission of submarine propulsion. This section reviews the past and current status of LFR development.

1.1 Lead–Bismuth Eutectic (LBE) for Submarine Propulsion

Heavy liquid metals (HLM) such as lead (Pb) or lead–bismuth eutectic (LBE) were proposed and investigated as coolants for fast reactors as early as the 1950s (e.g., in the USA). In most cases, with breeding a primary driver, sodium became the preferred choice in the 1960s, due to the higher power density achievable with this coolant, which resulted in lower doubling times, an important objective at that time. However, major contributions in the development of lead technology were carried out by Soviet (and then Russian) scientists and industries who have actively pursued lead-cooled reactor technology for more than 50 years (Gromov 1998).

In the early 1950s in the Soviet Union, research and design of the use of lead–bismuth alloy as the coolant for nuclear reactors was initiated by academician A. I. Leipunsky at the Institute of Physics and Power Engineering (IPPE) in Obninsk. The principal objective of these efforts was the design and construction of nuclear reactors for submarine propulsion.

The first of these systems, a 70 MWth 27/VT land prototype reactor, achieved criticality and started full power operation at IPPE in 1959. In 1963, the first nuclear submarine with an HLM-cooled reactor was put into operation. It was designated “Project 645, Submarine K-27, NATO designation November class K-27 variant” and utilized two 73 MWth reactors. Beginning in 1971, two new series of nuclear powered submarines termed “Projects 705 and 705K, NATO

designation Alfa class” were put into operation. Both of these series utilized a single 155 MWth reactor. The distinction between the two was based on their steam supply systems, one type of which was designed by the Experimental Design Bureau of Machine Building (OKBM), and the second was designed by the Experimental Design Bureau “Gidropress” (OKB Gidropress). In total, seven nuclear submarines of the Project 705/705K type were constructed following the original single submarine of the “Project 645” type. In addition, a second land-based prototype designated the KM-1 and mainly supporting Project 705K was put into operation at the A. P. Aleksandrov Scientific Technical Research Institute (NITI) in Sosnovy Bor in 1978.

An extensive research and development program focusing on HLM coolant technology and materials was carried out with emphasis on the chemical control of the liquid metal to avoid the possibility of plugging due to the formation of slag and to enhance corrosion resistance of internal components made from steels specifically developed for such service.

1.2 The Russian Design for Civilian Fast Reactors Cooled by HLM

In the 1990s, there was a renewal of interest in Russia concerning lead and LBE as coolants for civilian fast reactors. The lead-cooled BREST (the Russian acronym for Pb-cooled fast reactor) (Perera 2003) concept, developed in the early 1990s, is the most widely known; in addition, the Russians have placed considerable effort in the development of the LBE-cooled SVBR (the Russian acronym for lead–bismuth fast reactor) concept.

1.2.1 The BREST 300

BREST-300 is designed as a multipurpose reactor; it produces electric power, consumes and produces plutonium, produces radioisotopes for industry and medical applications, and transmutes long-lived fission products and actinides generated in reactor operations.

The main operating mode of this reactor system is base-load power production, although operation at reduced power levels is also anticipated.

It has a semi-integrated, multi-compartment metallic vessel (with characteristics of both pool- and loop-type cooling systems). The vessel, 19 m in height, has a diameter of 5.5 m at the bottom and 11.5 m at the top. The wide upper part of the reactor vessel is separated from its narrow central part by a barrel that forms an annular chamber, outside the central part of the vessel. In this semi-integral arrangement, the steam generator (SG) and the main circulating pumps are placed in the annular chamber, outside the central part of the vessel.

The core is loaded with wrapper-less fuel assemblies of square cross section. The fuel assembly lattice has 121 square cells of which 114 are taken up by fuel rods and 7 by guide tubes. The height of the fuel pellet column in the core is 1.1 m and the cover gas plenum is 0.9 m high. The content of plutonium and minor actinides (MA) is 13 wt%.

The fuel cladding consists of a thin-walled tube of 12% chromium–ferritic–martensitic steel. It has high corrosion resistance to lead, limited swelling, and satisfactory temperature dependence of strength and creep.

The outer diameters of the tubes to be used as cladding in the central, middle, and peripheral regions of the core are 9.1, 9.6, and 10.4 mm, respectively.

1.2.2 The SVBR-75

The SVBR-75 was designed as a modular compact unit to be installed in the SG compartments of shutdown VVER-440-type reactors.

The main characteristics are as follows (Toshinsky et al. 2002):

- Pool-type reactor
- Two-loop system for decay heat removal (DHR) using natural circulation
- Guard vessel
- Fuel subassemblies without wrapper
- SG with saturated steam generation
- Low-speed gas-tight motor of less than 500 kW power for main circulating pumps
- The ability to repair and/or replace all internal components of the reactor
- Subassembly by subassembly refueling of the whole core at a time
- Multi-fuel capability (UO₂, MOX with MA, nitrides fuels) with the same reactor design

The main plant parameters are as follows:

Thermal power (nominal), MW	280
Steam capacity, t/h	580
Steam pressure (saturated), MPa	9.5
Feedwater temperature, °C	240.9
Primary coolant flow rate, kg/s	11,760
Primary coolant temperature, inlet/outlet, °C	320/482
Core dimensions: diameter/height, m	1.645/0.9
Number of fuel pins	12,114
Number of control rods	37
Mean power density in the core, MW/m ³	140
Mean linear load of the fuel element, kW/m	24.3
Refueling interval, year	8
Core charge, (UO ₂) with uranium: mass, kg/enrichment, %	9,144/16.1
Number of main circulating pumps	2
Lead–bismuth coolant volume in the reactor, m ³	18
Reactor outline dimensions: diameter/height, m	4.55/7.55

1.3 HLM-Cooled ADS Systems

The features and the associated technologies of HLM coolants inspired several projects in the emerging field of ADS, and in particular lead and LBE have been considered as both coolants and neutron spallation targets for several such energy amplification projects under development in the USA, Europe, Japan, and the Republic of Korea since the mid-1990s.

At the Korea Atomic Energy Research Institute (KAERI) and Seoul National University (SNU) in the Republic of Korea, ADS systems have been developed since 1997 in order to explore proliferation-resistant and safe transmutation technology. One such ADS named Hybrid Power Extraction Reactor (HYPER) is intended primarily for transmutation of long-lived nuclear wastes. HYPER uses LBE as both coolant and spallation target.

In Japan, at the Japan Atomic Energy Research Institute (JAERI), an ADS with the thermal power of 800 MW has been designed, where 250 kg of MA and some long-lived fission products

(LLFP) can be transmuted annually. R&D has been conducted on ADS using LBE as a spallation target and coolant.

At SCK_CEN, Belgium, since 1997, studies in the field of LBE technology have been carried out for the Multi-purpose Hybrid Research Reactor for High-tech Applications (MYRRHA) project, aimed at the development of a research subcritical reactor driven by an accelerator, where LBE is used as spallation target and coolant.

The MYRRHA design has merged since 2005 with the European project IP-EUROTRANS, which includes also the detailed design of the associated linear proton accelerator and a generic conceptual design of the European Facility for Industrial Transmutation (EFIT), in which pure lead is used as the core coolant and spallation material. EFIT is loaded with U-free transmutation-dedicated fuel.

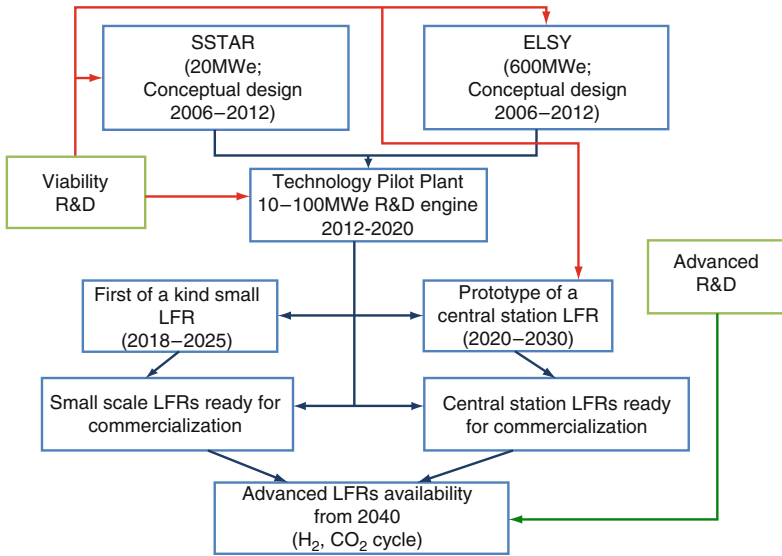

1.4 The LFR in Generation IV

The Generation IV (GEN IV) Technology Roadmap (U.S. DOE Nuclear Energy Research Advisory Committee and the Generation IV International Forum 2002), prepared by Generation IV International Forum (GIF) member countries, in 2002 identified the six most promising advanced reactor systems and related fuel cycles, and the R&D necessary to develop these concepts for potential deployment. Among the promising reactor technologies being considered by the GIF, the LFR has been recognized as a technology with great potential to meet the needs for both remote sites and central power stations.

In the GEN IV technology evaluations, the LFR system was top-ranked in sustainability because it uses a closed fuel cycle, and top-ranked in proliferation resistance and physical protection because it employs a long-life core. It was rated good in safety and economics. Safety was considered to be enhanced by the choice of a relatively inert coolant. The LFR was primarily envisioned for missions in electricity and hydrogen production and actinide management. Given its R&D needs for fuel, materials, and corrosion control, the LFR system was forecast to be deployable by 2025. The LFR system features a fast-neutron spectrum and a closed fuel cycle for efficient conversion of fertile uranium. The LFR can also be used as a burner of all actinides from reprocessed LWR spent fuel and as a burner/breeder with thorium matrices.

In 2007, the GIF LFR Provisional System Steering Committee (PSSC), after the evaluation of current international initiatives in the field, prepared a draft System Research Plan (SRP) for the LFR with molten lead as the reference coolant and lead–bismuth as a backup option.  *Figure 1* illustrates the basic approach being recommended in the LFR SRP. It portrays the dual-track viability research program with convergence to a single, combined demonstration facility (demo, also called technology pilot plant – TPP) leading to the eventual deployment of both types of systems. The dual-track approach is based on the development of the small secure transportable autonomous reactor (SSTAR) and the European Lead-cooled System (ELSY) reactor projects that represent two potential applications of the LFR.

SSTAR, whose development is performed under the US Department of Energy Generation IV Nuclear Energy Systems Initiative, is a small natural circulation fast reactor of 20 MWe/45 MWth that can be scaled up to 180 MWe/400 MWth. The key technical aspects of SSTAR are the use of lead as the coolant and a long-life sealed core in a small, modular system. The compact active core operates for a very long time (15–30 years) without refueling, and the fuel is either retained in the reactor vessel for recycle or removed as a single cassette during refueling and replaced by a fresh core.

■ Figure 1
LFR GIF-SRF conceptual framework

ELSY, whose development started in 2006 with the support of the Framework Program 6 (FP6) of Euratom, aims at demonstrating the design of a competitive and safe fast critical reactor using simple engineered technical features. The use of compact in-vessel SGs and of a simple primary circuit, with possibly all internals being removable, is among the reactor features for competitive electric-energy generation and long-term investment protection.

Besides Russia, the USA, and Europe, LFR studies are also being performed in Japan and Korea.

In Japan, the relevant activities are associated with each of the key research organizations including the Japan Atomic Energy Agency (JAEA), the Central Research Institute of the Electric Power Industry (CRIEPI), and the Tokyo Institute of Technology.

At JAEA, an LBE-cooled fast reactor design and the related fundamental corrosion experiments were carried out within the framework of the “Feasibility Study on Commercialized Fast Reactor Cycle Systems” from 1999 to 2005. Experimental studies to solve the corrosion problem have been carried out since 2001. At the early stage of this study, the maximum cladding temperature was set to 650 °C, and then changed to 570 °C based on the results of experimental studies. As a result, the core inlet and outlet coolant temperatures are 285 °C and 445 °C, respectively. The specific gravity of LBE is 12 times that of sodium. This property affects structural integrity, a particular concern for the very high seismicity in Japan. According to the feasibility study, it is estimated that the LFR plant size in Japan would be limited to less than medium-scale size of around 750 MWe, even with the adoption of 3D seismic isolation.

At CRIEPI, consideration has been given to the possibility of an LBE-cooled fast reactor as a candidate for the next generation of nuclear reactors. The interest at CRIEPI was the result of its efforts to use LBE as an intermediate coolant for a sodium-cooled fast breeder reactor. In this concept, an innovative steam generator (SG) was envisioned in which heat was transferred by direct contact between LBE and water within the intermediate loop. While an LBE-cooled

reactor based on this technology has not yet been designed, CRIEPI believes that this approach could represent a workable research direction

To evaluate the heat-transfer performance of LBE in the intermediate loop and the two-phase flow characteristics of LBE, water, and steam, the “CRIEPI Pb–Bi Test Loop on Thermal Hydraulics” was constructed in 1997. The results of the heat-transfer performance around SG tubes and the performance of gas lift pumps for LBE were tested in the loop and presented in Nishi et al. (2003).

To clarify the corrosion characteristics of LBE, the “CRIEPI Static Corrosion Test Facility” was constructed in 2001. The objective of this facility was to understand the corrosion behavior of stagnant LBE at 650 °C on high chromium martensitic stainless steel, a promising-candidate structural material for LFRs. A series of corrosion tests were performed jointly by CRIEPI and JAEA (Aoto et al. 2003).

To explore the advantages and disadvantages of lead as a coolant, an LBE-cooled 4S (the super safe, small, and simple reactor, normally a sodium-cooled system) was designed and studied by CRIEPI and TOSHIBA.

The Tokyo Institute of Technology proposed a small long-life fast reactor cooled by LBE and presented a preliminary design in 1991. Since then, the importance of the Tokyo Tech's study has become gradually widely recognized, and, as a result, programs were supported to promote LFRs in the following areas:

- Polonium (Po) behavior, treatment, cross-section measurements (FY 1998–2000)
- Corrosion (materials test, oxygen control) (FY 1999–2001)
- CANDLE burn-up (FY 2001–2003)
- Steam lift pump reactor designs and basic research (FY 2002–2004)

The Pb–Bi-cooled direct-contact boiling water fast reactor (PBWFR), the steam lift pump-type LFR (SLPLFR), and the constant axial neutron during the life of energy (CANDLE) reactor are the main recent activities in the area of reactor design.

In the PBWFR, direct contact boiling provides significantly higher heat transfer. The PBWFR electric power is 150 MW. The design limit of the cladding temperature is 650 °C. The LBE core outlet temperature is 460 °C. The LBE temperature rise across the core is 150 °C. The conditions of the secondary coolant steam are the same as those of conventional BWRs. The PBWFR plant is equipped with a reactor vessel air cooling system (RVACS) a primary reactor auxiliary cooling system (PRACS), and an auxiliary water supply tank to cope with the loss of feedwater. Hydrogen is dissolved in the feedwater at a concentration of 100–500 ppb to keep the oxygen concentration in the LBE coolant around 10^{-5} wt%.

The SLPLFR reactor concept has SGs in the reactor vessel, and subcooled water is injected into LBE above the core at a low flow rate. The resulting steam condenses in a dedicated heat exchanger, which serves also as the re-heater of the feedwater. In comparison with the PBWFR, the SLPLFR is expected to have a higher thermal efficiency with higher LBE temperature, lower pressure in the primary loop, and no Po or LBE droplet contamination in the turbines.

For the CANDLE reactor, the neutron flux shape and the nuclide and power density distributions remain constant but progresses in an axial direction during the core lifetime. The solid fuel is fixed at each position, and no movable reactivity control mechanisms are required. The change of excess reactivity during burn-up is theoretically zero for ideal equilibrium conditions. The core characteristics, such as power feedback coefficients and power peaking factors, do not change over the operational life. Since the k -infinity of replacement fuel is less than unity, the transport and storage of such fuels is easy and safe. Application of this burn-up strategy to

LFRs with metallic or nitride fuels enables the following excellent characteristics: initial fissile material is required only for the nuclear ignition region of the initial core, and only natural or depleted uranium is required for the remaining region of the initial core and for succeeding cores. The average burn-up of the spent fuel is about 40%; that is equivalent to 40% utilization of the natural uranium without reprocessing or enrichment.

The Korean LFR Program has two main objectives:

- A technology development requirement for nuclear waste transmutation
- A new electricity generation unit development requirement to match the needs of developing nations and especially remote communities without major electrical grid connections

To meet the first goal, the proliferation-resistant environment-friendly accident-tolerant continuable-energy economical reactor (PEACER) development was initiated with the objective of developing a system to transmute long-lived fission products in the spent nuclear fuel into short-lived low-intermediate-level waste.

For the second goal, Korea initiated the development of the Battery-Optimized Reactor Integral System (BORIS) that is an integral-type optimized fast reactor with an ultra-long-life core coupled with a supercritical CO₂ Brayton cycle power conversion system.

PEACER is a Pb–Bi-cooled fast reactor being developed at the Seoul National University, designed for power production and waste transmutation. PEACER incorporates a pancake-type core with a U–Pu–Zr metallic fuel with a high thermal conductivity in square lattice cooled by forced circulation by a main coolant pump (MCP), and the Rankine cycle for power generation. As with other Pb–Bi-cooled fast reactor concepts, the operating coolant temperature is low, spanning from 300 °C to ~ 400 °C to achieve corrosion-resistant conditions and a longer reactor lifetime.

PEACER provides two reactor designs of different capacity. PEACER-550 has a 1,560 MWth core, following the basic integral fast reactor design. PEACER-300 is designed to produce 850 MWth. There is no intermediate heat transport system. The steam at the turbine inlet is superheated to 633.15 K and 8 MPa. The thermal efficiency is estimated to be 35.3%.

PEACER is equipped with an active reactivity control and shutdown system (motor-driven) and a passive reactor shutdown system (gravity-driven). The active reactivity control and shutdown system consists of 28 control assemblies that are used for power control, burn-up compensation, and reactor shutdown.

BORIS is being developed as a multipurpose integral optimized fast reactor with an ultra-long-life core at the Seoul National University. BORIS aims at satisfying various energy demands, maintain inherent safety using the Pb coolant, and improved plant economics. BORIS is being designed to generate 22.2 MWth with 10 MWe for at least 20 consecutive years without refueling and to meet the Generation IV nuclear energy system goals of sustainability, safety, reliability, and economics. BORIS is conceptualized to be used as the main power and heat source for remote islands and barren lands, and also considered to be deployed for desalinization purpose. BORIS consists of modular components to enable rapid construction and easy maintenance, and incorporates an integrated heat exchanger system operated by natural circulation of Pb without pumps to realize a compact reactor.

1.5 The LFR and ADS Designs Considered in the Handbook

The renewed interest in lead technology for critical fast reactors and ADS systems has resulted in the initiation of several projects, all at preliminary stage, most of them having been briefly

described above. Their level of development, and their characteristics and objectives are in general very different and their prospects for full-scale development are uncertain at the moment of the issuance of this handbook.

In the following discussion, details will be discussed for four systems that are more developed or present a better characterization of the potential of lead coolant technology for critical and subcritical systems.

The four systems selected for further discussion are SSTAR, ELSY, MYRRHA, and EFIT.

1.5.1 SSTAR

The US LFR Program is focused on the development of a small transportable reactor system known as the SSTAR with the following objectives (Sienicki et al. 2007a):

- Sealed core with no on-site refueling or whole-core cassette refueling.
- Transportability: the entire core and reactor vessel are delivered by ship or overland transport.
- Long-life core: 15–30-year core life is the target.
- Autonomous load followed by simple integrated controls: minimum operator intervention or maintenance required.
- Local and remote observability: rapid detection/response to perturbations.
- Minimum industrial infrastructure required in host location.
- Very small operational (and security) footprint.

In furtherance of the above objectives, current system development activities are being directed toward a pre-conceptual design and viability assessment for a SSTAR 20 MWe (45 MWth) natural circulation LFR for international deployment consistent with overall programmatic goals.

In addition, following the development of initial pre-conceptual designs, the LFR program was realigned to focus upon a concept for a near-term technology pilot plant to demonstrate successful reactor operation with a lead coolant at realistic system temperatures and incorporating innovative engineering that will help show the economic benefits and industrial attractiveness of Pb as a primary coolant.

A sketch of the current reference concept for the SSTAR small, modular, fast reactor is shown in  Fig. 2 (Sienicki et al. 2007b). This pre-conceptual design is a small shippable reactor (12 × 3.2 m vessel), with a 30-year open-lattice cassette core and large-diameter (2.5 cm) fuel pins held by spacer grids welded to control rod guide tubes. The design integrates three major features: primary cooling by natural circulation heat transport; lead as the coolant; and transuranic nitride fuel in a pool vessel configuration. The main mission of the 20 MWe (45 MWth) SSTAR is to provide incremental energy generation to match the needs of developing nations and remote communities without electrical grid connections, such as those that exist in Alaska or Hawaii, island nations of the Pacific Basin, and elsewhere. This may be a niche market within which costs that are higher than those for large-scale nuclear power plants can still be considered competitive. The design features of the reference SSTAR, in addition to the lead coolant, 30-year cassette core, and natural circulation cooling, include autonomous load following without control rod motion, and the use of a supercritical CO₂ (S-CO₂) Brayton cycle energy conversion system. The incorporation of inherent thermo-structural feedbacks imparts walk-away passive safety, while the long-life cartridge core life imparts strong proliferation resistance. If these technical

Small Secure Transportable Autonomous Reactor (SSTAR)

■ Figure 2
Conceptual 20 MWe (45 MWth) SSTAR system

innovations can be realized, the LFR will provide a unique and attractive nuclear energy system that meets Generation IV goals.

Some of the key design parameters of SSTAR are summarized in [Table 1](#).

The research priorities of the SSTAR program are organized to address system design and evaluation, fuel cycle, energy conversion, and material issues.

The R&D efforts required to advance the SSTAR concept are intended to address viability issues associated with the small transportable LFR and activities leading to the design and construction of a demo or pilot LFR plant. Viability will be established through focused R&D tasks in the areas outlined below and guided by formulation of a technically defensible pre-conceptual design:

- **System design and evaluation.** R&D tasks for system design and evaluation address the areas of core neutronics, system thermal hydraulics, mechanical design, passive safety evaluation, containment and building structures, in-service inspection (ISI), and assessing cost impacts. Core design is essential to establishing the necessary features of a 15–30-year life core and determining core parameters that impact feedback coefficients. R&D tasks associated with this work include further optimization of the core configuration, establishing a start-up/shutdown rod and control rod strategy, and calculating reactivity feedback coefficients.

■ **Table 1**
Key parameters of SSTAR

Power (MWe)	19.8
Conversion ratio	~ 1
Thermal efficiency (%)	44
Primary coolant	Lead
Primary coolant circulation (at power)	Natural
Primary coolant circulation for DHR	Natural
Core inlet temperature (°C)	420
Core outlet temperature (°C)	567
Fuel	Nitride
Fuel cladding material	Si-enhanced F/M stainless steel
Peak cladding temperature (°C)	650
Fuel-pin diameter (mm)	25
Active core height/diameter (m)	0.976/1.22
Primary pumps	None
Working fluid	Supercritical CO ₂ at 20 MPa, 552 °C
Primary/secondary heat-transfer system	N °4 Pb-to-CO ₂ HXs
Safety grade DHR	Reactor vessel air cooling system + multiple direct reactor cooling systems

- **Fuel and fuel cycle.** Viability of both nitride fuel and whole-core cassette refueling is to be addressed in the fuel and fuel-cycle R&D.
- **Energy conversion.** Use of an S-CO₂ Brayton cycle for energy conversion offers the prospect of higher thermal efficiencies with lower Pb coolant outlet temperatures and small turbo-machinery reducing the footprint and cost of the power converter.
- **Materials.** Viability of long core lifetime, passive safety, and economic performance (both capital and operating costs) of the LFR concept will depend on identifying materials with the potential to meet service requirements.

1.5.2 ELSY

ELSY – the European Lead-cooled System – is a pool-type lead-cooled 600 MWe fast reactor, developed since September 2006, within the Sixth EURATOM Framework Programme (FP6).

ELSY aims at demonstrating the possibility of designing a fast reactor using simple engineered technical features, while fully complying with the Generation IV goals of sustainability, economics, safety, proliferation resistance, and physical protection (Cinotti et al. 2006, 2007a, b; GEN IV International Forum 2008).

■ **Figure 3**
ELSY primary system arrangement and coolant flow path

ELSY is an innovative project intended to globally address several of the most important technical challenges related to the use of lead technology in general, issues that have for the most part been only partially addressed in previous projects, namely:

- How to extend the LBE experience, with LBE to pure lead as a coolant?
- How to mitigate the seismic issue?
- How to design a highly compact primary system?
- How to avoid in-vessel storage of spent fuel?
- How to cool high power spent fuel elements during refueling?
- How to design a compact SG?
- How to avoid the risk of catastrophic primary system pressurization associated with water or steam collector failure?
- How to mitigate the effect of a steam generator tube rupture (SGTR)?
- How to make the reactor internals removable?
- How to handle fuel elements while maintaining a temperature of 400 °C in lead?
- How to support the fuel elements in lead?
- How to design a simple and reliable safety-related DHR system?

The elimination of an intermediate cooling system and the development of a compact and simple primary circuit with all internal components removable are among the features needed to assure reduced capital cost and construction time, competitive electric-energy generation, and long-term investment protection.

The relatively small size of the reactor vessel results from advanced solutions adopted for the primary system that features a cylindrical inner vessel, primary pumps installed in the inner zone of innovative flat-spiral-tube SGs, and fuel elements substantially supported by buoyancy.

In addition, the heads of the fuel elements extend above the vessel fixed roof as they are provided with long stems to allow fuel handling from the above-reactor hall under full visibility.

In spite of the reduced coolant speed and of the moderate power density core, the innovative solutions adopted for ELSY allow reduced primary system dimensions (main vessel preliminary dimensions of 12.5 m diameter and 8.7 m height), which are similar to, or even smaller than, those of advanced pool-type SFRs (➤ [Fig. 3](#)).

Safety relies on the beneficial physical characteristics of lead, redundant and diverse DHR systems, and other innovative features, which make the primary system more tolerant to the effects of a SGTR accident.

➤ [Table 2](#) provides the preliminary parameters of ELSY.

■ **Table 2**

Main parameters of the ELSY plant

Power (MWe)	600
Thermal efficiency (%)	40
Primary coolant	Pure lead
Primary system	Pool type, compact
Primary coolant circulation	Forced, at power, natural circulation + Pony motors for DHR
Primary pressure loss (bar)	~ 1.5
Core inlet temperature (°C)	~ 400
Core outlet temperature (°C)	~ 480
Fuel	MOX with consideration also of nitrides and dispersed minor actinides
Fuel cladding material	T91 (aluminized)
Fuel cladding temperature (°C)	(max) ~550
Main vessel	Austenitic stainless steel, hung, short height ~9 m; diameter ~12.5 m
Safety vessel	Anchored to the reactor pit
Steam generators	N°8, integrated in the main vessel
Secondary cycle	Water-superheated steam at 180 bar, 450 °C
Primary pumps	No. 8 mechanical, integrated in the steam generators
Internals	Removable
Inner vessel	Cylindrical
Hot collector	Small volume, above the core
Cold collector	Annular, outside the inner vessel, free level higher than free level of hot collector
DHR coolers	No. 4, DRC loops + a reactor vessel air cooling system
Seismic design	2D isolators supporting the reactor building

1.5.3 MYRRHA

Following the conceptual design phase of an experimental ADS conducted during the Euratom Framework Programme 5 (FP5) project PDS-XADS (Maes 2006), a more advanced design for an Experimental Transmutation Accelerator Driven System, namely MYRRHA/XT-ADS, is being carried out within the FP6 integrated project (IP) known as EUROTRANS (Knebel et al. 2006) and is continued within the FP7 central design team (CDT) in the near-term period (i.e., through 2012). The major technological issues identified in this work are as follows:

- System and plant design
- Necessary dedicated R&D support issues
- Material qualification program
- Fuel qualification program
- High-intensity proton accelerator performances and reliability

■ Figure 4
MYRRHA/XT-ADS primary system arrangement

For the medium term (i.e., to 2020), the emphasis will be on the construction of MYRRHA/XT-ADS at Mol, Belgium. For the longer term, the development and qualification of innovative fuels (especially minor actinide-bearing inert fuels) with appropriate cladding and associated reprocessing techniques is a challenging task. Having these innovative fuels is mandatory to prove the technological feasibility of transmutation. Since the development of these innovative fuels will require a long time, research on this topic has already been started, but for the viability demonstration of ADS, it is of high importance to focus on current fuel qualification efforts of the driver fuel for fast spectrum systems (➤ Fig. 4).

1.5.4 EFIT

EFIT is the conceptual design of a European Facility for Industrial Transmutation (EFIT), with a pure lead-cooled subcritical reactor of about 400 MWth with the capability for minor actinide (MA) burning and electricity generation.

■ Figure 5
EFIT primary system arrangement

EFIT will be loaded with U-free fuel containing MA, namely (Pu,Am,Cm) O_{2-x} – MgO-type fuel.

The neutronic design has confirmed the potential of EFIT to be an effective burner of MA with a net balance of -40.17 kg of MA/TWh and nearly a zero Pu balance (-1.74 kg/TWh).

MA burning, in addition to electricity generation, is an important added value of EFIT in the economic balance. However, a fraction of the electric power is used to produce the 16 MW proton beam and the accelerator and spallation target represent a significant part of the capital cost. It should be noted that the primary system volume per unit power is at least twice that of a pool-type SFR or LFR. Additional studies are necessary to understand if this penalty in the primary system dimensions is an unavoidable consequence of a subcritical system, or can be reduced by optimization.

Based on the feedback from the operation of MYRRHA/XT-ADS and further progress on system design and fuel and material research, the construction of an EFIT can be envisaged as the final goal.

2 Design Criteria and General Specifications

The requirements for the design of the LFR stem from engineering knowledge enhanced by the experience gained and the lessons learned in the field of sodium-cooled fast reactors (e.g., SPX1), in the LBE technology for use in Russian submarines and in the technological limits acquired in the frame of several international experimental activities.

These requirements aim at achieving the main design missions of the LFR, which are the demonstration of its technical feasibility for electric-energy generation and the demonstration of its capability to comply with the Generation IV goals (especially the capability of consuming MA and of good economic performance).

Most requirements, such as the MA-burning capability, are thus not absolute, however, and may undergo adjustment for optimization in the course of future design activities. It will be noted that the physical and neutronic properties of lead cannot be fully exploited simultaneously from the very beginning of the LFR design, because of technological and time constraints. The potential of burning MA from reprocessed spent fuel of LWR implies deployment of special, novel-design cores, which require qualification and testing in existing reactor systems.

On a global basis, priority is given to the demonstration of the technical feasibility of the LFR within a relatively short time frame with confirmation of structural material properties with effective oxygen control and with features such as a mixed oxide (MOX) fuel core that is self-sustaining in Pu, while being adiabatic in terms of consumption of the self-generated MA. It is expected that development of the LFR to the more ambitious goals of high-temperature operation and burning capability beyond the self-generated MA will be pursued in the future and developed as appropriate depending on R&D and design achievements, and budget.

Compliance with the guidelines of Generation IV is an integral part of the LFR requirements. The tentative main design solutions are listed by the four Generation IV goal areas and the eight Generation IV goals in the following sections. These solutions are deemed to be sufficient as starting features for a successful demonstration of the feasibility of the LFR.

The main LFR features identified in order to achieve the Generation IV goals are discussed below and summarized in [▶ Table 3](#). These features are based either on the properties of lead as a coolant or on specifically engineered designs.

■ Table 3

LFR potential performance against the four goal areas and the eight goals for Generation IV

2.1 Sustainability

According to Generation IV, *sustainability* is the ability to meet the needs of the present generation while enhancing the ability of future generations to meet society's needs indefinitely into the future. Appropriate resource utilization and waste minimization and management are the two main aspects of the sustainability.

2.1.1 Resource Utilization

Because lead is a coolant with very low neutron absorption and energy moderation properties, it is possible to maintain a fast-neutron flux even with large amount of coolant in the core. This allows the efficient use of a variety of fuel materials, including fuels with homogeneously mixed MA. The reactor can be designed to achieve a conversion ratio of ~ 1 (without the need for a blanket), along with long core life and a high fuel burn-up. The preliminary results of the ELSY project indicate that a core with an active length of 0.9 m containing about 35 t of heavy metals (HM) is critical with 17.6 wt% Pu and has a breeding ratio of about 1. Obviously a core with the same fuel content with a longer active length or larger fuel-to-coolant ratio will result in a breeding core.

The greatest experience on the use of heavy coolant is related to LBE because of its use in Russian submarine reactors and because of the technological development for subcritical (ADS) reactors.

LBE is not considered, however, to be a sustainable coolant technology, because of the limited availability of bismuth. It is not proven that current bismuth resources will allow a large international deployment of central station reactors. Lead is much more abundant than bismuth and much less expensive, and can be considered to be always available, even in the case of deployment of a large number of LFRs.

2.1.2 Waste Minimization and Management

A fast-neutron flux significantly reduces waste generation, with Pu recycling in a closed cycle being the first condition recognized by Generation IV for waste minimization. The capability of the LFR systems to safely burn recycled MA within the fuel will add to the attractiveness of the LFR and meet another important Generation IV condition.

Preliminary results of the ELSY core indicate the possibility to reach an MA content at equilibrium of 310 kg, which corresponds to 0.9% of the fuel inventory.

Obviously loading the core with an MA content greater/lower than 310 kg will result in net MA burning/generating respectively.

2.2 Economics

According to GEN IV, the economic goals broadly consider competitive life cycle and energy production costs, reducing financial risks of nuclear energy systems. Additional use of nuclear

energy is also considered, like low-temperature heat for water desalination or district heating and high-temperature heat for hydrogen production.

The cost advantages of the LFR are expected to result from relatively low capital cost, short construction duration, and low fuel production cost.

The economic utilization of MOX fuel in a fast spectrum has been already successfully demonstrated in the case of the sodium fast reactor (SFR), and a similar conclusion can be expected for the LFR.

Because of the favorable characteristics of molten lead, it will be possible to significantly simplify the LFR systems, and hence to reduce its overnight capital cost, which is a major cost factor for the competitive generation of nuclear electrical energy.

A simple plant will be the basis for reduced capital and operating cost. A pool-type, low-pressure primary system configuration offers great potential for plant simplification.

The use of in-vessel energy conversion equipment and the consequent elimination of the need for an intermediate system is a key factor to provide competitive generation of electrical energy in the LFR. In the case of conventional steam cycle power conversion, this approach is possible because of the absence of fast chemical reactions between lead and water, although the SGTR accident (i.e., risk of important pressure waves inside the steam generator unit (SGU)) must be considered in the design.

In the case of small-size plants, such as SSTAR, the use of molten Pb to CO₂ heat exchangers with supercritical carbon dioxide Brayton cycle energy conversion system can also be envisaged.

2.2.1 Risk to Capital

The use of a new technology represents a potential risk for investors. Such risk must be overcome by innovative design features that bring about plant simplification and assurance of excellent economic performance.

Corrosion by molten lead of candidate structural steels for the primary system is a main issue in the design of an LFR. New materials are being sought for special components such as pump impellers. For near-term deployment, the use of classical materials for most of the reactor components will be made possible by limiting the core outlet temperature. In spite of this limitation, the overall system efficiency remains high because there will be no intermediate system to degrade the thermal cycle.

In-lead refueling and in-service inspection and repair (ISI& R) of the core support structures in lead are additional critical aspects of licensing and operation.

In the ELSY project, it is proposed to face these apparent drawbacks by reducing the number of components/machine operating in lead, in particular by eliminating the core support plate and the in-vessel fuel-transfer machine, which has, as yet, never been designed or tested in lead.

This is considered possible because the very low vapor pressure of molten lead should allow relaxation of the otherwise stringent requirements for gas-tightness of the reactor head and this allows the adoption of simpler solution.

In general, for small, transportable systems, a limitation to the risk to capital results from the small reactor size. With particular relevance to the central station system, a reduction in the risk to capital results from combining plant simplification with the design of removable/replaceable in-vessel components.

2.2.2 Other Use of Nuclear Heat

In a future expanded market of nuclear energy, it is expected that additional uses of nuclear energy will be sought. For example, low-temperature heat for water desalination or district heating can be readily envisioned. In this respect, an LFR can play a role similar to other nuclear power reactors and, in particular, it will favor modular applications. In the case of large hydrogen demand, LFR could provide electricity for hydrogen generation by water electrolysis. The high boiling temperature of lead is potentially exploitable for hydrogen generation by high-temperature chemical processes, but this possibility is conditioned to time-consuming development/use of new materials that are resistant to lead corrosion at higher temperatures.

2.3 Safety and Reliability

Pure lead as a coolant is chemically inert in comparison to sodium and, moreover, it is preferred to LBE in terms of safety because of its substantially lower radiological concern, especially ^{210}Po .

One of the advantages in the use of lead in a fast reactor is the fact that lead retains hazardous radionuclides like iodine and cesium, even in the event of a very severe accident involving the failure of the reactor vessel, failure of the reactor building, and exposure of the coolant to the atmosphere. This advantage is considerably reduced in the case of LBE because of the much higher production of the radiotoxic ^{210}Po . The polonium production in an LBE-cooled reactor is so high that in the 80 MW LBE-cooled ADS developed in the Fifth Framework Programme of Euratom the polonium inventory was evaluated to be 2 kg at equilibrium. This amount of Po produces a decay heat in the primary system that equals the fuel-decay power, after 5 days of cooling.

Pure lead is not exempt from polonium formation. In pure lead, ^{209}Bi is produced from ^{208}Pb , and ^{210}Po results from the further activation of ^{209}Bi ; however, the rate of Po production is less by about four orders of magnitude than in case of LBE, and its decay power is negligible in comparison to that of the fuel.

The slightly higher density (4%) of lead in comparison to LBE has a marginal negative impact on the mechanical design, but the fact that the lead density is higher than that of an oxide fuel is beneficial in the event of an hypothetical severe accident, because the high density can further reduce the risk of re-criticality following a core melt.

In-vessel fuel handling is facilitated by the use of LBE that allows operation at lower temperatures, but the ex-vessel fuel and component handling is facilitated by pure lead because of the reduced polonium inventory.

In general, pure lead's characteristics facilitate the fulfillment of Generation IV objectives.

2.3.1 Operation Will Excel in Safety and Reliability

Safety is based both on the properties of lead as well as on the engineered solutions mentioned in the specific projects to meet the safety objectives. Molten lead has the advantage of allowing operation of the primary system at low (atmospheric) pressure. A low dose to the operators can also be predicted, owing to its low vapor pressure, high capability of trapping fission products, and high shielding of gamma radiation. In the case of accidental air ingress, in particular

during refueling, any produced lead oxide can be reduced to lead by injection of hydrogen gas, and the reactor operation safely resumed. Any leaked lead would solidify without significant chemical reaction affecting the operation or performance of surrounding equipments or structures.

Due to the low moderating capability of lead, it is possible to have relatively large spacing among the fuel rods with low pressure losses in spite of the high density of lead. In ELSY and EFIT, the specified moderate core ΔT between the inlet and outlet temperatures not only minimizes the potential for material corrosion, but also the thermal stress during transients, and the relatively low core outlet temperature minimizes the creep in steels.

In ELSY, an innovative reactor layout such as primary pumps installed in the hot collector has been developed, which, besides the economic advantages, improves several safety-related aspects, such as the following:

- Moderate volume of hot collector and large volume of cold collector.
- DHR coolers immersed in the cold collector. This favors natural circulation and eliminates the interference between hot coolant streaming from the core and cold coolant from the outlet of the DHR coolers.
- Free level of the cold collector, in normal operation, higher than the free level of the hot collector. This, in case of primary pump shutdown, favors a mild transition from forced to natural circulation of the coolant and hence ensures adequate heat removal from the core during a transient.

The installation of SGs inside the vessel is the real safety challenge of a LFR design.

Preventing and mitigating provisions must be conceived to address the possibility of high-pressure water and steam release into lead. These measures will be directed toward reducing the frequency of occurrence of such releases, reducing the potential amount or rates of such releases, and mitigating the consequences.

A robust SG design and an appropriate plant operation and ISI program is necessary to reduce the frequency of release.

A typical provision to reduce large releases is the elimination of the risk of failure of the water and steam collectors inside the primary boundary by installing them outside the reactor vessel. This provision aims to eliminate by design a potential initiator of a severe accident of low probability and potentially catastrophic consequences. The associated accident scenario has never been evaluated, but the complete disruption of the primary boundary and even of the overall core cannot be excluded.

In the case of SGTR, a sensitive and reliable leak-detection system coupled with a fast SG depressurization and isolation system are the basic features to minimize the risk of damage. High reliability requires redundancy of the leak-detection system achieved by the means of (i) acoustic system, (ii) steam detection in the reactor cover gas, and (iii) pressure increase detection of the reactor cover gas. Fast depressurization from high pressure in a few seconds will be achieved by operating on both the water side as well as steam side.

Several provisions can be provided to mitigate the consequences of the SGTR accident, which typically are the pressure-wave formation and propagation inside the primary system, and the pressurization of the primary boundary.

To this end, three provisions have been conceived in ELSY:

- The first provision is the installation on each tube of a check valve close to the steam header and of a Venturi nozzle or flow blockage device close to the feedwater header. With these

Figure 6
Double SG outer shell

devices, reverse steam flow is prevented and any leaking tube is, at least partially, promptly isolated.

- The second provision aims at ensuring that the flow of any feedwater–steam–primary-coolant mixture be redirected upward, and the risk of potentially disruptive pressure surges within the reactor vessel prevented by design. To this purpose, in the event of an SGTR, the normal radial flow is deviated upward by design features that are fully passive and are actuated by pressurization in the SG bundle. Thus, thin perforated companion inner and outer shells are placed in the annulus close to inner and outer shell, respectively, held apart to a few millimeters by spacers. The spacers are designed to collapse in the event that the inner companion shells are acted upon by a specified inner pressure. Thus, in case of an inner pressure surge, the companion shells would blow out against the inner and outer shell (Fig. 6) respectively, and since the holes of the corresponding perforations have been designed staggered and the bottom end of the annulus is closed, there will be no other exit path for the mixture, but the upward flow toward the cover gas plenum, that damps the pressure surge without risk of serious damage of the reactor internals.

- As a third provision, pressure-relieving ducts, each with two rupture discs, installed on top of each SGU, hydraulically connect the reactor cover gas plenum with the above-reactor enclosure in case of inner pressure surge, particularly brought about by the SGTR accident.

2.3.2 Low Likelihood and Degree of Core Damage

Lead allows a high level of natural circulation of the coolant; this results in less stringent requirements for the timing of operations and simplification of control and protection systems.

In case of leakage of the reactor vessel, lead is collected inside a safety vessel and the coolant is designed to maintain a minimum level that ensures the coolant circulation through, and the safe heat removal from, the core. In ELSY, a specific solution has been developed with spiral-tube SG feed from the bottom, which, without any penalty on the main vessel height, maintain a lead flow path beneath the minimum level.

For small-size reactors, since the vessel outer surface is relatively large in comparison with the reactor power, DHR, can simply be accomplished by a RVACS, which is a very reliable system. For medium- and large-size reactors, additional safety-grade systems are needed. The fact that molten lead does not react violently with air or water gives the designer some freedom in the choice of the liquid for the DHR loops, the use of air and water remaining the preferred and most simple approach.

For power control and reactor shutdown, two completely different strategies are applied in case of ADS system or critical LFRs. In the case of an ADS, power level is controlled by means of the generated proton beam current.

In case of a critical LFR diversified solutions are possible, in general, based on the control rod technology similar to SFRs, even if the use of lead as a coolant increases the spectra of the potential solutions. A control/shutdown rod can replace a fuel element in the core layout, or can be located inside a fuel element. A control rod can be moved by electrical equipment located in the gas space. A shutdown rod can be introduced from the bottom of the core by lead buoyancy, from the top through motor-driven action, by the gravity of structural masses located in gas space, or by gravity-driven action inside an evacuated tube.

At the date of issuance of this document, several solutions/proposals are under investigation, but with large uncertainties and only after an appropriate test campaign in lead it will be possible to select the most promising solutions and confirm the level of reliability and diversification that can be achieved.

2.3.3 Reduced Need for Offsite Emergency Response

In the LFR, fuel dispersion dominates over fuel compaction, thus reducing considerably the likelihood of the occurrence of severe re-criticality events in the case of core disruption. In fact, lead density, which is slightly higher than that of the fuel, and convective streams make it rather difficult to achieve scenarios leading to fuel aggregation with subsequent formation of a secondary critical mass, in the event of postulated fuel failure.

In addition, the ability of lead to trap and retain fission products, in particular iodine and cesium, and the fact that a loss of coolant accident (LOCA) will not result in significant pressurization of the containment are features of primary importance in reducing the potential consequences of severe accidents.

2.4 Proliferation Resistance and Physical Protection

The physical characteristics of lead, the selected fuel cycle, and the adopted design features can contribute to increase the proliferation resistance and physical protection (PR&PP) characteristics of an LFR. For PR, nevertheless, international safeguards for each of the major elements of the system fuel cycle remain an independent assurance against potential diversion of nuclear fuel to produce or provide materials for nuclear weapons.

2.4.1 Unattractive Route for Diversion of Weapon-Usable Material

The use of MOX fuel containing MA increases proliferation resistance (PR) because of the inherent properties of the nuclear material. Uranium enrichment is not necessary. A breeding (conversion) ratio close to 1 is achievable in a medium-size reactor without providing fertile regions in the core and hence improving PR. Fertile regions can nevertheless be necessary to maintain a breeding ratio close to 1 in small reactors or to achieve a higher level of breeding.

Moreover, the SSTAR system has been designed from the beginning to achieve nonproliferation goals by incorporating a sealed core and very long-life fuel.

High burn-up and hence a high spent fuel radiological barrier (up to about 100 GWd/tHM in the short term, up to about 200 GWd/tHM in the longer term when adequate structural material for fuel cladding has been made available) improves PR.

Other additional benefits that can result from the fuel cycle are the introduction of pyro- or advanced aqueous fuel-reprocessing methods featuring incomplete removal of fission products and MA, no separation of uranium and plutonium at any fuel-cycle stage, and inherently low decontamination factors for fuel, with the need for remote handling, which complicates operations but enhances proliferation resistance.

2.4.2 Increased Physical Protection Against Acts of Terrorism

The use of a coolant chemically compatible with air and water and operating at ambient pressure greatly enhances physical protection (PP). There is a reduced need for robust protection against the risk of catastrophic events, initiated by acts of sabotage because there is a little risk of fire propagation. There are no credible scenarios of significant containment pressurization. Significant PP features of the LFR systems include the following:

- System simplification, no intermediate cooling system, and consequent robustness
- Passive decay heat removal
- Compact security footprint
- Possibility of partial or full underground siting

3 Neutronics

Fast reactors cooled by HLMs such as lead or LBE rely primarily on the physics of very high-energy neutrons: the high mass number of lead (and bismuth) results in the maintenance of a very hard (high-energy) neutron spectrum.

■ Figure 7

Typical neutron spectrum in an LFR (e.g., ELSY), expressed as fraction of the neutron density per energy bin $\left(\frac{n_{\text{bin}}}{n_{\text{tot}}\Delta E_{\text{bin}}}\right)$

A typical neutron energy distribution in an LFR is shown in [Fig. 7](#) referring to ELSY. The mean neutron energy in a typical LFR lies in the range of 400–450 keV (depending also on the fuel type, i.e., oxide, nitride, or metallic).

The mean free path associated to the given spectrum, for a typical LFR, is of the order of 2–3 cm.

3.1 Neutronic Properties of Lead

In order to investigate the peculiarities of an LFR (for comparison with other reactor types), it is important to consider the range of neutronic properties of the coolant including moderation (slowing down) and absorption affinity.

3.1.1 Moderation

The hardness of the neutron energy spectrum described in the previous section and depicted in [Fig. 7](#) can be understood by taking into account the average lethargy change per elastic collision,

$$\xi = 1 - \frac{(A-1)^2}{2A} \ln\left(\frac{A+1}{A-1}\right),$$

■ **Table 4**
Average lethargy change per elastic collision and moderating power for some typical coolants/moderators

	ξ	$\xi\Sigma_s$
H ₂ O	0.920	1.425
D ₂ O	0.509	0.177
Helium	0.425	9.0e-6
Graphite	0.158	0.083
Sodium	0.0825	0.0176
Lead	0.00963	0.00284

■ **Figure 8**
Elastic cross section of naturally occurring lead isotopes (Data from ENDF/B-VII library)

where A is the mass number of the considered isotopes. ➤ [Table 4](#) resumes typical values of the average lethargy change per elastic collision and the moderating power for lead and other main coolants/moderators.

The elastic cross section of naturally occurring lead isotopes is shown in ➤ [Fig. 8](#). In the energy range of interest the elastic cross section assumes almost the same value for all isotopes.

■ Figure 9

(n,γ) absorption cross section of naturally occurring lead isotopes (Data from ENDF/B-VII library)

3.1.2 Absorption

The lead coolant is one of the main contributors to the neutron balance in the core: as a matter of fact, the captures in the coolant directly impact the reactivity of the unit cell of the system, and thus the neutronic design of the whole core (see [► Sect. 6](#)).

The (n,γ) absorption cross section of naturally occurring lead isotopes is shown in [► Fig. 9](#).

It is to be pointed out that the most highly absorbing isotope (^{204}Pb) has a natural abundance of only 1.4%, sustaining the low total absorption rate of lead.

3.2 Fuel Performances in LFRs

While a variety of fuels is accounted worldwide for LFRs (e.g., oxide in the European concept, nitride in the American one), their typical composition is a mixture of reactor-grade plutonium (referring to an isotopic vector as if extracted from the spent fuel of a typical LWR after a mean burn-up (BU) of some 50 GWd/tHM and a cooling period of 10 years) and depleted uranium (DU), eventually doped by the inclusion of some MAs. The only exception to this scheme is represented by the EFIT fuel: it is made of Pu oxide with a considerable fraction of MA oxide only (thus U-free) in an inert matrix (MgO in the preliminary hypothesis).

Besides the peculiarities of oxide versus metallic fuels (mainly influencing the thermal design of the pin, such as the fuel thermal conductivity and its melting temperature), a series of common properties can be pointed out referring to the overall performances of fissile and fertile isotopes in an LFR.

■ **Table 5**

Typical microscopic cross sections of main fuel isotopes in an LFR compared to the ones of LWRs

	Capture [barns]			Fission [barns]		
	ELSY	ENHS ^a	LWR	ELSY	ENHS	LWR
²³⁸ U	0.282	0.210	1.03	0.035	0.030	0.107
²³⁹ Pu	0.487	0.297	42.23	1.753	1.640	101.02
²⁴¹ Pu	0.475	0.313	37.89	2.501	2.110	109.17

^a The encapsulated nuclear heat source (ENHS) is a SSTAR-type reactor (see ▶ Sect. 1.5.1) candidate conceived by the University of California – Berkeley, the Lawrence Livermore National Laboratories and the Argonne National Laboratories.

3.2.1 Fission Cross Sections

An immediate drawback related to the hard neutron spectrum can be found in what concerns the fission cross sections of odd nuclides (about one to two orders of magnitude less than in thermal reactors): typical values are shown in ▶ Table 5 compared to corresponding capture cross sections. Despite the fact that an increase of the fission rates for even nuclides can be gained, resulting in a wider contribution to criticality among nuclides in the fuel inventory, the reduction of the fission cross sections implies larger inventories of fissile material to maintain criticality.

3.2.2 Average Number of Fission Neutrons

The hard spectrum represents a positive contribution in what concerns the average number of neutrons per fission, $\bar{\nu}$, which is higher (about 2.93 for almost all the systems considered in the present chapter) than in thermal reactors. The higher number of neutrons available in the system, once criticality has been achieved, can be exploited for captures in fertile material to provide a higher breeding.

3.2.3 Fuel Utilization

Supported also by the increase of $\bar{\nu}$, the fertility factor, η , (▶ Chaps. 2 or ▶ 9) increases monotonically above 100 keV: the main reason for this can be ascribed to the lower capture rate due to the higher separation of the bulk of the neutron spectrum from the absorption resonance energy range. LFRs, therefore, can rely on a more-efficient fuel utilization, allowing a higher relative arrangement of fertile material in the fuel, thus resulting in a higher conversion ratio (CR).

3.2.4 Spectrum Evolution with Burn-Up

The particularly hard spectrum of LFRs is poorly affected by the buildup of fission products (FPs) during operation. Hence, the neutronic properties of the system can be assumed to remain approximately constant during the whole-core life (e.g., the error introduced on criticality evaluation is few tens of pcm after complete irradiation of the fuel).

3.2.5 Effective Delayed Neutron Fraction and Prompt Neutrons Lifetime

In a typical LFR with iso-breeding Pu content (such as ELSY or SSTAR), the value of the effective delayed neutron fraction β_{eff} is in the range 370 (ELSY) to 420 (SSTAR) pcm. This value is smaller than that of LWRs (~ 650 pcm) because of the lower fraction of delayed neutrons per fission of a ^{239}Pu isotope than for ^{235}U . In case of MA-doped fuel (with equilibrium concentrations, i.e., some 1 at% of HM), the value of β_{eff} is further reduced to some 325 pcm because of the small delayed neutron fraction associated to the fission of MA isotopes.

The impact of more highly energetic neutrons also implies a lower prompt neutrons lifetime, λ (of the order of 10^{-6} to 10^{-7} s), in comparison with thermal reactors (about two orders of magnitude higher).

The direct drawbacks related to the values of these parameters are the narrower margin to prompt-criticality and the lower capabilities for reactor control in case of prompt-criticality accident.

3.2.6 LFR Capabilities of MAs Transmutation

Finally, the harder the spectrum, the higher the fission cross sections of MAs (triggering the highest level of threshold fission reactions among even nuclides). As far as MA transmutation is concerned, this implies that the balancing of production and removal rates for the latter (which represents the frontier between MA breeders and burners) is attained by a low content of MAs in the fuel.

The possibility of relying on a low fraction of MAs in the fuel allows more flexibility in waste transmutation for LFRs: performances being equal, the lower detriment to the total average fraction of delayed neutrons (since the low contribution associated to MAs) represents a larger operability margin to what concerns such a stringent constraint for reactor control.

3.3 Neutronic Performances of Typical Absorbers in an LFR

The choice of an effective neutron-absorbing material is fundamental in the design of a critical reactor because of the need to control and regulate its operation. In the hard spectrum of an LFR, particular care should be paid to the evaluation of the absorption cross sections of the control material candidates.

3.3.1 Boron Carbide

Boron carbide, B_4C , is the reference-absorbing material for FRs in general. Besides the availability of boron and the ease of its fabrication, therefore, the low costs related to the adoption to B_4C -based control systems, the neutronic properties of the ^{10}B isotope are excellent even in the fast spectrum because of its (n, α) reaction cross section (🔗 [Fig. 10](#)).

Since the main isotope responsible for neutron absorption is the ^{10}B , the natural abundance of which is 19.9% (the rest being ^{11}B , whose neutronic properties are practically unusable), reactor grade B_4C is usually enriched in ^{10}B (up to $\sim 90\%$).

Figure 10
 ^{10}B absorption cross section (Data from ENDF/B-VII library)

3.3.2 Indium–Cadmium Eutectic

An interesting alternative to boron carbide could be represented by the indium–cadmium eutectic (75 wt% In and 25 wt% Cd): at typical LFR-operating temperatures ($>400^\circ\text{C}$), this alloy is liquid ($T_{\text{melt}} = 122.5^\circ\text{C}$); thus its operability could be assured even in case of control rod thimble guide distortion after a severe accident.

A main drawback can be ascribed to this solution taking into account the absorption effectiveness of the eutectic in the hard spectrum of LFRs. Despite the high content of indium in the mixture (the absorption effectiveness of pure cadmium being about 60% of that of pure indium), preliminary evaluations performed on an ELSY In–Cd control system, when replacing a reference 90% ^{10}B -enriched B_4C configuration, showed reactivity reduction to about 14% of the latter configuration. Based on this assessment, large volumes in the core would need to be devoted to such a control system, resulting in the practical infeasibility for this solution.

3.3.3 Europium

The last candidate absorber for LFRs is europium sesquioxide (Eu_2O_3). This material, well known in reactor physics, has high (n, γ) absorption cross sections in the fast spectrum (comparable to that of ^{10}B for both naturally occurring isotopes ^{151}Eu and ^{153}Eu , \blacktriangleright Fig. 11).

In order to decide whether to choose this material instead of B_4C it is worth taking into account the following details:

- No He is produced (since the capture mechanism is Eu radiative absorption), thus no venting is required for europium sesquioxide control rods.

■ Figure 11

Naturally occurring europium isotopes (n, γ) absorption cross section (Data from ENDF/B-VII library)

- The daughter products are also good neutron absorbers, thus the loss of anti-reactivity worth is reduced with respect to B_4C absorbers.
- The Eu self-shielding is such that the effectiveness of a Eu_2O_3 control rod, in LFRs, is about 40% of that of an equivalent one made of enriched B_4C , thus close to that of natural B_4C .

4 Lead Properties

This chapter reports data on the main physical properties of technically pure molten lead with a few complementary data of LBE acquired from the open literature. (Technically pure lead is not synonymous with nuclear-grade lead, because lead as a coolant in a fast reactor is likely to require more stringent limitations than high-purity industrial lead, in terms of concentrations of impurities, which could become activated or affect corrosion, mass transfer, and scale formation on heat-transfer surfaces. The impurity concentrations are so low, however, that the physical properties of lead of both grades are the same, for the purpose of this compilation.) It will be noted that, in some cases, these are recommended as best-fit data, because of the significant discrepancies among the values given by different sources.

4.1 Physical Properties

The properties of molten lead are given by parameter in the form of the recommended value or correlation over a temperature range, and, eventually, in the form of a table of main parameters

relevant to heat transfer, of both pure lead and the LBE over the range of more frequent use, for quick check, and comparative analysis purpose.

In general, the reliability of the recommended correlations about thermal–physical property data of molten lead is satisfactory and the correlations can be used for engineering estimates and design calculations, in spite of the uncertainty still existing on heat capacity, boiling temperature, and thermal conductivity.

For the high-temperature range, the set of thermodynamic and transport properties (thermal conductivity, viscosity, and surface tension) relevant for reactor safety analysis are not reported, but the basic properties such as the liquid density, vapor pressure, and liquid adiabatic compressibility are estimated up to the critical point using semiempirical models based on the extrapolation of low-temperature data (OECD-NEA 2007), owing to the lack of experimental data published in the open literature.

Normal Melting Point

The melting point of technically pure lead is as follows:

$$T_{melt}^{\text{Pb}} [\text{K}] = 600.6 \pm 0.1.$$

The melting point increases by 0.0792 K per 1 MPa when pressure increases from about 15 to 200 MPa.

Volume Change at Melting

Similar to the majority of metals with FCC crystal structure, lead exhibits a volume increase upon melting. At normal conditions a volume increase

$$\Delta V_m / V_m = 3.7\%$$

is the recommended value for lead of technical purity.

Latent Heat of Melting at the Normal Melting Point

The recommended heat of melting of lead at the normal melting point (the enthalpy change on melting) is

$$Q_{melt}^{\text{Pb}} [\text{kJ/kg}] = 23.8 \pm 0.7$$

Normal Boiling Point

The value of

$$T_{boil}^{\text{Pb}} [\text{K}] = 2,016 \pm 10$$

is recommended for the boiling temperature of technically pure lead at normal conditions.

Heat of Vaporization at the Normal Boiling Point

The latent heat (enthalpy) of vaporization is a measure of the cohesive energy of atoms in a liquid metal. Therefore, it correlates with surface tension and thermal expansion. The literature values are very close, with the difference between maximum and minimum values less than 1%. The mean value and the mean deviation are as follows:

$$Q_{boil}^{\text{Pb}} [\text{kJ/kg}] = 858.2 \pm 1.9.$$

Saturation Vapor Pressure

The vapor pressure of a liquid metal is an important property, which is directly related to the latent heat of evaporation (cohesive energy, ΔH). The following correlation is recommended for the saturated vapor pressure of molten lead where temperature is in kelvin:

$$p_s^{\text{Pb}} [\text{Pa}] = 6.189 \times 10^9 \times \exp(-22,216/T).$$

The above equation can provide approximate values for equilibrium vapor pressures over a wide range of temperature and is recommended from the melting point up to the normal boiling point. ΔH is included as a constant owing to the relatively small variation with temperature.

Surface Tension

The surface tension of liquid surfaces (σ) is related to tendency to minimize the surface energy. It decreases with increasing temperature and reduces to zero at the critical temperature (T_c), where difference disappears between liquid and gas phases.

The temperature dependence of surface tension is linear for most liquid metals.

The recommended correlation is the following formula where temperature is in kelvin and is conservative in the range from the melting temperature of 600.6–1,200 K (327.6–927 °C):

$$\sigma^{\text{Pb}} [\text{N/m}] = 0.519 - 1.13 \times 10^{-4} \times T.$$

Density

The temperature dependence of density provides essential information for the development of an equation of state (EOS). It is used to determine the concentration of atoms in unit volume and hydraulic parameters in reactor design. Also, the measurement or calculation of basic physical properties, e.g., viscosity, surface tension, thermal diffusivity, requires knowledge of density. The set of the selected data can be fit as follows, with linear temperature dependence, where temperature is in kelvin:

$$\rho^{\text{Pb}} [\text{kg/m}^3] = 11,367 - 1.1944 \times T.$$

Thermal Expansion

The coefficient of thermal expansion (CTE), derived from temperature dependence of density of molten lead, is as follows:

$$\beta_p^{\text{Pb}} [\text{K}^{-1}] = 1/(9,516.9 - T).$$

Sound Velocity and Compressibility

The correlation recommended for the estimation of the sound velocity in the molten lead is:

$$u_{\text{sound}}^{\text{Pb}} [\text{m/s}] = 1,951.75 - 0.3423 \times T + 7.635 \times 10^{-5} \times T^2,$$

where the temperature is in kelvin.

At normal atmospheric pressure, the temperature dependence of the elastic modulus of molten lead can be described with the help of parabolic and linear functions as follows:

$$BS^{\text{Pb}} [\text{Pa}] = (42.15 - 1.652 \times 10^{-2} \times T + 3.273 \times 10^{-6} \times T^2) \times 109.$$

Heat Capacity

Available experimental data on heat capacity of heavy liquid metals are few. The following correlation is recommended for the heat capacity of molten lead in the temperature range of T_{melt} to 1,300 K (1,027 °C), where temperature is in kelvin:

$$c_p^{Pb} \text{ [J/kg/K]} = 175.1 - 4.961 \times 10^{-2} \times T + 1.985 \times 10^{-5} \times T^2 - 2.099 \times 10^{-9} \times T^3 - 1.524 \times 10^6 \times T^{-2}.$$

Critical Constants

Critical parameters. The mean rounded values of two sources are recommended for the critical temperature, pressure, and density of lead:

$$\begin{aligned} T_c^{Pb} &= 4,870 \text{ K (4,597 °C)}, \\ p_c^{Pb} &= 100 \text{ MPa}, \\ \rho_c^{Pb} &= 2,490 \text{ kg/m}^3. \end{aligned}$$

Viscosity

The following empirical equation, obtained by fitting selected values into an Arrhenius-type equation, is recommended to describe the temperature dependence of the dynamic viscosity of molten lead:

$$\mu^{Pb} \text{ [Pa s]} = 4.55 \times 10^{-4} \times \exp(1,069/T),$$

where temperature is in kelvin. This correlation is valid in the temperature range T_{melt} to 1,470 K (1,197 °C).

Electric Resistivity

The electrical resistivity of liquid lead, as of most liquid metals, increases linearly with temperature (in the temperature region of interest). The recommended empirical equation suitable for the calculation of the electrical resistivity is as follows:

$$r^{Pb} \text{ [}\Omega \text{ m]} = 0.666 \times 10^{-6} + 4.79 \times 10^{-10} \times T,$$

which is valid in the temperature range of 601/1,273 K (328/1,000 °C). The deviation of the selected data from this correlation is less than 1%.

Thermal Conductivity and Thermal Diffusivity

Experimental determination of thermal conductivity of liquid metals is difficult because of the problems related to convection and wetting. At present, few experimental data are available, sometimes presenting discrepancies between different sets of data. The high thermal conductivity of liquid metals is mainly due to free electrons. A simple theoretical relation exists for pure metals between electrical and thermal conductivities known as Wiedemann–Franz–Lorenz law. In an effort to find a physically reasonable compromise among the experimental data sets and taking into account the relation with the electrical conductivity, the following linear correlation is recommended for the thermal conductivity of molten lead:

$$\lambda^{Pb} \text{ [W/m/K]} = 9.2 + 0.011 \times T,$$

where temperature is in kelvin. This correlation is applicable in the temperature range of T_{melt} –1,300 K (1,027 °C).

Thermal diffusivity a is defined as follows:

$$a = \lambda / (\rho \times c_p).$$

So, it can be calculated using data for thermal conductivity, density, and specific heat. Fitting the data with a linear function yields a correlation that can be of practical use for calculating the dimensionless Péclet and Prandtl numbers.

The values of main parameters and transport properties at discrete temperatures in the range 400–600 °C for lead (and LBE for comparison with pure lead) in [▶ Table 6](#).

4.2 Chemistry Control and Monitoring Systems

The chemical properties data of solubility and diffusivity of oxygen and some metallic elements, e.g., Fe, Cr, and some oxides (e.g., iron oxides, chromium oxides, etc.) in the molten lead are of paramount importance for:

- Preventing oxidation of the coolant
- The assessment of the materials corrosion rate
- The design and engineering of HLM purification systems, for the development of a corrosion protection strategy that is based on protective oxide layers on the structural materials
- The source term assessment

The accuracy of the formula that fits the solubility data of oxygen is not reported in the literature, although solubility is one of the key parameters of lead chemistry. On lack of accurate data, a larger margin against risk of reaching saturation will have to be specified, particularly at the cold temperature of the thermal cycle (1 decade from saturation, say). Diffusivity of oxygen is of lesser concern, because, although the diffusion rate in the melt of atomic oxygen is slow, the coolant flow itself will provide for uniform concentration of the dissolved oxygen wherever turbulent flow prevails at a rate that can be 1,000 times the rate of diffusion through stagnant lead.

It will be noted, at the outset, that the aim of controlled dissolved oxygen in the melt is to protect the structural steels such as stainless steels and low-alloy steels from corrosion by means of an oxide barrier and that this technique is effective up to about 500 °C.

This implies the presence of dissolved oxygen in the melt in equilibrium with oxygen gas in the cover gas plenum above the melt.

4.2.1 The Thermodynamical Base

Oxygen gas dissolves in liquid metals in atomic form. The amount of dissolved oxygen is proportional to the square root of its partial pressure above the melt (relationship known as Sievert's law), provided that its concentration is less than 1 wt% and oxide-forming elements are absent. This holds true for the oxygen concentration range in the pure lead melt of LFR, the upper limit of which is the saturation concentration with respect to lead oxide and the lower limit the saturation concentration with respect to magnetite. Thus, iron is kept fully oxidized (as magnetite) and lead fully reduced (as metallic lead).

All elements less noble than iron, if present, are a fortiori completely oxidized and all elements more noble than lead, if present, are in their metallic form. Elements that are between iron and lead are kept at low concentration either by specification of the grade of the original

lead charge (arsenic, bismuth) or by prevention from leaching out of steel into the melt (nickel) and play therefore a small to negligible role in the economy of dissolved oxygen concentration at normal operation or during tests.

Oxygen concentration changes as a consequence of changing partial pressure above the melt according to Sievert's law and/or of changing temperature of the melt. The rate of change due to changes of the partial pressure may be slow if diffusion is the only driving force or relatively fast if turbulent motion is involved. The rate of change due to local cooling (heating up) of the melt, as it occurs in the SGs or in the core depends on the formation (dissolution) rate of the metal oxides.

It will be noted that any change of oxygen concentration is related to the dissolved oxygen. The total oxygen may have remained constant, while the oxygen concentration has changed, as in the case of formation of metal oxide particles or dissolution of metal oxide particles in the bulk of the melt.

The physical-chemical principles of metal oxide formation, particularly the relationship between free energy and equilibrium constant, are treated in handbooks on thermodynamics (Perry et al. 1963; Hougen et al. 1959; Moore and Boyce 1990) and concisely summarized here below.

The general chemical equation of metal oxide formation with 1 mol of oxygen is the reference for the calculations. Thus, for lead the equation becomes

Lead oxide formation in presence of water vapor can be conveniently expressed combining (1a) and the equation of water formation

as follows

Because the Gibbs free energy change ΔG is the driving force of a chemical reaction, on the equilibrium position ΔG vanishes, i.e., an equilibrium mixture of both products and reactants is obtained when the free energy change of the system between the initial condition and the final condition has become zero (position of minimum free energy toward which the system tends). If the initial condition is taken to refer to standard conditions, the calculation of the standard free energy change ΔG_T° at any temperature T allows the calculation of the equilibrium constant K at that temperature according to (2)

$$\Delta G_T^\circ = -RT \ln K, \quad (2)$$

where:

R = Gas constant, 8.314 J/K/mol

T = Temperature, K

If Pb and PbO involved in (1a) are pure liquid and solid, respectively, their concentrations remain constant, allowing their active masses to be taken as 1, and the equilibrium constant may be written in terms of the partial pressure of oxygen only,

$$K = \frac{1}{p_{\text{O}_2}}, \quad (3a)$$

and, by substitution in (2):

$$\Delta G_T^\circ = RT \ln p_{O_2},$$

allowing the dissociation or equilibrium p_{O_2} values to be calculated. The value of p_{O_2} , which is the reciprocal of K , is the equilibrium pressure of oxygen, below which the oxide will decompose (therefore also called dissociation pressure) and above which the metal will oxidize. Low dissociation pressure favors more ready formation of the metal oxide.

In the case of the water vapor formation, (1b) the equilibrium constant is in terms of partial pressures of all involved substances,

$$K_p = \frac{p_{H_2O}^2}{p_{H_2}^2 \times p_{O_2}}. \quad (3b)$$

In the case of dissolution of a metal oxide in the melt, $M_xO_y = xM + yO$, the equilibrium constant is in terms of the molar concentration of the solved elements,

$$K_c = [M]^x \times [O]^y. \quad (3c)$$

The same reasoning as for the dissociation pressure applies considering the reaction of lead oxide formation in presence of water vapor, (1c): at any temperature T , equilibrium exists only at that value of the $\frac{p_{H_2}}{p_{H_2O}}$ partial pressures ratio that satisfies (3b), once the value of the dissociation pressure has been substituted for p_{O_2} . If the pressure ratio is kept lower than the equilibrium ratio, all lead is in the oxide form and, vice versa, all lead is in metallic form (see also [Table 6](#), where related equilibrium values for both pressures ratio and oxygen dissociation pressure can be read at 400 °C for lead oxide and magnetite).

At low partial pressure of the oxygen gas above the melt, the knowledge of the equilibrium constant of water vapor offers a means of controlling p_{O_2} according to (3b): at a given p_{H_2O} , p_{O_2} varies with $\frac{1}{p_{H_2}^2}$, the inverse of the square partial pressure of the hydrogen gas. At low p_{O_2} , the measurement of the associated hydrogen partial pressure is easy.

The standard free energy is defined in terms of enthalpy and entropy as follows:

$$\Delta G_T^\circ = \Delta H_T^\circ - T\Delta S_T^\circ, \quad (4)$$

where conventionally $\Delta G_T^\circ = \Delta G_{T,prod}^\circ - \Delta G_{T,react}^\circ$, i.e., change in the free energy referred to the moles of the reactants and products shown in (1a), at 1 atm and at a stated temperature T , with the substances in the physical state normal under these conditions. As can be seen from (4), ΔG_T° is made up of an enthalpic and of an entropic term.

The enthalpic term may be calculated as follows if the enthalpy change for the reaction at another specified temperature, usually 298 K, and molar heat capacity data are available from data books:

$$\Delta H_T^\circ = \Delta H_{298K}^\circ + \int_{298}^T \Delta C_p dT \pm \text{latent} \cdot \text{heats}. \quad (5)$$

The entropic term may be calculated with the same procedure as for the enthalpic term as follows:

$$\Delta S_T^\circ = \Delta S_{298K}^\circ + \int_{298}^T \frac{\Delta C_p}{T} dT \pm \frac{(\text{latent} \cdot \text{heats})}{T_m}. \quad (6)$$

Latent heats are subtracted if reactants transform.

Figure 12

Standard free energy change for the formation of 2 mol of PbO (*upper line*) and half a mole of magnetite, Fe₃O₄

Table 7

Free energy change and dissociation pressures of lead oxide and magnetite at 400 °C and 480 °C

	$\Delta G^\circ_{400\text{ }^\circ\text{C}}$ (kJ/mol O ₂)	$p_{\text{O}_2,400\text{ }^\circ\text{C}}$ (atm)	$\Delta G^\circ_{480\text{ }^\circ\text{C}}$ (kJ/mol O ₂)	$p_{\text{O}_2,480\text{ }^\circ\text{C}}$ (atm)
PbO	-309.6	1.1×10^{-24}	-293.5	5.0×10^{-21}
Fe ₃ O ₄	-442.8	4.5×10^{-35}	-429.1	1.8×10^{-30}

4.2.2 Thermodynamical Data and Diagrams

Heats of formation can be read from Table 3.201 of Perry et al. (1963), absolute entropies at 298 K from Table 68 of Hougen et al. (1959), heat capacities from Table 3.173 of Perry et al. (1963) and Table 2.2 of Moore and Boyce (1990).

The following solubility at saturation – [wt%] – versus T of oxygen, (7), and of iron, (8), in molten lead has been determined experimentally within the temperature range 400–900 °C for iron (Gromov 1998):

$$\log C_{[\text{O}],s} = 3.2 - \frac{5,000}{T} \quad (7)$$

$$\log C_{[\text{Fe}],s} = 2.1 - \frac{4,380}{T}. \quad (8)$$

Change in the Standard Free Energy

The change in the standard free energy ΔG° versus T for the formation of 2 mol of PbO and half a mole of magnetite, Fe_3O_4 , calculated with the relationships written above and the thermodynamic data, is plotted on the following diagram of  Fig. 12 along with iso- $\frac{p_{\text{H}_2}}{p_{\text{H}_2\text{O}}}$ pressure ratio, and iso- p_{O_2} pressure lines of interest. Selected values at 400 °C and 480 °C are reported in .

The values of the dissociation pressures are so low that their direct measurement in the cover gas is impractical (.

The oxygen activity is defined as the ratio, at any temperature, of the actual dissolved oxygen concentration to the concentration of saturation for PbO, arbitrary chosen as standard state:

$$a[\text{O}] = \frac{C_{[\text{O}]}}{C_{[\text{O}],s}} \quad (9)$$

where $C_{[\text{O}],s}(T)$ is given by (7).

Values of $C_{[\text{O}],s}(T)$ by step of 10 K are listed in the following . They are noted as standard values, because used as reference values in (9) for calculating $a[\text{O}]$.

The activity $a[\text{O}]$ gives the measure how far (how close) the actual oxygen concentration in the melt is from the upper allowable limit, where lead oxide would start to form. Because

$$C_{[\text{O}],a} = k\sqrt{p_{\text{O}_2}}, \quad (10)$$

the smaller the $C_{[\text{O}],a}$, the smaller is the $a[\text{O}]$ value until it corresponds to the dissociation pressure of magnetite via (8) and (10).

The theoretically allowable activity ranges are listed in  at several temperatures. The ranges cannot be exploited in their full extension, however, because if the oxygen activity would be controlled at its upper limit, lead oxide precipitation would occur in the melt, and predictably on the colder heat-transfer surface of the SG tubes, while cooling down (too much dissolved oxygen) or, conversely, there would be dissolution of magnetite out of the mixed oxide film barrier of the austenitic steels, if the activity would be controlled at its lower limit (too little dissolved oxygen).

Table 8

Weight percent (wt%) of oxygen dissolved in molten lead as function of the temperature at equilibrium with the dissociation pressures of lead oxide, [O]_{sat, std}, and magnetite, [O]_{min}

Temp (°C)	Pure lead		
	[O] <i>sat, std</i> (wt%)	[O] <i>min</i> (wt%)	$-\log a[\text{O}]$
400	4.5e-5	2.94e-10	5.2
450	1.6e-4	2.03e-9	4.9
480	3.0e-4	5.74e-9	4.7
500	4.6e-4	1.10e-8	4.6
550	1.2e-3	4.86e-8	4.4
600	2.7e-3	1.82e-7	4.2

Thus, the operating activity range must be controlled between the two range limits with margin.

4.3 Thermal Hydraulics

There are two kinds of open issues in this area. The first is related to the fundamental nature of heavy liquid metals.

The Prandtl number of HLMs (Pr of lead at 400 °C is 0.019) is more than two orders of magnitude lower than that of water and air. This is because HLMs have a significantly higher thermal conductivity λ [W/mK], lower specific-heat capacity c_p [J/(kgK)], and lower kinematic viscosity.

Low Prandtl number means that the thickness of the viscous boundary layer is negligibly small compared to the thermal boundary layer. In gas or water flow, the thickness of the thermal and the viscous boundary layer are of the same order of magnitude, as Pr is ~ 1 .

With lead in laminar flow, molecular conduction of heat controls the heat transfer. Accordingly, the classical nondimensional correlations for heat transfer can be applied also to liquid metal.

Under turbulent flow conditions, however, eddy conduction of heat becomes important and heat transfer is determined by both molecular and eddy conduction in the fluid stream. While in ordinary fluids like air and water molecular conduction is only of importance near the wall, in a liquid metal the magnitude of the molecular conductivity is of the same order as that of the eddy conductivity. Thus, the molecular conduction is effective not only in the boundary layer but also to a significant extend in the bulk of the fluid stream. Therefore, relationships (or correlations) developed to determine the heat-transfer coefficients for turbulent flows in air or water cannot be used.

A further consequence of the importance of molecular conduction of thermal energy in turbulent liquid metal flow is that the concept of the hydraulic diameter cannot be used so freely to correlate heat-transfer data from systems that differ in configuration but retain a similar basic flow pattern. As an example in Pr ~ 1 fluids, basic heat-transfer data for flow through circular pipes can be used to predict Nusselt (Nu) numbers for flow parallel to a rod bundle by evaluating the hydraulic diameter of the rod bundle and using this in the nondimensional correlations for the circular pipe.

This calculation approach is invalid for liquid metal systems, and accordingly theoretical, numerical, or experimental heat-transfer relationships must be developed to deal with each specific configuration.

The second kind of issues is technological, and mostly related to the nature of the HLM-cooled system design and operation. Using coolant chemistry control and surface protective oxide formation to mitigate steel corrosion has consequences in heat-transfer performance, particular for the long-term or in abnormal situations, such as a buildup of oxides and high level of solid oxide particles. HLM-cooled nuclear reactors usually have open-lattice configurations to reduce pumping power needs and enhance passive safety. Flow circulation methods, transients, flow stability, and elimination of undesired instability are all important issues to be investigated.

It is necessary to develop and validate more suitable turbulent model(s) for computational thermal hydraulics, especially for complex geometries and critical components, such as the core.

The results of the experiments shall be used, in turn, to improve the related physical models, and to evaluate and benchmark the CFD codes.

5 Compatibility of Structural Materials with Lead

The use of lead or lead alloy as the coolant in advanced fast reactors implies high-temperature operation and requires structural steels qualified for use in these reactors. Known structural materials like the ferritic–martensitic T91 and the austenitic stainless steel 316L have been a first choice, but they can undergo severe dissolution attack.

Corrosion is, however, but one phenomenon among those relevant to the contact with the liquid metal to be investigated for the qualification of a structural material. Other important phenomena are material failure under static loading, such as brittle fracture, and failure under time-dependent loading, such as fatigue and creep.

5.1 Structural Materials Corrosion in Lead

Molten lead or lead alloy is corrosive toward structural materials. The main parameters impacting the corrosion rate of steels are the nature of the steel (material side), the temperature, the liquid metal velocity, and the dissolved oxygen concentration. A provision that can be adopted to reduce leaching out of steel-alloying elements (typically nickel, which is a component of the austenitic stainless steels and dissolves in the molten lead) is to maintain a controlled amount of oxygen dissolved in the melt. Dissolved oxygen forms a layer of metal oxide on the steel surfaces in contact with lead that protects the steel from dissolution and recovers the metal oxide layer in case of erosion by the flowing heavy metal (self-healing effect).

It has been demonstrated that, in the low-temperature range, e.g., below 450 °C, and with an adequate oxygen activity in the liquid metal, ferritic–martensitic, and austenitic steels build up an oxide layer, which behaves as a corrosion barrier.

However, in the higher-temperature range, i.e., above ~500 °C, corrosion protection through the oxide barrier seems to fail (Fazio et al. 2005). Indeed, a mixed corrosion mechanism has been observed, where both metal oxide formation and dissolution of the steel elements occur (➤ [Table 9](#)).

It has been demonstrated that, especially in the high-temperature range, the corrosion resistance of structural materials can be enhanced by FeAl alloy coating, a recent surface-coating technique developed for the purpose and shown effective for up to 600 °C.

Several exploratory experiments carried out in the past in LBE and pure lead on different type of steels did show that generally below 450 °C, and with an appropriate dissolved oxygen concentration in the liquid metal, both martensitic and austenitic steels build up an oxide layer (a barrier), which prevents leaching of alloy elements into the liquid metal and liquid metal penetration along grain boundaries. For temperatures above ~500 °C, the prevention of liquid metal–steel interaction through the oxide layer seems to fail due to the occurrence of a mixed corrosion mechanisms, where both oxidation as well as dissolution can occur. It has been demonstrated, however, that the corrosion resistance of the structural materials at temperatures above 500 °C can be enhanced by coating the steel surface with FeAl alloys. This is of paramount interest for the fuel cladding, for which coating shall be thin, in order not to significantly affect heat transfer, besides the properties of mechanical stability and adhesion to

■ **Table 9**

Protective action via controlled dissolved oxygen at increasing temperature

Effective corrosion protection	Transition zone		Additional protection needed
Compact stable oxide barrier on ferrite–martensite and austenite	Oxide formation on ferrite–martensite		Unstable metal oxide layer
	Mixed corrosion mechanism: oxidation/dissolution on austenite		Stable FeAl alloy coating
400 °C	500 °C	550 °C	600 °C

the substrate material requested to any protective oxide layers. Coating material is FeCrAlY. It contains aluminium, which forms alumina in situ. To increase the adhesion and improve the stability, such coatings can be melted or fused together with the surface of the substrate, for example, by using large-area pulsed electron beams as is done in the GESA process, developed by the Karlsruhe Institute of Technology (KIT) in Germany.

The long-term stability in flowing liquid metal of the oxide layer (for temperatures <500 °C) as well as the GESA FeAl alloy coating (for temperatures >500 °C) has not yet been proven, however.

Planned European tests (i.e., the DEMETRA program under IP-EUROTRANS) include therefore corrosion tests in flowing liquid metal (with representative parameters of the fuel cladding and in-vessel components) to estimate corrosion kinetics, and to assess the long-term stability of the protective layers. The experimental program will go along with modeling activities, which help to define the corrosion kinetics for the types of steels under investigation.

It is worthwhile to note that the limitation on the upper temperature of the thermal cycle is considered a temporary compromise solution that allows the reactor design to proceed until new high-temperature materials become available, which will allow greater exploitation of the favorable properties of heavy metal coolants; these longer-term developments are likely to hold the key of the commercial viability of advanced fast reactors to be deployed for hydrogen as well as electric-energy generation.

Thus, the present design approach for ELSY is to limit the mean core outlet temperature to less than 500 °C, and to protect the T91 steel, as the construction material of the unavoidably thermally high-loaded fuel cladding tubes, with Fe/Al alloy coating.

5.2 Effect of Lead on Properties of Structural Materials

The use of heavy liquid metals, and especially of lead-cooled or lead-alloy-cooled (primarily LBE) fast reactor (LFR) concepts of Generation IV requires an assessment of their compatibility with structural materials under the fast-neutron spectrum typical of fast reactors. Although western countries did acquire substantial experience with sodium-cooled fast reactors, the expertise on compatibility of stainless steels with sodium is not transferable to lead and lead alloys, owing to the significant differences in their physical and metallurgical properties. Thus,

the older literature dedicated to the mechanical properties of steels, from carbon steels to high Cr steels, in contact with lead and lead alloys is essentially of Russian origin.

Because the 316L austenitic stainless steel and the T91 martensitic steel have been preselected for the design of future European transmutation facilities (EFIT, XT-ADS) and eventually also for the lead-cooled ELSY, the effect of LBE or lead on the mechanical behavior of these steels is being extensively investigated in Europe and worldwide, and results are available, but they are not yet exhaustive. The effect of lead or LBE on the tensile properties of T91 is well documented, thanks to the European TECLA and MEGAPIE-TEST programs of FP5. It has been shown that under MEGAPIE-relevant conditions, (i.e., temperatures below 400 °C and very low dissolved oxygen concentration in the liquid metal, i.e., reducing conditions below the potential of iron oxide formation), not only no oxide barrier forms on the steel (i.e., direct contact between steel surface and liquid metal), but worsening of the mechanical performance of the steel also occurs, if surface cracks are present. Particularly, low cycle fatigue (LCF) tests performed on T91 samples with different pretreatments did show that strong LBE attack appreciably reduces the LCF resistance of the steel, with respect to pre-oxidized samples and to the as-received samples. These tests as well as slow strain rate and tensile tests provide evidence of the effect of the surface condition on the mechanical behavior of the T91 when in contact with LBE. The latest results of LCF tests performed on the AISI 316L steel in air and LBE have shown a fatigue lifetime reduction in LBE for higher strain ranges.

Today, and in spite of a lack of quantitative results on fatigue and fracture, based on analysis of the data collected on the tensile and fatigue tests, the question of the susceptibility to LME (embrittlement) of T91 in contact with LBE can be addressed, particularly how to proceed from the metallurgical and chemical points of view to prevent LME. Thus, there are some data available on real systems about wetting, which is one of the two main conditions for occurrence of LME, in addition to abundant theoretical literature. The knowledge of the stress level responsible for plastic deformation, even at microscopic scale, as the second main condition for occurrence of LME, would allow eventually the definition of the criteria for preventing LME failure. Environment-assisted cracking (EAC) is a phenomenon closely related to LME, which permits an interpretation of the results of some tensile tests conducted on T91 or 316L steel in lead or LBE environments.

Information on the effect of lead or LBE on the creep properties of both T91 and 316L is scarce. There is almost no information on creep strength, creep damage, and creep crack growth rates in the currently available accessible literature.

Proposed explanations consider liquid-metal-accelerated creep (LMAC), whereby liquid metals can accelerate, at the same time, creep and the nucleation growth of vacancy voids near the metal surface in traction or compression.

Creep tests were performed in Russia in the context of the BREST-OD-300 reactor system, on a chromium steel 10Kh9NSMFB (containing 1.2% Si) in flowing liquid lead under 70–100 MPa between 420 °C and 550 °C, showing an earlier transition into the third stage of creep and a decrease of the duration of the steady creep stage, explained as a consequence of the lead corrosiveness. More detailed information about the test conditions and composition and structure of the steel–lead interface would be of interest at all stages of the test. This would imply access to the Russian literature on structural materials in contact with liquid metals for nuclear applications.

Information on fracture mechanics, from fracture toughness to crack growth behavior in contact with LBE, does not exist. There is a large body of literature devoted to the fracture of structural materials, hardened and often embrittled under irradiation, covering a wide range

of experimental test conditions. This is, indeed, information of primary importance, which, for example, did allow for an estimate of the service life of the MEGAPIE target window. There is no such information available for structural materials in contact with lead. It is sometimes stated that the ductile to brittle transition temperature, which may increase by approximately 100° after irradiation, should be only little increased by contact with HLMS. If proven, this fact would be of paramount importance and hence it must be verified experimentally.

In summary, dedicated test plans will have to be set up in order to provide data, particularly in the higher-temperature range, on tensile, creep, creep-fatigue and fracture mechanics, and fatigue crack growth of steels in contact with the selected HLM, including testing of irradiated specimens. Results of similar experiments carried out in the frame of different technologies, such nuclear fusion, shall not be disregarded as they can be conveniently used as a guide for the HLM-dedicated experiments. Austenitic stainless steels ($T \leq 500^\circ\text{C}$) and ferritic-martensitic steels ($T \leq 600^\circ\text{C}$) are likely to remain the main candidate materials for the future power reactors in spite of uncertainties in the areas of irradiation-induced embrittlement at low temperatures and radiation damage from high He/dap ratio. Prospective candidate materials are the ODS martensitic steels (temperature window can be increased to 650°C), and in the longer term the ferritic ODS steels, ceramic composites, and refractory alloys for the higher temperatures.

6 Core

The LFR core design approach is here presented and discussed. An integrated neutronic-thermal-hydraulic approach is envisaged in order to address the whole process toward the most effective solution to what concerns the design goals, according to the related technological constraints.

Starting from the peculiarities of lead- or LBE-cooled systems, the overall design approach will be presented and actualized according to general typologies of reactors: critical, subcritical (i.e., ADS), and “adiabatic.” The latter typology stands for critical reactors able to operate while maintaining unaltered the inventory of “valuable” isotopes (e.g., all TransUranics, TRUs) along the cycle (in an “extended” nuclear equilibrium state), thus not exchanging with the environment (hence the term adiabatic) any bulk materials except either natural or depleted uranium as an input stream, and fission products (FPs) as output. This solution, implementing the fuel-cycle closure within the reactor itself, represents the most charming candidate for giving body to the sustainable nuclear development aimed by the Generation IV initiative.

6.1 Introductory Remarks for LFR Core Design

Besides the main changes in the neutronic performance of the system, due to the hard spectrum set up by lead (see [◆ Sect. 3](#)), several other peculiar aspects must be accounted for in approaching the core design of an LFR.

These peculiarities, mainly related to the thermal-hydraulic properties of the coolant and the specific technological constraints introduced by the choice of lead, have to be added to the list of criteria and specimens commonly considered in the standard design route of FRs, for a proper core conceptualization of such systems.

6.1.1 Preliminary Evaluation of Lead and LBE Impact on Core Design

The low (here “low” is intended with respect to sodium in SFRs) coolant flow velocity in LFRs (because of structures erosion, see ▶ Sect. 6.1.2) imposes the need of large coolant channels to ensure the proper cooling of the system, immediately leading to low power densities in the core due to the high coolant volumetric fraction in the elementary cell (as mentioned in ▶ Sect. 1.1). Despite the fact that low pressure drops can be attained in the core, a first drawback impacts the overall dimensions of the core, which – on the other hand – has to comply with the need to reduce the system volume because of seismic risk. A second drawback is related to the specular reduction of the fuel volumetric fraction in the cell, which results in the need of increasing the cell reactivity (either by increasing the number of pins – modifying as a consequence also the system power – or the fuel enrichment – hence affecting the breeding capabilities). It must be noticed that the absolute magnitude of the latter effect is limited by the low-absorption cross sections of lead (see ▶ Sect. 3.1).

6.1.2 Technological Constraints for LFR Design

The first constraint following the choice of lead as coolant is related to the high melting point (327 °C) of the latter (123.5 °C in case of LBE), resulting in a lower limit on coolant inlet temperature T_{inlet} . According to this, and considering the need to mitigate the embrittlement of ferritic–martensitic steels (FMS, preferable to austenitic stainless steels, SS, for neutronics since the lower Ni content; see ▶ Sect. 5.2) because of neutron irradiation, a typical value for the minimum allowed temperature is set to 400 °C for lead (350 °C in case of LBE).

On the other hand, the high corrosion of FMS in the lead environment (see ▶ Sect. 5.1) imposes an upper limit on coolant outlet temperature T_{outlet} and/or on the ratio between the maximum linear power q' and the fuel-pin diameter d (determining the thermal head between the clad and the coolant to evacuate the fission power from the fuel pin). Recalling ▶ Sect. 5.1, the maximum wall temperature for the clad, T_{clad} , must be kept within 500 °C to prevent corrosion unless superficial coatings are foreseen: the preliminary evaluations on several aluminization techniques seem to confirm good resistances to corrosion up to 600 °C under active oxygen control.

Structural integrity must be preserved also against erosion phenomena: an upper limit of 2 m/s on the coolant flow velocity v through the channel must be therefore taken into account. As for corrosion, surface coatings may allow for maximum coolant velocities up to 3 m/s.

Finally, the hard spectrum of LFRs imposes stringent constraints to what concerns the structural damage (the number of displacements per atoms, DpA, indeed depends mainly on the hard tail of the neutrons spectrum). According to this, the in-pile residence time for fuel assemblies (FAs) made of FMS must be set to keep the fast-neutron ($E > 0.1$ MeV) fluence below 4×10^{23} n/cm²: hence the corresponding limit on maximum irradiation in an LFR might force a reduction in the planned fuel burn-up performance.

6.2 Conceptual Design Approach

The core design aims at determining the main parameters that univocally define a reactor configuration providing the required neutronic features and complying with all the (mainly)

thermal-hydraulic constraints (among these, the ones specific to lead are listed in [Sect. 6.1.2](#)). Since there is a strong interdependence among the core parameters, it is therefore a complex task to balance the pros and cons considering any consistent combination of these parameters.

If one defines a “reactors space” as a hyper-space, where the axes represent the independent core parameters, core design can be visualized as the research for an optimal operating point in this multi-parameter diagram: the technological limits introduce boundaries narrowing the viability domain, the parameter interdependence laws define hyper-surfaces representing the relationships between degrees of freedom and constraints, and the goal features provide the criteria to orient the choice for the most suitable operating point in the design domain.

6.2.1 Critical Reactors

In order to define the viability domain in the reactor space, each single constraint must be translated into an equivalent inequality defining the actual range for the corresponding parameter. In particular, the ranges for the coolant inlet temperature and the clad wall temperature are fixed according to

$$T_{inlet} = \max \{ T_{melt}, T_{embrittlement} \} + \Delta T_{margin} \quad (11)$$

$$T_{clad} = T_{corrosion} - \Delta T_{margin}. \quad (12)$$

The coolant flow velocity must be analogously limited according to

$$v \leq v_{erosion}. \quad (13)$$

Besides the specific constraints of LFRs, the maximum fuel temperature must be accounted for to prevent (with a sufficient margin) the possibility of fuel melting. According to this, the maximum fuel temperature can be translated into an equivalent upper limit on the maximum linear power, q'_{max} , expressed by the conductivity integral relation:

$$q'_{max} \leq 4\pi \int_{T_{f-g}}^{T_0} k_f(T) dT, \quad (14)$$

where $T_0 = T_{f,melt} - \Delta T_{margin}$ is the maximum allowable temperature for the fuel (at the center of the pellet), T_{f-g} is the temperature at the pellet surface (i.e., at the fuel–gap interface) and $k_f(T)$ is the thermal conductivity of the fuel.

Once the viability domain in the reactor space has been determined, the starting point for the neutronic design of a core is represented by the thermal-hydraulic design of the fuel pin and the coolant channel: as a matter of fact, both the pin radius r and lattice pitch p depend only on the thermal-hydraulic consistency of the system. Since the system must be dimensioned to prevent out-of-range working everywhere in the core, the most peaked fuel pin is assumed as reference for the design.

The core inlet and outlet average temperatures of the coolant can be identified according to the technological constraints introduced in [Sect. 6.1.2](#), so that the maximum outlet temperature in the hottest channel can be inferred in turn by introducing the expected estimate for the radial distribution factor f_{rad} . (The “radial distribution factor” can be defined as the ratio

between the power released from the hottest pin to the average pin power in the core. It should be noticed that uneven outlet temperature distributions are usually mitigated (by gaging the inlet orifice of wrapped FAs and/or by segmenting the core into zones with differently enriched fuels or different fuel volumetric fractions to flatten the power distribution) not to damage the thermal efficiency of the system.)

A preliminary evaluation of the active height h_{fuel} can then be introduced together with the gas plenum height h_{plenum} and, according to the latter, the clad thickness s_c determined to stand the pressure of gaseous FPs corresponding to the aimed BU.

By introducing an attempt value for the axial maximum-to-average factor f_{ax} (guessed or borrowed from previous calculations or analogous systems), an estimate of the power distribution along the pin can be inferred by assuming

$$q'_{max}(z) = q'_{max} \int_0^{h_{fuel}} \cos\left(\frac{\pi}{L}\left(z - \frac{h_{fuel}}{2}\right)\right) dz. \quad (15)$$

The parameter L in (15) must be computed so that the length of the arc over which the cosine is defined provides the assumed axial distribution factor, that is

$$\int_{-\beta}^{\beta} \cos(\alpha) d\alpha = \frac{1}{f_{ax}} \rightarrow \frac{\sin(\beta)}{\beta} = \frac{1}{f_{ax}} \Rightarrow L = \frac{\pi h}{2\beta}.$$

The coolant temperature profile along the hottest channel, $T_l(z)$, can then be retrieved as

$$T_l(z) = T_{inlet} + (T_{outlet} - T_{inlet}) f_{rad} \frac{\int_0^z q'_{max}(z') dz'}{\int_0^{h_{fuel}} q'_{max}(z') dz'}. \quad (16)$$

At last, the gap thickness, s_g , can be preliminarily dimensioned to host the fuel swelling related to the aimed BU, not to incur pellet-clad mechanical interaction (PCMI).

In order to guarantee the respect of the clad wall and fuel centerline temperature limits, the dimensioning of the fuel pin (or, equivalently, of the fuel pellet since all remaining radial dimensions have been already fixed), together with the evaluation of the maximum admissible linear power, can then be carried out by taking into account the thermal fluxes through the pin. As a matter of fact, the thermal resistance of the fuel, the gap, and the clad act in series in determining the succession of temperature gains providing the necessary thermal heads to evacuate the local fission power from the fuel to the coolant, in the typical temperature profile of  Fig. 13.

All these gains depend on the geometry and the materials of the pin only, as expressed by

$$T_0(z) - T_{f-g}(z) = \frac{q'_{max}(z)}{4\pi \langle k_f \rangle} \quad (17)$$

$$T_{f-g}(z) - T_{g-c}(z) = \frac{q'_{max}(z)}{2\pi k_g} \ln \frac{r_g}{r_f} \quad (18)$$

$$T_{g-c}(z) - T_{c-l}(z) = \frac{q'_{max}(z)}{2\pi k_c} \ln \frac{r_c}{r_g} \quad (19)$$

$$T_{c-l}(z) - T_l(z) = \frac{q'_{max}(z)}{2\pi h_l r_c}. \quad (20)$$

■ **Figure 13**
Radial temperatures profile in the elementary cell

In the previous system, single subscripts refer to materials (f for fuel, g for the gas filling the gap, c for clad, and l for the coolant), while coupled subscripts refer to materials interfaces ($f-g$ for fuel–gap interface, $g-c$ for gap–clad interface, and $c-l$ for clad–coolant interface); k_i indicates the thermal conductivity of material i , and h_l indicates the heat-transfer coefficient of the coolant.

It is therefore possible to put together (17–20) in order to obtain a single expression for the dimensioning of the pin (which can be limited to r_f):

$$T_0(z) = T_l(z) + \frac{q'_{max}(z)}{2\pi} \left(\frac{1}{2\langle k_f \rangle} + \frac{1}{h_g r_f} + \frac{1}{k_c} \ln \frac{r_f + s_g + s_c}{r_f + s_g} + \frac{1}{h_l (r_f + s_g + s_c)} \right) \quad (21a)$$

The same relation holds for hollowed fuel pins too, with minor changes: said γ_f the ratio between the hollow and pellet radii, (21a) becomes

$$T_0(z) = T_l(z) + \frac{q'_{max}(z)}{2\pi} (1 - \gamma_f^2) \left(\frac{1}{2\langle k_f \rangle} \left(1 + \frac{\gamma_f^2 \ln \gamma_f^2}{1 - \gamma_f^2} \right) + \frac{1}{h_g r_f} + \frac{1}{k_c} \ln \frac{r_f + s_g + s_c}{r_f + s_g} + \frac{1}{h_l (r_f + s_g + s_c)} \right). \quad (21b)$$

The logical process for the fuel-pin dimensioning can be represented by the dependencies scheme of ► [Fig. 14](#).

Once the fuel radius (and the eventual hollow one) has been defined, the coolant channel must be dimensioned. The pitch of the pins lattice, p , is to be chosen according to the average coolant temperature gain along the average channel. The increase of the coolant temperature in the channel is derived from the enthalpy balance equation

$$\rho_l A v c_p \Delta T = \frac{q'_{max}}{f_{rad} f_{ax}} h_{fuel}, \quad (22)$$

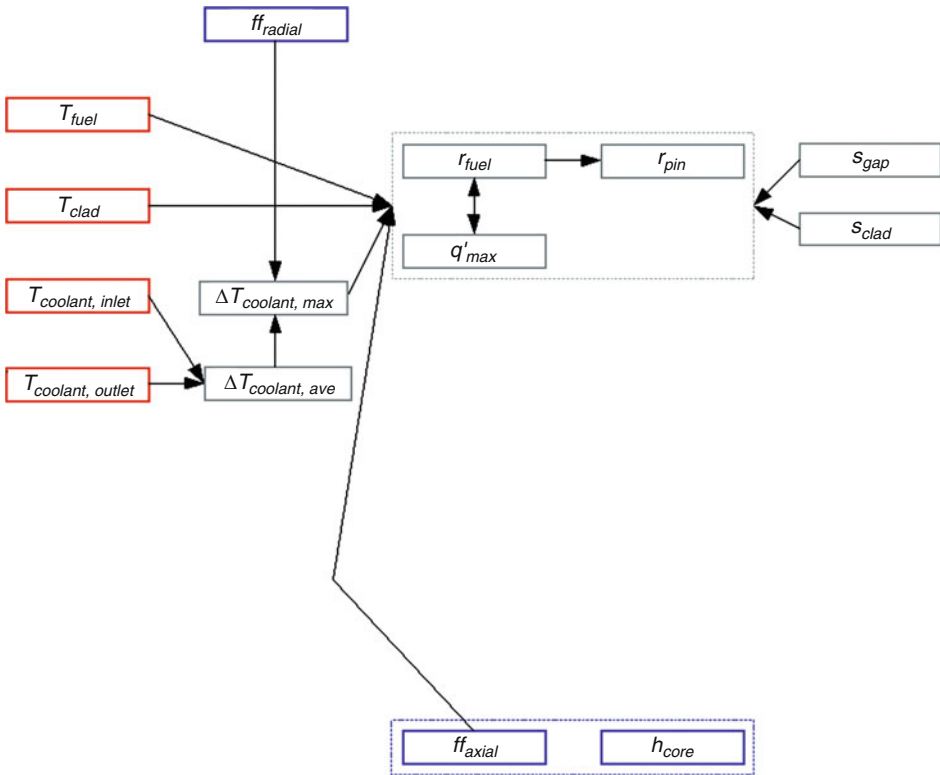

Figure 14
Scheme of core parameters dependences for fuel-pin diameter dimensioning

where ρ_l and c_p are the coolant average density in the channel and heat capacity, respectively (see Sect. 4.1) and A , the flow area of the channel, depends on the fuel-pin radius and lattice pitch according to

$$A = \begin{cases} \frac{p^2 \sqrt{3}}{2} - \pi r_c^2 & \text{hexagonal lattice} \\ p^2 - \pi r_c^2 & \text{square lattice} \end{cases} \quad (23)$$

The reference pitch value must be set by taking into account also the maximum allowed coolant velocity, (13), and the pressure drops through the channel.

The latter comes from the requirement of providing a sufficient natural circulation, in case of unprotected loss of flow (ULOF) accident, so as to guarantee nominal heat removal from the core within an acceptable temperature range ΔT_{ULOF} (ΔT_{ULOF} is the temperature gain along the channel, which is established in order to provide the required prevalence for natural circulation). According to core integrity, it is important that ΔT_{ULOF} settles so as to keep T_c below the critical clad failure temperature: as a matter of fact, the allowed temperature gain in accidental condition is higher than the normal one because the higher-temperature range is supposed to last for a limited time span (typically 30 min before human intervention), during which the clad must mechanically resist to the stresses due to the internal pressure of gaseous FPs for all surface

corrosion at the time of the accident.) According to this, the channel must be dimensioned so as to keep the pressure losses in.

The thermal head assessing in natural circulation can be easily determined as

$$\Delta p = \Delta \rho g h_{buoyancy} \cong 3\alpha \Delta T_{ULOF} \rho_{inlet} g h_{buoyancy}, \quad (24)$$

where g is the strength of the gravitational field, $h_{buoyancy}$ is the buoyancy height (i.e., the height of the primary circuit hot-leg, from core midplane to SGs midplane) and α is the linear thermal expansion coefficient of the coolant.

This forcing term must overtake the pressure drop through the whole primary circuit, expressed, separating the contribution within and outside the core, as

$$\Delta p = \Delta p_{core} + \Delta p_{system} = f \frac{h_{channel}}{D_h} \frac{\rho_l v^2}{2} + \Delta p_{system}, \quad (25)$$

where f is the effective friction term in the channel, D_h and $h_{channel}$ are, respectively, the hydraulic diameter and the length of the channel.

Putting together (24) and (25), and applying (22) to ULOF case, the following expression involving the geometry of the channel can be extracted

$$3\alpha \Delta T_{ULOF} \rho_{inlet} g h_{buoyancy} = f \frac{h_{channel}}{D_h \rho_{inlet} (2 - 3\alpha \Delta T_{ULOF})} \left(\frac{\langle q \rangle}{Ac_p \Delta T_{ULOF}} \right)^2 + \Delta p_{system} \quad (26)$$

for testing whether the temperature gain set up for coolant circulation is acceptable. In (26), the average power per fuel pin has been defined as

$$\langle q \rangle = \frac{q'_{max} h_{fuel}}{f_{rad} f_{ax}}.$$

The logical process of coolant channel dimensioning can be represented by the dependencies scheme of  Fig. 15.

Once the elementary cell has been determined, the axial and radial form factors are used to infer the average linear power in the core:

$$\langle q' \rangle = \frac{q'_{max}}{f_{rad} f_{ax}}. \quad (27)$$

This can be used in turn to calculate the total development of the fuel H needed to achieve the desired nominal power P_{th} :

$$H = \frac{P_{th}}{\langle q' \rangle}. \quad (28)$$

Combining the total development of the fuel H with the preliminary core height h_{fuel} to retrieve the number of fuel pins, n_{pins} , the radius of the core equivalent cylinder results

$$r_{core} = \sqrt{\frac{1}{\pi} n_{pins} A_{cell}} = \begin{cases} \sqrt{\frac{H}{\pi h_{fuel}} \frac{p^2 \sqrt{3}}{2}} & \text{hexagonal lattice} \\ \sqrt{\frac{H}{\pi h_{fuel}} p^2} & \text{square lattice} \end{cases}. \quad (29)$$

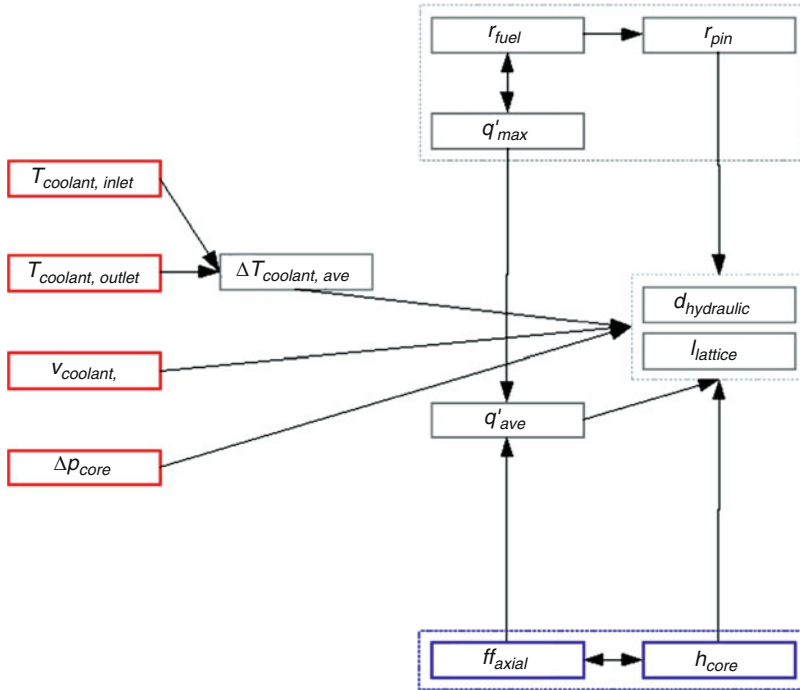

Figure 15
Scheme of core parameters dependences for coolant channel dimensioning

The aimed BU performances also allow to preliminary evaluate an in-pile residence time for the fuel. According to this, the core can be also segmented into batches for refueling, so to define the mean fuel aging at beginning of cycle (BoC) and end of cycle (EoC), averaging the in-pile residence time of the FAs belonging to different batches just before (EoC) and immediately after (BoC) the refueling. This approach leads to a one-batch approximation (which has been proven (Artioli et al. 2009) to be equivalent – in terms of criticality swing along the cycle – to the real n -batches refueling strategy) for the criticality analysis of the core.

The assessment of criticality can be performed taking into account that the overall shape of the system fixes the geometrical buckling of the reactor. Considering the system as a homogeneous volume V , the neutrons net balance, expressed as the ratio of the material buckling upon the geometrical one, can be translated into a balance between the net production in the reactor over the net leakage from the latter:

$$\frac{Prod}{Leak} = 1 \Rightarrow \frac{\int_V v \Sigma_f \phi dV - \int_V \Sigma_a \phi dV}{\int_V \nabla \cdot \vec{j} dV} = 1. \quad (30)$$

The volumes in the cells are fixed by the thermal-hydraulic analysis of the channel. The neutron spectrum is, therefore, also fixed by the volumetric fraction of the coolant, fuel, and structural materials in the cell. For criticality, neutronic calculations must be performed to assess the composition of the fuel (i.e., its enrichment), which is used as an almost free parameter to match the

required reactivity during the cycle and the power distribution flattening: as a matter of fact, the fuel must be enriched so to adjust the material buckling coherently with the geometrical one. The increase of the fuel enrichment both acts in increasing the fission term and in reducing the absorption one (i.e., the fissile is added to the detriment of the absorbing fertile).

It is clear that modifying the mutual abundances of fissile and fertile also changes the breeding capacity of the system, which could represent a design goal acting as feedback parameter in the design process; the same is valid for the eventual dispersion of MAs in the fuel. Furthermore, it is to be noticed that the enrichment also determines the flux level, according to the fixed power density in the fuel: the higher the enrichment, the lower the flux needed to achieve the same power density

$$q' \propto \phi \rho_{\text{fuel}} \sigma_f. \quad (31)$$

For instance, in designing experimental reactors, the flux level could represent a binding criterion: again, also the peak neutron flux can be used as a feedback parameter for core design.

As a matter of fact, the collection of resulting output performances due to the present core configuration should be used as feedback to adjust the core design in order to achieve completely all the aimed goals, in an iterative process.

The overall dependencies scheme for core design is shown in  Fig. 16.

Case study: ELSY

The technological constraints in ELSY design were fixed as follows:

- $\max\{T_0\} = 2,100^\circ\text{C}$ to prevent traditional MOX fuel melting
- $T_{\text{inlet}} = 400^\circ\text{C}$ for limiting structurals embrittlement

 Figure 16

General scheme of core parameters dependences

■ **Table 10**
First issue of ELSY core parameters

Parameter	Reference value
Fuel pellet (solid) radius	4.50 mm
Gap thickness	0.15 mm
Clad thickness	0.60 mm
Fuel pin radius	5.25 mm
Pins lattice pitch (square)	13.9 mm
Active height	90 cm
Coolant velocity	1.61 m/s
Maximum linear power	347 W/cm

- $\max\{T_c\} = 550^\circ\text{C}$ for limiting corrosion under active oxygen control
- $\max\{v\} = 2\text{ m/s}$ for limiting erosion

An acceptable value of the coolant outlet temperature was also set to 480°C .

Under such hypotheses, and assuming also that in case of unprotected transient due to ULOF the cladding is allowed to reach a maximum temperature of 700°C when assessing natural circulation, the iterative design process led to the assessment of the core parameters. The resulting parameters are listed in [► Table 10](#).

The overall core layout (Sarotto et al. 2008) resulted by arranging all the fuel pins needed to achieve the aimed thermal power (1,500 MWth) according to square 21×21 pins patterns. The resulting 162 FAs have been organized to reproduce the pseudo-cylindrical core shown in [► Fig. 17](#).

The enrichments needed to ensure both criticality and power/FA distribution flattening (with a 1.2 limit for maximum-to-average power/FA ratio) for the reference core led also a unitary breeding ratio (BR), which permits a moderate criticality swing during the cycle, limiting therefore the anti-reactivity required to compensate it. On the other hand, the smear density of the fuel within the clad (0.89) allows a maximum fuel BU of 60 GWd/tHM, which is below the aimed value (100 GWd/tHM).

Considering the BU goal priority with respect to the BR one, the smear density had to be reduced to 0.84 in order to obtain the aimed BU. The adopted solution was to hollow the fuel pellet (2 mm hole diameter) without altering any other core parameter.

The removal of part of the fuel resulted in an increase of the enrichments to maintain the criticality. In first approximation (i.e., neglecting the reactivity gain due to the fewer captures by the lower U amount), it could be thought to create the hole in the pellet by selectively removing the U only, leaving unaltered the Pu amount by increasing its content (i.e., enrichment) in the remaining fuel. Within the clad, the total fuel volume is thus reduced by a factor

$$\frac{V'_f}{V_f} = \frac{\pi(r_f^2 - r_h^2)}{\pi r_f^2} = \frac{4.5^2 - 1.0^2}{4.5^2} = 0.95, \quad (32)$$

■ Figure 17

Preliminary ELSY core scheme (1/4) surrounded by dummy elements within the barrel and FA layout

which in turn can be ascribed to an equivalent loss of U only, according to

$$\frac{V'_U}{V_U} = 1 - \frac{1 - \frac{V'_f}{V_f}}{VF_U} = 1 - \frac{0.05}{0.83} = 0.94. \quad (33)$$

The achievement of the target BU implies thus a degradation of the BR according to the same relative reduction of U amount: as expected, the BR for the new system was found to be 0.94 (Sarotto et al. 2009).

Case study: ENHS

In the ENHS design scheme all the main dependences among the core parameters have been referred to the core pitch-to-diameter (p/d) ratio, inheriting the same approach of thermal reactors design. The desirable BR is therefore achieved by adjusting the core p/d ratio; moreover, the larger is the p/d ratio, the smaller become the coolant friction losses through the core and the larger becomes the power that can be removed from the core by natural circulation.

The technological constraints in ENHS design were fixed as

- $\max\{T_0\} = 900^\circ\text{C}$ to prevent metallic fuel melting
- $T_{inlet} = 400^\circ\text{C}$ for limiting structurals embrittlement
- $\max\{T_c\} = 600^\circ\text{C}$ for limiting corrosion

An acceptable value of the coolant outlet temperature was also set to 550°C .

The natural circulation goal can be achieved, smoothing the constraints to the core design, by tuning the height of the riser in order to adjust the thermal head to the actual pressure drops.

■ **Table 11**
First issue of the ENHS core parameters

Parameter	Reference value
Fuel pellet (solid) radius	5.630 mm
Gap thickness	0.870 mm
Clad thickness	1.300 mm
Fuel pin radius	7.800 mm
Pins lattice pitch (hexagonal)	21.216 mm
Active height	125 cm
Riser height	13 m
Coolant velocity	0.44 m/s
Maximum linear power	179 W/cm

The core design process led to the following core parameters (► [Table 11](#)) (Hong and Greenspan 2005).

The overall core layout resulted by arranging all the fuel pins needed to achieve the aimed thermal power (125 MWth) according to a uniform, core-wise hexagonal lattice. No FA has been introduced in the model, because of the modularity of the core: fuel pins are therefore directly connected to the lower diagrid to reproduce the aimed pseudo-cylindrical core configuration. ► [Figure 18](#) shows the ENHS battery module layout where both the core and the coolant riser are represented as resulting from the core design.

The enrichments needed to ensure the criticality for the reference core led to an insufficient BR (0.97) with respect to the aim of $\Delta k_{\text{eff}} \sim 0$. In order to increase the BR, the p/d parameter had to be adjusted to permit a reduction of the Pu amount, thus a higher U amount and, in turn, a higher BR.

The reduction of the fissile inventory can be obtained by increasing the intrinsic reactivity of the system, i.e., by a reduction of the capture losses in the coolant.

The aimed BR (1.02) was then obtained by moving to a lower p/d ratio (reducing the pitch): the optimal p/d ratio resulted then 1.34 (Greenspan et al. 2008).

The smaller flow area in the fuel cell (thus the higher pressure drops through the core) set the coolant velocity to a lower value, necessary to increase the driving ΔT (clad wall – coolant bulk) and thus the prevalence due to the thermal head. Nevertheless, the small reduction of the pitch required to adjust the BR (from 21.216 to 20.904 mm) allows a clad temperature still below the safety limits.

6.2.2 Subcritical Reactors

The recent interest in ADS systems has been driven by the possibility of setting up power reactors able to burn considerable quantities of MAs by eliminating the safety-related drawbacks due to the inclusion of MAs in the fuel: as a matter of fact, relying on a large margin to criticality

■ Figure 18
ENHS battery module layout and simplified sketch of its central region

allows to neglect the reduction of the delayed neutrons fraction of such systems, leaving room to increase the MAs content – from a neutronic point of view – at will.

The design of an ADS core must therefore take into account the two aims at optimizing the MAs-burning capabilities and producing energy: about these two main points the logics of the core design must be exploited to highlight the rationales for answering three basilar questions:

1. What exactly is meant by burn MAs “at best”?
2. How the burning capability can be optimized?
3. What about the two main goals whether they were contradictory?

A first consideration can be brought taking into account that the fuel of an ADS will be composed of a “driver” material, containing Pu, which is the main responsible for the criticality of the system, and the “target” MAs. The mutual abundances of Pu and MAs in the fuel set both fission and transmutation reaction rates: according to  Fig. 19, the higher the MAs content, the higher the reaction rates of MAs to Pu transmutation (overcoming the opposite Pu to MA transmutations).

Another important remark must be made to what concerns the normalization of the reaction rates in the system: according to the fission Q-value, for every terawatt hour (TWh) of energy produced, some 42 kg of fuel is actually fissioned, the contributions of Pu and MAs being split according to their mutual abundances. On the other hand, a different MA disappearance rate can be observed, representing the further net contribution of MAs to Pu transmutation: hence MA removal rates higher than 42 kg/TWh must be interpreted as 42 kg MAs actually fissioned, and the remaining transmuted into new Pu (the system would therefore act as a Pu breeder); vice versa, MAs removal rates lower than 42 kg/TWh imply that the complement is represented by Pu fissions, reducing the inventory of the latter (the system would also act as a Pu burner).

It is worth noticing that the rate of Pu production/removal directly impacts also the criticality swing along the cycle: according to this, and taking into account the accumulation of

 Figure 19

Fission and transmutation rates as a function of Pu and MA mutual abundances in the fuel

■ Figure 20

Fuel enrichment as a function of core size

poisoning FPs during operation, the goal of zeroing the criticality swing points at a Pu/MAs assortment in the fuel different from the one needed to obtain an equilibrium Pu content.

The last preliminary consideration takes into account that the Pu content in the fuel is set according to the required reactivity inventory for the system: assuming that the pin lattice is almost fixed because of thermal-hydraulic design (as for critical reactors, see previous subsection), the power size of the reactor can be translated into its geometrical size. According to this, the more pins are arranged in the core, the lower is the Pu content in the fuel to provide the aimed reactivity, as shown in [Fig. 20](#).

[Fig. 20](#) also highlights a direct relationship between the core power and the MAs burning performances: bigger cores allow the arrangement of a higher relative amount of MAs in the fuel, and thus provide higher MAs removal rates.

According to these introductory remarks, the previous three main questions can be answered, providing the final design strategy for an ADS core:

- Unless precise policies for producing new Pu are envisaged, the burning of MAs at best means that no “expensive” neutrons must be used to either burn or breed Pu, thus devoting all the net fission losses to MAs (-42 kg/TWh of MAs and 0 kg/TWh Pu balances, according to the so called “42-0” approach).
- Since looking for an MAs burning performance better than -42 kg/TWh is meaningless, the optimization leads to the research of the minimum cost of the TWh or, considering the velocity of burning 42 kg/h/TWh, the minimum cost of the deployed power (which is the same optimization required for the energy production).

Exploiting these general remarks, the design approach for an ADS core immediately follows, as depicted in [Fig. 21](#).

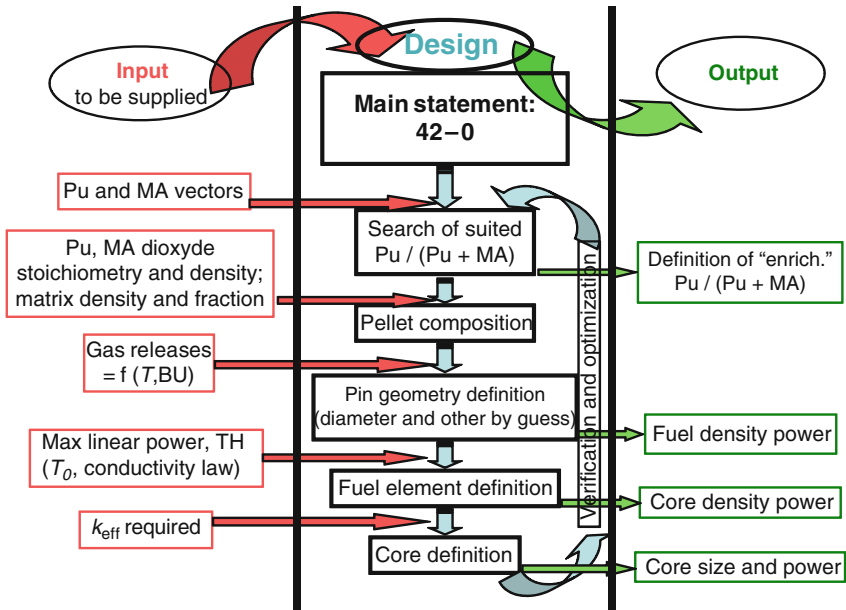

Figure 21
ADS core design scheme

Figure 22
Mutual interdependences between main core parameters

The mutual influence between the main core parameters (roughly shown in Fig. 22, where the arrows thickness represent the strength of the corresponding interdependences) can be better visualized into a properly compiled worksheet (“A-BAQUS” (Artioli 2007)), organized according to the general logic scheme of Fig. 21.

The A-BAQUS worksheet is organized per quadrants, with multiple axes representing the main core parameters. In the first quadrant, the two axes represent the relative Pu content in the fuel (thus the fuel enrichment e) and the percentage of inert matrix in the pellet, as shown in Fig. 23.

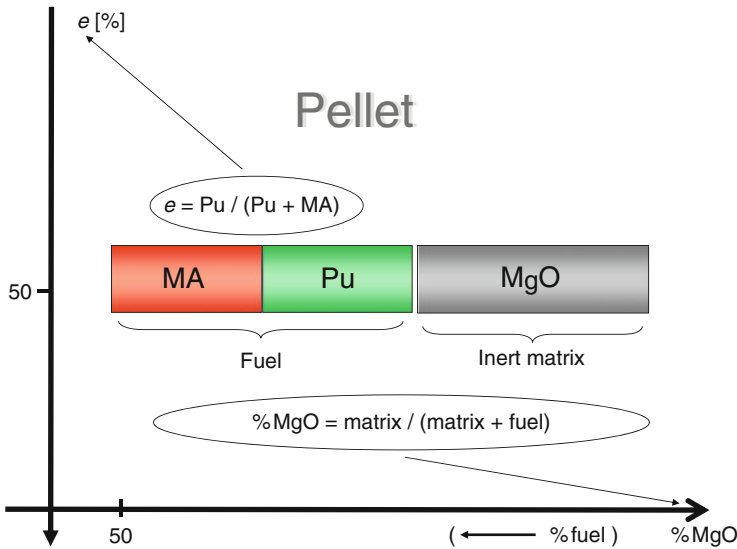

Figure 23
First quadrant of the A-BAQUS worksheet

In the same quadrant it is possible to add two more axes, relating the fuel enrichment to the MAs transmutation capabilities (● Fig. 24) and the criticality swing along the cycle (● Fig. 25) as described in the previous lines.

The fourth quadrant of the A-BAQUS worksheet (● Fig. 26) relates the fuel fraction in the pellet to the core thermal power. It is to be noticed indeed that, once the fuel pin and coolant designs are fixed, the higher the inert matrix fraction (thus the lower the fuel fraction), the more pins are needed to reestablish criticality (fuel enrichment being equal) increasing the core size and, in turn, increasing the core power.

The last (third) quadrant of the A-BAQUS worksheet relates the core power to the proton current to be provided by the accelerator module. It is known indeed that to maintain a constant power level during operation, a neutron source (by spallation from an in-core target) has to be provided, proportional to the aimed flux level in the system (thus to the core power P) and to the average number of neutrons per fission ν , and inversely proportional to both the fission Q -value and the average number of neutrons emitted by spallation per incident proton S . In order to relate the neutron source to the proton current, also the effective multiplication of the system, M_{eff} , and the specific multiplication of the neutron source, M_s , are to be accounted for. The overall law to determine the proton current i can be therefore expressed as

$$i = \frac{P\nu}{SQ} \frac{1 - k_{\text{eff}}}{\phi^* k_{\text{eff}}}, \quad (34)$$

where ϕ^* is the ratio between the source multiplication and the effective multiplication of the system:

$$\phi^* = \frac{M_s}{M_{\text{eff}}} = \frac{\frac{k_s}{1 - k_s}}{\frac{k_{\text{eff}}}{1 - k_{\text{eff}}}}.$$

Figure 24 Additional MA transmutation performances axis in the first quadrant of the A-BAQUS worksheet

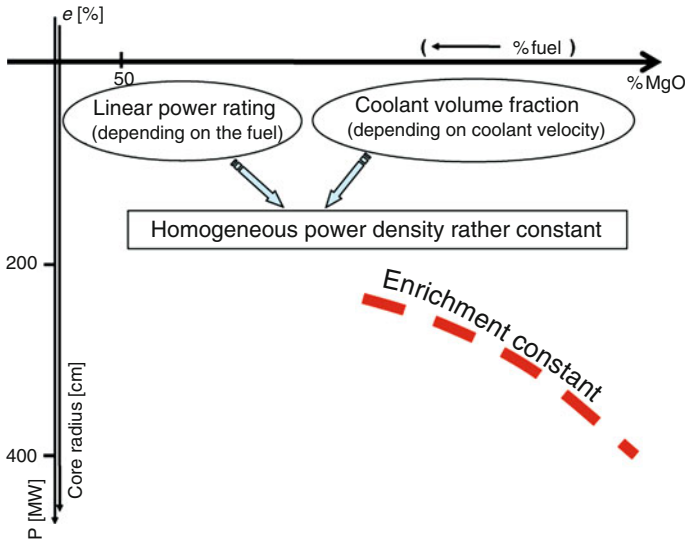

Figure 25 Additional criticality swing axis in the first quadrant of the A-BAQUS worksheet

■ **Figure 26**
Fourth quadrant of the A-BAQUS worksheet

Finally, since the criticality of the system may evolve during operation, the accelerator is required to provide a proton current range to keep the power constant along the cycle, as shown in [Fig. 27](#).

Case Study: EFIT

In order to design the EFIT ADS system, the A-BAQUS worksheet has been used to conceive the optimal configuration according to the aimed goal. Among the possible core optimizations (Δk swing = 0, high MAs transmutation rate, etc.), the 42-0 approach has been chosen as the leading criterion because of the general goal of “burning MAs at best” highlighted for the whole project (the zero-net Pu balance was also found consistent with the choice of a U-free fuel) (Artioli et al. 2008).

The technological constraints pointed out for the EFIT system are as follows:

- 50% minimum matrix volumetric fraction (VF) to ensure the thermal conductivity of a CERCER (Pu,MA) O_{2-x} -MgO (thus U-free) fuel within the pellet
- $\max \{T_0\} = 1,650 \text{ }^\circ\text{C}$ for preventing inert matrix melting/disintegration (corresponding to a $q'_{max} < 180 - 200 \text{ W/cm}$, depending on the matrix VF)
- $\max \{T_c\} = 550 \text{ }^\circ\text{C}$ for limiting corrosion
- $\max \{v\} < 1 \text{ m/s}$ for limiting erosion effects

An acceptable value of the coolant outlet temperature was also set to $480 \text{ }^\circ\text{C}$.

Starting from the design of an elementary cell respecting all the technological constraints listed above, a set of preliminary calculations have been carried out to provide the information necessary to draw the respective curves on the A-BAQUS worksheet for different core optimization strategies, as shown in [Fig. 28](#).

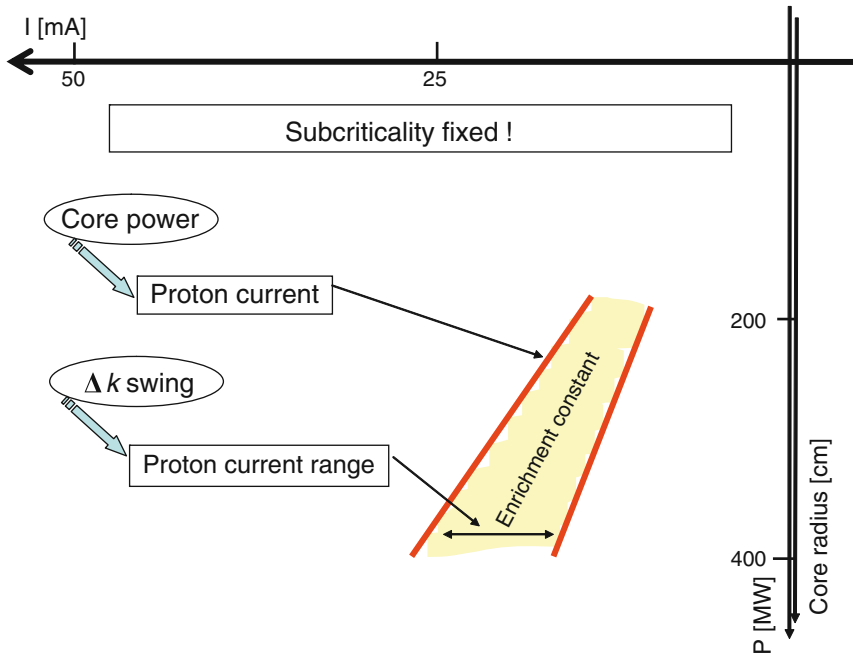

Figure 27
Third quadrant of the A-BAQUS worksheet

The core design process (Sarotto et al. 2008), targeting also a maximization of the power density to keep the core dimensions (because of seismic risk) and a power/FA distribution flattening for improving the thermal yield of the plant (aiming at a costs minimization for the produced terawatt hour), then led to the core parameters listed in Table 12.

Since the fuel enrichment must be constant to guarantee the aimed MAs transmutation performances, the core flattening task has been pursued by segmenting the core into three zones with different fuel volumetric fractions. In order to simplify the construction of different pins, in the inner zone the matrix volumetric fraction has been increased (with respect to the values in the intermediate and outer fuel), while the outer zone relies on enlarged pins (as far as possible), as sketched out in Fig. 29.

A general view of the final EFIT core, according to the 42-0 approach, is shown in Fig. 30.

6.2.3 Adiabatic Reactors

Aiming at designing adiabatic reactors, to ensure the sustainability of nuclear energy through the closure of the fuel cycle within the reactor itself, it is fundamental to clearly point out the parameters univocally defining the goal, borrowing the same approach implemented in the EFIT design (see Sect. 6.2.2).

In order to design an adiabatic reactor, as a first step the equilibrium isotopic composition of the fuel must be fixed (Artioli et al. 2010). This constraint in turn determines the intrinsic

Figure 28

The A-BAQUS worksheet showing some curves correlating the core parameters under different optimization strategies

Table 12

EFIT main core parameters

Parameter	Reference value
Fuel pellet (solid) radius	3.55/3.55/4.00 mm
Matrix volumetric fraction	57/50/50%
Gap thickness	0.16 mm
Clad thickness	0.60 mm
Fuel pin radius	4.31/4.31/4.76 mm
Pins lattice pitch (hexagonal)	13.63/13.63/13.54 mm
Active height	90 cm
Coolant velocity	1.00 m/s
k_{eff} (BoC)	0.97400
Δk swing (BoC – EoC)	500 pcm
Thermal power	400 MW
Proton current at BoC	13.2 mA

*Pin "size" to obtain the same max PD
but T_{out} should be unacceptable*

■ Figure 29

Pellet (fuel and matrix), coolant, and structural volumetric fractions in the different EFIT elementary cells

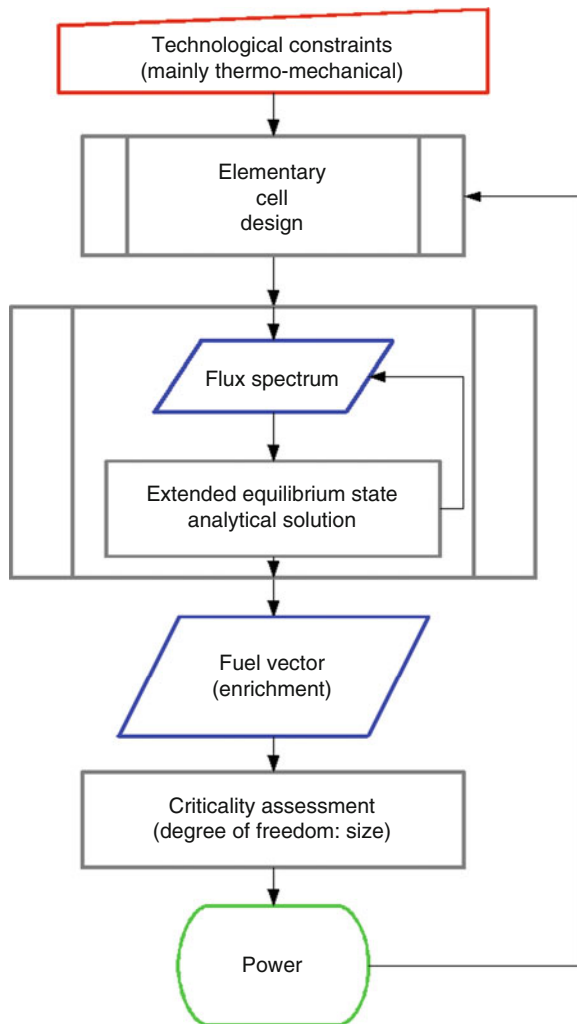

■ Figure 30

Final EFIT core scheme: different gray tones in the three innermost regions refer to inner, intermediate, and outer FAs position, arranged around the cylindrical spallation target and surrounded by four rings of dummy elements

reactivity of the fuel: hence, the core designer is not able to design nuclear reactors to achieve an aimed power by setting the core size, and consequently adjusting criticality by tuning the fissile content in the fuel (➤ Sect. 6.2.1); he must rather set up a critical arrangement for the given fuel.

According then to the thermal-hydraulic feasibility of the resulting core, and exploiting its viability, the system power will be univocally determined. This acts as – *si parva licet* – a “Copernican” revolution in the way of conceiving reactors, reversing the mental approach of subordinating the core design to its power: the whole design will be based on the fuel enrichment, fixed for the adiabaticity of the system; it will be possible then to tune the power by

■ Figure 31

Logical flowchart for adiabatic reactors design according to the new paradigm

iteratively adjusting the elementary fuel cell and the corresponding fuel vector acting on the fuel volume fraction. A logical scheme for the design of an adiabatic core, according to this new paradigm, is shown in [Fig. 31](#).

The starting point for the whole process is the definition of the equilibrium vector. In order to retrieve the volume fractions of the materials in the elementary fuel cell (which determine the neutrons spectrum), a preliminary dimensioning of the fuel pin and coolant channel, i.e., both the pin radius and lattice pitch, is needed. As described in the previous section ([Sect. 6.2.1](#)), it is possible indeed to determine those parameters a priori, by investigating the thermal-hydraulic consistency of the system according to the technological constraints represented by the allowable maximum temperatures for the coolant, the clad, and the fuel as well as the maximum allowable coolant velocity and pressure drops through the core.

Once the fuel vector has been determined, whether its reactivity (i.e., the k_{∞} of the elementary cell) is enough higher than 1, the number of pins to be arranged in the core to get the criticality of the system is univocally determined, balancing the material buckling with the geometrical one. The number of pins in turn defines the corresponding core power. According to this reverted scheme, the dependency among the core parameters can be represented by the scheme of [Fig. 32](#).

Hence, in an adiabatic core the dimensioning of the elementary cell unequivocally determines a core power. The matching between the aimed power and the criticality of the system can be set by acting on the fuel volume fraction, thus redefining from scratches the elementary cell in an iterative process (since the latter affects the neutron spectrum).

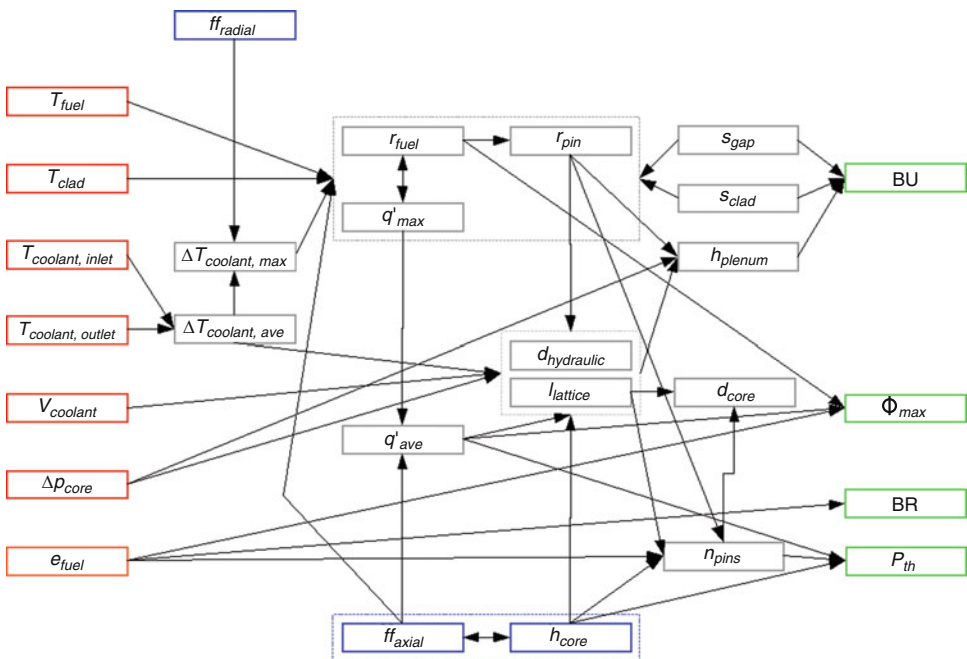

Figure 32

General scheme of adiabatic core parameters dependences in the new paradigm

6.3 Design Diagnostics and Post-Process Feedbacks

As described in the previous section, according to the technological constraints, the core design is carried out by exploiting the mutual relationships among the core properties in order to outline the most exhaustive working point with respect to the aimed performances. In general:

- At first, the design constraints are translated into a set of viability ranges for the directly implied parameters.
- Hence, axial and radial form factors are guessed (or inferred by previous analyses), corresponding to an initial hypothesis on the reactor shape.
- The remaining equations are then put together and solved, taking also into account the design goals, providing the complete set of core parameters.

After the final core configuration has been assessed, a finalization phase follows, performing detailed calculations in order to retrieve actual estimates of the core performances. Besides a careful analysis to check the consistency of both system criticality and core temperatures to the design assumptions, further information must be retrieved, to be used as feedback information for the whole design process as well as to infer the core management strategies and anti-reactivity requirements.

6.3.1 Overall BU Performances

The first feedback information comes from a detailed neutronics calculation accounting for the actual FAs refueling and reshuffling in the exact n -batches strategy to check the consistency of the one-batch approximation preliminary assumed for core design (see [Sect. 6.2.1](#)).

According to this more detailed evaluation of fuel BU performances, both the actual criticality swing and power distribution evolution in the core (as a matter of fact, a segmentation of the core into zones with different fissile content – the most common solution to achieve power/FA distribution flattening – implies differently enriched FAs breed unevenly, altering the total power contributions redistribution) during the cycle can be checked.

This detailed analysis allows the determination of whether fuel swelling due to gaseous FPs does not overcome the designed in-clad void space, originating excessive PCMI, as well as determining that the limit for the maximum DpA on cladding is not exceeded.

According to these results, the allowed in-pile residence time and fuel management strategy can be fixed.

6.3.2 Sizing and Placement of Control Systems

A last analysis must be performed to check whether the supposed control, compensation, and regulation systems are actually able to provide the required anti-reactivity for safe shutdown and cold arrest, as well as the anti-reactivity for criticality swing compensation and regulation during the cycle.

The results of this detailed analysis also provide useful information in order to resize or reposition the regulation/compensation and shutdown systems (taking also into account the required redundancy and differentiation) if needed.

6.4 Reactivity Coefficients

The evaluation of the reactivity coefficients for the system is the last-step in core design. A complete list of parameters such as the following must be computed:

- The coolant void reactivity worth
- The Doppler coefficient
- Dimension coefficients and
- Density coefficients

These parameters are computed to provide the required information for kinetic and dynamic analyses of the system: the viability of a core configuration is assessed indeed after a complete safety analysis concerning both operative and incidental transients.

The required reactivity coefficients are evaluated simulating perturbed configurations, where each parameter is singularly changed, and evaluating the criticality change for the system.

6.4.1 Lead Void Reactivity

The evaluation of the lead void reactivity coefficient is performed assuming all the coolant in the active zone is removed. Unlike SFRs, the lead boiling scenario can be assumed as unreal (the boiling temperature for lead being 1,749 °C, far from common reactor coolant operating temperatures, versus 883 °C boiling temperature for sodium): according to this, the complete voiding computation hypothesis is kept for coherence with sodium-cooled reactors rather than for realistic accidental scenarios, even assuming large coolant losses (as for LOCA, mitigated by the pool-type plant design) or strong injections of steam in the core following a massive SGTR.

Nevertheless, the evaluation of the reactivity insertion due to the complete voiding of the cooling channels leads, for present LFR designs, to the typical values reported in [Table 13](#).

It is worth noticing that different computation hypotheses are taken into account, referring to more realistic loss of coolant conditions. For instance, interesting results are obtained assuming that the core together with the upper and/or the radial reflectors is voided. Under such hypothesis, due to the high reflective power of lead, the coolant void coefficient is greatly reduced, even up to a sign change, as shown in [Table 14](#) for ELSY (Sarotto et al. 2009).

It is worth noticing that although negative void reactivity coefficient is not necessary for the safety of lead or LBE-cooled fast reactors, in any case it is possible to reconceive the core design to feature such a feedback. The main approaches for turning the positive void coefficient negative rely:

Table 13
Typical void reactivity coefficient of present LFR designs

System	Reactivity coefficient (pcm)
ELSY	+4,000
ENHS	+2,700
EFIT	+6,400
MYRRHA	-2,300

■ **Table 14**

Void reactivity coefficient of ELSY according to different voiding scenarios

Scenario	Reactivity coefficient (pcm)
Active zone	+4,042
Active zone and upper reflector	-1,232
Active zone, upper and radial reflectors	-5,251

- On an enhancement of the neutrons leakage probability, for instance by:
 - Reducing the fuel length
 - Incorporating neutron absorbers in the core boundary
 - Using a gas lift pump – that is, introducing gas bubbles throughout the coolant in the core and fission gas plenum regions
 - Incorporating neutron streaming channels in and adjacent to the core
- On the introduction into the core of materials having enhanced absorption cross section at high energy
- On the introduction into the core of materials that will keep the neutrons spectrum softer in case of coolant voiding

6.4.2 Doppler Effect

The Doppler effect, acting as a self-shielding reduction because of absorption resonances broadening, is a main issue in reactor dynamics. Its effect on reactivity, behaving almost logarithmically as a function of the fuel temperature, is usually expressed by evaluating the Doppler coefficient α , defined as

$$\frac{dk}{dT_f} = \frac{\alpha}{T_f}.$$

The Doppler coefficient is usually inferred by two criticality calculations on systems identical but for the fuel temperature. For ELSY (MOX fuel), a typical value of the Doppler coefficient results -700 pcm (Sarotto et al. 2009).

6.4.3 Dimension and Density Reactivity Coefficients

The reactivity variations of a system due to either dimensional or density perturbations provide useful information for transient analysis. The main dimension and density reactivity coefficients are expressed as

$$\frac{\partial \delta k / k}{\partial \delta p / p}, \quad (35)$$

where p represents the perturbed parameter and δp the corresponding elementary perturbation.

A typical set of elementary perturbations, singly introduced to modify the reference system, lists:

- A radial extension of the core by scaling all radial dimensions, with nominal densities
- An axial extension of the core by scaling all axial dimensions, with nominal densities (thus introducing some “slab” portion of core)
- A relative extraction of the control rods from their operative position
- A reduction of the coolant density in the active zone
- A reduction of the coolant density in the whole system
- A reduction of the fuel density
- A reduction of the steel density
- A reduction of the absorbers density

Some other coefficient may be added to the list above to complete the set of information regarding the core neutronics, such as:

- An increase of the Pu enrichments in the core
- A reduction of the U density in the fuel (maintaining the Pu density unchanged)
- A reduction of the Pu density in the fuel (maintaining the U density unchanged)

Once the set of elementary perturbations has been pointed out, some relative variations have to be assumed for each parameter in order to define the perturbed configuration to be simulated. A typical computational scheme (showing the values assumed for each elementary perturbation and the corresponding effect on criticality for ELSY (Sarotto et al. 2009)) is resumed in [Table 15](#).

By combining the computed criticality change to the relative perturbation of the corresponding parameter, the aimed dimension and density reactivity coefficients can be finally retrieved.

Table 15

ELSY computational scheme for dimension and density reactivity coefficients evaluation and corresponding reactivity effect

Perturbation	Variation	Δk_{eff} (pcm)
Radial extension of the core	$R_{\text{core}} + 2.5\%$	+239
Axial extension of the core	$H_{\text{core}} + 5\%$	+842
Partial extraction of absorbers from the core	$L_{\text{ins}} - 1 \text{ cm}$	+36
Reduction of coolant density in the core	$\rho_{\text{cool}}^{\text{core}} - 5\%$	+161
Reduction of coolant density in the whole system	$\rho_{\text{cool}}^{\text{sys}} - 5\%$	-22
Reduction of fuel density	$\rho_{\text{fuel}} - 5\%$	-1,614
Reduction of steel density	$\rho_{\text{steel}} - 5\%$	+170
Reduction of absorbers density	$\rho_{\text{abs}} - 5\%$	+13
Increase of Pu enrichments	$E_{\text{Pu}} + 1 \text{ pt}$	+3,507
Increase of U density in the fuel	$\rho_{\text{U}} + 5\%$	-1,190
Increase of Pu density in the fuel	$\rho_{\text{Pu}} + 5\%$	+2,734

6.4.4 Feedback Reactivity Coefficients

The dimension and density reactivity coefficients introduced in the previous subsection provide the elementary information to compute the feedback reactivity coefficients used for actual system transient analysis. As a matter of fact, every transient the system undergoes is the result of a complex combination of a multitude of single effects: for instance, in case of positive transient of power (TOP), every material in the core increases its temperature so that, besides the most immediate Doppler and density effects, also geometrical effects must be accounted because of the dilation of the whole system.

Therefore, in order to provide a unique combined reactivity coefficient, all the involved effects, examined in the previous step, must be related to a common parameter driving all the elementary perturbations. The most suitable parameter, which can also be identified the cause of all perturbations, is temperature. The aimed feedback reactivity coefficient will be therefore expressed as

$$\frac{\partial \delta k/k}{\partial T} = \sum_i \frac{\partial \delta k/k}{\partial \delta p_i/p_i} \frac{\partial \delta p_i/p_i}{\partial T}, \quad (36)$$

where the sum is extended over all the elementary contributions participating to the effect under investigation.

In general, also the feedback reactivity coefficients are separated to provide a more flexible input capability to security analysis tools. The most common feedback reactivity coefficients are therefore related to the diagrid-driven radial dilation of the core, and to the axial dilation of the latter.

To what concerns the diagrid-driven dilation feedback reactivity coefficient, the following expression relating the single reactivity coefficients is adopted:

$$\begin{aligned} \left. \frac{\partial \delta k/k}{\partial T} \right|_{\text{diagrid}} = & \frac{\partial R_{\text{core}}}{R_{\text{core}}} \left\{ \frac{\partial \frac{\delta k}{k}}{\partial \frac{\delta R_{\text{core}}}{R_{\text{core}}}} + \frac{\partial \frac{\delta \rho}{\rho}}{\partial \frac{\delta R_{\text{core}}}{R_{\text{core}}}} \left[\frac{\partial \frac{\delta k}{k}}{\partial \frac{\delta \rho_{\text{fuel}}}{\rho_{\text{fuel}}}} + \right. \right. \\ & \left. \left. + \frac{\partial \frac{\delta k}{k}}{\partial \frac{\delta \rho_{\text{steel}}}{\rho_{\text{steel}}}} + \frac{\partial \frac{\delta k}{k}}{\partial \frac{\delta \rho_{\text{abs}}}{\rho_{\text{abs}}}} + \left(1 - \frac{\partial \frac{\delta \rho_{\text{cool}}}{\rho_{\text{cool}}}}{\partial \frac{\delta \rho}{\rho}} \right) \frac{\partial \frac{\delta k}{k}}{\partial \frac{\delta \rho_{\text{cool}}}{\rho_{\text{cool}}}} \right] \right\}. \quad (37) \end{aligned}$$

A similar expression holds also in the case of axial dilation of the system:

$$\begin{aligned} \left. \frac{\partial \delta k/k}{\partial T} \right|_{\text{axial}} = & \frac{\partial H_{\text{core}}}{H_{\text{core}}} \left\{ \frac{\partial \frac{\delta k}{k}}{\partial \frac{\delta H_{\text{core}}}{H_{\text{core}}}} + \frac{\partial \frac{\delta \rho}{\rho}}{\partial \frac{\delta H_{\text{core}}}{H_{\text{core}}}} \left[\frac{\partial \frac{\delta k}{k}}{\partial \frac{\delta \rho_{\text{fuel}}}{\rho_{\text{fuel}}}} + \frac{\partial \frac{\delta k}{k}}{\partial \frac{\delta \rho_{\text{steel}}}{\rho_{\text{steel}}}} \right] \right\} \\ & + \frac{\partial \frac{\delta k}{k}}{\partial l_{\text{CRs insertion}}} \frac{\partial l_{\text{CRs insertion}}}{\partial T}. \end{aligned}$$

7 Reactor System

All primary system configurations proposed so far for an LFR are of the pool type (Cinotti et al. 2008, 2009; Alemberti et al. 2009; Smith et al. 2009). This is the obvious result of the cost and technical difficulties associated with a loop-type configuration. In fact at present a good design practice is to limit the lead speed to 2 m/s to reduce both pressure loss and erosion of structural material and this would result in large-diameter heavy tubes for a loop-type reactor.

Several configurations have been proposed for the primary system ranging from the natural circulation (SSTAR) solution, the enhanced circulation solution using gas injection (XT-ADS) in the riser, and the solution of forced circulation (ELSY).

Natural circulation is convenient for simplification of small reactor (tens of megawatts electrical), whereas forced circulation is necessary for compactness of large reactors (hundreds of megawatts electrical). Mechanical pumps are generally proposed because of the low efficiency of electromagnetic pumps in lead.

Because of the low allowed lead speed, the primary flow path must be simple and as short as possible to reduce the mass of lead to guarantee a successful mechanical behavior under seismic loads for which a reduced vessel length is an additional need.

7.1 Reactor Vessel and Safety Vessel

It is a classical approach in case of a liquid-metal-cooled reactor to have a reactor vessel that contains the primary system surrounded by a safety vessel that collects potential leakage of coolant from the reactor vessel.

The reactor vessel is in general shaped as a cylinder with a hemispherical bottom and a flat roof. The lead level is kept below the roof to accommodate the thermal gradient between the vessel in contact with lead and the colder roof. The reactor vessel can be supported directly by the roof as in SSTAR or by a connection below the roof to a conical shell as in ELSY. The object of the ELSY solution is to separate the mechanical load due to the lead weight from the thermal gradient of the connection to the roof.

The roof is a thick plate with penetrations for the components and the above-core structures that are laded on it.

The safety vessel can be conceived as an additional steel vessel surrounding the reactor vessel or can be integrated in the reactor pit as a liner of the concrete walls. In the latter case the safety vessel is protected, reactor side, by an insulating layer and is kept cold by a reactor concrete cooling system (RCCS) consisting of water pipes located inside the reactor pit concrete.

RVACS pipes can be located outside the safety vessel in the first case and between the two vessels in the second case.

The volume above the lead free level is filled with inert gas.

7.2 Reactor Internal Structures

The cylindrical inner vessel configuration is the classical configuration adopted for LFRs in natural circulation because of its simplicity and reduced pressure loss. This configuration is characterized by a core, located centerline in the bottom part of the reactor vessel and its upper structures surrounded by a cylindrical structure that contains inside the hot lead of the riser and,

■ **Figure 33**
 Detail of the ELSY primary system arrangement and coolant flow path

with the reactor vessel, delimits an annular volume of cold lead where the main components are located, namely the SGs, the pumps, the purification units, and the dip coolers of the DHR systems (● *Fig. 33*). The differential weight of the lead inside the riser and the lead in the riser produce the driving head necessary for the natural circulation of lead of the primary system. SGs can be freely installed inside the cold collector, with the inconvenience of a thermal stratification in the cold collector and in the reactor vessel or hydraulically connected with more complicate reactors internals and additional difficulties for component replacement.

In case of forced circulation, the hydraulic connection between the SG and the riser is definitely necessary.

A particular innovative solution has been identified in ELSY to adopt an inner vessel of perfect cylindrical shape, while ducts are mechanically connected to the SGs to be fed. The cylindrical inner vessel, as usual, constitutes the lateral restraint of the core but, differently from

previous solutions, is not connected to the core support plate, which can be avoided, thanks to more advanced solutions. The core support plate constitutes in general a critical component submitted to fast-neutron flux, difficult to replace and with difficulty/impossibility of ISI and repair. A simple cylindrical inner vessel can be supported in the upper part by the roof with a releasable connection for its replacement in case of need.

A peculiar load to be considered for the seismic design of the internals of an LFR is the load associated to lead sloshing that can be only partially mitigated by the adoption of seismic isolators. In fact seismic isolators of the reactor building drastically reduce the acceleration of the reactor structures but also lower the frequencies and move them closer to the frequencies typical of the sloshing phenomena.

To be removable, the internals can be hung from and supported by the reactor roof, a metallic plate welded to the reactor vessel. The reactor roof with its sealed penetration for the components together with the reactor vessel constitute the primary containment.

7.3 Steam Generator

Several types of SG have been proposed for LFRs, the most common being the helical-tube SG for which a deep experience exists for SFR applications. An innovative SG has been introduced instead in the ELSY project looking at several advantages in terms of reactor cost, safety, reactor operability, and simplicity of the lead flow path.

This innovative SG is composed of a stack of spiral-wound tube bundle (► Fig. 34) arranged in the bottom-closed, annular space formed by a vertical outer and an inner shells. The inlet and outlet ends of each tube are connected to the feedwater header and steam header, respectively, both arranged above the reactor roof.

The tube spirals, one spiral for each tube, two spirals per layer, are arranged one above the other and equally spaced.

The coolant flows radially through the perforated inner shell and, past the tube spirals, through the outer shell. This scheme is thermally almost equivalent to a pure countercurrent scheme because the feedwater in the tube circulates from the outer spiral to the inner spiral, while the primary coolant flows in the opposite direction from the inner to the outer shell of the SG. There is no window as primary coolant inlet port and consequently there is no constraint, typical of the classical design, to locate deep enough the bottom edge of the window to cope with the case of leaking reactor vessel, in fact the shell perforations extend below the accidental coolant free level and ensure adequate flow rate for core cooling. As a by-product, the SGU can be positioned at a higher level in the downcomer and the RV shortened, accordingly.

The suction pipe is an integral part of the SG bottom structure and extends outside the SG circular orthogonal projection to match the contour of the port cut out in the wall of the cylindrical inner vessel. The horizontal duct between the SG and the inner vessel normally constitutes a major obstacle for the replacement of the component to which is connected, namely, the SG or the inner vessel because of its interference with the smaller penetration through the reactor roof. Feeding the SG from the bottom offers the additional advantage of providing a procedure to extract the SG from the reactor vessel provided that the two geometrical condition of ► Fig. 35 are satisfied.

The first small displacement, radial, aims at disengaging the SG horizontal duct from the inner vessel taking profit of the clearance between the SG and its penetration through the reactor roof. The second displacement, vertical, brings the horizontal duct nearly in contact

■ Figure 34
Steam generator with a spiral-wound tube bundle

with the lower surface of the reactor roof. The third displacement, radial, brings the horizontal duct inside the orthogonal projection of the roof penetration. The fourth displacement, vertical, allows the complete extraction of the SG from the reactor vessel.

With removable SG's and PP's, also the cylindrical inner vessel can be designed as a removable unit, and eventually the design goal of all removable internals becomes feasible.

It should be noted that the reason in favor of the helical-tube SG, with respect to other conventional SG concepts, has always been that it copes better with high thermal loading, in spite of higher cost.

The rationale of the spiral-tube SG versus the helical-tube GV can be stated as follows:

- Tolerant to thermal loading as the helical-tube GV
- Predictable lower cost because the tube spirals are easier to assemble and require simpler supports
- Adequately fed also in case of coolant free level drop further to the reactor vessel leakage accident

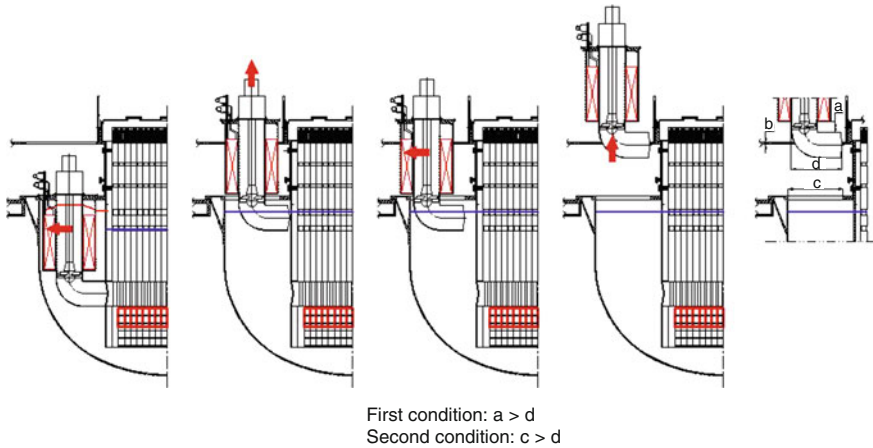

Figure 35
Geometrical conditions for the SG replacement with the connecting duct

- Less space required (tube bundle volume reduced of a factor 2 owing to the simpler-tube support system) and shell-side pressure loss reduced by about factor 2 (less tubes to flow through)

The installation of SGs inside the reactor vessel is a major challenge of an LFR design, which includes the need for a sensitive and reliable leak-detection system and a highly reliable depressurization and isolation system.

In ELSY careful attention has been given to the issue of mitigating the consequences of the SGTR accident to reduce the risk of pressurization of the primary boundary; to this end, innovative provisions have been conceived that make the primary system more tolerant of the SGTR event (see [▶ Sect. 2.3.1](#)).

7.4 Primary Coolant Circulation

Small-size reactors (e.g., SSTAR) can rely on lead natural draft, which can be of the order of 1,500 Pa for each meter of relative elevation between core and SG.

The use of airlift can deliver a draft of about 5,000 Pa for each meter of the riser length, and it can be a solution to shorten the reactor vessel of small-size reactors in comparison to the use of the natural circulation.

Forced circulation with mechanical or electromagnetic pumps is necessary to deliver a head of 1–2 bar necessary to reduce the size of large power reactors.

At present electromagnetic pumps has been disregarded by all LFR designers, presumably because of their low efficiency.

Mechanical pumps for LFRs are a suitable solution with high efficiency and great simplicity. A pump impeller placed a few meters deep in lead can guarantee the required net positive

section head (NPSH) and consequently a short shaft is sufficient to connect the pump impeller to the pump motor located on the reactor roof. No supporting bearing in lead is necessary. In case of ELSY for additional compactness, the shaft and the impeller of the pump are located in a free volume inside the spiral-tube SG.

8 Decay Heat Removal System

A LFR normally relies on the secondary system (the water-steam system, in the case of ELSY) to remove decay heat.

The water-steam system, however, is not a safety-grade system and additional, more-reliable safety-grade systems are necessary to meet the safety objectives.

A reliable system for DHR is the RVACS.

Unfortunately, the RVACS by itself can be used only in small-size reactors, the reactor vessel outer surface of which is relatively large to enable the transfer of the generated reactor decay power.

For a large power reactor it is necessary to install additional loops equipped with coolers immersed in the primary coolant, a DHR system hereinafter called the DRC (direct reactor cooling) system.

The DRC system is comprised of loops that operate with stored water (W-DHR).

The DRC loops, because of their greater complexity, will result in a lower reliability than the simple RVACS.

Stringent safety and reliability requirements of the DHR system will be achieved by redundancy and diversification. Diversification of the DHR system is provided with steam condensers on the steam loops.

Additional cooling functions are also necessary to permanently cool the concrete of the reactor pit and to control the air temperature of the reactor pit itself during ISI of the reactor vessel.

8.1 Reactor Vessel Air Cooling System

Different RVACS configurations have been proposed for LFR based on SFR experience. The RVACS system developed for ELSY consists basically of an annular pipe bundle of U-pipes arranged between the reactor vessel and the safety vessel in a nest-type configuration with atmospheric air flowing pipe-side in natural or forced circulation (➤ *Fig. 36*). In spite of the improvements in this design relative to earlier concepts, even in ELSY, the performance is sufficient only in the long term (after about 1 month after shutdown) and additional loops are needed for short-term DHR.

8.2 Water Loops and Associated Dip Coolers

The fact that molten lead does not react violently with air or water gives the designer some freedom in the choice of the coolants to be used in the DHR loops, the use of air and water remaining the preferred approach.

■ Figure 36
The nest configuration of the ELSY RVACS

A typical scheme of a DRC system for LFR based on water, the W-DHR loops, with coolers immersed in the primary system, is presented in ▶ Fig. 37.

Each W-DHR loop is made of a cooling water storage tank, a water–lead dip cooler, interconnecting piping, and steam vent piping to discharge steam to the atmosphere.

The dip cooler tube bundle is made of bayonet tubes (see ▶ Fig. 38). The bayonet consists of three concentric tubes, the outer two of which have the bottom end sealed. Water evaporation or air heating takes place in the annulus between inner and the intermediate tube. The annulus between the outer and intermediate tube is filled with He gas at a pressure higher than the lead pressure at the bottom end of the bundle. All annuli are interconnected to form a common He gas plenum, the pressure of which is continuously monitored. A leak from either wall of any of the outer tubes is promptly detected because of depressurization of the common gas plenum.

The proposed bayonet RC dip coolers are different with respect to classical bayonets, which consist each of only a pair of concentric tubes. The two outer tubes do not constitute a double walled tube, but are mechanically and, thermally decoupled. This configuration allows localizing the most part of the thermal gradient between lead and boiling water across the gas layer,

■ Figure 37

The DRC W-DHR process scheme

avoiding both risk of lead freezing and excessive thermal stresses across the tube walls during DHR steady state operation and transients.

The typical outer diameter of the outer tube is about 25 mm.

8.3 Steam Condensers on the Steam Loops

Steam condensers on the steam loops provide diversification of the DHR system. The steam condenser is immersed in a water pool and connected at the inlet to the main steamline and at the outlet to the feedwater line. When main and feed line are isolated and the isolation valve below the bottom header of the condenser is opened, the system is able to remove decay

■ Figure 38
Bayonet tubes of the DHR dip coolers

power using the SG tube bundle and by steam condensation returning the condensate to the feed line.

9 Nuclear Island

The following considerations on LFRs are based on the hypotheses of a central reprocessing and fuel fabrication plant physically separated from the reactor. This is applicable to both the small reactors (SSTAR type) and large reactors (ELSY type).

As regards to the spent fuel reprocessing and fabrication of fresh fuel, the situation of the LFR is similar to that of the SFR.

A significant difference between the two LFR systems is that SSTAR foresees the supply and replacement of the entire core, whereas ELSY foresees quite standard operational practices with periodic access to the core for fuel handling and partial replacement of the core.

It should be noted that the genesis for the SSTAR concept was the idea of developing a reactor that was, by design, low in proliferation risk and therefore deployable virtually anywhere in the world. The objectives resulting from this goal included factory fabrication (and fuelling) transportability of the reactor system to the site and installation without the requirement for handling fresh fuel or for developing a fuel supply infrastructure ultra-long core life to enable long-term operation without refueling and robustness and simplicity of design (e.g., reliance on natural convection flow for heat removal) to minimize operational complexity and maintenance requirements.

In the case of ELSY, considerable work has been carried out to define the overall plant layout.

► **Figure 39** below provides an overview sketch of the current reference plant layout.

The reference design shown incorporated forced-draft cooling towers. A second option has also been studied based on natural-draft cooling towers.

The ELSY reactor building is sixstoried, two stories of which are below ground level. It is of cylindrical shape. Its base plate, located below grade, rests on seismic supports and a single foundation slab. The lowest floor is the storage area for fresh and spent fuel assemblies.

With respect to spent fuel, it is possible either (i) to store all spent fuel inside the reactor building or (ii) to provide a limited storage capacity inside the reactor building (namely, sufficient storage for a single core) with additional capacity in an auxiliary dedicated building.

The reactor building is designed to withstand anticipated earthquake stresses and it is provided with double barrier containment. The outer containment barrier is made of reinforced concrete with a steel liner on the inner surface, and is designed to withstand the double-ended rupture of one main steam manifold.

■ **Figure 39**
ELSY general layout

The ARE performs as the first containment barrier and contained work area whenever the vessel head is removed and in-vessel components and fuel assemblies are lifted from the reactor vessel by the means of large and small cranes, respectively, both cranes being arranged in the ARE.

Besides the reactor vessel, the reactor building houses water storage pools required to supply the safety-grade DRC system and the piping for the RVACS. Two additional water storage pools for the secondary loops reactor cooling system are located outside the reactor building at both sides of the steam tunnel. The three DHR systems are connected to four chimney stacks, allowing for the release of the RVACS hot air and the steam of the other systems.

The four chimneys are arranged symmetrically around the reactor building, one chimney stack in each quadrant.

The reactor building is supported by seismic isolation bearings to decouple the building from the ground, lengthening the period of the building, and lowering the response for the structures.

10 Concluding Remarks and Open Issues

The LFR systems offer great promise in terms of the potential for providing cost-effective, simple, and robust fast reactor concepts that are essential to long-term sustainability of the nuclear energy option.

Recent efforts, particularly in the development of the ELSY concept, have gone a long way toward verifying the advantages of lead-cooled systems. Clearly additional work needs to be done, but overall, the prospects continue to appear very positive.

ELSY aims at demonstrating the possibility of designing a fast reactor using simple engineered technical features, while fully complying with the Generation IV goals of sustainability, economics, safety, proliferation resistance, and physical protection.

The elimination of the intermediate cooling system and the compact and simple primary circuit with all internal components removable are among the features to assure reduced capital cost and construction time, competitive electric-energy generation, and long-term investment protection.

The design of the industrial prototypes of the central station LFR and of the SSTAR should be planned in such a way as to start construction as soon as beginning of the TPP operation at full power has given assurance of the viability of this new technology.

Molten lead has the advantage of allowing operation of the primary system at atmospheric pressure. Low doses to the operators can also be anticipated, owing to lead low vapor pressure, high capability of trapping fission products, and high gamma radiation shielding.

In case of leakage from the reactor vessel, the free level of the coolant can be designed such as to guarantee the coolant circulation through, and the safe heat removal from, the core. Any leaked lead would solidify without significant chemical reaction affecting the operation or performance of surrounding equipment or structures.

Fuel dispersion dominates over fuel compaction, thus reducing considerably the likelihood of the occurrence of severe re-criticality events in the case of core disruption. In fact the lead density, which is slightly higher than the fuel density, and convective streams make it rather difficult to imagine scenarios leading to fuel aggregation with subsequent formation of a secondary critical mass, in the event of postulated fuel failure.

The use of MOX fuel containing MA increases proliferation resistance because of the difficulties in partitioning pure Pu from this nuclear material.

Despite the high density of lead, the pressure loss can be kept pretty low (about one bar across the core for a total of about 1.5 bar across the whole primary system) because low neutron energy losses in lead allow for a larger fuel rods pitch. Moreover, lead allows a reliable natural circulation of the primary coolant, which results in a suitable grace time for operation and simplification of control and protection systems.

The use of a coolant chemically inert with air and water and operating at atmospheric pressure greatly enhances physical protection. In the case of accidental air ingress, in particular during refueling, any produced lead oxide can be reduced to lead metal by injection of hydrogen gas and the reactor operation safely resumed.

There is less need of robust protection against the risk of catastrophic events, initiated by acts of sabotage, because there is a little risk of ignition and fire propagation. There are no credible scenarios of significant containment pressurization.

The hard neutron spectrum of LFRs (because of the low moderation and neutron-absorption properties of lead) allows both an efficient use of the fuel and a high number of neutrons per fission: according to this, the core of an LFR can be easily designed to provide a unitary breeding ratio along with long core life and high fuel burn-up.

Furthermore, the hard neutron spectrum significantly reduces MA generation, a fact that is basic for the envisaged close fuel cycle. The possibility of relying on a low fraction of MAs in the equilibrium fuel allows more flexibility in exploiting LFRs for MAs burning both in critical and subcritical cores. Proper design of the critical core, for instance, can be achieved by the adiabatic core concept, i.e., a core self-sustaining in both Pu and MAs, thus being able to be fed with either natural or depleted uranium only, and producing fission fragments as the only waste to be disposed of in a geological repository. Lead-cooled ADS systems, on the other hand, can be envisaged for large-scale MA transmutation, exploiting lead properties also for the spallation target. The EFIT core design demonstrated the possibility of effective MA burning (along with a zero Pu balance) and electricity generation.

Corrosion of structural materials in lead is one of the main issues for the design of LFRs.

A larger effort has been dedicated to short- or medium-term corrosion experiments in both stagnant and flowing LBE. A few experiments have been carried out in pure Pb and knowledge is still missing on medium- or long-term corrosion behavior in flowing lead. Experiments confirm that corrosion of steels strongly depends on the operating temperature and amount of dissolved oxygen. Indeed, at low oxygen concentration and associated reducing environment, corrosion brings about dissolution of the structural steel instead of creating the oxide layer by surface oxidation. Moreover, a relationship between oxygen concentration, coolant flow velocity, temperature, and stress conditions of the structural material has been observed as well. It has been demonstrated that, generally, in the low-temperature range, e.g., below 450 °C, and with an adequate dissolved oxygen activity, ferritic–martensitic and austenitic steels build up a stable oxide layer, which behaves as a barrier against leaching of steel elements providing thereby effective corrosion protection.

Conversely, in the higher-temperature range, i.e., above ~ 500 °C, corrosion protection through the oxide barrier by dissolved oxygen only seems to fail. Indeed, a mixed corrosion mechanism has been observed, whereby both metal oxide formation and dissolution of the steel elements occur. Especially in the high-temperature range, the corrosion resistance of structural materials can be enhanced by FeAl alloy coating.

Thus, at the present status of development of the corrosion protection technology, near-term deployment of the LFR is possible only by limiting the mean core outlet temperature to around 500 °C. The possibility of operating at higher temperature offered by the high boiling point of lead will be exploited only in the longer term after successful qualification of new, high-temperature materials such as ODS steels, ceramics, and refractory metals and relevant corrosion protection techniques.

Acknowledgment

The work on LFR in GIF is supported by the European Commission through the Euratom Framework Programmes, by the US Department of Energy Generation IV Nuclear Energy System Initiative and by the Tokyo Institute of Technology. The ELSY, CDT, and IP-EUROTRANS consortia in Europe are coordinated by Ansaldo Nucleare, SCK-CEN, and KIT, respectively.

Abstract: The technology of nuclear power could be quite different from today's if it had been practical in the beginning to supplement fission neutrons with accelerator-produced neutrons. The purpose of this chapter is to illustrate the possible benefits of implementing supplementary neutrons from accelerators in an optimized reactor. GEM*STAR (Green Energy Multiplier* Subcritical Technology for Alternative Reactors developed by *Accelerator Driven Neutron Applications* (ADNA Corp) is a subcritical thermal-spectrum reactor operating with molten salt fuel in a graphite matrix and in a continuous flow mode initially at $k_{\text{eff}} = 0.99$. The model described is able to use natural uranium as fuel and generate twice as much electric power as a light water reactor (LWR) generates from the same mined uranium. GEM*STAR at $k_{\text{eff}} = 0.99$ also can be fueled with unprocessed LWR spent fuel, and it can generate as much electricity as the LWR had generated from the same fuel. Because GEM*STAR uses liquid fuel, it can recycle its own fuel at $k_{\text{eff}} = 0.95$ without any operations on the fuel. This recycle can be repeated several more times, always without reprocessing, as accelerator or fusion neutron generation technology development reduces the cost of neutrons. GEM*STAR therefore increases the electricity from mined uranium many times while avoiding the serious problems of current nuclear-power technology arising from enrichment, reprocessing, fast reactor deployment, and near term high-level waste storage. GEM*STAR also offers technology for nuclear energy generation that promises reductions in nuclear electricity cost and eliminates major proliferation concerns. The technology can use a modest source of intermittent "green" electricity such as wind or solar as input power to drive an accelerator that, in effect, multiplies the green energy by a factor of about 30 with 24–7 continuity and without compromising any environmental objectives of green energy sources. This chapter is not a complete history of molten salt, graphite, and accelerator technologies, but a description of how these orphan elements of nuclear power development may be integrated for a GEM*STAR solution to the main barriers that constrain the full deployment of today's nuclear power technology.

1 Introduction

The fundamental problem for nuclear power technology has always been too few neutrons per fission. The performance of the earliest reactors was limited by the number of neutrons from fission of ^{235}U and the loss of too many of these neutrons to capture in ^{238}U . Uranium enrichment technology was therefore developed to overcome parasitic losses of neutrons. As a consequence, enrichment coupled nuclear power to nuclear weapons, and this coupling has always been a burden to nuclear power.

In addition, concerns about long-term uranium supply have been present from the beginning of the nuclear age; therefore, fast breeder reactors (FBR) were introduced to convert ^{238}U to ^{239}Pu , which could be used as a fission fuel. However, ^{239}Pu is also an excellent weapon material, and so the coupling between nuclear energy and nuclear weapons was tightened further.

Light water reactors (LWRs), which produce ^{239}Pu and consume some of it as fuel, have been the primary source of the world's nuclear energy production till the present. Both the LWR and the breeder reactor spent fuel require reprocessing to extract the plutonium for energy production and for removal of fission products that otherwise would spoil the breeder reactor neutron economy through useless neutron absorption. The scale of reprocessing necessary for nuclear to provide a substantial part of the world's energy supply requires a major international reprocessing industry and an accompanying worldwide plutonium economy. Reprocessing further binds nuclear energy to nuclear weapons.

Advocates of reprocessing make a distinction between weapons plutonium (W-Pu), with about 7% of ^{240}Pu accompanying the ^{239}Pu and commercial plutonium (C-Pu), with about 30% of ^{240}Pu . Neutrons from the spontaneous fission of ^{240}Pu cause problems in starting the chain reaction of the nuclear weapons that introduces significant uncertainties in the explosive energy release. How useful C-Pu might be for nuclear weapons is not discussed in the open literature, but US President Carter, a nuclear engineer, issued an executive order against reprocessing in the USA owing to nuclear weapons proliferation centered on C-Pu concerns that stayed in effect until the second Bush administration. The second Bush administration instead proposed a Global Nuclear Energy Partnership (GNEP) (DOE 2008) that placed strict controls on where and who would do reprocessing that obviously recognized a nuclear weapons issue from C-Pu.

It seems unlikely that the Democratic Obama administration will support either breeder reactors or reprocessing under GNEP. So the controversy over reprocessing, which has extended for 30 years, and the coupling it provides between nuclear weapons and nuclear energy seems likely to remain an issue for the foreseeable future. This concern along with others have created a widespread perspective in the USA and perhaps elsewhere that nuclear technology will not develop beyond today's LWRs, which are viewed as only an interim solution to the CO_2 problem until other "green energy" alternatives can be developed.

Another problem accompanying reprocessing is the separation of high-level nuclear waste from fission products and leak-through to the waste stream in chemical reprocessing of higher actinides including neptunium, plutonium, americium, and curium. Near-term reprocessing also requires a near term final solution for the reprocessing wastes with the present US solution being near-term repositories such as Yucca Mountain (now canceled). A fundamental flaw to a single geologic storage site for nuclear waste for a nation of the size of the USA is the obvious unfairness of forcing what much of the public feels to be the most dangerous waste on one state perceived to be politically the weakest.

The need for some form of geologic storage is advanced by those who oppose reprocessing and advocate the "once-through" approach where both the accumulated and future LWR spent fuel is sent directly to geologic storage (Bunn et al. 2003; von Hippel 2007). This viewpoint implies that the uranium resource is large enough, so that, by the time there is a need for conversion or breeding of ^{238}U into ^{239}Pu , alternative nonnuclear energy sources could take care of the world's energy needs. Repositories used in this way are also future mines of plutonium and the point has been made (Peterson 1996) that it would be much faster and much cheaper to mine plutonium from the world's many repositories instead of taking either the enrichment or the reactor approach to weapons material production. We would add here that the US Nuclear Regulatory Commission's concerns about performance of Yucca Mountain extend well beyond the 13,000 years, the time required for ^{240}Pu to decay to ^{236}U , resulting in the conversion of stored LWR plutonium from C-Pu to W-Pu. Considering the problems with geologic storage both from just the waste management perspective and as plutonium mines, any alternative nuclear technology approach should include an approach to geologic storage that addresses both nagging concerns.

The obvious problems of nuclear power summarized above including enrichment, reprocessing, fast reactors for breeder or conversion, and geologic storage should *all* be addressed by any new fuel cycle technology. There is little advantage to addressing one or two and leaving the others hanging as is the case for the several Generation IV reactor technologies. In addition, any alternative system must be at least economically competitive with today's LWRs as even new

LWRs face cost issues that move nuclear power costs uncomfortably close to other approaches for electricity production.

The Green Energy Multiplier* Subcritical Technology for Alternative Reactors (GEM* STAR) technology discussed later in this chapter appears to satisfactorily address the issues of proliferation, cost, and waste disposition. It is based on the beneficial combination of three technologies largely neglected since 1970 that substantially enhance the graphite thermal reactor neutron economy. The three technologies include (1) supplemental neutrons from accelerators, (2) liquid fuel in the form of molten salt, and (3) the selection and implementation of graphite to reduce graphite parasitic neutron capture and optimize neutron reflection. Some history on these three topics follows before the discussion of the integration of the three technologies into GEM* STAR.

2 Supplemental Neutrons from Accelerators

Cyclotrons and electrostatic accelerators played an essential and well known role in the early development of nuclear technology, and it was natural to apply them to the development of nuclear energy both in the weapons and energy realms. Thus, the first significant quantity of enriched ^{235}U was obtained from the large fleet of systems based on these technologies called Calutrons which was developed under the leadership of E.O. Lawrence of the UC Berkeley Laboratory. However, Calutron production of ^{235}U could not compete with the high production and lower costs of gaseous diffusion methods for the same purpose.

In the early 1950s, concerns about the US supply of uranium focused attention on the need to produce ^{239}Pu from neutron capture on ^{238}U . Lawrence brought much higher power accelerators into the picture as intense sources of neutrons around 1955 with the construction (Lawrence in the Cold War 2002) of Mark I of the materials test accelerator (MTA) in a hanger at an air force base in Livermore, California. The MTA was a drift tube linear accelerator (linac) designed for both high current and high energy with a diameter of 19 m and a length of 27 m, commonly referred to as “large enough to fly an airplane through.” The history of high vacuum technology annals refers to it as the most challenging vacuum project of the day. The accelerator required 18 MW of radio frequency (r.f.) power and intermittently reached unprecedented currents of 50 mA of deuterons at an energy of 10 MeV for an average power of 0.5 MW. The beam current was two million times larger than that of the Berkeley cyclotrons.

A Mark II version of the MTA was planned for another site to produce 1 A of 350 MeV deuterons with a beam power of 350 MW. The accelerator probably would have produced about ten neutrons per deuteron and ^{239}Pu at the rate of about 500 kg/year (enough for about 100 nuclear weapons per year). However, the discovery of abundant uranium in Colorado and New Mexico along with the success of plutonium production reactors at ORNL and Hanford, Washington ended the MTA initiative. The discontinuance of the MTA project in 1958 and of a major role of accelerators in large scale applied nuclear technology was a major disappointment to Lawrence, whose laboratory had discovered ^{239}Pu and also led in the development of both cyclotrons and linacs. He died the same year at the age of 57, and a major early role for accelerators in nuclear energy died as well. For the next 40 years, the advancement of accelerator technology for neutron production was driven by basic rather than applied science.

If the number of fission neutrons were about 25% lower, nuclear energy as we know it today would probably have not been possible, but almost certainly high power accelerator technology starting from the MTA would have advanced much faster, probably enabling economic

electricity production long ago from subcritical reactors anyway. The Mark II 350 MWb accelerator would have produced 250 times more beam power than the accelerator power specified later in this report for the production of 220 MW_e of electricity from the burning of natural uranium. An attempt was made in Canada to introduce accelerators into nuclear energy (Lewis 1966) with the intense neutron generator (ING) project that included an accelerator of 1 GeV protons with a current of 300 mA. The goal was to use accelerator technology to produce fissile material for reactors without enrichment, but the success of the Canadian CANDU reactor that burned natural uranium as fuel undercut the need for the ING.

The first major demonstration of a reliable high power accelerator did not occur until 1973 with the completion of the Los Alamos Meson Physics Facility (LAMPF) (Rosen 1973) that accelerated as much as 1.3 mA of protons to 800 MeV for a maximum beam power of 1 MWb. The typical LAMPF beam current was 1 mA. The next major effort for high beam power was the Los Alamos Accelerator Production of Tritium (APT) project (Lawrence et al. 1996) that included detailed design and costing for a 1.6 GeV linac with a continuous current of 100 mA at a beam power of 160 MWb. Costing was also done for powerful accelerators for a US Accelerator Transmutation of Waste (ATW) project (Smith et al. 1999) that used a pair of 1 GeV accelerators with 45 mA of beam power each producing a power of 45 MWb. Accurate costing is also available for the recently completed spallation neutron source (SNS) at ORNL with an energy of 1 GeV and a current of 1 mA. Accurate costing is also available for the continuous spallation neutron source (CSNS) designed (Shapiro et al. 2003) for BNL with a beam energy of 1.25 GeV and a current of 8 mA for an average beam power of 10 MWb. Of the four accelerators mentioned above after LAMPF, only the SNS was actually constructed.

A rough time-trend in neutron cost for linear accelerators is shown in  Fig. 1 with costs in 2008 dollars per gram (or per mole). The first point is the cost of neutrons from an electrostatic tandem accelerator used with a stopping length deuterium gas target as measured recently (Bowman et al. 2009b) with a proton energy of 15 MeV. The second point is an estimated neutron cost for the Los Alamos LAMPF accelerator, which is the first reliable proton accelerator operating near the megawatt range. The third point is for the SNS that was recently completed with firm cost numbers and a mercury target. Although the mercury target might not be practical for GEM*STAR, the solid target that replaces it will have a roughly equivalent neutron cost even if the source brightness is less than anticipated. The fourth point is estimated for GEM*STAR using a combination of six accelerators of 1.3 mA each and an energy of 0.5 GeV with costing based on the APT, ATW, SNS, and CSNS cost estimates as described later in this chapter. This lowest neutron cost is obtained by the use of a uranium target with beryllium multiplication and with a length somewhat less than the GEM*STAR graphite core dimension. Although the trend since 1970 seems to be a consistent reduction in cost by about two per decade, every technology has practical limitations and linear accelerators with spallation targets might not be reduced further by more than a factor of two or to about \$0.3 million per gram.

For a subcritical system with $k_{\text{eff}} = 0.99$, 40 g of neutrons per year is sufficient to produce about 1 GWe for 1 year. At \$0.05/kWh, this electricity can be sold for about \$450 million with the 40 g of neutrons costing \$24 million per year. Although implementing accelerator technology into nuclear power at the beginning of the nuclear age was out of the question, the million-fold reduction in neutron cost over the past 60 years strongly suggests the need to examine the economic viability for subcritical systems in 2010. GEM*STAR, with deep burning of natural uranium as fuel, promises economic competitiveness for nuclear energy and increased safety without the need for proliferation-prone enrichment, reprocessing, fast reactors, or near-term geologic storage and the associated additional costs of this burdensome infrastructure.

■ Figure 1

Approximate cost of neutrons per gram (or per mole) from high power linear proton accelerators. Although the long-term trend since 1970 is a reduction of about two per decade, the technology might be reaching its limits and further improvements below about \$0.3 million per gram might not be practical. For a subcritical system with $k_{\text{eff}} = 0.99$, 40 g of neutrons per year is sufficient to produce about 1 GWe for 1 year. At \$0.05/kWh, this electricity can be sold for about \$450 million with the 40 g of neutrons costing \$24 million per year as shown later in this report. Although implementing accelerator technology into nuclear power at the beginning of the nuclear age was out of the question, the million-fold reduction in neutron cost over the past 60 years strongly suggests economic viability for subcritical systems in 2010

The prospect for realizing this promise is boosted by the practical implementation of molten salt fuel and the use of improved graphite, both of which are described below.

3 Molten Salt Technology

Any discussion of molten salt technology must first start with the molten salt reactor experiment (MSRE) at ORNL in the 1960s described in detail in a 114 page report (Weinberg et al. 1970). The purpose of this experiment was to enable online liquid fuel reprocessing for the removal of fission products and to use other advantages of this approach to demonstrate the practicality of a thorium breeder reactor. The MRSE need not be described in detail here, but the introduction (Weinberg et al. 1970) to the record of the MSRE operation is quoted below.

The MSRE is an 8-MW_t reactor in which molten salt fluoride salt at 1,200 °F (700 °C) circulated through a core of graphite. Its purpose was to demonstrate the practicality of the key features of molten salt power reactors.

Operation with ^{235}U in the fuel salt began in June 1965 and by March 1968 nuclear operation amounted to 9,000 equivalent full-power hours. The goal of demonstrating reliability had been attained. Over the last 15 months of ^{235}U operation, the reactor had been critical 80% of the time. At the end of a 6-month run, which climaxed this demonstration, the reactor was shut down and the uranium in the fuel was removed very efficiently in an on-site fluorination facility. ^{233}U was then added to the carrier salt making the MSRE the world's first reactor to be fueled with this fissile material. Nuclear operation was resumed in October 1968 and over 2,500 equivalent full-power hours were produced with ^{233}U .

The MSRE has shown that salt handling in an operating reactor is quite practical, the salt chemistry is well behaved, there is practically no corrosion, the nuclear characteristics are very close to predictions, and the system is dynamically stable. Containment of fission products has been excellent and maintenance of radioactive components has been accomplished without unreasonable delay and with very little radiation exposure.

The conclusion of the Experiment Report (Weinberg et al. 1970) included the following:

From the months of operation and experiments a very favorable picture emerged. In properly designed equipment, handling the high-melting salt proved to be easy. Maintenance of the radioactive systems was not easy, but there were no unforeseen difficulties and control of contamination was, if anything, less difficult than expected. Fuel chemistry and materials compatibility lived up to expectations, showing no adverse effects due to the reactor environment. The noble gases, xenon and krypton, were stripped efficiently. It was found that noble metal fission products, whose behavior had hitherto been uncertain, partially plated out on metal surfaces and partially came off the salt surface as smoke, thus providing important information for future reactors. Although the operation of the MSRE showed that the design of some equipment and systems could be improved, key components performed well.

The on-site removal of the original uranium from the fuel and the loading of the ^{233}U into the stripped carrier salt extended the usefulness of the MSRE and the simplicity and efficiency of these steps illustrated one of the virtues of the fluid-fuel molten-salt systems.

The nuclear start-up experiments and operation at power confirmed the adequacy of the data and procedures used to predict the behavior. The system was quite stable and easy to control even during ^{233}U operation with a delayed neutron fraction lower than in any other reactor. Finally burn-up over an extended period at high power should yield very accurate information on ^{233}U cross section ratios in a neutron energy spectrum typical of molten salt reactors. A net result of the MSRE operation is enhanced confidence in the practicality and performance of future molten salt reactors.

In spite of the success of the MSRE summarized above, the molten salt breeder was competing with the liquid metal fast breeder reactor (LMFBR), which exhibited a higher breeding ratio. The MSR requirement of an online fuel cleansing system was viewed as a liability compared to the LMFBR solid fuel being reprocessed off site in a central location.

Another potential problem developed with the alloy used in contact with the molten salt. The metal testing and demonstration went through several stages settling first on a nickel-based alloy Hastelloy, then Hastelloy-N, and then Modified Hastelloy-N. The last alloy was a great success relative to corrosion issues, but the lifetime of the alloy in the thermal neutron flux was disappointingly and puzzlingly short. The problem was recognized early as buildup of ^4He in the pores of the alloy from the $\text{Ni}(n,\alpha)$ reaction, but the reason for a fast He buildup was not understood. The origin of the short life of the alloy was discovered after the MSRE program had suffered the loss of most of its financial support. The most abundant isotope ^{58}Ni (68%) has a substantial neutron capture cross section that yielded ^{59}Ni , which had an even larger cross

section for the (n,α) reaction. The only solution probably was the removal of ^{58}Ni by isotope separation, which would almost certainly prove economically impractical. (The required ratio of the mass difference between ^{58}Ni and ^{60}Ni divided by the nuclide mass is 1/30 whereas the same parameter for ^{235}U isotopic separation is about 1/80. There is therefore some possibility that isotopic separation of nickel might become economically practical.) The GEM*STAR system described later in this chapter does not use modified Hastelloy-N in regions where the thermal neutron flux is high.

A fully engineered conceptual design was completed for a 1,000 MW_e molten salt breeder reactor (MSBR) (Weinberg et al. 1970). This design was criticized because of the need for transport of the hot molten salt out of the reactor to external heat exchangers and back to the reactor for reheating. The salt flow rate is necessarily high between the reactor and the heat exchanger and in case of a highly damaging earthquake, much of the highly radioactive salt might spill out on the plant floor from broken piping before the pumps could be stopped. GEM*STAR uses internal heat exchangers with transfer of heat from the fuel salt to a lower melting point secondary salt so that the primary fuel salt never leaves the reactor tank.

The MSBR reactor was said to be less safe because of inferior containment arising from the use of fuel in liquid instead of solid form. Yet today's LWRs use solid fuel clad in low-melting-point zircalloy that melts almost immediately, with the fuel melting soon after, should water coolant on the surface of the fuel disappear. In this situation the cladding offers little containment, and the consequence of cladding failure is the release of all the accumulated noble gases. In contrast, liquid fuel allows for the removal of noble gases continually so that the most volatile source of dispersible radioactivity is absent should an accident occur with a molten salt system.

The MSBR also was less attractive to reactor vendors than solid fuel reactors because the MSBR reactor owners would not have to purchase manufactured solid fuel from the reactor vendors (Lamarsh 1983). The typical LWR was sold close to the cost of the manufacturer with the primary financial gain coming from spent fuel contracts that might extend over the life of the reactor.

A bitter battle was fought in the USA over breeding in the liquid fueled MSBR versus the solid fueled LMFBR with the latter having the benefit of an earlier start and a stronger funding base. In its favor, the LMFBR achieved a better breeding ratio for ^{239}Pu from uranium than the MSBR did for breeding ^{233}U from thorium. Then director of ORNL Alvin Weinberg was fired eventually for pushing for the MSBR after the decision for termination had been made. Later, perhaps partly in an attempt at compensation, the government started construction of the first US commercial scale breeder reactor called CRBR at Oak Ridge. Part way through the construction, the project lost the support from commercial nuclear industry leaders and construction was terminated. A smaller fast reactor called the fast fuel test facility (FFTF) was eventually constructed at Hanford, Washington, but support for its operation was too weak to enable a long period of operation. Nevertheless, large scale fast reactors were pursued aggressively and built in France, Russia, and Japan; although none has been economically successful. Plutonium-breeding reactors are still vigorously advanced in many countries along with the reprocessing necessary for their operation on the doubtful basis that they eventually will be required for better utilization of the uranium and thorium resources and that the FBR is the only technology that can accomplish this.

However, the success of the MSRE at ORNL attracted attention worldwide and studies of the technology were conducted in Russia in particular and also in France, Germany, and Japan. The collection of all ORNL reports relevant to molten salt reactors is available at

Figure 2
Phase diagram for LiF-UF₄-ThF₄

<http://www.energyfromthorium.com/pdf/>. The majority of them were generated at ORNL and many of them were devoted to measurements of the chemical and physical properties of various relevant mixtures of molten salts. The purpose of similar work conducted outside ORNL was to check the ORNL findings. Such studies were not pursued aggressively as investigators soon found that the quality of the ORNL results made such repetition unnecessary (Ignatiev 1995, personal communication).

An important example is shown in **Fig. 2**, which shows the melting point for the LiF-UF₄-ThF₄ mixture (Weinberg et al. 1970). The three corners correspond to the melting points of each of the three salts unmixed. The mid-point of one side gives the melting point for a 50–50 mixture of the materials marked at the ends of that side. So on the bottom side the melting point of a 50–50 mixture of LiF and UF₄ is about 700 °C. The lowest melting point of the mixture at 490 °C, called the eutectic mixture, is at 73:27 LiF: UF₄. Likewise, the eutectic point for LiF: ThF₄ is at 568 °C with a ratio of 70:30. Examination of the area in the lower left corner shows that almost any mixture of ThF₄ and UF₄ with 66% LiF will melt near 550 °C. The minimum temperature of the salt during normal GEM*STAR operation is 650 °C, so burning U or Th or any combination of them requires no change in reactor design or minimum operating temperature.

For about 30 years after the shut-down of the MSRE project, the interest in molten salt continued but in a relatively quiescent mode owing to an absence of significant financial support in any country. Perhaps the strongest initiative toward revival of molten salt technology was made during the origins of the accelerator transmutation of waste (ATW) (Bowman et al. 1992) project at LANL in the early 1990s. During most of the ATW project, the optimal combination of accelerator and reactor technology was taken to be a subcritical graphite-moderated reactor

with molten salt fuel. Although the LANL program stimulated a worldwide examination of the integration of accelerators into reactor technology, support in every country has always been restricted essentially to discretionary internal laboratory funding, and the accelerator-based technology never gained a firm funding foothold. The thermal spectrum approach was pursued further (Bowman 1998, 2000a) by ADNA Corporation after the LANL ATW effort ended. A patent (Bowman 2001) was granted in 2001 with the key element being the continuous flow of molten salt fuel that is part of the basis for the GEM*STAR system, described later in this chapter.

The study of molten salt reactors has regained some momentum by stepping away from the focus of the original MSR program at ORNL on optimizing the neutron economy sufficiently for thermal reactors to enable full use of the thorium and uranium fuel resource. The ORNL technology was steered toward niche activity such as weapons plutonium burning (Gat et al. 1992) and waste burning (Gat and Dodds 1993) in the early 1990s. Other means of deployment of molten salt reactors were also studied (Moir and Teller 2005) later. A more significant departure was the consideration of fast-spectrum molten-salt reactors (Furukawa et al. 1994). The fast spectrum offers some advantages including the elimination of graphite in the core and therefore concerns about the graphite lifetime, the use of NaF instead of ${}^7\text{LiF}$ in eliminating the need for isotopic separation of ${}^7\text{Li}$, the advantage of a harder neutron spectrum for transmuting non-fissile nuclides, and the claim of a neutron economy superior to the thermal spectrum. Recent papers (Forsberg et al. 2004; Merle-Lucotte et al. 2006; Forsberg 2007) provide many references to studies of fast-spectrum molten-salt reactors including the use of salt only as a coolant and not as a fuel. The latter designs are proposed for high temperature reactors capable of supplying heat at about 850 °C for hydrogen production and sometimes as small reactors for isolated regions.

In spite of 50 years of study of many reactor designs, the LWR supplies more than 90% of the world's nuclear electric power and the percentage is likely to grow higher as there are few current plans to build types other than LWRs for the foreseeable future. Today's typical advanced reactor design addresses only one problem of nuclear energy and neglects many others: the need for enrichment, reprocessing, expensive sodium-cooled fast reactors, lower cost of electricity, simple use of LWR waste as fuel, the elimination of a near term high-level waste stream requiring geologic repository storage, and weapons plutonium burn-up. One may argue that the goal for reactor development should be a single reactor design that satisfies all of these requirements and also enables the use of a significant part of the U and Th energy resource. The best option for that single design may well rest with the ORNL MSR thermal-spectrum design of 50 years, modified for subcritical operation and graphite-optimized to enhance the neutron economy.

The well-moderated thermal spectrum of a graphite-moderated molten salt reactor has a little known but notable advantage over other reactors because it has a much lower neutron loss from fission product capture than any other reactor design. The isotopes produced in fission are centered in the mass region where the p-wave neutron strength function peaks and generally away from the s-wave strength function (Mughabghab 1984). In the thermal neutron region where only s-wave neutron interaction is possible, the capture cross section therefore is *inhibited*. However, in the higher keV region of fast reactors, the angular momentum bias against p-wave capture disappears and p-wave neutron capture is *enhanced*.

Neutron resonance spacing also is an important factor when the spacing is much larger than the width of the neutron spectrum. In the well moderated molten salt reactor, nearly the entire neutron spectrum is contained in the energy band between 0.01 and 0.20 eV. The typical spacing between resonances for fission products is much larger than 0.2 eV, so fission product

resonances, where neutron capture is greatly enhanced, rarely fall in the 0.2 eV window. In the few cases where they do such as ^{151}Sm , the isotope is quickly transmuted to a much lower cross section nuclide. For ^{135}Xe , the same would be true except that volatile species can be quickly removed from liquid fuel. Taking these burn-up and removal factors into account the effective capture cross section for fission products has been calculated (Bowman 2000a) and found to be 6.0 barns for a thermal fluence of $3 \times 10^{22} \text{ n/cm}^2$ or 0.03 n/barn. (The same methodology has been applied for GEM*STAR, giving 8.6 barns at its lower fluences.) The fission cross section for ^{239}Pu at the same energy is about 100 times larger.

For a fast spectrum an abundance-weighted average of all of the fission product capture cross sections at 50 keV gives 0.145 barns (McLane et al. 1988) compared with the fission cross section of ^{239}Pu at the same energy of 1.5 barns; only 10 times larger. *The neutron loss to fission products is much larger in a fast spectrum reactor than in a well moderated molten salt reactor.*

The harder neutron spectrum of a fast reactor that enables more fission of even-even actinides than a thermal spectrum is the primary basis for the claim of a more favorable neutron economy for a fast reactor than a thermal reactor burning predominately ^{239}Pu . The inferiority of the fast spectrum with regard to neutron loss to fission product is uniformly ignored. The clinching argument added in favor of the fast spectrum is that higher actinides must be reduced as much as possible owing to the problems they cause with reprocessing. GEM*STAR does not require reprocessing. The usual arguments for superiority of a fast spectrum whether with molten salt or a solid fuel reactor are therefore not on sound footing.

Finally, it should be mentioned that the graphite-moderated molten-salt reactor will also be superior to the LWR with regard to fission-product neutron losses. An LWR is sufficiently loaded with fissile material that the neutrons are absorbed at an average energy of about 6 eV. The width of the LWR neutron spectrum is several eV rather than 0.2 eV, so the spectrum is more than ten times likely to include a neutron resonance with neutron-enhanced absorption. The LWR losses to fission products therefore might be comparable to that of fast spectrum reactors.

4 Graphite Developments

The earliest reactors were constructed of graphite and so graphite received extensive attention in the beginning years of reactor technology. General graphite studies were summarized by Nightingale (1962) and Poulter (1963). Studies of bulk graphite nuclear properties are summarized in ANL-5800 (1963) and most of the experimental methods are described by Beckurts and Wirtz (1964) and Glasstone and Edlund (1952). The high neutron absorption property of boron was always a concern and the term “reactor-grade graphite” was used to describe graphite with less than about 3 ppm by weight of boron. The investigation of the nuclear properties of graphite largely stopped in about the mid 1950s. With the widespread availability of low enriched uranium (LEU) in the nations with nuclear weapons stockpiles, uncertainties in the expected performance of new graphite reactors could be compensated simply and cheaply by adjusting the ^{235}U fraction of the LEU fuel.

With the advent of Monte Carlo codes such as MCNP5 (The MCNP5 Code, developed at the Los Alamos National Laboratory, Distributed by the Radiation Safety Information Computational Center, ORNL, www-rsicc.ornl.gov.) with capability to include complex geometry and an accuracy in neutron transport calculation limited only by the data input, more was asked and expected of neutron transport calculations. In order to perform optimally in neutron transport in the thermal neutron range, the MCNP5 code contains models for the molecular and

■ Figure 3

Apparatus for measuring the neutron diffusion and absorption of graphite. A pulsed proton beam from the Triangle Universities Nuclear Laboratory accelerator at Duke University enters the tank from the right where it strikes a target producing neutrons

crystalline structure for several materials including graphite. For graphite the model assumes a perfect crystal structure, which would be appropriate for practical calculations for natural (mined) graphite that has nearly a perfect crystal structure. Unfortunately, mined graphite contains too much boron making it impractical for use in a reactor. Therefore, manufactured graphite must be used for reactor construction and the crystal structure of manufactured graphite is much inferior to that of mined graphite. Most manufactured graphite also exhibits a significant anisotropy in properties such as thermal and electrical conductivity, strength, and also neutron transport properties.

Neither the imperfect crystal structure nor the anisotropy of manufactured graphite can be taken into account in present Monte Carlo codes like MCNP5; therefore, there is a substantial basis for doubting the reliability of such codes for neutron transport in reactor design. This doubt was confirmed by an initial series of neutron transport experiments that led to the first experimental measurement of the diffusion coefficient and boron content of manufactured graphite (Bowman et al. 2009a) in many years. The apparatus is shown in ► Fig. 3. The thin steel container was filled with granulated manufactured graphite. A hole across the diameter allowed a pulsed proton beam to enter from the right and to strike a target at the center of the tank producing a pulse of neutrons. The neutrons moderated and then died away exponentially by both neutron diffusion out of the tank and neutron absorption in the graphite. The decay time thus enabled a measurement of the combination of neutron diffusion and neutron absorption. A second experiment was performed on the same apparatus by placing a neutron source under the tank and measuring the neutron intensity as a function of position along the tank axis. The intensity decreased exponentially from the bottom to the top (aside from top and bottom corrections) owing to a combination of neutron absorption in graphite and neutron diffusion out of the side of the tank. A combination of the two experiments allowed the separation and determination of the graphite absorption and the diffusion coefficient.

The experiment was performed on granulated manufactured graphite, avoiding differences associated with the anisotropy of manufactured graphite. The diffusion coefficient was found

to be 25% larger than that calculated from MCNP5. The natural boron content was found to be less than 0.2 ppm by weight, and, therefore, much less than that is expected in reactor grade graphite. The smaller boron content reduced the neutron absorption in graphite below that which is expected from reactor grade by about 5% and taking this together with the increase in diffusion coefficient gave a total reduction in neutron absorption in graphite of 30%.

In order to pin down the origin of the difference between what MCNP5 predicted and what was measured, another experiment was done at the LANSCE facility at LANL. Very-high-resolution Bragg edges were studied (Bowman et al. 2008) by transmission on both granular and solid samples from 1 meV to 1 eV that enabled the separation of neutron diffraction from inelastic scattering. The Bragg diffraction was found to be very much reduced and the inelastic scattering correspondingly enhanced compared with the MCNP5 predictions for perfect crystalline graphite, indicating a high degree of crystalline distortion in the manufactured graphite. The distortion was even larger than that measured (Arnold et al. 1949) in older manufactured graphite and this was attributed partly to the addition of high pressure on the graphite during the last phase of the graphite manufacturing process that was not present in the early years of graphite production. By comparison with the MCNP5 calculations on perfect crystalline graphite (Bowman et al. 2008), the disorder in the manufactured graphite was found to be equivalent to that associated with the atomic vibrations from heating perfect crystalline graphite to about 1,500 °C (1,800 K) as shown in ► Fig. 4. This means that the energy-dependent ratio of diffraction to inelastic scattering measured at room temperature would be essentially the same at the reactor operating temperature of 700 °C, and that this ratio would not change significantly unless the reactor temperature approached 1,500 °C.

The measurements (Bowman et al. 2008) also showed a significant difference in the inelastic to diffraction ratio depending on the orientation of the graphite during the extrusion step (Nightingale 1962) of the manufacturing process. This implies that the optimal geometry for a graphite reactor is not necessarily a cube but perhaps a rectangular parallelepiped, depending on whether the extrusion direction is confined to the vertical direction or the extrusion direction is laid criss-cross in the horizontal direction. Also the reflective properties of graphite would be better if the graphite extrusion direction is the same direction as neutron flow into the reflector. While the effects might be small on the neutron economy from these geometric considerations, the impact on practical reactor design can still be significant (Poulter 1963) because 1% improvement in the neutron economy can translate to a 40% decrease in the reactor volume.

The next experiments planned for graphite will be performed on a cubic block of solid graphite of roughly $8 \times 8 \times 8$ ft.³ dimension that would enable an improvement in accuracy of both the diffusion coefficient and the graphite absorption by about a factor of two. This experiment will be followed by a restacking of the graphite with the extrusion direction criss-crossed in the horizontal direction and then with the extrusion direction in the vertical direction. The diffusion coefficient measured along the z-axis should differ by about 15% for the two graphite orientations. The last experiment would be to heat the cube to about 300 °C and repeat the z-axis measurement. At 300 °C the experiment should have a sufficient sensitivity to detect any significant temperature effect on the diffusion coefficient.

A larger diffusion coefficient is of no advantage for homogeneous reactors, but offers a major gain for heterogeneous reactors. This subtle point follows from consideration of the diffusion equation for a homogeneous medium without fissile material, which can be written as

$$D\Delta^2\phi - \Sigma_{ca}\phi = 0, \quad (1)$$

Figure 4

Inelastic scattering cross section in barns versus neutron energy. The MCNP5 calculations for the inelastic scattering from perfect crystalline graphite are shown for several temperatures. The *solid curve* is the measured (Bowman et al. 2008) inelastic scattering cross section at room temperature for graphite manufactured under high pressure. Note that, at 0.025 eV the measured inelastic scattering is 10 times higher than the MCNP5 calculation for perfect crystalline graphite and about the same as that predicted by MCNP5 for perfect crystalline graphite at 1,800 K. The MCNP5 calculation shows that the diffraction is depressed as the temperature rises, and the inelastic scattering enhanced, because the thermal motion of the atoms moves them farther from their equilibrium position in the crystals. For the manufactured graphite, the inelastic scattering is enhanced over diffraction because of the distortions in the crystal lattice introduced by manufacturing under high pressure

where D is the diffusion coefficient, ϕ is the neutron flux, and Σ_{ca} is the macroscopic neutron capture cross section defined as the carbon atom density times the carbon capture cross section. The first term is the rate of neutron entry into a differential volume element and the second is the rate of absorption in the volume element. Dividing (1) by D gives the form

$$\nabla^2 \phi - [\Sigma_{ca}/D]\phi = 0. \quad (2)$$

Clearly, the neutron loss during diffusion is reduced by the presence of a larger diffusion coefficient. However, for a homogeneous medium of carbon and uranium fissile material, (2) must be rewritten with capture and fission terms added as

$$\Delta^2 \phi - [\Sigma_{ca}/D]\phi + [(-\Sigma_{Uc} + \nu \Sigma_{Uf})/D]\phi = 0, \quad (3)$$

where ν is the number of neutrons per fission. Obviously *both* the fission term and carbon capture are reduced by a larger value for D , so there is no advantage to a larger diffusion coefficient for a homogeneous (carbon and fuel) reactor.

For a lightly loaded heterogeneous reactor in which a thermal neutron scatters many times on graphite before encountering uranium fuel, the larger diffusion coefficient of graphite reduces loss in graphite during diffusion while having no effect on the neutron absorption in fissile material. Nearly, all modern graphite reactors are effectively homogeneous reactors that cannot take advantage of the larger diffusion coefficient that can be manufactured into modern graphite. GEM*STAR is purposely a heterogeneous reactor that optimizes the neutron economy, not only with regard to the diffusion coefficient but also with regard to the ^{238}U resonance escape and fast fission factor characteristics for ^{238}U that Fermi employed (Stephenson 1954) to achieve the world's first chain reaction.

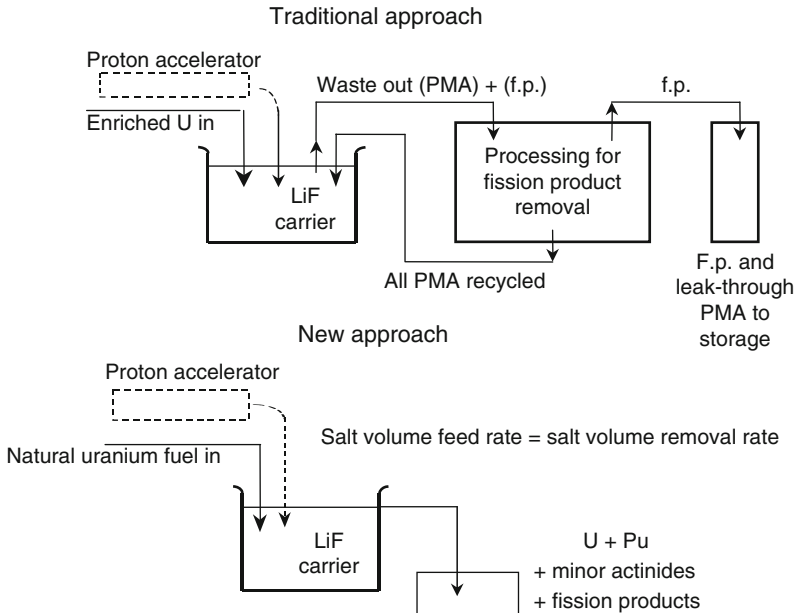

To summarize the graphite developments, modern codes for neutron transport in graphite based on a perfect crystalline structure grossly overestimate diffraction scattering and underestimate inelastic scattering. Because the distortion of the crystal structure of graphite depends on the manufacturing process, measurements instead of calculations will be required for predicting graphite reactor performance. The known anisotropies in the diffusion coefficient, which cannot be taken into account in today's codes, are likely to impact optimal reactor design and means must be found to address this issue. The boron content is much lower in some of today's manufactured graphite than traditional reactor-grade graphite. And finally, the cost of graphite today, taking inflation into account, is much lower than it was 40 years ago, so that graphite is not the significant cost factor for future reactors as it was for reactors of the past.

5 Integrating Accelerators, Molten Salt, and Graphite

The most recent serious attempt to introduce accelerators into nuclear energy technology was launched in the 1990s at Los Alamos National Laboratory (Bowman et al. 1992) as ATW and it attracted broad international attention and collaboration for several years. The technology was constrained however to *assisting* the established nuclear energy infrastructure including LWRs, breeder reactors, enrichment, reprocessing, and near-term geologic waste storage. Introducing an accelerator, which is not cost-free, to achieve modest incremental improvements into this already exceedingly complex infrastructure proved impractical, and any effort to use accelerators to simplify or eliminate any of the established elements encountered overwhelming political opposition. The ATW project did not succeed under the constraint that it was to provide little real impact on nuclear energy's problems.

GEM*STAR is an alternative nuclear power technology being developed by ADNA Corporation in the private sector using a continuous flow of liquid fuel without fission product (other than noble gases) or minor actinide removal (Bowman 1998, 2001). ➤ *Figure 5* shows the conventional molten salt approach and our new approach. The conventional approach is essentially that of the molten salt program of ORNL during the 1960s. Fissile and other actinide material flow in and irradiated fuel containing fission products flow out to an online chemistry facility that removes the fission products along with some leak-through actinides. The purified actinides and the non-fissile carrier salts are returned to the reactor. The system can achieve high burn-up of thorium without an accelerator, but it requires costly reprocessing, creates a flow of high-level waste that must be managed, and enables simple access to ^{233}U as weapons material. Subcritical operation with an accelerator would enable the system to operate on natural uranium, but would also provide access to plutonium for weapons use.

GEM*STAR operates on the system shown in the lower part of ➤ *Fig. 5* with a simple equilibrium overflow system where the volume flow in equals the volume flow out. The outflow

■ Figure 5

The *upper* part of the figure shows the system studied at ORNL using on-line reprocessing for plutonium, minor actinide (PMA), and fission product (f.p.) removal, but also with an accelerator added. The *lower* part of the figure shows the Green Energy Multiplier* Subcritical Technology for Alternative Reactors (GEM*STAR) approach with a simple equilibrium overflow system where the volume flow in equals the volume flow out. The outflow can be recycled several times using more non-fission neutrons each cycle as technology advances reduce the cost of neutrons

can be recycled several times at lower k_{eff} using ever larger fractions of non-fission neutrons – made economical as advances in technology reduce the cost of neutrons. It must be emphasized that the flow is not through a continuous tube inside the tank but that the inflow is thoroughly mixed continuously while in the tank. While any single atom might rarely come out almost immediately after entry or stay inside indefinitely, there is an average residence time and the neutron flux times the average residence time defines the average neutron fluence that the fuel coming out of the tank had experienced in the tank.

The system operates in equilibrium on the first cycle at $k_{\text{eff}} = 0.99$, but must be managed through a nonequilibrium period starting with k_{eff} less than 0.99. During the approach to equilibrium that might take several years, a protocol is followed by choice of initial fuel loading and by varying the fuel-carrier fraction, and the flow rate to eventually reach $k_{\text{eff}} = 0.99$ and stable operation. It is obvious but important to note that once equilibrium is reached, the composition of the outflow is the same as that inside the tank. Therefore, the outflow from a mother GEM*STAR can be transferred to a daughter GEM*STAR that can be immediately started *in equilibrium*. In this way, a situation similar to conventional breeding is established in which a mother might provide start-up fuel for many daughters with the daughters doing the same. The time for outflow of a full load of equilibrium fuel is typically about 5 years, roughly corresponding to a conventional breeding ratio of about 1.15. Obviously the GEM*STAR out-flow is

a financial asset particularly during the start-up and growth of GEM*STAR deployment as the outflow does not pass through any reprocessing step.

The system is subcritical initially at $k_{\text{eff}} = 0.99$ with the continuous in-out flow enabling stable operation without loss of neutrons to control rods. GEM*STAR uses a particular graphite that absorbs 30% less neutrons than ordinary reactor grade graphite as discussed earlier. The improved graphite, along with $k_{\text{eff}} = 0.99$, and avoidance of control rod loss enables an improvement in the neutron economy by about 8%. This change is the equivalent of raising the number of neutrons per fission from ^{235}U , from 2.43 to about 2.62 with significant consequences.

As shown later in this chapter, today's spent fuel presently bound for permanent geologic storage, can be burned without reprocessing in GEM*STAR. As much energy can be generated from it with $k_{\text{eff}} = 0.99$ as was generated in the LWR using fresh low-enriched uranium. Furthermore, existing accelerator technology enables the same energy to be produced at $k_{\text{eff}} = 0.95$ from recycling the GEM*STAR outflow at $k_{\text{eff}} = 0.99$ (with the required accelerator power only rising from 3 to 15%). The output can be recycled yet again at $k_{\text{eff}} = 0.90$ with the likely assumption that accelerator efficiency can be increased by two (neutron cost further reduced by two) before reaching the limits of today's understanding of accelerator design. And that is not the end. It can be shown (Bowman and Magill 2006) that long before fusion even nears practicality as a competitive energy source, it will produce neutrons more cheaply than accelerators enabling the recycling to continue much further.

But how much time would be available for developing and deploying practical fusion neutron sources? The present 100 GWe from US LWRs will result in 140,000 tons of spent fuel if their lifetime is extended from 40 to 80 years. If 100 GWe of new LWR power is brought on, the total spent fuel when both are retired will be 280,000 tons. If GEM*STAR systems start to replace the LWRs starting in 2020 and the US nuclear electricity grows to 200 GWe and continues indefinitely and GEM*STAR generates as much energy per tons of the spent fuel as the LWRs did, the GEM*STAR units can operate on LWR fuel for 80 years at $k_{\text{eff}} = 0.99$. With today's accelerator technology, another 80 years would be available from further recycle of original LWR fuel at $k_{\text{eff}} = 0.95$. With a factor of two improvement in accelerator performance beyond today's technology, recycle at $k_{\text{eff}} = 0.90$ could proceed toward the use of the original LWR fuel extensively for another 80 years, reaching about 240 years into the future. By that time, more advanced fusion neutron sources would be required to further recycle the original LWR fuel.

Three more recycles with fusion neutrons would extend the use to another 250 years. Therefore, 500 years hence the energy generation from today's LWR spent fuel would end with about 20% of the ^{238}U burned and about 20% of the mass being fission products. But that's not the end of the fission resource. We show in this chapter that natural uranium will perform as well in GEM*STAR as LWR spent fuel starting with $k_{\text{eff}} = 0.99$, so that another 500 years is added by only doubling the uranium used in the USA to date. Going even further we also show in the following section that depleted uranium can be used if we start with $k_{\text{eff}} = 0.95$, and there are about 7 tons of depleted uranium for every ton of low enriched fuel for LWRs enabling another 7×500 years. Finally, there is four times as much thorium as uranium in the earth's crust (Lide 1991), and GEM*STAR can burn thorium starting at $k_{\text{eff}} = 0.95$ for another $4 \times 8 \times 500$ years. By any measure, the fission energy resource opened up with supplemental neutrons from accelerators and from fusion and without invoking enrichment, FBR breeding, reprocessing, and near term high-level waste storage is enormous.

Since fusion neutrons help generate half of the energy in the above fission scenario, one might argue that one should instead proceed on to direct fusion energy production to open up an even more vast energy resource instead of just harnessing fusion to produce neutrons

cheaply. However, the earth's deuterium–tritium fusion energy resource is actually less than that from fission. The total of the U and Th in the earth's crust is 12.3 mg/kg (Lide 1991). Fusion energy ultimately relies on ${}^6\text{Li}$. The amount of Li is 20 mg/kg (Lide 1991) including 1.5 mg/kg amount of ${}^6\text{Li}$. Taking into account the masses, the atom ratio of U + Th to ${}^6\text{Li}$ in the earth's crust is 0.22. However, the energy per fission of U or Th is 200 MeV and that from ${}^6\text{Li}$ is about 20 MeV, so that this measure gives twice as much fission energy from the earth's crust as from fusion. With fusion energy appearing to be far into the unforeseeable future, one could make a strong case for directing some fusion research funds to the primary goal of efficient and cheap production of neutrons for fission.

At each step in the GEM*STAR recycle, there is no need for any chemical separations whatsoever on the fuel. By leaving in the higher actinides and fission products (other than noble gasses), these concurrently are transmuted to stable species instead of being separated out for attempts at special burn-up treatment as in the US DOE's current plan for the future of nuclear power (Report to congress 2006). It is shown below that the higher actinide species will be reduced by about a factor of 10/MWh produced after about six recycles. The long-lived fission products will also be transmuted because they have larger thermal capture cross sections on average than the shorter lived or stable fission products. Whenever final disposition of the GEM*STAR remnant fuel must be undertaken after at least several centuries, the mass and long-term radioactivity will be very significantly reduced from that of the current once-through process, made necessary by cost and proliferation concerns for more complex fuel cycles.

6 Calculations of GEM*STAR Burn-Up Performance

Determining the performance of a GEM*STAR system is relatively simple, due to its equilibrated state during operation. For each isotope in the feed fuel, one calculates the resulting equilibrium chain of isotopes within the system by specifying a neutron fluence and using estimates of the spectral average neutron cross sections. These chains are then combined, and the actinide fraction in the feed minus the equilibrium fraction in the full mixture, gives the burn-up fraction and the fission product fraction to add. Next, all the molten fuel components and other reactor elements are assembled in the design geometry, and MCNP is used to determine the “as-built” average cross sections. If these differ from before, the new ones are used to recalculate the equilibrium isotope distributions within each chain, the result reassembled, and MCNP run again. The process converges quickly, and k_{eff} is taken from the last iteration. Due to the larger diffusion coefficient in our graphite, a fraction of the neutron captures on carbon predicted by MCNP are redistributed among all the other reactions, weighted by their respective rates. This results in an increased k_{eff} , calculated by summing the products of fission rates times the average number of neutrons produced per fission, and dividing by the sum of neutron loss rates (see  Fig. 7). The process is then repeated for a different neutron fluence, generating points on a graph of k_{eff} and burn-up fraction versus neutron fluence for the specified isotope distribution in the feed fuel. The equilibrium equations are derived below, and then each step above is illustrated, noting any approximations or minor corrections applied.

The calculation of burn-up of a nuclide by successive neutron captures in a neutron flux with known capture and fission cross sections can be carried out using a set of coupled time-dependent differential equations first studied by Bateman (1927) that have complicated analytic solutions. For practical problems, alpha and beta decay might need to be taken into account and this is not possible with the Bateman equations. Instead the burn-up with decay can be

calculated with the ORIGEN 2 (Radiation Safety Information Computational Center (RSICC), Oak Ridge National Laboratory) code. However, even Origen 2 is not directly applicable to the in-out flow of the GEM* STAR system as it can only account for the start-to-finish isotopic evolution of a single load of fuel.

The lower part of  shows schematically the situation for burning natural uranium used as a fluoride salt. To explain in more detail, UF_4 is combined with 7LiF in a 1:2 mole concentration. This is a eutectic mixture that melts at about $520^\circ C$ compared to the melting points of $1,035$ and $848^\circ C$ for UF_4 and 7LiF , respectively as shown in . This salt is added slowly to a tank filled with the same mixture at maximum operating temperature of about $750^\circ C$. The tank also contains 93 volume percent of solid graphite with the melted salt occupying the other 7% of the tank volume. The system with the graphite and uranium is adjusted to $k_{eff} = 0.99$ and driven by supplementary neutrons so that the average thermal neutron flux in the tank is about $10^{14} \text{ n/cm}^2 \text{ s}$.

The tank is full and therefore overflows when more $UF_4 - {}^7LiF$ salt is added, for example, at the rate of about 0.80 l/h . The average atom in the tank is resident for about 4 years. In this flux for this period, considerable fission and capture take place on the uranium isotopes producing fission products and higher actinides besides uranium isotopes. The following definitions enable the writing of the differential equations that describe the time dependence for any nuclide in the tank.

V	Salt volume in the tank and internal heat exchanger
v	Volume flow rate into the tank in cm^3/s
N_i	Concentration of the nuclide i per cm^3
$\sigma_{ai} = \sigma_{ci} + \sigma_{fi}$	Absorption, capture and fission cross section of nuclide i
ϕ	Neutron flux averaged over the tank
F	Atom density of feed nuclide N_1 in atoms per cm^3

The rate of change in the tank of the total amount of the starting nuclide N_1 is

$$V \frac{dN_1}{dt} = Fv - \phi N_1 \sigma_{a1} V - N_1 v. \quad (4)$$

Neutron absorption in nuclide N_1 can lead to fission or by neutron capture (and any rapid beta decay) to nuclide N_2 . The total amount N_2 in the volume is then given by

$$V \frac{dN_2}{dt} = +\phi N_1 \sigma_{c1} V - \phi N_2 \sigma_{a2} V - N_2 v. \quad (5)$$

Similarly, the amount of the product nucleus N_3 is given by

$$V \frac{dN_3}{dt} = +\phi N_2 \sigma_{c2} V - \phi N_3 \sigma_{a3} V - N_3 v. \quad (6)$$

This set of differential equations can be solved for the time dependence of the concentration of all of the nuclides N_1 , N_2 , and N_3 , in the tank from the feed of N_1 . However, after the system has run for a while under proper controls the nuclide concentrations will equilibrate. This is the condition of most interest, and it may be calculated by setting all of the equations to zero, resulting in a set of algebraic equations instead of differential equations. Therefore, in equilibrium,

$$N_1/F = 1/[1 + \phi \sigma_{a1} (V/v)], \quad (7)$$

$$N_2/N_1 = \phi \sigma_{c1} (V/v)/[1 + \phi \sigma_{a2} (V/v)], \quad (8)$$

$$N_3/N_2 = \phi \sigma_{c2} (V/v)/[1 + \phi \sigma_{a3} (V/v)] \quad (9)$$

and similar equations for other daughters. Obviously the amounts of all daughters originating from a constant feed F will be at equilibrium as follows:

$$N_1 = F/[1 + \phi \sigma_{a1}(V/v)], \quad (10)$$

$$N_2 = N_1(N_2/N_1), \quad (11)$$

$$N_3 = N_1(N_2/N_1)(N_3/N_2). \quad (12)$$

And in general, since the ratio V/v is the average time that a nucleus stays in the flux, one can define a neutron fluence $F = \phi(V/v)$ with units n/cm^2 on an atom, giving

$$\begin{aligned} N_1 &= F/[1 + \phi \sigma_{a1}(V/v)] = F/[1 + F\sigma_{a1}], \\ N_i &= N_1 \prod_{j=2,i} (N_j/N_{j-1}) = N_1 \prod_{j=2,i} \{ \phi \sigma_{c(j-1)}(V/v) / [1 + \phi \sigma_{aj}(V/v)] \} \\ &= N_1 \prod_{j=2,i} \{ F\sigma_{c(j-1)} / [1 + F\sigma_{aj}] \} \quad i \geq 2. \end{aligned} \quad (13)$$

A simple hand calculation can be performed using (13) and starter values of flux and cross section estimates to get a distribution of isotopes from the feed of a single nucleus. If natural uranium is the feed material, it has two main isotopes ^{235}U and ^{238}U . Therefore, two separate calculations must be performed and the results added. In our calculations for uranium feed, the isotopes calculated included $^{235,236,238}\text{U}$, ^{237}Np , $^{238,239,240,241,242}\text{Pu}$, ^{243}Am , and $^{244,245,246}\text{Cm}$. The nuclides $^{241,241m}\text{Am}$ arising from the decay of ^{241}Pu were neglected owing to the ^{241}Pu decay half-life being long compared to the dwell time of a nucleus in the flux. The effect of neglecting the americium isotopes is very small on the neutron economy because the fission of ^{242m}Am yields 3.25 neutrons and the ^{242}Am decays mostly to ^{238}Pu as if the decay from ^{241}Pu to ^{241}Am had not taken place.

The calculation was done in several steps.

Step 1

In order to apply (13), one must specify a fluence. For a flux of $7.2 \times 10^{13} \text{ n/cm}^2 \text{ s}$ and an average residence time V/v of 4 years, the fluence $\phi(V/v)$ is about 0.009 n/barn or $0.009 \times 10^{24} \text{ n/cm}^2$. One then needs the capture and fission cross sections for each of the nuclides averaged over the neutron spectrum and volume of the reactor to get $\langle \sigma_{ci} \rangle$ and $\langle \sigma_{ai} \rangle$. These cross sections are not the thermal cross section because the flux extends up to the original fission neutron energy range. The flux shape to some degree depends on the isotopic composition, so the flux-averaged cross section also depends on the isotopic composition. The cross sections therefore must be obtained from MCNP5 calculations of interaction rates for all of the isotopes in an iterative process.

The average cross sections for a fluence $F = 0.009 \times 10^{24} \text{ n/cm}^2$ can be estimated from the interaction rates provided by an MCNP5 calculation which are shown in [Table 1](#). These need only be starting estimates of cross sections since they are updated by later iterations.

The abundance values are normalized for MCNP5 so that when the fractions of Li, F, and fission products are added to the sum of column 2 in [Table 1](#), the total is 1.0000. The small amount of ^4He added to the salt does not influence the spectrum but gives a means of calculating the collision rate of neutrons in the salt because the scattering cross section was set to one barn for all energies by means of a modified input library. The starred values for He in [Table 1](#) are not the capture rate but the He scattering rate and the He scattering cross section, respectively.

Table 1
Effective cross section calculation in barns

(1) Isotope	(2) Abundance	(3) Capture rate	(4) σ_c	(5) Fission rate	(6) σ_f	(7) σ_a
²³⁵ U	3.06E-4	0.0204	28.1	0.109	149	177
²³⁶ U	7.17E-5	0.00169	9.93	0	0	10.1
²³⁷ Np	3.93E-6	0.000597	64.0	0	0	64.2
²³⁸ U	1.09E-1	0.367	1.42	0.00972	0.038	1.46
²³⁹ Pu	3.19E-4	0.0891	118	0.192	253	371
²⁴⁰ Pu	1.21E-4	0.0581	203	0.000087	0.304	203
²⁴¹ Pu	4.56E-5	0.0116	108	0.0332	307	415
²⁴² Pu	3.35E-5	0.00301	37.9	0	0	38.0
⁴ He	1.31E-3	0.00315 ^a	1.00 ^a			

^aScattering rate and scattering cross section (manually set to 1 barn)

The capture rate R_{238} for ²³⁸U is given by $R_{238} = N_{238} \int \phi(E) \sigma_{c238}(E) dE$ and the scattering rate for He R_{He} is given by $R_{He} = N_{He} \sigma_{sHe} \int \phi(E) dE$. The average value for

$$\sigma_{c238} = \left[\int \phi(E) \sigma_{c238}(E) dE \right] / \left[\int \phi(E) dE \right] = [R_{238}/N_{238}] [R_{He}/N_{He} \sigma_{sHe}] \quad \text{or}$$

$$\sigma_{c238} = [N_{He} \sigma_{sHe}/R_{He}] \times [R_{238}/N_{238}] = [0.00131 \times 1.00/0.00315] \times [0.367/0.109] \quad \text{or}$$

$$\sigma_{c238} = [0.416] \times [3.37] = 1.40 \text{ barn.} \quad (14)$$

The factor 0.416 in (14) derived from the He can then be used to calculate cross sections for all of the other isotopes in Table 1 from the abundances and the reaction rates calculated from MCNP5.

Step 2

Using the cross sections above in the set of (13) enables the calculation of the burn-up for a fluence of $0.009 \times 10^{24} \text{ n/cm}^2 \text{ s}$ as shown in Table 2.

The ratios in column 6 correspond to those indicated in (13) and are derived from data in columns 4 and 5. The fractions in column 7 are successive products of the ratios in column 6 indicated in (13). For example, the value 0.375 for ²⁴⁰Pu in column 6 is found from dividing the number 1.062 for ²³⁹Pu in column 4 by the number 2.83 in column 5. The number 0.00109 in column 7 is obtained by multiplying the number 0.375 in column 6 for ²⁴⁰Pu by the number 0.00292 in column 7 for ²³⁹Pu.

The first three numbers in column 8 of Table 2 are the numbers in column 7 multiplied by the isotopic abundance 0.0072 of ²³⁵U in natural uranium. Similarly, the last five numbers are multiplied by the abundance 0.9928 of ²³⁸U in natural uranium. The sum of all of the numbers in column 8 (except for the feed) is 0.985. This number subtracted from 1.0000 gives the fission burn-up of 1.5% of the fed natural uranium. Retaining more significant digits throughout the calculations gives a burn-up of 1.19%.

■ **Table 2**

Burn-up calculations at a fluence of $F = 0.009 \times 10^{24} \text{ n/cm}^2$

(1) Isotope	(2) σ_c	(3) σ_a	(4) $F\sigma_c$	(5) $(1 + F\sigma_a)$	(6) Ratio	(7) Fraction	(8) Normalized
F(²³⁵U)			1			1	0.0072

²⁴² Pu	37.9	38.0	0.341	1.342	0.724	0.000304	0.000302

Step 3

The MCNP5 code is then used to calculate k_{eff} for the fluence of $0.009 \times 10^{24} \text{ n/cm}^2$. The graphite is included along with the code's $S(\alpha, \beta)$ distribution for room temperature graphite. The isotopic distributions in column 8 of [Table 2](#) are fed as the actinide component of the fuel along with the ^{10}B fraction and the He, ^7Li , and F fractions not shown in [Table 2](#). The ^{10}B is for the purpose explained in the next paragraph. The ^7Li and actinide (Ac) fractions in the salt are constrained by the eutectic 2:1 mole ratio of ^7LiF to AcF_4 .

The fission products present absorb neutrons and these neutron losses must be taken into account. Some of the fission product absorption cross sections are quite large so that a fission product nucleus can capture more than one neutron in one dwell period in the reactor. The average fission product neutron capture cross section can be taken into account (Bowman 2000b) including the possibility of multiple neutron capture. An average capture of 8.6 barns is found at thermal energy for a fluence $F = 0.01 \times 10^{24} \text{ n/cm}^2$. The average fission product capture cross section depends weakly on the fluence, but the effect is small compared to other uncertainties in the data for fission products. The fission product cross sections generally exhibit an inverse dependence on velocity ($1/v$). The fission products are therefore represented in the calculation by a proper amount of ^{10}B via the $^{10}\text{B}(n, \alpha)$ reaction, which also exhibits a $1/v$ dependence in the range of interest. The fission product fraction produced in the burn-up of [Table 2](#) is $2 \times 0.0119 = 0.0238$. Using ^{10}B to represent the fission products in MCNP5 as the code does not have all of the fission product capture data, we find that the ^{10}B fraction must be $0.0238 \times 8.6/3,837 = 0.0000533$ with the absorption of ^{10}B being 3,837 barns. This ^{10}B fraction probably overestimates the fission product absorption because the ^{10}B cross section averaged over the spectrum is considerably lower than the thermal value of 3,837 barns. However, owing to the uncertainty of the fission product cross sections, if the calculation errs with regard to fission product absorption, it overestimates the fission product absorption and underestimates overall GEM*STAR performance.

The calculation geometry, shown in plan view in [Fig. 6](#), is a cube surrounded by a 50-cm thick reflector. The cube is 503 cm on a side and it contains 33×33 square cylinders that

■ Figure 6

Plan view of geometry for MCNP5 burn-up calculation. The outside dimension of the cube is 603 cm on a side with a 50-cm thick graphite reflector on all six sides. The array of graphite elements is 503 cm on a side and it contains 33×33 square bars that are 503 cm long and 15.2 cm on each side running from the reactor bottom to the top. The inner set of bars running from top to bottom consisting of the central array of 27×27 cylinders is referred to here as the core. The rest of the bars nominally three cylinders thick is the blanket. The *square cylinders* of the core have a hole along the axis with 2.3 cm radius for the salt flow corresponding to a fuel volume fraction of 7.2%. The *square bars* in the blanket have a hole along the axis of radius 5.23 cm for the fuel salt and corresponding to a 37% salt volume

are 503 cm long and 15.2 cm on each side. There is an inner set of cylinders consisting of the central array of 27×27 cylinders referred to here as the core. The rest of the cylinders, nominally three cylinders, thick is the blanket. The square cylinders of the core have a hole along the axis with 2.3 cm radius for the salt flow corresponding to a fuel volume fraction of 7.2%. The square cylinders in the blanket have a hole along the axis of radius 5.23 cm for the fuel salt and corresponding to a 37% salt volume.

The Monte Carlo calculation yields $k_{\text{eff}} = 0.962$. The surface leakage fraction is 0.0083, the graphite absorption fraction is 0.0445, and the loss of neutrons to fission product absorption is 0.00984. Owing to the problems in MCNP in handling neutron transport in graphite, the value of k_{eff} calculated is too low by several percent. Corrections to this value of k_{eff} are calculated later for GEM*STAR graphite.

It should be noted that the cross sections used in step 1 could now be used as the starting point values for a completely new calculation at a different fluence. In general, one must expect some change in the cross sections between different burn-up conditions. Steps 1–3, therefore, would be repeated starting with the cross sections derived from the burn-up calculations at 0.009 n/barn to calculate cross sections and burn-up at a different fluence. In general, when a calculation is started in parameter space far from a previous calculation making it necessary to estimate the cross sections, a few iterations are necessary. However, it almost always converges by the third iteration.

7 Corrections for MCNP5 Graphite Absorption

Measurements by the ADNA team (Bowman et al. 2009a) show that the diffusion length for GEM*STAR graphite is 24% larger than is calculated by the $S(\alpha, \beta)$ tables of MCNP5. The measurements also showed that the boron content was lower (< 0.2 ppm) than “reactor grade” graphite (~ 0.6 ppm) providing together a total 30% reduction in graphite absorption from “reactor grade” graphite. Taking account of this correction involves reducing the MCNP5 results for neutron loss in graphite by 24% and redistributing these neutrons to absorption in other nuclides in proportions calculated using MCNP5. The result is a larger absorption in the fuel salt, and therefore a higher k_{eff} . But this method is only practical for pure graphite regions. Another (and much faster) method to account for the new graphite results is by scaling the capture cross section of carbon down by the ratio of the diffusion coefficients, rather than redistributing neutrons. These two methods have been compared and found to be equivalent, although the scaling method allows for a continuous correction, rather than the discreet component correction, otherwise required. This latter method was used to generate  Fig. 7. Nevertheless, to illustrate the first method, calculations were first performed with MCNP5 assuming no boron in the graphite, so the MCNP5 results had to be corrected for the 24% lower neutron loss in diffusion through graphite. The example calculation presented here is somewhat tedious but straightforward (fractions have been normalized to unity).

The leakage fraction of neutrons is 0.0083. The fraction of neutrons lost to carbon absorption in the core of the reactor is found to be 0.0445 and the 24% reduction in loss means that the fraction $0.0445 \times 0.24 = 0.0107$ can be redistributed. The reflector loss by absorption is 0.0120 and so 0.0030 will not be absorbed. However, these neutrons are near the surface and about half of them will leak out. Therefore, the total neutrons to be redistributed will be $0.0107 + 0.0029/2 = 0.0121$. The redistributed loss of neutrons to graphite absorption and leakage is:

Core graphite absorption 0.0445×0.76	0.0338
Reflector absorption 0.0120×0.76	0.0091
Graphite leakage $0.0083 + 0.0014$	0.0097
Total neutrons loss to graphite and leakage	0.0527

■ Figure 7

Burn-up and k_{eff} dependence on fluence for natural uranium for the core-and-blanket geometry. The *dashed curve* is the result of the MCNP5 calculation without the 24% increase in the diffusion length and reduced boron contaminant for graphite. The *solid curve* shows the results of using the improved graphite. The *vertical line* at a fluence of 0.006 n/barn is where one obtains twice the electric energy extracted from mined uranium as a light water reactor (LWR) extracts

Results from MCNP5 of thermal neutron absorption in the fuel are listed in column 2 of ▶ [Table 3](#). The numbers for ^{238}U and ^{240}Pu must be adjusted because resonance and higher kilovolt capture in these nuclides is a significant part of the total absorption. Generally, about 1/3 of the total absorption in weak thermal absorbers is nonthermal so the entries in ▶ [Table 3](#) are 2/3 of the total ^{238}U and ^{240}Pu absorption.

Column 3 of ▶ [Table 3](#) shows the additions to the reaction rates from redistribution of the 0.0121 fraction of neutrons not absorbed in graphite. The sum of column 3 is therefore 0.0121 and the sums of columns 2 and 3 must equal the sums of columns 4 and 5. Corresponding high energy reactions in the core are listed in ▶ [Table 4](#).

Because the blanket was thin compared to the core, corrections were applied to the core and not the blanket. The sum of the fission in the blanket was 0.0442 and the capture was 0.1094. The corrected k_{eff} can be calculated as

$$k_{eff} = [\text{the sum of the product of fissions times neutrons per fission}] / [\text{total absorption}].$$

The numerator is:

$$\begin{aligned} \text{Num.} &= 0.425 \times 0.101226 + 2.88 \times 0.174956 + 2.94 \\ &\quad \times 0.030042 + 2.88 \times 0.00712 + 2.77 \times 0.0442 = 0.9806. \end{aligned}$$

The number of neutrons per fission ν is 2.425 for thermal fission of ^{235}U , 2.88 for ^{239}Pu , and 2.94 for ^{241}Pu . The number 2.77 is the weighted value for fission in the blanket.

■ **Table 3**
Adjustment of thermal neutron absorption in the core

(1) Nuclide	(2) MCNP5	(3) Correction	(4) Capture	(5) Fission

¹⁹ F	0.0058	0.000107	0.005907	
Total	0.6597	0.012120	0.365644	0.306224

■ **Table 4**
High energy reactions in the core

Nuclide	Capture	Fission
²³⁸ U capture (1/3)	0.0979	
²³⁸ U fission		0.00706
²⁴⁰ Pu capture (1/3)	0.0167	
²⁴⁰ Pu fission		0.00006
Total	0.1146	0.00712

The denominator is:

$$\begin{aligned} \text{Denom.} = & [0.101226 + 0.174956 + 0.030042 + 0.00712 + 0.0442 + 0.1145 \\ & + 0.3656 + 0.1094 + 0.0527] = 0.99972. \end{aligned}$$

The graphite-absorption-corrected $k_{\text{eff}} = 0.9806/0.9997 = 0.981$ compared to the MCNP5 value of 0.962 for an increase of about 1.9%. If one applies the same correction for a fluence of zero, meaning either very fast flow-through or zero burn-up, we find the same increase of 1.9%. One should note that the ¹³⁵Xe fission product is continuously removed in GEM* STAR, and that the use of ¹⁰B to simulate fission-product absorption was probably too absorptive, so an even higher k_{eff} might be possible.

The calculation of k_{eff} and burn-up described above was performed for fluences up to 0.014 n/barn for a natural uranium feed. Similar calculations using the carbon capture cross section scaling method described earlier were also performed, allowing the boron contamination in the graphite to be included, and the results are shown in [Fig. 7](#). The dashed curve is the MCNP5 calculation and the solid curve is the MCNP5 calculation with improved graphite.

Regarding the burn-up fraction of natural uranium in [Fig. 7](#), one may note that LWR fresh fuel enriched to 4.2% in ^{235}U is obtained by isotopic separations that remove about 0.50% of the 0.72% of the ^{235}U in natural uranium resulting in depleted uranium with 0.22% ^{235}U . Therefore, $1 + [(4.2 - 0.7)/0.5] = 8$ tons of natural uranium is required to produce one ton of uranium enriched to 4.2%. So when an LWR fissions 4% of its fed fuel, it is actually burning only $4\%/8 = 0.5\%$ of the mined uranium.

The peak in the k_{eff} curve is an interesting feature for this equilibrium calculation. A fluence of zero corresponds to such a fast flow-through that no ^{239}Pu or fission products are created. The neutron economy is inferior to a graphite reactor with metallic natural uranium fuel because the fast fission in metal fuel is about four times that in our eutectic molten salt fuel. However, the combination of water cooling, metal fuel, and graphite moderator is a potentially unsafe combination and gas cooling seems not to be compatible with liquid fuel.

Our design goal of $k_{\text{eff}} = 0.99$ at a fluence enabling twice the burn-up of an LWR *without enrichment* seems difficult at first to achieve. However, it is important to note that so far throughout this chapter the simplification has been made that k_{eff} of the reactor by itself is sufficient to describe the reactor response during driven operation. In practice, the reactor has higher neutron multiplication near its center compared to near the walls. Thus, the details of how the neutrons from the target are coupled into the reactor are quite important but are currently proprietary. For completeness, and to illustrate the important impact such refinements can have, [Fig. 8](#) shows the result for a modified GEM* STAR design incorporating a practical central target, where rather than defining a k_{eff} for the system, each proton impinging on the target has all of its interactions and subsequent particles, including fission neutrons, fully tracked. The energy released by fission during this process is compared to the energy of the incoming proton and then accelerator efficiency and thermal to electric conversion efficiency are included to yield the *electrical* multiplication. At a fluence of 0.004 n/barn, the electrical multiplication of a green electrical source is 40 and the burn-up at 0.5% is the same as LWRs for mined uranium. For an electrical multiplication of 10, the uranium resource usage is stretched by 3.5 times without resorting to the complications of breeder technology.

8 GEM* STAR Reactor Parameters

The illustrative parameters described next are for the core-and-blanket configuration shown in [Fig. 6](#) with burn-up of 0.0102, $k_{\text{eff}} = 0.99$, and a fluence of 0.013 n/barn. We continue to use this model for illustration, but the reader should be aware that implementation of a central target as described in the previous section is necessary to achieve the results which follow. Each unit operates at a fission power of 500 MW_t and generates 220 MW_e of electricity when deployed in an array of five units as shown in [Fig. 9](#) using six accelerators. The green energy multiplication for the array of five is 29 and the electricity production is 1.1 GWe. For the deployment of only one unit, the accelerator-produced neutrons are not as efficiently used and the power is 180 MW_e and the multiplication is 23.

Figure 8

Performance of a GEM*STAR system with a central target burning natural uranium. The *squares* assume, a 35% efficient accelerator, and a thermal to electric conversion efficiency of 44%. The *triangles* are the same using normal MCNP that cannot account for the distorted crystalline structure of graphite. The *diamonds* show the actinide burn-up fraction for operation in equilibrium

Figure 10 shows a view of one GEM*STAR unit as a vertical slice through the center of the cubic reactor core. The density of the graphite is 1.63 g/cm^3 and that of the salt is 3.8 g/cm^3 , so the graphite would float if not constrained by a graphite or Hastelloy cap across the top of the tank that is not shown. The design includes two cooled tanks under the subcritical reactor to collect the outflow. The outflow tube allows the main tank to be pressurized sufficiently with helium to enable salt from the overflow tanks to be pushed out of them through the lid of the reactor and to storage cylinders well away from the reactor. The helium pressure required is about four atmospheres and the containment must be able to contain that pressure. Helium continually flows at lower pressure above the fuel surface to remove volatile fission products such as noble gases and tritium fluoride that are then removed from the helium to enable He recycling. These volatiles are short-lived, and can be readily stored until decay.

Although target details are proprietary, a conceptual system is included for illustration. Two accelerator targets of 4-m length, made of 15-cm thick Be metal tubes containing deuterium gas are shown. High energy neutrons are produced by a proton beam on a stopping length thickness of deuterium gas and these neutrons are multiplied by a factor of two by the beryllium. A 1-m high and 5-m long slot in the graphite reflector is not shown. It enables target neutrons that pass readily through the metal wall to reach the reactor core. A graphite reflector of 50 cm thickness is included on three sides around the target to reflect the neutrons toward the core.

1,100 MWe power plant from five 222 MWe units

■ Figure 9

Five GEM*STAR units ganged together to produce 1.1 GWe. The 33-m accelerators generate proton beams striking deuterium targets that are expected (Bowman et al. 2009b) to produce neutrons with the same energy cost as a 1-GeV and 1.35 mA proton beam on a lead spallation target or a 0.5 GeV and 1.35 mA proton beam on a uranium spallation target

The core consists of square bars with $15.2 \times 15.2 \text{ cm}^2$ cross section and 503 cm length. They have a hole along the axis with radius 2.30 cm for salt flow. They are arranged in a square 27×27 array and provide a salt/graphite ratio of 0.072. A blanket is included outside of the core consisting of three layers of the same prisms but with holes of radius 5.23 cm. The total volume of the core and blanket together is a 33×33 array. A graphite reflector 50 cm thick is included on all six sides outside of the blanket. The total volume of the core is 86 m^3 . The total volume of salt in the core is 6.1 m^3 giving a salt to graphite volume ratio of 0.072. The volume of fuel in the blanket is 15.6 m^3 with fuel to graphite ratio of 0.37. The fuel in the internal heat exchanger region outside the reflector is 8.9 m^3 and the total fuel volume is 30.6 m^3 . There is a small amount of additional fuel in the plena above the top reflector and below the bottom reflector. The mass of natural uranium in a full load is 76 tons U, or 100 tons of UF_4 , and 4.6 tons of ^7Li .

The actinide isotope fractions in Table 2 enable the calculation of the total inventories in the reactor of 215 kg of ^{235}U and 223 kg of ^{239}Pu . This fissile inventory is at least an order of magnitude lower than the ^{239}Pu in a fast breeder or fast burner reactor of the same power. For a burn-up fraction of 1.2%, the amount fissioned in passing a full volume of 76 tons of actinide through is 912 kg. If the passage time is 4.5 years with fuel burn of 200 kg/year, the fission power is found to be 500 MW_t, which at 44% thermal-to-electric conversion efficiency is 220 MW_e. For a fluence of $0.014 \times 10^{24} \text{ n/cm}^2$, and a total volume flow-through time of 4.5 years, the thermal flux is $1.0 \times 10^{14} \text{ n/cm}^2 \text{ s}$ averaged over all of the fuel with 29% of the fuel in the internal heat exchanger. The lifetime of graphite is usually taken to be a fluence (Weinberg et al. 1970)

■ **Figure 10**

Schematic drawing of a 220 MWe subcritical reactor with dimensions approximately of a 20-ft. cube (see text), which would be located underground. Two targets are present on opposite sides of the reactor. Molten salt fuel is poured into the top and is circulated by pumps down the outside of the reactor, back up to the underside of the reactor, and through the reactor graphite to the top. With each addition of salt an equal salt volume overflows through the tube in the center and down into the inner holding tank. On average an atom of salt spends about 4.5 years in the tank before flowing out. When full, the inner tank overflows into the outer holding tank. Together the two holding tanks can contain all of the salt fuel used over the 40-year life of the reactor. Heat is removed via an internal heat exchanger using a secondary salt in concentric tubes that carry the salt into the reactor at 550 °C and out a 650 °C. The fuel salt is confined everywhere on the outside by modified-Hastelloy-N and otherwise by graphite. Continuously flowing He across the surface of the fuel salt removes noble gases and other volatiles. Overheating of the salt results in expansion that reduces the salt density providing negative feedback and also may result in fail-safe overflow into the storage tanks below. The salt also circulates slowly by thermal convection and air flows upward over the reactor sides enables passive removal of the heat in case of loss of coolant pumping

of 3×10^{22} n/cm² of the flux above 50 keV with the fast fraction being about 30% of the total. According to the ORNL-MSBR design (Weinberg et al. 1970), a lifetime of 4 years is expected for a thermal power density of 22 kw/l. The GEM*STAR average power level is 4.0 kw/l giving a graphite lifetime of about 22 years. Because 29% of the fuel is outside of the core, the average flux actually required is 1.4×10^{14} n/cm² s and the core-blanket graphite lifetime is about 17 years.

The fuel salt does not leave the vessel for heat removal. ● **Figure 10** shows salt being pumped down the four outside walls of the graphite reflector in an 8.9-cm thick channel that is 608 cm wide and 1,200 cm high. Inside this channel 300 concentric tubes carry a lower melting point

secondary salt for heat transfer from the fuel salt. The composition of this salt is $\text{NaBF}_4 : \text{NaF}$ in the mole ratio 92:8 with a eutectic melting point of 385°C . The heated secondary salt then flows outside the reactor vessel to steam generators.

The cooler secondary salt flows down through the inner tube of a concentric pair to the bottom and returns inside the outer sleeve to the top. The wall thickness for both the inner and outer tubes is 3.2 mm. The I.D. of the inner tube is 44 mm. The O.D. of the outer tube is 76 mm. The secondary salt enters the top at a temperature of 550°C , flows at 3.2 m/s down to the bottom where its temperature is about 570°C and flows up at 2.8 m/s reaching 650°C at the top. The primary salt starts at the top at 750°C and exits at 650°C traveling at a velocity of 1.3 m/s. The velocity of salt upward through the tank is about 0.4 m/s and the total circulation time is about 20 s.

In case of a loss-of-coolant accident, the fuel salt will continue to circulate by convection. The heat capacity of the 350 tons of graphite in the core, blanket, and reflector and this natural convection will conduct the heat into the steel wall, which is always cooled by natural air. Fail safe means for interrupting accelerator beam power and for dropping in the on-off rods stop the power production. Naturally convective air cooling flowing up beside the reactor's four metal sides is always present.

The time to reach equilibrium from start-up is estimated to be about two volumes or 9 years although this time can be considerably shortened by appropriate initial starting composition and fuel management during the approach to equilibrium. After equilibrium, if fuel is added each hour, the volume added each time would be about 0.78 l corresponding to a volume fraction of 0.000025. This would roughly correspond to changing the multiplication from $1/(1 - 0.99) = 100$ to $1/(1 - 0.9900230) = 100.25$ and increasing the fission power by 0.25%. The fission power would then decline by that amount over the hour between fuel additions for constant accelerator power.

The accelerator parameters can be calculated from the fission rate at 200 kg of uranium burned per year (producing 220 MW_e) corresponding to 1.6×10^{19} fissions per second. At k_{eff} of 0.99, the fission chains average 100 fissions in length so 1.6×10^{17} fission chains are started per second. If on average 2.6 neutrons are released in fission from ^{235}U and ^{239}Pu and it takes this many to start a fission chain for k_{eff} near 1.00, then the number required from the accelerator is 4.2×10^{17} n/s if all made it inside to the fuel-blanket. However, about 10% will be lost so that the total required is 4.8×10^{17} n/s. A 1-GeV proton beam on a lead target produces about 30 neutrons per proton by spallation, so the number of protons required is 1.6×10^{16} protons per second or 1.35 mA and 1.35 MWb of beam power from each of two accelerators. If the accelerator efficiency for conversion of buss-bar to beam power is 35%, the electric power requirement for one accelerator is 3.9 MW_e . The green energy source for powering the two accelerators would supply the 7.8 MW_e giving a multiplication of 29 for GEM*STAR. The acceleration gradient of a 1-GeV proton linac is probably about 5 MV/m so the accelerator length would be about 200 m.

It might be possible to produce neutrons on a deuterium target (Bowman et al. 2009b) with the same energy efficiency but with a 100-MeV accelerator. In that case, the linac accelerator length would be about 20 m and the proton current for each accelerator would be 15 mA. In the same paper (Bowman et al. 2009b), the advantage of having half the beam from two accelerators each with its own target is discussed. With two accelerators, each 100-MeV accelerator would produce 13.5 mA for a power of 1.35 MWb each. GEM*STAR parameters for the reactor, the heat exchanger, and the accelerator-target are given in [► Tables 5-7](#), respectively. The same neutron input rate could be supplied using uranium targets driven by two 0.5 GeV 1.35 mA proton accelerators. Thus three linac-target options are available probably producing neutrons

Power consumption for one accelerator (MWe)	3.9
Accelerator length (m)	30

at the same rate including 1 GeV and 1.35 mA on a lead spallation target, 0.5 GeV and 1.35 mA on a uranium spallation target, and 0.10 GeV 13.5 mA on a deuterium target.

An appropriate size for a demonstration facility might be 5% of GEM* STAR for a fission power of about 25 MW_t and an electric power of 11 MW_e driven by a single 100 MeV accelerator with a proton current of about 1.5 mA.

9 Burning LWR Spent Fuel

The same core-blanket geometry as was used for natural uranium burning was used to calculate the LWR spent fuel burn-up. The calculation procedure also was the same with the fission product absorption being bundled together as before and being represented again by the equivalent absorption of boron. Of course, the calculation was significantly more complex because there were only ²³⁵U and ²³⁸U as starting nuclides for natural uranium fuel, but for spent fuel there were in addition ²³⁷Np, ^{238,239,240,241,242}Pu, ²⁴¹Am, and ^{244,245}Cm. The starting concentrations

(CURE 1990) were taken for a burn-up of 33,000 MW-days/tons of heavy nuclides that had been out of the LWR for 10 years.

➤ **Table 8** shows the results of the calculation for $k_{\text{eff}} = 0.99$. Columns 1 and 2 give the isotopic composition and fractions of the feed from the LWR spent fuel. If the total actinide fission fraction from the LWR of 0.034 is added to the sum of the second column, the second column adds to one. (The number for the fission product nuclides would of course be twice as large as 0.034.) The row across the top lists the isotopes that flow out of GEM*STAR. The numbers in the rows of the table show the transmuted fractions of the starting isotope in column 1. So numbers across the second row show the results for the ^{235}U feed. There is an entry in the second row for every isotope up to ^{239}Pu . Beyond ^{239}Pu the fractions are too small to record. The bottom row sums each column of the table giving the isotopic composition of the outflow of GEM*STAR at $k_{\text{eff}} = 0.99$. The total of the sums of columns 3–15 across the bottom line is 0.9336. Because the starting fission fraction from the LWR was 0.034, the burn-up by fission in the first GEM*STAR cycle is $1 - 0.9335 + 0.0340 = 0.0324$. The value for k_{eff} from MCNP5, which does not take into account the beneficial effects of distorted crystal structure is 0.962. The correction for the distorted crystalline structure, is 0.028 taking k_{eff} to 0.99.

The first burning of LWR spent fuel detailed in ➤ **Table 8** is then followed by a second cycling of the output at $k_{\text{eff}} = 0.95$ and the output of the second cycling is cycled again at $k_{\text{eff}} = 0.90$. The cycling continues with the full series calculated here being for $k_{\text{eff}} = 0.99, 0.95, 0.90, 0.83,$ and 0.76 . The first three cycles would use accelerator neutrons and the last two would use fusion neutron sources. ➤ **Figure 11** shows k_{eff} and the cumulative burn-up fraction for each cycle along with the additional energy in gigawatt-years that would be extracted from the fuel loading from a typical LWR generating 1 GWe-years of energy per year (five modules).

➤ **Table 9** includes more details about the five cycles for burning of the spent fuel from one LWR operating at 1,000 MWe. It begins with starting the LWR waste burning in a GEM*STAR reactor in 2020 at $k_{\text{eff}} = 0.99$ and generating 1 GWe. Because it took 40 years for the LWR to generate its total waste stream, it also takes 40 years for GEM*STAR to make the first pass at $k_{\text{eff}} = 0.99$ generating the same 1 GWe power as the LWR. The second cycle therefore starts in 2060 with a more powerful accelerator referred to in the table as Acc. 2 and $k_{\text{eff}} = 0.95$ where the fission chain averages 20 in length. In this second cycle the *cost per neutron* is the same because the accelerator uses the same technology as Acc. 1, but the system required five times more neutrons so the total neutron cost is a factor of 5 larger. Therefore, whereas the accelerator added about 3% to the final cost of electric power for $k_{\text{eff}} = 0.99$, it will add about 15% for $k_{\text{eff}} = 0.95$. For the third cycle at $k_{\text{eff}} = 0.90$, twice as many neutrons must be generated by Acc. 3 compared with Acc. 2. Accelerator technology advanced beyond that of today is therefore required to *reduce the cost per neutron by two* to keep the cost of electric power the same for Acc. 3 with $k_{\text{eff}} = 0.90$ as with Acc. 2 and $k_{\text{eff}} = 0.95$. Acc. 3 technology is needed in 2100, so reduction of the cost of neutrons by two would be required over the next 90 years.

Achieving the factor of two reduction in cost per neutron for Acc. 3 is probably possible, but today's accelerator technology probably cannot be extended beyond this point. So new accelerator technology would be required to reduce the neutron cost by an additional factor of two by 2140. Alternatively the fourth and fifth cycles would have to use fusion technology reducing the cost per neutron even further in order to keep the relative neutron cost at 5. The fifth and last cycle would begin in 2180 and end about 200 years from now in 2220. At that point the repeated recycle will have reduced the electricity-generated weighted actinide waste per LWR fuel load by a factor of $1/0.068 = 15$. With accelerators alone in the first three cycles, the reduction factor is $1/0.183 = 5.5$.

■ Figure 11

Five successive burn cycles for LWR spent fuel in GEM*STAR. The *top line* shows k_{eff} for each of the five cycles. The *bottom line* shows the cumulative burn-up fraction for the five cycles. Note that each subsequent cycle consumes a larger fraction of the remaining ^{238}U . The *middle line* shows the cumulative energy extracted from five successive recycles of LWR spent fuel. Note that if the total energy generated from the fresh fuel sent into the LWR is of interest, one must add 1.0 to the right ordinate. In each case, the power to produce the neutrons is assumed to never exceed 15% of the output power (see [Table 9](#))

■ Table 9

LWR fuel repeated cycle summary

Cycle	1	2	3	4	5
k_{eff}	0.99	0.95	0.90	0.83	0.77
Start date	2020	2060	2100	2140	2180

End date	2060	2100	2140	2180	2220
Neutron multiplication	100	20	10	6	4
Relative neutron cost	1	5	5	5	5
Energy-weighted LWR waste remnant	0.5	0.324	0.183	0.114	0.068

Because the fission products are not removed by reprocessing, they accumulate in the salt as fluoride compounds. The valence of the fission product atoms averages slightly less than two and there are two product nuclei per fission. The fission of uranium releases four fluorine atoms whereas the capture process on ^{238}U leading to PuF_3 releases one fluorine atom. Overall actinide transmutation in the MSRE experimental reactor at ORNL was found to yield

a slight excess of free fluorine. The free fluorine was not removed but the excess fluorine in the salt was stabilized by using beryllium metal in the salt stream to produce BeF_2 .

The fission product fluoride salts in effect become part of the carrier salt. At the end of the fifth cycle when [Fig. 11](#) shows that 20% of the actinide has been fissioned, the total mole fraction of fission products in the salt has reached about 6.7%. The fission product also is transmuted to some degree while present in the neutron flux. For example, the long lived species ^{99}Tc and ^{129}I from the LWR are reduced by a factor of about three by the end of the five cycles. Of course, these isotopes also are produced in GEM*STAR, so the reduction factor is not as large as for the actinides.

[Fig. 12](#) shows the energy-weighted actinide distribution as the fuel is recycled and the distribution of actinide isotopes cycle by cycle. The sum of the fractions in the back row adds to 1.000 when (off-scale) ^{238}U is added as well as the fission products from the LWR in the amount 0.034. The sum of the isotopes shown in the figure is 0.0209, which can be confirmed by adding all of the isotopes in the second column of [Table 2](#) except ^{238}U . The first pass through with Acc. 1 generated as much energy as that from the LWR, so the total energy is about twice as large and the distribution calculated in [Table 2](#) across the bottom of the table is divided by roughly two. Likewise, as the cycling proceeds through all five cycles, each distribution is divided by the total energy produced up to that point from one original loading of fresh fuel to the LWR. In the fifth cycle the isotope distribution is divided by 7.3 as shown in [Fig. 11](#). It should be noted that when the ^{240}Pu fraction in the front row is multiplied by 7.3 that the fraction of ^{240}Pu is almost as large as found in the output with Acc. 1 and likewise for ^{239}Pu . This is necessarily the case as both isotopes are constantly being replenished by neutron capture on ^{238}U .

The calculation assumes that there is no delay between cycles. If 50 years elapses between cycles, 85% of the ^{244}Cm will have decayed to ^{240}Pu . Then 65% of the ^{240}Pu would undergo fission as ^{241}Pu . In that case, the value of k_{eff} is substantially higher for later cycles than shown in [Fig. 11](#) and the external neutron requirements correspondingly smaller.

It is also instructive to consider the equilibrium distributions of [Fig. 12](#) without the energy production weighting, which is shown in [Fig. 13](#). By the second recycle at $k_{\text{eff}} = 0.95$ and with Acc. 2, almost all of the power originates from ^{238}U . The ^{244}Cm is a large advantage from a proliferation perspective for two reasons. First its 18-year half life for alpha decay results in a large production of neutrons from the $^{19}\text{F}(\alpha, n)^{16}\text{O}$ reaction that strongly inhibits removal and handling of fuel for immediate chemical extraction of weapons-useful plutonium. Second, its decay leads to ^{240}Pu and to an isotopic mix where the ^{239}Pu concentration is about 25% and the delayed neutron fraction from both ^{240}Pu and ^{242}Pu is too large for the Pu to be an interesting weapons-useful material.

10 Other Fuels

The versatility of the molten salt fuels allows a wide variety of fuels for GEM*STAR for various stages of burning or values for k_{eff} .

10.1 Thorium and Depleted Uranium Fuels

As far as the eutectic mixture ${}^7\text{LiF} : 0.5\text{UF}_4$ is concerned, Th can be exchanged almost one for one with U with little influence on the mixture melting point as shown in [Fig. 2](#).

Figure 12

The equilibrium isotropic distribution as the LWR spent fuel is recycled. The back row is the isotropic distribution from an LWR burned to 33,000 MW-days/tons of actinide. The ^{238}U component is not shown because it is off scale for all distributions in the figure, nor is the fissioned fraction of 0.034 shown. When the ^{238}U and the fission fraction are added to the back distribution, the total is 1.00. The second distribution from the back is from the first burn with the accelerator at $k_{\text{eff}} = 0.99$. Because as much electric power is generated from the LWR recycled fuel as was generated from fresh fuel, this distribution is divided by two and so on for the rest of the distributions

Figure 13

The distributions of [Fig. 12](#) without the energy weighting

■ Figure 14

Burn-up of thorium as function of neutron fluence. The *lower curve* is k_{eff} as calculated from MCNP5 and the *upper curve* is k_{eff} with the graphite correction. The *middle curve* is the burn-up fraction

► Figure 14 shows k_{eff} and burn-up as a function of fluence for a pure thorium fuel. Of course, at start up the fission power is zero, but builds up as ^{233}U grows in. For GEM*STAR's equilibrated continuous flow operation, Th fuel has the disadvantage that k_{eff} never reaches above about 0.963, but the burn-up in the first cycle is large at about 10% for a fluence of $0.12 \times 10^{24} \text{ n/cm}^2$. The reason for the inferior value for k_{eff} compared to natural uranium is obviously the absence of a feed of fissile material using thorium. However, because the ^{233}U capture-to-fission ratio is one-half of that for ^{235}U and one-fourth of that for ^{239}Pu , the burn-up is larger and the ^{235}U produced from multiple ^{233}U neutron capture provides additional fissionable fuel.

Regarding the weapons usefulness of the equilibrium ^{233}U for $k_{\text{eff}} = 0.96$, the $^{234}\text{U}/^{233}\text{U}$ atom ratio is 0.27. While higher enriched ^{233}U might be produced by using smaller fluences such as $0.03 \times 10^{24} \text{ n/cm}^2$, the same constraints against this from the supply of start-up fuel and the inaccessibility of the outflow can be used as explained elsewhere in this paper to avoid production of weapons-useful uranium.

Although calculations have not been done for feeding depleted uranium with ^{235}U present at the 0.20% level, it is expected that optimal performance will be found at $k_{\text{eff}} = 0.96$ with a burn-up of 5%. Because the burn-up for the same amount of fuel at the same k_{eff} is twice as high for thorium as for depleted uranium, thorium might appear to be more attractive fuel than depleted uranium. However, thorium has to be mined and refined to ThF_4 whereas depleted uranium is stored in vast quantities as highly purified almost free UF_6 , which only needs to be converted to UF_4 . As a practical matter the depleted uranium probably would be consumed first.

10.2 Fueling GEM*STAR Over the Long Term

Because uranium and thorium can be exchanged in arbitrary fractions while maintaining a 66.6% mole fraction of ${}^7\text{LiF}$, there is a wide range of options for fueling GEM*STAR. The fueling of stage 1 of GEM*STAR operation is next considered for $k_{\text{eff}} = 0.99$. The obvious initial choices are natural uranium and spent LWR fuel since both burn at $k_{\text{eff}} = 0.99$. Natural uranium would be a good reference fuel because UF_4 is produced on the path to the UF_6 needed for isotopic separation. The fuel feed for GEM*STAR from [Table 5](#) is 76 tons of uranium flowing through in 4.5 years or 17 tons/year with a burn-up fraction of the total uranium of 0.013. The cost of UF_4 is close to that of UF_6 , which was \$150/kg on 11/1/08, which corresponds to 2.9% of the cost of electricity assuming the power is sold at \$0.05/kWh.

The burn-up fraction for (low enriched) LWR spent fuel at $k_{\text{eff}} = 0.99$ is 0.0324 as shown in [Table 8](#). This burn-up fraction is three times higher than that for natural uranium at $k_{\text{eff}} = 0.99$, so the flow rate of spent fuel is 1/3 of that for natural uranium or $17/3 = 5.6$ tons/year. Therefore, the upper limit to what the reactor operator would pay for fluorinated LWR spent fuel is $3 \times \$150/\text{kg}$ or \$450/kg. Presently reactor operators pay \$0.001/kWh into a waste storage fund, which corresponds to about \$350/kg, and this payment in principle absolves the operators of any further responsibility as the spent fuel is owned by the US government. The government has already been paid \$350/kg for the spent fuel and a GEM*STAR reactor operator might be willing to pay the federal government \$450/kg for the fluorinated spent fuel. So if the federal government could perform the fluorination of the spent fuel for \$800/kg, it would break even on the fluorination.

Alternatively if a private organization could do the fluorination at less than \$800/kg, it could turn a profit by being paid \$350/kg by the US government to take it off its hands and selling it at \$450/kg to the reactor operator. Another possibility is that small-scale fluorination technology might be developed enabling fluorination on sites of existing reactors at the rate of one ton per 2 weeks, which is the rate required to keep up with a 1-GWe reactor spent fuel production rate of 26 tons/year. Such an arrangement would eliminate the transport costs for fluorination and offer other advantages as well. Because the spent fuel usage rate for GEM*STAR is only 5.6 tons/year for a production of about 220 MW_e, about five GEM*STAR units would need to be ganged together to match the power of the 1-GWe LWR and the total power from the site would double if an LWR continued to operate on the same site.

It seems likely that stage 1 at $k_{\text{eff}} = 0.99$ would continue until all of the LWR spent fuel was processed. Owing to the advantages of GEM*STAR technology over that of LWRs, spent fuel from LWRs would eventually cease to be generated bringing an end to the use of LWR fuels in step 1. That would not necessarily spell the end of stage 1 operation at $k_{\text{eff}} = 0.99$ as natural uranium is perhaps the fuel of choice for step 1 anyway. Natural uranium would be used at step 1 until its cost owing to scarcity rose to justify moving to stage 2 at $k_{\text{eff}} = 0.95$ with a larger accelerator requiring about 15% of the reactor's generated electricity and with the accelerator capital cost rising to about 15% of the reactor cost. Therefore, if the capital and operating costs are about equal for GEM*STAR at $k_{\text{eff}} = 0.95$, the cost of electric power for stage 2 would rise by 30% to \$0.052/kWh. The switch from stages 1 to 2 might happen when UF_4 costs have risen about four times from \$150/kg to \$750/kg, so that the stage 1 fuel cost percentage has risen from 3.6% to about 15%. However, it should be mentioned that a 50–50 combination

of natural uranium and depleted uranium would exhibit equilibrium $k_{\text{eff}} = 0.97$ and operation with this combination might precede step 2 until the supply of depleted uranium is exhausted.

For stage 2 of GEM*STAR at $k_{\text{eff}} = 0.95$, the thorium and depleted uranium fuels are options in addition to the outflows from the first-cycle-use of natural uranium and LWR spent fuel in stage 1. It should be emphasized that k_{eff} initially for the first loading of pure thorium would be zero, and that k_{eff} for pure depleted uranium would be low also. The value for k_{eff} could be brought up to 0.95 eventually by using only accelerator neutrons, but the power output would be low during this build-up period. However, equilibrium k_{eff} could be reached far quicker by mixing some natural uranium with the first load of thorium or depleted uranium. The multiplication would be boosted by the ^{235}U in the natural uranium and initially there would be no neutron losses to fission products. Because natural uranium would be needed only in the first load, this means of boosting multiplication could be implemented even after the price of natural uranium has become very high.

It should also be mentioned that because the equilibrium k_{eff} is the same for thorium, depleted uranium, stage 1 outflow from natural uranium burning, and reburning of LWR spent fuel, these four fuels for stage 2 could be mixed in arbitrary combinations of two, three, or four of the types as long as the ^7LiF carrier is maintained at the 0.666 mole fraction of the fuel salt. For stages 3–5 any fuel mixture also would be suitable.

Stages 1 and 2 can use today's accelerator technology for electricity production at a cost shown later to be lower than that from new LWRs or coal without CO_2 sequestration, so it is important to estimate how much electricity has been produced at end of stage 2. The IAEA estimates the "reasonably assured uranium reserves" at 36 million tons (Global Uranium Resources, IAEA, June 2005). There is roughly four times as much thorium in the earth's crust as uranium, so the total of the Th and U material is about 180 million tons. Today's LWRs produce 1GW_e -year of electric energy fissioning 3.4% of the 26 tons of low-enriched heavy metal fuel fed per year. With reburning in GEM*STAR through stages 1 and 2, an additional 5% is fissioned for a total of 8.4%. The energy production from the other fuels that contain very little or no ^{235}U is less at about 5% after finishing stages 1 and 2. The reserves of Th and U are much larger than the spent fuel from the LWRs, so 5% burn-up is the useful figure for calculating the total energy recoverable by burning through stage 2.

GEM^*STAR stages 1 and 2 electricity = $(180 \times 10^6 / 26)(0.05 / 0.034) = 10^7 \text{GW}_e$ -year. The world's present nuclear electricity power is roughly 400 GW_e and should increase by 10 if the world is to receive the full benefit of nuclear power. GEM*STAR technology would therefore carry the world's electricity needs at today's prices for 2,500 years *without advances beyond today's accelerator technology without reprocessing, fast reactor technology, or near-term permanent geologic storage*. Advances in accelerators long before the end of that period could be used to reduce the cost of electricity still further. Alternatively accelerator advances reducing the cost of neutrons by two in this period could be used to proceed to stage 3 where the burn-up would be about another 5% extending the fission energy resource from 2,500 to 5,000 years by the end of stage 3 at no increase in electricity cost. Cheaper sources of neutrons from fusion would enable burn-up in stages 4 and 5 and extending the fission resource to 10,000 years without reprocessing.

11 Other Factors Affecting GEM* STAR Success

11.1 Ultimate Ocean Disposal?

GEM* STAR fuel is in the form of fluoride salts that are somewhat water soluble. Data on the solubility of UF_4 are rare with the best coming from a study of the solubility of UF_4 powder mixed with polyethylene in cylinders 5 cm in diameter and 10 cm high (Adams et al. 1997). Different percentages of UF_4 were studied but the maximum density was 90% UF_4 by weight. Extrapolating to a density of 100% the estimate is at least 10 g/l of distilled water, so ultimate remnant waste disposal in the ocean might be an option. Waste disposal in the ocean has not been viable because waste in the form of almost insoluble oxides or metals could lie on the ocean floor a long time before they were finally dissolved and might even be covered by sediment before dissolution. Disposal of waste in the sub-seabed of the ocean has also been considered but rejected because it would lie nearly unprotected for eons. It could be readily retrieved possibly for military purposes, so some international guarding arrangements would have to be established.

Waste dissolution in the ocean water would be an ideal international solution for all nations as all nations share ownership of the oceans. Ships could be built to pull water up from deep ocean depths where the fluoride salt waste on board would be ground into powder and dissolved on board and then pumped back to the same depth. GEM* STAR waste burned through the fifth cycle is still 80% ^{238}U or ^{232}Th . The concentration of natural uranium in the ocean is 0.003 g/tons of seawater. The mass of the world's oceans is 2×10^{20} tons so the mass of uranium in the ocean is 6×10^{11} tons, which may be compared with the earth's "reasonably assured reserves" of uranium of 3.6×10^7 tons. If all the readily available mined uranium were to go into the ocean, its concentration compared to that already dissolved would be only 60 parts in 1,000,000.

Spent fuel is of course radioactive and one needs to estimate the impact of radioactivity on the ocean if it were dissolved into the ocean. The GEM* STAR plan is to recycle the fuel through stage 5 before considering the fuel waste (although because 80% of the ^{238}U and ^{232}Th are still present, the remnant might not be considered waste). The GEM* STAR remnant would then be placed in interim underground storage for 300 years using Hastelloy containers and then dissolved into the ocean if there is no further use for it.

One approach to estimating the risk of the radioactivity in the ocean would be to calculate the ingestion toxicity, which is the volume of pure water required to dilute uniformly dissolved radioactive to drinking water standards. If one does this using the CURE (1990) Report dilution for the waste from stage 5, the result is 1.4×10^9 m³/tons of spent fuel. If all of the 36 million tons of U and Th were burned through stage 5, the radioactivity evenly distributed in sea water would be a factor of about 2,000 below the limit for radioactivity in drinking water.

Another approach is to compare the radioactivity with the radioactivity of uranium and ^{40}K in sea water. If all 36 million tons of uranium and thorium spent fuel at stage 5 were dissolved in sea water after interim storage underground for 300 years, the radioactivity would be about equal to that from the natural uranium dissolved in sea water and would be about 1% of the decay rate of ^{40}K .

To make dissolution on ship practical, the radioactivity concentration of water from the ship would have to be about 100 times higher than the dilution limit and natural mixing processes would have to be relied on to dilute by the additional factor of 100. One ship's capacity would then be about 1,000 tons/year requiring about ten ships to meet the rate of disposing of stage

5 GEM*STAR waste from generating worldwide 10 times the nuclear power we have today. Of course geologic storage beginning in about 500 years remains an option.

11.2 GEM*STAR Comparison with Fast Breeder Reactors

Since 1970, the primary focus of nuclear reactor development has been on FBR. The reason was that nuclear energy was believed to have no long term future owing to the limited abundance of ^{235}U , and many still support this viewpoint. Because the cost of electricity from FBRs is higher than that from the LWRs, one probable implementation strategy would be to continue to generate electricity from LWRs until the cost of the uranium increased to the point that it was economical to implement FBRs.

With GEM*STAR the nuclear energy resource could be doubled, as has been shown above, simply by feeding natural uranium using a modest accelerator with $k_{\text{eff}} = 0.99$ and generating twice the energy from mined uranium as the LWR generates. No reprocessing, enrichment, vast plutonium inventory, fast reactors, or onerous international oversight such as those which were proposed for the GNEP would be necessary. One could argue therefore that instead of focusing nuclear technology development, as for the past 40 years, on addressing the consequences of the limited ^{235}U resource, it would have been better to focus on supplementing the fission neutrons via accelerators.

Looking back, it seems obvious that if there had been no ^{235}U at all in natural uranium, accelerator development would have been pursued with the massive resources that have been spent on enrichment, reprocessing, and fast reactor development to enable burning the ^{238}U as ^{239}Pu . Nuclear electricity probably would be at least as abundant as it is today based on ^{239}Pu and ^{233}U . Nuclear weapons would also be with us, based on accelerator-produced ^{239}Pu with reprocessing being needed only for nuclear weapons. In the later part of the twentieth century, nuclear technologists would have debated the merits of using surplus ^{239}Pu and ^{233}U to move on to FBRs that did not require accelerators, or of continuing the improvement of accelerator and fusion neutron sources.

11.3 Fusion Neutron Sources

With our present understanding of accelerator technology, it seems unlikely that the cost of neutrons from today's accelerators could be reduced by a factor of four to enable stage 4 burning. However, it can be shown (Bowman and Magill 2006) that fusion neutrons must be much cheaper than accelerator neutrons long before a practical fusion reactor can produce electricity competitively priced with fission. The expectation for the ITER magnetic fusion project in Cadarach, France and the NIF project at Livermore, CA is that they will reach physics break-even defined as fusion energy yield matching the laser energy required to confine and heat the plasma. Engineering break-even, which is far more challenging, is to generate and convert fusion energy to the buss-bar power necessary to generate the laser light needed for inertial confinement or the energy required to heat a plasma and confine it by magnetic fields. Yet a practical fusion reactor lies well beyond engineering breakeven. Making neutrons cheaper than accelerators can produce them is a much more practical goal for fusion technology development than an economically competitive fusion power reactor.

It is estimated above that the implementation of GEM* STAR with accelerators would extend the use of nuclear energy for 5,000 years before it became necessary to rely on fusion neutron sources. Of course, if fusion neutrons became cheaper than accelerators at any time during the 5,000-year period, fusion neutron sources would take over from accelerators. This prospect could be moved ahead if the strategic aim for fusion research could switch from the present aim for economically competitive fusion power to producing neutrons cheaper than neutrons from accelerators. Present accelerator neutrons can be produced by spallation at a cost of 33 MeV of proton beam power for a lead target or perhaps 80 MeV of buss-bar power; with a uranium target the costs are lower by a factor of 2–40 MeV of buss-bar power. Fusion neutrons would have to be produced at a cost of 40 MeV of buss-bar power per neutron to be competitive with today's accelerators (after consuming half of the fusion-generated neutrons to produce tritium from ${}^6\text{Li}$) and at 20 MeV per neutron to reach the probable limit of accelerator technology.

Obviously, a practical fusion power plant requires fusion development far beyond that required for a fusion neutron source that is competitive with accelerator technology. It has already been shown here that even if ${}^6\text{Li}$ based fusion power became practical, the fusion energy resource does not exceed that from fission, which is capable of supplying the world's needs for electricity for thousands of years. Perhaps then a more beneficial and practical goal for fusion research than a power plant should be to produce neutrons more cheaply than accelerators. A path to a fusion source of neutrons that is cheaper than accelerators, which could never become a practical fusion reactor, might be quite different technology from the technical path toward an eventual fusion power plant.

12 Nonproliferation Advantages of GEM* STAR

The two channels to nuclear weapon proliferation that concern the world are the production of highly enriched uranium (HEU) and conversion of ${}^{238}\text{U}$ to produce weapons plutonium (W-Pu). As the primary advantage of GEM* STAR is that it can burn natural uranium as fuel and not produce W-Pu in the process, it eliminates the need for LEU for commercial nuclear power. With GEM* STAR's features of higher usage of mined uranium than LWRs and recycle without reprocessing, nuclear can become the world's dominant source of electric power for centuries without enrichment.

As GEM* STAR can also burn spent fuel from today's LWRs without invoking reprocessing and its associated plutonium waste stream, the commercial plutonium (C-Pu) accumulated to date, and that which will be generated before a change-over to GEM* STAR is complete, also can be consumed as fuel in GEM* STAR as a somewhat richer fuel than natural uranium and transformed to a Pu isotopic mixture even more challenging than C-Pu for nuclear weapons use. GEM* STAR therefore cuts off any role in the production of nuclear energy for enrichment and reprocessing and consumes the by-product Pu from LWRs as well.

The remaining option for acquiring nuclear weapons is the misuse of GEM* STAR technology. A key factor in eliminating this prospect is the requirement for very isotopically pure ${}^7\text{Li}$. GEM* STAR can tolerate very little neutron absorption in lithium and still be an economically practical technology today and in the foreseeable future. The burning of the natural uranium at a fluence of 0.007 n/barn, which results in twice the burn-up of mined uranium as in our LWRs, requires ${}^7\text{Li}$ with an isotopic purity of 0.9999. At this level the loss of neutrons to the 0.0001 ${}^6\text{Li}$ contaminant is 1/3 of that lost to fission products. Of course, higher losses could be tolerated

with larger accelerator power with a corresponding higher ultimate cost of electricity that could price GEM* STAR out of the electricity market.

The production of ^7Li at this purity level is not like uranium enrichment, a technology developed long ago and now widely available to nations that want to put in the required resources to duplicate it. Large amounts of ^6Li have been produced in the weapons programs of several nations with a resulting production of ^7Li with ^6Li in the 1% or higher level. In the USA, this was produced by the $\text{LiOH}\cdot\text{H}_2\text{O}$ plus mercury column exchange process. This purification level by a factor of 7.5 is still quite far from the factor of 750 required at a production rates of 1 tons/year per 200 MWe GEM* STAR. With an upper limit for the separation factors of about 1.03 achievable per stage by the column exchange method, 220 stages would be required to reach the 0.9999 purity level.

ADNA Corporation has developed economically practical alternative means to reach the desired purity levels of ^7Li at the production rates required. Of course, the method will be protected as corporate proprietary technology. ADNA's business plan is not to share this technology so as to make ^7Li production a profit center. Of course, it recognizes that unfair pricing of ^7Li would drive the eventual rediscovery and duplication of the method. ADNA however intends to sell ^7LiF to foreign nations for mixing with their own domestic sources of natural UF_4 provided such sales of GEM* STAR units and their required ^7LiF are made with approval of the US government.

Having closed off the primary routes of enrichment and reprocessing for proliferation today by means of GEM* STAR, it is necessary to consider the misuse of GEM* STAR technology by those nations that might purchase these power plants. It is in principle possible to produce W-Pu in GEM* STAR from natural uranium by operating the plants at a lower fluence of 0.001 n/barn instead of the optimum level for electricity production of 0.007 neutrons/barn. In this latter standard mode of operation, the flow through of a full volume of fuel takes 4 years and the fuel outflow of fuel is into tanks under the reactor that are inaccessible and sufficiently large for storage for 40 years of operation.

If the accelerator power were not changed but the fluence lowered to 0.001 n/barn, the fuel flow rate would be seven times higher with resulting production of W-Pu at a substantial rate. GEM* STAR is equipped with a fixed leak rate fixture buried in the most inaccessible part of the reactor. If the fuel feed rate is increased beyond the leak rate, the system will simply overflow and a commode-like fail-safe system will empty the entire loading of reactor fuel into the storage tanks underneath.

The other option is to reduce the feed rate by a factor of seven and reduce the accelerator power by a factor of seven giving the lower fluence of 0.001 n/barn necessary to produce W-Pu. Such an action would require $4 \times 7 = 28$ years for a complete flow-through of one core volume and the fuel in the storage tank would still be inaccessible to a high degree. Such an action also could not be hidden as there are many direct and indirect methods to detect operation at a power level lower by seven than nominal with consequent actions following. For example, the USA could simply forbid any further sales of ^7LiF to the reactor owner.

Finally, there is the possibility of misusing the GEM* STAR accelerator by moving it to another site and using the beam to produce W-Pu by neutron absorption in a subcritical array of natural uranium by means widely known to the nuclear engineering community. The GEM* STAR accelerator structure can be manufactured as a single welded unit that cannot be cut into pieces and reassembled elsewhere. Of course, the owner could tear down the GEM* STAR reactor and target and replace it with a W-Pu-producing assembly, but the radioactivity and the presence of used fuel in and under the facility would significantly complicate such

a measure. The nation probably could copy and duplicate the accelerator elsewhere, but that can be done already today as the GEM*STAR accelerator has no advanced features that are not commonly available knowledge.

The latter examples are extreme measures that might be taken to circumvent GEM*STAR's natural nonproliferation features. ADNA believes that it is probably impossible to devise any nuclear plant that could not be misused or reconstructed to produce W-Pu. However, ADNA's objective is to devise a design that makes the misuse so complicated, expensive, and time consuming that a nation desiring nuclear weapons would instead simply produce HEU using the centrifugal technology that seems to be widespread. Any new nuclear electricity technology that eliminates the need for uranium enrichment and reprocessing of spent fuel, that consumes LWR spent fuel while increasing the ^{240}Pu fraction, and that forces a decision to obtain nuclear weapons down the already existing uranium enrichment path cannot be considered a proliferation-prone technology. No new practical paths to weapons material are opened by GEM*STAR and the major paths existing today are closed.

13 Cost Estimation

Several recent projects involving accelerators approximately the size of those required for GEM*STAR provided cost estimations for the accelerator and also provided other information that enables a cost estimation for the reactor. These enable a cost estimation for GEM*STAR without a "starting from zero" estimation by GEM*STAR advocates.

13.1 GEM*STAR Accelerator Costs

The accelerator transmutation of waste (ATW) project that originated at Los Alamos National Laboratory in the early 1990s evolved into a US Department of Energy program based on an accelerator-driven sodium-cooled fast reactor for fissioning away the plutonium and other higher actinides in LWR spent fuel and for transmuting ^{99}Tc and ^{129}I to stable species. Reprocessing was therefore required to separate out the fission product and uranium destined for geologic storage. Also it was necessary to fabricate the higher actinides, ^{99}Tc and ^{129}I into solid fuel assemblies for insertion and removal from the fast spectrum reactor.

A report on cost for this particular ATW concept was prepared (Smith et al. 1999) by the Pacific Northwest National Laboratory (PNNL), which was considered to be a neutral organization because PNNL was not involved as an originator or advocate of the ATW technology. The report estimated costs separately for the accelerator/beam transport, the transmuter/target/power generator, the reprocessing facility, and the solid fuel fabrication facility. An overall operations cost for the full facility was also estimated. The station included two accelerators with each accelerating 45 MW of beam power, eight 840 MW_t subcritical fast reactors that generated altogether 2,480 MW_e of electricity, and the associated reprocessing plant to chemically separate the actinides and prepare the solid fuel. Eight of these stations were required to burn the higher actinide over a period of 60 years from the roughly 100 LWRs presently operating in the USA for an assumed life of 40 years. The total electric power from the transmuters was then 30% of that from the LWRs that produced the waste.

Another reference for reliable accelerator costing was that for the SNS accelerator at ORNL completed in 2007. Also costs were taken from the 10 MWb CSNS report (Shapiro et al. 2003)

■ **Table 10**

Accelerator costs in 2008 dollars (millions)

(1)	(2)	SNS		PNNL		GEM*STAR
		Actual (3)	Scaled ^a (4)	Estimation (5)	Scaled ^a (6)	Single Acc. ^a (7)
Proton energy	GeV	1.0		1.0		0.5
Average power	MW	1.0		45.0		0.65
Average current	mA	1.0		45.0		1.3
Length	m	186.0		–		93.0
Buss-bar power	MW	3.1		122.0		1.8
Efficiency	%	28.0		37.0		37.0
Capital cost	M\$	113.0	43.0	1413.0	54.0	48.5
Capital cost per MW	M\$	113.0	66.0	31.4	84.0	75.0
Annual operations cost	M\$/year	2.1	0.8	58.0	2.2	1.5
Annual operations cost per MW	M\$/year-MW	2.1	1.0	1.3	3.4	2.2
Annual electricity cost	M\$/year	2.1	1.4	84.0	1.2	1.3
Annual electricity cost per MW	M\$/year	2.1	2.1	1.6	1.8	1.9

^aThe costs in these column are not for one stand-alone accelerator, but the costs are the total costs for six identical accelerators built concurrently for a 1,100 MW_e GEM*STAR system and then divided by six. For a single or a pair of accelerators, the costs would have to be scaled upward using the 0.6 exponential factor as explained in the text. Therefore the capital and operations costs in the seventh column would need to be increased for each of a pair of accelerators by the factor $(6/2)^{0.6} = 1.93$. For the six accelerators required for 1,100 MW_e, the factor is $(6/6)^{0.6} = 1$ and no adjustment is required.

already mentioned. ➤ [Table 10](#) gives the costs in 2008 dollars inflated by the factor 1.3 for the elapsed period from 1999 to 2008 for the PNNL numbers and by the factor 1.03 for the SNS.

The cost estimate for the GEM*STAR accelerators is made assuming that accelerators are constructed in pairs in the same building but with independent power supplies so as to avoid any common-mode failures. Therefore, we estimate the cost of building two accelerators of energy 0.5 GeV and 1.3 mA for a combined beam power of 1.3 MW (using a uranium target).

The estimated costs for the GEM*STAR accelerators based on the costs of other accelerators of other powers must take into account a scaling factor based on power or size. This scaling factor is typically 0.6. Therefore, to derive the capital cost from a single 45 MW accelerator for a set of six accelerators with a total power of 3.9 MW, the factor $(3.9/45)^{0.6} = 0.23$ is applied to the \$1,413 million for the PNNL estimate to find a combined cost for the set of six to be \$326 M. For the cost per accelerator 1/6 of this figure or \$54 M is entered in column six of ➤ [Table 10](#). This is the cost for a power of 0.65 MW, so the cost per megawatt of \$54 M/0.65 MW = \$84 M is entered below in the same column. The same factor of 0.23 also is applied to the operations cost for the set of six and then this number divided by six to obtain the next two entries in the sixth column. There is no economy of scale associated with the power cost so the electric power cost for one accelerator is proportional to the beam power. The factor $0.65/45 = 0.0144$ may be applied to the PNNL estimate of \$84 million to find the annual electric power cost of one GEM*STAR accelerator to be \$1.2 million.

The actual cost from the SNS project must be scaled by the same procedure so that for example the factor $(3.9/1)^{0.6} = 2.26$ gives the total cost for the six accelerators as $\$113 \text{ M} \times 2.26 = \256 million . This number divided by six is then entered in the fourth column.

The cost figures in columns 4 and 6 come out roughly comparable when using the 0.6 scaling factor in spite of starting from accelerators with power different by a factor of 45. The cost figures in columns 4 and 6 are therefore averaged to derive the estimate per accelerator in column 7 *when six are concurrently built*. The cost figures in column 7 must be multiplied by six to find the capital, operating, and electricity costs for an 1,100 MW_e GEM* STAR system. It is important to note that the electricity costs assume a rate of \$0.08/kWh. These costs will be lower if the system is self-powered using GEM* STAR electricity that would otherwise be sold into the grid and higher if a green energy source is used to drive the accelerator with green energy selling at a regulated price that is considerably higher than GEM* STAR electricity.

It should be emphasized that these accelerator costs are derived from a first-of-a-kind actual cost for the SNS and a PNNL estimate. If 100 GEM* STAR units of 1,100 MW_e were constructed so as to burn the spent fuel from the US LWR fleet of 100 reactors as fast as the spent fuel was generated, 600 accelerators would be required. This should be large enough to realize a significantly lower accelerator cost owing to mass production, so the cost estimates from [Table 10](#) are likely to be upper limits.

13.2 GEM* STAR Reactor Costs and Breakeven Electricity Price

The PNNL cost estimates taken from Table F-1 of Smith et al. (1999) for the reactor included the reactor itself along with the beam transport, vertical bending magnets, and a target are given in [Table 11](#) with an inflation factor of 1.31 for the period from 1999 to 2008. The uranium fuel cost is for natural uranium in the form of UF₄ at a December 2008 cost of \$150/kg. From [Table 5](#) the initial inventory is 380 metric tons and the annual use rate is 84 metric tons.

Assuming an on-time of 90% for the system, an interest rate of 7% on the capital, and a 30-year term gives a breakeven electricity sales income of \$390 million/year and a breakeven electricity cost of \$0.043/kWh for a 1,100 MW_e system.

■ Table 11

Capital and operating costs for 1,100 MW_e GEM* STAR

	Capital ^a (\$M)	Operating (\$M)
Six accelerators modules	291	17
Five subcritical reactors modules	2,000	58 ^b
Five turbine-generator modules	700	–
Natural uranium fuel	57	13
Site support	195	34
Total	\$3,243 M	\$122 M

^a“Overnight” construction costs

^bIncludes operating costs for the turbine generators

■ **Table 12**
Capital and operating cost for a 220 MW_e GEM*STAR

	Capital (\$M)	Operating (\$M)
Two accelerators modules	187	5.5
Subcritical reactors module	400	22.4
Turbine-generator module	140	–
Natural uranium fuel	12	2.6
Site support	40	13.1
Total	\$779 M	\$43.6 M

► *Table 12* shows the figures for a 220 MW_e GEM*STAR system. The figures of ► *Table 11* are scaled by the 1.93 factor in the capital column for the pair of accelerators and the site support and in the operating column for the operating reactor and the site support.

For a 7% interest rate, the breakeven electricity cost from the figures in ► *Table 12* is \$0.062/kWh.

If, instead of building two accelerators, the initial 220 MW_e GEM*STAR was built at a site where an accelerator of the required capacity already existed that could supply 0.65 MW of beam power, only one accelerator would need to be built. In that case, using the above figures, the GEM*STAR reactor owner and operator could afford to pay \$13 million per year for beam to the existing accelerator owner and meet the same breakeven cost of \$0.062/kWh for electric power for a 220 MW_e GEM*STAR unit.

The methodology used here in implementing the estimates of the PNNL report was to

1. Assume that the PNNL-costed reactor, and power generation equipment have the same complexity as GEM*STAR.
2. Prorate the PNNL cost to the construction “overnight” of a group of five GEM*STAR systems generating a total of 1,100 MW_e.
3. Add an inflation adjustment by a factor of 1.3 for the interval from the time of the PNNL study in 1999–2008.
4. Use the PNNL report’s NOAK (n-production of a kind) cost figures rather than the first of a kind (FOAK) cost figures.
5. Use an interest rate of 7% for retiring the debt on borrowed construction funds over 30 years and calculate the annual cost of debt retirement.
6. Prorate the PNNL annual operations costs for the relevant components.
7. Determine the break-even price for electricity sales.
8. Consider factors that might reduce or raise the costs estimated for various elements of GEM*STAR.

Perhaps the most uncertain element of this methodology is the assumption that a fast reactor and a graphite reactor of the same power have the same capital cost. The comparisons of the two technologies are much too complex to discuss in detail in this chapter. However, it is useful to mention that the reactor volume to produce the same electric power is half as large for the GEM*STAR reactor as for the fast reactor. Perhaps it is also useful to note that the total raw materials cost for the GEM*STAR system of 1,100 MW_e is about \$15 million compared to

the deduced GEM*STAR reactor cost without power generation of \$2,000 million. Finally, we mention that the GEM*STAR reactor vessel is filled with graphite, molten salt, and an internal heat exchanger and the fast reactor with metallic fuel and liquid sodium. Both reactors use low-vapor-pressure coolants, so neither requires the high pressure reactor vessel needed by an LWR.

14 Summary

The worldwide nuclear power community has spent the past 50 years improving the LWR as an electricity generator, trying to extend the usage of mined fuel, and developing and deploying a closed fuel cycle. While the technology for closing the cycle is available and has been for years, its costs, safety, and proliferation concerns have prevented deployment. As long as uranium is abundant, the once-through LWR seems likely to continue to dominate nuclear power (von Hippel 2007; Bunn et al. 2003) while continuing to be dogged by proliferation and waste disposition concerns. If nuclear power continues on the path of the past, it is unlikely that it will have a chance to live up to its promise until a generation of green energy technology and CO₂ sequestration efforts have been found to be reliable, uneconomic, or both.

This chapter discusses three orphan nuclear technologies that, by themselves, have not been found to lead to new nuclear energy technology competitive with LWRs. When advanced graphite, continuous flow-through molten salt, and supplemental neutrons from accelerators are applied in the optimum arrangement described here, it appears that nuclear electric power will undercut the price of any existing or new green energy technology. It will obviate reprocessing, fast reactors, and near-term geologic storage and eliminate the proliferation concerns that are endemic to them.

GEM*STAR technology is not dependent on a national grid as GEM*STAR reactors can undergo start-up with modest power from intermittent electricity sources, can multiply those sources by thirty or more, and can maintain constant power with less than a 3% voltage drop as their wind and solar power sources turn on and off.

GEM*STAR's UF₄ fuel form, accelerator technology, advanced graphite, and molten salt technologies are not locked up in government security programs or otherwise controlled except perhaps by private sector proprietary protections. Therefore, GEM*STAR technology can be developed in the private sector for deployment as soon as regulatory oversight allows it.

Abstract: This chapter describes the various industrial steps which constitute the front end of the nuclear fuel cycle, i.e., the complete set of operations needed to produce a functional fuel element ready to be loaded in a nuclear reactor. This chapter also provides data concerning the element uranium, its abundance and its most relevant properties. The exploration, mining, concentration and site rehabilitation processes are then described.

Light water reactors (LWR), which make the vast majority of the nuclear reactors operating today, and those under construction, cannot use “natural” uranium for their fuel: it must be “enriched” in isotope 235 and the enrichment process itself requires the uranium to be “converted” into a gaseous compound.

Once enriched to the required assay, uranium is then fabricated into solid ceramic “pellets,” piled into leaktight metallic “pins.” These pins are then “assembled” to constitute the fresh fuel element.

The chapter also provides additional information on MOX fuel assemblies used to recycle plutonium in LWR, as well as some data on plutonium and thorium.

One shall also find an explanation of the fascinating “Oklo Phenomenon,” which occurred almost 2 billion years ago in some uranium deposits of Gabon, in this chapter.

This chapter is expanded and updated from part of a previous Springer publication (Barré 2005a).

1 Description

In the conventional sense, a fuel is a substance which can be combined with oxygen to produce heat, by combustion. By extension, the nuclear fuel is a substance which can produce heat by fission of its heavy nuclei by neutrons.

Cars do not burn crude oil straight out of the well, and light bulbs are not plugged directly on hydraulic dams. For fissile nuclei to produce heat by undergoing fission in reactor cores, they must follow a “Fuel Cycle,” combining many different industrial steps in a sequence (Barré 2005a; Cochran and Tsoufalnidis 1999; Marshall 1981; Patarin et al. 2002; Wilson et al. 1996). One calls the complete chain of industrial operations leading to the supply of a fuel assembly (or element) to a nuclear plant as the “Front End” of the fuel cycle.

Fuel cycles differ from one reactor type to the other and according to the choice of the fissile/fertile nuclei involved. Let us first describe the most usual fuel cycle, the uranium cycle for light water reactors (LWR) (► Fig. 1). The front end encompasses the following steps:

- Uranium exploration
- Uranium ore mining
- Ore concentration (milling) as “yellowcake,” at the mine mouth
- Shipment of the concentrate
- Conversion to uranium hexafluoride UF_6
- Isotopic enrichment of the uranium
- Fuel fabrication

Between these steps there are, of course, many controls. Each step is, by itself, a complete industrial process which is described in more details hereafter. For reactors using natural uranium and for those recycling plutonium or ^{233}U , the enrichment step is bypassed. The fuel fabrication is the most reactor-specific process.

2 Uranium Exploration and Mining

2.1 The Element Uranium

Uranium and Thorium ores are the raw material and natural resources of nuclear power. They are neither abundant nor very rare metals on the Earth's crust: their abundance is comparable to that of Tin, Tungsten or Molybdenum, of the order of 3 g/tons for uranium, 7 g/tons for thorium.

Discovered in 1789 by Klaproth, uranium, atomic number 92 of the periodic classification of Mendeleev, is the heaviest naturally occurring element on Earth. As a metal, its volumic mass is 19 g/cm^3 , and its melting temperature is $1,133^\circ\text{C}$. It is naturally radioactive and constitutes a mixture of two main isotopes, both radioactive, ^{238}U for 99.28% and ^{235}U for 0.715% (To be precise, there is also 0.006% ^{234}U). Without this tiny fraction of ^{235}U , there would probably be no nuclear power today because ^{238}U has a low probability of being fissioned by neutrons, at least in the energy range of the neutrons released in the fission process, while ^{235}U is easily fissioned by neutrons of any energy.

On the other hand, ^{238}U is very useful because it captures neutrons and then undergoes a series of β decays leading to ^{239}Pu , a fissile isotope of plutonium, analogous to ^{235}U : ^{238}U is "fertile." The specific activity of uranium is 24.4 kBq/g ($0.66 \mu\text{Ci/g}$), half of which is due to ^{238}U and half to ^{234}U , the contribution from ^{235}U being negligible.

Once upon a time... uranium was born in a dying star. It is inside stars that light elements combine, "fuse," to produce heavier elements, liberating energy in the process: hydrogen

■ **Table 1**
²³⁸U decay chain

Nuclide	Decay mode and energy (MeV)			Half-life
	α	β	γ	
²³⁸ U	4.19		0.048	$4.51 \cdot 10^9$ y
²³⁴ Th		0.19	0.03, 1.001	24.1 d
²³⁴ Pa		0.14	0.043	6.75 h
²³⁴ U	4.77		0.053	$2.47 \cdot 10^5$ y

²¹⁸ Po	6.00			3.05 m
²¹⁴ Pb		0.67	0.053	26.8 m
²¹⁴ Bi		1.51	0.61, 1.76	19.7 m
²¹⁴ Po	7.69			$1.64 \cdot 10^{-4}$ s
²¹⁰ Pb		0.015	0.046	22 y
²¹⁰ Bi		1.16		5.01 d
²¹⁰ Po	5.31			138.4 d
²⁰⁶ Pb	Stable			
²³⁵ U	4.46		0.168	$7.04 \cdot 10^8$ y
²³² Th	4.08		0.063	$1.41 \cdot 10^{10}$ y

produces helium, which produces carbon, and so on, until one reaches atomic mass 56, which is the approximate atomic mass of the element iron. The iron nucleus is the most stable of all, with a binding energy of 8.7 MeV per nucleon. To synthesize nuclei heavier than iron, you need to capture neutrons in an extremely high flux, and these endothermic reactions need a lot of added energy: these neutrons and this energy are found during the explosion of supernovae, which, in addition, disperses these heavy elements throughout the interstellar space. The uranium in the Earth's crust was, therefore, born in an old star, during the last cataclysmic seconds of its existence. The dispersed matter must have been used later to form the solar system. In that way, fission energy can be said to be the fossil energy of the stars as coal and oil are the fossil energy of past organic life on Earth.

Uranium is well distributed in the Earth's crust, usually associated with oxygen, and its decay products (► [Table 1](#)). The average content of granite is 4–5 parts of uranium per million (ppm). It is also found in seawater, in huge quantities, perhaps of the order of 4–5 billion tons, but with a very low concentration ~3 parts per billion (ppb). Uranium is only mined from deposits where its concentration exceeds 0.1%, unless it is a by-product of some other mineral production: phosphates, gold, and copper. Some uranium deposits, in veins, are extremely rich: mines in Saskatchewan reach 10% uranium, but most mines exploit ores close to 0.2% U. This is why uranium ores must be concentrated at the mine mouth before transportation.

■ **Table 2**
Usual uranium ores

Mineral	Chemical composition
Uraninite (~pitchblende)	UO ₂
Coffinite	(U ₈ Si ₆ O ₄₀) _{1-x} (OH) _x
Brannerite	(U,Y,Ca,Fe,Th) ₃ Ti ₅ O ₁₆
Betafite	(U,Ca)(NbTaTi) ₃ O ₉ nH ₂ O
Davidite	(Fe,Ce,U)(Ti,Fe) ₃ (O,OH) ₇
Uranothorite	(Th,U)SiO ₄
Uranothorianite	(Th,U)O ₂
Carnotite	K ₂ (UO ₂) ₂ (VO ₄) ₂ 3H ₂ O
Tyuyamunite	Ca(UO ₂) ₂ (VO ₄) ₂ 5–9H ₂ O
Torbernite	Cu(UO ₂) ₂ (PO ₄) ₂ 8–12H ₂ O
Autunite	Ca(UO ₂) ₂ (PO ₄) ₂ 12H ₂ O
Uranophane	Ca(UO ₂) ₂ Si ₂ O ₇ 6H ₂ O

Uranium is a significant constituent of about 100 different minerals, but most minable ores belong to a dozen minerals, listed in ► [Table 2](#). Usually, uranium deposits are classified into four types: vein-type deposits (Canada, Australia), uranium in sandstones (USA, Niger), uranium in conglomerates (South Africa, Canada), and other deposits (like the pegmatites of Namibia, and most phosphates deposits). Most of the deposits formed during the Precambrian era (>600 million years) or during orogenic events such as the Hercynian and Alpine mountain formations in Europe (respectively 300 and 50 million years, respectively) (Valsardieu 1997).

One distinguishes between “primary” minerals, usually black or blackish, formed at some depth inside the crust, where uranium is tetravalent (pitchblende, uraninite, coffinite, and brannerite) and “secondary” minerals, derived from the former by surface oxidation. Secondary minerals are brightly colored, in green, yellow or orange, and uranium is hexavalent.

2.1.1 Uranium Resources

The concept of “resources” or “reserves” must be qualified, because behind any specific figure there are many hypotheses, not always explicit: hypotheses concerning the costs of extraction (the higher the accepted costs, the largest the resources because one can access to lower grade ores), and hypotheses concerning the state of the technologies of exploration, detection, and production. For instance, resources of petroleum have been vastly increased over the last decades by “secondary extraction” technologies.

The “Bible” of uranium resources is the Red Book (OECD 2008) jointly published every second year by OECD/NEA and IAEA. This is a compilation of data supplied by countries that are members of these organizations. The completeness and accuracy of the data vary from

Table 3
NEA-IAEA resources classification (million tons)

Cost of recovery (US\$/kgU)	Identified Resources		Undiscovered Resources	
	Reasonably Assured RAR	Inferred Resources	Prognosticated Resources	Speculative Resources
<40	1.8	1.2		
<80	2.6	1.8	2.0	
<130	3.3	2.1	2.8	4.8
Cost unassigned				7.8

country to country. In addition, with uranium prices extremely low during the last decades (see below), very little was done in terms of exploration by uranium mining companies just able to survive. This means that the figures now available are the results of exploration efforts carried out mostly during the 1970s, and are probably underestimated. Since 2004, uranium spot prices having soared, exploration has resumed worldwide, and the 2008 issue of the Red Book is already more optimistic than the previous one (► [Table 3](#)).

This being said, the Red Book uses a standardized classification to give figures of uranium resources always expressed in *recoverable* metric tons.

If we consider the identified resources recoverable at a cost <130 \$/kgU, the world total figure is quoted around *5.5 million tons U* (it was 4.7 Mt U in the 2006 Red Book). The highest figure for the “ultimate” recoverable resources might be of the order of *16 million tons U*.

88% of the *identified* resources are in the following 10 States:

Australia	24.1%	Namibia	6.0%
Kazakhstan	17.2%	Brazil	5.9%
Canada	9.2%	Niger	4.8%
South Africa	7.2%	Russian Federation	3.6%
USA	7.2%	Uzbekistan	2.4%

Notably absent are big consumers such as Japan and the European countries – not to mention India and China.

During the 1990s, the world production oscillated between 30,000 and 35,000 tons U per year, but it reached close to 70,000 tons in 1980. Since the origins of the nuclear era, more than *2 million tons U* have been produced. Of these, only 1.15 million tons U has been used in the supply of nuclear fuel for civilian nuclear reactors; 85% of the remaining 850,000 tons in military stockpiles. The history of uranium production (► [Fig. 2](#)) has been rather hectic

- Huge growth from 1946 to 1960, for military purposes
- Slump from 1960 to 1970 when the needs of the emerging nuclear power industry could not match the decrease in the military needs
- Growth – and overproduction – in the 1970s, fuelled by excessive expectations of nuclear power development, and aggravated by the US policy of requiring “feed” delivery by the

■ **Figure 2**
Historical uranium production

utilities 10 years in advance of the delivery of enriched uranium (over which the US government had a monopoly)

- Slow decrease during the 1980s, reflecting the lowered nuclear expectations throughout the world and the numerous cancellations of nuclear projects in the USA
- *Crisis*, since 1990, with production around or below 35,000 tons/y versus a stabilized demand close to 60,000 tons/y (Maillet et al. 1980), and a technical capacity around 45,000 tons/y

“Spot” prices reflect these variations: below 7 \$/lb U_3O_8 in 1972, they jumped above 40 \$/lb in the mid 1970s, to crumble after 1980. They have been meandering around 12 \$/lb from 1995 to 2003. Till 1993, the main reason was overproduction and resale of the inventory of canceled power plants. Since then, the “civilization” of Russian and American military stockpiles, due to the end of the cold war and the reduction of nuclear arsenals, has been adding around 200,000 tons U to the overflowing civilian stockpiles. As a result, many mines have closed, exploration has dramatically slowed down, and many mergers and acquisition have shaken the uranium mining community.

From 1985 to 2000, the number of production sites world-wide has decreased from 102 to 46, and the number of companies involved in uranium mining has shrunk from 38 to 23. But with the expectation of a “nuclear Renaissance,” the trend has been dramatically reversed since 2004. Spot prices even reached 140\$/lb in the summer of 2007 before going down to around 55\$ by the end of 2008.

But this yo-yo behavior has much less impact on nuclear electricity costs than similar volatility had on fossil origin power. As shown in [Table 4](#) below, fuel price volatility as currently observed induces very different generation cost variations according to the technology. For the same factor 3 variation in fuel price, the gas generation cost impact is about twice that of coal. *But, in spite of a factor 8 variation instead of 3, the nuclear generation cost impact remains 4 times less than that of coal, 7 times less than that of gas.*

■ **Table 4**

Impact of fuel prices variations on kWh costs for uranium, gas and coal

	2002 indicative values	2007 indicative ^a	Variation	Cost impact (US\$/MWh)
Uranium volatility US\$/lb U ₃ O ₈	12.5	100	Factor 8	
Resulting fuel cost ^b (US\$/MWh)	4.3	10.1		+5.8
Gas volatility (US\$/MMBtu)	3.5	9.5	Factor 3	
Resulting fuel cost (US\$/MWh)	23.1	62.6		+39.5
Coal volatility (US\$/t)	30	90	Factor 3	
Resulting fuel cost (US\$/MWh)	10.5	31.5		+21

^aIn the higher range

^bIncluding uranium + conversion + enrichment + fuel fabrication

- Assumptions on fuel energy yields
 - Uranium: burnup 60 GWd/t, heat conversion 36%
 - Gas: heat conversion 57%
 - Coal: heat conversion 43%
- Indicative fuel price variations as observed in the past decade
- For comparison, total generation costs are in the range 50–70 US\$/MWh

2.1.2 The Oklo Phenomenon

As we have seen, the half-life of ²³⁸U is 4.51 billion years while ²³⁵U decays by half in “only” 710 million years. Therefore, the relative abundance of ²³⁵U increases if we go back in time: at the creation of the solar system, it was close to 17%, and about 3.58% 2 billion years ago. About 3.5% is the level to which we painfully enrich the uranium today to fuel our LWR... In the 1950s, some authors played with the idea that fission chain reactions could have occurred naturally when the enrichment was so high, but so many conditions would have been required that it seemed far fetched, and there was no evidence left anyway.

In June 1972, at the Pierrelatte enrichment plant devoted to Defense Applications, a routine mass spectrometry analysis of UF₆ feed material exhibited a discrepancy: only 0.7171% of the uranium in the samples ²³⁵U, instead of the magic 0.7202! Even though the discrepancy was small, it was so unusual that the French Atomic Energy commission CEA, operator of the plant,

started a thorough investigation (Barré 2005b). First, it was not an artifact: the anomaly was confirmed on several measurements on other samples. Accidental contamination by depleted uranium from the plant itself was then eliminated and so was the use of reprocessed uranium as there was no ^{236}U in the samples. The investigators then traced the anomaly back through all the stages of uranium processing, from Pierrelatte to Malvesi to Gueugnon where the concentrates exhibited the same low ^{235}U concentrations. These concentrates all came from COMUF which operated two uranium mines in Gabon, at Mounana and Oklo, the mill being located at Mounana. Very soon it appeared that all the anomalous ore came from the northern part of the – very rich – Oklo deposit. In some shipments, the level of ^{235}U was as low as 0.44%. Between 1970 and 1972, in the 700 tons of uranium delivered by the Mounana mill, the deficit of ^{235}U exceeded 200 kg, hardly a trifle!

Oklo uranium was indeed different from natural uranium everywhere else. Why?

“Natural” isotopic separation was excluded: if it had produced depleted uranium, where was the enriched fraction? As soon as August, the hypothesis of very ancient fission chain reactions was formulated, and investigators started to search for fission products (or, rather, the granddaughters of hypothetical fission products). The spectrum of fission products is so distinctive that it constitutes an unmistakable marker that fission reactions have taken place. The presence of such fission products was clearly identified: at some point in the uranium deposit history, it had become a “natural” nuclear reactor. Later on, it was found that there were actually 15 reactor sites in Oklo, and another one in Bangombé, 30 km away from the main deposit. The discovery was duly heralded but many questions remained unanswered. When did the reactor “started”? How long did it “operate”?

It is only around 2.2 billion years ago that the patient work of photosynthesis accomplished by the first algae released enough oxygen in our atmosphere for the surface waters and ground water to oxidize. Only then could the uranium diluted in granite be leached out and concentrated before mineralization in places where oxidoreduction would occur. Rich deposits cannot be older. On the other hand, since 1.5 billion years, ^{235}U abundance has decayed below a level which makes spontaneous fission workable. It took a lot of studies, in geology, chemistry, and reactor physics to narrow the bracket of time to the present estimated value: the reactions must have started 1950 ± 30 million years ago (Naudet 1991).

The deposits were located in very porous sandstone where the ground water concentration may have been as high as 40%, probably due to the partial leaching of the silica (quartz particles) by the hot groundwater, at a time where, the radioactivity of Earth being higher than today, the thermal gradient underground was probably higher too. During the reactors operation, the water temperature rose significantly, accelerating this “desilicification” process and, by difference, increasing the concentration in uranium, therefore compensating for its depletion by fission. As a matter of fact, the concentration of uranium in the reaction zones is extremely high, sometimes above 50%, and the higher the uranium concentration, the lower its ^{235}U content. Furthermore, losing its silica, the surrounding sandstone became clay and thus prevented an excessive migration of groundwater, keeping the uranium in place.

From the fine analysis of the spectrum of fission products, we know that a number of the fissions occurred in plutonium, bred by neutron capture in ^{238}U and now fully decayed to ^{235}U since its half-life is only 24,000 years (By the way, so much for the notion that plutonium is “artificial”). This allowed the physicists to calculate that, varying from one zone to another,

reactions did take place during an enormous period of time ranging from 150,000 to 850,000 years! But if the operating time was immense, the power density in the “core” was only *one millionth* of its value in a commercial reactor today.

By combining geology and temperature considerations, it is now believed that the reactors in the northern part of the deposit operated at a *depth of several thousand meters*, under deltaic and marine sediments. At such depth, the conditions of pressure and temperature were close to those of the pressurized water reactors (PWR) of today (350–400°C, 15–25 MPa), while the southern zones operated at roughly 500 m deep, with conditions resembling more to those of a Boiling Water Reactor (250°C, 5 MPa).

Even though significant alteration occurred in recent times when the tectonic uprising and erosion brought the reactors close to the surface, and especially when the Okolo Néné River gouged the valley, the heavy elements thorium, uranium and plutonium did not move at all, nor did the rare earths fission products, as well as zirconium, ruthenium, palladium, rhodium, and a few others. On the other hand, krypton, xenon, iodine, barium, and strontium have moved, but maybe only after a few million years.

Soon after the discovery, and beyond the pure scientific thrill, the nuclear community was very excited by its implications, notably as a “natural analog” for the geologic disposal of high level radioactive waste (HLW). There, in Oklo, Mother Nature had contained *precisely the same radioactive elements* not for hundreds of thousands, not for millions, but for a couple of billion years, and without engineered barriers or special packaging. But the comparison cannot be pushed too far. Let us say Oklo provides a good presumption, but not a demonstration.

There is no reason to believe that what occurred at least 16 times near Oklo did not happen anywhere else on the Earth, especially in old and rich deposits like that which exist in Australia or Canada... but more than 3 decades after its discovery, Oklo remains unique. It remains unique as a geologic curiosity, and it remains unique as a nuclear detective story.

2.2 Uranium Exploration

In the early days of the Atomic era, uranium prospecting was a pioneer’s job, for lonesome adventurers roaming the deserts of Colorado or Wyoming, with their horses and their Geiger-Müller counter. Today, things are less romantic and more organized, but the basics are the same: detecting the γ rays of some of the decay products of ^{238}U , mostly ^{234}Th , ^{222}Rn and ^{214}Bi , or some gaseous products of spontaneous fission such as ^{85}Kr or ^{135}Xe .

Nowadays, one starts with the geological study of a large area to detect favorable conditions for deposit formation, notably with the help of satellite cartography (since the first ERTS and LANDSAT satellites in the early 1970s).

If a given area looks interesting, the next step is aerial radiometric survey, with planes or helicopters carrying large and sensitive scintillation counters or γ spectrometers, and flying over stripes of land about 1 km wide. This method allows for a rapid identification of the regions having the highest uranium content, and worth further exploring. Radiometric methods, when properly interpreted, will detect uranium ores, but will not give information on the quantity and concentration of the uranium.

If the radiometric measurements are promising enough, geologists go on the spot to perform analysis of ground samples and groundwater, and to drill for logging.

2.3 Uranium Mining and Milling

In order to extract the uranium, access must be gained to the deposit, either by stripping off the sterile rock covering it (as in the case of open-pit mining), or by digging roadways into the sterile rock if the ore lies deeper (as in the case of underground mining), or by in situ leaching (ISL).

Open pit mining is very common for copper, for instance. After removing the topsoil and the overburden with scrapers, the ore is excavated with hydraulic shovels and front loaders, and carried to the mill by trucks traveling on a long helical ramp from the ore bed to ground level. After exploitation, the overburden will be pushed back into the pit and covered by the topsoil for rehabilitation (see below).

Underground mining is commonly used for coal or iron. What is specific to underground uranium mining is the additional hazard caused by the radon gas ^{222}Rn accumulated in the galleries: powerful ventilation must be maintained to keep the radon concentration at an acceptable level and prevent miners' irradiation. Given the cost of underground mining, it is used for relatively high grade ore. Some ores have such a high uranium concentration, in Saskatchewan for instance, that remote mining techniques are used.

ISL, sometimes called solution mining, is a relatively inexpensive way to exploit underground ores in arid and secluded areas where possible underground water pollution is less of a concern: Wyoming, Australia, and Uzbekistan. Several wells are drilled to reach the ore location, then a leaching solution (usually acidic, $\text{pH} \sim 2-3$) is injected in one well and pumped from the surrounding wells (► Fig. 3). A new mine in South Australia, with reserves in excess of 20 million tons U, will produce ~ 1 million tons U per year from 84 wells, with a total manpower under 50 people.

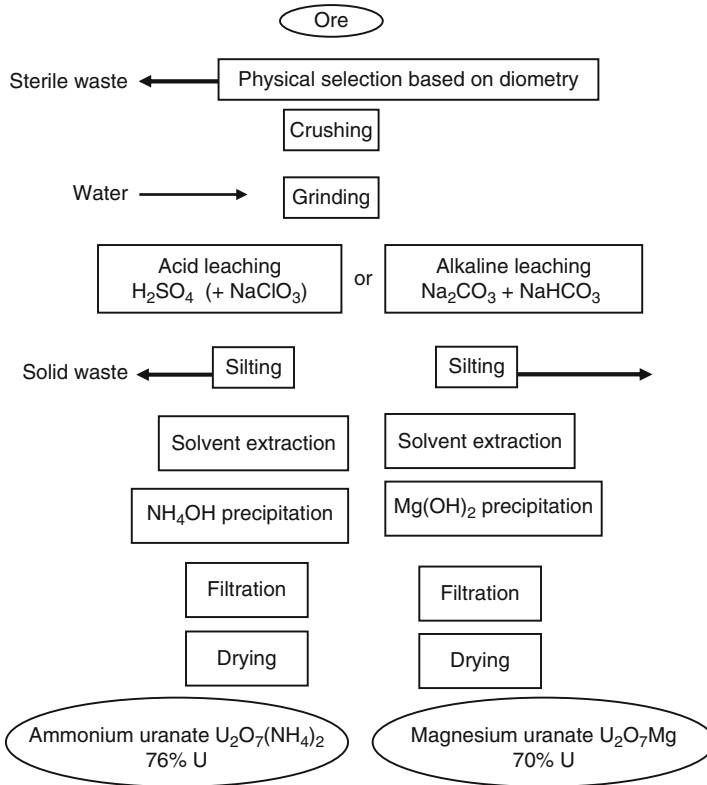

Figure 3
ISL

■ **Figure 4**
Schematic milling processes flow chart

One should mention a fourth method of uranium extraction which bears no resemblance to mining: extraction from seawater is technically possible and has been developed on a laboratory scale, notably in Japan, using either resins (Asahi) or other specific adsorbent (JAERI). It is too early to evaluate the possible costs involved, but they will be much higher than the presently depressed commercial prices. One specific problem is the huge volumes of seawater to handle in the process: most prospective designs consider floating plants anchored in the middle of strong oceanic currents.

After the uranium has been mined, it is concentrated in a mill located close to the mine mouth. ➤ *Figure 4* schematizes the various concentration processes (Rigo and Faron 1995).

2.4 Sites Rehabilitation

At the end of the commercial exploitation, mining operations leave a significant impact on the environment:

- Open pits, and underground galleries
- Leftover buildings and pieces of equipment from the mill

- Excavated materials and *mill tailings*, usually in tailings ponds. Mill tailings, in huge quantities, contain all the radionuclides of the uranium decay family, including radium and radon

Before leaving the site, the operator must therefore “rehabilitate” it at his expenses and subject to strict regulatory rules and close scrutiny. Rehabilitation includes the following operations:

For the mine site itself: filling it with sterile excavated materials, or, alternately, transforming open pits into artificial lakes, and thereafter, remodeling the landscape, tree plantations, etc.

For the mill: complete dismantling of the plant buildings, with the possible exception of some office buildings which can be converted to other uses after cleanup, and storage of uranium contaminated equipment together with the tailings, followed by the monitored cleanup of any contaminated soil.

The most important aspect is the safe disposal of the mill tailings. During operation, they are stored in pits or ponds, and controlled under national regulations. After termination, the operator must assure their durable containment, to safeguard the surrounding environment from radioactive contamination, and prevent exposure of people to unwanted radiation (less than 1 mSv/y for the most exposed group): covering with soil to delay – and therefore limit by decay – radon release, and resist erosion and rain seepage; reinforcement of the levees, water drainage, treatment if need be, and monitoring; suitable plantations.

In addition, there shall remain for a long period of time a regular monitoring of air, water, and food chains in the neighborhood.

3 Conversion

According to its specific process, a uranium mill would deliver concentrates made of:

- Usually uranates (magnesium, sodium or ammonium uranates) such as $Mg_2U_2O_7$, containing up to 65% uranium
- Sometimes oxides, containing up to 80% uranium: black UO_2 , orange UO_3 or yellow U_3O_8

packed in 200 l barrels or 1 m³ containers. Some stringent standards must be met in terms of concentration for some impurities: Boron content, for instance, must be strictly below 0.1%, and preferably <0.005%.

Before fuel fabrication, these concentrates must be transformed either into metallic uranium (MAGNOX metal U fuels, or feed for AVLIS), into pure dioxide UO_2 , or into a gaseous uranium compound necessary for the other enrichment processes. Most usually, the name “conversion” refers to the latter operation (OECD 2006).

The only gaseous uranium compound with a significant vapor pressure at room temperature is *uranium hexafluoride* UF_6 . Fortunately, fluorine has only one stable isotope ¹⁹F, whose atomic mass is much smaller than uranium’s.

At 20°C, the saturation pressure of UF_6 is 80 torr, and it reaches an atmospheric pressure of 760 torr at 55°C: DG and UC plants operate around 50–65°C. The phase diagram of UF_6 is schematized in [► Fig. 5](#).

There are two families of conversion processes, according to whether the purification step takes place at the head end, by solvent extraction, or at the back end of the flowchart, by distillation [► Fig. 6](#).

Figure 5
Phase diagram of uranium hexafluoride UF_6

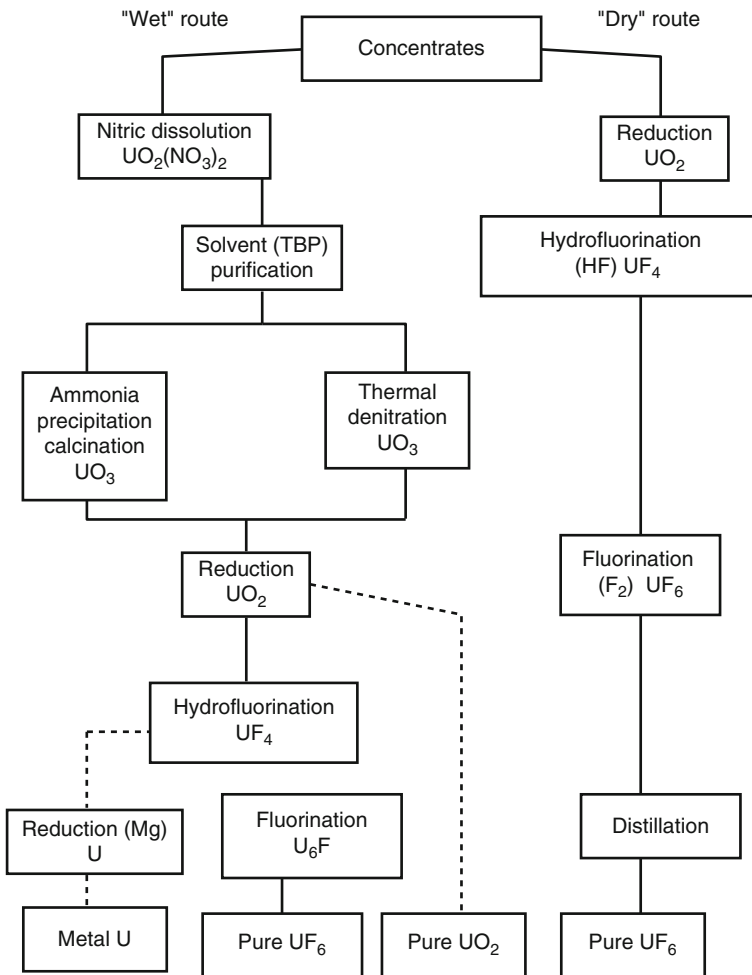

Figure 6
The two conversion routes

The dry route, often used in the USA, is simpler and produces no liquid effluent, but it is only practical if the concentrates are U_3O_8 . COMURHEX, in France has selected the more versatile wet road, where tributylphosphate extraction gives pure (<0.1 ppm total impurities) uranyl nitrate at an early stage in the process. For historical reasons, relating to the early UNGG program, conversion is performed in two separate plants: from concentrates to UF_4 in Malvesi, and final fluorination in Pierrelatte.

At room temperature, UF_6 is a solid (density 4.68 g/cm^3), which facilitates storage and handling. It reacts violently with water and most organic fluids or solids (one cannot use lubricants or rubber seals with it). Both uranium and fluorine being toxic, as well as decomposition product HF, all containers or circuits carrying UF_6 must be leaktight, with metallic seals. UF_6 also corrodes most metals but for aluminum and nickel and some of their alloys.

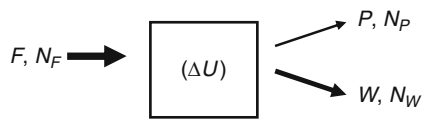

After enrichment, UF_6 is converted back to oxide and the recovered HF is recycled.

4 Uranium Enrichment

Maintaining a chain reaction with natural uranium is not easy because many neutrons are captured by ^{238}U . It is only possible in thermal reactors moderated by graphite or heavy water D_2O . Early British (MAGNOX) and French (UNGG) reactors used graphite as a moderator and were fueled with metallic natural uranium. Canadian reactors CANDU are moderated by D_2O and use the dioxide of natural uranium UO_2 as their fuel. This is because the UK, France and Canada started their nuclear power generation program at a time when enrichment was only mastered by the USA where it had been developed for military purposes during the Manhattan Project.

The capacity to enrich uranium, to increase the isotopic proportion of fissile ^{235}U , allowed for the use of ordinary water H_2O as moderator in the reactors of the nuclear submarines, to be followed by all the LWR, which constitute today more than 85% of the nuclear power plants in the world. But if one needs almost pure ^{235}U to make nuclear weapons, the LWR fuel is enriched only to between 2 and 5% in ^{235}U .

4.1 Principle, Cascade, SWU, HEU, LEU

Enrichment is the partial separation of “feed” natural uranium into its two main isotopes ^{238}U and ^{235}U , to yield a “product” containing a mole fraction N_P of ^{235}U higher than the naturally occurring $N_F = 0.71\%$, leaving a “waste” fraction depleted to $N_W\%$ ^{235}U . An enrichment facility can be considered as a black box with one intake and two exits, each one characterized by a mass flow (F , P or W) and by a concentration in ^{235}U (N_F , N_P or N_W) as shown in  Fig. 7.

 Figure 7

Enrichment process (schematic)

The equilibrium is described by the following equations:

$$F = P + W \quad \text{mass conservation} \quad (1)$$

$$F \cdot N_F = P \cdot N_P + W \cdot N_W \quad \text{isotopic conservation} \quad (2)$$

$$(\Delta U = P \cdot V(N_P) + W \cdot V(N_W) - F \cdot V(N_F)) \quad \text{value conservation (see below)} \quad (3)$$

Instead of using the mole fraction N , one often uses the abundance ratio $R = N/(1 - N)$; the efficiency of the separation is characterized by the separation factor $\alpha = R_P/R_F$.

Most of the physical properties of a pure element, density, fusion and vaporization temperature, etc. exhibit slight but measurable differences according to its isotopic composition, but very few of these differences can be the basis for isotopic enrichment. The same can be said of the chemical properties. Even for the most efficient methods, α is usually very close to unity, and one must constitute “cascades” by coupling many elementary stages to reach the desired enrichment N_P , as schematized in [▶ Fig. 8](#). In order to minimize the feed supply, the cascade is divided into two sub-cascades: most of the stages are used to enrich the product, while a few are devoted to deplete the tails to reach N_W , an operation known as “stripping.”

The simplest way to constitute a cascade is to feed stage “ n ” with the product of stage ($n - 1$) and the tail of stage ($n + 1$). Of course, not to remix what has been painfully separated, the assay of product $n - 1$ and tail $n + 1$ must be identical: this condition determines the optimum flow in each stage of the cascade, the optimum “shape” schematized in [▶ Fig. 9](#).

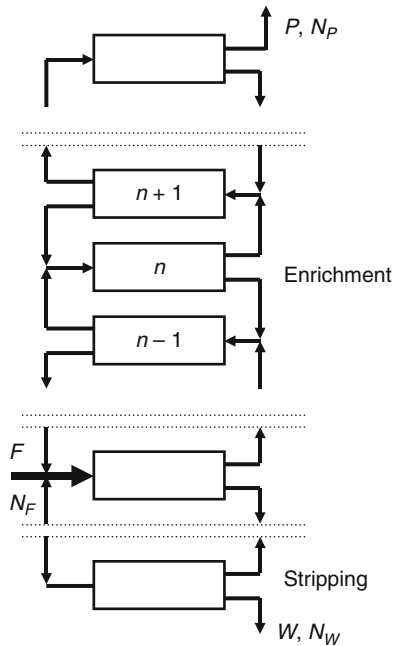

Figure 8
Coupling stages to form a cascade

Figure 9
"Profile" of an ideal cascade

Figure 10
Mass flows in the enrichment process

The choice of N_P is, of course, determined by reactor physics, by the burnup to be reached in the fuel. The choice of N_W results from an economic optimization between the cost of feed uranium and the cost of the enrichment service: the higher the value of N_W , the more feed you need to obtain a given quantity of product. To carry out this optimization, one introduces the concept of "separative work," noted ΔU , which derives from the increase of a "value function" V :

$$V(N) = (2N - 1) \text{Ln} \left(\frac{N}{(1 - N)} \right) \tag{4}$$

$$\Delta U = P \cdot V(N_P) + W \cdot V(N_W) - F \cdot V(N_F) \tag{5}$$

ΔU has the same dimension as F , P and W , and is expressed in *separative work units* (SWU) (Villani et al. 1979). ➤ Figure 10 illustrates typical values of these parameters optimized for the economic conditions of the 1990s (Bottom figures correspond to the EURODIF plant).

3.7% ^{235}U is a typical assay for a PWR fuel capable of reaching 45 GWd/t. From 1% to 5% ^{235}U , one refers to *low enriched uranium* (LEU). Above 20% and up to weapon grade 93%, it is called *highly enriched uranium* (HEU), and subject to very strict safeguards and export restrictions to prevent risks of proliferation of nuclear weapons. The usual enrichment for Research and Irradiation experimental reactors fuel is 19.8%, just below the HEU threshold.

To obtain 1 kg of commercial LEU, one needs typically 5 SWU, while 1 kg of weapon grade HEU requires around 200 SWU. A 1 GWe PWR needs of the order of 100,000 SWU per year.

4.2 Enrichment Technologies

There are many possible classifications of the various uranium enrichment processes, according to the property one wants to emphasize, for instance: statistical processes such as gaseous diffusion (GD) or centrifuge versus selective processes such as AVLIS, reversible processes such as most chemical processes versus irreversible processes such as calutrons, etc. One can also distinguish between established processes and processes under development, or according to the proliferation resistance, which, itself calls for several criteria (ease and time to reach HEU, size and visibility of the facilities, holdup inventory, criticality limitations, need for power, etc.). Of course, for civilian purposes, economics is the key criterion, with its components: plant depreciation, operation and maintenance, and power consumption.

It all started with mass spectrographs, the giant “calutrons” of the early stages of the Manhattan Project: Under a strong magnetic field, ions follow different circular trajectories according to their charge-to-mass ratio. You can therefore completely separate individual uranium ions one by one, but with a very low throughput. This method was soon discarded in favor of more efficient processes. It was considered so obsolete that nobody cared to control this technology that – for this very reason – Iraq chose to revive for its clandestine military program.

Then GD dominated the market, followed by ultracentrifuge (UC). Some developments were carried out on aerodynamic processes (the German nozzle process and the South African Helicon) and on chemical isotopic separation methods (the French CHEMEX and the Japanese Asahi), and the most recent developments center on laser enrichment.

4.2.1 Gaseous Diffusion

In a vessel containing a mixture of gases in thermal equilibrium with its surroundings, according to Knudsen law, molecules move with an average speed inversely proportional to the square root of their molecular mass:

$$V_i = \left(\frac{8RT}{\pi M_i} \right)^{1/2} \quad (6)$$

As a consequence, in gaseous UF_6 , molecules of $^{235}\text{UF}_6$, mass 349, travel more rapidly than molecules of $^{238}\text{UF}_6$, mass 352, and in a given time interval they impact more often the walls around them. If the walls are porous, $^{235}\text{UF}_6$ molecules are slightly more likely to sneak their way through the pores than $^{238}\text{UF}_6$ molecules, at least if the pore diameter is much smaller than the mean free path of the molecules. If there was a pressure difference between the two faces of

■ Figure 11
GD (elementary process)

■ Figure 12
GD (schematic)

the porous wall, the low pressure side would, therefore, be slightly enriched in $^{235}\text{UF}_6$. Ideally, in pure Knudsen regime, the separation factor across the pore would be proportional to the square root of the ratio of the masses, in our case, $\alpha_0 = 1.0043$. The ideal enrichment factor $\varepsilon_0 = 4.3 \cdot 10^{-3}$, is very small. *In reality, several perturbing factors lower the actual enrichment factor to around $2 \cdot 10^{-3}$.*

GD, schematized in [► Fig. 11](#), implements this phenomenon to enrich UF_6 by pushing it through a very thin porous “barrier” deposited over a porous support (with larger pores) which can withstand the pressure difference.

The elementary separative stage is constituted of three basic components ([► Fig. 12](#)):

- The “Diffuser,” cylindrical container in which several barriers are set up in parallel, inside their cylindrical support tubes. These barriers define two compartments inside the diffuser, a high pressure compartment inside the barriers and a low pressure compartment outside them
- The compressor which circulates the gas and gives it the right pressure entering the diffuser
- A heat exchanger to remove the calories produced by compression

Of course, one also needs a series of ducts and valves, etc.

In the old US plants, diffusers were horizontal, and barrier supports were made of sintered nickel. In the Tricastin EURODIF plant, the most modern GD plant, diffusers are vertical and

■ Figure 13
EURODIF layout (schematic)

barrier supports are made of ceramic. The actual layout of a EURODIF enrichment stage is shown in ► Figs. 13 and ► 14 shows the actual cascade profile, to be compared with ► Fig. 9: with such a small enrichment factor, one needs as many as 1,400 stages to reach commercial LEU assay (<5%). As a matter of fact, the four huge buildings housing the EURODIF plant contain only a single cascade. It would be quite uneconomical to build 1,400 stages of different sizes, so the cascade is “squared,” using only three diffuser sizes, and adjusting slightly the mass flows.

Being a thermodynamically irreversible process, GD requires a lot of power for the compressors, around 2,400 kWh per SWU: to power its 10.8 million SWU per year, EURODIF needs the full output of three 900 MWe PWR plants located just nearby. On the other hand, it can supply enriched uranium for 100 similar PWR plants. GD plants need a long time to reach equilibrium and have a very significant quantity of uranium “held up” inside the cascade. Furthermore, once a cascade is set up, it is extremely difficult to rearrange it to reach a significantly higher enrichment: a civilian GD plant cannot easily be made to fabricate HEU, and certainly not without a high visibility and a long delay.

4.2.2 Ultracentrifugation

Early works on the gaseous centrifuge method were carried out by Zippe in Germany during World War II. In the 1960s, this process began to appear competitive for large-scale enrichment; it is the process used in Russia and by the Anglo-German-Dutch Company URENCO.

Figure 14
Actual EURODIF "profile"

When a gas rotates, its molecules are subject to a centrifuge force which results in a pressure gradient perpendicular to the rotation axis:

$$P(r) = P(0) \exp\left(\frac{M\omega^2 r^2}{2kT}\right), \quad (7)$$

where ω is the angular rotation speed.

Under this pressure gradient, a separation appears, the heavier molecules concentrate at the periphery while the lighter species migrate preferentially toward the center, where the gas density is near zero. Assuming a centrifuge of radius R , the separation factor at a distance r from the axis would be:

$$\alpha_0 = \left(\frac{\exp(M_8 - M_5)\omega^2(R^2 - r^2)}{2kT}\right). \quad (8)$$

With $\omega R = 800$ m/s, $T = 300$ K, and $r = 0.7R$, the separation factor for UF_6 would be equal to 1.23, much larger than the value for gas diffusion – but the mass flow is much smaller.

To improve very significantly the performances of the centrifuge, one creates a vertical countercurrent circulation at the periphery (see Fig. 15), with a thermal gradient for instance: it is somehow equivalent to creating an internal cascade, the upward current being progressively enriched in ^{235}U while the downward current is progressively depleted. With this set-up,

■ **Figure 15**
Centrifuge (schematic)

one shows that the separative capacity of a single rotating bowl, expressed in SWU, can be written as

$$SWU \sim \frac{L \cdot D \cdot (\omega R)^4 \cdot (M_8 - M_5)^2}{T^2}. \quad (9)$$

It is proportional to the length of the bowl, to the diameter of the bowl, to the fourth power of the peripheral speed, and inversely proportional to the square of the temperature.

One should, therefore, use a long bowl and rotate it at the highest possible peripheral speed inside a vacuum case to prevent heating (and contain the fragments of an exploding bowl). But there are constraints: the bowl material must resist the enormous strain of the centrifuge force on its thin wall: it must also withstand the operating temperature and resist UF₆ corrosion. The drum must be extremely well balanced. Reaching the rotational speed is very tricky because one must “pass” a number of critical resonance values. The gas temperature must not go below the solidification point because any plate-out of solid UF₆ would unbalance the rotor and cause it to explode, etc.

The mass flow is so small that one needs a huge number of centrifuges, but as the enrichment factor is significant, one needs a limited number of stages, each constituted by many parallel centrifuges. The most advanced centrifuges, with composite materials and peripheral speeds of more than 700 m/s, are credited with an individual separative power ranging between 30 and 100 SWU/y. From 1977 to 1985, the Americans almost completed a large enrichment plant (8.8 MSWU/y) GCEP, at Portsmouth, which had huge centrifuges, more than 10 m high and believed to have an individual capacity of several hundred SWU/y. No technical reason was given when the project was discontinued, but such “monsters” were probably not reliable enough and, therefore, uneconomical at the time. Nevertheless, this project was restarted a few years ago.

Even with 100 SWU/y/machine, a 5 million SWU/y plant would need 50,000 machines to constitute parallel cascades of less than ten stages. Such a large number of machines require a very high level of reliability.

Since isotopic separation in a centrifuge is a thermodynamically reversible process, it requires a lot less energy than GD, of the order of 50 times less. The cost structure of the SWU is, therefore, very different between the two methods. Those plants can be unobtrusive and could, if unsafeguarded, be used to produce highly enriched weapon-grade uranium.

With the advent of the carbon-carbon composites which allow for very high peripheral speed, UC has become the most competitive process. The technology developed by URENCO is now jointly owned with AREVA, and the new Georges Besse II enrichment plant under construction in France is based on that process. Several new centrifuge enrichment plants should also be built in the USA in the near future.

4.2.3 Other Methods

The AVLIS process (atomic vapor laser isotopic separation, in French SILVA) is based on the selective ionization of the uranium atom by a laser light of convenient wavelength. The electronic spectrum of the uranium atom, with its 92 electrons, comprises many excitation levels, ranging in wavelength from infrared to ultraviolet. Because of the complexity of the interactions between the nucleus and the electrons, some of the excitation levels are not identical for ^{235}U and ^{238}U . The difference in energy is small, but sufficient to be used for isotopic separation.

The ionization energy for the uranium atom is about 6 eV, which cannot be easily provided in one quantum: one reaches the ionization level in three stages, two successive excitations of about 2 eV each, and a final ionization from the most excited level. This kind of energy can be supplied by yellow-orange dye lasers. The separation process would therefore be the following

(► Fig. 16):

A eutectic uranium-iron is melted in a crucible by electron bombardment. The atomic vapor is irradiated by laser rays of the proper wavelengths which ionize the ^{235}U atoms. ^{235}U ions are then deflected by a high-voltage electrical field toward collector plates (which also collect

Figure 16
 AVLIS process (schema)

a certain percentage of the vapor). The remaining vapor, depleted in ^{235}U , is condensed on a collecting roof. Taking into account the isotopic dilution on the collecting plates, one should be able to enrich natural uranium to commercial LEU ($\sim 5\%$ ^{235}U) in one single step.

The huge laser power needed is supplied by batteries of high power yellow green lasers (copper vapor lasers or doubled YAG), the wavelength being adjusted by tunable color lasers downstream (Maillet et al. 1980; Schäfer et al. 1990).

The physics of the process has been demonstrated at the laboratory scale, but the technology is very demanding, especially concerning the collector materials. The power requirements, notably for uranium vaporization, are slightly larger than for the centrifuge process, but far smaller than GD. Following the Americans, the French have discontinued the development of AVLIS in 2003 after a demonstration run which produced several kilograms of 3% enriched uranium.

One drawback of AVLIS is that it breaks the UF_6 “chain” from refining to fuel fabrication, introducing a metal technology “link” in-between. This is why a sister technology has been pursued for some time, called MLIS for molecular laser isotopic separation. Infrared lasers would selectively excite $^{235}\text{UF}_6$ molecules in a gaseous mixture of UF_6 and a lighter gas at low temperature ($\sim 100\text{ K}$), and the excited molecules would later be broken into solid UF_5 and fluorine by an ultraviolet laser.

This process as such was not completely demonstrated when abandoned in the mid-1980s. A promising variant to be developed is SILEX, an Australian concept which appears to be based on molecular aggregates and utilizes UF_6 as well as another gas. In 2006, GE Energy (now GE-Hitachi) entered a partnership to develop the SILEX process renamed “Global Laser Enrichment.” In August 2007, GE-Hitachi announced it planned “to complete a test loop program at the end of 2008 which, if successful, would open the way for the first commercial enrichment plant to be constructed.”

5 Fuel Fabrication

5.1 Elements of Fuel Design

With few exceptions – molten salt reactors for instance – the nuclear fuel is fabricated into discrete objects called “elements,” “bundles,” “assemblies” or “subassemblies” (Bailly et al. 1999), where the nuclear materials are inserted inside mechanical, usually metallic, structures. A set of fuel elements constitutes the core of the reactor.

In the reactor, the fuel performs two essential functions: It supplies the heat in the core, and it prevents the radioactive fission products from migrating into the primary coolant circuit (it is the “first barrier” in the safety analysis). It must, therefore, have the capability to sustain for several years the chain reaction in a stable manner while keeping its structural integrity. As a consequence, fuel design must take into account the requirements issued from the core physics and from the coolant chemistry.

Core physics defines the fuel composition, the proper mixture of fissile, and fertile and control materials in order to achieve the required burnup, i.e., the quantity of energy supplied by the fuel during its lifetime, expressed in GWd/t , gigawatt day per metric ton of heavy metal contained in the fuel. Core physics also determines the fuel geometry, taking into account the neutronic and thermal-hydraulic properties of the coolant, as well as the neutronic properties of the structural materials (cladding, other fuel structures as the case may be).

Coolant chemistry dictates some properties of the cladding such as corrosion resistance at operating temperature or above, and even with the fuel material itself, which must not interact chemically with the coolant in case of cladding failure.

Beyond these generic considerations, fuel design and fuel fabrication are very specific for a given reactor type.

5.1.1 Fissile/Fertile Couple

With few exceptions (HEU fuel for some research or space applications reactors), the fuel is a mixture of fissile and fertile nuclides, and the conversion of fertile into fissile during the irradiation makes up partially for the fissile depletion, thus extending the lifetime of the fuel. In a “breeder,” the conversion rate is even higher than the depletion rate.

We have seen that natural uranium itself is a mixture of fissile ^{235}U and fertile ^{238}U , but with a very low concentration in fissile nuclei which severely limits its uses. Any combination, in the proper proportion, of one of the three fissile nuclides ^{233}U , ^{235}U , and plutonium (actually a mixture of ^{239}Pu and ^{241}Pu) with one of the two main fertile nuclides ^{238}U and ^{232}Th can provide the basis for a fuel cycle.

5.1.2 Fuel Material

The simplest fuel material is uranium in the metal form. It is still used in the last gas-cooled MAGNOX power reactors, because only the metal can sustain the chain reaction in a natural uranium/graphite core where the neutron balance is tight, and in some experimental and irradiation reactors. It may also be used as a metallic alloy in fast neutrons reactors. Uranium is a highly reactive metal which oxidizes rapidly in air at room temperature. At temperatures below 600°C , uranium crystallizes in the orthorhombic system (α phase) which is anisotropic: when the metal is formed by rolling or extrusion, the crystals orient themselves along preferred directions which results in dimensional changes when the metal is irradiated (the so-called growth), or thermal cycled.

In most other occurrences, the fuel material is ceramic: it can be uranium carbide or uranium nitride, but most often, by far, it would be uranium dioxide UO_2 . Uranium dioxide has a number of qualities: it is refractory (melting temperature is $2,865^\circ\text{C}$), it is structurally stable and does not interact with high temperature water and oxygen, and it has a very low capture cross section for thermal neutrons. UO_2 density is 10.97 g/cm^3 , and it has a poor thermal conductivity (around $2 \times 10^{-3}\text{ W/m/K}$ at $1,000^\circ\text{C}$).

5.1.3 Cladding Materials

The fuel cladding serves several purposes: it contains the fission products, it protects the fuel against corrosion by the coolant, provides a heat exchange surface with the coolant, and it must do so for extended periods of time (from several weeks to several years) during which it is submitted to irradiation by fast neutrons. In addition, it must have a low neutron absorption cross section not to impair the neutron economy in the core (The cross section, expressed in barns $-1\text{ barn} = 10^{-24}\text{ cm}^2$ – is a measure of the probability for a given reaction to take place when a given nuclide is irradiated with neutrons of a given energy).

■ **Table 5**
Thermal neutrons absorption cross sections

Material	Barns
Beryllium	0.01
Magnesium	0.06
Zirconium	0.18
Aluminum	0.23
Tin	0.63
Niobium	1.1
Iron	2.6
Molybdenum	2.7
Chromium	3.1
Copper	3.8
Nickel	4.6

To provide a good heat transfer, the cladding material must have a good thermal conductivity and a good bonding with the fuel. If such bonding is not possible, an intermediate layer must be introduced: high pressure gas (most often), liquid metal or pyrocarbon in some occurrences. With the exception of the silicon carbide coating of high temperature reactors (HTR) particles (see ▶ [Sect. 5.4](#)), most claddings are made of metals or metallic alloys. ▶ [Table 5](#) gives the thermal neutron cross section values for several metals used as cladding or entering into the composition of cladding alloys.

Beryllium would appear ideal but its mechanical properties, especially under irradiation, are not good. Magnesium alloy MAGNOX is used in namesake reactors but would not withstand a water environment. Aluminum is used in low temperature MTR irradiation reactors but would not resist corrosion at higher water temperatures. Alloyed zirconium is the basic choice for LWR and CANDU fuels. Stainless steel was used in LWR, and is the cladding for sodium cooled FBR (with fast neutrons, absorption in the cladding is negligible).

5.1.4 Absorber Materials

A reactor loaded with fresh fuel is supercritical (This means it has more fissile material in the core than would strictly be necessary to maintain the fission chain reaction going.), if one considers only the reactivity of the fuel: this excess reactivity, which wears out during irradiation, is necessary to compensate for a number of effects for LWR, summarized in ▶ [Table 6](#).

To keep the chain reaction just critical and the power level constant, a combination of neutron absorbers must be introduced in the core, taking into account that most of the above mentioned reactivity effects happen within a few days, only the burnup effect lasting over the complete power cycle.

■ **Table 6**
Reactivity balance (%) in typical LWR

Changes in the core	PWR	BWR
Fuel temperature defect, from cold to hot, full power	1.5	1.5
Moderator effect (same)	2.5	2.0
Equilibrium fission product poisoning	3.5	3.3
Burnup compensation	10.0	6.5
Control margin and xenon–samarium override	1.2	1.0
Shutdown margin	1.0	1.0
Total	19.7	15.3

From (Barré 2005a)

Neutron absorbers, usually referred to as “control poisons,” may be chemical compounds of boron, cadmium, gadolinium, erbium or hafnium. These poisons may be homogeneous in the coolant (soluble boric acid in PWR primary water), homogeneous in the fuel (“burnable” gadolinium oxide in BWR fuel pellets), or heterogeneous in movable “control rods” or fixed burnable absorber rods.

5.2 The LWR Fuel

The fuel assemblies of both families of LWR, PWR, and BWR share a lot of characteristics, which reflect the fact that both use the same material – ordinary water – as coolant as well as moderator:

- The nuclear material is a ceramic made of sintered dioxide of LEU or of mixed uranium and plutonium dioxide, manufactured in cylindrical “pellets.”
- The pellets are inserted inside leaktight metallic “rods” (or “pins”). The rods are pressurized with helium, both for thermal bonding and mechanical resistance.
- The rods are assembled inside a metallic “skeleton” which insures the mechanical stability in the core and during handling and transportation.

Early cladding material was stainless steel, but now cladding is usually made of zirconium-based alloys: zirconium has a low capture cross section (see 📍 [Table 5](#)), a high melting temperature (1,845°C), and a good resistance to corrosion by high temperature water. It is relatively abundant, but must be purified from any trace of hafnium which comes with it, and is a powerful neutron absorber. Alloying materials, varying in proportion from design to design, are used to improve the mechanical properties of zirconium and minimize its growth under irradiation. The various “Zircaloy” alloys use tin (1.2–1.7%), iron, chromium and nickel; niobium is used in advanced cladding materials. Tin improves the mechanical properties, and other additives are used against corrosion.

📍 [Table 7](#) gives typical parameters of PWR and BWR fuel assemblies.

BWR fuel is zoned axially, both in enrichment and in burnable poison, to accommodate for the change in water density between the bottom and the top of the fuel.

■ **Table 7**
Typical LWR fuel assemblies

Characteristics	PWR	BWR
Burnup (GWd/t)	45–60	40–50
Pellet diameter (mm)	8.2	9.5
Pellet length (mm)	13.5	11.5
Cladding material	Zircaloy 4	Zircaloy 2
Pin outer diameter (mm)	9.5	12.3
Cladding thickness (mm)	0.57	0.89
FA length (m)	4.8	4.1
Rod length (m)	4.5	4.5
Number of rods/pins	264	72 (8 tie rods)
Average fuel rating (kW/m)	17.9	15.4
Geometry	17 × 17	9 × 9
Structure	Rods maintained by spacer grids around a skeleton made of guide tubes	4 bundles with spacer grids inside a wrapper tube
Control absorbers	Rods within guide tubes	Cruciform between 4 FA

5.2.1 Fuel Pellets Production

Solid UF₆ is supplied by the enrichment plant to the fabrication plant as a solid stored in steel containers. There, the containers are heated to release gaseous UF₆. From then on, the following operations are performed:

- *Conversion*: UF₆ is heated in an oven with water vapor and hydrogen, to produce UO₂ powder, according to the reaction $UF_6 + 2H_2O + H_2 \rightarrow UO_2 + 6HF$
- *Mixing*: UO₂ is oxidized to U₃O₈ and mixed with a “porogen” material to adjust the final density
- *Precompaction*: the mixture is precompacted, then crushed and made into small granules, which flow easily
- *Pelletization*: the granules and a lubricant (zinc stearate) are pressed into pellets under high pressure
- *Sintering*: the “green” pellets are sintered at 1,700°C in a continuous oven and in a hydrogen atmosphere. In the process, the pellet density increases to ~94% of the theoretical value
- *Grinding*: the pellets are ground to the design diameter and “cupped” at the ends. Each of them is then automatically checked for dimensions, shape, and surface aspect. The finished pellets are finally outgassed in vacuum at high temperature to remove any trace of moisture and organic contaminants

The process described above is the “dry” route. Conversion can also be “wet” through precipitation of ammonium diuranate $(\text{NH}_4)_2 \text{U}_2\text{O}_7$, followed by calcination of the precipitate. Reject pellets are crushed and reintroduced in the precompaction stage.

5.2.2 Fuel Rods Fabrication

Zirconium is delivered as a “sponge,” which is first melted in vacuum in an arc furnace where alloying elements are added, and poured as ingots. Ingots are forged and quenched to preserve the microstructure, then drilled, rolled, and annealed to obtain a long tube of the right diameter and thickness. The tube is 100% controlled for dimensions and internal defects, using ultrasonic transducers. Cut to the design length, the tubes are fitted with a welded bottom plug.

The pellets are introduced inside the tubes up to the proper fuel length and maintained in place by a spring introduced in the upper plenum, designed to provide room for the release of fission gases during fuel irradiation. The top plug is then welded to the tube; this plug has a small hole through which helium is introduced, around 25 bars, before the closure of the hole. The completed fuel rod is then controlled: leaktightness of the welds, length of the pellet column, etc.

5.2.3 Assembly

The skeleton is first partially assembled with the inconel bottom end piece, the zircaloy guide tubes (for PWR), and the zircaloy spacer grids. The rods are pulled into place through the grids by a special machine, and the top end piece is fitted. Complete fuel assemblies are then checked for dimensions and rod spacing and stored in vertical position, waiting for transportation to the reactor site. ➤ [Figure 17](#) shows a typical PWR fuel assembly.

5.3 MOX Fuel

Recycle of plutonium (see ➤ Sect. 5.7) in LWR is performed by loading into the core a given percentage of “MOX” fuel assemblies along with the standard LEU fuel assemblies. MOX fuel has identical structures to standard fuel: the only difference is that pellets are made from a mixture of depleted uranium oxide and plutonium oxide $(\text{U,Pu})\text{O}_2$. To protect the operators from the radiotoxicity of plutonium, MOX fabrication must be performed remotely, inside glove boxes.

Because of very large resonances in the neutron absorption cross sections of the plutonium isotopes at low energy (0.3 and 1 eV), the neutron spectrum is “harder” in MOX/water media than in uranium/water. The concentration of plutonium must, therefore, be lowered at the periphery of a MOX assembly to adapt the neutron flux with LEU neighbors and thus avoid power heterogeneity. The average concentration $\text{Pu}/(\text{U}+\text{Pu})$ in a MOX assembly is roughly the double of the ^{235}U enrichment of a LEU assembly in the same batch.

The basic ingredients are UO_2 and PuO_2 , the latter coming from the reprocessing plant after oxalic precipitation of the plutonium nitrate and calcination of the oxalate. Simple mixing of the two powders would not provide enough homogeneity: this is ensured by simultaneous

■ **Figure 17**
17 × 17 PWR fuel assembly

milling at the head-end of the process. After milling, the powder does not flow easily and must be granulated. MELOX, the only industrial size MOX fabrication plant, located in Marcoule (France) and operated by AREVA NC, uses the MIMAS (MICronized MASTer blend) process shown in ► [Fig. 18](#), where a first master mixture of rather high plutonium concentration is later adjusted by mixing additional UO_2 .

Typical recycle scheme would have reloads with 30% MOX assemblies, but it is planned to load 100% MOX reloads in the future Ohma Japanese ABWR plant. The savings in enriched

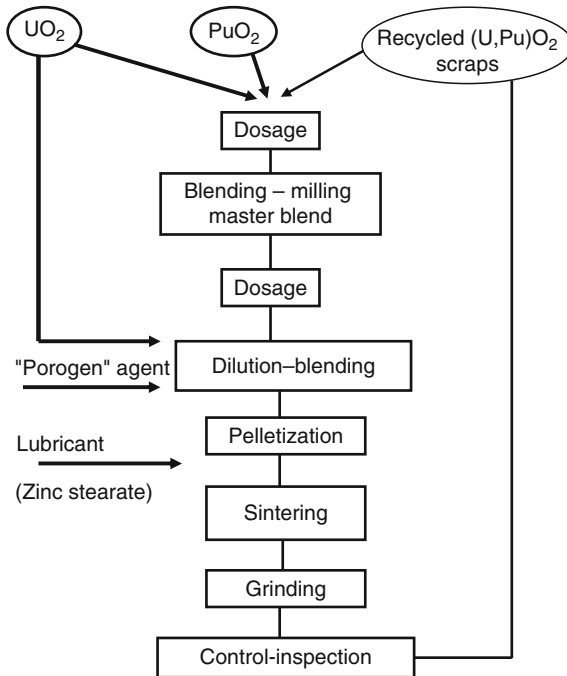

Figure 18
MIMAS blend flowchart

uranium more or less balance the increase in fabrication costs due to the remote operation and maintenance of the plant.

With the end of the cold war, as was already pointed out, significant inventories of weapon grade fissile materials have been released. To “civilize” weapon-plutonium, recycling as MOX is the preferred way, though some of it might be disposed of by mixing ceramic plutonium “pucks” with vitrified HLW.

5.4 Other Fuel

5.4.1 CANDU

As shown in Table 8, CANDU fuel bundles have the same basic components from the same basic materials than LWR fuel assemblies, though they use natural uranium oxide. The fuel bundles, loaded horizontally in the force tubes, are much shorter, and the pellets are thicker.

5.4.2 FBR

When a neutron interacts with a heavy nucleus, it can either fission it, or be captured in a number of different reactions. Very schematically, when the energy of the neutron is higher

■ Table 8
Typical non-LWR fuel assemblies

Characteristics	CANDU	Superphénix
Burnup (GWd/t)	7	> 120
Pellet diameter (mm)	12	7.1
Pellet length (mm)	16	
Cladding material	Zircaloy 4	Austenitic steel
Pin outer diameter (mm)	13	8.5
Cladding thickness (mm)	0.4	0.56
FA length (m)	0.495	5.4
Rod length (m)	0.493	2.7 (1.0 fuel)
Number of rods/pins	37	271
Average fuel rating (kW/m)	57 (peak)	200
Geometry	Circular array	Hexagonal array
Structure	Bundle with spacers	Pins separated by helical spacer wire inside hexagonal wrapper tube
Control absorbers	Metal rods (steel, Cd)	B ₄ C in special subassemblies

(“fast” neutron, rather than “thermal” or “slow”), the total probability of interaction is smaller, but the relative probability of fission is higher. In addition, in the fission process, ²³⁹Pu emits 2.9 neutrons on the average, versus 2.5 for ²³⁵U. This explains why plutonium fuelled fast neutron reactors have a better neutron economy than LEU fuelled thermal reactors such as LWR. So much so that, with a proper core design, fast neutron reactors can breed *more* ²³⁹Pu from ²³⁸U than they burn plutonium: this is called breeding, and those reactors are called breeders, FBR. Breeding allows, with a number of successive recycles, to progressively extract almost all the energy content of uranium, versus less than 1% in LWR. On the other hand, breeders are expensive and will only become competitive when uranium prices are far higher than today. As the total probability of interaction is smaller, *the fissile inventory must be larger*.

In order to keep the neutron fast, the coolant in the core must not slow down the neutrons exiting from the fuel: it cannot be water (ordinary or heavy), it can be a gas or a liquid metal. Only liquid sodium has been used to a significant degree in “liquid metal fast breeders,” LMFBR, like BR2 in the USA, Phénix and Superphénix in France, PFR in the UK, BN 600 in Russia, and Monju in Japan.

The basic LMFBR fuel is a MOX with much higher plutonium concentration (20%). If one wants to breed, the core itself is surrounded by a “blanket” of pure UO₂ fuel. In a LMFBR neutron spectrum, captures in the cladding do not matter much, but the material must be compatible with high temperature molten sodium and resist the irradiation by high fluxes of fast

neutrons: the choice is austenitic stainless steel. The pellet fabrication process is slightly different from LWR MOX, in that the pellets are smaller (► [Table 8](#)), and there is no “mother mixture” and no need for grinding.

5.4.3 HTR

HTR, first developed during the 1970s and 1980s in Germany and the USA, may be doing a comeback based on their high thermal efficiency and their very high degree of “intrinsic” safety. These characteristics derive from the use of helium gas as coolant, graphite as moderator, and, above all, a very unusual type of fuel.

The equivalent of a “fuel rod” in other reactors is a tiny ceramic particle of uranium (or plutonium, or thorium) oxide or carbide, the “kernel,” coated with a number of layers, acting together like a cladding. The diameter of a fully coated fuel particle is of the order of 1 mm. There would be around 10 billion such particles in the core of a large reactor!

Those particles are “assembled” in a graphitized matrix, either to form spherical pebbles of 6 cm diameter directly loaded in a heap inside the core cavity of a *Pebble Bed* reactor, or to form cylindrical “compacts” piled up in columns inside the holes drilled in graphite prismatic blocks which act as “fuel assemblies” (see ► [Fig. 19](#)). The whole core is, therefore, entirely refractory: core meltdown is excluded, and it has been shown experimentally that the coating of the particles retains its integrity up to 1,600°C.

■ **Figure 19**
Fuel element of a “prismatic” type HTR

Fertile or fissile kernels are manufactured by powder aggregation or by a sol-gel process, and the layers are deposited around the kernel by pyrolytic cracking of gases in a fluidized bed reactor. From the inside to the outside one finds:

1. A buffer layer of porous carbon to prevent interaction between the hot kernel and the outer layers and to provide space for the gaseous fission products
2. A first layer of dense pyrocarbon
3. A layer of silicon carbide which stops the diffusion of fission products (mainly cesium and strontium outside the coated particle)
4. A second layer of dense pyrocarbon. Together, the two pyrocarbon layers act as a pressure vessel against the gases released during the fission

5.5 In-Reactor PWR Fuel Behavior

While in the reactor, the fuel undergoes a series of transformations interacting with one another, inside the pellets, in the cladding material, and at the interface. The net result of these numerous transformations determines the useful life of a fuel assembly and its “burnup,” which is the quantity of energy the fuel can produce before being “spent” (Marshall 1981).

The first series concerns the neutron physics, the reactivity of the fuel:

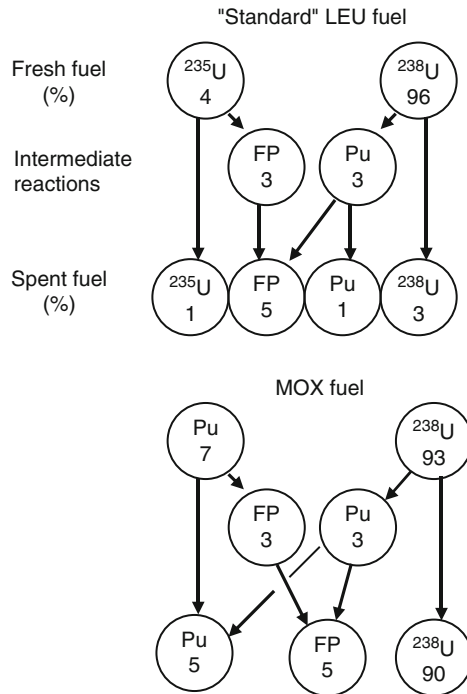

- As irradiation proceeds, the fissile nuclei are progressively consumed, while some of the fertile nuclei are transmuted into fissile nuclei. The balance between these two transformations is usually negative – with the exception of “breeder” reactors – and the fuel gets depleted in fissile nuclei (🔍 *Fig. 20*).
- In parallel, fission generates fission products. Some of those fission products, or their daughter nuclei, capture neutrons efficiently, thus “poisoning” the fuel by impairing the fission reaction.

Consequently, the reactivity of the fuel decreases throughout its lifetime, until it is no longer capable of sustaining the chain reaction (To compensate for this “reactivity swing” in the fuel assemblies, fresh fuel must be – deliberately – poisoned, and those control poisons are progressively removed, or burned in situ, to keep the average reactivity of the whole core constant throughout a cycle of production. As control poisons one uses cadmium alloy rods inserted inside the fuel element, and boric acid diluted in the primary coolant water. In addition, to reach very high burnups, “burnable” poisons, gadolinium or erbium compounds, are incorporated in the fuel pellets).

The “spent” fuel must then be unloaded from the core.

The higher the burnup to be reached, the higher must be the initial concentration in fissile nuclei, i.e., the higher the initial enrichment of LEU fuel or the higher the initial plutonium/uranium ratio in MOX fuel. Conversely, the higher the burnup, the fewer the fuel assemblies to manufacture and to reprocess for a given energy output. The optimum burnup is, therefore, the result of an economic compromise between the costs of enriched uranium supply, fuel fabrication and reprocessing.

But this is not enough: one must demonstrate that, under normal and accidental conditions, the fuel retains its integrity even at its highest burnup. This is where the other transformations above mentioned play a crucial role.

■ **Figure 20**
Schematic physics in PWR fuel assemblies (45 GWd/t_{HM})

The structural integrity of the pellet itself is affected in many ways by the irradiation:

- Most of the energy released by the fission phenomenon appears as kinetic energy communicated to the two fission fragments: their slowing down which produces heat inside the fuel also produces a lot of point defects in the fuel pellet crystallites.
- As a result, the fuel pellets swell, fragmentize, and come in close contact with the cladding.
- Many of the fission products have chemical properties different from those of uranium and plutonium, and alter the stoichiometry of the uranium and plutonium oxides.
- Some of the fission products are gases which either contribute to pellet swelling or permeate outside, increasing the internal pressure of the cladding.
- At high burnups, transmuted plutonium accumulates at the outer "rim" of the pellet, transforming in effect a thin annulus of the pellet into MOX fuel, with a possible loss of cohesion at the interface.

Even more important, the cladding, which constitutes the first safety barrier containing the radioactive elements produced in the fuel, must retain its leaktightness. During its life in the reactor core, the cladding material experiences many "aggressions":

- Corrosion is the first aggression. Even in the absence of irradiation, zirconium reacts actively with oxygen and reduces water to form an oxide, zirconia, ZrO_2 . At low temperature, a thin

coating of impermeable zirconia layer protects the alloys from further oxidation (not unlike aluminum), but at reactor temperatures, above 300°C, the corrosion goes on, together with a secondary hydride formation by the hydrogen released in the water reduction reaction. Under irradiation, this phenomenon is accelerated, and the corrosion rate becomes a limiting factor of lifetime (the zirconia layer is not allowed to exceed 100 microns). Some alloying elements decrease drastically the corrosion rate of zirconium, but their choice remains rather empirical.

- The difference of pressure between the inside of the fuel rod (initially pressurized with helium) and the water of the primary circuit induces a creep which closes the internal gap between the pellet and cladding, sometimes during the second irradiation cycle (A typical PWR fuel assembly stays in the core during four 1-year cycles). From then on, deformations of the pellet, notably during rapid variations of power – the so-called ramps – interact with the cladding and threaten its integrity, a phenomenon known as pellet-cladding interaction (PCI).
- Neutron irradiation itself induces hardening and anisotropic growth of the zirconium. In addition, fission produced iodine may attack the cladding from the inside and induce stress-corrosion, etc. One could add that alteration of the mechanical properties under irradiation also affects spacer grids, especially springs, and guide tubes of the fuel assemblies, therefore, also limiting the fuel lifetime.

All in all, the proper choice of the cladding alloy and its mechanical and thermal treatments is of key importance in the competition between nuclear fuel vendors for optimum burn-up and optimum performance for their utility customers.

6 Thorium

Thorium, element 90 in the periodic classification, is present in nature with only one isotope, ^{232}Th , which is fertile like ^{238}U , giving birth to fissile ^{233}U after a neutron capture and two β^- decays. ^{232}Th is radioactive α , with a half-life of $1.41 \cdot 10^{10}$ years. As thorium has no fissile isotope, it cannot start a fuel cycle on its own. One needs ^{235}U or plutonium to start the thorium cycle (► Fig. 21).

Though it is roughly four times more abundant in the continental crust than uranium, thorium is an essential constituent of only a few minerals: thorite (ThSiO_4), thorianite (ThO_2) and monazite ($\text{Ce,La,Nd,Th} \text{PO}_4$). The beach sands of India, Brazil and Madagascar are rich in monazite, and thorium is sometimes a by-product of uranium mining. As thorium has few applications – thoria is a highly refractory ceramic, and was also used for the luminescent gas lights, but is now abandoned because of its radioactivity – reserves and resources of thorium have not been assessed with the same precision as those of uranium.

There may be two reasons to get interested in thorium:

- On the one hand, ^{233}U is an excellent fissile material which can (barely) allow breeding in a “thermal” reactor (this has been demonstrated in the last experimental core of the Shippingport PWR, dubbed “LWBR.”
- On the other hand, the long term radio-toxicity of the high level waste issued from the $^{232}\text{Th}/^{233}\text{U}$ cycle is significantly lower than from the ^{238}U /plutonium cycle.

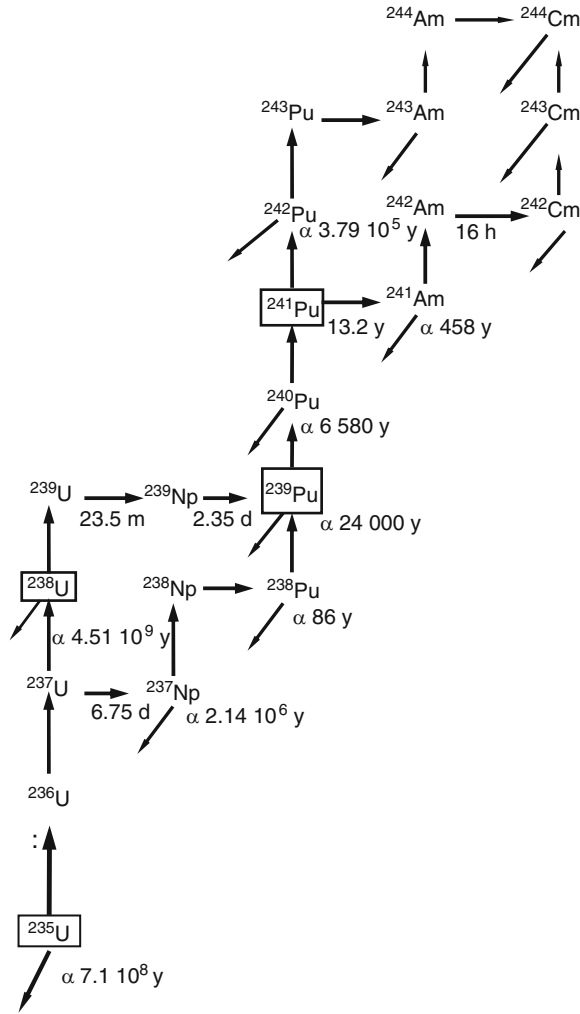

Figure 21
The thorium cycle

The thorium cycle has been used in a number of experimental reactors. India, poor in uranium resources but rich in thorium, is the only country currently developing the thorium cycle but it is considered for use with the molten salt reactor, one of the six “generation 4” concepts.

7 Plutonium

Element 94 of the periodic classification, plutonium exists only as traces in nature, but is produced when uranium fuel is irradiated in reactors, through neutron capture in ^{238}U . Spent fuel elements are, therefore, analogous to “plutonium mines,” from which plutonium is extracted by “reprocessing.”

■ Figure 22
Uranium, plutonium, and minor actinides

■ Table 9
Isotopic composition of discharged plutonium (weight%, PWR fuel, 3 years cooling time) (OECD 1999)

Burnup	²³⁸ Pu	²³⁹ Pu	²⁴⁰ Pu	²⁴¹ Pu	²⁴² Pu	Pu fiss.
33 GWd/t _{HM}	1.7	57.2	22.8	12.2	6.0	69.4
60 GWd/t _{HM}	3.9	49.5	24.8	12.9	8.9	62.4

There are five major isotopes of plutonium, ranging in atomic mass from 238 to 242. Neutron capture in ^{238}U produces ^{239}Pu , and further neutron captures produce the higher isotopes, while ^{238}Pu comes from a series of reactions (🔗 Fig. 22). The amount of ^{238}U converted to plutonium increases with the time the fuel stays in the reactor and, similarly, the longer the irradiation time, the greater the proportion of higher plutonium isotopes.

^{239}Pu and ^{241}Pu are fissile isotopes, similar to ^{235}U , while ^{240}Pu can be considered “fertile” like ^{238}U , and ^{242}Pu just captures neutrons to produce higher actinides. Globally, the longer the irradiation time, the less fissile the plutonium (🔗 Table 9).

By comparison, weapon-grade plutonium of low irradiation would be over 90% ^{239}Pu .

Abstract: Transuranium elements, neptunium, plutonium, americium, and curium, are formed via neutron capture processes of actinides, and are mainly by-products of fuel irradiation during the operation of a nuclear reactor. Their properties significantly impact the nuclear fuel cycle, affecting and often determining requirements and procedures related to handling, storage, reprocessing, and disposal of fuels and high-level waste. It is still debated if, in particular, plutonium is an unwanted waste or, possibly, a resource for the production of energy. A standard universally agreed route for the treatment of transuranium elements is not yet established. This chapter provides an overview of past and ongoing experience and perspectives related to studies on transuranic recovery and incorporation in fuels and targets for advanced nuclear fuel cycles and their disposal as the main component of high-level nuclear waste. In particular, the chapter describes the main properties of transuranium fuels, the specific requirements for their fabrication, their irradiation behavior, and their impact on the back-end of the fuel cycle. For the latter, a major issue is the development of options for reprocessing and separation of transuranium elements from spent fuel to make them available for further treatment. The effects caused by their presence in irradiated fuel and high-level nuclear waste on long-term storage and final disposal are also discussed.

The final destination of transuranium elements is still an open issue. The global context is characterized by a diversified set of options being pursued, which is reflected in this chapter. It is important to have a picture of the knowledge and experience gathered until now through relevant investigation campaigns worldwide. This is necessary to ensure that the renewed interest in nuclear energy as a key component of sustainable development of energy production brings the necessary focus to implement viable, safe, and technologically effective options for the treatment of transuranium elements.

1 General Introduction

The transuranium elements are the chemical elements with an atomic number greater than that of uranium (92). Due to their short half-life compared to the age of the earth, these elements are no longer found in the earth's crust. Neptunium and plutonium found in trace amounts in some uranium ores are thus not of primordial origin but are formed by the capture of neutrons. However, the widespread occurrence of some of the transuranium elements on earth is nowadays mainly related to human activities making use of nuclear reactions: nuclear weapons and nuclear reactors.

The importance of transuranium elements in the fuel cycle of nuclear reactors was recognized rapidly after the discovery of plutonium by Seaborg and McMillan in 1940. ^{239}Pu formed by neutron activation of the uranium (^{238}U) matrix of the nuclear fuel can be used as fuel for nuclear power plants and the concept of breeding plutonium – i.e., producing more fissile material than the fraction fissioned to produce energy – has been the subject of research since the 1950s. Especially in the 1960s and 1970s, when a rapid expansion of civil nuclear power took place and the expectation prevailed that the uranium resources in the world were insufficient to sustain it, fast breeder reactors were developed world-wide and the first prototypes were constructed in the USA, Europe, and USSR.

From the beginning of the development of nuclear power reprocessing of spent nuclear fuel, i.e., recovering of plutonium has been considered an essential part of the fuel cycle. The plutonium thus obtained was intended as startup fuel for fast breeder reactors. In Europe, the primary choice for the fast breeder reactor fuel was mixed uranium–plutonium oxide (MOX) as driver fuel and uranium oxide as fertile blanket, combined with aqueous reprocessing technology

based on plutonium and uranium refining by extraction (PUREX) process. In the USA, the emphasis was originally on metal fuel in combination with pyrochemical reprocessing technology using electrorefining in molten salts (Burkes et al. 2009), but the oxide fuel cycle gained strong interest before the program was stopped in the 1980s. Also dense ceramic fuels such as mixed carbides and mixed nitrides have been the subject of extensive research worldwide.

During irradiation of uranium fuel in a reactor not only plutonium is formed, but also other transuranium elements such as neptunium, americium, and curium. These elements are present in the spent fuel in relatively small quantities compared to plutonium, and for that reason they are often called minor actinides (MA). From the technological point of view, the minor actinides have been considered as uninteresting by-products, though in the past they have found limited applications as high specific power sources for special cases such as smoke detectors, pacemakers, or deep space probes (as an alternative to ^{238}Pu). Therefore, in today's nuclear fuel cycle the minor actinides are destined to final disposal in a geological repository either as vitrified high-level waste (HLW) from the reprocessing of spent fuel, or as part of spent fuel in the case of direct disposal (see ► Sect. 6).

However, the relevant isotopes of americium (^{241}Am , ^{243}Am), curium (^{244}Cm), and, to a lesser extent, neptunium (^{237}Np) are highly active and undergo highly energetic decay. As a result, the radiotoxic inventory of the vitrified waste is relatively high over significant time periods (>10,000 years). This has become one of the key concerns of the general public with respect to nuclear power. It is even more relevant for spent fuel from light water reactors (LWR) that is not reprocessed but disposed of directly, as its radiotoxic inventory is about a factor of 10 higher, because it also contains the plutonium that was produced during reactor irradiation (see ► Fig. 1).

► Figure 2 schematically illustrates the composition of typical irradiated LWR UO_2 . ► Table 1 reports the composition of different types of spent LWR fuel. Typically, ~1% of spent UO_2 fuel is Pu. The content of MA is higher in spent LWR MOX fuel. The use of Pu-based fuel has an impact on the fractions of MA in spent fuel and the waste stream that is destined to final disposal, depending on the type of reactor irradiation (Grouiller et al. 2003).

Since the late 1980s the nuclear research community has been strongly involved in exploring technical solutions to reduce the radiotoxic inventory of the nuclear waste (spent fuel, HLW). The prevailing concept is the further separation of the minor actinides from the spent fuel during reprocessing, generally called *partitioning*, and their destruction by re-irradiation by neutrons, or *transmutation*. The most effective MA destruction process by neutrons is fission, by which the minor actinides are transformed into fission products whose contribution to the radiotoxic inventory becomes very small after about 250 years (► Fig. 1). The technical feasibility of the partitioning and transmutation (P&T) concept is extensively studied (CEA 2004). From the reactor physics point of view, it is clear that the transmutation can be realized best in fast neutron systems, in which the minor actinide nuclides can be fissioned efficiently due to the favorable fission-to-capture ratio for neutrons and the favorable neutron economy. Besides the further development of the fast neutron system, key technological issues remaining to be solved are the establishment of an efficient partitioning scheme for the minor actinides from the spent fuel, and the design of minor actinide fuel that can be introduced in a reactor without adverse effects on the system safety.

These key issues are strongly related to the P&T strategy pursued. In general, one can discriminate between two different concepts:

1. Separation of individual minor actinide elements and their transmutation in dedicated systems optimized to obtain the best overall efficiency. Since the separation of neptunium can

Calculations performed using the webKorigen application available at the Nucleonica web portal (<http://www.nucleonica.net>)

be achieved by adjustment of the PUREX process, and its transmutation can be realized by adding it to fast reactor (U, Pu)-based fuel, the research is focused on defining effective solutions for americium and curium. This option must rely on the feasibility of the chemical separation of Am and Cm from the lanthanide fission products as well as from each other. The use of subcritical transmutation devices such as accelerated-driven systems (ADS) in multiple recycling steps or the incorporation of these elements in once-through targets that are subjected to extremely high burn-out levels in a single irradiation, have been proposed in recent years.

- Grouped separation of the minor actinides and their transmutation in fast reactors systems, for example those studied in the Generation IV (Gen IV) International Forum (GIF), in multiple recycling steps. Here the feasibility of the difficult grouped separation must be demonstrated, and the impact of the overall presence of curium (neutron emission and heat production) on the fuel cycle operations (fabrication, handling and transport, and storage) must be assessed.

It is thus clear that the separation technology and fuel technology for minor actinides are critical for the further development of P&T strategies. In this chapter we present the state-of-the-art of these technologies, in view of the two concepts mentioned above.

2 Fundamental Aspects of Transuranium Fuels

2.1 General

The properties of nuclear fuels in general and of transuranium fuels in particular are important for the optimization of the conditions for their fabrication and to predict/assess their performance during irradiation. As discussed in detail in ► Chap. 13, detailed knowledge of the thermodynamic and thermophysical properties of the fuel materials is needed, as well as the stability of the fuels with respect to radiation. For example, the melting temperature and the thermal conductivity together define the margin between the operation temperature and melting point of the fuel, an important criterion for the safety of the fuel. Similarly, knowledge of the evolution of such properties as a function of burnup of the fuel is needed (see next section).

A large knowledge base exists for U and U/Pu-based fuels, but the knowledge of MA bearing fuels is still relatively poor. Some basic data have been generated during the 1950s and 1960s when the science of the actinide elements was explored worldwide but generally not at the high temperatures relevant to nuclear fuels. Transmutation studies have stimulated renewed interest, both by experiments and theoretical calculations, in the properties of MA compounds.

2.2 Characteristics of Transuranium Fuel Forms

Transuranium fuels are characterized by a high concentration of plutonium and minor actinides which have a significant impact on the physical, chemical, and radiation properties of the fuel, affecting the fabrication process, the handling, and the irradiation behavior (Konings and Haas 2002). ► **Table 2** shows the radioactive decay characteristics of various nuclides that must be taken into account. In particular, the γ dose rates of the americium and curium isotopes are orders of magnitude higher than those of uranium or even ^{239}Pu . This means that lead shielding is a prerequisite for safe handling and treatment of any fuel compounds which include MA. In addition, ^{244}Cm presents a very high neutron dose rate due to spontaneous fission, which requires further shielding using materials with high hydrogen density like water or polyethylene. Finally, the power produced by ^{244}Cm is significant and necessitates forced cooling when stored.

Transuranium fuels have by definition a complex composition containing multiple actinide elements. Since the content of fissile isotopes in the reprocessed plutonium and minor actinide products is generally high, a non-fissile matrix is required as support. Two combinations of matrix and fissile phase can be distinguished: solution phases (solid, liquid) or composites (Chauvin et al. 1999).

A solid solution is, in principle, a homogeneous mixture of two or more end member compounds that are distributed randomly/substitutionally on the same crystallographic lattice site, forming a single phase. In a solid solution fuel the fission takes place homogeneously in the fuel, and the effects of radiation are homogeneously distributed in the matrix. The best known example in nuclear technology is the mixed oxide (U, Pu) O_2 in which a substitutional replacement exists in the complete composition range between the end-members UO_2 and PuO_2 . This is not always the case; for example, the solubility of Pu in alpha-uranium metal is only about 5–10%; beyond that two phases with different U/Pu concentrations coexist (Kurata 1999).

■ Table 2

Characteristics of ^{235}U and the main transuranium isotopes

Nuclide	$T_{1/2}$ y	Main decay mode	Spontaneous fission rate ($\text{s}^{-1} \text{g}^{-1}$)	Specific activity (Bqg^{-1})	γ Dose rate ($\text{mSv h}^{-1} \text{g}^{-1}$)	Specific power (Wg^{-1})
^{235}U	7.04×10^8	α	1.6×10^{-6}	8.0×10^4	1.3×10^{-3}	6.0×10^{-8}
^{237}Np	2.1×10^6	α	5.1×10^{-5}	2.61×10^7	–	–
^{238}Pu	87.7	α	1.18×10^3	6.33×10^{11}	–	0.567
^{239}Pu	24100	α	1.0×10^{-2}	2.3×10^9	1.5×10^{-2}	1.93×10^{-3}
^{240}Pu	6564	α	479	8.4×10^{10}	–	7.06×10^{-3}
^{241}Pu	14.3	β^-	9.19×10^{-4}	3.82×10^{12}	–	3.28×10^{-3}
^{242}Pu	3.75×10^5	α	805	1.46×10^8	–	–
^{241}Am	432.7	α	0.505	1.27×10^{11}	312	0.114
^{242m}Am	140	α	62	3.87×10^{11}	12	4.49×10^{-3}
^{243}Am	7370	α	0.27	7.33×10^9	44	6.43×10^{-3}
^{242}Cm	0.45	α	7.47×10^6	1.23×10^{14}	–	122
^{244}Cm	18.1	α	4.0×10^6	3.0×10^{12}	4.9	2.83

The physical properties of the solid solution fuel generally vary gradually between the end-members. For example, the melting temperature of the $\text{UO}_2\text{--PuO}_2$ solid solution varies very regularly, close to the thermodynamic ideal behavior. The thermal conductivity of solid solutions does not follow simple rules. This is due to the fact that the thermal conductivity is strongly dependent on the phonon scattering and hence strongly influenced by substitution or non-stoichiometry of the crystal lattice. The thermal conductivity of the $\text{UO}_2\text{--PuO}_2$ solid solution for low Pu content is somewhat lower than that of UO_2 (Carbajo et al. 2001). However, the thermal conductivity of $(\text{U}_{0.5}\text{Np}_{0.25}\text{Am}_{0.25})\text{O}_{1.93}$ is significantly lower (Schmidt et al. 1986) as shown in ► Fig. 3, but close to that of $(\text{U, Pu})\text{O}_{2-x}$ with similar O/M ratio. Thus the substitution of Am has a much smaller effect than the vacancy formation, which is a consequence of the fact that americium is easily reduced to the trivalent state.

A composite (dispersion) is a mixture of two immiscible phases, the main phase generally serving as the neutronically inert matrix and the dispersed phase containing the fissile material (► Fig. 4). By choosing the right combination of phases, the properties of the composite material can be tailored for the specific conditions expected in-pile (Chauvin et al. 1999). A special form of composite fuel is the high temperature reactor fuel, in which a spherical particle (oxide, carbide, or oxycarbide) is coated with several protective layers (carbon, SiC) and dispersed in graphite. In composite fuels the fission process takes place in the dispersed phase and the effects of the irradiation will be concentrated in and immediately around that phase, giving rise to a much higher, albeit localized extent of radiation damage. The extent of damage to the matrix will depend on the size and volume fraction of the dispersed phase (► Fig. 5).

A liquid solution is a special fuel form mainly relevant for molten salt reactors. In this case, the fissile phase is dissolved in a dilute form in a binary or ternary salt matrix that is liquid at

the operating temperature of the reactor. Since the fuel is liquid – hence no long range order is present – the effects of radiation damage are negligible.

2.3 Properties of Transuranium Elements and Compounds

The unique character of the actinides in the periodic system is due to the fact that their properties change as a function of the filling of the $5f$ electron shell. In the light actinides the

5*f* electrons participate to the valence band (itinerant), whereas in the heavy actinides the 5*f* electrons are localized in the core, just as in the 4*f* lanthanide series (Edelstein et al. 2006). The transuranium elements, from neptunium to curium, have a special position as they show a gradual change from itinerant to localized electron behaviour. As a result, the physicochemical behavior of the transuranium elements and their compounds show distinct differences that must be taken into account for fuel design and performance applications. For example, whereas plutonium can occur in a wide range of oxidation states (from 3+ to 6+) like the *d*-transition metals, curium is predominantly trivalent, like the lanthanides (Table 3).

The change in physicochemical properties is most pronounced in the actinide metal series. This is strongly reflected in the different metal valence states (Metallic bonds can be considered as a lattice of positively-charged ions (cations) that share delocalized electrons): tetravalent (Th–Pu), trivalent (Ac, Am–Cf, Lr), and divalent (Es–No). Also the change in melting point of the actinide metals is remarkable (Fig. 6), decreasing by about 500 K going from U to Pu (Konings et al. 2006). This has an important technological impact as the melting point of a metal fuel containing large amounts of transuranium elements is significantly lower than that of pure uranium metal fuel, thus reducing the margin to melting during operation in-pile. The vapor

■ **Figure 6**
The melting temperature of the actinide metals

pressure of the light actinide metals increases significantly in the series reaching a maximum at Am, for which the vapor pressure is 0.1 kPa at 1,500 K. Also this has technological implications, because it will complicate the fabrication of metal fuel and may lead to unwanted redistribution during irradiation. Finally, one needs to address the thermal conductivity of the actinide metals. This property is not very well known for the transuranium elements, but the values determined experimentally (Np, Pu) or predicted (Am, Cm) are lower than those of uranium.

The fluorite cubic dioxide (face-centered cubic or fcc) is a stable phase in all light actinide–oxygen binary systems, showing significant ranges of hypostoichiometry for all of the dioxides, whereas hyperstoichiometry only occurs in uranium dioxide. The properties of the actinide dioxides show gradual changes: melting point and chemical stability decrease along the actinide series in a systematic way (Konings et al. 2006). The oxygen potential above AmO_2 is very high (Chikalla and Eyring 1967; Otake et al. 2008), and CmO_2 even decomposes above 700 K (Smith and Peterson 1970). For these elements binary oxides with O/M lower than 2 must be considered, for example, the substoichiometric AnO_{2-x} phase or the sesquioxide An_2O_3 . The mutual solubility of the actinide dioxides is high. UO_2 and PuO_2 form a complete solid solution, and this is very likely the case for the other dioxides. Due to the lower melting points of the transuranium dioxides ($T_{\text{fus}} = 2,386$ K for AmO_2 , $T_{\text{fus}} = 2,478$ K for Am_2O_3 , and $T_{\text{fus}} = 2,543$ K for Cm_2O_3) compared to UO_2 ($T_{\text{fus}} = 3,120$ K), mixed transuranium oxide fuels will have a significantly lower melting point than $(\text{U}, \text{Pu})\text{O}_2$ fuel.

For uranium-free fuels and targets, solid solution fuels with ZrO_2 stabilized in its cubic form by calcium oxide (calcium stabilized zirconia, CSZ) or yttria (YSZ) are considered. These oxides also have the fcc structure and thus can dissolve the actinide oxides. Taking also into account the low thermal conductivity of these actinide-bearing oxide solid solutions, the margin to melting for mixed oxides with high concentrations of minor actinides will be significantly lower than for UO_2 , when operated at the same linear power.

The actinide carbides show complicated phase relations with AnC , AnC_2 , and An_2C_3 as potential stable phases, all showing wide ranges of non-stoichiometry (Holley et al. 1984). The cubic AnC_{1-x} phase is known for $\text{An} = \text{Th}$ to Pu , but with very different lower phase boundary compositions. This phase is in equilibrium with metal. The AnC_2 phase is known for $\text{An} = \text{Th}$, U , and Pu , though in the $\text{U}-\text{C}$ and $\text{Pu}-\text{C}$ systems it is still under debate whether the dicarbide is a high temperature phase or also stable at room temperature. The An_2C_3 is known for $\text{An} = \text{U}$ to Cm , but U_2C_3 is probably a high temperature phase. The monocarbide has been studied as fuel material, but in practice the carbide fuels are a two-phase mixture of the mono- and (as a minor fraction) the sesquicarbide, to avoid metal phase formation during irradiation. This means that the minor actinides likely concentrate in a secondary phase.

■ Figure 7

The thermal conductivity of the actinide nitrides (after Minato et al. 2009)

The melting points of the monocarbides are high (>3,000 K), which, combined with a high thermal conductivity, makes these materials particularly suited as dense fuels for high power applications.

The mononitride is the dominant phase in all An–N phase diagrams and has a rock-salt cubic structure. The relevant properties of the actinide nitrides UN, NpN, and PuN are fairly well established, but those of AmN and CmN are not very well known (Minato et al. 2009). It has been demonstrated that solid solutions exist between all the AnN phases. A systematic decrease of melting point, chemical stability, and the thermal conductivity along the actinide series UN–AmN is observed (see e.g., the thermal conductivity in ► Fig. 7). The thermal conductivity of the nitrides is high and, unlike the metals and oxides, increases with increasing temperature. A major concern is the thermal stability of the nitrides at high temperatures, as they decompose to nitrogen gas and actinide metal, the latter in liquid and gaseous state. Especially for AmN this decomposition is expected to be significant, as was found experimentally for (Pu, Am)N (Ogawa et al. 1995). Also for nitride fuels an inert matrix has been considered and ZrN has been identified as an interesting candidate (Kleykamp 1999).

The pure actinide fluorides (ThF₄, UF₄, PuF₃, AmF₃) and chlorides melt above the operating temperature of a molten salt reactor. For that reason the proposed fuels for molten salt reactors are a mixture of these actinide phases with potential matrix phases that guarantee a low melting temperature of the binary or ternary composition. Originally, the work on the molten salt fuel has focused on LiF–BeF₂ solvent (which is excellently suited for breeding ²³³U from ²³²Th), but this salt shows a relatively low solubility for PuF₃ (Barton 1960; Mailen et al. 1971) as can be deduced from ► Fig. 8. To increase solubility another component such as NaF must be added as matrix component. The binary phase diagrams of the relevant LiF–NaF–BeF₂–PuF₃ systems are well established, with the exception of the BeF₂–PuF₃ system (Beneš and Konings 2009). However, no phase diagrams with other transuranium fluorides are known.

3 Transuranium Element Fuel and Target Fabrication

3.1 General Aspects

This section deals with the fabrication of fuels for Gen IV fast reactors and for systems dedicated to transuranium element transmutation, such as the accelerator driven system (ADS). In the former, U-based fertile fuels are the preferred choice, however, other options such as fertile free fuels, often considered for ADS applications, can also be deployed. The fertile free fuel option, also known as inert matrix fuel (IMF), has considered YSZ (e.g., (Zr_{0.85}Y_{0.15})O_{1.925}), magnesium aluminate spinel (MgAl₂O₄), magnesium oxide (MgO), and metallic molybdenum as matrices for the fuel.

The fuel composition and specifications for the Gen IV gas, lead, and sodium fast reactor (GFR, LFR, and SFR) place severe requirements on the fabrication processes. The high-level goals of Gen IV foresee group (U, Pu, Np, Am, and Cm) recycling of the actinides to ensure proliferation resistance in the fuel cycle. In this way, Pu would never be freely accessible for a potential misuse. The main difficulties might not ensue from the liquid to solid conversion itself, rather from the steps required thereafter, wherein the fuel would be brought to the required transuranic content by the introduction of U (depleted, U_{dep}, or natural), transformed in the desired chemical composition (metal, oxide, nitride, or carbide), and formed into the required shape for the irradiation facility being considered.

For the IMF, similar fabrication philosophies apply. By replacing U with YSZ, it is possible to envisage separation schemes involving transuranium elements coextraction and/or separation of Pu and MA streams. Fabrication of YSZ-based fuels and targets can follow similar routes to UO_2 -based fuels, as YSZ just as UO_2 forms a solid solution with Pu and the MA. In addition, the conversion step can also be used to produce actinide oxides in powder or bead form, for blending with a second material, with which no chemical interaction occurs. Such composite fuels permit microstructure tailoring to improve the fuel performance.

This section describes processes used to fabricate experimental fuels in solid solution and composite fuel forms. Thus far, all fabrication of minor actinide bearing fuel has been made on lab scale level, without an industrial implementation.

Handling transuranium elements requires hermetically sealed gloveboxes to prevent the risk of incorporation of highly toxic radioactive materials into the body. The glovebox operating atmosphere should be inert. For oxide fuels, the oxygen to metal (O/M) ratio is an important fuel design parameter and sintered product materials should be maintained in atmospheres with less than 1% O_2 and preferably with less than 100 ppm H_2O . In contrast, the preparation of nitrides and carbides poses more severe atmospheric requirements. Both react readily with O_2 and H_2O , which is detrimental to the quality of the product, and incorporation of oxygen increases with every processing step. A much more severe problem is the pyrophoricity of these materials, being particularly important for carbides in all geometries, but most importantly for finely divided powders with a high surface area. For nitride and carbide fabrication, the O_2 and H_2O contents in the gloveboxes should be maintained below 10 ppm.

The incorporation of the minor actinides in the fuel necessitates additional biological shielding, and concomitant automation of the entire process from conversion to the solid all the way through to assembly loading in the reactor. Lead provides shielding from γ emitters and a combination of water, lead, and cadmium (or boron) provides shielding from neutrons, emanating directly through spontaneous fission (e.g., ^{244}Cm) or by (α, n) reactions with light elements (O, N, or C) either in the fuel or in the aqueous and organic solvents of the processing solutions. While today's MOX plants for pellet production are highly developed with extensive (actually complete) automation, they are so designed that operator intervention can be made via the gloveboxes. Minor actinide presence in the fuel can necessitate the use of hot cells or hybrid facilities, combining glovebox standards with remote operation by telemanipulators (pin and assembly fabrication are not as extensively automated). At least one laboratory scale MA fuel facility has been developed (namely the JRC-ITU Minor Actinide Laboratory), consisting of a chain of seven conventional glove boxes, shielded by 50 cm water and 5 cm lead, for which the limiting masses are 150 g of ^{241}Am and 5 g of ^{244}Cm . Operation is achieved not only by telemanipulators, but also by remote control. Within this concept, operator intervention is possible, when all transuranium elements, including surface pollutants, are removed or stowed in protected zones. Alternative approaches could involve use of fully remotely operated hot cells, without human intervention possibility as was planned for the thorium fuel cycle (Grahmann et al. 1975). Determination of shielding is discussed in detail elsewhere (Magill 2003), and indeed there are commercial software packages available enabling its quantification (<http://www.nucleonica.net>, <http://www.euronuclear.org/e-news/e-news-17/nucleonica.htm>).

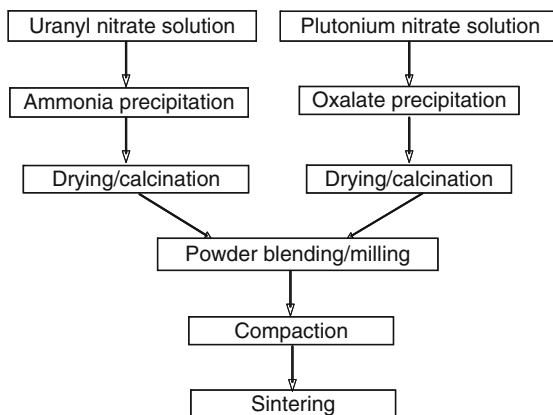

Transposing MOX fuel fabrication philosophy will probably not be satisfactory for another reason, namely dust. Both European commercial fuel fabrication plants (MELOX in France and SMP in the UK) base their fabrication on the use of powder metallurgy methods. While dust is an issue in that it must be collected and reintroduced in the process, it poses no severe insurmountable problem for MOX fuel fabrication. In contrast, however, processes devoid of

dust generation are desirable for minor actinide (MA) fuel production. Nevertheless, such powder metallurgical methods have been used for the production of small quantities of materials for dedicated irradiation tests (Tanaka et al. 2007).

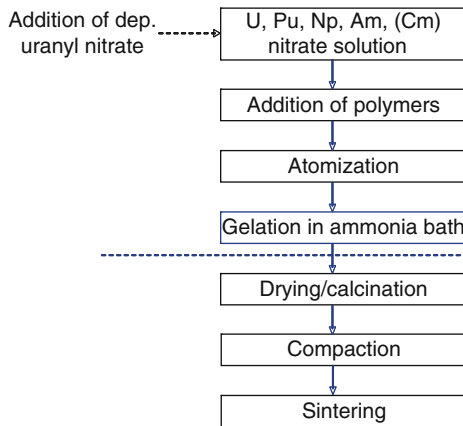

This chapter concentrates on pellet fuel type. There are no specific details given on sphere-pac or VIPAC fuel. In general, they can be based on the procedures described below for pellet type fuel. For sphere-pac, sol-gel and infiltration methods are used to generate spherical particles, which are sintered without compaction into pellets. Different size fractions are loaded into a fuel pin which is then vibrated to generate a fuel column, typically with a smear density of about 82% of the theoretical density (TD). The feed particles for VIPAC fuel is nonspherical and consists of irregular sintered particles, which are loaded in the tube for vibration. Due to their irregular nature higher vibrational amplitudes are required to pack these fuels. Typically, sphere-pac and VIPAC require two or three distinct particle sizes to provide the highest densities. These processes have been used to produce uranium-based fuels containing neptunium (Bart et al. 2007; Bychkov et al. 2002; Mayorshin et al. 2000, 2005).

3.2 Solid Solution Oxide Fuels Fabrication by Wet Routes (Precipitation, Sol-Gel, and Infiltration)

The Gen IV fast reactors (FR) and the ADS should operate in a closed fuel cycle. The actinides must be recovered from the reprocessing unit, where they are in solution form. Conversion to oxide is at the moment the only logical route for aqueous liquid to solid conversion, as there is no available method to produce the nitride or carbide powder directly. Indeed, oxide fuel for fast reactors represents a well developed technology. Former fast reactor fuel production relied on the separation (by the PUREX process) of U and Pu in the reprocessing step, so that the fuel production plant had a feed of UO_2 and PuO_2 as raw materials, from which blends could be made. Following a milling procedure, pellets were compacted and sintered. This dual feed system (see ► Fig. 9) had the advantage that the blend for individual fuel pins or assemblies could easily be manufactured. This is a tried and tested technology for U and Pu oxide recuperation, and is used commercially today for LWR fuel production.

■ Figure 9
Fast reactor mixed uranium-plutonium oxide (MOX) fuel production

■ Figure 10

Sol-gel route for group conversion (homogeneous recycling) of Gen IV fuels

Due to the risk of explosion posed by ammonium nitrate, Pu is generally precipitated by the addition of oxalic acid in solution or solid form (Drain et al. 1999). The Pu oxalate is thermally treated to give the oxide. Recently a co-extraction process (COEX) for all actinides has been developed and the oxalate coprecipitation of U, Pu, and MA solutions tested (Chapelet-Arab et al. 2006; Grandjean et al. 2005, 2006, 2007; Arab-Chapelet et al. 2007, 2008). Reduction of U(VI) in solution to U(IV) is required. The conversion is performed in a vortex reactor typically used for industrial conversion of Pu nitrate solutions. Conversion of the mixed oxalate to the oxide is performed by thermal treatment. Ammonia precipitation offers an alternative route and does not require U(IV) reduction, but care must be taken of the NH_4NO_3 by-product, which possesses an explosion risk when dry.

Consideration must be given to the quality of the powder, in terms of its particle size, when it is generated in the conversion step. Conventional precipitation (oxalate or ammonia) methods result in very fine powders (typically 2–5 μm), which easily become airborne and contaminate the internal surfaces in the gloveboxes. Despite the experience of the past, new solutions to fuel production must be invoked to eliminate fine powders and enable the industrialization of the processes for MA-bearing fuels. One of these was tested in the 1980s (Babelot and Chauvin 1996). MOX fuels with Am, and Np were produced using the sol-gel route (see ► Fig. 10), which at its heart relies on an ammonia precipitation, but maintains the intermediate product not in the form of powder, rather beads with diameters between 20 and 600 μm , depending on the characteristics of the droplet dispersion device. Extension of this process to Cm is possible in principle, but very rigorous cost evaluation and processes to deal with ensuing highly active neutron and alpha-emitting waste need development. This process, or a similar one using hexamethylenetriamine (HMTA) (Kasemeyer et al. 2001), has yet to be applied to Cm fuel production.

A novel process based on minor actinide infiltration has been developed for the production of dust free oxides (see ► Fig. 11) (Fernandez et al. 2002; Somers and Fernandez 2005). In particular, MA-bearing liquid waste streams are essentially eliminated. In a first step, porous beads are manufactured by a sol-gel method to give the oxide in the form of microspheres (20–120 μm in diameter). For YSZ, these beads can be produced in an inactive facility, while for fertile fuels either UO_2 or (U, Pu) O_2 beads can be produced using conventional glovebox

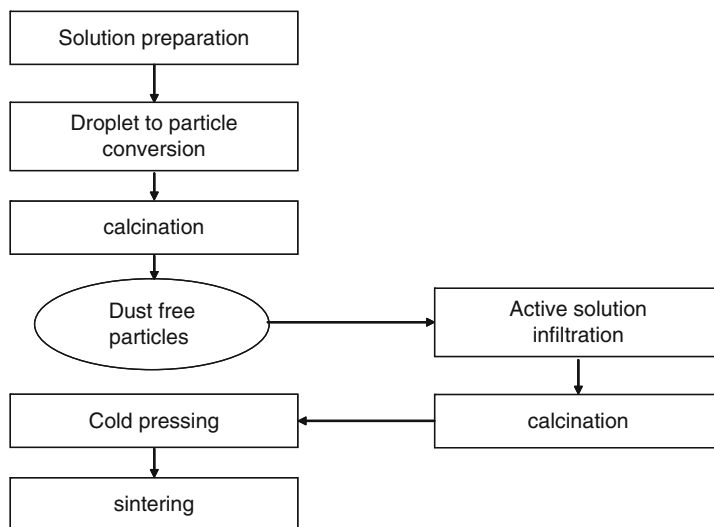

Figure 11
Production of GenIV oxide fuels based on the infiltration of porous beads oxide beads with the minor actinide nitrate solution

technology in use today. The porous microspheres act as a host for the second stream containing minor actinides, which are introduced by simple infiltration of their nitrate solution. Following calcination, the oxide is formed and the only waste is NO_x . At this stage, the material consists of two distinct oxide phases. Due to the excellent sintering properties of the sol-gel microspheres, however, a solid solution is obtained on heating. There are no liquid wastes containing minor actinides, and the conversion results in the difficult to handle minor actinides being securely located in particles that do not generate dust.

This infiltration process has been tested for the production of $(\text{Zr}, \text{Y}, \text{Am})\text{O}_{2-x}$ ($\text{Zr}, \text{Y}, \text{Pu}, \text{Am})\text{O}_{2-x}$ fuel irradiation experiments in the Phénix and HFR Petten reactors (Croixmarie et al. 2003; Fernandez et al. 2006). The precursor beads were $(\text{Zr}, \text{Y})\text{O}_2$ and $(\text{Zr}, \text{Y}, \text{Pu})\text{O}_2$, respectively. The process has yet to be demonstrated for UO_2 -based fuels, where the potential solubility of UO_2 in the nitrate infiltrant solution must be surmounted, though preliminary results show that even this potential drawback can be overcome (Fernandez, Richter, Somers, unpublished).

3.3 Powder Metallurgy for the Production of Solid Solution Fuels

Powder metallurgy is the industrially tried and proven method for the production of UO_2 and MOX fuels for LWR. Its inherent dusty character will pose difficulties for its deployment in MA fuel fabrication plants, and will necessitate technological solutions, possibly requiring full hot cell fuel fabrication facilities.

Recently, powder metallurgy routes have been used to produce $(\text{U}, \text{Pu}, \text{Am})\text{O}_2$ and $(\text{U}, \text{Pu}, \text{Np}, \text{Am})\text{O}_2$ fuels for a series of irradiation tests in the Joyo fast neutron flux reactor (Tanaka et al. 2007). The fabrication was performed in a suite of hot cells, with fully remote operation and maintenance facilities. The precursor actinide oxide powders were weighed and ball milled

to obtain a micronized blend, which was then pressed and sintered. The tests have shown that MOX fuels with 30% Pu and up to 5% Am and Np can be prepared in solid solution form using this route.

3.4 Oxide Fuels with Composite Microstructure

Fuels with two distinct phases have been considered for LWR MOX fuel. The micronized master blend (MIMAS) route has been widely deployed to produce a fuel consisting of Pu rich (ca. 25%) particles distributed in a UO_2 matrix. In contrast, the short binderless route (SBR) provides a fuel with a Pu distribution approaching a solid solution. The heterogeneity (or lack thereof) can be used to tailor the properties of the fuels. Though MA fuel forms based on UO_2 have yet to be investigated, they have been widely tested in programs for MA transmutation in IMF.

Am oxide-bearing fuels have been produced with the MA distributed in fine particles throughout magnesium aluminate spinel (MgAl_2O_4) and MgO matrices. The fabrication of the MgAl_2O_4 -based fuel used a variation of the infiltration process (Richter et al. 1997) shown in  Fig. 11. In this case however, the host material to be infiltrated was in the form of a porous pellet formed by the compaction of spinel granules and subsequent calcination to remove lubricants from the pressing step. This pellet infiltration technique not only eliminates Am-bearing liquid waste streams, just as its bead infiltration counterpart, but also eliminates powder pressing in the fabrication steps involving MA. The resulting product is a composite of fine Am-bearing particles in the spinel matrix. Due to the macroscopic dimensions of the pellet, control of the Am distribution needs extensive testing.

Powder metallurgy has been used for the production of a two phase microdisperse fuel of AmO_2 dispersed in MgO (Croixmarie et al. 2003). The process consists of powder mixing, light compaction (150 MPa), compact pulverization to give particles of 150 μm , renewed mixing, compaction at 250 MPa, and then sintering. The resulting product consisted of Am oxide particles with diameters less than 50 μm dispersed in MgO. A similar procedure has been followed for two MgO-based fuels, but the fissile component was $(\text{Pu}, \text{Am})\text{O}_2$ with 50 and 80% Am, prepared by oxalate precipitation of the corresponding solutions (Jorion et al. 2007).

Damage, due to α recoil and fission product generation, will occur throughout a solid solution fuel. In contrast, composite fuels can be designed to minimize the damage due to fission in the matrix, to a shell typically about 13 μm , surrounding the fissile component. Thus, if the distance between individual fissile particles is large enough, damage in the bulk of the matrix is reduced, and the deterioration of key properties in the matrix during irradiation is limited. The radiation effects in dispersion fuels with very small inclusions will approach that of a solid solution (see  Fig. 5), whereas the effect will be located in a 13 μm region around the inclusions, if they are larger. The maximum size of the inclusion is limited due to the temperature gradient in the host particle and should generally not exceed 300 μm .

An experiment has been performed in the Phénix reactor to investigate this effect (Croixmarie et al. 2003). The production of the fuel followed a hybrid route, integrating advanced wet chemical processing and powder metallurgy. Porous YSZ beads were fabricated by the sol-gel method and sieved to obtain two distinct size fractions (40–60 and 80–100 μm) before infiltration with the Am nitrate solution and subsequent calcination to give the oxide. The final pellet was then obtained by blending the $(\text{Zr}, \text{Y})\text{O}_2$ – AmO_2 beads with MgO, with subsequent compaction, and sintering steps. The fabrication process was successfully

demonstrated, but extreme caution against demixing of the denser actinide phase in the MgO blend was required. A similar procedure has been applied for the production of ceramic-metal (CERMET) fuel pellets for experiments in the high flux reactor (HFR) Petten and Phénix (Fernandez et al. 2006). Wet chemical routes were used to prepare the YSZ–AmO₂ and PuO₂–AmO₂ precursor beads, which were then blended with Mo powder. Due to the higher density of Mo, fewer problems of demixing were encountered.

The uniformity of a composite fuel can be determined by slicing a pellet axially, and polishing its surface. The analysis is achieved by dividing the observed surface into at least nine regions of equal size. The surface occupied by the inclusion in each field, S , is determined, and the average over all fields, S_a , and the standard deviation, σ , is measured. The homogeneity distribution factor, HD, is given by

$$HD = \frac{\sigma}{S_a}. \quad (1)$$

Values of HD less than 20 are required in fuel specifications.

3.5 Minor Actinide Carbide, Nitride, and Metal Fuels

3.5.1 General Considerations

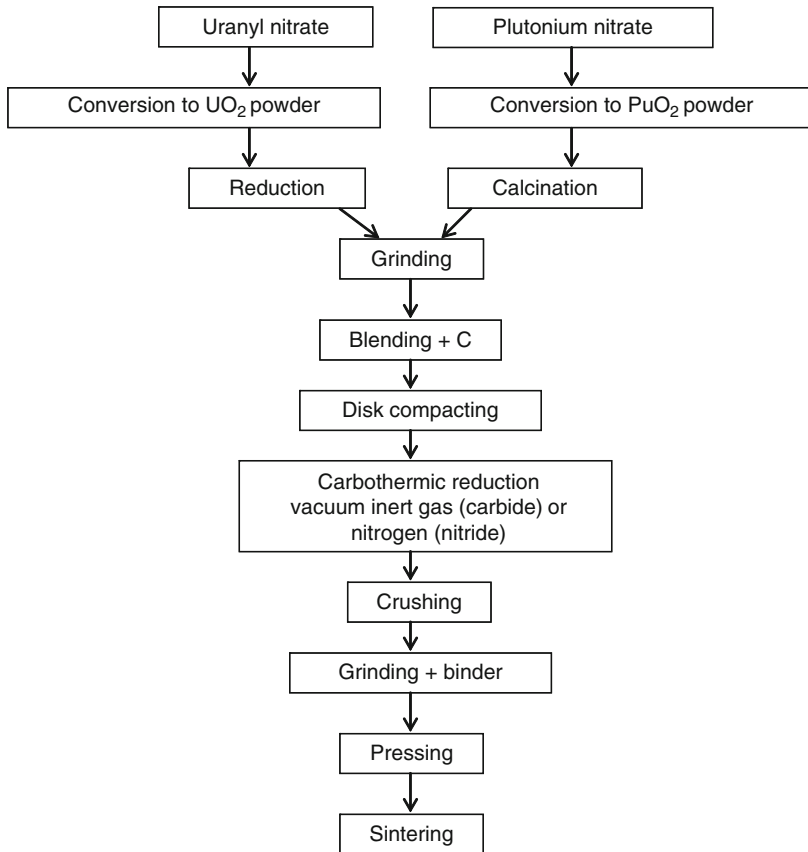

Carbides, carbonitrides, and nitrides can be produced by the general reaction given by

For nitrides, this reaction is performed under flowing nitrogen and requires high temperatures in excess of 1773 K. In the case of the pure carbide, $x = 0$, no nitrogen is used and the powders are heated directly in Ar, or preferably under vacuum. The progress of the reaction can be monitored by the CO in the furnace off gas. This reaction has been widely used for the production of U/Pu mixed metal carbides, nitrides, and carbonitrides and also Zr/Np/Am nitrides for MA incineration tests. An important point is the intimate mixing of the starting materials, usually achieved by co-milling the oxides with carbon. A generalized flow sheet is provided in  Fig. 12.

The production of MA-bearing carbides for fuel testing has not been investigated at all. The production of (U, Pu)C has been studied significantly at a laboratory scale and is complicated by the possibility of sesquicarbide M₂C₃ formation; considerable empirical adjustment of process parameters is needed (Richter et al. 1974, 1978). Manufacturing of carbides under vacuum (10⁻² mbar) gave better results than under Ar. The reaction temperature was 100 K lower, and less N impurity in the product was obtained (Matzke 1986). Nevertheless, Pu losses as high as 10% were observed during manufacturing (Richter et al. 1979; Vollath 1977). This poses a criticality risk in an industrial plant, as Pu is plated out, most likely on the cold surfaces of the furnaces. Increasing the CO partial pressure in the furnace during the carbothermal reduction step from 0.008–0.07 mbar reduces the Pu losses from 7.2–0.2%, respectively (Richter et al. 1979).

The rate or efficiency of the carbothermal reduction for nitride or carbide production depends intrinsically on the homogeneity and fineness of the blend of the U, Pu oxide and carbon powders. Milling times of up to 36 h have been mentioned (Vollath 1977). Poor intimacy in the mixture results in local impurities. If the carbon is locally deficient or in excess, either oxide or carbon impurity persist in the final product. The carbothermal reaction is favored by high surface area powders (>10–15 m² g⁻¹) and small agglomerate sizes (< 15 μm) (Louwrier et al. 1976).

■ Figure 12

Classical carbothermal reduction to produce carbides (or nitrides)

The carbothermal reduction step is often made on compacts, pressed at relatively low pressure to sustain the intimacy of the powder blend. Thereafter, the products have to be crushed in a hammer mill and then ball milled to produce a powder reactive enough to be pressed again to yield a high density pellet upon sintering at temperatures of 1923–2073 K either under Ar or vacuum. A wide range of pellet densities have been reported for the production of carbides. Poorly milled powders from the carbothermal production process yield low density pellets (80% of the theoretical density, TD), whereas highly milled powders can yield pellets in excess of 90% TD. Still higher (>95% TD) densities can be achieved by the addition of Ni as a sintering aid (Horspool et al. 1967; Anselin et al. 1965).

In a novel method to overcome the comminution steps to micronize the product after the carbothermal reduction process, Richter et al. (1985) and Richter (1987) introduced the direct pressing method, which involves the compaction of the uranium oxide, plutonium oxide and carbon blend into pellets for the carbothermal reduction step, which gives a product with a density of about 35–50% of the theoretical density. In contrast to the conventional process, the pellets are put back into the press and compacted again without recourse to an intermediate comminution step. Their density then increases to 65–75% TD which is increased to the target

specifications in the final sintering step. Direct pressing eliminates handling of powders with a high affinity for oxygen and thus the products have lower oxygen content. In addition, dust and consequent pyrophoricity risk is reduced. Finally, the removal of powder milling steps also diminishes impurities.

Excess sesquicarbide MC_{1+x} in the product can be reduced to MC by reaction with H_2 (Harder et al. 1965) i.e.,

This treatment is preferentially performed on the powder derived from carbothermal reduction. However, the presence of M_2C_3 in the fuel is not detrimental and is usually specified at no more than 5–15% M_2C_3 . In the case of nitrides, however, addition of hydrogen induces a parasitic reaction, causing the production of HCN, which also can react with the oxide (Bardelle and Warin 1992).

Specifications for nitrides (and carbides) stipulate low densities (80–85% TD) to limit effects of fuel swelling. In addition, their thermal stability must be guaranteed (i.e., they should not densify in pile). Arai et al. (1992) quotes the use of a pore former, which decreases the pellet density from 95 to 82% of the theoretical density. In this way, pellets with a low open porosity, despite the low density were produced; the stability is caused by 20–30 μm pores derived from the pore formers (Arai et al. 1992, 1988, 1989; Tanaka et al. 2004).

3.5.2 Production of Minor Actinide Nitrides

A large number of actinide nitride compounds (either as single minor actinide nitrides, their mixtures, or mixed compounds with U, Pu, and Zr nitrides) have been produced (Ogawa et al. 1995; Arai and Minato 2005; Minato et al. 2003; Takano et al. 1999, 2001, 2003; Arai and Nakajima 2000; Nakajima et al. 1997; Arai et al. 1997a; Suzuki et al. 1994; Muromura 1982; Okamoto et al. 1993). In all of these studies, the fabrication route was carbothermal reduction of the oxides. In many cases, however, pelletizing was not attempted; rather the samples were used for property determination. The vaporization behavior of the nitrides is a major issue (and even more important for carbides). For the first AmN production from the oxide, the reaction temperatures in the carbothermal reduction step were reduced to 1623 K to alleviate this problem (Voit, private communication). A major part of the effort on nitride fuels has been for the production of fuel for a dual strata actinide transmutation system, in which the minor actinides would be destroyed in a dedicated transmuted facility (e.g., an ADS). Thus the major interest has been incorporation of the minor actinide nitrides in IMF, such as YN or ZrN. Carbothermal reduction of AmO_2 with Y_2O_3 and ZrO_2 have been performed (Minato et al. 2003). In YN, a solid solution obeying Vegard's law was obtained in the range investigated (less than 30 mol% Am). In the (Zr, Am)N system there is an immiscibility gap.

Other laboratories (Voit, private communication) have undertaken programs to produce (Zr, Am, Np)N fuels. Significant Am losses due to vaporization during the fabrication steps were encountered. This was possibly accentuated by the use of a powder blend as the starting material. In subsequent tests, an attempt was made to "solutionize" the starting oxides, by

heating a mixture of them (and carbon) at 1673 K for up to 12 h under Ar, prior to launching the carbothermal reduction step (Voit, private communication). Using this method, low fertile (U, Pu, MA)N and non-fertile (Zr, Pu, MA)N materials have been prepared. The MA contents were significant (Np and Am 10–15 mol%).

A process to produce minor actinide nitrides (see [Fig. 13](#)) based on a modified method of that described in [Fig. 11](#) has been developed elsewhere (Fernandez, Walter, Somers, unpublished). The sol-gel route is used to manufacture the ZrO_2/C or $(U, Pu)O_2/C$ microspheres. These are then infiltrated with an Am nitrate solution and are thermally treated to give $ZrO_2/AmO_2/C$ or $(U, Pu)O_2/AmO_2/C$ microspheres. Due to the small particle size of the AmO_2 infiltrant ($< 2-3 \mu m$) and the high sinter activity of the sol-gel material, a solid solution of the oxide is readily attained at temperatures less than 1473 K. The carbothermal reduction can then be applied, and the resultant nitride powder pressed and sintered to give the product pellets. This process is in the infancy of its development but has been used to fabricate (Zr, Pu)N,

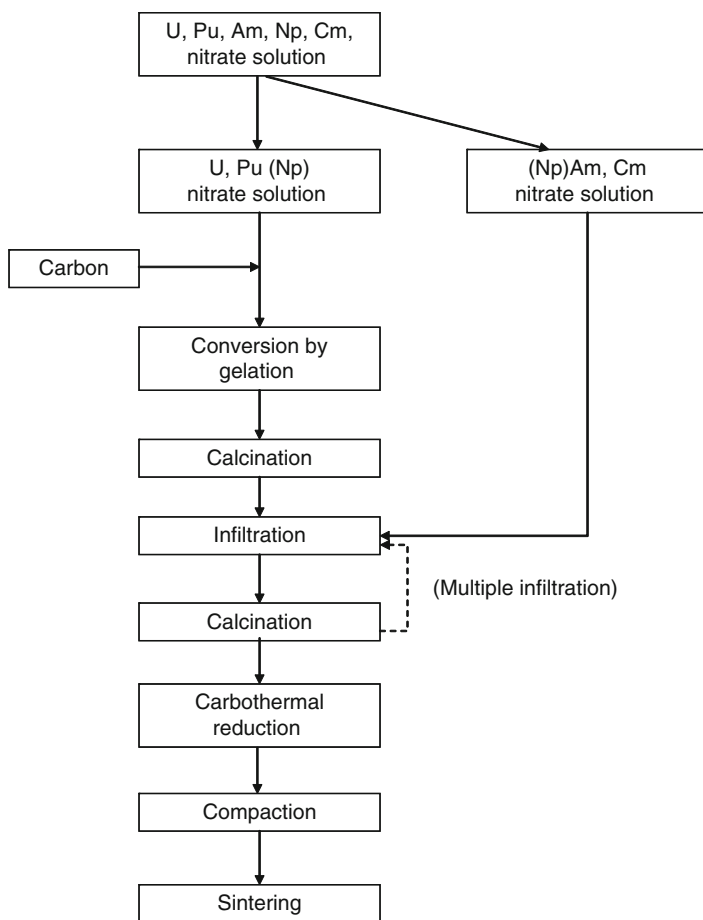

Figure 13

Production of nitrides by a combination of sol-gel, infiltration, and carbothermal reduction

(Zr, Am)N and (U, Pu, Am)N. Pellet densities remain low (70% of the theoretical density), but further process development is possible.

This process bears some similarities with processes used to fabricate (U, Pu)X fuels via aqueous processing routes (Ganguly 1988; Ganguly and Hegde 1997; Prunier et al. 1991, 1992, 1993; Ingold and Ledergerber 1994; Ledergerber et al. 1986). This fabrication method is often known as the sol–gel microsphere pelletization (SGMP) route and was focused on pellets as products. In addition, a variant of this method for the production of sphere-pac fuel was tested in the AC-3 experiment in the fast flux test facility (FFTF) (Adler et al. 1987; Bart et al. 2008). At the heart of both processes is a sol–gel step in which the U and Pu nitrate solutions are mixed in the desired quantity and converted to solid microspheres (400–800 μm) using the internal gelation route (see  Fig. 10). A solution is prepared close to 273 K, with the addition of hexamethylenetetramine (HMTA) and urea, along with carbon as a dispersed powder. The solution is atomized into drops on passing through a vibrating orifice. These drops fall into hot silicon oil, where the HMTA decomposes to produce ammonia, which causes a precipitation of the U, Pu hydroxide. Due to the dual phase system, the particles stay nearly spherical, and have a reasonable strength. Following washing and calcination steps, the microparticles consist of (U, Pu)O₂ and C and are ready for carbothermal reduction, under similar conditions as the powders from the conventional or direct pressing routes.

For the sphere-pac fuels, the nitride or carbide microspheres (with specific size and mass ratios) can be filled directly into fuel pins, and with gentle vibration the fuel pin is fabricated, e.g., for the AC-3 irradiation test in the FFTF reactor (Adler et al. 1987; Latimer et al. 1992). Pressing into pellets requires relatively high pressures (900–1,200 MPa) to give green densities of about 65% TD. Sintering resulted in pellet densities of 81–87% TD. The sol–gel routes have several positive attributes. No dusts are produced, thus reducing the radiotoxicity hazard and pyrophoricity risk. The free flowing spheres facilitate automation and remote operation. Less fabrication steps are required. Excellent homogeneity in U and Pu is achieved, due to the starting solution, and finally the pellets have open porosity for swelling accommodation and fission gas release.

3.5.3 Production of Minor Actinide Bearing Metal Fuels

Metallic fuel has been fabricated extensively for irradiation testing, and the fuel of choice is designated as U–20Pu–10Zr, an alloy with 20% mass Pu and 10% mass Zr. This particular composition was chosen to increase the solidus temperature and widen the range within which desired phases are obtained. Many of the fuels have been fabricated using an injection casting process, whereby a liquid metal alloy is formed and driven (or drawn) into a predefined holder, where, on cooling, it forms a slug. The moulds are often glass or quartz and slug lengths of 300 mm have been obtained (Burkes et al. 2009; Crawford et al. 2007a, b; Hofmann et al. 1997).

There have been few attempts to fabricate metallic fuels with minor actinides. In an early study the casting process was used to manufacture metallic fuel with 2.1 and 1.3% Am and Np, respectively (Keiser et al. 2008; Meyer et al. 2009). Although complete Np retention in the fabrication step could be demonstrated, losses of 60% Am were noted and were attributed to a volatile Am species in the melt. It was also proposed, that these losses could be minimized if high purity Am metal feed stock were available. Otherwise, a dramatic decrease in the processing time is required.

■ **Table 4**
Metallic fuels prepared for the METAPHIX irradiation experiment in the Phénix reactor

U-19Pu-10Zr- (3Np-1.6Am-0.4Cm-3.5Nd-0.5 Y-0.5Ce-0.5Gd)
U-19Pu-10Zr- (3Np-1.6Am-0.4Cm)

Minor actinide bearing metallic fuel was developed for an irradiation experiment (METAPHIX) in parallel elsewhere (Kurata et al. 1997; Ohta et al. 2007a). The fuels in [Table 4](#) were fabricated for irradiation in the Phénix fast reactor using arc melting procedures, which have the advantage that the time in the molten state is relatively short, but throughput is only sufficient for small quantities. U-Pu-Zr and U-Pu-MA-Zr alloys were prepared by arc melting in an argon atmosphere. To improve the homogenization of the alloys, U-Pu or U-Pu-MA alloys were first compounded by arc melting and then molten Zr was added. It proved difficult to prepare homogenized alloys containing highly dispersed rare earth (RE) metals by melting alone, as the miscibility between RE and the U-(Pu-MA)-Zr matrix is low even in the liquid phase. In these cases, powders of U-Pu-Zr and RE were first prepared and then blended mechanically before melting. The four types of alloy prepared were cast into metal fuel rods in yttria moulds that prevented reaction with molten alloys including RE.

Recently, other researchers have used the arc melting procedure to fabricate fertile and non-fertile metallic fuels (MacClean and Hayes 2007; JaECKI et al. 2005; Carmack et al. 2009). The non-fertile fuels have no U present, and are dedicated targets for actinide burning studies. Some of the materials produced are listed in [Table 5](#).

4 Irradiation Behavior of Transuranium Fuels

4.1 Mixed Oxide Fuels

The irradiation experience with transuranium mixed oxide fuels is currently restricted to the SUPERFACT irradiation experiment performed in Phénix (France) during the 1990s (Walker and Nicolaou 1995; Prunier et al. 1997). In this experiment, the irradiation behavior during normal conditions, of minor actinide fuels with four different concentrations was studied and compared with standard Phénix fuel. $(U_{0.55}Np_{0.45})O_2$ and $(U_{0.60}Np_{0.20}Am_{0.20})O_2$ fuels represented the case of heterogeneous transmutation reactor cores, with the minor actinides concentrated in a limited number of high concentration pins or elements; $(U_{0.74}Pu_{0.24}Np_{0.02})O_2$ and $(U_{0.74}Pu_{0.24}Am_{0.02})O_2$ fuels represented the homogeneous transmutation reactor core in which the actinides are added in relatively small quantities to all fuel pins or elements. All fuels were produced by sol-gel technique, resulting in a homogeneous distribution of the minor actinides in the matrix. The linear power was about between 17 and 28 kW/m for high minor actinide content pins, between 38 and 32 kW/m for low minor actinide content pins, and 43 and 37 kW/m for the accompanying standard Phénix pins.

The postirradiation examinations showed good in-pile performance of the SUPERFACT fuels, not very different from the standard MOX fuel of Phénix. The nondestructive

examinations of the four fuel types did not show any anomaly in their behavior. In particular, no accelerated corrosion was observed. The high concentration of americium in the (U_{0.60}Np_{0.20}Am_{0.20})O₂ fuel led to a significant increase of the fuel column length and to a significant diametrical deformation of the cladding. This is probably due to the beginning of a mechanical interaction between the oxide fuel and the cladding. The fission gas release rates (60–80% of the theoretical yield) were in good agreement with those of standard fuels, even for the fuels with a high concentration of minor actinides. The interpretation of the physicochemical and ceramographic examinations of the fuels led to the following conclusions (Babelot and Chauvin 1999):

- The beginning of a pellet-cladding mechanical interaction was observed for the (U_{0.60}Np_{0.20}Am_{0.20})O₂ pins.
- Cesium was found at the end plugs. Its accumulation was probably due to the particularity of the pins with high Am and Np contents (short fuel column).
- The cesium-profiles for the neptunium-containing fuels showed anomalous behavior of this fission product compared to the other pins.
- The corrosion depth of the cladding was as expected.
- The fuel temperature was probably higher for the americium-containing fuel.
- The fission gas production and release were as predicted for the operating power.
- The Am pins had a higher helium production, mainly due to the activation products with high specific alpha-activity. The released helium contributed to an increase of the internal

■ Figure 14

Ceramographs of the SUPERFACT pellets after irradiation: *left*, $(U_{0.74}Pu_{0.24}Am_{0.02})O_2$, *right*, $(U_{0.60}Np_{0.20}Am_{0.20})O_2$ from Walker and Nicolaou (1995). (©Elsevier BV, reproduced with permission.)

pressure of the pin. In addition, higher porosities and swelling, probably due to the helium still confined in the fuel, were found.

Typical ceramography images of some SUPERFACT fuels at the end of irradiation are shown in ► Fig. 14.

The measured extent of transmutation of americium at the maximal flux level was 31.5% for the fuels with high minor actinide content and 28% for the fuels with low minor actinide content. From neptunium analyses an average extent of transmutation of 30% was determined. The comparison of the measured values with calculations is satisfactory in the case of americium. In the case of neptunium, comparison with the calculations showed less agreement for the fuels with low minor actinide content.

In the TRABANT-1 experiment a sol-gel fuel with composition $(U_{0.55}Pu_{0.40}Np_{0.05})O_2$ was irradiated at a linear power of 52–57 kW/m in the High Flux Reactor (HFR, Netherlands). This fuel reached a burnup of 9.3% and showed a good in-pile performance as derived from the nondestructive analysis (Picard et al. 2000).

Recently, an americium-bearing (5 wt.%) mixed oxide fuel irradiation test was performed in the Joyo reactor (Japan) (Tanaka et al. 2009). The test consisted of a short (10 min at maximum power of 43 kW/m) and a steady state irradiation. The results from the short irradiation have been reported and reveal that within the short period at maximum power a significant restructuring of the fuel occurred. A central void had developed and re-distribution of U, Pu, and Am was detected near the void.

These results clearly indicate the complexity of minor actinide oxide fuels. At low linear power the fuels with low minor actinide content behave well, but at high power (high operating temperature) restructuring starts to play a role leading to significant re-distribution of not only Pu but also Am. This will be even more significant for fuel with high content of americium, in which also a significant helium production will occur due to the complex transmutation scheme for ^{241}Am ► Fig. 15).

Figure 15
The transmutation scheme of ^{241}Am by thermal neutrons

4.2 Metal Fuels

Although there is a large knowledge on fuel performance of U–Pu–Zr ternary metal fuel (Hofman and Walters 1993), very little is known about the behavior of metal fuel containing minor actinides. Meyer et al. (2009) reported the results of an experimental irradiation of U–Pu–Zr metal fuel pins containing 1.2 wt.% Am and 1.3 wt.% Np and found that the fuel behaved like standard metallic U–Pu–Zr fuel. In the METAPHIX project, fast reactor metal fuels containing minor actinides (MA: Np, Am, Cm) and rare earths (RE) have been irradiated in the fast reactor Phénix. In this experiment four types of sodium-bonded fuel alloys, U–19Pu–10Zr, U–19Pu–10Zr–2MA–2RE, U–19Pu–10Zr–5MA–5RE, and U–19Pu–10Zr–5MA (wt.%), were irradiated up to three different burnup levels, namely ~2.4, ~7, and ~11 at.%. The linear power during the irradiation decreased gradually from 30–32 kW/m (beginning of irradiation) to 25–26 kW/m (end of irradiation). Results of the nondestructive and post-irradiation examinations of the low burnup experiments have been reported (Ohta et al. 2007b; Breton et al. 2007; Ohta et al. 2009), and indicate normal behavior compared to standard fuel.

4.3 Carbide and Nitride Fuels

There is no reported irradiation experience with minor actinide containing carbide or nitride fuel. The existing irradiation experiments are all limited to (U, Pu)C and (U, Pu)N.

4.4 Molten Salt Fuels

The operational experience with molten salt fuel is limited to the molten salt reactor experiment (MSRE) at Oak Ridge National Laboratory (ORNL) in the 1960s. The fuel of MSRE was based on the LiF–BeF₂ solvent (0.66:0.34 mole fraction) with 5% ZrF₄ as oxygen getter. During the 4 years of operation, several fissile sources were used, including $^{235}\text{UF}_4$, $^{233}\text{UF}_4$, and $^{239}\text{PuF}_3$.

4.5 Other Fuel Types

Extensive research on various types of dispersion type transmutation targets has been performed by the Experimental Feasibility of Targets for Transmutation (EFTTRA; a collaboration of CEA, FZK, JRC-IE, JRC-ITU, NRG, and EDF) group (Warin et al. 2001). A variety of matrices for dispersion type transmutation targets was studied in irradiation experiments in

■ Figure 16

Ceramographies of the EFTTRA-T4 target showing the porosity at different radial positions from the pellet rim (a) to the pellet center (d) Konings et al. (2000) (©Elsevier BV, reproduced with permission)

the HFR and Phénix. In the EFTTRA-T4 experiment, a $\text{MgAl}_2\text{O}_4\text{-AmO}_2$ target was irradiated in the HFR during 358 full power days, during which 96% of the initial ^{241}Am was transmuted and 28% of the initial americium atoms were fissioned. The irradiation performance of the target was not optimal, however, as swelling up to 18% in volume was observed (Konings et al. 2000; Wiss et al. 2003). The reason for this swelling was revealed by the ceramographic analysis (► Fig. 16), which indicated a porosity increase from 3% in the unirradiated to about 18% in the irradiated pellet. This could be attributed to the accumulation of helium in gas bubbles produced by alpha-decay of ^{242}Cm , a product in the transmutation chain of ^{241}Am (see ► Fig. 15). The MgAl_2O_4 was found to be amorphous by transmission electron microscopic studies, which could be an additional contribution to the swelling. Similar experiments with UO_2 instead of AmO_2 indicated that swelling occurred in these cases also at low operating temperature (Neeft et al. 2003), but not at higher operating temperature (Georgenthum et al. 2001).

No irradiation experience has been reported for zirconia-based targets containing minor actinides, but results have been obtained for Pu-based $(\text{Zr, Y, Er, Pu})\text{O}_2$. Hellwig et al. (2005, 2006) reported results of the irradiation of this material in the Halden reactor. The postirradiation examination showed that:

- The observed fuel temperatures are significantly higher than that of standard UO_2 as could be expected from the significantly lower thermal conductivity of this material.
- A strong densification took place at the beginning of the irradiation.
- The fission gas release is comparable to UO_2 at the same irradiation temperatures.

Further studies with americium-containing targets/fuels will have to prove whether restructuring of the fuel occurs with americium redistribution.

■ Table 6

Summary of the irradiation experiment with minor actinide fuel

Experiment name	Reactor	Fuel type	Materials	Status
FACT		Mixed oxide		Completed
SUPERFACT	Phénix	Mixed oxide	(U, Pu, MA)O ₂ (U, MA)O ₂	Completed

4.6 Summary

A summary of the irradiation experiments with minor actinides is given in ► [Table 6](#).

5 Reprocessing

5.1 Introduction

Nuclear energy systems of the future, as they are defined by the GIF, should provide sustainable energy generation for the future (<http://www.ne.doe.gov/genIV/neGenIV1.html>). Major objectives are an effective fuel utilization and waste minimization through recycling of all actinides. It is therefore obvious that the corresponding fuel cycles will play a central role in realising these goals.

Partitioning and transmutation (P&T) is being developed since several decades as a radioactive waste management option (Magill et al. 2003), where major parts of the long-lived waste constituents are incinerated for instance in ADS, prior to a direct geological disposal of the

resulting waste. The direct nuclear fuel disposal is the option chosen by countries such as Sweden, Finland, Spain, and the USA, whereas industrial fuel reprocessing has already been used for several decades in France and UK and will soon be implemented in Japan. Germany has adopted a mix of both options. After reprocessing, the HLW raffinate is vitrified and contains all long-lived fission products but also the MA. As discussed above, the major advantage of the P&T option is the reduction of the long-term radiotoxicity in nuclear repositories and thereby an increased public acceptance. In the P&T strategy most of the MA, long-lived fission products ^{99}Tc , ^{129}I , and ^{135}Cs and heat generating fission products ^{90}Sr and ^{137}Cs , are separated in addition to the industrial reprocessing (separation of U and Pu). The separated MA and some long-lived fission products are transmuted in a fast neutron spectrum, either in a fast reactor (FR) or in an ADS.

Over the last couple of decades, considerable scientific and technical effort has been devoted to develop partitioning processes through domestic and international projects: SPIN (France) (Salvatore 1993), OMEGA (Japan) (Mukaiyama et al. 2002), GNEP (AFCI: USA) (<http://www.gnep.gov/>), bilateral cooperations and EURATOM Framework Programs (Madic et al. 2001, 2000, 2004; Madic and Hudson 2004; Adnet et al. 2005).

Two types of processes can be applied to the separation of long-lived radionuclides: hydro-chemical (wet) and pyro-chemical (dry) processes. Both have advantages and disadvantages and should be applied in a complementary way. In a so-called double strata concept e.g., as proposed in the above mentioned OMEGA project, the well established industrial reprocessing of commercial LWR fuel with recycling of U and Pu based on PUREX extraction could be combined in the first stratum with an advanced aqueous partitioning scheme also based on liquid-liquid extraction to separate also the long-lived radionuclides. The MA could be transmuted in the second stratum in an ADS or FR of the new generation reactors systems proposed in the GEN IV roadmap. A large variety of fuels is under investigation in the development projects of these reactor systems (see ► Sects. 3 and ► 4) and this is one of the reasons why pyrochemical techniques could be selected as reprocessing options in the second stratum. Other reasons are:

- Good fuel and target solubility in molten salts, suitability for the treatment of highly refractory materials (e.g., ceramic-based targets). The dry reprocessing technique can be applied as well for the recycling of the homogeneously distributed minor actinides in a fast reactor fuel as in the ADS where the minor actinides are irradiated as oxides, carbides, metals, or in inert matrices with concentrations up to 20%.
- Possibilities to treat materials with minimum cooling time. Due to the higher radiation resistance of the inorganic reactants used in the processes, the reprocessing of short-cooled spent fuel is possible. The doubling time of the bred fissile material decreases because the out-of-pile time of the fuel is reduced. For the spent fuel, cooling times as short as a few months seem possible compared to the present 5 years and longer needed for aqueous reprocessing.
- Integrated irradiation-reprocessing facility. Reprocessing and compact process equipment considerably reduces the number of cost-intensive and complicated transports of nuclear materials.
- Lower criticality hazard due to the absence of water and thus of a neutron moderator in the process.
- Proliferation resistant process. Compared with aqueous methods, dry reprocessing of fuels results in less pure and thus more proliferation resistant fractions of Pu, Np, or Am.

The pyrochemical processes have however also a number of drawbacks:

- Much lower level of technological development compared to aqueous processes.
- Low separation factors compared with hydrochemical processes.
- Aggressive process media (molten salts and liquid metals), high melting points and thus high operation temperatures require very resistant materials.
- In the case of metallic fuels, a highly pure atmosphere and thus a sophisticated technology is required.
- Processes difficult to develop for continuous operation (especially for electrowinning).
- Technological and process wastes need special treatment.

The decision on the partitioning process to be applied should depend on the boundary conditions, such as the type of fuel material to be treated, but aqueous- and pyro-partitioning are not to be seen as options in competition to achieve the partitioning of long-lived MA and fission products from spent nuclear fuel.

In any case, an efficient and selective recovery of the key elements from the spent nuclear waste is absolutely essential for a successful sustainable fuel cycle. This necessitates that Am and Cm can be selectively separated from lanthanide fission products, certainly the most difficult and challenging task in advanced reprocessing of spent nuclear fuel due to the very similar chemical behavior of trivalent elements. There are three major reasons to separate actinides from lanthanides:

- Neutron poisoning: lanthanides (esp. Sm, Gd, Eu) have very high neutron capture cross sections, e.g., >250,000 barn for Gd-157.
- Material burden: in spent LWR fuels, the lanthanide content is up to 50 times that of Am/Cm.
- Segregation during fuel fabrication: upon fabrication, lanthanides tend to form separate phases, which grow under thermal treatment; Am/Cm would also concentrate in these phases.

5.2 Advanced Aqueous Reprocessing

The PUREX process is the industrial hydro-chemical reprocessing technique to separate U and Pu from spent fuel and is based on the dissolution of the fuel in nitric acid. For the separation of MA the process has to be modified/extended using also hydro-chemical extraction techniques (Takanashi et al. 1998).

In the fuel solutions feeding to the first decontamination cycle, Np is present as a mixture of Np (IV), Np (V), and Np (VI). In the standard PUREX process, Np is partially extracted by tri-n-butylphosphate (TBP); this part follows the U stream and is separated in the second U purification cycle and then added to the HLW and vitrified. In the PUREX process adapted for Np recovery, Np is completely oxidized to the oxidation state VI and then co-extracted with U and Pu in the first decontamination cycle. Finally, as in the standard process, Np is recovered through a reducing scrub in the second U cycle. After separation, the Np nitrate, contaminated by β - γ emitters, may be purified by solvent extraction with TBP and finally transformed to oxide by calcination of the oxalate.

Extensive research and development for an extended PUREX process for MA recovery is carried out worldwide; the goal is to synthesize special extractants and to develop the corresponding process schemes required for a selective separation of Am and Cm from high

level liquid waste (HLLW). The process development requires a good basic understanding of the relevant extraction mechanisms.

5.2.1 Fundamental Studies

As aqueous partitioning is based on liquid–liquid extraction from an acidic solution into an organic phase, it is of crucial importance to know about extraction selectivity, thermodynamics, mechanisms, and kinetics. In aqueous MA partitioning schemes, two main routes are possible, see ► Fig. 17. The optimal strategy would be of course a process where MA are selectively directly extracted from the PUREX raffinate, HLLW. However, at present, no extractant could be found capable of selective and efficient separation of the MA at high acidities (>2 M HNO₃) in a highly radioactive solution containing all fission products (FP), among them lanthanide elements (Ln) in a mass excess of 20 times compared to MA. Partitioning of MA involving co-extraction of Ln and a subsequent separation of the two element groups is therefore the only viable option at present.

Extraction mechanisms: One of the major questions to be solved for the extraction of lanthanides (III) and actinides (III) from aqueous nitrate solutions concerns the knowledge of the nature of the extracted species. A dual mechanism of extraction could be envisaged. It would be based on the formation of solvates having the general formula $M(\text{NO}_3)_3\text{L}_n$, (with $M(\text{III}) = \text{Ln}(\text{III})$ or $\text{An}(\text{III})$ and $L =$ organic extractant and could form at low aqueous nitric acid concentrations. For concentrated aqueous nitric acid solutions the formation of ion-pairs,

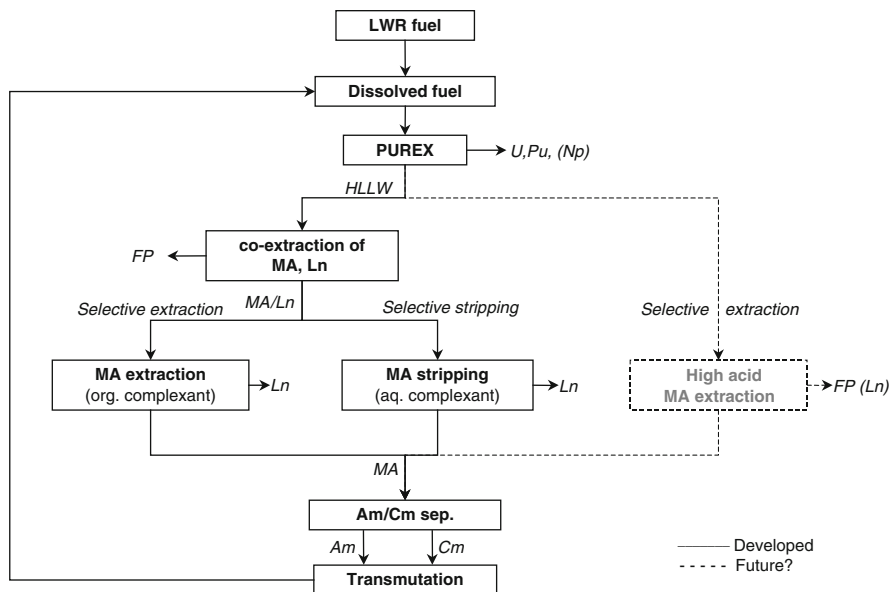

Figure 17

Strategies for the separation of the minor actinides from high level liquid waste (HLLW)

■ **Figure 18**
Structure of the bis-triazinyl-pyridines BTP molecule

with the general formula $[LH^+]_n$, $[M(NO_3)_n^{3+}]_{n-3n}$, as encountered when extracting actinide (VI) or actinide (IV) ions from nitric acid, is being proposed.

Several experiments, involving UV-visible and ^{13}C -NMR spectroscopy and solvent extraction, have been conducted to identify the extracted species. From the data obtained it can be concluded that an ion-pair mechanism involving a protonated ligand is very unlikely.

An extracting molecule which has been extensively studied especially in Europe is the diamide with the general formula: $(R(R')NCO)_2CHR''$ (where R , R' , and R'' are alkyl or oxyalkyl groups, the general structure being given in  Fig. 18. A so-called reference molecule is N,N' -dimethyl- N,N' -dibutyltetradecyl-1,3-malonamide (DMDBDTMA)). A comparison of diamides with different R' groups (butyl, phenyl, and chlorophenyl) in their ability to extract $An(III)$ or $Ln(III)$ from aqueous nitrate media shows that a less basic malonamide has better extraction properties of the $M(III)$ nitrate. If in the central R'' position the alkyl group is replaced by a di-octylhexylethoxy group, the diamide DMDOHEMA exhibits better affinities for $M(III)$ nitrates.

Arrhenius activation energies close to 40 kJ/mol for all $M(III)$ studied, indicate that the extraction is chemically limited at the aqueous/organic interface. For a diffusion limited kinetic regime, this energy is generally close to 20 kJ/mol. The extraction kinetics of $M(III)$ nitrates by DMDBDTMA are much slower than the extraction of $U(VI)$ or $Pu(IV)$ nitrates by TBP (extractant of the PUREX process).

Crystal structures were determined by X-ray absorption spectroscopy and using synchrotron light for a large number of lanthanide – and actinide – diamide complexes. Molecular modeling studies have been conducted to compare calculated structures and X-ray determined crystal structures and to propose structural explanations for experimental differences observed during extraction of $M(III)$ metallic nitrates by several malonamides.

Using the Quanta/CHARM code, the lowest energy conformation calculated for DMDPhMA, DMDCHMA, and BDMDPhMA, were found to be similar to the experimentally determined crystal structures. Also differences between structures of DMDPhMA and BDMDPhMA and that of DMDCHMA were confirmed by calculations. The differences in $M(III)$ extraction efficiency between cyclohexano (DMDCHMA) and phenyl substituted (DMDPhMA and BDMDPhMA) malonamides can be correlated with the difference of the preferred conformations of the malonamide extractants.

Using the Gaussian 94 program, protonation of cyclohexano (DMDCHMA) and phenyl (DMDPhMA) substituted malonamides show that *mono*-protonated malonamide contains an intramolecular hydrogen bond, while the *di*-protonated malonamide does not.

A quantitative structure-activity relationship (QSAR) study related to the extraction of $Nd(III)$ nitrate by a set of 17 malonamides supported the above mentioned improved

Figure 19

M(III) nitrate extracting properties in the presence of an oxygen ether atom in the R'' substituent.

Separation of trivalent actinides from lanthanides: To explain the great affinity of actinides for nitrogen-bearing molecules, numerous fundamental studies were carried out using a wide range of experimental methods. Lanthanide/actinide separations often depend on a slightly stronger interaction of the trivalent actinides with ligands containing soft donor bases (S, Cl, or N), or with amine extractants in contact with aqueous solutions containing high concentrations of chloride or thiocyanate. Therefore, the formula, stability, and structure of the complexes containing Ln(III) and An(III) ions were determined both in aqueous solution and in various solvent media. It has been demonstrated that bonds between the nitrogen atoms of these ligands and Ln(III) and An(III) ions include some definite covalent character, which can be explained by the fact that enthalpy is the driving force of these reactions. The covalence observed in bonds with the electron-donor nitrogen atoms of ligands seems higher for An(III) ions than for Ln(III) ions; this could be an indication for the higher affinity of these ligands for An(III). However, sometimes the difference is too small to really explain very high differences in the distribution factor. Those are mainly observed for bis-triazinyl-pyridines BTP molecules (the general structure is shown in [Fig. 19](#)) which have proved to be among the most suitable nitrogen-bearing extractants for developing an An(III) separation process. Their affinity for An(III) ions is more than a hundred times higher than for Ln(III) ions.

Theoretical studies in the fields of quantum chemistry and molecular mechanics have provided greater insight into certain crucial aspects of reactions between these metal ions and nitrogen-bearing ligands ([Fig. 19](#)). In particular, the synergetic extraction mechanism of Ln(III) ions using a mixture of a nitrogen-bearing ligand and a carboxylic acid has been identified by computer calculations. The calculated synergetic complex seems to be consistent with the experimental results (Madic et al. 2002).

First attempts on the theoretical investigation of the actinide-BTP complexes have been conducted by means of quantum chemistry, molecular mechanics, and molecular dynamics (Drew et al. 1998; Guilbaud and Dognon 2000). The structure of Ln(*n*Pr-BTP)₃ crystals has been determined using X-ray diffraction (Drew et al. 2001). It has been confirmed that the complex is composed of three ligands directly bonded to the metal ion. The BTP molecules act as tridentate ligands. They coordinate via the N in the pyridine as well as via the triazinyl N atoms in the 2-position. Cm and Eu complexes with *n*Pr-BTP have been characterized by means of extended X-ray absorption fine-structure spectroscopy (EXAFS), time-resolved laser-induced fluorescence spectroscopy (TRLFS) and quantum-chemical investigations (Gompper et al. 1995). According to the EXAFS study, 9 N atoms are coordinated directly to the metal cations. The coordination structure with three ligands is the same for Cm and Eu (Cm(*n*Pr-BTP)₃ and Eu(*n*Pr-BTP)₃, respectively) and the bond lengths are the same in both complexes. This result

was supported by quantum-chemical calculations. In all calculations, the BTP ligand is nearly planar. This means that the selectivity of $n\text{Pr-BTP}$ for An(III) over Ln(III) is not of structural origin. Besides, there was no evidence for directly coordinated nitrate groups. The results of the TRLFS measurements revealed that the extracted Cm species always contains three ligands, independent on the ligand-to-metal ratio. The fact that $\text{Cm}(n\text{Pr-BTP})_3$ is formed at much lower ligand-to-metal concentration ratios is consistent with $n\text{Pr-BTP}$ high selectivity for An(III) over Ln(III) in solvent extraction.

5.2.2 Process Development

Two alternative approaches based on the scheme shown in  Fig. 17 are described hereafter.

The first approach is based on co-extraction of trivalent MA and lanthanides (Ln) and to separate in a second step MA from Ln (Serrano-Purroy et al. 2005). For the co-extraction, the most important processes are:

- The TALKSPEAK process (USA) (Nash 1993) and DIDPA process (Japan) (Morita et al. 1996) use acidic organophosphorus extractants.
- The TRUEx process (USA) (Arai et al. 1997b) and SETFICS (Japan) (Koma et al. 1998b) are based on the use of CMPO (*n*-octyl-phenyl-di-isobutyl-carbomoylmethyl-phosphine-oxide) as extractant.
- The TRPO process (China) uses a trialkyl phosphine oxide. The hot demonstration of this process using genuine HLLW has been done at JRC-ITU (Glatz et al. 1994).
- The diamide extraction (DIAMEX) process using malonamides as extractant (Nigond et al. 1994) has been developed at CEA (France) and is also the reference process under investigation in the European partitioning projects.

For an efficient recycling scheme, losses of the relevant elements should be as low as possible (0.2% or less); therefore a compromise between extraction and back extraction efficiency has to be made.

The MA/Ln separation can be achieved by the so-called selective actinide extraction process (SANEX). The major options are:

- The BTP (bis-triazinyl-pyridines) developed at the Forschungszentrum Karlsruhe-Institut für Nukleare Entsorgung (FZK-INE, Germany) (Kolarik et al. 1999) or BTBP (bis-triazine-bis-pyridine) are capable of selective extraction of MA at high nitric acid concentration (2 M).
- The TPTZ (tripyridyltriazine) developed at CEA to be used at much lower nitric acid concentrations (Hill et al. 1999).
- Variants of the dithiophosphinic acids (ClPh)₂PSSH in a mixture with TOPO at Forschungszentrum Jülich, Germany (Modolo and Odoj 1999).

Promising results have been obtained on simulated as well as on genuine solutions at lab-scale. Among many extractants tested worldwide, the combination of DIAMEX and BTP (Madic et al. 2000; Geist et al. 2006) appears to be the best combination for an efficient recovery of MA from HLLW or transmutation targets. Diamides do not require feed adjustment, can be easily recycled in the process and do not leave any residue upon incineration. Concerning the separation of MA from Ln, BTP is the most efficient extractant, giving at the same time the highest

separation factor with no feed acidity adjustment required. Separation factors between MA and lanthanides up to 80 are reached in a single stage extraction. These values are considerably improved in a continuous multistage process and an Am/Cm product containing less than 1% of Ln is obtained. However, due to its high sensitivity to hydrolysis and radiolysis, an industrial application of the BTP molecule requires further developments to improve these properties.

The second option is the co-extraction of actinides and lanthanides with DMDOHEMA (DiMethyl-DiOctyl-HexylEthoxy MalonAmide) of DIAMEX followed by selective stripping of the trivalent actinides from the loaded diamide solvent using a mixture of HEDTA (actinide-selective polyamino-carboxylate complexing agent) and citric acid (Miguirditchian et al. 2007).

The scientific feasibility of this process has been demonstrated by the CEA in the ATALANTE facility in Marcoule (Baron et al. 2007). A MA recovery of ~99.9% and less than 0.3 wt.% Ln in the MA fraction was achieved with a flowsheet, where the DIAMEX solvent was supplemented by an acidic extractant, diethylhexylphosphoric acid (HDEHP), to ensure effective extraction at pH > 2.

The Japan Atomic Energy Agency (JAEA) has studied an advanced aqueous process combined with a U crystallization process (Koma et al. 1998a). The main features compared with the conventional PUREX are:

- The purification steps of U and Pu in the conventional PUREX are eliminated, resulting in co-extraction of U/Pu/Np, and simplification of the system. A compact-sized centrifugal type equipment is used to reduce the size of the reprocessing facility.
- Crystallization is used to separate excess U before extraction of U/Pu/Np.
- A combination of the SETFICS process, developed by Japan Nuclear Cycle Development Institute (JNC, now JAEA), and the transuranium extraction process (TRUEX) is applied for the recovery of Am and Cm. The recovery ratio of U/transuranium elements is about 99.7%, and the decontamination factor of the reprocessed product is higher than 100.

As shown in  Fig. 20, another process developed by JAEA, known as the “Four-Group Separation Process”, includes:

- An extraction of all transuranium elements including Np (V) with diisodecylphosphoric acid (DIDPA) at 0.5 M nitric acid.
- A separation of Tc and platinum group metals by precipitation through denitration.
- A separation of Sr and Cs by adsorption with inorganic ion exchangers.
- Selective back-extraction of Am and Cm by 0.05 M diethylenetriaminepentaacetic acid (DTPA).

In  Table 7, the separation efficiency and estimated recovery values obtained in the various processes described above are compared to target values for the recovery of transuranium elements and some key fission products in advanced reprocessing.

The values achieved are quite high and almost satisfy the targeted recovery. The recoveries of Tc and noble metal alloys are around 90–95% which is lower than the targeted recovery. This lower recovery is not so important, as their contribution to the potential radiotoxicity of HLW is not significant.

With respect to aqueous reprocessing, dedicated research facilities are available in France (CEA, Marcoule) and UK (BNFL, Sellafield) where extensive studies are being performed on spent fuel material. Facilities for smaller scale hot-tests are available in other countries and at

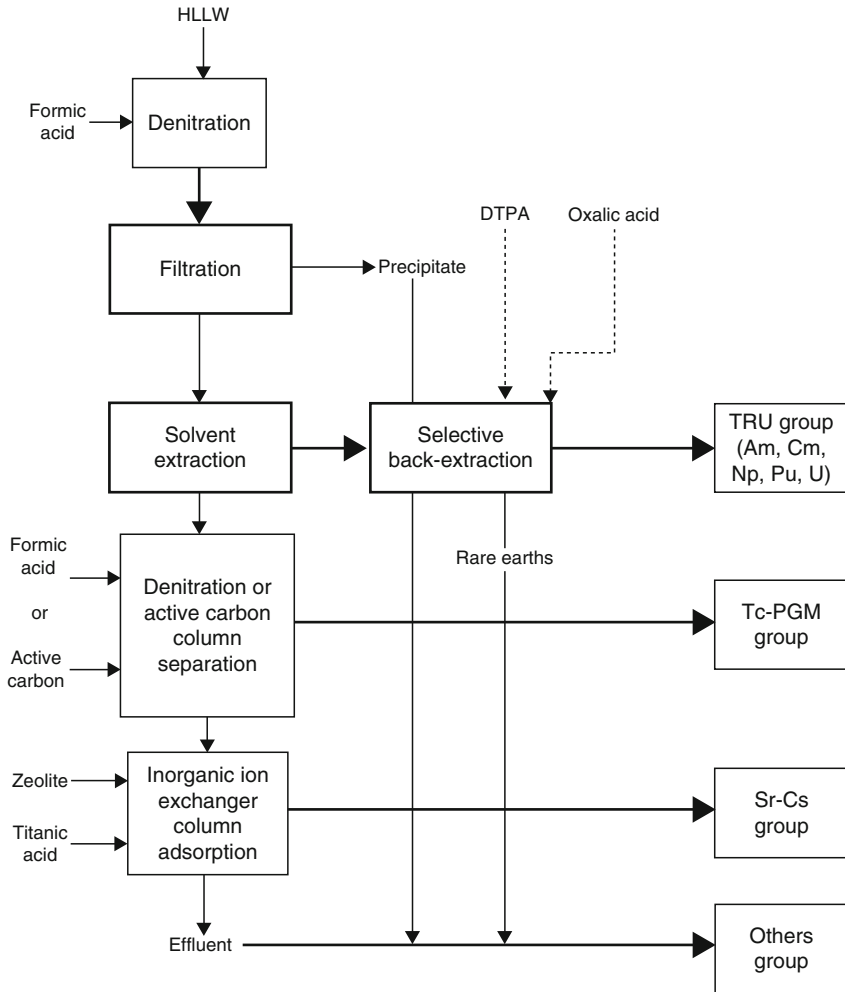

Figure 20 Four group partitioning process (Morita et al. 2004)

the JRC-ITU. In addition, European Universities are strongly involved in this research through the European Commission Framework Programs, especially in the fields of synthesis of new extractants and molecular modeling.

5.3 Pyro-Reprocessing

Pyrochemical processes rely on refining techniques at high temperature (500–900°C) depending on the molten salt eutectic used. Typically, chloride systems operate at lower temperature compared to fluoride systems. In nuclear technology the processes are mainly based on electrorefining or on extraction from the molten salt phase into liquid metal.

■ **Table 7**

Target recovery, experimentally obtained separation efficiency and estimated recovery of elements in the four group partitioning process

Elements	Target recovery (%)	Separation efficiency (%)	Estimated recovery (%)	
T ^a	Np	99.5	>99.95	99.85
	Pu	99.9	>99.99	99.85
R	Am	99.99	>99.99	99.97
U	Cm	99.9	>99.99	99.97
Tc	99	~98	~95	
Sr, Cs	99	>99.9	>99.9	

^aTransuranium elements

■ **Figure 21**

Metal and oxide fuel pyroprocess flow sheet (Laidler et al. 1997)

5.3.1 US Pyrochemistry Projects

The electrometallurgical process was applied for the first time as a part of the integral fast reactor (IFR) system. Pyrochemical separation processes for the recovery of uranium and to some extent for plutonium have been investigated since decades (Laidler et al. 1997) and remain the core process in the present EBR-II Spent Fuel Treatment Program. Many of the pyroprocessing systems presently proposed for development are adaptations of this process as depicted in

➤ [Fig. 21.](#)

The fuel is recycled using an electrochemical process that employs molten salts and liquid metals. The molten salt medium for electrorefining is a solution of LiCl–KCl eutectic and dissolved actinide chlorides, such as UCl_3 . The operating temperature is 500°C . With this system, chopped spent fuel is loaded into the electrorefiner in a basket. The fuel is electrochemically dissolved into the system in an operation in which the basket is the anode and another electrode in the salt phase is the cathode. Uranium with small amounts of transuranium elements can be collected on steel electrodes (solid cathodes), and transuranium elements can be co-deposited with uranium in liquid-cadmium cathodes. A liquid-cadmium cathode is a ceramic crucible containing molten cadmium that can be lowered into the salt phase. The cadmium in the crucible is at cathodic potential. The cathode products from electrorefining operations are further processed to distill adhering salt and cadmium and to consolidate the recovered actinides. The recovered actinides are remotely fabricated into new fuel for recycle.

The alkali, alkaline earth, rare earth, and halide fission products are primarily in the salt phase. The elements that distribute into the salt phase are eventually incorporated in a ceramic HLW. More than 90% of the noble metal fission products and fuel alloy material are retained in the chopped cladding segments in the anode baskets. The cladding hull segments and the retained fission products are eventually stabilized into a metal HLW.

Adaptations of this technology exist for the treatment of both oxide and nitride fuels. The flow sheet for the treatment of nitride fuels is similar to that of metal fuel. In this system, the nitride fuels are also fed directly into the electrorefiner. The actinides are dissolved from the fuel cladding and collected electrochemically in liquid cadmium or bismuth cathodes. Nitrogen evolves in the process. It is collected and recycled back into the liquid cathodes so that actinide nitrides are formed, a potentially difficult step. After distillation of the cadmium, the recovered nitrides are sized and then fabricated into new fuel using vibro-packing. This process is being developed in Japan.

5.3.2 European Pyrochemistry Projects

For more than 50 years, pyrometallurgy has been studied as an alternative strategy for reprocessing spent fuel. Until now, two processes have been developed at pilot scale, both in chloride media, the first one starting from and ending with an oxide fuel and the second one starting from and ending with a metallic fuel.

On the basis of these past studies, pyrometallurgy has been considered as the reference route for molten salt reactor fuel treatment, but also as an alternative technology that could be applied to some types of fuels today envisaged for Gen IV systems or ADS in case they would not be compatible with current hydrometallurgical processes.

In the European pyro-reprocessing projects, basic properties of An and some FP in molten salts (chlorides and fluorides) and in liquid metal solvents have been studied. The data allow development of a conceptual design and assessment of reprocessing processes suitable for fuels and targets proposed for advanced fuel cycles. The feasibility of separating U, Pu and MA from FP using pyrometallurgy in a molten chloride or fluoride system was assessed.

Basic data: A very significant investigation was done for thermodynamic data acquisition in molten chloride media, with a comprehensive study of An, Ln, and other important fission products. In comparison to molten chloride salts, studies in molten fluoride are much less

developed. Even if a lot of experiments were carried out in various salts, it seemed difficult to get relevant thermodynamic data. This is mainly due to the lack of a reliable reference electrode.

The studies carried out on liquid metals were at a sufficient level to confirm the choice of aluminum for an electrochemical process in molten chloride as well as for a reductive extraction process in molten fluorides. These results were used to optimize the two reference core processes at a satisfactorily level.

Two efficient processes for the separation of An from Ln have been selected as promising core processes and defined: (1) electrorefining process on solid aluminum cathode in molten chloride, (2) liquid–liquid reductive extraction in liquid aluminum–molten fluoride. Some reference flow sheets have been assessed. Moreover, several new experimental installations for process tests have been constructed.

To be implemented, the whole process must produce the lowest achievable amount of waste, and when a waste is produced, it must be in a convenient form for storage or disposal. In the decontamination of spent chloride salts coming from electrorefining, the complementary techniques of zeolite ion-exchange filtration and phosphate precipitation, have been selected for their potential to clean up the spent salt efficiently. Although some specific matrices for salt confinement were identified (sodalite, pollucite), a lot of work remains to be done in this field.

System studies were performed including: (1) double-strata concept (ADS), (2) IFR and (3) Molten Salt Transmutation Reactor (MSTR). A first step defined the general principles used for the assessment of pyrochemical separation processes, the common methodology for technical and economical comparisons and the selected flow-sheets. During the second step, the work focused on detailed flow-sheeting studies and mass balance calculations and the three options were studied. The major interest of these studies is the validation of the “process approach,” which is deemed very useful for identifying key issues and reorienting R&D programs. Nevertheless, as these flow sheets address different scenarios and fuels it is very difficult to compare them in terms of advantages and drawbacks.

Basic data acquisition: Basic properties of An and some FP in molten salts (chlorides and fluorides) and in liquid metal solvents have been studied (McPheeters et al. 1997; Serp et al. 2004; Caravaca et al. 2007).

Significant work was done in basic data acquisition in molten chloride media, mainly at JRC-ITU with a comprehensive study of actinides (U, Pu, Np, Am, Cm), lanthanides and some other important fission products. Thermochemical properties are derived from the electrochemical measurements and from basic thermodynamic data for instance in the case of Np of NpCl_3 and NpCl_4 in the crystal state (Masset et al. 2005; Konings et al. 2001a). It could be demonstrated, that NpCl_3 has a strong nonideal behavior in molten LiCl–KCl eutectic.

Core processes: Initially three potential chemical routes were identified for a development as core process. The first one based on selective precipitation was rapidly withdrawn due to the poor decontamination factors obtained. The second route is an electrochemical one, which includes electrolysis or electrorefining techniques, either in chloride or in fluoride molten salts. The third one is based on the liquid–liquid reductive extraction from a molten fluoride salt and liquid Al.

In parallel, some studies were carried out on electrolysis in molten fluoride or liquid–liquid reductive extraction using molten chlorides, but in a less extensive way.

Important studies were carried out also in the institutional program of the Nuclear Research Institute Rez (NRI, Czech Republic) on fluoride volatilization.

Electrorefining on solid aluminum cathode in molten chloride media: To comply with the sustainability goals defined for innovative reactor systems, a major objective is the development of a grouped actinide recycling process based on molten salt electrorefining. Special emphasis is given to a selective electrodeposition of actinides with an efficient separation from lanthanide fission products. In contrast to the IFR concept, where U is deposited on a solid stainless steel cathode and transuranium elements on a liquid Cd cathode, the electrorefining processes rely on a co-deposition of all actinides on a solid Al cathode material, because stable actinide alloys are formed. A redissolution of trivalent actinides can thus be avoided in contrast to e.g., W cathodes. Also the redox potentials on solid cathodes show a much larger difference in the reduction potential between actinides and lanthanides. In  Fig. 22 the reduction potentials for U^{3+} , Pu^{3+} , Am^{3+} , La^{3+} , and Nd^{3+} determined by transient electrochemical techniques (mainly cyclic voltammetry and chronopotentiometry) on different materials are shown.

On Bi and Cd, the selectivity of the minor actinide recovery seems to be limited due to the small difference in reduction potentials between actinides and lanthanides.

The choice of the cathode material onto which the actinides are deposited in the electrolysis was essential in this context (Masset et al. 2005b). Solid Al has been selected because of two reasons:

1. Stable actinide deposits (alloys) are formed and are consequently very adherent to the cathode; at the same time a redissolution of the trivalent An by comproportionation with the trivalent actinides in the salt to form divalent An according to: $Am(III) + Am(0) = 3Am(II)$ can be avoided.
2. The difference in the reduction potentials compared to Ln is sufficiently high to avoid their co-deposition.

In these electrolytic processes, the rate of the alloy formation depends on the diffusion of the involved elements in and through the solid alloy phase. Therefore, the maximum amount of actinides that can be collected on a single Al electrode has been investigated in constant current electrorefining experiments in which the cathodic potential was maintained at a suitable level for the separation of An from Ln. With increased charge passed, i.e., with the build-up of a surface layer of An–Al alloy, the applied current is gradually reduced in order to stay above the

 Figure 22

Reduction potentials of some actinides and lanthanides on different cathode materials

■ Figure 23

Process scheme for molten salt electrorefining of metallic fuels

cathodic potential limit. Based on this information, a process scheme as shown in ► Fig. 23 is proposed.

The electrorefining process is operated in the batch mode. After multiple use of the eutectic salt bath, an exhaustive An electrolysis is required to avoid losses >0.1% to the waste, before the cleaning of the salt bath takes place. It is evident that the Ln content in the electrodeposited An–Al alloy in the exhaustive electrolysis contains more Ln than in the runs where metallic fuel is deposited and must eventually be recycled. For the cathode processing, three options are possible, chlorination, back-extraction and electrorefining. Among those chlorination is the most promising. This step is needed to recycle the An to the fuel fabrication.

Laboratory experiments have shown that 3.72 g of actinides could be deposited in 4.17 g Al, corresponding to 44.6 wt.% An in Al or 68 wt.% of the maximal loading when $AnAl_4$ alloys are formed (Cassayre et al. 2006). A successful demonstration of the Am/Nd separation was carried out using a mixture of 255 mg Am, 281 mg Pu, and 140 mg Nd. Am and Pu were co-deposited in two steps on two Al cathodes of 0.8 g each. The cathodes used were made of Al foam to increase the reaction surface area. The Nd content in the deposit of only about 0.5% proves the feasibility of a selective actinide separation by electrolysis onto Al electrodes.

The results were confirmed further in a multiple run experiment inducing an accumulation of Ln in the salt. These fuels had already been developed in the frame of the IFR concept in the mid 1980s in the USA. The same type of fuel is used for transmutation studies (METAPHIX Project) initiated by Central Research Institute of Electric Power Industry (CRIEPI), Japan in collaboration with JRC-ITU. This fuel containing 2% of Am and lanthanides ($U_{61}Pu_{22}Zr_{10}Am_2Ln_5$) was fabricated at JRC-ITU. The remnants of the fuel fabrication campaign are used for the present studies.

In the pyro-reprocessing, the metallic alloy is anodically dissolved in a LiCl–KCl eutectic (Serp et al. 2004) and the An are collected together onto Al cathodes as alloys, leaving Ln in the salt phase.

To simulate a large-scale pyro-processing by molten salt electrorefining operated as a batch process similar to the industrial Al fabrication process. An experiment of 25 successive runs was carried out. The experiment has also demonstrated the feasibility of a grouped actinide

Figure 24

Cyclic voltammogram of $U_{61}Pu_{22}Zr_{10}Am_2Ln_5$ on W and Al wires. Reference electrode: Ag/AgCl-1 wt.%, $v = 100$ mV/s, $T = 450^\circ\text{C}$. Salt composition in wt.%: U-0.29, Np-0.12, Pu-0.28, Am-0.06, Zr < 0.07, and Ln-1.0

recovery from larger amounts of fuel without changing the salt bath. A total amount of more than 5 g of $U_{61}Pu_{22}Zr_{10}Am_2Ln_5$ fuel was treated in this experiment and various process parameters were studied. \blacktriangleright Figure 24 shows the cyclovoltammogram of the alloy on Al and W electrodes.

The goal of this 25-run test was to find optimal conditions for the recovery of Am. The recovery rate of An was difficult to evaluate because new fuel was added in each run. Nevertheless, a stable recovery rate $[m_{An}/(m_{An} + m_{Ln})]$ better than 99.9% was achieved throughout the whole experiment. Uranium, the main constituent of the fuel with a less electronegative electrodeposition potential (see \blacktriangleright Fig. 22) is preferentially deposited in the earlier runs. At the same time the relative Am content in the actinide deposit and the separation from lanthanides (m_{Am}/m_{Ln}) increases despite an increasing content of Ln (not-electro-deposited) in the salt.

The results of this 25-run electrorefining experiment where genuine fuel materials were used and where the salt bath has not been changed, are very promising in view of a large-scale development of pyro-reprocessing in advanced nuclear fuel cycles.

5.3.3 Liquid-Liquid Reductive Extraction in Molten Fluoride/Liquid Aluminum

This process was extensively studied by CEA both as an institutional program and also in European research programs (Lacquement et al. 2005; Conocar et al. 2006). An experimental device and a protocol have been developed to study the distribution of An and Ln in

molten fluoride/liquid metal medium. The results obtained with Pu, Am, Ce, and Sm in the (LiF–AlF₃)/(Al–Cu) medium revealed the potential of the system for separating the actinides from the lanthanides.

With a salt composition corresponding to the basic eutectic (LiF–AlF₃, 85–15 mol%), up to 99% of Pu and Am could be recovered in a single stage, with Ce and Sm separation factors exceeding 1,000. The effect of the AlF₃ concentration in the salt has been investigated. The distribution coefficients decrease as the initial AlF₃ concentration rises. A thermodynamic model of extraction versus fluoroacidity has been developed on the basis of the experimental results for Ce and Sm. The model clearly reveals the difference in solvation between divalent and trivalent Ln in fluoride media.

The results obtained were confirmed by lab-scale experiments under realistic conditions. Two runs have been done at 830°C with LiF–AlF₃ (85–15 mol%) as salt phase: one with the Al–Cu alloy (78–22 mol%) as metallic phase, the other with pure Al. The objective of the second test was to check that the absence of Cu did not penalize the extraction, in terms of both performances and implementation of the process. For each test, the initial concentrations in the salt were the following (wt.%): PuF₃ (11), AmF₃ (0.2), CeF₃ (2.5), SmF₃ (0.5), EuF₃ (0.5), and LaF₃ (0.5). Seventeen grams of salt and metal have been contacted. The results show similar high distribution ratios of Pu and Am in the same order of magnitude than those previously measured at low concentration without Ln (► Table 7).

In the test without Cu, the distribution coefficient of Cm (trace concentration in Am starting material) has been measured for the first time; it is very close to those of other actinides (U, Np, Pu, Am). The distribution coefficients of the Ln are low and allow high separation factors from actinides. The results obtained with Al–Cu and Al are close (see ► Table 8). In these tests the chemical feasibility of the An/Ln group separation by liquid–liquid extraction in molten fluoride with liquid aluminum are assessed. The experimental results compared to those obtained without the presence of Cu in the metallic phase, are summarized in ► Table 8.

The results show that the distribution ratios of Pu and Am have similar high values independent from the presence of Cu in the metallic phase and in all cases there is a high separation

■ Table 8

Mass distribution coefficients and separation factors of actinides and lanthanides with and without Cu in the metallic phase

Al–Cu (78–22% mol)			Al		
M	DM	SAm/M	M	DM	SAm/M
Pu	197 ± 30	0.73 ± 0.21	Pu	273 ± 126	0.78 ± 0.47
Am	144 ± 20	1	Am	213 ± 30	1
Ce	0.142 ± 0.01	1,014 ± 213	Cm	185 ± 31	1.15 ± 0.35
Sm	0.062 ± 0.006	2,323 ± 488	Ce	0.162 ± 0.02	1,315 ± 289
Eu	<0.013	>11,000	Sm	0.044 ± 0.004	4,954 ± 1,139
La	<0.06	>2,400	Eu	<0.03	>7,100
			La	0.03	7,100

efficiency from Ln. Also in this process, the actinide back-extraction from the Al is an important step in view of fuel refabrication. A bibliographic study has identified three possible routes:

- Electrorefining, whose main drawback is its complexity (three steps are necessary)
- Volatilization of the Al matrix by a chlorinating reagent is a simple and efficient method. Nevertheless, high volume of chlorinating gas is necessary and an additional step to convert AlCl_3 into Al should be done in order to recycle Al
- Oxidizing liquid–liquid extraction in molten chloride.

5.3.4 Technical Uncertainties of the Pyro-Reprocessing

The Spent Fuel Treatment Program at ANL demonstrated many parts of the pyroprocess fuel cycle, but for a large scale application there are still key aspects that have yet to be demonstrated on a large scale with radioactive materials. The main outstanding issue is the recovery of transuranium elements. Large-scale equipment has been fabricated for a MA recovery, but with the termination of the IFR program, the equipment and process was never tested beyond the laboratory scale.

The remote fabrication of IFR fuel was not part of the Spent Fuel Treatment Program, but the same technology was used to fabricate cold fuel for the Experimental Breeder Reactor II (EBR-II) and a demonstration of another pyroprocess (melt refining) for recycling EBR-II fuel in the 1960s employed remote fabrication for 34,500 fuel elements (Laidler et al. 1997).

One challenge for a pyro-reprocessing system is selecting the appropriate materials of construction for the high temperature processes. Material improvements are needed in order to lessen the formation of dross streams and increase material recovery and throughput.

The quantity of waste generated from pyro-reprocessing that requires geological disposal appears to be comparable at present to modern commercial aqueous processes. Advancements are being pursued to further reduce the disposal volumes through zeolite ion exchange processes. This technology has not been demonstrated beyond the laboratory scale.

Most of the radioactive work performed to date has been on the pyro-reprocessing cycle for metal fuel. Laboratory work has been performed on the head-end operations for oxide reduction and on the nitride fuel cycle. Demonstrations of these technologies with actual spent fuel have started at a laboratory scale. Additionally for nitride fuels, demonstrating the recycle of nitrogen is critical because ^{15}N is specifically required for the fuel to eliminate the formation of radioactive ^{14}C .

5.3.5 Head-End Conversion Processes

Today all commercial reactors are operated with oxide fuels and advanced reactor systems selected in the GEN IV roadmap rely also on oxides as one of the major fuel options. The pyrometallurgical process based on oxides developed in Russia, Research Institute of Atomic Reactors (RIAR), Dimitrovgrad, does not include MA recycling. Pyro-reprocessing, where all actinides are recycled, is based on metallic materials; therefore, a head-end reduction step for oxides fuels is needed to convert oxides into metals. This conversion can be performed chemically, e.g., by reaction with lithium dissolved in LiCl at 650°C . The recovered metal can directly be subjected to electrorefining and the Li_2O converted back to lithium metal by electrowinning. A more elegant method is the so-called direct electroreduction. In this case, the heat generating

fission products are removed and the fissile materials are recovered as an alloy, which can again be directly reprocessed by electrorefining.

Numerous experiments are carried out today to study this conversion process. The lithium reduction process using lithium metal as a reducing agent is carried out in molten lithium chloride. The reduction of UO_2 (Sakamura et al. 2006) and simulated spent LWR fuel (Sakamura et al. 2008) was studied mainly by CRIEPI in Japan in collaboration with AEA Technology in the UK. The optimized thermodynamic conditions for the reduction of transuranium elements (Iizuka et al. 2006) and the behavior of major fission product elements (Kurata et al. 2004) were determined. Li is converted into Li_2O , and constantly removed during the process from the molten salt bath to prevent the reoxidation of the reduced fuel material. Li is recovered by electrochemical decomposition of the Li_2O and recycled to the process (Herrmann et al. 2007).

A simulated spent oxide fuel in sintered pellet form, containing the actinides U, Pu, Am, Np, and Cm, and the fission products Ce, Nd, Sm, Ba, Zr, Mo, and Pd, was reduced with Li metal in a molten LiCl bath at 923 K. The pellet remained in its original shape, it became porous and a shiny metallic phase was observed throughout the pellet. The Pu/U ratio did not change during the reduction process. The reduction yield of U and Pu determined by measuring the H_2 formed upon reaction of the reduction product with HBr and using a gas burette was more than 90%. A small fraction of Pu has formed an alloy with Pd. The rare earth elements were found in the gap of the porous U–Pu alloy. As expected from the oxygen potential of Ce, Nd, Sm, and Li, they remained in an oxide form.

Small fractions of the actinide and rare earth elements were leached from the pellet into the molten LiCl bath or were found as precipitate on the crucible bottom. A large part of Am was found in the rare earth oxide phase rather than in the reduced U–Pu alloy. This represents of course a major problem in a grouped actinide recovery. Also the handling of highly reactive Li and problems in developing the corresponding equipment especially for the lithium recovery are major drawbacks of this process.

The electrochemical reduction process is clearly the more reliable technique to convert oxides into metal. The difficult handling of Li metal and recycling through reconversion from Li_2O can be avoided. The oxide ion produced at the cathode is simultaneously consumed at the anode and thus the concentration of oxide ion in the bath can be maintained at a low level. A more complete reduction of the actinide elements can be achieved and the subsequent electrorefining to separate actinides as described in the previous paragraph can be carried out in the same device.

At present, an electrochemical process is being developed mainly in the USA at the Idaho National Laboratory (INL) and, in collaboration with the JRC-ITU, also in Japan at CRIEPI. Both unirradiated and irradiated fuel materials were treated with slightly different concepts.

In the INL process, the oxide fuel is loaded into a permeable stainless steel basket as crushed powder. The basket immersed in a molten LiCl – 1 wt.% Li_2O electrolyte at 650°C is used as cathode and a Pt wire is used as anode. The reduced fuel is retained in the basket. The oxygen ions liberated at the cathode diffuse to the Pt anode, where they are oxidized to oxygen gas. The corresponding reactions are:

where M = metal fuel constituent

Figure 25
Schematic drawing of the electrochemical oxide to metal conversion process (Sakamura et al. 2006)

The Li_2O present in the salt is reduced to Li together with U and reduces the fuel oxide chemically. Consequently, the INL process is a combined chemical/electrochemical process.

The CRIEPI/JRC-ITU process is schematically shown in [Fig. 25](#).

The fuel is not crushed but loaded as fuel rod segments in a cathode basket, made of Ta. The anode is made of C, the corresponding reactions are:

The molten salt can be either $LiCl$ or $CaCl_2$. In $CaCl_2$, the higher temperature of 1,123 K in comparison to 923 K for $LiCl$ induces a faster diffusion of oxygen ions to the anode. At the same time an increased initial reaction rate leads to the formation of a thin dense metal layer at the fuel surface hindering the diffusion of oxygen ions into the salt.

The INL process scheme was successfully demonstrated using irradiated spent LWR oxide fuel in a hot cell. More than 98% of the U was reduced. Cesium, Ba, and Sr were dissolved in the salt phase, as expected. The rare earth and noble metal fission products remained with U and transuranium elements such as Pu and Np were reduced together with U, however, about 20% of the Am remained as oxide.

The CRIEPI/JRC-ITU process was tested on various MOX compounds. Mixed oxide fuels with a Pu content 5–45% were reduced. It could be shown that U and Pu are efficiently co-reduced, but due to the problems mentioned above, the complete reduction requires very long reaction times. The reduction of irradiated FR fuel particles at JRC-ITU was considerably faster

due to an increased reaction surface and a complete reduction of all fuel constituents including fission products and MA was achieved.

6 Impact of Transuranium Elements on Storage and Waste Disposal Concepts

6.1 General Aspects

The necessity to physically concentrate and isolate from the biosphere radiotoxic nuclides generated during the operation of nuclear power plants is a key safety aspect and a common requirement for existing and future concepts of nuclear fuel cycles. As described in the previous sections of this chapter, the so-called back-end of the fuel cycle encompasses different options, ranging from direct disposal of spent fuel, to reprocessing of U and Pu followed by disposal of vitrified HLW (containing MA and fission products), to reprocessing of U and Pu including partitioning and transmutation of MA (and, in some cases, also of long-lived fission products) followed by disposal of the resulting waste.

With respect to radionuclide isolation, and concerning the spent fuel and/or the end wasteform, two main stages can be defined and are present in all fuel cycle back-end concepts: handling, transport and storage in temporary storage facilities, and final disposal in a geologic repository.

The stability of the wasteform depends on some properties of the waste material, in particular on its composition, chemical state, and radioactivity level. In the case of spent fuel, the irradiation history and conditions (burnup, temperature) determine properties and behavior of the spent fuel rod (fuel + cladding) during storage.

The radioactive decay process is the main factor affecting the property evolution of the wasteform. The radioactive decay heat must be dissipated to maintain the waste package material at a temperature below the safety limit. This, together with criticality safety considerations, ultimately determines the spacing of nuclear waste containers, hence the size of the geological repository sites. Additionally, the accumulation of microstructural damage and of helium, specifically associated with the alpha-decay, may progressively alter the properties of the waste material and ultimately affect its mechanical stability. This may also result in a modification of the corrosion behavior of the waste form in the event of direct contact with groundwater.

6.2 Transuranium Elements and Wasteforms

6.2.1 Transuranium Elements in Spent Fuel

Transuranium elements account for more than 99% of the total alpha-activity of irradiated fuel shortly after discharge, and are responsible for the long-term activity and heat production of spent fuel, as shown in  Fig. 26, which depicts the specific evolution of the contribution due to the alpha-, beta-, and gamma-activity of spent fuel expressed as dose rate as a function of time. Already after a few hundred years, the alpha-activity component dominates the overall activity and dose surrounding spent fuel.

■ Figure 26

Dose rate evolution for spent LWR fuel with a burnup of 60 GWd/tM (Quiñones et al. 2008) (© MRS)

6.2.2 Transuranium Elements in Waste Glass

HLW glass associated with current reprocessing of spent fuel contains all transuranium elements separated from spent fuel with the exception of Pu (Gras et al. 2007). Pu disposition in glass is also considered (Muller et al. 2001). Typically, a loss of U and Pu around 1% is considered to occur in the fraction of these elements recuperated by reprocessing, and is included in the vitrified waste load. The total weight fraction of material separated from spent fuel loaded in today's HLW glass is around 14.4%; the mass of actinide oxides in the glass amounts to ~0.4 wt.%, the rest being constituted by fission products (Gras et al. 2007).

6.2.3 Transuranium Elements in Advanced Cycle Waste Forms

The evolution of the fuel cycle for existing reactors (both LWR and Canada Deuterium Uranium (CANDU) reactors) includes in most concepts an increase in the fuel burnup and/or the use of MOX fuel. The corresponding spent fuel or the reprocessing of this type of fuel will be characterized by a higher content of MA per unit of fuel treated. Therefore, there is a trend in the evolution of current back-end concepts towards achieving and assessing behavior and safety implications of waste form formulations that accommodate different inventories of transuranium elements (NEA (OECD Nuclear Energy Agency) 2008; Gombert et al. 2008).

Advanced fuel cycles for future generations of reactors envisage various waste forms for final disposal, ranging from spent fuel or IMF/target after one irradiation (once-through-then-out, deep-burn concepts), to vitrified waste or ceramic matrices containing the radionuclides separated as waste in reprocessing and/or partitioning stages. The implementation of partitioning and transmutation (P&T) concepts will entail the removal of transuranium elements from the waste stream destined for disposal in a geologic repository. 📌 Figure 27 illustrates the power generated by decay in HLW, including spent fuel and different degrees of recycling of the

■ Figure 27

Power generation as a function of time of different types of high-level waste (HLW) expressed as heat per unit energy produced during reactor operation of the corresponding fuel (Gras et al. 2007) (© Elsevier)

transuranium elements. This diagram highlights the potential gain stemming from the recycling of Cm together with Pu and Am (comparison between red and blue curve). The inclusion of curium in the recycled fuel is currently being debated, as, against the medium-term advantage in terms of reduction of the heat generated in the waste, one has to consider that the handling of Cm requires special measures and thus would cause an increase in the complexity and cost of the facilities and the procedures associated with fabrication of Cm-containing fuel. Moreover, the efficiency of Cm destruction even in fast reactors is quite limited.

6.3 Special Wasteforms for the Immobilization of Transuranium Elements

In the case of recycling of Pu and Minor Actinides, the remaining reference species controlling the long term radiotoxicity of the waste would be long-lived fission products like ^{99}Tc , ^{129}I , ^{135}Cs (with $t_{1/2}(\text{y}) = 2.1 \times 10^5$, 1.6×10^7 , 2×10^6 , respectively). Specific waste forms for these fission products are considered, and are the object of study in various research groups worldwide (Weber et al. 2009).

Crystalline waste forms to immobilize transuranium elements, including Pu from dismantled warheads, are also an object of study. The main compounds proposed for these applications are derived from natural minerals which have contained actinides over geological time-spans.

The main requirements are good resistance against radiation damage and against water corrosion, high loading fraction of transuranium elements, and ease to fabricate and process. Typically, these proposed waste forms are compared to HLW glass in terms of properties, performance, and fabrication routes (Vance 2007; Boyer et al. 1997).

Phosphates like monazite, (RE, An)PO₄, where RE = rare earths and An = actinides, and other phases like rare earth apatite (McCarthy 1977), powellite CaMoO₄, and pollucite CsAlSi₂O₆ have mineral analogs which proved to be durable in nature, and are among the first compounds which were proposed for these applications (Ringwood et al. 1979).

Synroc (synthetic rock) is a multi-phase Ti oxide ceramic where transuranium elements could substitute in zirconolite (CaZrTi₂O₇) and perovskite (CaTiO₃) phases. The synroc formulation would include also hollandite, Ba(Al, Ti)₂Ti₆O₁₆ as suitable host for fission products (Caurant et al. 2006). The initial concept of synroc envisaged a direct coupling to incorporate ~20 wt.% of PUREX reprocessing oxide waste; however, up to 35 wt.% waste loading is considered possible. In addition to its flexibility (additional phases can be added according to the target materials to be immobilized), good leaching resistance characterizes this waste form concept: the corrosion rate of these crystalline phases is up to three orders of magnitude lower than that for waste glass. Single phase zirconolite (Belin et al. 2008) and, to a lesser extent, perovskite, are also studied specifically for immobilization of transuranium elements.

Fluorite-structure materials like cubic ZrO₂, or fluorite-derived structures like pyrochlore, are also considered. Pyrochlores have the general formula A₂B₂O₇, where A and B can be a wide variety of metal cations, with different valences. With respect to the fluorite structure two cation sites and one-eighth of the anions are absent (Sickafus et al. 2000). Both tri- and tetravalent transuranium elements could be incorporated; the matrix would provide good resistance against radiation damage (depending on the host composition) and against corrosion (Lian et al. 2003; Lutique et al. 2003; Strachan et al. 2003). However, by increasing the resistance against amorphization (this can be achieved by replacing Ti with Zr in the B sites), the fabrication process becomes more cumbersome in terms of higher sintering temperature and lower amount of impurities that can be tolerated in the structure.

In some cases, composite materials are under examination, in particular for transmutation in nuclear reactors followed by direct disposal. In these concepts, a refractory compound with high radiation resistance like ZrO₂ is typically hosted in a high thermal conductivity matrix like e.g., a metal (CERamic METal composition, CERMET). The combination allows exploiting the advantages of both host compounds while optimizing the irradiation and postirradiation processes.

6.4 Long-Term Behavior of Waste Containing Transuranium Elements

As shown in  Figs. 26 and  27, if present in the waste form transuranium radionuclides would dominate the long-term radioactivity of HLW. Their presence or absence in the waste will significantly change the time scale during which the radiotoxicity of the waste will exceed the levels of relevant natural geological formations (uranium mines), hence the time limit by which the safe isolation of the waste from the biosphere has to be ensured.

The impact of transuranium elements on the evolution and behavior of the waste form will have physical and chemical aspects.

■ Figure 28

Alpha-decay and helium production as a function of time in spent UO₂ and MOX fuel with different burnup (eol = time of discharge from the reactor; dpa = displacement per atom)

6.4.1 Consequences of Alpha-Decay Damage and Helium Build-Up in the Waste Form

The physical aspects characterizing the long-term solid state evolution of the waste form are related to the specific decay power and the effects associated with the accumulation of alpha-decay damage and He in the material. Alpha-decay damage consists of atomic displacements in the lattice caused by the slowing down of the alpha-particle and the recoil nucleus. The slowing down process occurs by energy transfer (via nuclear and electronic energy loss mechanisms) associated with collision of atoms in the material. The net result of the decay events is the accumulation of microstructural defects and He atoms in the waste material.

It is necessary to assess the waste form behavior under accumulating decay damage conditions to ensure that the required functionality of the material is maintained over the time interval of interest.  Figure 28 shows the evolution of the decay events due to transuranium elements in current LWR spent fuel with different burnup, expressed as He produced and alpha-decays as a function of time (Rondinella et al. 2003).

Formation of point defects, dislocation loops, and, finally, extended defects and small He bubbles are all features observed as a function of accumulated alpha-dose in a (U, Pu)O₂ matrix (Rondinella et al. 2005, 2007; Eyal 1997; Maugeri et al. 2009). Similar microstructural features can be observed also in other crystalline waste forms subjected to alpha-decay damage (Weber et al. 1998; Ewing et al. 2004; Wiss et al. 2007; Wald and Weber 1984). In the case of spent fuel, the defects caused by decay superimpose those from fission damage that occurred during in-pile

■ Figure 29

Transmission electron microscope micrographs showing dislocation loops (appearing as small black dots on the images) caused by alpha-decay damage in the UO_2 matrix: (a) spent fuel, 85 GWd/t, ~ 0.1 displacement per atom (dpa) due to alpha-decay after fuel discharge from reactor; (b) unirradiated (U, Pu) O_2 , ~ 0.2 dpa due to alpha-decay

irradiation. ➤ [Figure 29](#) shows the build-up of dislocation loops in the lattice of unirradiated (U, Pu) O_2 and in spent fuel.

The accumulation of microstructure alterations results in macroscopic property changes. Three extreme consequences, potentially affecting the waste form, are associated with this process:

- Amorphization may cause an increase of the corrosion rate in water by a factor 20–50; this effect may be relevant for crystalline waste forms other than UO_2 (Noe and Fuger 1974).
- Dimensional changes, in particular swelling, may be associated to amorphization and/or to phase transition and hardening in the material: their unwanted consequence consists of interaction/pressurization affecting the mechanical stability of the clad/container that might eventually compromise the integrity of the waste package (Wiss et al. 2007; Weber 1981; Matzke 1982).
- The ultimate consequence of radiation damage and helium accumulation in the waste may be the loss of mechanical integrity. Disaggregation of the waste material would hamper the handling of the waste form during/after intermediate storage prior to disposal, or result in a significant increase of surface area, which, in turn, would produce higher initial mobilization rates of nuclides from the waste upon exposure to water (e.g., in the event of failure of all containment barriers in a final repository).

Sufficient data is available demonstrating that low burnup UO_2 as waste form will not reach the range of conditions that could lead to the above-mentioned extreme consequences. Given the trends toward using higher burnup and transuranium elements-rich fuels/waste forms, the behavior of waste matrices subject to higher specific decay and helium accumulation rate has to be confirmed. Compared to low burnup UO_2 , the use of MOX fuel (see ➤ [Fig. 28](#)) or of

advanced fuels containing MA would increase the specific activity of the material, hence the damage and He accumulated during a given time interval, by several orders of magnitude. For advanced fuel containing MA, in particular, possible implications concerning storage time after fabrication and before reactor irradiation have to be fully evaluated. However, data available from existing high specific activity spent fuels, like SUPERFACT, indicate that no significant degradation of the mechanical stability occurred during more than 20 years of storage, i.e., after accumulating a damage level corresponding to a few dpa. This is due to the fact that the build-up of radiation damage in the material is not linear. Recombination mechanisms, especially significant at relatively high temperature or in materials with a relatively large density of defects, would cause saturation and partial recovery of the defects in the lattice of materials like UO_2 before reaching extreme deterioration of the material properties (Matzke 1982). These observations point to a positive conclusion concerning the long-term behavior of spent uranium dioxide fuel even at high specific activity regimes.

In the case of ceramic matrices for the immobilization of transuranium elements (described in [Sect. 6.3](#)), the most radiation resistant matrices, with behavior similar to UO_2 , appear to be ZrO_2 and ZrO_2 -based compounds. Amorphization, and in some cases, dramatic alteration of the mechanical integrity of the solid phase have been observed in other compounds, depending on host composition and waste loading.

6.4.2 Corrosion Behavior of the Waste Form in Contact with Water

The chemical aspects related to the evolution of the waste form affect its corrosion behavior if exposed to steam and/or groundwater. The likelihood of accidental type of events is minimized by the adoption of rigorous safety procedures during all stages of the fuel cycle; their impact would in any case be limited in time and extension. The contact between HLW and groundwater is an occurrence possible only after a very long time has elapsed since placement of the waste in the final repository. The eventual timeframe of such contact is of the order of 10 or 100,000 years after closure of the geological repository. The corrosion process would then be governed by the chemical conditions in the repository and by the properties of the waste form at the time of the water exposure. The chemistry of the transuranium elements plays an important role in determining the extent of the mobilization and transport of safety relevant radionuclides (Edelstein et al. 2006). [Table 9](#) summarizes chemical properties of transuranium elements relevant for corrosion in aqueous environment. Indicative solubility or, in the case of Pu, apparent concentration ranges are reported, which refer to redox conditions corresponding to different types of geologic repositories. The sorption characteristics are also indicated. High sorption tendency would correspond to significantly lower transport through the geologic media.

If no P&T option is considered, after a few 100 or 1,000 years the radiotoxicity of HLW will be dominated by the transuranium elements contribution, as illustrated by the data in [Fig. 1](#). After 10,000 years, the content, hence the possible role of Am and Cm in the corrosion process will become negligible. Together with long-lived radiotoxic fission products like ^{99}Tc and ^{129}I , transuranium elements Pu and Np will constitute the main sources of hazard. Among these, ^{237}Np is the nuclide with the longest half-life. The content of ^{237}Np in spent fuel will actually increase during the first 10,000 years due to the decay of ^{241}Am . Moreover, Np presents higher solubility and lower tendency to adsorb onto mineral phases compared to Pu, in particular under oxidizing conditions. Pu has a strong tendency to sorption, which in general limits its

■ Table 9

Summary of relevant properties of transuranium elements at near neutral pH

Element	Solubility (mol/l)	Sorption	Oxidation states in aqueous solution	Remarks
Pu	10^{-8} – 10^{-7a} <i>oxidizing</i> $< 10^{-9}$ <i>reducing</i>	High	+3, +4, +5, +6	Redox sensitive, relatively high amounts can be found in the groundwater ^a ; low solubility, high sorption, colloid transport
Np	10^{-6} – 10^{-3} <i>oxidizing</i> $< 10^{-8}$ <i>reducing</i>	Low <i>oxidizing</i> high <i>reducing</i>	+4, +5, +6	Redox sensitive, high solubility under oxidizing conditions, low sorption, colloid transport
Am	10^{-9} – 10^{-3}	High	+3, +5	Oxidation state +3 up to very strong oxidizing conditions
Cm			+3, (+4)	Oxidation state +4 is not stable

^aThe total amount of plutonium that can be measured when analyzing a groundwater solution by spectrometric methods represents an “apparent” concentration. This apparent concentration includes contributions from colloids and sorbed Pu, in excess of actual dissolved plutonium ions

mobility; Pu could, however, be transported mainly through colloid adsorption. Neptunium is often considered the transuranium element of reference for the studies on the long-term safety of the geologic repository (Eckhardt 2000). Both Np and Pu are affected by the presence of complexing species like carbonates and are redox sensitive, i.e., their oxidation state is affected by the redox potential and the pH of the groundwater; the oxidation state, in turn, is a key parameter in determining the mobility behavior of the element. The highest solubilities (and most rapid migration behavior) correspond for Np to the 5+ oxidation state, which would occur under oxidizing conditions. Under reducing conditions the 4+ state is stable and the solubility is significantly lower (see ► Table 9). Similar considerations on the oxidation states can be made also for Pu, although this element presents a more complex behavior, characterized by disproportionation of the 5+ state and the simultaneous presence of different oxidation states (Neck et al. 2007). The solubilities for Pu are generally lower than those for Np.

For most geologic repository concepts, the occurrence of a chemically reducing environment is envisaged as an additional element contributing to minimize the dissolution in water of redox sensitive species present in the waste. In the case of spent LWR fuel, the chemical solubility of the UO₂ matrix will be lower by several orders of magnitude in the absence of oxygen and/or other oxidizing agents. However, an important effect related to the presence and the activity of transuranium elements in the waste is the possible enhancement of dissolution due to the radiolysis of the water molecule caused by alpha-particles and recoil atoms produced in alpha-decay events occurring near the surface of the waste. ◉ Figure 30 shows the evolution of specific alpha-activity as a function of time for different types of spent LWR fuel (Rondinella et al. 2000; Carbol et al. 2005).

■ Figure 30

Specific alpha-activity of irradiated LWR fuel as a function of time. UO₂ and MOX fuel with different burnup levels are represented (Rondinella et al. 2000; Carbol et al. 2005). The shaded area marks the range of alpha-activity below which the dissolution of UO₂ is controlled by chemical solubility rather than radiolytic dissolution-enhancing effects (Rondinella et al. 2004)

The radiolytic process generates an equal number of oxidizing and reducing species, including radicals and molecular species. It has been observed in laboratory simulated experiments that alpha-radiolysis can produce a net enhancement of the dissolution rate of a UO₂ matrix for alpha-activities down to levels in the interval between $\sim 3 \times 10^6$ and $\sim 4 \times 10^7$ Bq/g (shaded area on the diagram in [Fig. 30](#)) (Rondinella et al. 2004), corresponding to spent fuel with an age ranging between one thousand to tens of thousand years (Carbol et al. 2005; Johnson et al. 2005). The enhancement is due to the establishment of oxidizing conditions very near the surface of the waste, almost independent of the nominal redox conditions of the repository. Due to the limited range of alpha-particles in water ($\sim 37 \mu\text{m}$ for a 5 MeV particle), alpha-radiolysis affects only a thin water film surrounding the waste surface.

If radiolysis were the only factor affecting the corrosion behavior of the waste, it would become crucial to ensure (through appropriate design of the containment and isolation barriers enclosing the waste) that no contact with groundwater occurs before a time of the order of some tens of thousand years has elapsed. However, the radiolytic enhancement, caused mainly by the presence of transuranium elements in the waste, is just one of the factors shaping the overall expected behavior of the waste in a repository. If one considers the integral behavior, with all conditions characterizing the repository applied, the dissolution enhancing effect of radiolysis will be offset by other, dissolution-inhibiting agents that will be assuming a governing role in determining the overall interaction process between the waste and the surrounding

environment. Among these beneficial agents the reducing and immobilizing effect on redox sensitive radionuclides due to the presence of relatively large amounts of iron in the vicinity of the waste form will play a major role (Cui et al. 2009a). Additionally, the corrosion reaction of iron with groundwater under anaerobic/anoxic conditions (typical of a chemically reducing geologic repository) will generate hydrogen overpressures. Hydrogen dissolved in groundwater at low temperature (below ~ 370 K) is chemically inert. However, in presence of a suitable catalyst (e.g., the 4d-metallic fission products alloy particles formed in the fuel during irradiation or the UO_2 surface itself) (Cui et al. 2009b), a suppressing effect of the oxidative corrosion is observed that may ultimately block the corrosion of the spent nuclear fuel matrix (Carbol et al. 2009).

27 Decommissioning of Nuclear Plants

Maurizio Cumo

University of Rome, Rome, Italy

maurizio.cumo@uniroma1.it

1	<i>Nuclear Plants Decommissioning Overview</i>	3005
1.1	Definition and Scope of Decommissioning	3005
1.2	Introduction to Some Decommissioning Challenges	3007
1.2.1	Organization and Management	3007
1.2.2	Safety-Related Issues	3008
1.2.3	Decommissioning Funding	3009
1.2.4	Waste Management	3010
1.3	Decommissioning Strategies	3010
1.3.1	Overview	3010
1.3.2	Issues Affecting the Choice of Decommissioning Strategy	3013
1.4	Decommissioning in the World	3015
2	<i>Decommissioning Organization and Management</i>	3026
2.1	Overview	3026
2.2	Issues Affecting Decommissioning Organization and Management	3027
2.2.1	Decommissioning Strategy	3027
2.2.2	Safety Issues	3028
2.2.3	Work Approaches	3028
2.2.4	Impact on Staffing	3029
2.3	Organization and Management in the Various Phases of Decommissioning	3030
2.3.1	The Planning Phase	3030
2.3.2	The Transition Phase	3031
2.3.3	The Active Phases of Decommissioning	3032
2.3.4	The Safe Enclosure Phase	3032
2.3.5	The Post-Dismantling Period	3034
2.3.6	Spent Fuel and Waste Storage	3034
2.4	Management for Active Phases of Decommissioning	3034
2.4.1	Overview	3034
2.4.2	The Decommissioning Management Team	3035
2.4.3	Change Management	3035
2.5	Decommissioning Planning and Licensing	3037
2.5.1	Overview	3037
2.5.2	Decommissioning Planning	3039
2.5.3	Stages of Planning	3039

2.5.4	Content of Decommissioning Plan	3040
2.5.5	Decommissioning Optimization	3041
2.5.6	Project Risk Management	3043
2.5.7	Regulatory Approval	3043
2.5.8	Work Packages and Procedure	3044
2.6	Role of Quality Assurance	3046
2.6.1	Overview	3046
2.6.2	Control of Modifications to the Plant	3046
2.6.3	Radiation Protection and Environmental Safety Control	3046
2.6.4	Control of Outside Contracted Services	3047
2.6.5	Surveillance and Inspections	3047
2.6.6	Information Management	3047
2.6.7	Safety Audits	3049
2.6.8	Management, Assessment and Reporting of Incidents and Events	3049
2.7	Responsibilities and Qualifications	3049
2.7.1	Licensee	3049
2.7.2	Decommissioning Project Manager (DPM)	3050
2.7.3	Technical Support	3051
2.7.4	Decommissioning Operations	3052
2.7.5	Administration Services	3053
2.7.6	Interfaces	3055
3	<i>Plant and Site Characterization</i>	3056
3.1	Initial Plant Characterization	3056
3.1.1	Radioactivity Sources	3056
3.1.2	The Concept and Extent of Characterization	3059
3.1.3	Structure Characterization	3060
3.1.4	System and Equipment Characterization	3061
3.2	Site Characterization	3062
3.2.1	Surface Soil Contamination	3062
3.2.2	The NRC Acceptance Criteria	3062
3.2.3	Subsurface Soil Contamination	3063
3.2.4	Surface Water Contamination	3063
3.2.5	Groundwater Contamination	3064
4	<i>Decontamination Techniques</i>	3064
4.1	Overview	3064
4.1.1	Objectives of Decontamination Techniques	3066
4.1.2	Selection of Decontamination Technologies	3068
4.1.3	Survey of Applied Decontamination Techniques	3069
4.2	Decontamination of Segmented Components	3071
4.2.1	Overview	3071
4.2.2	Chemical Decontamination	3073
4.2.3	Electrochemical Decontamination	3076
4.2.4	Mechanical Decontamination	3078
4.2.5	Decontamination by Melting	3081
4.2.6	Other Decontamination Techniques	3085
4.3	Decontamination of Building Surfaces	3085

4.3.1	Overview	3085
4.3.2	Basic Techniques	3086
4.3.3	Scarifying	3086
4.3.4	Guidelines	3089
4.4	Chemical Decontamination Techniques	3089
4.4.1	Overview	3089
4.4.2	Water/Steam	3090
4.4.3	Strong Mineral Acids	3091
4.4.4	Acid Solutions	3092
4.4.5	Organic/Weak Acids	3093
4.4.6	Alkaline Solutions	3095
4.4.7	Complexing Agents	3095
4.4.8	Oxidizing and Reducing (REDOX) Agents	3096
4.4.9	Organic Solvents	3101
4.4.10	Multiphase Treatment Processes	3101
4.4.11	Selection of Chemical Decontamination Processes	3104
4.5	Mechanical Decontamination Techniques	3105
4.5.1	Overview	3105
4.5.2	Water Flushing	3105
4.5.3	Dusting/Vacuuming/Wiping/Scrubbing	3105
4.5.4	Steam Cleaning	3108
4.5.5	CO ₂ Blasting	3108
4.5.6	Wet-Ice Blasting	3109
4.5.7	Hydroblasting	3110
4.5.8	Ultra-High-Pressure Water	3110
4.5.9	Shot Blasting	3111
4.5.10	Wet Abrasive Cleaning	3111
4.5.11	Grit Blasting	3112
4.5.12	Grinding	3113
4.5.13	Scarifiers	3113
4.5.14	Milling	3115
4.5.15	Drill and Spall	3116
4.5.16	Paving Breaker and Chipping Hammer	3116
4.5.17	Expansive Grout	3116
4.5.18	Asbestos Removal	3117
4.6	Other Decontamination Techniques	3117
4.6.1	Electropolishing	3118
4.6.2	Ultrasonic Cleaning	3120
4.6.3	Vibratory Finishing	3121
5	<i>Cutting and Dismantling Techniques</i>	3122
5.1	Overview	3122
5.2	Thermal Cutting Techniques	3122
5.2.1	Gas Processes	3123
5.2.2	Arc Processes	3127
5.2.3	Plasma-Arc Processes	3133
5.2.4	Laser Cutting	3136

5.2.5	Combined Cutting Processes	3136
5.3	Hydraulic Cutting Techniques	3138
5.3.1	High Pressure Water Jet Cutting	3140
5.3.2	Abrasive Water Jet Cutting	3140
5.4	Mechanical Dismantling Techniques	3141
5.4.1	Grinder	3141
5.4.2	Hacksaw and Guillotine Saw	3143
5.4.3	Shears	3144
5.4.4	Milling Cutters and Orbital Cutters	3144
5.4.5	Knurl Tube Cutter	3145
5.4.6	Diamond Saws and Cables	3146
5.5	Conclusions	3147
6	<i>Remote Control Techniques</i>	3148
6.1	Basis of Remote Operation	3148
6.1.1	Overview	3148
6.1.2	Safety Enhancement	3148
6.1.3	Cost Reduction	3148
6.1.4	Productivity Improvement	3154
6.1.5	Utilization of Facility Resources	3154
6.1.6	Accessibility	3154
6.1.7	Disadvantages of Remote Operation	3154
6.2	Remote Operation Technologies	3155

Abstract: Decommissioning a nuclear plant can be defined as the termination of operations and the withdrawal of the facility from service, followed by its transformation into an out-of-service state without radiological risks and, in some cases, its complete removal from the site. Decommissioning activities shall be carried out in a cost-effective manner assigning top priority to health and safety of the general public and the environment, as well as of the decommissioning workers. This chapter covers all aspects related to the closure of the operating life of nuclear plants and provides a description of all the activities and tools involved in both the decision-making and operative processes of decommissioning.

Nuclear plant decommissioning is a complex, long, and highly specialized activity. In some countries, therefore, it is even called “de-construction” because it is in many respects similar to the construction activity and, in addition, it deals with partly activated and contaminated structures. Activities to perform include technological tools, industrial safety, environmental impact minimization, licensing, safety analysis, structural analysis, etc. Other aspects are short- and long-term planning, calculation of cash flow and financing, waste disposal, and spent fuel strategy.

A lot of technical information is drawn from direct experience of nuclear operators. The widely used references are those from the OECD-NEA, UNO-IAEA, US-NRC, and the European Commission. They cover the results of working groups, special studies, comparisons of technologies, and recommendations.

1 Nuclear Plants Decommissioning Overview

1.1 Definition and Scope of Decommissioning

Decommissioning a nuclear power plant can be defined as the termination of operations and the withdrawal of the facility from service, followed by its transformation into an out-of-service state without radiological risks and, in some cases, its complete removal from the site. Decommissioning activities shall be carried out assigning top priority to health and safety of the general public and the environment, as well as of the decommissioning workers.

Decommissioning is also understood as the actions taken to allow the removal of all regulatory controls on a facility that used radioactive material. These actions include both technical and administrative ones that must be accomplished to show that the facility can be released for unrestricted use or otherwise reused.

They may just consist of performing some decontamination activities and a radiological survey to show that acceptable conditions have been met, or they may include dismantling a system or an entire building.

The operating lifetime of nuclear facilities is determined by economic and safety considerations. Nuclear power plants are normally designed for an operating lifetime of several decades. By appropriate refurbishment, replacement, or upgrading of some equipment, the life of a plant can now be extended to up to 60 or more years. In many cases, it is even very advantageous to extend the operating life of a Nuclear Power Plant (NPP) beyond the amortization period and the initial design life, into the so-called “life extension,” because electrical energy can be produced at a very low cost while matching the required levels of health and safety of the public and the environment. However, ultimately it becomes either technically or economically advantageous to dismantle the facility and, in some cases, to replace it with a new one.

The closure of the operating life of a nuclear installation and the decommissioning sequences should be planned at the design stage, when several design features can be adopted to facilitate dismantling. Also during plant operation several possibilities exist that may facilitate the decommissioning, e.g., better plant configuration control, system, and building radiological status record. In any case decommissioning planning shall start at least some years in advance of the plant closure. The decision of definitive plant closure may be related to:

- Termination of the design life of major components
- Excessive operating costs (e.g., compared with competing energy sources)

Although decommissioning normally occurs at the end of the operating lifetime of the plant, it may also be required for various other reasons:

- The conclusion of a research program that has achieved its goal
- Safety issues that cause an activity using radioactive material to be discontinued
- The initial technology using the radioactive material has become obsolete or uneconomical
- An accident or unplanned event requiring the final decommissioning to be performed
- Changes in government policy that make it unfeasible to continue the operating life

Challenges in the latter cases may be more severe as, in general, all the decommissioning funds might have not been accumulated because the work force had not been adequately planned for a soft phase out and because all preparation and planning activities had not been performed. In addition, especially in case of accidents, some special challenges may be present as, for example, in the cases of major severe accidents such as Chernobyl and Three Mile Island.

Some thousand nuclear facilities worldwide are estimated to require decommissioning over the coming decades. Of these, a thousand facilities are associated with the production of energy and fuel cycle. These include nuclear power plants, reprocessing plants, hot cells, interim storage facilities, enrichment plants, and uranium mill plants. There are approximately 400 other research reactors that require some form of decommissioning. When the number of commercial companies and universities that use radioactive materials is added, the number grows to several thousand. This figure does not include many of the civil and military support complexes associated with former sites for nuclear weapons production or military vessels, such as aircraft carriers and submarines powered by nuclear reactors.

In the context of decommissioning, nuclear installations can be classified as follows:

- Nuclear power plants for electricity production (or, in general, thermal energy production)
- Research, experimental, or isotope production reactors with various thermal powers
- Fuel fabrication plants
- Spent-fuel reprocessing plants
- Experimental laboratories related to the fuel cycle
- Hot cells for activities on activated materials, contaminated materials, or radioisotopes

Among the above mentioned installations, there are also other small installations in the nuclear and even in the nonnuclear field that treat or contain some radioactive materials and that, at the end of their operating life, require some precautions. However, this section does not cover these cases. The experience acquired so far in the first important works of decommissioning constitutes a precious support for designing future reactors.

1.2 Introduction to Some Decommissioning Challenges

1.2.1 Organization and Management

The decommissioning process must be carefully planned and implemented in a safe and economical manner. To set proper decommissioning conditions is a task that should start during the initial design of the facility by including features that facilitate the eventual dismantling and decontamination efforts. This might include, for example, proper material choice to minimize activation, placing hatches in concrete floors and walls to allow for the removal of large pieces of equipment using modular biological shielding or lining a process cell or other areas that might be contaminated during the life of the facility. Decommissioning preparation may continue during the entire life of the plant until conditions allow for the removal of regulatory controls.

Normally, decommissioning operations begin at sites where the operating staff is present. The first strategic choices to accomplish the decommissioning of a facility, which have a substantial effect on the project organization, are the following:

- The first approach is for the licensee to perform the decommissioning with in-house resources supplemented by specialist contractors as needed.
- The second approach is for the licensee to contract with an experienced outside organization to perform the decommissioning activities and then provide general oversight and support services.

There are advantages and disadvantages in each approach.

If the licensee performs the decommissioning activity, there is maximum use of the existing staff, which has a wealth of hands-on experience. Some of the decommissioning activities are similar to maintenance activities for which procedures are already established. An example is the removal and replacement of components as a normal activity during the operation of the plant. The use of existing staff provides continuity of local employment. However, some of the more experienced staff may leave because they see their employment ending when decommissioning is completed and will go to other sites where new jobs or long-term career prospects are available.

A disadvantage of using former staff to perform the decommissioning activity is that such staff may have difficulty in accepting the cultural changes needed as the plant changes from an operational mode to decommissioning mode, e.g., from routine operations to unique tasks requiring more preparation. This causes them to be less motivated than an organization that performs decommissioning activities on a routine basis.

Even in an in-house approach, it is inevitable that at least some contractors are used on-site. This could range from one or two specialist contracts (e.g., plasma cutting) or, at the other extreme, using contracts for selected areas of the site. The extent of contractor usage is dependent on the policy on staff retention, cost, and the availability of suitable contractors.

When an outside contractor is hired to perform the decommissioning activities, the licensee maintains a smaller staff because of its role and responsibility as a supervising organization. The outside contractor takes control of major portions of the facility and ensures that the activities are performed safely and in accordance with the regulatory requirements. These experienced contractors are normally more efficient than the in-house resources during the decontamination and dismantling activities. They have performed these activities on a routine basis and are more familiar with the available technologies that can be used to assist them in their efforts,

such as decontamination of concrete walls and floors. The contractor can also arrange for any subcontractors if needed and this will probably be fewer than if the licensee himself or herself performs the decommissioning activities.

When using contractors the licensee still keeps control of the project. In order to maintain this control, the licensee is required to be in constant contact with the contractor to ensure that all safety and regulatory requirements are met and that the project goals are achieved. It is important that the licensee be familiar with various contracting mechanisms to minimize the risk of cost overruns. Resources and skills needed for the supervising work may be significant. The licensing regime is based on the premise that the licensee is in day-to-day control of the facility, processes, and activities and that its staff manages the operation of the facility. The licensee is an “intelligent customer” for services provided by contractors. This is still necessary during periods of care and maintenance and waste storage. Therefore, the licensee needs to be able to demonstrate that an adequate organization is, and will be, in place to discharge those responsibilities until the facility is finally removed from regulatory control and its period of responsibility has ended.

Project financing may be another challenging issue. The Project Management shall assure that necessary funds are available when necessary. There may be a number of reasons why the funds necessary for decommissioning are not available when the facility is shut down. It may be that the facility was closed prematurely before the total amount of funds was collected. The funds may also be lacking because of poor planning or the lack of a national requirement for prudent financial planning. Another cause may be that political conditions have changed, such as in the case of some of the former Soviet Union countries, and the funds are not available to complete the decommissioning process. No matter what the reason is, the lack of funding can cause substantial delays in the process and can have a significant impact even on safety during the resolution of this problem.

Another issue is maintaining “corporate” knowledge during the operation of the facility and until it is finally released from regulatory control. This could be especially troublesome if a long safe storage period is selected, which might cover a period that would exceed a person’s normal working lifetime. Without the working knowledge of the systems and of accidents or incidents that occurred during the life of the plant, the planning process is made more difficult and unknown or unexpected situations may occur during the decontamination or dismantling activities.

This issue is expanded in [▶ Sect. 2.](#)

1.2.2 Safety-Related Issues

There are some issues related to safety concerns that must be addressed during the development of the decommissioning plan and the planning process. These issues can have a significant effect on the selection of the option that might be chosen. In most cases, failure to resolve these issues leads to placing the facility in a safe storage mode with the deferral of the final decontamination and dismantling activities.

Radiological risks are much lower than during plant operation. This is the case, in particular, with instances where NPP’s decommissioning starts when spent fuel has been removed from the facility and therefore the total radiological inventory has been dramatically reduced to about 1% of the previous one. However, industrial risks may increase due to the decommissioning operation involving chemical and mechanical nonroutine activities, handling of large and heavy pieces, use of protective clothings limiting worker freedom of movement, etc.

Maintaining safety culture in the entire organization and keeping safety as the first priority is another challenge during decommissioning that may appear more an industrial conventional activities than an operation that require high skills and attention to radiological issues.

Another challenge that may also affect the Safety Authority is the capability to properly adapt the regulatory requirements to actual plant conditions and the real associated risks. It is clear that radiological risks tend to zero as the decommissioning process progresses. It is necessary to focus the attention on real risks that may change in nature and dimension.

The lack of a disposal or storage site that would accept the waste generated during the decontamination and dismantling activities may involve both project management and environmental issues. In general, it is not a good practice to generate radioactive waste if there is no national policy on waste management or a facility available to handle and dispose the waste. It is highly recommended that a facility be available for all of the waste streams that will be generated during the decommissioning. However, if an off-site disposal facility is not available, it is reasonable to proceed with the decommissioning, and treat and condition the resulting waste that may be stored temporarily on-site.

All these aspects and other are expanded in  Sect. 8.

1.2.3 Decommissioning Funding

Decommissioning is not producing revenues in general, but it is an activity aimed at solving liabilities and site restoration. Therefore, funding is a key issue to assure a safe, efficient, and economic decommissioning.

Several methods of financing these future decommissioning costs can be used, depending on the circumstances of each utility and the country in which it operates. In several countries, a fund of some type has been established or proposed to ensure the availability of financing.

This is usually done by estimating the cost of decommissioning at the end of the normal plant lifetime and requiring payments, either annually or on a charge per kilowatt-hour basis, to ensure that this sum is in place. This estimate is updated regularly and the charge adjusted accordingly.

The drawback of this system is that the amount estimated would not be in place if the plant were to be shut down before the end of its normal lifetime. To avoid this, a fund could be established at the start of the plant's operation that would cover the cost of decommissioning whenever it is necessary. However, this represents a heavy burden for the utility at the moment when construction and start-up costs are already high, and thus, although it may be imposed by law, this solution is not favored by many utilities.

To assure proper funding (initially and during decommissioning) cost calculations is a very important question.

The cost of decommissioning nuclear power plants is based on the following factors:

- The sequence of decommissioning stages chosen
- The timing of each decommissioning stage
- The decommissioning activities accomplished in each stage

In addition, costs depend on such country-specific and site-specific factors as the type of reactor, waste management and disposal practices, and wage rates. As mentioned previously, a number of other factors influence the choice of decommissioning strategy and therefore the involved costs.

Total decommissioning costs include all costs from the start of decommissioning until the site is released for unrestricted use.

The cost estimates are based on previous decommissioning and decontamination experience, the cost of maintenance, surveillance, and necessary component replacements, and the cost of similar, nonnuclear work.

Cost estimates vary in a wide range even for similar plants in different countries. Calculation assumptions may have also a very significant impact on these differences. The cost of decommissioning therefore may range from 150 to 500 M\$ and more per unit. This subject is expanded in  Sect. 9.

1.2.4 Waste Management

Radioactive wastes are an inevitable legacy of nuclear operations and they must be managed safely. As facilities near the end of their operating lifetimes, tasks associated with their decommissioning assume greater importance.

Governments are sharing experience and information on safety and technological aspects of decommissioning operations required for many types of nuclear facilities. As more facilities are scheduled to go out of service in the coming years, these services and activities can provide valuable support to countries in preparing, planning, and implementing programs for the safe management of radioactive waste associated with decommissioning operations.

The management of the waste generated by dismantling is a component of the complete cost of the operations. Wastes include:

- Nonradioactive wastes (primarily concrete and rubble), which are, a priori, the largest share of total waste.
- Very low-level radioactive waste, more than half of which is scrap. Depending on the nature of this waste, its activity and the relevant regulations, it can be either recycled or stored in packages in a dedicated facility without posing a danger to the public.
- Short-lived or low-medium-level activity waste, which accounts for by far the smallest share. This waste is governed by national regulations that dictate disposal procedures, in either a surface storage or interim storage facility before being sent to a medium-level long-lived waste storage center.
- There are also cases of long lived or intermediate to high level wastes; these may be present in the Gas Graphite NPP's or in the fuel cycle facilities (like reprocessing facilities) where spent fuel has been dissolved.

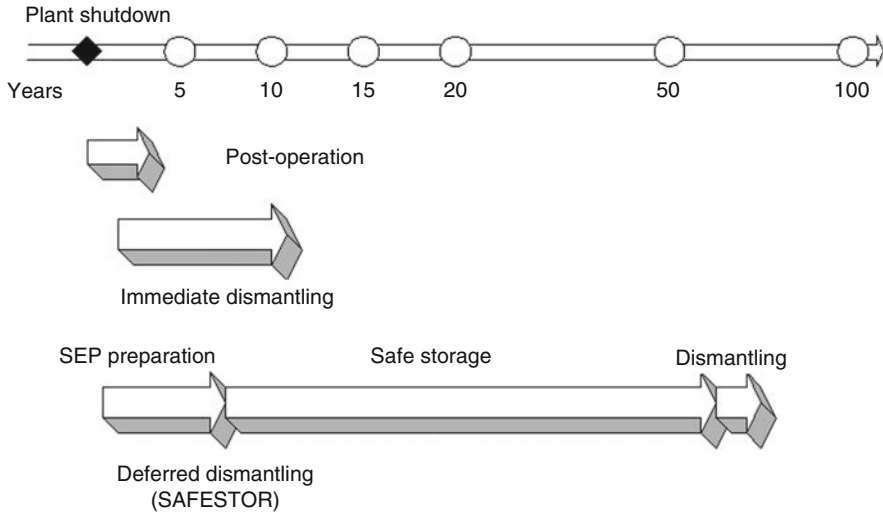

All wastes from dismantling or operations will be sent to a disposal facility. If this is not available, then decommissioning may proceed according to the chosen strategy shipping the waste to a long-term centralized storage center, if available, or may be stored on an interim basis on-site.

1.3 Decommissioning Strategies

1.3.1 Overview

There are three main options used for decommissioning ( Fig. 1):

- Immediate dismantling of the facility
- Safe storage or deferred dismantling of the facility
- Entombment of the facility

■ **Figure 1**
Decommissioning strategies and timescale

Each of these options has advantages and disadvantages.

- The immediate dismantling option (early site release or DECON in the USA) allows the facility to be removed from regulatory control relatively soon after shutdown or termination of regulated activities. Usually, the final dismantling or decontamination activities begin within a few months or years, depending on the facility. The Fort St. Vrain nuclear power plant in the USA is an example where this option has been successfully implemented.
- The safe storage option (Safe Enclosure or SAFSTOR in the USA) postpones the final removal of controls for a longer period, usually on the order of 40–60 years. The facility is placed into a safe storage configuration until the eventual dismantling and decontamination activities occur. This is the case, for example, of the Gas Graphite Reactor of Vandellós 1 in Spain.
- The entombment option (ENTOMB in the USA) entails placing the facility into a condition that allows the remaining radioactive material to remain on-site without the requirement of ever removing it totally. This option usually involves reducing the size of the area where the radioactive material is located and then creating a monolith or other structures that lasts for a period of time, which ensures that the remaining radioactivity is no longer of concern. Most regulators do not prefer this approach as it, in practice, creates a low-level radioactive waste-disposal facility on the site. An example where this option has been implemented is the Hallam nuclear plant in the USA. In general, this option is badly suited for large nuclear power plants because of their size and the amount and type of radioisotopes involved.

Practically, in any option, when operations at a nuclear power plant are terminated, the nuclear fuel, the mobile radioactive materials in the process systems (e.g., process fluids) and the radioactive waste produced during normal operations are removed as soon as the plant ceases

to operate. Certain equipment can also be removed and disposed. It is usual to consider spent fuel removal from the plant as a precondition for the start of decommissioning. All subsequent activities can be grouped according to the goal of reaching some well-defined stage of the decommissioning process.

It is usual to identify three main stages. Each of these stages can be defined by two characteristics: the physical state of the plant and its equipment and the surveillance needed to maintain this physical state:

- Stage 1 decommissioning requires that the spent fuel has already been removed from the reactor and from the plant, draining the liquid systems, disconnecting the operating systems, blocking and sealing the mechanical openings such as valves and plugs, and controlling the atmosphere inside the containment building. The facility is kept under surveillance, access is limited and routine inspections are carried out to ensure that the plant remains in a safe condition.
- Stage 2 decommissioning requires all equipment and buildings that can be easily dismantled to be removed or decontaminated and made available for other uses, leaving only the reactor core structure and its extensive shielding. The containment building and the ventilation system may be modified or removed if they are no longer needed for safety reasons, or they may be decontaminated to allow access for other purposes. Other buildings and equipment that are not radioactive may be converted to serve new purposes as well. Surveillance during Stage 2 is reduced, but it is advisable to continue periodic spot checks of the buildings as well as surveillance of the surrounding environment.
- Stage 3 decommissioning requires that, unless the site, buildings, or equipment are to be reused for other nuclear purposes, all materials with radioactivity levels exceeding those closely equivalent to the natural radiation environment be removed and the site released without restrictions or further surveillance.

In the case of nuclear reactors, about 99% of the radioactivity is associated with the fuel that is removed in Stage 1. Apart from any surface contamination of plant, the remaining radioactivity comes from “activation products” such as steel components that have long been exposed to neutron irradiation. Their atoms are changed into different isotopes such as ^{55}Fe , ^{60}Co , ^{63}Ni , and ^{14}C . The first two are highly radioactive, emitting gamma rays. However, their half-life is such that after 50 years from closedown their radioactivity is much diminished.

These three stages may be carried out by rapidly progressing from one stage to the next or carried out over a prolonged period lasting as long as 100 years or more. Although most countries intend to complete all the three stages, a facility could remain at Stage 1 or 2 for a relatively long period of time, or its decommissioning may proceed directly from Stage 1 to 3.

Although the above definitions are widely used, there are slight differences in the definitions in various countries and in the international organizations.

A licensee may also choose to adopt a combination of the first two choices, in which some portions of the facility are soon dismantled or decontaminated, while other parts of the facility are left in SAFSTOR.

The decision may be based on factors other than radioactive decay, such as the availability of waste disposal sites. To be acceptable, decommissioning must be completed within 60 years. A period beyond that is considered only in accordance with the US Nuclear Regulatory Commission (NRC) regulations.

1.3.2 Issues Affecting the Choice of Decommissioning Strategy

A number of factors must be weighed and balanced when preparing the decommissioning plan for a nuclear power plant. The plan may vary with each facility and these factors must be evaluated on a case-by-case basis.

National Nuclear Strategies

Some questions concerning national strategies and goals for nuclear power development that are relevant to decommissioning are:

- Is there a national policy for the disposal of shutdown nuclear facilities?
- Is this an industry or a government responsibility?
- What is the national radioactive waste management policy?

The answers to these questions may change with time and the decommissioning plan may need to be revised to take into account technical developments, availability of waste disposal sites, changes in health protection requirements, and other factors.

Plant Characteristics

The kind of reactor, the location of the facility, and the total amount of radioactivity it contains are important elements in the selection of a decommissioning strategy. The amount and distribution of the radioactivity are determined by the type of reactor and its operating history. For example, a boiling-water reactor (BWR) circulates steam containing radioactivity in the turbine circuit, whereas in a pressurized water reactor (PWR) the radioactivity is contained in the primary coolant system and does not contaminate the turbine circuit.

The radioactivity produced in nuclear power plants is made up of both short-lived and long-lived radionuclides, but principally of short-lived isotopes which decay in 5–30 years. Thus a significant reduction in radioactivity can be achieved by placing the facility in safe storage for that length of time. This delay reduces the occupational exposure of the decommissioning workers and the amount of waste needing controlled disposal.

Protection of Health, Safety, and the Environment

A primary concern in any decommissioning program is to provide for the health and safety of the workers and to protect the general public and the environment. Public exposure and environmental impacts are expected to be minimal and well within the regulatory limits for operating facilities. Therefore, they are not likely to be significant factors in selecting a decommissioning alternative.

However, protection of the decommissioning workers is an important consideration and a significant effort is made in all nuclear operations to keep the exposure as low as reasonably achievable. A cost-benefit analysis should be carried out to determine the extent to which the delayed dismantlement has a positive effect. Although this depends on the physical state of the power plant, as well as available resources and equipment, it is known that a deferral of Stage 3 for 80–100 years would significantly reduce personnel management and protection costs while raising maintenance and surveillance costs. Delaying decommissioning beyond 100 years would not achieve similar benefits as the decay rate of the radioactive substances is significantly slowed by then. Furthermore, surveillance beyond 100 years is a heavy commitment.

In choosing a decommissioning strategy, a radiological impact assessment should be made to determine:

- Individual and collective doses (i.e., the total dose over a population group exposed to the given source) to workers during the dismantling, including waste handling

- Individual and collective doses to the public throughout the operation, including those generated by waste management, transport and disposal and the residual ones, if any, generated by site use after its release.
- A risk assessment of the probability of a fire or explosion and deterioration of the installation or loss of integrity of the containment barriers leading to the release of radionuclides to the environment

Radioactive Waste Management

As indicated above, decommissioning nuclear power plants require the removal of the fuel prior to completion of Stage 1. Thus the first question is about the availability of reprocessing or storage facilities for this spent fuel. In some cases this might be a determining factor, but usually spent fuel management solutions are planned as part of power plant operations.

Although there is no generally applicable classification of radioactive waste, it is often advisable to refer to low-level, intermediate-level, and high-level waste, depending on their radionuclide content, heat-generation rates, and methods of treatment.

The availability of disposal sites for low- and intermediate-level waste is the most important factor in several countries, which are choosing decommissioning strategies. Most of the waste from nuclear power plant decommissioning is low-level waste, although a small amount of intermediate- and high-level waste is also produced. Low- and intermediate-level decommissioning waste can be disposed in the same repositories that accept the waste continuously produced by the operating facilities. The decommissioning waste volume from a nuclear power plant is of the same order of magnitude as the volume of operation waste produced throughout the normal lifetime of the plant. The volume of decommissioning waste can be substantially reduced using such techniques as surface decontamination, compaction, segmentation, special packaging, incineration, and vitrification.

Future Use of the Site

A nuclear facility site is a valuable resource, particularly for the location of replacement power or processing facilities. Among its advantages are the low seismic activity of the site, proximity to a large supply of water, access to an electrical distribution system, and acceptance by local residents. If the site is to be used for other power generating or nuclear facilities, it does not need to be decommissioned to the same standards as for unrestricted release to the public domain. In sites containing power plants that were constructed at different times, the end of their normal operating life comes at different times, and therefore decommissioning may be limited to Stage 1 until the last unit is shut down. Decommissioning of all units would be more efficient, and maintenance, surveillance, and security could be provided by personnel from the units still in operation, at little or no additional cost.

Development of Decommissioning Technologies

All three stages of decommissioning have been carried out in small tests, training and power demonstration reactors, and supporting fuel cycle facilities. Thus, extended experience has not yet been acquired in decommissioning the major reactor types. Present technology is believed to be adequate for decommissioning to any of the three stages by applying the techniques developed for small plants to the decommissioning of commercial-size power stations. Nevertheless, continued development in some areas to reduce worker exposure, costs, and waste volumes is desirable. Such areas include the development of better equipment and methods for remote dismantlement to reduce worker exposure, the development of better methods to discriminate among radioactivity levels in waste quickly, methods to process wastes rapidly, and techniques

for minimizing waste generation through treatment and volume reduction. New equipment is expected to improve worker protection and reduce costs. Many major decommissioning projects currently in progress or planned increase the available knowledge substantially.

Cost and Availability of Funds

While safety considerations are given priority, the costs of decommissioning can also be a very important factor. At the end of the facility's operations, immediate dismantlement to Stage 3 would obviously be much more costly than to remain at Stage 1. If funds for decommissioning have been set aside while the facility is operating, the immediate cost will be less important than if the decommissioning costs must compete for funds with the owner's other capital needs. In order to prevent this item from becoming a controlling factor, plant owners should plan to have funds set aside to cover the cost of the chosen decommissioning strategy, which in any case would, at most, increase electricity generation costs by only a small percentage.

Social and Other Considerations

Certain social factors should be taken into account when evaluating the decommissioning options. For example, the chosen strategy could affect land values, the aesthetic aspects of the site, and perceived risks associated with the long-term shutdown and delayed dismantlement of a plant on the site. Another consideration, particularly important in areas where employment is scarce, is that immediate dismantlement requires a larger staff and work force than other strategies, resulting in a slower and smoother reduction of the number of job posts.

1.4 Decommissioning in the World

As of 31 December 2007, 119 power reactors, of a total of 557 constructed worldwide, have been shut down and 438 are still in operation. The age of operating reactors ranges from less than 1 year, in the case of new facilities, to up to 41 years.  [Figure 2](#) shows the number of reactors still in operation by age (years from first connection to grid). As of 31 December 2007, 129 (29.5%) of power reactors still in operation are more than 30 years old, 341 reactors (77.8%) are more than 20 years old, and 97 reactors (22.2%) are 20 years old or less. The worldwide distribution of nuclear power reactors definitively shut down as of 31 December 2007 is shown in  [Table 1](#).  [Table 2](#) shows the worldwide distribution of power reactors under decommissioning process. Theoretically, the operational lifetime of power reactors, and hence the needs for decommissioning, can be predicted from the reactor's type or from the operational license issued by the respective regulatory authority.

Over the past 35 years, considerable experience has been gained in decommissioning various types of nuclear facilities. To date, 119 commercial power reactors, as well as over 250 research reactors and a number of fuel cycle facilities, have been retired from operation.

To decommission its retired gas-cooled reactors at the Chinon, Bugey, and St. Laurent nuclear power stations, Electricité de France chose partial dismantling to Stage 2 and postponed Stage 3 dismantling for 50 years. As other reactors continue to operate at those sites, and monitoring and surveillance do not add to the electricity cost. The French are building at Marcoule a recycling plant for steel from dismantled nuclear facilities. This metal contains some activation products, but it can be recycled for other nuclear plants.

Decommissioning has begun at ten UK reactors. For instance, at the Berkeley nuclear power station (2×138 MWe, Magnox reactors), closed for economic reasons in 1989 after 27 years of operation, defueling was completed in 1992. The plant may now be left for 30 years, after which a

Figure 2
Number of power reactors in operation by age as of 31 December 2007 (IAEA 2008)

containment may be built around the residual buildings for a further storage period of perhaps 100 years.

Japan's Tokai-1 reactor, a UK Magnox design, was decommissioned after 30 years of service in 1998. After 5–10 years storage, the unit will be dismantled and the site released for other uses. Total cost is expected to be about 25 billion yen.

Germany chose more rapid direct dismantling over safe enclosure for the closed Greifswald nuclear power station in former East Germany, where five reactors had been operating. Similarly, the site of the 100-MWe Niederaichbach nuclear power plant in Bavaria was declared fit for unrestricted agricultural use in mid-1995. Following the removal of all nuclear systems, the radiation shield and some activated materials, the remainder of the plant was below accepted limits for radioactivity and the state government approved final demolition and clearance of the site.

The 250-MWe Gundremmingen-A unit was Germany's first commercial nuclear reactor, operated from 1966 to 1977. Its decommissioning work started in 1983, and moved to the more contaminated parts in 1990, using underwater cutting techniques. This project demonstrated that decommissioning can be undertaken safely and economically without long delays, recycling most of the metal.

^a Adopted strategy:

- 1 = Immediate dismantling and removal of all radioactive materials
- 2 = Deferred dismantling, placing all radiological areas into safe enclosure
- 3 = Deferred dismantling, including partial dismantling and placing remaining radiological areas into safe enclosure
- 4 = On-site disposal, involving encapsulation of radioactive materials
- 5 = Other

^{b,c} Current phase:

– For decommissioning:

- 1 = Drawing up the final decommissioning plan
- 2 = Reactor core defueling
- 3 = Waste conditioning on-site (only for decommissioning waste)
- 4 = Waste shipment off site (only for decommissioning waste)
- 5 = Safe enclosure preparation
- 6 = Partial dismantling
- 7 = Active safe enclosure period
- 8 = Passive safe enclosure period
- 9 = Final dismantling
- 10 = Final survey
- 11 = License terminated (end of decommissioning process)

– For fuel management:

- 1 = Transfer to at reactor facility
- 2 = Transfer to away from reactor facility
- 3 = Storage in an on-site facility
- 4 = Storage in an off-site facility
- 5 = Shipment to a reprocessing plant
- 6 = Under water storage
- 7 = Dry storage
- 8 = Encapsulation

Experience in the USA has varied, but 14 power reactors are using the Safstor approach, while 6 are using, or have used, Decon. Procedures are set by the NRC.

For the Trojan plant (1,180 MWe, PWR), Safstor was combined with some dismantling, but the timescale is typical and the task was undertaken by the utility itself. The plant closed in 1993, steam generators were removed, transported, and disposed at Hanford in 1995, and the reactor vessel was removed and transported to the Hanford disposal site in 1999. The buildings are being decontaminated, but demolition is not planned until 2018.

Rancho Seco (913 MWe, PWR), which was closed in 1989, will be in Safstor until 2008, till funds are available for dismantling.

At multiunit nuclear power stations, the choice has been to place the first closed unit into storage until the other ones end their operating lives, so that all can be decommissioned in sequence. This optimizes the use of the staff and the specialized equipment required for cutting and remote operations and achieves cost benefits.

Then, after 14 years of comprehensive cleanup activities, including the removal of fuel, debris, and water from the 1979 accident, Three Mile Island 2 was placed in post-defueling monitored storage (Safstor) until the operating license of Unit 1 expires in 2014, so that both units will be decommissioned together. Safstor was also adopted for San Onofre 1, which was closed in 1992, until licenses for Units 2 and 3 expire in 2013, but after NRC changes, dismantling was brought forward in 1999.

A US Decon project was the 60-MWe Shippingport reactor, which operated commercially from 1957 to 1982. It was used to demonstrate the safe and cost-effective dismantling of a commercial scale nuclear power plant and the early release of the site. Defueling was completed in 2 years, and 5 years later the site was released for use without any restrictions. Because of its size, the pressure vessel could be removed and disposed of intact. For larger units, such components will have to be cut up in many pieces.

Immediate Decon was also the option chosen for Fort St. Vrain, a 330-MWe high temperature gas-cooled reactor which was also closed in 1989. This took place on a fixed-price contract for 195 M\$ (hence costing less than 1 cent/kWh, despite a short operating life) and the project proceeded on schedule to clear the site and relinquish its license in 1997, the first large US power reactor to achieve this.

2 Decommissioning Organization and Management

2.1 Overview

Careful planning and management are essential to ensure that decommissioning is accomplished in a safe and cost-effective manner. Guidance on organizational aspects may lead to better decision making, reductions in time and resources, lower doses to workers, and reduced impact on public health and the environment.

Published information on organizational aspects of decommissioning is scarce in comparison with that on technological aspects. The United Nations Organization-International Atomic Energy Agency (UNO-IAEA) recently published a dedicated report on the experience available globally on organizational aspects of decommissioning. Older IAEA Technical Reports discussed planning and management aspects for decommissioning research reactors and other small nuclear facilities; planning and management were also dealt with as one part of the overall decommissioning project.

The decommissioning of a large nuclear facility is a major project. Thus, best project management and organization practices, tools and techniques, and QA processes are vital. A dedicated waste management strategy is essential for safe and cost-effective decommissioning. Clear lines of communication among all interested parties and responsibilities and accountabilities are of great importance.

A decommissioning project is subject to continuous change, and procedures for the management of changes are essential, starting with a timely plan to deal with the social impact that can occur during plant shutdown.

Clearly stated end states of the decommissioning activities are established. The end states are derived from the objectives of the organization charged with completing the work and are in compliance with the requirements of the regulatory body and other organizations. Further, the agreed upon end states will be readily verifiable, independently measured, and reported in a quantitative way.

The safety of the workforce, public, and environment is paramount throughout the decommissioning project.

Adequate funding provisions are essential prior to implementing the decommissioning process and regular reviews are undertaken to ensure that adequate provisions are in place throughout the decommissioning project.

It is important that the Decommissioning Project Manager (DPM) be identified and the decommissioning team established in time to allow the development and approval of the decommissioning plan. It is important to use a dedicated organization with the necessary responsibilities and qualifications.

Key personnel from the operating facility staff are normally part of the decommissioning management team due to their familiarity with the facility and its systems.

The licensee remains in control and possesses sufficient in-house experience to understand the safety requirements even if use is made of contractors during decommissioning. Assurance is required that contractors provide a service of adequate quality.

The actual organization of the decommissioning team can vary greatly and should be based on the expertise of individual team members, the type of facility, the decommissioning strategy, and government policies. The team composition may also change during the progress of the decommissioning project.

Management of interfaces with organizations external to the decommissioning team is important. This ensures that all interested parties are kept informed of the project's progress and have an opportunity to properly manage their input.

2.2 Issues Affecting Decommissioning Organization and Management

2.2.1 Decommissioning Strategy

Early planning of decommissioning activities provides a sound basis for decommissioning cost estimation and funding provisions. As already discussed, planning for decommissioning begins during the design of the facility and continues during its construction and throughout its operational life. In the case of a facility that is shut down without a decommissioning plan, such a plan should be prepared without undue delay.

There are several important elements (spent fuel management, availability of disposal routes for any radioactive waste generated) influencing the choice of a decommissioning

strategy (immediate dismantling, safe enclosure, and deferred dismantling). But the choice of the strategy for decommissioning is essential to define the timing and sequence of decommissioning activities. A generalized decommissioning strategy can be characterized as follows:

- Carry out a post-operational cleanup and achieve the safe enclosure stage of decommissioning as soon as possible after normal operations have ceased so as to minimize future care and maintenance costs and maximize the use of operational experience
- Dismantle more completely if this is justified by safety, environmental protection, economic or social considerations, or by making maximum use of existing expertise
- Defer dismantling, in other cases, until disposal routes for the radioactive wastes generated are available, or if this reduces substantially the total dose through radioactive decay

For facilities such as nuclear power plants, it may be cost effective to defer dismantling if the site is not required for other reasons or if all nuclear power plants on the site will be dismantled in sequence. Dismantling may be undertaken to allow the reuse of buildings or part of the site, if the space is required, or to reduce surveillance and maintenance costs. For smaller facilities immediate total dismantling may be the best solution. As a general rule for radioactive decay considerations, alpha contaminated facilities should be decontaminated and dismantled soon after closure, whereas facilities involving beta and gamma contaminated or activated materials often benefit from radioactive decay and hence from deferral of the decommissioning work.

The policies of the country and the licensee, with respect to the discounting of future costs, will have a major impact on what project work is judged economic to perform to lower surveillance costs. Considerations influencing decommissioning options are discussed in several IAEA publications.

2.2.2 Safety Issues

The protection of the public, the workforce, and the environment is a major factor in the organization and management of the overall decommissioning project. Compliance with all legal requirements, both national and international, is essential. To achieve appropriate standards of safety during the lifetime of the project, the safety documentation is refined and reviewed as required. In this way, it can be ensured that the safety documentation correctly and accurately reflects the status of the decommissioning project and provides the necessary demonstration and justification that the safety standards are being applied.

By applying the standards, the licensee has access to appropriate health and safety expertise to provide advice, auditing, and peer review of the safety documentation. Results of monitoring and surveillance need to be properly interpreted and recorded, and the licensee must be able to take preventive and remedial action as needed.

2.2.3 Work Approaches

Normally, decommissioning operations begin at sites which already have an operating staff. There are two general approaches that can be followed to accomplish the decommissioning of a facility, both of which have a substantial effect on project organization:

- The licensee performs the decommissioning with in-house resources supplemented by specialist contractors as needed

- The licensee contracts with an experienced outside organization to perform the decommissioning and provides general oversight and support services

In both cases the licensee must have control of the project. In order to maintain this control efficiently, the licensee is required to be the overall project manager. The licensing regime is based on the premise that the licensee is in day to day control of the facility, processes, and activities and that its staff manages the operation of the facility. Therefore, the licensee needs to be able to demonstrate that an adequate organization is (and will be) in place in order to discharge these responsibilities until the facility is finally removed from regulatory control.

The licensee must weigh all the options carefully and select the option best suited to fulfill its needs, such as cost–benefit, safety, and environmental considerations, as well as social benefits. Multi-attribute analysis is a useful technique to assist the decision making process.

2.2.4 Impact on Staffing

There are inevitable constraints on the approach to staffing for decommissioning. For example, in a reactor plant, staff numbers are likely to be held close to operating plant levels until the fuel has been removed and primary circuit decontamination has been completed. The number of people needed then falls, and the skills needed by the staff becomes somewhat different from those in operation (➤ Fig. 3).

In the USA it is estimated that a single-unit nuclear power plant undergoing early dismantling has a workforce in the range of 100–200 persons. This is approximately one third to one tenth of the number of persons originally employed. During the safe enclosure period the numbers of staff are reduced further to between 20 and 70. For a multiunit power plant site, each unit in safe enclosure would require a staff level of 20 or fewer because common resources are

■ Figure 3
Staff reduction profile during decommissioning

shared. Within the safe enclosure phase for a single-unit facility, staff numbers will increase to 100–200, supplemented by contractor personnel to carry out the remaining dismantling activities. Within these constraints, a range of approaches can be adopted to suit the plant and the social environment in which it is situated. There are a number of basic points to be addressed and important decisions to be made on the following:

- Staff reduction profile
- Use of operating staff to undertake decommissioning project tasks
- Sharing key resources among different plants
- Policies for choosing what work will be put out to contract

The staff reduction profile depends on the work to be done. When such a profile has been established, commitments can be made to staff as to the length of their remaining employment, and progress on staff reduction can be monitored against the planned profile. Maintaining a high number of operational staff necessitates that they undertake decommissioning tasks. This requires training in new skills and reorientation of attitudes towards a project completion outlook.

The use of an outside contractor to perform most of the decommissioning activities may have a negative impact on the local workforce. In order to encourage a job completion attitude, it is helpful if arrangements can be made to guarantee future relocation of staff to other plants, projects, or similar organizations. One way of approaching this would be to form teams of skilled, experienced personnel who could effectively provide services to similar plants as contractors.

It is important to provide appropriate incentives to staff (and contractors) to work effectively and in a manner that completes the decommissioning program safely within the schedule and budget, encouraging staff to seek completion of the work rather than apparently perpetuating their jobs through delay.

Even when using outside contractors, the licensee remains accountable for safety on-site. As such, the licensee is required to have systems in place that guarantees that the contractor personnel are suitably qualified and experienced, and can understand the hazards on the site and are adequately supervised.

2.3 Organization and Management in the Various Phases of Decommissioning

2.3.1 The Planning Phase

In the period well in advance of final shutdown, the decommissioning-oriented organization does not need to be large or employed full-time. The expertise required includes aspects such as decommissioning, waste management, cost estimation, and licensing. Assistance is needed from personnel with detailed knowledge of the plant, technical experts, and planning system specialists. It is also important for this team to learn from experience elsewhere so as to be able to consider the range of options available.

As planning for decommissioning is important but not necessarily urgent, it may tend to be treated as of lower priority than the operational problems. The decommissioning team needs to be protected from such diversions. It will also be appropriate to supplement the core team with

Figure 4
Decommissioning oriented team during plant operation

additional personnel from the licensee's organization, spending limited periods attached to the team to contribute an essential practical element.

The team reports to the senior management, who is not responsible for day to day operations of the plant. A major benefit of the work of the team is establishing accurate decommissioning costs and risks, which could provide important information for allocating and managing the decommissioning fund. The cost of a small organization such as this should be considered an investment in order to achieve a better managed decommissioning project. A simple functional structure could be as depicted in [Fig. 4](#).

Once a decision has been made to decommission a facility, and preferably before operation ends, it is essential to identify and appoint a DPM having the required skills, qualifications and experience, and with the necessary authority. The DPM, in consultation with the management of the operating organization, should set up a decommissioning project management team to perform the necessary project planning. This includes the development of a decommissioning plan, and its approval where necessary, and control of the resources during the physical decontamination and dismantling activities. As decommissioning proceeds, the decommissioning project management team expands to include persons with necessary and adequate qualifications and experience.

2.3.2 The Transition Phase

There are two main transition periods associated with any decommissioning project:

- The transition from an operating facility to the decommissioning period
- The transition from the dismantling period to a post-dismantling period (restricted or unrestricted site release and reuse)

The first transition period takes the facility through a deactivation phase after it has been shut down. During this period, many hazards connected with the operational phase are removed before turning the facility over to the decommissioning team. This includes removal of the spent fuel, draining of systems, and removal of the waste generated during operation. The management structure always reflects the changing circumstances and continuing responsibility of the licensee for the operation, including decommissioning, of the licensed site.

In moving from operation to decommissioning, a cultural change is needed, which is reflected in the appointment of the decommissioning team. [Table 3](#) shows the differences between decommissioning and operational states.

The organization at the commencement of decommissioning will be that which has ended the operational phase of the plant's life. In some cases, a new operator takes over the decommissioning process. Even in these cases, however, most of the operating team is likely to be retained

■ **Table 3**

Differences between decommissioning and operational states

Decommissioning state	Operations state
Temporary design life of structures to assist dismantling	Permanent design of structures for operation
Safety management systems based on decommissioning tasks	Safety management systems on operating nuclear facility
Control based on as-built structures	Control based on drawings
Reduced safety risks but changing situation	Significant safety risks but permanent and routine
Management of changing situation during decommissioning	Management of steady state during operation
Reduced administrative infrastructure	Steady state administration infrastructure
Retraining staff for new activities	Routine training and refresher training
Visible end of employment – refocus their work objective	Permanent employment with routine objectives
New or developing regulations/regulatory requirements	Established and developed regulations for operation

for the initial phases of decommissioning. The operating team needs to evolve to suit the job. Part of the planning is to define how the changes in the organization, staffing, contractor usage, usage of mobile teams, etc., are controlled and when these changes occur, bearing in mind that at least part of the decommissioning project team needs to be in place before operation ends.

During the transition period, plant operations, maintenance, and provision of emergency arrangements are still required and may form a separate part of the organization, which should be derived from the team that operated the facility. This approach may profit from the accumulated experience and help reduce local employment concerns.

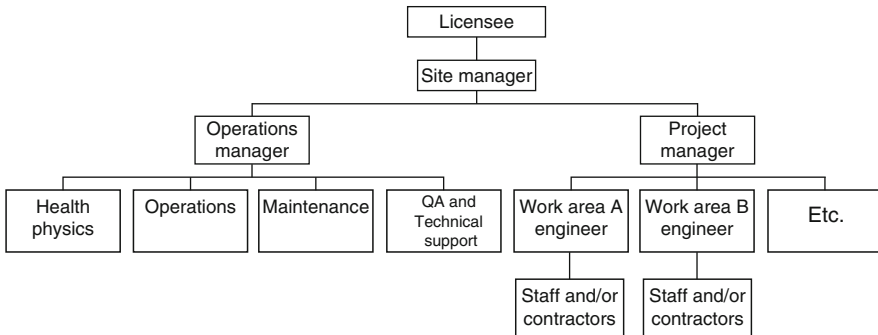

In some cases, this organization may continue into the decommissioning period for some time. A reasonable structure for the site management is depicted in ► [Fig. 5](#).

2.3.3 The Active Phases of Decommissioning

The management and organization during active phases of decommissioning work, either during immediate or deferred dismantling, is discussed in ► [Sect. 2.4](#).

2.3.4 The Safe Enclosure Phase

The safe enclosure phase, if any, is characterized by a plant of relative engineering simplicity requiring minimal operation, inspection, and maintenance and where the hazards are well defined and controlled, preferably in a state of passive storage. A minimal organization is in

■ **Figure 5**
Organization in the transition phase between operation and decommissioning

■ **Figure 6**
Organization in the safe enclosure phase

place during the safe enclosure phase: as it is a phase of stability rather than of change, there are few or even no project staff. It is presumed that sufficient work has been performed to allow relaxation of the need for emergency arrangements of any size. The necessary measure for the physical protection of the facility may also be reduced. Finally, off-site environmental monitoring may also be scaled down.

As a specific example, the Dresden-1 BWR decommissioning project was part of a multi-plant site that was aimed at safe enclosure. This project required seven permanent staff and was supported by 27 persons from other parts of the site organization providing services such as security and emergency planning.

Construction and maintenance organizations would support the project on an as-needed basis.

The size of the safe-enclosure phase organization depends on the level of dismantling and stabilization/immobilization of wastes that has been undertaken. It may even be appropriate to utilize multi-site mobile teams to perform much of the dismantling work. A simple structure is outlined in [Fig. 6](#).

A significant degree of multi-skilling may reduce staff numbers in this organization. Links to a centralized organization would also reduce the number of staff on-site, particularly for a multi-plant site licensee. The role related to record maintenance is very important to the successful completion of decommissioning.

2.3.5 The Post-Dismantling Period

The second important transition phase previously mentioned is from the dismantling period to another state, which might vary depending on the final end point of the decommissioning project. This end point could be either an authorized reuse for other purposes after specified conditions have been met, or the unrestricted release or clearance of the site. Depending on specific circumstances, authorized release of the site may or may not imply the continued presence of a surveillance unit, whereas clearance implies that all organizational units regarding decommissioning will disappear. Until the site release criteria have been met, it remains a nuclear site with associated controls. The persons responsible for record keeping will then transfer relevant records as required by the regulatory body.

Site remediation may be required to meet authorized reuse or clearance criteria. This could involve several activities such as radiological clearance or immobilization, removal of remaining nonradioactive structures, and landscaping.

A final report is prepared and presented to the regulatory authorities before the decommissioning team is dispersed towards other duties and while all relevant data, experience, and knowledge are still readily available. This report demonstrates that the facility and associated areas have been decommissioned to the state specified in the decommissioning plan, or in approved modifications to the plan.

2.3.6 Spent Fuel and Waste Storage

Spent fuel or some decommissioning waste may remain stored on-site in an independent facility after decommissioning. Provisions are made by the licensee to assign personnel with sufficient experience to the responsibility for the long-term care, maintenance, surveillance, and safeguards of such storage arrangements.

2.4 Management for Active Phases of Decommissioning

2.4.1 Overview

Decommissioning planning addresses issues such as worker and environmental protection, preparation of plans, safety assessment, working procedures, time schedules, training, and other technical and administrative aspects. Appropriate additional management, technical, and administrative personnel may need to be recruited and assigned responsibility for one or more functions. It is important to select persons who are technically or professionally qualified and have related practical experience. In particular, persons experienced in coordination, management, and engineering are assigned to the decommissioning project in an early phase, so that they can start effective planning and can successfully accomplish it without undue delays.

For extensive projects such as decommissioning large nuclear facilities, it is helpful to identify important technical, operational, and administrative aspects when defining individual management requirements, even if these aspects may be managed by the same personnel.

2.4.2 The Decommissioning Management Team

The decommissioning team includes staff having all the skills, qualifications, and experience necessary for the decommissioning task, together with a suitable supervisory structure under which it can operate. It is preferable, particularly in the early stages of the project, to include, in the decommissioning team, persons who were involved in the operation of the facility and have knowledge of the plant and its history.

Experienced staffs are preferred, and the team is built up so that all persons are suitably qualified for the tasks they have to perform. Training programs may be established to ensure that the staffs meet the requirements during decommissioning and that records are kept to demonstrate the adequacy of the training. Also, training of the decommissioning team would allow them to perform the decommissioning in accordance with current standards in technology.

The responsibility for managing and implementing the decommissioning project is with the licensee, who appoints a DPM. This is the best way to ensure maximum management commitment, motivation, and understanding of requirements for the program. The DPM would act on behalf of the licensee and would be in charge of the detailed aspects of the planning and management of the decommissioning program.

The DPM selects and recruits a decommissioning management team and assigns specific responsibilities to each group within the organization. The DPM implements the strategy to allocate all or part of the decommissioning program to external organizations. Basic requirements for a decommissioning team are the same, irrespective of who carries out the operations.

Possible functional organizational structures for a decommissioning management team required to successfully implement and complete the decommissioning of a facility are shown in  [Fig. 7](#) (management team where the licensee performs most of the decommissioning tasks using in-house resources) and in  [Fig. 8](#) (management team where the licensee hires an outside organization to perform most of the work and the licensee provides supervision and verification of the activities). In either case, the licensee retains overall responsibility for the project and ensures that all regulatory authority requirements are fulfilled.

Many details on aspects such as workforce requirements, work plans and procedures, selection of speciality contractors, and scheduling for the decommissioning of reference nuclear installations are given in a series of publications by the US NRC.

2.4.3 Change Management

The period between the announcement to shut down a nuclear plant and the start of decommissioning may pose significant challenges to plant management. They need to prepare for new technical and organizational challenges in a climate where there could be pressure to reduce staff numbers. Moreover, increased levels of uncertainty can threaten staff morale and commitment, and the decision to shut down may itself be preceded by periods of rumor and uncertainty. In an industry where security of employment has often been taken for granted, this may be unsettling for plant personnel. The plant management needs to put in place a timely plan to deal with social impact that may occur during plant shutdown.

The move towards decommissioning can thus be regarded as a process of major organizational change. So far, attention has largely focused on the technical aspects of decommissioning,

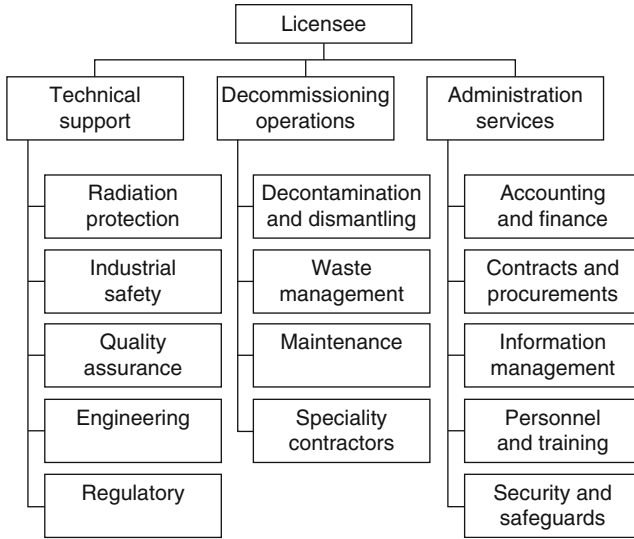

Figure 7
Organization chart: licensee performing decommissioning

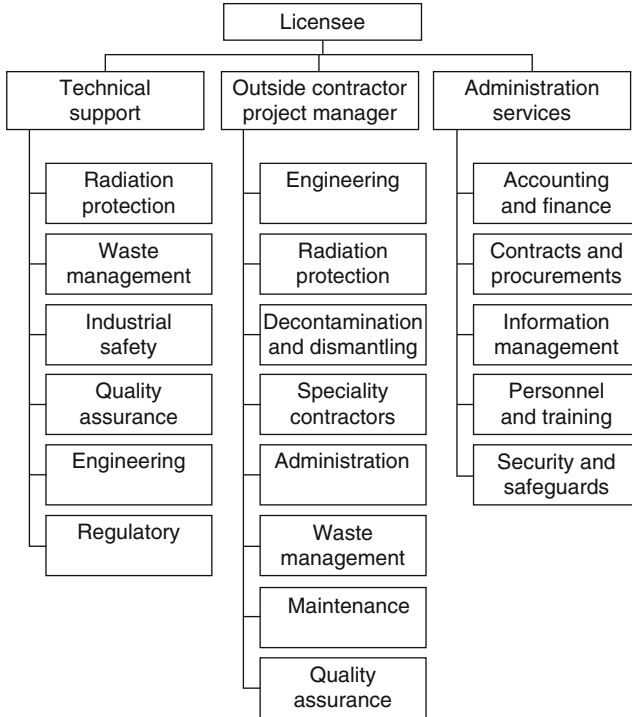

Figure 8
Organization chart: licensee with outside contractor performing decommissioning

with relatively little attention given to organizational and other human factors. Nuclear licensees have embarked on extensive change programs in recent years to reduce fixed costs and to enhance the profitability of their companies. This has involved proposals to achieve significant reductions in personnel. These changes need to be carried out in accordance with rigorous and comprehensive management of change arrangements.

One essential point regards the licensee's considerations as to whether and how any proposed organizational change might impact upon safety. In the context of decommissioning, the organizational challenge is heightened by the changing demands on the workforce. Not all proposed organizational changes have the potential to affect safety. However, where changes involve the loss or redeployment of personnel who have a safety or support role, analysis of the organization's need for the safety function and the way in which it is carried out, both currently and in the future, has to be performed. At all times the licensee's organization remains able to meet projected resource and competence needs.

Decommissioning is often a stage of the plant's life-cycle where large numbers of external contractors are employed. These groups bring specialist skills to bear which were not called for during normal operation. Contractorization may also be viewed by plant management as a way of making up for any shortfalls in staffing levels which have resulted from the premature release of experienced staff (e.g., those who have secured early retirement deals or who have moved to jobs elsewhere which appear to offer a more secure future).

Contractorization can bring benefits, but it is very important that the licensee retains sufficient competent personnel to understand, own, and use the plant safety case, and to act as "intelligent customer" for work by contractors. This is especially important during decommissioning. Older plants may not have a comprehensive set of drawings and procedures, so that many historical aspects of plant design and operation which need to be accessed during decommissioning are vested in individuals rather than in paper work. These persons have to be retained as long as their knowledge and experience can plausibly be required, and it is also preferable that this experience be documented in a form available for use by other personnel.

2.5 Decommissioning Planning and Licensing

2.5.1 Overview

Successful decommissioning depends on careful and organized planning including clear identification of the objectives of the decommissioning process. The end states are derived from the objectives of the organization charged with completing the work and are in compliance with requirements by the regulatory body and other competent authorities. Moreover, the agreed upon end states will readily be verifiable and can be independently measured and reported in a quantitative way.

Once a strategy has been developed, the decommissioning plan is prepared for each nuclear facility. The extent of such plans and their content and degree of detail required may be different, depending on the complexity and hazard potential of the nuclear facility and on regulations. Typical contents of a final decommissioning plan are indicated in [▶ Table 4](#).

Planning to allocate adequate financial resources to ensure the decommissioning of a nuclear facility is made preferably at the early stages of the plant's life-cycle. Especially in the case of deferred decommissioning, where there may be long safe enclosure periods, these

■ **Table 4**

Example of contents of a decommissioning plan

Section	Contents
Introduction	Objectives, scope, goals to be achieved
Facility description	Physical description of the site and the facility and its operational history Radioactive and toxic material inventory
Decommissioning	Objectives, decommissioning alternatives strategy Selection and justification of the preferred option
Project management	Resources Organization and responsibilities Review and monitoring arrangements Training and qualification Reporting and records Risk management
Decommissioning activities	Decontamination and dismantling activities Waste management Maintenance programs
Safety assessment	Dose prediction for tasks, demonstration of ALARA for tasks risk and uncertainty analyses Operating rules and instructions
Environmental impact assessment	Demonstration of compliance with environmental standards and criteria
Quality assurance program	Setting up a QA (quality assurance)/QC (quality control) program Verification of compliance with established QA requirements
Radiation protection and safety program	Radiation monitoring and protection systems Physical security and materials control Emergency arrangements Management of safety Justification of safety for workers, general population and environment
Continued surveillance and maintenance	Development of surveillance and maintenance programs
Final radiation survey	Demonstration of compliance with the cleanup criteria
Costs	Cost estimate Provision of funds

financial provisions are reviewed periodically and adjusted, if necessary, to allow for inflation and other factors such as technological advances, waste disposal costs, and regulatory changes. Responsibility for this review may reside with the licensee, the regulatory body, or other parties depending on the national legal framework.

A radiological characterization and material inventory assessment is carried out for the facility at the early stages of decommissioning planning. This provides support for a number of activities, including waste management, decontamination and decommissioning methodologies, and safety and environmental assessments.

A safety and environmental impact assessment (EIA) forms an integral part of the decommissioning plan. The licensee is responsible for preparing this assessment and submitting it for review by the regulatory body, as required. The safety and EIA should be commensurate with the complexity and the associated hazard potential of decommissioning.

2.5.2 Decommissioning Planning

Planning for decommissioning is an essential prerequisite to ensure that decommissioning activities can be accomplished in a safe, timely, and effective manner. The licensee is responsible for this planning. The regulatory body provides guidance in this respect, and reviews and approves the decommissioning plan before the start of decommissioning activities.

Successful decommissioning depends on careful and organized planning including clear identification of the objectives of the decommissioning process. The end states are derived from the objectives of the organization charged with completing the work and are in compliance with requirements set by the regulatory bodies and other authorities. Moreover, the agreed upon end states will readily be verifiable and can be independently measured and reported in a quantitative way.

When the timing of the final shutdown of a plant is known, the licensee should initiate detailed studies and finalize proposals for decommissioning.

If the selected decommissioning option results in phased decommissioning – with significant periods of time between phases – the higher level of details may only be required for the next immediate phase being executed.

After a general plan has been developed, detailed planning and engineering can begin. As detailed data are made available from the radioactive inventory of the nuclear facility and the site characterization program, decisions on the handling of components, structures, and soil can be made.

Multiple levels of planning documents are usually prepared. A hierarchical work breakdown structure is developed to divide the work into manageable packages, which identify what has to be done and how, and addresses the basic safety considerations of the activity. Another level of documents is constituted by the detailed work procedures.

2.5.3 Stages of Planning

Three stages of planning are envisaged:

- Initial planning
- Ongoing planning
- Final planning

A preliminary plan for decommissioning should be prepared by the licensee before a license application for a new facility is submitted. A generic study showing the feasibility of decommissioning may suffice for this plan. In any event, the plan need not be compiled in detail since many factors in the future can affect it, for example, improvements in technology and changes in regulations and government policy. Environmental aspects of the decommissioning, such as the quantities of wastes and radioactive effluents, should be considered during the initial planning. The plan should also address the costs and the means of financing the decommissioning work. In some countries, the regulatory body requires that the licensee to provide a preliminary cost estimate and assurance of funding.

During the operation of a facility, the preliminary plan should be reviewed in respect of the ease of decommissioning, the environmental impact and, where applicable, cost estimates and financial provisions. All significant system and structural changes should be documented in technical files and kept available for those responsible for the final planning of decommissioning activities. Records of spills or spread of contamination, including details of the radio nuclides involved and their quantities, should be retained.

Regular audits should consider such aspects as operational procedures that may have impacts on decommissioning and operational records and other documentation which is useful for the final decommissioning plan.

When the date and circumstances of the final shutdown of a nuclear facility are known, an application for permission to decommission the facility must be submitted to the regulatory body without undue delay.

In many cases, steps such as the final shutdown, reduction of staff, management of operational wastes, measurements for inventory determination, transport of fissile materials off the site, and decontamination to facilitate decommissioning may be taken under the provisions of the operating license or amendment thereof.

In support of the application to decommission a facility, a decommissioning plan must be submitted for approval and must include a safety assessment and an appropriate level of environmental assessment. If final (Stage 3) decommissioning is deferred, a revised decommissioning plan shall be prepared and submitted for approval before final dismantlement can begin.

Most planning steps are the same for all decommissioning options. The degree of detail required may, however, be different.

2.5.4 Content of Decommissioning Plan

When the timing of the final shutdown of a nuclear facility is known, the licensee should start detailed studies and finalize proposals for decommissioning. Following this, the licensee should submit an application containing the decommissioning plan for review and approval by the regulatory body. The decommissioning plan may require amendments or further refinements as decommissioning proceeds and may require further regulatory involvement.

If the selected decommissioning option results in phased decommissioning – with significant periods of time between phases – the level of detail of the items in [Table 4](#) may only be required for the next immediate phase being executed. As a result of executing an individual phase of the decommissioning, some modification of the planning for subsequent phases may

need to be done. In such cases, subsequent sections of the decommissioning plan may require updating and reviewing.

A decommissioning plan should typically include:

- Choice of the decommissioning strategy, with a description of the steps involved in effecting its completion. Generally, the rationale for the choice of a given strategy should be elaborated, with allowance for such factors as the availability of a waste disposal or storage facility, radiological aspects, and the long term integrity of buildings and structures.
- Description of techniques, tools, and procedures to be used for the decommissioning.
- Time schedule for the decommissioning.
- Analysis of radiological and nonradiological risks for workers.
- Environmental impact analysis, including estimation of maximum individual doses to the public and collective dose commitment from the airborne and liquid releases during decommissioning, as well as from steps such as transport, recycling, reuse, and waste management and residual activity on the site.
- Safety assessment and evaluation of the radiological consequences of postulated accidents during decommissioning.
- Results of surveys, special measurements, and calculations to determine the inventory and distribution of radionuclides in the facility.
- Description of the anticipated inventory (activity, volume, mass, location, physical, and chemical form) of radioactive, toxic, and hazardous material arising from the decommissioning and the manner of disposing of or recovering such material, including means for handling, transporting, and storage.
- Quality assurance program applicable to, including the qualifications of the organization proposing the decommissioning and its contractors.
- Description of the measures incorporated in the procedures and equipment to ensure that the basic principles of radiation protection, health, and safety are followed.
- Description of the methods for ensuring the availability and proper functioning of the systems and structures needed for radiation protection, health, and safety during dismantling. This is particularly important when only some parts of the structure and systems are being dismantled.
- Description of the methods proposed for the final radiometric measurements to ensure compliance with authorized limits for the release of equipment, materials, buildings, and the site.
- Emergency planning during decommissioning.
- Outline and format of the final decommissioning report to the regulatory body at the completion of the planned decommissioning.

2.5.5 Decommissioning Optimization

Consideration should be given at the design stage and subsequent phases of a facility to the various aspects that might optimize the process, with particular attention to:

- Funding
- Minimization of workers' exposure
- Minimization of waste production

Before any decommissioning activities take place, sufficient funds should be available. The owner/operator is responsible for ensuring that a fund for decommissioning is set up.

The cost estimate for decommissioning should include the costs of planning and engineering during the post-operation phase, decontamination, dismantling, and transportation and disposal of the radioactive wastes due to decommissioning. The costs of maintenance, surveillance, and security of the facility should be included if the decommissioning is done in several phases.

It is difficult to set up a decommissioning fund to cover the unplanned premature shutdown of a facility, since the condition of the facility varies considerably depending on the cause of shutdown and the type of facility. However, the financial consequences of such a shutdown may impose a considerable burden on the licensee as a result of obligations to the public (third-party indemnification) and the potential costs of the cleanup which may be required prior to decommissioning. Such funds may be assured through insurance schemes.

Some procedures and practices could aid decommissioning and reduce radiation exposures, as long as this does not reduce overall safety. These considerations may include, among others, an examination and assessment of material composition with the aim of reducing the radioactive inventory, and the provision of easily decontaminable surfaces and an effective system for storing, updating, and accessing records relevant to decommissioning.

Records to be retained should include drawings of structures, descriptions of equipment in areas where radioactive materials are used and the location of possible inaccessible contamination.

If the site is not to be treated for unrestricted release, the plant may be stored in a safe condition for a prolonged period. During this storage period, the facility should be adequately maintained and monitored. Physical security of the facility should be maintained as long as required.

Since some equipment and structures may be removed during this storage period, measures should be taken to prevent releases of radionuclides to clean areas and the environment. This may require periodic checking of some characteristic parameters selected as a result of an assessment of safety. Records should be kept of modifications to the facility to ensure that adequate information is available for conducting final decommissioning.

In support of the plan for deferred decommissioning, the licensee must submit to the regulatory body a description of:

- Maintenance of building and structures, including containment where applicable
- Physical security of the facility
- Systems necessary for keeping the nuclear facility under proper control, including air ventilation and monitoring systems
- Inspection and surveillance plan
- Environmental monitoring program
- Accident analysis
- Emergency planning
- Quality assurance program, including organization and responsibilities

For deferred decommissioning, it may be necessary to ensure that decommissioning funds are secured, and the necessary amounts are updated periodically to cover the cost of inflation during the period of deferment or that other appropriate steps are taken to ensure the availability of funds.

2.5.6 Project Risk Management

Experience has shown that large projects may fail to meet their objectives, in terms of time, cost, and quality. This is a particular concern for projects where there is limited previous experience, the technology has not fully matured and there are risks associated with technical performance. This could be the case for nuclear facility decommissioning and environmental restoration projects which may have uncertainties. Project failure may often be identified as resulting from events which had not been anticipated during project planning, but which might, by hindsight, have been accommodated if identified at the outset.

Accordingly, formal Project Risk Management (PRM) techniques have been developed to address these problems. Such techniques adopt the basic approach of attempting to identify all potential hazards before they materialize and implementing actions to prevent their materialization or to limit their consequences. The process includes commercial and managerial as well as technical risks. A further key role of formal PRM is the allocation of ownership of risk, i.e., the identification of the party who is responsible for a given risk and who bears responsibility for its management. Risk allowance as part of contract negotiation can help prevent disputes later during project implementation, and provide justification for any provision for risk to be made in pricing or program.

Typically, implementation of formal PRM involves the following key steps:

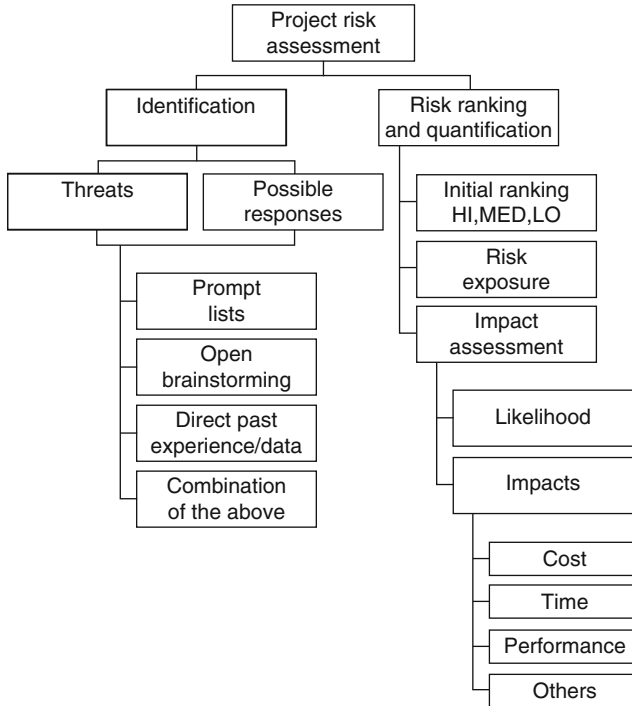

- Development of PRM strategy, to identify the objectives for PRM implementation in the given context and define the requirements for risk assessment, risk analysis, and risk management planning over the project life-cycle
- Risk assessment, a workshop to identify risks to project success and potential consequences (cost and program), as well as to identify possible actions that might be adopted to manage them (the logical process and implementation mechanisms of project risk assessment are described in  Fig. 9)
- Risk analysis, to quantify the overall impact of identified risks on project cost and program and to evaluate the effectiveness of potential responses
- Risk management, to select the preferred responses for addressing the identified risks and to allocate residual risks most appropriately among the parties involved. This is an ongoing process throughout the project.

2.5.7 Regulatory Approval

To ensure compliance with national, regional, and local regulations, standards and laws, it is important that the licensee, before or during the planning stage, identify all relevant legislations likely to be applied in the decommissioning program. If specific requirements for decommissioning have yet to be developed or finalized, decommissioning activities could be undertaken on a case by case basis under existing regulations; for example, the arrangements for carrying out modifications on operational facilities. In such cases, it would be advisable for the licensee to be in regular consultation with the regulatory body throughout the development and implementation of the decommissioning program.

The regulatory body or other competent authorities may review:

- The decommissioning strategy
- The decommissioning plans and programs

■ Figure 9

Summary of elements of project risk assessment and analysis

- The procedures employed during the decommissioning process, in particular clearance of materials/wastes
- The surveillance and inspections
- The safety assessments
- The funding provisions

The timescale for review of the decommissioning tasks by the regulatory authorities should not be underestimated. This can have a significant impact on the whole project time-scales and, consequently, on the costs.

The regulatory body verifies that the final condition of the facility meets the approved objectives established at the beginning of the project.

2.5.8 Work Packages and Procedure

While the decommissioning plan and safety and environmental assessment are being reviewed by regulatory bodies, detailed planning and engineering can begin. As detailed data are made available for the radioactive inventory of the nuclear facility and the site characterization program, decisions on the handling of components, structures, and soil can be made.

Multiple levels of planning documents are usually prepared; an example is described below. A hierarchical work breakdown structure is developed to divide the work into manageable packages, which identify what is to be done and how, and address the basic safety considerations of the activity. Another level of documents is constituted by the detailed work procedures.

The work packages identify the purpose and provide a description of the task, applicable criteria and the activity sequence of events. The criteria include engineering and technical requirements; health, safety, and environmental protection requirements; and reference to applicable standards. Work packages refer to other documents such as the Radiological Health and Safety Manual, Waste Management Manual, Security Plan, Quality Assurance Program, Fire Protection Program, etc.

The detailed work procedures identify the step-by-step instructions for performing each task, the required equipment and associated operating parameters (cutting speeds, gas pressures, power requirements, etc.), safety precautions and disposal methods, as applicable. Detailed work procedures are either general or specific work procedures. General work procedures are used for repetitive activities such as construction of contamination control tents, rigging and lifting, pipe cutting methods, and maintenance of filtered equipment (high-efficiency particulate air (HEPA) vacuum cleaners, ventilation units, liquid filtration systems, etc.). Specific work procedures apply only to unique tasks such as core dismantling activities or asbestos removal, where general work procedures cannot be fully applied.

As the work packages and detailed work procedures are developed, the baseline cost estimate, schedule, and personnel radiological exposure estimates are refined. These can then become the guidelines against which the project performance is measured.

The decommissioning plan identifies and justifies the decommissioning work activities. However, before work commences, work packages are developed for these activities and analyzed in sufficient detail to allow the decommissioning team to execute the work with a clear understanding and without the need for further significant explanation. The packages are arranged into interrelated groups, and a schedule of activities, usually represented by a bar or Gantt chart, is prepared. Formal project management techniques are applied to the creation and management of work packages. A critical path network, i.e., a diagram indicating the sequences and interdependencies of the various work packages may be used. The work packages are planned as soon as possible, because such planning greatly assists in the development of detailed cost estimates and the identification of specialist support and equipment that may be needed. Without this level of planning it is difficult to schedule the decommissioning of a large nuclear facility with any degree of certainty.

Procedures for allocating work packages to the decommissioning team are developed. Work monitoring arrangements are set up so that the project management schedule can be reevaluated when unexpected circumstances arise. The DPM holds periodic formal review meetings with all supervisors and safety staff to assess work done, current status of the facility, and future tasks. Each member of the team should then be aware of what is to be done next in other parts of the program and in other related activities.

From the formal project meeting, progress reports including revised cost estimates are prepared periodically and are presented to the regulatory body, licensee, and other authorities, as required, including the organization providing the funds.

2.6 Role of Quality Assurance

2.6.1 Overview

Any activity having an impact on the health and safety of workers, the public or the environment, or affecting the success of the project, is covered by a quality assurance (QA) program including management and organizational aspects. For such activities, it is necessary to have written procedures, documentation, control guidance on the selective applications of QA procedures, and accurate information and techniques to verify compliance with QA procedures.

A QA program continues to be needed for all activities to be controlled. It is generally adapted from the one used during operation, concentrating on those aspects associated with the management of change. As such, it needs to evolve throughout the decommissioning program. A number of phases can be seen in the program during decommissioning. To give an example, when a reactor is being defueled or the primary circuit is decontaminated, hazards, and activities are not dissimilar to those experienced during operation. During dismantling and demolition the management of change predominates, and the QA program needs to reflect that. At the end of the period of change, the site may go into surveillance with low staff numbers. At this stage, it needs a very simple QA program.

It is important to recognize that the reduction in costs, staff, and administration generally can be achieved by a progressive simplification of the QA program as decommissioning proceeds. This originates ultimately from an adaptation of the safety assessment case, because of lower nuclear hazards as work progresses. This allows a reduction in rules for operating plant systems, maintenance requirements, and their implementing documents. Plant items can be released from service and decommissioned. The overall effect is to reduce the need for staff. The QA program is designed to control this change process so that each step occurs in a coordinated way, and the QA program itself needs to evolve to suit the changing circumstances.

In performing the planning for the decommissioning project, it should be recognized that health and safety are not always affected to the same degree for every facility, and a graded approach to QA can be developed to ensure an adequate level of quality for factors such as maintenance and equipment reliability. Less stringent controls could be utilized for functions not affecting safety, but it must be justified.

The QA program is initiated before the decommissioning activities commence. A summary of the QA program is incorporated in the decommissioning plan and includes, as a minimum, the basic elements to be discussed in the following subsections.

2.6.2 Control of Modifications to the Plant

Procedures for carrying out modifications to the plant may have existed for the operational phase of the facility. These can be utilized, simplified where possible and adapted for the decommissioning phase.

2.6.3 Radiation Protection and Environmental Safety Control

The radiation protection specialist assesses the procedures and instrumentation that are used for various types of radiological and environmental survey to ensure appropriateness.

Decommissioning procedures are reviewed to ensure that the appropriate data for radiological assessments are being used. Criteria for the collection and analysis of radiological samples during the decommissioning process are reviewed by the radiation protection specialist. An independent analysis may be performed to ensure that the results are accurate and reproducible.

2.6.4 Control of Outside Contracted Services

Contractors are used for a wide variety of tasks. A common use is for a self-contained specific project. In such cases the licensee still maintains the capability of defining, monitoring, and supervising the work. However, contractors may also be employed to provide services such as health physics expertise, or maintenance. These contractors need careful management by the licensee to ensure that the licensee retains control of intellectual property and assets remain available to the licensee. If the contractor is replaced, a proper handover is arranged so that the new contractor's staffs are trained to be suitably qualified and experienced when they take over.

The licensee has the responsibility for ensuring that contractors achieve the required quality, although contractors are responsible for the quality of their own work. Once their detailed work plan is approved by the licensee, this assurance is achieved by a program of surveillance and inspections.

2.6.5 Surveillance and Inspections

Procedures of surveillance and inspections are an integral part of quality assurance. In facilities where most of the decommissioning work is carried out by external contractors, surveillance should be documented to show what was inspected, by whom, the results of the surveillance, and the corrective action if there was any nonconformance.

Internal quality audits may be performed to assure that all parts of the program are working properly.

Other inspection activities may include calibration of measuring equipment, verification of characterization, packaging and disposal of radioactive waste, or inspections of quality of materials and equipment purchased. The opportunity exists, during early surveillance and inspection work, to assess the as-built condition of the facility against the existing drawings and documentation. This assessment could be carried out when modifications to the facility are required.

2.6.6 Information Management

An important element to emphasize in the development of a QA program for decommissioning is the collection and retention of records and information relevant to the facility. In the case of deferred dismantling of a facility, the maintenance of accurate and complete information relating to the locations, configurations, quantities, and types of radioactivity and other

hazards remaining at the facility is vital to the successful and safe execution of surveillance and maintenance and of subsequent final decommissioning activities. Furthermore, for clearance, it is important to document that all radioactive materials and other hazards present at the beginning of decommissioning have been accounted for and their ultimate destination has been confirmed. It is also important to have documentary evidence that all cleared waste and materials and the site itself have been properly monitored before being released from regulatory control.

QA verifies the procedures and equipment which will be used to acquire, record, and manage important information related to all aspects of the program and ensures the retrievability of documentation. QA verifies that the records required at the end of decommissioning contain information on all operations described in the plan, including items such as:

- Records of waste or materials origin, processing, characterization, transport arrangements, and destination
- Details of the license, other authorization documents and all criteria and standards used during decommissioning
- Details of the equipment and procedures used
- All recommendations, audit reports, corrective actions, agreements, endorsements, and consents in respect of any stage of the decommissioning program
- All safety assessment documentation
- Any independent reviews prepared in accordance with national requirements
- All references cited in the safety documentation, or a statement as to where the referenced document can be located
- Drawings used during decommissioning activities
- Details of the final radiological survey for release of the site

Some operational records need to be retained during and after the decommissioning period for:

- Legislative requirements
- Aiding further decommissioning activities
- Possible litigation in the future

The characterization of records generally includes the following:

- Requirement for the record (e.g., which legislation)
- Record type (i.e., what is recorded)
- Retention period
- Producer of record
- Responsible holder of record
- Storage medium
- Storage location

The choice of a suitable storage medium is an important consideration. Four media are primarily in use today: paper, microfilm, editable electronic media (magnetic disks/tapes), read-only electronic media (CD-ROM image). 📌 *Table 5* summarizes the advantages and disadvantages of each medium. The solution will probably be a mixture of media to suit the record type, in all cases with adequate backup facilities. In any case, before the original record is destroyed, it is essential to establish the legality of the record keeping medium adopted.

■ **Table 5**
Advantages and disadvantages of record-keeping media

Medium	Advantages	Disadvantages	Costs
Paper	Readily available Storage understood Legally acceptable	Bulky Requires controlled storage conditions	Low
Microfilm	Compact Standard technology Legally acceptable	Awkward to access Requires controlled storage conditions	Medium
Editable electronic	Can be updated Compact	Need to keep hardware and software available Only useful for new records Corruptible Legality unclear	Medium
Read-only electronic	Compact Accessible Easy storage	Need to keep hardware and software available Legality unclear	High

2.6.7 Safety Audits

Periodic safety audits of decommissioning activities are performed and documented to evaluate the effectiveness of worker training, surveillance equipment operability and adequacy, management control, safety controls, compliance with ALARA, the emergency program, documentation systems, and exposure assessments. Audits also review and evaluate the conformance of established specifications and procedure requirements.

To review and track safety audit results, a safety review structure is established to implement an audit program and control the application of radiation protection and environmental safety policies during decommissioning. All necessary procedure requirements are established at the very beginning of the planning stage and should be appropriately documented.

2.6.8 Management, Assessment and Reporting of Incidents and Events

Procedures are in place and agreed with regulatory bodies and other competent authorities for the management, assessment, and reporting of incidents and events. This includes the reporting of incidents under the INES system.

2.7 Responsibilities and Qualifications

2.7.1 Licensee

Depending on the regulatory system, a specific license or authorization, different from the facility operating license, may be required to undertake any decommissioning activity. In some

cases, during the decommissioning period, the facility may be operated by a new licensee separate from the former licensee, but which, nevertheless, satisfies the requirements and is deemed competent to hold a license.

Although the licensee in charge is legally responsible for carrying out the decommissioning activities, including funding, in accordance with the regulatory requirements, the financial liability or funding sources for decommissioning may be held by one or more third parties. This is especially true for government-owned facilities. The licensee then ensures that adequate funds are available and committed before commencing any decommissioning activity.

The licensee is responsible for all decommissioning activities and directs the DPM to ensure the safety and cost effectiveness of the project. The licensee provides the necessary liaison with the regulatory authority and the public, and makes available adequate funds to ensure that decommissioning is completed. The licensee defines the limits of the DPM's delegated powers, which may vary among organizations.

2.7.2 Decommissioning Project Manager (DPM)

The DPM leads the project management group and is directly responsible to the licensee of the facility. This function coordinates and supervises all activities during the whole period of decommissioning or until the desired stage of decommissioning is achieved. The DPM directs the decommissioning team to ensure safety and cost effectiveness of the project. The DPM is responsible for controlling the expenditure of funds and ensures that the decommissioning can be completed within the available budget. The DPM is also responsible for managing staff numbers, skills, and organization to meet the objectives of the decommissioning project.

Typically, the DPM has previous project management experience in a radiological environment. It is preferable if the individual has previous experience in either decommissioning or large-scale maintenance or refurbishment.

Of major importance, during the whole decommissioning period, is for the DPM to monitor, control and evaluate expenditure and activity progress against budgetary estimations and the planned timescale. This involves generation and updating of expenditure profiles and percentage-completed-activity diagrams, together with data on key project milestones, and the extent to which milestones have been achieved or progress has been delayed. This information is essential for the overall management of the project. This enables optimal management of funds or reveals a lack of funding and a need for reevaluation of the further decommissioning activities. Furthermore, the evaluation of the real cost of performed decommissioning activities allow to redefine the cost of work packages, which can be integrated into the cost reevaluation of the resulting decommissioning activities. Finally, achievement of technical and safety milestones are also of particular interest to the regulatory body and the fund manager.

A key function of the DPM is to monitor the progress by meetings, regular reports, performance statistics, post-task and post-project reviews, and by benchmarking performance against similar projects, where available. It is only by monitoring and measuring performance that it is likely that deficiencies are identified and improvements can be obtained. Some suggested key performance indicators (KPI) are detailed in  [Table 6](#).

■ **Table 6**

Some performance indicators in decommissioning activities

Task	Performance indicators
Safety	Accident frequency rate per 100,000 h worked Radiation doses compared to ALARA assessments and legal limits Site reportable events
Project	Project lifetime decommissioning costs (cash and discounted) Waste volume quantities Surveillance costs Site infrastructure costs Estimated cost of subprojects to completion versus sanctioned sums Milestones achieved

2.7.3 Technical Support

The technical support includes staff experienced in technical topics such as radiation protection, industrial safety, quality assurance, and engineering, as discussed in the following section.

Radiation Protection

As part of the decommissioning plan, the radiological protection program is prepared and implemented to ensure the safety of workers and the general public, as well as protection of the environment. Such a program is intended to optimize the working methods according to the ALARA principle. It typically includes on-site, off-site and personal monitoring, record-keeping of dosimetric data and assessment of the results obtained. The involvement of skilled personnel and the use of adequate equipment for dosimetry, personnel protection, radiation and contamination surveys, and clearance measurements for materials/waste are crucial to the safe decommissioning of the facilities.

A radiation protection specialist is responsible for ensuring compliance with radiation work procedures. This person advises or directs the activities of the health physics technicians, who monitor all decommissioning activities and measure and record the radiological information. The radiation protection specialist maintains the occupational exposure records and develops and implements the radiological emergency preparedness plan.

The radiation protection specialist is the advisor to the project personnel on all matters relating to radiation protection. Experience with decommissioning activities is desirable. Including an operational health physics staff from the plant into the team could be of a great advantage, especially in old facilities where operational records may not be up to date.

Industrial Safety

A general industrial safety program must be prepared and implemented to ensure the safety and health of the workers and protection of the environment from nonradiological hazards. This is constructed to comply with all applicable health and safety legislation. Such a program includes approved safety practices, monitoring of worker areas, and identification or specification of the personnel's protective equipment.

An industrial safety specialist is responsible for developing and implementing the industrial safety policy. The specialist advises the project personnel on all industrial safety matters (e.g., fires, toxic substances, noise, dust, etc.) and develops and implements the nonradiological emergency preparedness programs. Consideration is normally given to the provision of medical surveillance for the decommissioning staff.

Quality Assurance

A quality assurance (QA) program is established at the earliest practical time during the decommissioning planning, consistent with the schedule of accomplishing the proposed activities. The program is designed to provide a flexible degree of monitoring of ongoing work, based on a detailed planning, inspection and auditing, and operated with a minimum of personnel involved.

A member of the decommissioning team is assigned the position of QA representative for the project and utilizes the QA department of the organization. To ensure the independence of the QA department, this group has direct access to the licensee, independent of the decommissioning team. The QA representative maintains audit and job records and verifies that established procedures are followed with support from the QA department of the organization. More details on QA during decommissioning are given further on.

Engineering

The engineering group is responsible for the detailed characterization of the facility and its systems and components, including current status and any historical information. The engineering group is also responsible for developing detailed work procedures and specifications for the scheduled tasks. They also identify the need for special equipment and tool and evaluate the technical side of the decommissioning subcontracting. The engineering group helps establish the plans and detailed task schedule, track progress, and identify any potential concerns. It incorporates specific radiological data provided by the radiation protection team. The engineering group and the radiation protection team work closely together, as required, during the decommissioning project.

The required engineering expertise can be drawn from the existing operating facility itself, supplemented by additional specialist resources as necessary. The group typically includes at least a civil engineer, an electrical engineer, and a mechanical engineer.

Regulatory Control

This group provides guidance to the decommissioning team for compliance with regulatory requirements during the decommissioning process. In this way, compliance with license requirements can be demonstrated. For this purpose administrative and technical resources are vital.

2.7.4 Decommissioning Operations

Personnel for the decommissioning operations group are drawn from the plant operations team wherever possible, to obtain maximum benefit from the experience acquired during the operation of the facility. In an organization performing decommissioning in-house, this group provides the workforce that performs most of the decommissioning activities. Typical functions of this group are described in the following sections.

Decontamination and Dismantling

The decontamination and dismantling group is responsible for performing the main actions associated with decommissioning operations in accordance with agreed procedures. This group dismantles or removes components from their design locations and packages the material for further processing. They may decontaminate or segregate components or structures to assist in dose reduction or to meet clearance criteria. This group may perform volume reduction at the removal site if this is more cost effective than having a centralized waste reduction facility operated by the waste management group. This group possesses the necessary skills and trades to carry out these tasks.

Waste Management

The waste management group is responsible for ensuring that requirements and procedures developed for the handling, treatment, conditioning, storage, and transport of the generated waste are met. This group ensures that the waste acceptance criteria are met, in particular, before shipment of the waste to the disposal site. They may be responsible for volume reduction if a centralized waste reduction facility is established, and in developing a waste minimization program. This group, together with the radiation protection and industrial safety groups, characterizes the waste and identifies the various waste streams including verification and compliance with clearance criteria. The waste management group arranges for transport and disposal of the waste and prepares the necessary documentation.

Maintenance

Before decommissioning commences, a routine inspection and maintenance program is implemented for all safety-related systems and components that are required to support the decommissioning activities (e.g., ventilation, fire control, water, filters, radiation monitors, specified pumps, motors, fans). These systems and components have to be maintained throughout the decommissioning project to comply with safety requirements. A special group is responsible for providing inspections of this equipment and keeping records of maintenance performed, defects found, and remedial actions taken. The group may consist of electricians, plumbers, and other specialists familiar with the various support systems.

Specialist Contractors

During decommissioning, specialist contractors may be employed to provide services to the facility's decommissioning team. In the case of large nuclear installations, the list of specialized contractors may include, among others, transport contractors and remotely operated equipment specialists. Use of contractors may increase the overall cost effectiveness of the decommissioning project by improving the efficiency of specialist operations and therefore reducing the need for specialist staff training.

2.7.5 Administration Services

The administrative aspects of the project are the responsibility of the DPM, but expertise may be provided by specialists such as accountants, contract and procurement agents, information managers, personnel and training officers, lawyers, and security personnel. Key aspects of administrative management are described below.

Accounting and Finance

A financial case has to be organized for the selected decommissioning option, which includes a detailed cost estimate and the rate and time-scale of expenditures. The detailed cost estimate would be done as a joint activity between the technical support staff, who define the work packages and resources required, and the administrative staff or external specialist contractor, who have the financial cost estimating expertise. After approval of the estimate, the licensee has to agree on an expenditure budget for the decommissioning program with the organization that is providing the funds. This consists, as a minimum, of a summary of decommissioning activities, the agreed expenditure limit for each activity, and the points of time when funds are required.

For a decommissioning project on a multi-plant site, where other operations are continuing, the licensee may be able to utilize existing accounting services for recording and monitoring expenditures. For a single-plant site it may be appropriate to employ accounting services.

Contracts and Procurement

Contracts and procurement functions are required to assist the DPM in negotiating contracts for speciality contractors, procurement of special installations and equipment, special services, and procurement of consumables. However, it is a responsibility of the DPM to ensure that any contracted work is done in a timely, economic, and safe manner. Before contracts are awarded, the qualifications and experience of the contractor's staff and the quality assurance procedures operated by the contractor are verified. The size of the procurement and contracts group depend on who is going to perform most of the decontamination and dismantling activities, the in-house decommissioning team or the contractor(s).

For decommissioning projects the procurement of large quantities of consumable items, such as the personnel's protective equipment, is a possibly underestimated issue. Because of the quantity and diversity of this equipment, an extra burden may be placed on the contracting organization. The process of resupplying these items is reviewed periodically to ensure continued best value. In addition, the technical support staff ensures that special equipment (e.g., instrumentation, decontamination units, transport containers, and dismantling tools) has been identified in advance and procured in time to suit the planned sequence of decommissioning activities.

Information Management

A system is set up using QA requirements by which the data, operational records and reports are regularly received, registered, controlled, and stored. The regulations may require that all, or some, of these records be kept after decommissioning has been completed. For all decommissioning projects, a technical-data management group is in place; its purpose is to control the large amount of technical data that are generated by the decommissioning team during the decommissioning process. For example, large amounts of technical data may be collected, including survey data which could amount to many thousands of records. Once collected, all these data must be analyzed, retained, and put into a comprehensible and retrievable form.

Personnel and Training

The services of an experienced personnel manager and staff are essential to look after all personnel problems associated with the decommissioning staffing issues which may arise with operational staff after the shutdown of the facility. The principal aspects are likely to be substantial changes in the workforce, involving staff reductions and/or redeployments, and staff counseling related to some uncertainty arising from the closure of the plant or finalization of various stages of the decommissioning program.

It may be difficult to maintain all necessary skills as the workforce changes. This requires a commitment to the retraining of staff, including contractors, in order to meet the different challenges as the work progresses. The nature of the work may push for a reduction in the number of staff originally employed at the plant. Maintaining a site memory, that is, people with immediate personal knowledge of the plant and its history, may require a potentially higher retention of operating phase personnel. Emergency arrangements may also provide a similar pressure for staff retention.

The pressure to reduce costs by reducing staff tends to promote a degree of multi-skilling. Workers who performed only one or two tasks during the operational phase may now be required to perform multiple tasks as part of their normal duties. An example might be that during operations, a pipefitter may have only to cut installed piping. During decommissioning, this person may also be required to remove piping and perform waste minimization and decontamination activities. This may require retraining of this person.

Where operating staff are retrained in certain tasks, this training can be provided under contract from specialists who may go on to supervise the work. In some countries, specialist qualifications are being produced for decommissioning workers.

Finally, it is important to recognize that DPMs may also need retraining, if they are to operate as effective DPMs rather than as operating plant managers. Because of the potential for the decommissioning to be performed over long time periods, refresher courses and retraining are required at established intervals or in view of important activities.

Security and safeguards If spent fuel or other material subject to safeguards (such as plutonium or enriched uranium) remains on the site during decommissioning operations, presence of a security has to be maintained until the material has been removed. Once this material is removed, the safeguard functions can be reduced, but staffs are still retained for general security duties.

2.7.6 Interfaces

The licensee and decommissioning team cannot perform their duties without interfacing with organizations involved or interested in the decommissioning process. This interface may have to go through different parts of the licensee's organization. These organizations provide technical, social, or regulatory input to the decommissioning process. Their involvement can perform a valuable review function and provide constructive input to the decommissioning team. These organizations typically include:

- Regulatory authorities (clearance levels, waste transportation, environmental protection, radiation protection)
- National standards groups, professional societies
- General public (communities, pressure groups, etc.)

A common term used for these organizations is "stakeholders." A stakeholder is a person or group who can affect (or is affected by) an action. Among these, the main subjects are local, regional, and national governments, waste management organizations (nuclear and hazardous), shareholders, international organizations, the nuclear industry, labor unions, customers, and media. It is important that adequate lines of communication with the organizations be established.

As an important interfacing example, licensing-related activities normally continue at a significant level after the decommissioning has been initiated, and staff must have adequate time to continue licensing activities. These activities include possible revisions of the decommissioning plan, safety documents, emergency arrangements, and maintenance and modification procedures.

3 Plant and Site Characterization

3.1 Initial Plant Characterization

3.1.1 Radioactivity Sources

The radioactive inventory in nuclear facilities to be decommissioned can be divided into two categories:

- Radioactivity induced by neutron activation of certain elements in reactor components and adjacent structures
- Radioactive substances deposited on the internal and external surfaces of various systems as contamination. Included in this category are daughter radionuclides which become significant after periods of decay

Some nuclides contained in materials exposed to the neutron flux in nuclear reactors, accelerators, or fusion devices are transformed into radioactive isotopes. The level and type of radionuclides found in neutron irradiated materials depend on:

- The nuclides in the materials
- The duration of the exposure and the intensity of the neutron flux
- The energies of the incident neutrons

The relevant radionuclides composing the induced radioactivity in reactor and accelerator components and adjacent structures are shown in [Table 7](#). In other types of facilities, where neutron flux is minimal or nonexistent, activation products are not a serious concern during decommissioning.

Radioactive contamination of internal surfaces of reactor systems is caused by the deposition from the reactor coolant of neutron activated particles and dissolved elements, and from fission products and actinides released from possible fuel cladding cracks or other fuel failures, which may become very significant in the case of relevant accidents. External surface contamination in nuclear plants is primarily due to leakage and spills from reactor systems, and to maintenance and waste management activities.

Radioactive contamination in other fuel cycle facilities, such as fuel fabrication and reprocessing facilities, glove box lines, and storage basin is due to deposition of radioactive materials from the process stream. This contamination generally consists of uranium, thorium, plutonium, and their daughters in conversion, enrichment, and fabrication plants. Fission product contamination is also present in reprocessing plants.

In facilities not associated with the nuclear fuel cycle the radioactivity arises from radionuclides in the process stream, for example ^{99}Mo in a radiopharmaceutical hot cell facility.

■ Table 7

Major radionuclides identified in nuclear facilities characterization (SOGIN)

Isotope	Half-life (years)	Principal decay mode	Associated γ energy (MeV)	Materials where isotopes can be found
Neutron activation products found in nuclear reactors				
H ³	12.3	β^-	–	C, O, S
C ¹⁴	5,730	β^-	–	G, M, S
Na ²²	2.6	EC, β^+	0.51–1.28	O
Cl ³⁶	3.1×10^8	β^- , EC	–	C
Ar ³⁹	269	β^-	–	C
Ca ⁴¹	1×10^5	EC	–	C
Ca ⁴⁵	0.4	β^-	–	C
V ⁴⁹	0.9	EC	–	S
Mn ⁵⁴	0.9	EC, γ	0.83	A, M, S
Fe ⁵⁵	2.7	EC	–	C, M, O, S
Co ⁵⁷	0.7	EC, γ	0.12–0.14	S
Co ⁶⁰	5.3	β^- , γ	1.2–1.3	C, M, O, S, Z
Ni ⁵⁹	7.5×10^4	EC	–	C, M, O, S, Z
Ni ⁶³	100	β^-	–	C, M, O, S
Zn ⁶⁵	0.7	β^+ , γ , EC	0.51–1.12	A
Zr ⁹³	1.5×10^6	β^-	–	O, Z
Nb ⁹⁴	2×10^4	β^- , γ	0.70–0.87	M, O, S, Z
Mo ⁹³	3.5×10^3	EC, γ^-	0.3	M
Ag ^{108m}	130	EC, γ	0.4–0.6–0.7	M, O, S
Ag ^{110m}	0.7	β^- , γ	0.6–0.9	M, O, S
Ba ¹³³	10.7	EC, γ	0.08–0.36	C
Sm ¹⁵¹	93	β^- , γ	0.02	C
Eu ¹⁵²	13.4	β^- , γ , EC	0.1	C, G
Eu ¹⁵⁴	8.2	β^- , γ	0.1–1.3	C, G
Uranium and transuranic elements found in facilities handling fissile materials				
				Plant type
U ²³²	72	α , γ	0.06–1.3	1
U ²³³	1.6×10^5	α , γ	0.04–1	1
U ²³⁴	2.4×10^5	α , γ	0.05–0.1	1
U ²³⁵	7×10^8	α , γ	0.2	3
U ²³⁷	0.02	α , γ	0.2	2

■ Table 7 (continued)

Isotope	Half-life (years)	Principal decay mode	Associated γ energy (MeV)	Materials where isotopes can be found
Uranium and transuranic elements found in facilities handling fissile materials				
U ²³⁸	4×10^7	β, γ	0.05	2, 3
Np ²³⁷	2.1×10^6	α, γ	0.02–0.08	2, 3
Pu ²³⁸	87.7	α, γ	0.04–1.1	2, 3
Pu ²³⁹	2.4×10^4	α, γ	0.05	2, 3
Pu ²⁴⁰	6,537	α, γ	0.04–0.9	2, 3
Pu ²⁴¹	14.7	α, γ	0.03–0.15	2, 3
Pu ²⁴²	3.8×10^5	α, β^-, γ	0.04	2, 3
Am ²⁴¹	432	α, γ	0.05–0.8	2, 3
Am ²⁴³	7,380	α, γ	0.07–0.6	2, 3
Fission products found in reprocessing plants				
Sr ⁹⁰	29	β^-		
Ru ¹⁰⁶	1	β^-		
Cs ¹³⁴	2	γ	0.8	
Cs ¹³⁷	30	β^-, γ	0.7	
Ce ¹⁴⁴	0.7	β^-, γ	0.1	

C concrete; G graphite; O other; A aluminum; Z Zr alloys; S stainless steel; M mild steel; EC electron capture

These factors play a key role in several aspects of decommissioning process:

- Decommissioning planning
- Schedule and manpower requirements
- Personnel exposure
- Amount and methods of decontamination
- Cost evaluations
- Waste amount calculations

Nuclear Reactors

The radionuclides of concern vary considerably depending upon the type of facility being decommissioned. In the case of a nuclear reactor, the major radionuclides of concern during the first 50–100 years are ⁶⁰Co, which emits high energy gamma rays. Thereafter, other radionuclides such as ⁶³Ni and ¹⁰⁸Ag_m may become predominant.

The dose levels of gamma radiation from activation products such as ⁶⁰Co in the reactor vessel and internal components of the reactor vessel determine the amount of remote operation and shielding that is required. In the longer term, other radionuclides such as ⁶³Ni, ⁵⁹Ni, ¹⁰⁸Ag_m, and ¹⁴C are of greater concern because their long half-lives render them radioactive for hundreds of years.

^{59}Ni has not been of major importance previously because reactors had not been in operation long enough to create significant quantities of this radionuclide. However, a reactor in operation for 40 years may contain significant amounts of ^{59}Ni in certain reactor vessel components. ^{14}C is of concern for graphite moderated reactors.

Of importance, but not well documented, is the radiation resulting from the activation of trace elements to produce radionuclides such as ^{94}Nb that could give rise to significant activity in the very long term. Trace elements may be natural impurities or introduced from scrap metal added to virgin metals during manufacture. For example, niobium is added during the manufacture of steel to improve welding characteristics. When scrap steel is added to the virgin metal melt, diluted niobium remains in trace quantities.

Fission products and actinides may also be present in reactor facilities as a result of fuel failures. If the facility has experienced an accident during its operating lifetime, significantly higher inventories of fission products and actinides may be present.

Radioactive isotopes are also generated by activation in the concrete structures surrounding the reactor. Generally on some tenths of centimeters are involved at a significant level, but this may introduce additional concerns both from radioprotection point of view and from the amount of radioactive wastes that are produced.

Other Nuclear Facilities

In other nuclear fuel cycle facilities, the radionuclides of concern depend on which part of the cycle the facility was used for.

In the case of facilities at the front end of the nuclear fuel cycle, the members of the uranium and thorium decay chains are the most important radionuclides.

For plutonium facilities or those handling highly enriched uranium, actinides such as ^{239}Pu is the main problem. These radionuclides are much more difficult to handle than either fission products or activation products owing to their high specific radiotoxicity and the associated inhalation hazard. However, in reprocessing plants the fission and activation products also contribute significantly to the total potential hazard. For ^{233}U facilities the actinides and the decay product ^{208}Tl (2.6 MeV gamma energy) are the major concerns.

In the case of nonnuclear fuel cycle facilities, the radionuclides of concern depend on the product being used or produced. Examples of nuclides of importance in some plants include: ^{60}Co for gamma irradiation, ^{131}I and ^{51}Cr in radiopharmaceutical facilities, and ^{226}Ra in gypsum residues from the phosphate industry.

In fusion facilities the major radionuclides of concern are activation products similar to those that occur in nuclear reactors.

3.1.2 The Concept and Extent of Characterization

It is necessary to determine whether the description of the current radiological status of the facility is adequate to fully understand the types and levels of radioactive material contamination and the extent of radioactive contamination at the facility. This information is used during the review of the licensee's decommissioning activities, to evaluate the cost estimates for decommissioning, and decommissioning health and safety plans. This information should include summaries of the types and extent of radionuclide contamination in all media at the facility, including buildings, systems and equipment, surface and subsurface soil, and surface and ground water.

A good estimate of the amount and type of radioactivity in a nuclear facility is important because it can directly affect the whole approach to decommissioning including the choice of the time to start decommissioning and the desirability of delay between stages. This information assists the planners in determining factors such as the need for decontamination, shielding or remotely operated equipment, shipping and disposal, and potential radiation exposures to the work force.

The facility inventory should include detailed inventories for individual components and should describe specific radionuclide content, chemical forms, physical forms, and volume distribution. The inventory should be maintained current as decommissioning progresses, and in case of delayed dismantling, the inventory should be projected into the future to demonstrate the required period of confinement of radionuclides.

If the residual radioactivity consists mainly of short-lived radionuclides, a significant reduction in radioactive inventory can be achieved by delaying the dismantlement of the facility. In the opposite case, no major advantage can be achieved by deferring dismantlement.

3.1.3 Structure Characterization

The purpose of the description of the contaminated structures is to evaluate whether the licensee has fully described the types and activity of radioactive material contamination in the structures, as well as the extent of this contamination. This information should be sufficient to allow the evaluation of the potential safety issues associated with remediating the structures, whether the remediation activities and radiation control measures proposed by the licensee are appropriate for the type of radioactive material present in the structure, whether the licensee's waste management practices are appropriate, and whether the licensee's cost estimates are plausible, given the amount of contaminated material that has to be removed or remediated.

Note that, in some instances licensees may choose to dismantle contaminated structures and dispose of the building debris as radioactive waste in lieu of decontaminating the building.

Similarly, licensees may choose to decontaminate portions of buildings to levels appropriate for unrestricted use and dismantle portions of the building to gain access to areas where contamination has migrated, such as floor/wall joints. In these instances, all of the information described below may not necessarily be included in the decommissioning plan. Regulatory staff should discuss these activities with these licensees to ensure that adequate information is provided in the decommissioning plan to allow the staff to perform the evaluations described above, without requiring the licensee to expend substantial resources characterizing the structures.

The information supplied by the licensee should be sufficient to allow the understanding of the types and activity of radioactive material contamination in the structure, as well as the extent of this contamination. The review should verify that the following information is included in the contaminated structures section of the facility decommissioning plan:

- A list or description of all structures at the facility where licensed activities occurred that contain residual radioactive material in excess of site background levels
- A summary of the structures and locations at the facility that the licensee has concluded have not been impacted by licensed operations and the rationale for the exclusion
- A list or description of each room or work area within each of these structures
- A summary of the background levels used during scoping or characterization surveys

- A summary of the locations of contamination (i.e., walls, floors, wall/floor joints, structural steel surfaces, ceilings, etc.) in each room or work area
- A summary of the radionuclides present at each location, the maximum and average radionuclide activities in $\text{dpm}/100\text{ cm}^2$, the chemical form of the radionuclide and, if multiple radionuclides are present, the radionuclide percentages
- The mode of contamination for each surface (i.e., whether the radioactive material is present only on the surface of the material or if it has penetrated the material)
- The maximum and average radiation levels in milli-Sievert per hour (mSv/h) or micro-Sievert per hour ($\mu\text{Sv}/\text{h}$), as appropriate, in each room or work area
- A scale drawing or map of the rooms or work areas showing the locations of radionuclide material contamination and radiation levels. All maps should include compass direction indicators.

3.1.4 System and Equipment Characterization

The purpose of the description of the contaminated systems and equipment at the facility is to evaluate whether the licensee has fully described the types and activity of radioactive material contamination in facility systems or on equipment, as well as the extent of this contamination.

This information should be sufficient to allow the evaluation of the potential safety issues associated with remediating the systems or equipment, whether the remediation activities and radiation control measures proposed by the licensee are appropriate for the type of radioactive material present in the systems or equipment, whether the licensee's waste management practices are appropriate and whether the licensee's cost estimates are plausible, given the amount of contaminated material that has to be removed or remediated.

Note that, in some instances, licensees may choose to remove and dispose (either as radioactive waste or as usable equipment in another radiation area) contaminated systems and/or equipment, in lieu of decontaminating the system or equipment. In these instances, all of the information described below may not necessarily need to be included in the decommissioning plan. Regulatory staff should discuss these activities with licensees to ensure that adequate information is provided in the decommissioning plan to allow the staff to perform the evaluations described above, without requiring the licensee to expend substantial resources characterizing the equipment or system.

The information supplied by the licensee should be sufficient to allow for the understanding of the types and activity of radioactive material contamination present in systems or on equipment, as well as the extent of this contamination. The review should verify that the following information is included in the contaminated systems and equipment section of the facility decommissioning plan:

- A list or description and the location of all systems and equipment at the facility that contain residual radioactive material in excess of site background levels
- A summary of the radionuclides present in each system or on the equipment at each location, the maximum and average radionuclide activities in $\text{dpm}/100\text{ cm}^2$, the chemical form of the radionuclide, and, if multiple radionuclides are present, the radionuclide ratios
- The maximum and average radiation levels in mSv/h, or $\mu\text{Sv}/\text{h}$, as appropriate, on the surface of each piece of equipment

- A summary of the background levels used during scoping or characterization
- A scale drawing, map of the rooms, or work areas showing the locations of the contaminated systems or equipment; all maps should include compass direction indicators.

3.2 Site Characterization

3.2.1 Surface Soil Contamination

If a deep soil contamination did not occur, generally characterization of a 15–30 cm layer of top soil may be considered sufficient at the beginning of the process to identify any necessary soil treatment and at the end of decommissioning to demonstrate that the site may be delicensed. This information is generally sufficient to allow the regulatory staff to evaluate the following:

- The potential safety issues associated with remediating the surface soil
- Whether the remediation activities and radiation control measures proposed by the licensee or person responsible are appropriate for the type of radioactive material present in the surface soil
- Whether the licensee's waste management practices are appropriate
- Whether the licensee's cost estimates are plausible, given the amount of contaminated soil that has to be removed or remediated
- And finally to delicense the site.

3.2.2 The NRC Acceptance Criteria

As an example, the US NRC requirements and guidances are included in the following documents:

- 10 CFR 30.36(g)(4)(i).
- 10 CFR 40.42(g)(4)(i).
- 10 CFR 70.38(g)(4)(i).
- 10 CFR 72.54(g)1.
- “Draft Branch Technical Position on Site Characterization for Decommissioning.”
- NUREG-1575: “Multi-Agency Radiological Survey and Site Investigation Manual.”
- NUREG-1754 – “Technology, Safety and Costs of Decommissioning Reference Non-Fuel Cycle Nuclear Facilities,” Addendum 1.

The information to be supplied by the licensee should be sufficient to allow the NRC to fully understand the types and activity of radioactive material in surface soil, as well as the extent of this contamination. The NRC review should verify that the following information is included in the description of contaminated soil in the facility decommissioning plan:

- A list or description of all locations at the facility where surface soil contains residual radioactive material in excess of site background levels
- A summary of the background levels used during scoping or characterization surveys
- A summary of the radionuclides present at each location, the maximum and average radionuclide activities in pico-Curies per gram (pCi/g), the chemical form of the radionuclide, and, if multiple radionuclides are present, the radionuclide percentages

- The maximum and average radiation levels in mSv/h at each location
- A scale drawing or map of the site showing the locations of radionuclide material contamination in surface soil. All maps should include compass direction indicators.

3.2.3 Subsurface Soil Contamination

The purpose of the review of the description of subsurface soil (i.e., soil below the top 15–30 cm of soil in the soil column) contamination is to determine if the licensee has fully described the types and activity of radioactive material contamination in the subsurface soil, as well as the extent of this contamination. This information should be sufficient to allow the regulatory staff to evaluate the following:

- The potential safety issues associated with remediating the subsurface soil
- Whether the remediation activities and radiation control measures proposed by the licensee are appropriate for the type of radioactive material present in the subsurface soil
- Whether the licensee's waste management practices are appropriate
- Whether the licensee's cost estimates are plausible, given the amount of contaminated soil that has to be removed or remediated

The information supplied by the licensee should be sufficient to allow the NRC to fully understand the types and activity of radioactive material in subsurface soil, as well as the extent of this contamination.

The NRC review should verify that the following information is included in the description of contaminated subsurface soil in the facility decommissioning plan:

- A list or description of all locations at the facility where subsurface soil contains residual radioactive material in excess of site background levels
- A summary of the background levels used during scoping or characterization surveys
- A summary of the radionuclides present at each location, the maximum and average radionuclide activities in pCi/g, the chemical form of the radionuclide, and, if multiple radionuclides are present, the radionuclide ratios
- The depth of the subsurface soil contamination at each location
- A scale drawing or map of the site showing the locations of subsurface soil contamination. All maps should include compass direction indicators.

3.2.4 Surface Water Contamination

The purpose of the review of the description of contaminated surface water is to evaluate whether the licensee has fully described the types and activity of radioactive material present in surface water bodies at the facility, as well as the extent of this contamination. This information should be sufficient to allow the regulatory staff to evaluate potential safety issues associated with remediating the surface water, whether the remediation activities and radiation control measures proposed by the licensee are appropriate for the type of radioactive material present in the surface water, whether the licensee's waste management practices are appropriate and cost estimates are plausible, given the amount of contaminated water that has to be removed or remediated.

The information supplied by the licensee should be sufficient to allow the staff to fully understand the types and activity of radioactive material contamination in surface water at the facility, as well as the extent of this contamination. The staff's review should verify that the following information is included in the description of surface water contamination in the decommissioning plan:

- A list or description and map of all surface water bodies at the facility that contain residual radioactive material in excess of site background levels
- A summary of the background levels used during scoping or characterization surveys
- A summary of the radionuclides present in each surface water body and the maximum and average radionuclide activities in pico-Curies per liter (pCi/l).

3.2.5 Groundwater Contamination

The purpose of the review of the description of contaminated groundwater is to evaluate whether the licensee has fully described the types and activity of radioactive material present in groundwater at the facility, as well as the extent of this contamination. This information should be sufficient to allow the regulatory staff to evaluate potential safety issues associated with remediating the groundwater, whether the remediation activities and radiation control measures proposed by the licensee are appropriate for the type of radioactive material present in the groundwater, whether the licensee's waste management practices are appropriate and whether the licensee's cost estimates are plausible, given the amount of contaminated water that will need to be removed or remediated.

The information supplied by the licensee should be sufficient to allow the staff to fully understand the types and activity of radioactive material contamination in groundwater at the facility, as well as the extent of this contamination. The staff's review should verify that the following information is included in the description of groundwater contamination in the decommissioning plan:

- A summary of the aquifer(s) at the facility that contain residual radioactive material in excess of site background levels
- A summary of the background levels used during scoping or characterization surveys
- A summary of the radionuclides present in each aquifer and the maximum and average radionuclide activities in pCi/l.

4 Decontamination Techniques

4.1 Overview

Decontamination is defined as the removal of contamination from surfaces of facilities or equipment by washing, heating, chemical or electrochemical action, mechanical cleaning, or other techniques. In decommissioning programs, the objectives of decontamination are:

- To reduce radiation exposure
- To salvage equipment and materials

- To reduce the volume of materials requiring storage and disposal in licensed disposal repositories
- To restore the site and facility, or parts thereof, to an unconditional-use situation
- To remove loose radioactive contaminants and fix the remaining contamination in place in preparation for protective storage or permanent disposal work activities
- To reduce the magnitude of the residual radioactive source in a protective storage mode for public health and safety reasons, to reduce the protective storage period or to minimize long-term monitoring and surveillance requirements

Some form of decontamination is required in any decommissioning program, regardless of the form of the end product. As a minimum, the floor, walls, and external structural surfaces within work areas should be cleaned of loose contamination, and simple water rinsing of contaminated systems is performed.

The question of whether to decontaminate piping systems, tanks, and components arises often.

A strong case may be made in favor of leaving adherent contamination within piping as well as components in a dispersed form on the internal metal surfaces rather than concentrating the radioactivity through decontamination. In most cases, decontamination is not sufficiently effective to allow for the unconditional release of the item without further treatment after dismantling. Therefore, savings both in occupational exposure and cost could be achieved by simply removing the contaminated system and its components and only performing certain packaging activities (e.g., welding end caps on pipe sections, using adequate equipment to cut and crimp smaller piping to reduce chances of airborne activity). However, additional cost for the disposal of materials must be weighed in this scenario.

A decontamination program may also require a facility capable of treating secondary waste from decontamination (e.g., processing chemical solutions, aerosols, debris, etc.). The concentrated waste, representing a more significant radiation source, must be solidified and shipped for disposal in licensed disposal facilities unless properly treated in the waste reduction/recycling/reclamation processing alternative.

The optimal waste-reduction configuration must be defined after an economic assessment of treatment versus transportation/disposal costs has been completed. Each of these additional consequences may increase:

- Occupational exposure rates
- The potential for a release
- The uptake of radioactive material

These could conceivably result in even higher doses than those received from removing, packaging, and shipping the contaminated system without extensive decontamination. Resolution of this question depends on specific facts, such as the exposure rate of the gamma-emitting contamination, the contamination level, and the effectiveness of the containing component and piping (wall thickness) in reducing radiation fields in the work area.

The proven and emerging decontamination techniques which may be used to accomplish the goals of decommissioning activities have been discussed by the Technical Advisory Group of the Organization for Economic Cooperation and Development-Nuclear Energy Agency (OECD-NEA), a Cooperative Program on Decommissioning. The work focused on decontamination of both metallic and concrete surfaces for dose reduction as well as for waste decategorization or for conditional or unconditional release of materials.

4.1.1 Objectives of Decontamination Techniques

There are three main reasons for considering the use of decontamination techniques:

- The importance of removing contamination from components or systems to reduce dose levels in the installations; access to the installations could then be made easier so that it becomes possible to use hands-on techniques for dismantling rather than the more expensive use of robots or manipulators
- The aim of minimizing the potential for spreading contamination during decommissioning activities, especially when dealing with systems containing highly radioactive particles and actinides
- It may be possible to reduce the contamination of components or structures to such levels that they may be disposed at a lower, and therefore more economical, waste treatment and disposal category or, indeed, be unconditionally released for recycling or reuse in the conventional industry, or disposed as waste exempt from regulatory concern

Several decontamination techniques have been developed to support maintenance work in nuclear installations. With relative success, the same techniques have also been adopted when decommissioning nuclear installations and components (🔗 [Table 8](#)). Objectives differ among these applications, however.

In maintenance work, the highest degree of decontamination is sought, avoiding any damage to the component so that it may be adequately reused. In contrast, the main aim of decontamination for decommissioning is the removal of as much activity as possible, not only to decategorize waste, but to reach clearance levels so that the material from the system may be reused without radiological restrictions. In many cases, it is necessary to remove all oxides liable to trap contaminants and a thin layer of structural material in order to achieve this aim. The radionuclides indeed tend to concentrate in the intergranular regions, together with other impurities accumulated during the growth of the metal grains. Therefore, much more aggressive decontamination methods are required than those used during the service life of a plant. In this view, technical methods presenting high decontamination factors at high contamination levels do not always allow for achievement of the very low levels required to release the material (e.g., inner surfaces of piping) without restrictions, provided that measurement of these very low levels is feasible.

During decontamination for maintenance, components and systems may not be damaged and the use of very aggressive decontamination methods is not appropriate. In decontamination for decommissioning, however, it is mainly the use of somewhat destructive techniques that make it possible to meet the objectives to release the material at clearance levels.

Another aspect in which techniques for thorough decontamination of materials differ from maintenance or laboratory scale decontamination is the need for industrialization. The large amount of contaminated materials produced during decommissioning procedures and available for decontamination generally do not favor methods or techniques that are labor intensive or difficult to handle, or that present difficulties when automation is envisaged. The latter is also true in the case of decontaminating the full system for maintenance.

Other factors presenting differing influences on the choice of techniques are, for example, secondary-waste production and the possibility of recycling products from decontamination

■ Table 8

Decontamination techniques in decommissioning nuclear installations

Task	Scope	Object	Techniques
Decontamination before dismantling	Reduction of occupational exposure	Pipeline system	Chemical Mechanical
		Pool, tank	Hydro jet Blast Strippable coating, etc.
Decontamination after dismantling	Recycle of contaminated metal Reduction of radioactive waste	Pipes, components	Electropolishing Chemical immersion Blast Ultrasonic wave Gel
Decontamination of building	Unconditional release of building Reduction of radioactive concrete waste	Concrete surface	Mechanical: scabblers Mechanical: shaver Mechanical: drill and spalling Mechanical: steel grit blast Thermal stress: microwave irradiation Thermal stress: flame scarfing

processes. These may be among the parameters for decision-making, for decontamination both for maintenance and decommissioning.

The absolute requirement for effectively obtaining residual contamination levels that prove to be below clearance limits is also a factor of primary influence when making the choices of decontamination techniques to be used. Even if techniques for the decontamination of complex geometries (e.g., pipe bends, small diameter piping) exist, the nonaccessibility of areas may prevent direct radiological measurements being used to show that shifting clearance levels are met.

Presently, the interest of the nuclear industry is moving from decontamination techniques for maintenance to decontamination for decommissioning. Limited data are available from decommissioning on the efficiency of usable techniques to meet the low unconditional-release criteria. In most cases, using available techniques, the clearance levels are only met in an asymptotic way. Not all methods and techniques available present the possibility of decontaminating below the required clearance levels. So, in some cases, decontamination is carried out in different stages, the last step specifically aiming to obtain the required objectives.

When selecting a specific technique for system and/or component decontamination based on these considerations, the following requirements must be considered mainly:

- Safety. The application of the method should not result in increased radiation hazards due to external contamination of workers or even inhalation of radioactive dust and

aerosols formed during its implementation; it should not add other hazards (e.g., chemical, electric, etc.).

- **Efficiency.** The method should be capable of removing radioactivity from a surface to a level which would enable hands-on work instead of robotics, or which would permit recycling/reuse of the material or, at least, a lower waste treatment and disposal category.
- **Cost-effectiveness.** Where possible, equipment should be decontaminated and repaired for reuse; however, the method should not be costly exceeding the costs for waste treatment and disposal of the material, whether including replacement of the equipment or not.
- **Waste minimization.** The method should not give rise to large quantities of secondary waste, the treatment and disposal of which would result in excessive requirements for work and costs, thereby causing additional exposures.
- **Feasibility of industrialization.** Due to the large quantities of contaminated materials involved, methods or techniques should not be labor-intensive, difficult to handle, or difficult to automate.

4.1.2 Selection of Decontamination Technologies

Very early in the process of selecting decontamination technologies for decommissioning, it is important that a cost–benefit analysis be performed to see if it is actually worth decontaminating the component or facility, or to determine whether a mild decontamination at low cost is more advantageous than an aggressive decontamination at a higher cost. This analysis is usually accompanied by extensive experimental work on selected samples from the facility in view of characterization, before the final choice of a decontamination technique is made.

To achieve a good decontamination factor ($DF = \text{contamination after the treatment} / \text{contamination before the treatment}$), a decontamination process must be designed for site-specific application taking into account a wide variety of parameters, some of which are listed below:

- Type of plant and plant process: reactor type, reprocessing plant, etc.
- Operating history of the plant
- Type of material: steel, zircaloy, concrete, etc.
- Type of surface: rough, porous, coated, etc.
- Type of contaminant: oxide, crud, sludge, loose, etc.
- Composition of the contaminant (i.e., activation products, fission products, actinides, etc.), and the specific radionuclides involved
- Ease of access to areas/plant to be decontaminated, external or internal surfaces to be cleaned
- Regulatory requirements and decontamination factors required
- Destination of the components being decontaminated: disposal, reuse, etc.
- Time required for application
- Proven efficiency of the process for the type of contamination in the facility
- Type of component: pipe, tank, pump, valve, etc.

Other factors which are important in selecting the method, but which do not affect the decontamination factor are:

- Availability, cost, and complexity of the decontamination equipment and consumables
- Need and capability of treatment and conditioning of the secondary waste generated
- Potential exposure to hazardous materials and/or chemicals used in the decontamination process
- Occupational and public doses resulting from decontamination (justification of the practice)
- Other safety, environmental and social issues
- Availability of trained staff
- Extent to which the plant needs to be decontaminated to achieve acceptable conditions
- Salvage value of materials which would otherwise be disposed
- Extent to which the facility must be modified to do the decontamination
- Enclosed and ventilated spaces, etc.

In addition, the choice of a process or of a combination of several processes finally depends on several other factors such as:

- The specific nature of the application, the complexity of the system
- The feasibility of industrialization
- The cost–benefit analysis taking into account all aspects of the decontamination operation, i.e., until disposal of remaining radioactive waste

The decision whether to proceed with decontamination and the final process selected depends on the best overall balance of the above factors to minimize the overall impact of the decommissioning activities on workers, the public, and the environment, at acceptable costs.

4.1.3 Survey of Applied Decontamination Techniques

A list of decontamination processes suitable for the purposes of decommissioning is given in  [Table 9](#). For decontamination of metals, the processes are divided into chemical, electrochemical, and physical processes. Moreover, a distinction has been made between the processes used in closed systems (e.g., full-system decontamination of the primary circuit of a reactor or the partial decontamination of closed loops), and the processes used in open tanks (e.g., decontamination of dismantled pieces). For the decontamination of concrete, surface-decontamination processes and demolition processes have been selected.

Some specific characteristics of selected decontamination techniques for segmented components and for building surfaces are discussed in the following sections. In addition, some critical elements of choosing techniques for a practical decontamination problem are mentioned. In addition, practical experience in decontamination has shown that a universal decontamination process does not exist. As such, future users should familiarize themselves with the characteristics of proposed techniques, to make adequate choices based on specific requirements and thorough case studies.

4.2 Decontamination of Segmented Components

4.2.1 Overview

Simplified overviews of some decontamination techniques in view of their efficiency regarding some selection criteria may be found in the literature. Practical experience indicates that these overviews have to be considered with great care. Small changes in details of application of the selected techniques may have significant impacts on the qualification of influencing parameters.

Chemical decontamination uses concentrated or diluted chemical reagents in contact with the contaminated item, to dissolve the contamination layer covering the base metal and eventually a part of the base metal. In most cases, required decontamination levels may be obtained

by continuing the process as long as necessary, taking care to ensure that tank walls or piping are not penetrated by corrosion.

In mild chemical decontamination processes, dissolution of the contamination layer is envisaged, but the process should be nondestructive to the base metal and is generally used for operating facilities. Aggressive chemical decontamination techniques involving dissolution of the base metal should only be considered in decommissioning programs where reuse of the item will never occur. Chemical flushing is recommended for remote decontamination of intact piping systems.

Chemical decontamination has also proven to be effective in reducing the radioactivity of large surface areas such as drip trays as an alternative to partial or complete removal. They are also suitable for use on complex geometries as well as for a uniform treatment of inner and outer pipe surfaces. These techniques, however, require efficient recycling of reactive chemicals. Insufficient recycling of decontamination products results in very large amounts of secondary waste, which are difficult to treat, and increase costs.

Electrochemical decontamination may be considered in principle to be a chemical decontamination assisted by an electric field. It may be considered the opposite of electroplating since metal layers are removed from a surface rather than added as a coating.

Electrochemical decontamination has been applied by immersion of the contaminated item in an electrolyte bath or by passing a pad over the surface to be decontaminated. The electric current causes the anodic dissolution and removal of metal and oxide layers from the component. The electrolyte is continuously regenerated by recirculation.

These processes may only be applied to conductive surfaces. They are highly effective and give a high decontamination factor. Their use is limited:

- When immersion is used, by the size of the bath
- When a pad is used, by the geometry of the surfaces and the available clearance around the part being treated

This makes the method almost inapplicable for industrial decontamination of complex geometries (e.g., pipes, valves, pumps, etc.). The volume of effluents may be limited. Moreover, handling the parts to be immersed or the pad may lead to additional exposure to workers.

Decontamination by melting presents the particular advantage of homogenizing a number of radionuclides in the ingots and concentrating other radionuclides in the slag and filter dust resulting from the melting process, thus decontaminating the primary material.

Melting may provide an essential step when releasing components with complex geometries, simplifying monitoring procedures for radioactive metal characterization. In addition to the decontamination effects of melting, the problem of inaccessible surfaces is eliminated, and the remaining radioactivity content is homogenized over the total mass of the ingot.

Therefore, melting may be a last step in the decontamination and release of components with complex geometries after they have been decontaminated, for example, by chemical methods which remove radionuclides, such as ^{60}Co . It should be noted that ^{60}Co originating from activation of the base metal remains in the ingot after melting.

Mechanical and manual decontamination are physical techniques. Recently, mechanical decontamination has included washing, swabbing, foaming agents, and latex-peelable coatings. Mechanical techniques may also include wet or dry abrasive blasting, grinding of surfaces,

and removal of concrete by spalling or scarifying. These techniques are most applicable to the decontamination of structural surfaces.

Some of them are also applicable to nonmetallic surfaces, such as plastics.

Abrasive blasting systems, both wet and dry, have been used with success. They employ mechanical methods, derived from conventional industry, that give very high decontamination factors. The longer the operations are continued, the more destructive they are. However, wet abrasive systems produce a mixture of dust and water droplets that might be difficult to treat. Care must be taken not to introduce the contamination into the material surface (hammering effect), jeopardizing the ability to meet clearance levels. These techniques are not appropriate for complicated surfaces where uniform access is not easy.

Innovative decontamination techniques have been proposed in recent years in the framework of radioactive waste management research and development programs. Mostly, these emerging technologies are hybrid technologies comprising one or more of the following methods: chemical, electrochemical, mechanical, laser, or sonic.

4.2.2 Chemical Decontamination

Chemical decontamination is usually carried out by circulating the selected reagents in the system. However, segmented parts may be decontaminated by immersing them in a tank containing the reagent, which is then mainly agitated. Application of specific chemical decontamination depends on many factors, e.g., shape and dimensions of the item to be decontaminated, kind and nature of chemical reagents, type of material and contamination, availability of proper process equipment, etc.

Many chemical reagents and techniques have been developed for the routine decontamination of systems during operation and decommissioning of nuclear facilities. Chemical decontamination processes are basically divided into two groups. Mild chemicals including noncorrosive reagents such as detergents, complexing agents, dilute acids, or alkalis. Aggressive chemicals include concentrated strong acids or alkalis and other corrosive reagents. The dividing line between these two groups of processes is usually at an about 1–10% concentration of the active reagent.

Mild chemical decontamination techniques have generally been used for items where the objective is to remove contamination without attacking the base material. Their advantages are low corrosion rates and low chemical concentrations, which facilitate the treatment of the spent decontamination solutions (secondary waste). Although some low-concentration decontamination techniques have low decontamination factors and require long contact times, they may be made more effective by combining them with processes using noncorrosive oxidizing or reducing agents, and complexing and chelating agents, and applying them in several stages. In many cases, the effectiveness may also be improved by increasing the treatment temperature by 20–90 °C. The selection of redox and chelating agents depends on the composition of the surface corrosion products to be removed.

Aggressive chemical and electrochemical decontamination techniques may involve one or more stages, using different chemical solutions. Intermediate rinses are recommended in order to avoid potential problems with recontamination. The advantages of the process include

short-time application and high decontamination factors (usually from 10 to 100 decrease in activity levels). Its limitations include high chemical concentrations and potential problems for effluent-treatment systems.

A multi-step process (i.e., the application of a strongly oxidizing solution followed by a complexing acid solution) is a common technique for removal of the contaminated oxide layer from metal surfaces, such as stainless steel. The first (alkaline) stage is intended to oxidize the chromium oxides to yield soluble chromate ions. The second (acid) stage is primarily a dissolution reaction for the complexing of dissolved metals.

Alkaline permanganate solutions are the most common reagents for the first stage. At the second stage, a variety of reagents such as ammonium citrate, ammonium citrate followed by ethylenediaminetetraacetic acid (EDTA), oxalic acid, a mixture of citric and oxalic acid, sulfuric acid, etc., have been used successfully for decontamination of stainless steel, carbon steel, inconel, zircaloy cladding, etc. Sulfuric, phosphoric, hydrochloric, and hydrofluoric acids and other reagents have been successfully used separately as individual aggressive decontaminants, generally at concentrations from 2 to 15%. The required decontamination level may necessitate repeating the process a number of times. Care must be taken if the dissolution process might result in unacceptable surface corrosion, e.g., where direct reuse of an item is required. Chemical techniques are generally suitable for use on complex geometries as well for uniform treatment of inner and outer surfaces of equipment, particularly where good contact between the chemical and the surface is provided, (e.g., tank immersion).

Factors considered for in-line chemical decontamination are also valid for the immersion process. However, because the tanks are usually open at the top, a proper ventilation system must be installed, and special care must be taken to avoid contact between the operators and the highly corrosive reagents. It should be noted that chemical reagents at excessively high temperatures might provoke undesirable effects, such as toxic or explosive gases, e.g., hydrogen.

Chemical decontamination requires efficient recycling of reactive chemicals, as insufficient recycling of decontamination products may increase the amount of secondary waste, which may be difficult to treat. It may generate mixed waste, and may result in corrosion and safety problems when misapplied. In addition, it requires both different reagents for different surfaces, and drainage control.

For large jobs, it generally requires constructing a chemical storage and collecting equipment as well as addressing criticality concerns, where applicable. Chemical decontamination is usually not effective on porous surfaces.

In general, knowledge of chemical cleaning methodology is a prerequisite for assessing decontamination technology, as most of the procedures and chemicals used to decontaminate nuclear materials and equipment are also used for cleaning equipment and materials in the chemical processing industry. Both chemical cleaning and decontamination require the same areas of knowledge and experience: chemistry of fouling, corrosion technology, and waste-generation/removal techniques. Furthermore, the same engineering knowledge is required to devise suitable procedures for mixing, pumping, and heating solvents and other chemical-cleaning constituents. Compliance with basic health and safety practices regarding chemical agents is required, in addition to the radiological safety aspects. As a minimum, workers should go through a training program and be equipped with glasses, full-body protective coveralls, impermeable gloves, and foot covers. Additional safety equipment depends on the toxicity of contaminants.

Chemical Reagents

For decommissioning programs, there is a wide range of chemical reagents to choose from, since corrosion of the base metal is of little concern. Certain chemical reagents exhibit a time dependency in the mixing, heating, recirculation, and draining cycle, which affects both the chemical solution stability and the solubility of contained contamination. Each process under consideration should be evaluated for the effect of a loss-of-flow accident and associated cooling of the solvent. Considered factors should include toxic or explosive-gas generation, excessive plate-out, and excessive corrosion.

The selected process must include appropriate emergency procedures, e.g., emergency draining, gas detection, and emergency ventilation.

When the concentration of the contaminants in the solution increases during the decontamination process, the item being cleaned may become re-contaminated. This problem can be minimized by cleaning the least contaminated items first and by cleaning or replacing (recycling if possible) the solution, if the concentration of contaminants exceeds certain levels.

Some multi-step processes are commonly used for removing highly adhesive contamination layers. In many cases, chemical decontamination may be used as a step in a multi-step process (e.g., before electropolishing).

Spent Decontamination Solutions

The selection of the chemical reagent obviously determines the chemical characteristics of the secondary waste arising from the process. Continuous renewing of the solution increases the decontamination effectiveness, but the quantity of spent solution to treat and to dispose of also increases dramatically. In more recent years, the regeneration of chemicals has become a fundamental part in all chemical decontamination processes. Several conventional chemical processes may be used for regenerating the spent solutions, possibly in combination with, for example, ion exchange, evaporation/distillation, and electrodialysis.

The problem of limiting the secondary waste arising from the decontamination process may result in the selection of similar processes, like electropolishing or ultrasound with chemicals, rather than solely chemical decontamination. As stated previously, only a detailed cost-benefit analysis can provide the actual criteria for selecting the best option for a specific decontamination task.

Guidelines

When selecting a suitable chemical decontamination process, in addition to the outlined general considerations and in view of the variety of chemical decontamination processes available, several criteria must be considered in a detailed analysis based on site-specific conditions.

Most criteria are related to the specific features of a nuclear installation, such as:

- Location of the contamination (e.g., inner vs. outer surfaces of closed systems)
- Physical integrity status of the systems
- Materials (e.g., steel, concrete)
- History of operation (to determine the contamination-strata profile)
- Nature of the contamination (e.g., oxide, crud, particulate, sludge)

- Effectiveness of previously used chemical decontamination processes
- Distribution of contamination (e.g., surface, cracks, homogeneous distribution in bulk material)
- Exposure to humans and the environment
- Safety, environmental, and social issues
- Exposure-level-reduction requirements (e.g., recycling vs. disposal)
- Quantity and type of secondary waste from decontamination and conditioning
- Ultimate fate of decontaminated materials
- Time
- Cost

Taking into account the general considerations presented in these sections on chemical decontamination, an overview of the main advantages and disadvantages of this technique is provided in [▶ Table 10](#) for the selection of the most appropriate technique.

4.2.3 Electrochemical Decontamination

Electrochemical decontamination may be considered in principle a chemical decontamination assisted by an electrical field. Electropolishing is a process widely used in nonnuclear industrial applications to produce a smooth polished surface on metals and alloys. It may be considered the opposite of electroplating, as metal layers are removed from a surface rather than added as a coating.

Electrochemical decontamination uses direct electric current, which results in the anodic dissolution and removal of metal and oxide layers from the component. The dissolution may be obtained by immersing the items to be decontaminated in an electrolyte bath as anode, or fitted with anodes.

This method is useful for decontaminating items with easily accessible surfaces.

Current may also be delivered to a submerged component by moving a pad over the surface to be decontaminated, as an efficient method for regular surfaces. The electrolyte is continuously regenerated by recirculation.

For in-tank electropolishing, at least two (stainless steel) tanks are required. One tank contains the electrolyte, electrodes, and parts to be decontaminated. The other tank holds the water used for rinsing the parts after decontamination.

Power supply amperages of up to 2,500 A are common. To control the vapors released from the electrolyte during the electropolishing process, an extraction hood is located alongside the electropolishing tank. Provisions for heating and agitating the electrolyte as well as rinsing the tank are also required.

Electrochemical decontamination processes may only be applied for removing radionuclide contamination from conducting surfaces, such as iron-based alloys (including stainless steel), copper, aluminum, lead, and molybdenum. They are highly effective and give a high decontamination factor.

Important operating parameters for electrochemical decontamination are obviously electrolyte concentration, operating temperature, electrode potential, and current density.

The effectiveness of the decontamination may be limited by the presence of adhering materials on the surface of the items to be decontaminated. Materials such as oil, grease, oxides

■ Table 10

Advantages and disadvantages related to chemical decontamination

Advantages	Disadvantages
<ul style="list-style-type: none"> • Chemical decontamination is relatively simple and similar to classical cleaning in the conventional industry for which a lot of experience exists. It may also be relatively inexpensive where additional equipment is not required • Chemical decontamination is a known practice in many nuclear plants and facilities • With proper selection of chemicals, almost all radionuclides may be removed from contaminated surfaces. Problems of recontamination may be reduced by continuously rinsing the surface with water • With strong mineral acids, a decontamination factor of more than 100 decrease in activity levels may be achieved, and in many cases, the item may be decontaminated up to releasable levels • Chemical decontamination may also remove radioactivity from internal and hidden surfaces. However, in this case, its effectiveness may be low, and measurement at release levels will be a problem • Chemical decontamination involves relatively minor problems of airborne contamination, similar to those of the closed-system approach 	<ul style="list-style-type: none"> • The main disadvantage of chemical decontamination is the generation of secondary liquid waste, resulting in relatively high volumes compared to other processes, such as electropolishing. The treatment and conditioning of this secondary waste requires appropriate processes to be considered when selecting the decontamination option. Moreover, in some cases (e.g., internal and hidden surfaces), the effectiveness of the decontamination may be relatively low • Usually the solution must be heated up to 70 to 90 °C in order to improve the kinetics of the decontamination process • A further disadvantage in obtaining high decontamination factors is that corrosive and toxic reagents may require particular care • Chemical decontamination is scarcely effective on porous surfaces

(rust), and paint or other coatings should be removed before decontamination. The use of electrochemical decontamination is limited:

- When immersion is used, by the size of the bath
- When a pad is used, by the geometry of the surfaces and the available free space around the parts being treated

This makes the method almost inapplicable for industrial decontamination of complex geometries (e.g., small-diameter pipes).

Chemical Reagents

Phosphoric acid is normally used as electrolyte in electropolishing because of its stability, safety and applicability to a variety of alloy systems.

Moreover, the nondrying nature of phosphoric acid helps minimize airborne contamination, and the good complexing characteristics of phosphoric acid for metal ions is a significant factor in minimizing recontamination from the electrolyte.

Other electrolytes, such as nitric acid and sodium sulfate, have been investigated and proposed as alternatives to phosphoric and sulfuric acid. The need for new electrolytes was initially motivated by the incompatibility of phosphoric and sulfuric acids with the existing treatment facilities and the possibility of producing secondary liquid waste which is easier to process or regenerate.

Today, problems associated with the treatment of secondary liquid waste have only partly been resolved.

Secondary-Waste Generation

Electrochemical decontamination by electropolishing causes a steady increase of dissolved iron in the phosphoric acid. If the iron content exceeds 100 g/dm^3 , a precipitation of iron phosphate occurs and ends the efficiency of the decontamination process.

Therefore, the acid has to be exchanged or regenerated periodically. In doing so, the volume of effluents is limited; however, handling the parts to be immersed or the pad, may lead to additional exposure of workers.

Guidelines

When selecting a suitable electrochemical decontamination process, criteria must be considered in a detailed analysis based on site-specific conditions. These are similar to the criteria already mentioned, but taking into account that electrochemical decontamination processes require conducting surfaces.

From the general considerations presented in the foregoing sections on electrochemical decontamination, some main advantages and disadvantages of this technique may be indicated as in  [Table 11](#) to allow selection of the most appropriate technique.

4.2.4 Mechanical Decontamination

Mechanical decontamination methods may be classified as either surface cleaning (e.g., sweeping, wiping, and scrubbing) or surface removal (e.g., grit blasting, scarifying, drilling, and spalling). Mechanical decontamination may be used either as an alternative to chemical decontamination, or simultaneously with chemical decontamination or in sequence with chemical decontamination.

In general, mechanical decontamination methods may be used on any surface and achieve very good results. When these methods are used in combination with chemical methods, even better results may be achieved. Moreover, when dealing with porous surfaces, mechanical methods may be the only choice.

There are two basic disadvantages with the mechanical methods. First, the methods require the surface of the workpiece to be accessible (i.e., the workpiece should generally be free of crevices and corners that the process equipment cannot easily or effectively access). Second, if necessary precautions are not taken, many methods may produce airborne dust. If contamination is a concern, it requires a containment to protect the workers' health and to prevent the spread of contamination.

■ Table 11

Advantages and disadvantages related to electrochemical decontamination

Advantages	Disadvantages
<ul style="list-style-type: none"> • Electropolishing is commercially available. Major equipment is relatively inexpensive and process and processing procedures fairly simple. It is capable of decontaminating to background levels for decommissioning purposes, removing practically all radionuclides covering the surface, including plutonium, uranium, radium, cobalt, strontium, cesium and americium, giving typically decontamination factors of more than 100 in activity levels • Electropolishing may decontaminate flat areas, corners, recessed geometries, tanks, etc., where measurement down to release levels do not cause any problem. It produces a smooth polished surface with a low inherent ability to be recontaminated. The thickness of metal removed during decontamination is generally less than 25 μm • When compared to the volume of liquids required for chemical decontamination, electrolyte volumes for electrode contamination are relatively small 	<ul style="list-style-type: none"> • For the most widely used processes (i.e., in-tank), the item to be decontaminated must be removed from the plant and immersed in the tank with electrolyte. For the in situ process, access or entry for the device into the item to be decontaminated is required. Therefore, the use of electrochemical decontamination is limited by the size of the bath, when immersion is used, and by the geometry of the surfaces and the available free space around the part being treated, when a pad is used. This makes the method less applicable for industrial decontamination of complex geometries (e.g., small diameter pipes) • The treatment of the electrolyte for disposal (if not recyclable) requires neutralization and processing in a treatment system for liquid radioactive waste • Electropolishing does not remove (or removes with difficulty) fuel fines, sludge or any insulating material from the surfaces • Hidden parts as the inside of tubes are treated poorly • Handling of components may lead to additional exposure to workers

As with chemical decontamination, the selection of the most effective technique depends on many variables, such as the contaminants involved, surface material, and cost. The selected treatment may have to be applied several times to meet the established decontamination objective. Because each of these techniques may be modified according to site-specific conditions, the actual effectiveness and implementability of a technique should be explored in site-specific feasibility studies.

Surface-cleaning techniques are used when contamination is limited to near-surface material.

Some techniques may remove thin layers of the surface to eliminate the contamination. However, these techniques differ from surface-removal techniques in that the removal of the

contaminant from the surface is the goal rather than the removal of the surface layer itself. Certain surface-cleaning techniques generate contaminated liquids that need to be collected and treated. Many surface-cleaning techniques may be used for both equipment and building decontamination, and some may be used as a secondary treatment following surface layer removal.

Because these techniques are versatile, it may be advantageous to locate a centralized decontamination facility on-site in which one or more of these techniques are used. Such a facility could then be used to decontaminate components that are dismantled in large pieces, or segmented.

Abrasive-Blasting Decontamination Systems

Wet and dry abrasive-blasting systems, derived from conventional industry, may provide very high decontamination factors. The longer the operations are continued, the more destructive they are. Care must be taken not to introduce contamination into the material surface (hammering effect), so that the ability to meet clearance levels is not jeopardized. Wet abrasive systems also produce a mixture of dust and water droplets that might be difficult to treat.

A wet abrasive-blasting system is a closed-loop, liquid abrasive decontamination technique.

The system uses a combination of water, abrasive media, and compressed air, and is normally applied in a self-contained, watertight, stainless-steel enclosure.

There is no danger of airborne contamination, since a self-contained air ventilation system with absolute filter maintains a negative pressure inside the cabinet. Radioactive waste is mechanically separated from the cleaning media (e.g., by cyclone/centrifuge separation, sieving, etc.). Water may be filtered and recycled, and no soluble or hazardous chemicals are required.

Wet abrasive cleaning is being used in many nuclear facilities to remove smearable and fixed contamination from metal surfaces, such as structural steel, scaffoldings, components, hand tools, and machine parts.

The equipment may be used on close-tolerance parts, such as turbine blades or valves, where the removal of metal is not desired, or it may be adjusted to remove heavy-duty corrosion and paint by varying the amount of air pressure and abrasive media.

The dry abrasive-blasting technique, commonly called sandblasting or abrasive jetting, has been used in nonnuclear industries since the late 1800s. This technique, which uses abrasive materials suspended in a medium that is projected onto the surface being treated, results in a uniform removal of surface contamination. Compressed air or blasting turbines are normally used to carry the abrasive. The removed surface material and abrasive are collected and placed in appropriate containers for treatment and/or disposal. Recirculation of abrasives allows the minimization of secondary waste.

Dry abrasive-blasting is applicable to most surface materials except those that might be shattered by the abrasive, such as glass or plexiglas. Application on aluminum or magnesium should also be avoided due to the risk of dust explosions. It is most effective on flat surfaces, and because the abrasive is sprayed, it is also applicable on hard-to-reach areas. Nonetheless, materials such as oil and grease, or obstructions close to or bolted to components, must be removed before application, and precautions should be taken to stabilize, neutralize, or remove combustible contaminants, because some abrasives may cause some materials to detonate or generate dust explosions.

Static electricity may be generated during the blasting process; therefore, the component being cleaned, or the installation itself, should be grounded. Industrial remotely-operated units are available.

Abrasive Media Used

Depending on the application, a variety of materials may be used as abrasive media:

- Minerals (e.g., magnetite or sand)
- Steel pellets, aluminum oxide
- Glass beads/glass frit, silicon carbide, ceramics
- Plastic pellets
- Natural products (e.g., rice hulls or ground nut shells)
- Carbon dioxide (dry ice, for “cold” oxides, painted surfaces, etc.)

Silica has also been used as an abrasive; however, its use is not recommended since it is moderately toxic as a highly irritating dust and is the chief cause of pulmonary disease.

Prolonged inhalation of dusts containing free silica may result in the development of a disabling pulmonary fibrosis known as silicosis.

Secondary Waste Generation

As indicated previously, abrasives may be applied under either wet or dry conditions. Under dry conditions, dust-control measures are needed for dusts and/or airborne contamination. This problem may be reduced by using filtered vacuum systems in the work area.

When water is used to apply the abrasive, large volumes of waste are produced, including the wastewater, the abrasive, and the removed debris. Proper treatment and disposal of this waste is necessary. Recirculation of abrasives and recycling of the wastewater (treated or not before reuse) allows a significant reduction of the amount of secondary waste.

➤ *Table 12* gives some results on work rates and secondary-waste production during decontamination work carried out with both a dry and a wet abrasive-blasting system on the scale of a pilot project. Water consumption includes washing water to clean components and installation after each decontamination cycle.

Guidelines

When selecting a suitable abrasive decontamination process, again its criteria must be considered in a detailed analysis based on site-specific conditions. These criteria are very similar to the criteria already mentioned, taking into account the specific characteristics of the abrasive-blasting decontamination process.

Some main advantages and disadvantages of dry and wet abrasive blasting are provided in ➤ *Table 13* for the selection of the most appropriate technique.

4.2.5 Decontamination by Melting

During the decommissioning of nuclear plants, large quantities of slightly contaminated metallic scrap are generated. These scraps may also result from maintenance and from the replacement of equipment. Much of this waste consists of bulky equipment (e.g., heat exchangers, moisture separators, steam generators, etc.) that, if disposed in appropriate repositories,

■ Table 12

Some results of dry and wet abrasive blasting decontamination of metals (SOGIN-NIS)

Parameters		Dry abrasive blasting	Wet abrasive blasting
Efficiency		Very high	Lower
Grit consumption		55 g/kg metal	109 g/kg metal
Secondary-waste production	Intervention clothing	5.3%	8.2%
	Grit waste	5.5%	10.9%
	Water consumption	–	6.9 l/kg metal
Decontamination rate	Plates	57.4 kg/h	48.0 kg/h
		2.8 m ² /h	2.3 m ² /h
	Profiles	127.7 kg/h	106.8 kg/h
		1.8 m ² /h	1.3 m ² /h
Grit cost		0.5 euro/kg	2.25 euro/kg

■ Table 13

Advantages and disadvantages of dry and wet abrasive blasting decontamination of metals

Advantages	Disadvantages
<ul style="list-style-type: none"> • Generally, abrasive-blasting techniques have proved effective. In many cases, the equipment is well developed and commercially available. Industrial equipment is also available for remote operation • Several methods remove tightly adherent material, including corrosion layers. Special tools for cleaning the inside of tanks and pipes are also available • The abrasive-blasting technique is effective in a relatively short time 	<ul style="list-style-type: none"> • Abrasive-blasting techniques generally produce a large amount of waste, if recirculation and/or recycling of abrasives and/or water is not available. In some cases, it is difficult to control the amount of base metal removed. In dry abrasive systems, dustcontrol measures are needed to control dust and/or airborne contamination. Wet abrasive systems also produce a mixture of dust and water droplets that might be difficult to treat • Care must be taken not to introduce the contamination into the material surface (hammering effect) in order for the ability to meet clearance levels

would consume considerable volumes of the available space. Moreover, in many cases, this equipment contains valuable material that can be recycled, including pressure-vessel steel, stainless steel, and inconel. By melting slightly contaminated scraps, it is possible to recover much of these valuable metals, while simultaneously sparing valuable space at final disposal facilities. The pieces of equipment considered frequently also have complex geometries, making it extremely difficult, time-consuming, and expensive to determine the exact location and level of radioactivity on the internal surfaces. After melting, however, the radioactivity may be precisely determined from samples of each ingot. Moreover, an ingot may be released for restricted or unrestricted reuse, or stored for decay to appropriate limits.

The melting completely destroys components and, as a decontamination technique, is effective only for contaminants that are volatile or that concentrate in the slag (e.g., plutonium) rather than in the molten metal. The decontamination efficiency varies widely, depending on the considered radioisotope. The radionuclides remaining in the molten material are distributed homogeneously and effectively immobilized, thus, reducing the possibility of the spread of contamination. In some cases, when ingots are found to be so active as to be sent to a final repository, melting would have achieved the maximum volume reduction and thus preserved valuable repository capacity. As an alternative, some ingots with activity levels above unconditional-release limits may be re-melted to make shielding blocks or cold-rolled to fabricate containers for radioactive waste, and thus recycled within the nuclear industry.

A particularly advantageous consequence of melting is its “decontamination” effect on ^{137}Cs , a volatile element that has a half-life of 30 years. During melting, ^{137}Cs accumulates in the dust collected by ventilation filters and is removed. The dominant remaining radionuclide in the ingots (for most reactor scrap) is ^{60}Co . This element has a half-life of only 5.3 years. Other remaining nuclides have even shorter half-lives. Consequently, ingots with reasonably low-activity concentrations may be stored for release in the near future. Moreover, exposure of foundry workers to radiation during the subsequent re-melting of ingots is drastically reduced as a result of the removal of the ^{137}Cs . The secondary waste consists of the slag from segmenting and melting, as well as dust from the ventilation filters. This secondary waste only constitutes between 1 and 4% of the weight of the melted scrap.

Current Melting Practices

Limited quantities of metallic scrap thus far have been released from nuclear facilities for melting at conventional facilities. These releases have been permitted based on each case and the qualifying release limits for radioactivity have varied for different countries. The prevailing practices and conditions at these conventional foundries during the direct melting of contaminated scrap had previously provided the basis for calculating the exposure of workers and the public.

However, within the last 10 years, the melting of contaminated steel in special-purpose plants for recycling has developed as a new industry. Established techniques are being utilized for minimizing the quantity of active metallic waste. A number of plants melt or formerly melted contaminated metals on an industrial scale.

➤ *Table 14* illustrates the accomplishments of some of these facilities. All operate in “controlled” areas using safety precautions, including filtered ventilation and health physics supervision. Moreover, the slag and dust collected in the filters are treated as radioactive waste.

➤ *Table 15* provides some additional details of interest.

At the Studsvik Melting Facility, the ingots are stored, if necessary, to permit them to decay until they may be released for re-melting at commercial foundries. Prior to release, the material is certified by the appropriate radiation protection authorities. After re-melting, the materials may be used without radiological restrictions.

The main advantages from this re-melting strategy are:

- The volatile nuclides like ^{137}Cs have been removed in the first melt. Consequently, dust is no longer a radiological problem in further re-melting processes.
- There is no surface contamination.
- The slag has been removed as radioactive waste.

■ **Table 14**
Operating melting facilities

Facility	Melted scrap (tons)	Recycled/released
CARLA ^a	7,000	6,800 tons recycled in nuclear industry, 50 tons free release
STUDSVIK ^b	1,500	230 tons released, remaining stored for decay (or dis-posal)
INFANTE ^c	3,600	Stored/recycling in nuclear industry
SEG ^d	2,000	Recycling in nuclear industry

^aCARLA Plant, Siempelkamp, Germany (start 1989)

^bSTUDSVIK Melting Facility, Sweden (start 1987)

^cINFANTE Plant, Marcoule, France (start 1992)

^dScientific Ecology Group (SEG) Plant, Oak Ridge, USA (start 1992)

■ **Table 15**
Characteristics of operating melting facilities

Facility	Furnace type	Metal treated	Charge size (tons)	Products	Radiological limitations
INFANTE	Electric arc melting furnace	Carbon steel, stainless steel	12	Ingots, shield blocks, waste containers	Maximum 250 Bq/g for ⁶⁰ Co, other limits for other nuclides
STUDSVIK	Induction for steel, small electric arc for aluminum	Carbon steel, stainless steel, aluminum	3	Ingots	No specified limits
CARLA	Induction	Carbon steel, stainless steel, aluminum, copper, lead (R&D)	3.2	Ingots, shield blocks, waste containers	Maximum 200 Bq/g for beta-gamma nuclides, maximum 100 Bq/g for alpha nuclides, separate limits for uranium
SEG	Induction	Carbon steel, stainless steel, aluminum, (planning to melt copper and titanium)	20	Ingots and shield blocks at present, waste containers and reinforcing steel after 1994	Normally <2 mSv/h, greater dose rates with prior review and approval

Advantages of Melting as a Decontamination Technique

Melting presents the particular advantage of redistributing a number of radionuclides among the ingots, slag, and filter dust resulting from the melting process, thus decontaminating the primary material.

Melting may provide an essential step when releasing components with complex geometries, simplifying monitoring procedures for radioactive metal characterization. In addition to its decontamination effects, the problem of inaccessible surfaces is eliminated and the remaining radioactivity content is homogenized over the total mass of the ingot. So melting may be a last step in the decontamination and release of components with complex geometries, after these pieces have been decontaminated, for example, by chemical methods that remove radionuclides, such as ^{60}Co , that would remain in the ingot after melting.

4.2.6 Other Decontamination Techniques

In special cases, other decontamination techniques (e.g., ultrasonic, laser, high-pressure water jetting or steam spraying, thermal erosion, pastes, gels, foams, etc.) have also been used in decommissioning. Some of them, however, require more or less complex application procedures or still need more development to allow industrial applications.

4.3 Decontamination of Building Surfaces

4.3.1 Overview

When decontaminating building structures, mainly mechanical surface-removal techniques have to be considered. Surface-removal techniques are used when future land-use scenarios include reuse, when it is impractical to demolish the building (e.g., a laboratory within a building), or in view of waste minimization. The techniques considered in the following sections remove various depths of surface contamination (e.g., floors vs. walls), and may be used to reduce the amount of contaminated material for disposal. For example, if a contaminated building is demolished, all the debris is considered contaminated and requires special handling.

However, by first using a surface-removal technique, the volume of contaminant is limited to the removed surface material. The eventual demolition may then be performed conventionally. In this instance, a cost-benefit analysis should be prepared and consider such potential concerns as packaging, shipping, and disposal costs involved when using a surface-removal technique as compared with conventional demolition and disposal.

Before any surface-cleaning or surface-removal activity, surface preparation and safety precautions are required. Surfaces to be treated must be free of obstructions (e.g., piping and supports should be dismantled or segmented), and should be vacuumed to minimize release of airborne contamination during application of the surface-removal technique. Moreover, precautions are needed to prevent explosions when treating an area containing combustibles. In this instance, all combustibles should be neutralized, stabilized, or removed.

Due consideration should be given to industrial hazards associated with the use of these techniques and to unacceptable damage that may be caused.

Finally, contaminated debris (i.e., the removed portion of the surface) must be collected, treated and/or disposed, and any liquids used during the removal process, either as part of the process or as dust control, must be processed/recycled.

In cases in which a contaminant has penetrated the material beyond the surface layer, further treatment may be required.

Most of the surface-removal techniques usually leave an undesirable surface finish. If a smoothly finished surface is required (i.e., if the building is to be reused), a concrete cap or some other surface-smoothing treatment must be applied. Due consideration should also be given to the industrial hazards associated with the use of these techniques and to unacceptable damage that may be caused (i.e., stability of the building).

4.3.2 Basic Techniques

Decontamination processes to be used for contaminated concrete depend greatly on the characteristics of the concrete surface to be cleaned. They may vary from very simple hand-based processes to jackhammer or drilling removal techniques. The former is normally used for cleaning painted or smooth surfaces covered by loose contamination and the latter for decontaminating concrete in which the contamination has penetrated deeply.

Simple processes, such as brushing, washing and scrubbing, and vacuum cleaning, have been widely used, as the need for decontamination/cleaning was first noted in the nuclear industry, and each nuclear facility has, to some extent, a certain practical experience of these kinds of decontamination processes. These processes are generally labor-intensive, but they have the advantage of being versatile. They are often used as a first step (e.g., to vacuum dust and remove loose contamination) before or during dismantling, to prepare items for more aggressive decontamination using stronger processes.

Other, more aggressive techniques are grinding, spalling and drilling, high-pressure water jetting, foam decontamination, the use of strippable coatings, high-frequency microwaves, laser, and induction heating. The use of most of these techniques is limited to specific applications in particular cases. Some of them have disadvantages, such as spreading of contamination or producing a lot of undesirable secondary waste. Other ones are also less suitable for industrial applications. When decontaminating concrete surfaces, mainly mechanical scarifying techniques such as needle scaling, scabbling, or shaving are used.

4.3.3 Scarifying

Scarifiers physically abrade both coated and uncoated concrete and steel surfaces. The scarification process removes the top layers of contaminated surfaces down to the depth of uncontaminated layers. A decade ago, concrete scarifying was considered a radical approach to decontamination owing to poor tool performance and inability to provide a uniform surface profile upon removal of the contaminants. Today's refined scarifiers are not only very reliable tools, but also provide the desired profile for new coating systems, in the event the facility should be released for unconditional use.

Needle Scaling

Needle scalers are usually pneumatically driven and use uniform sets of 2, 3, or 4 mm needles to obtain a desired profile and performance. Needle sets use a reciprocating action to chip contamination from a surface. Most of the tools have specialized shrouding and vacuum attachments to collect removed dust and debris during needle scaling with the result of no detectable concentrations above background levels.

Needle scalers are an excellent tool in tight, hard-to-access areas (e.g., pipe penetrations, etc.), and may also be used for wall and ceiling surface decontamination. This technique is a dry decontamination process and does not introduce water, chemicals, or abrasives into the waste stream.

Only the removed debris is collected for treatment and disposal. Production rates vary, depending on the desired surface profile to be achieved.

Scabbling

Scabbling is a scarification process used to remove layers of concrete surfaces. Scabbling tools typically incorporate several pneumatically operated piston heads striking (i.e., chipping) a concrete surface.

Available scabblers range from one- to three-headed hand-held scabblers to remotely-operated scabblers, with the most common versions incorporating three to seven scabbling pistons mounted on a wheeled chassis.

Scabbling bits have tungsten-carbide cutters, the bits having an operating life of about 100 h under normal use. Both electrically and pneumatically driven machines are available.

Because scabbling may cause a cross-contamination hazard, vacuum attachments, and shrouding configurations have been incorporated, so that scabbling may be done with no detectable increase in airborne exposures.

In practice, floor scabblers may only be moved to within some 5 cm of a wall.

Therefore, other hand-held scabbling tools are needed to remove the last 5 cm of concrete flooring next to a wall, as well as to remove surface concrete on walls and ceilings.

This technique is a dry decontamination method – no water, chemicals, or abrasives are required. The waste stream produced is only the removed debris. Work rates are not easy to predict, due to the variety of concrete composition and characteristics as well as to the different types of bits that may be used.

Scabblers are best suited for removing thin layers (up to 15 or 25 mm thick) of contaminated concrete (including concrete block) and cement. It is recommended for instances where:

- Airborne contamination should be limited or avoided
- The concrete surface is to be reused after decontamination
- Waste minimization is envisaged
- When the demolished material is to be cleaned before disposal

The scabbled surface is generally flat, although coarsely finished, depending on the bit used. This technique is suitable for both large open areas and small areas.

Concrete Shaving

As an alternative for floor scabbling, a floor shaver has been developed. This machine is similar to a normal floor scabbling unit. It has a quick-change diamond-tipped rotary cutting head designed to give smooth-surface finish, easier to measure, and ready for painting. It is capable of cutting through bolts and metal objects, which would have damaged the scabbling head of a traditional scabber. Actual cutting performance results in:

- A three-times higher mean working rate for floor decontamination compared to scabbling
- A 30–45% lower waste production than by scabbling with a comparable decontamination efficiency
- Much less physical load on the operators due to the absence of machine vibration

- End products (concrete dust) that, combined with suitable additives, may be incorporated in a cement matrix

Based on the positive experience with the floor shaver, a remote-controlled diamond wall-shaving system has been developed as a solution for concrete decontamination of larger surfaces.

The machine consists of:

- A remote-controlled hydroelectric power pack for the remote-controlled shaving unit
- Vacuum systems to fix temporarily vacuum pads holding the horizontal and vertical rails of the shaving unit
- A simple xy-frame system containing a guide rail, a vertical rail, and a carriage for the shaving head
- A quick-change diamond-tipped rotary shaving head with a dust-control cover for connection to existing dust-extraction systems

The entire system is built up in sections, which are portable by a single operator. It removes a concrete layer in a controlled and vibration-free manner with the removal depth being controllable between 1 and 15 mm per pass, and producing a smooth-surface finish.

The cutting head is designed to follow the contours of the surface being removed, and depth adjustments may be set manually in increments of 1 mm to minimize waste production. With 300 and 150 mm wide shaving heads, both large areas and awkward corners may be accessed. When the vertical rail is fitted to the wall with the cutting head shaving, the horizontal rail may be disconnected and moved forward, thus ensuring continuous operation.

Production rates vary, depending on the structure and the hardness of the concrete, the depth setting, the cutting speed and the type of diamond used. Heads can be used for shaving up to 2,000 m².

Hydraulic/Pneumatic Hammering

Cutting and decontamination of concrete structures may be carried out with hydraulic or pneumatic hammers, either hands-on or using an electrically-powered, hydraulically-controlled robot.

The latter may be equipped with a hydraulic hammer, an excavator bracket, or other tools, and is well suited for decontaminating floors and walls. A mini electro-hydraulic hammering unit (weighing only 350 kg) is commonly used in areas where contamination has penetrated deeply into the concrete surface, increasing the decontamination possibilities, and reducing significantly the workload for the operators.

Dust Collection

For dustless decontamination of concrete, scabblers, scarifiers and shavers may be integrated into a system of remotely and manually operated scarifying equipment. With these systems, dust, and debris are captured at the cutting-tool surface, which minimizes cross-contamination. For hand scabblers and smaller systems, dust evacuation is carried out using industrial vacuum cleaners (capacities of up to 500 m³/h), and equipped with absolute filtering systems at the outlet.

Larger scabbling or shaving machines are connected to vacuum systems with capacities of up to 2,500 m³/h, or higher. They incorporate a cyclone to evacuate larger concrete particles, a filtering system with cleanable prefilters and absolute filter, and a vacuum pump. The cleanable

■ **Table 16**

Typical work rates obtained with different kinds of scarifying techniques (SOGIN-NIS)

Scarifying technique	Layer thickness removed (mm)	Removal speed (m ² /h machine working time)
Needle scaler	2	0.1
Hand scabblor (1 head)	2	0.6
Floor scabblor (7 heads)	3	4.6
Wall scabblor (3 heads)	3	4.6
Wall scabblor (7 heads)	4	8.4
Floor shaver	1.5	13.6
Wall shaver	1.5	21

filtering system incorporates a fill-seal drum changeout (contamination-free exchange) method that allows the operator to fill, seal, remove, and replace the waste drum under controlled conditions. The unit may accommodate different drum sizes and several scabblers, shavers, and needle scalers at longer distances.

Production Rates

Typical work rates obtained with needle scalers, scabblers, and shavers are indicated in [Table 16](#).

4.3.4 Guidelines

When selecting an appropriate decontamination technique for building surfaces, the general considerations already presented should be taken into account. In any case, the use of techniques that would make contamination penetrate further into the substrate should be avoided. In addition, as general rules:

- For decontaminating painted floors and walls, where it may be proved that contamination has not penetrated into the substrate, simple processes such as brushing, washing, scrubbing, and vacuum cleaning may be used
- For decontaminating concrete surfaces which are not painted and in which the contamination has slightly or more deeply penetrated the substrate, more aggressive techniques (e.g., scabbling, shaving, jackhammering or drilling) must be adopted

4.4 Chemical Decontamination Techniques

4.4.1 Overview

Chemical reagents are widely used in the nuclear industry as decontaminants. The objective of chemical decontamination in the nuclear industry is to remove fixed contamination on surfaces of piping, components, equipment, and facilities.

The advantages of chemical decontamination are that it can be used for inaccessible surfaces, requires less work-hours, can decontaminate process equipment and piping in place, and can usually be performed remotely.

Chemical decontamination also produces few airborne hazards, uses chemical agents that are readily available, produces wastes that can be handled remotely, and generally allows the recycling of the wash liquors after further processing.

The disadvantages of chemical decontamination are that it is not usually effective on porous surfaces, can produce large volumes of waste (although volume may be reduced by a radioactive waste treatment system), may generate mixed waste, and can result in corrosion and safety problems when misapplied.

In addition, it requires different reagents for different surfaces, drainage control; the construction of chemical storage and collecting equipment for large jobs; and addressing criticality concerns, where applicable.

4.4.2 Water/Steam

Water is a universal decontamination agent that acts by dissolving the chemical species or by eroding and flushing loose debris from the surface. It can be used on all nonporous surfaces, and its effectiveness can be enhanced by increasing its temperature, adding a wetting agent and detergent, or using a water jet. Steam is effective partially because of its velocity impinging on the surface, and it can be made more effective with detergents.

Steam can be used on any nonporous surface that can withstand the temperature, but it is most useful on accessible surfaces. Steam generally provides better decontamination factors (DF) than water for flat-coated or polished surfaces. Dry steam has been applied in some cases to uncoated concrete.

Most ionic compounds are soluble in water; therefore, water/steam is the first choice for sluicing bulk salts and solids from tanks. For surfaces with grease or oil, it is not effective unless detergents are added. Water is most effective when the contaminant has been in contact with the surface for only a short time.

Water by itself has little effect in removing longstanding contaminants and those that are chemically bonded to the substrate. It has almost no effect on hard metal oxide and carbonate or silicate scales, and it reacts violently with metallic sodium or potassium. Most transition metal compounds have limited solubility in water, unless the pH is lowered.

The advantages of using water as a decontaminant are that it is cheap, available, nontoxic, noncorrosive, and compatible with most radioactive waste systems. In addition, water/steam requires few support services that are present in the plant. Because of its safe nature, it can be used in large facilities and environmental flushing operations. Remote operations can be accomplished with fire hoses, jets, or steam lances. Most cleaning operations use a water flush before other agents are employed.

The advantage of using steam is that the mass of water is reduced.

The disadvantages of water as a decontaminant are that large volumes are usually required and contaminants can resettle onto other surfaces. In particular, the use of water has the tendency to spread radioactive contamination, which complicates the control of cleanup. If fissile materials are present, criticality concerns become paramount.

4.4.3 Strong Mineral Acids

The strong mineral acids used in decontamination are:

- Hydrochloric acid: HCl
- Nitric acid: HNO₃
- Sulfuric acid: H₂SO₄
- Phosphoric acid: H₃PO₄

These acids can be used by themselves as dilute solutions, in formulation mixtures with acid salts and other compounds, and in combination with each other – such as HNO₃-HCl. Their main purpose is to attack and dissolve metal oxide films and lower the pH of solutions to increase solubility or ion-exchange of metal ions. They can be used on almost all metal surfaces except reactive metals like zinc. The acids work rapidly and very effectively.

All the acids are relatively cheap (except H₃PO₄), and all are commonly available industrial compounds.

The advantages of using the strong acids are that they are relatively cheap, quick, and effective. The disadvantages are that they present safety and handling problems, require neutralization before waste treatment, and are incompatible with many materials. Explosive or poisonous gases can be produced in reactions with some compounds.

Typical examples of the effectiveness of using strong acids for decontamination follow.

Hydrochloric Acid

HCl is one of the first chemical cleaning agents used for utility boilers. It was used in decontaminating the BONUS reactor CrMo steel main steam system and stainless steel purification system in preparation for entombment.

A reagent grade solution (10% by volume) was found to be effective at an operating temperature of 70 °C. One-inch square samples for testing in the United Nuclear Corporation laboratory were cut from sections of piping contaminated with ⁶⁰Co, ⁵⁸Co, and ⁶⁵Zn and small quantities of fission products, including ¹³⁷Cs. Laboratory testing consisted of 30-min cycles in static tests (soaking) of candidate solutions and then 30-min cycles in dynamic tests (stirred) of solutions. The most effective solutions were given a final dynamic test on larger samples from the reactor systems.

Laboratory data indicated HCl decontamination of stainless steel gave repeatable DFs of approximately 10. No inhibitor was used because the systems were not going to be returned to service, and the expected corrosion would not affect the residual radioactivity containment integrity of systems.

Actual system decontamination at BONUS confirmed the laboratory results. Stainless steel CrMo systems were decontaminated with a DF of approximately 10 overall. A brief description of the acid-flushing system is included in the discussion of H₃PO₄.

Nitric Acid

HNO₃ is used for dissolving uranium and its oxides in stainless steel and Inconel systems. A typical solution is 10% by volume at 75 °C. However, it cannot be used on carbon steel because of the high corrosion rate.

HNO₃ is a strong oxidizing agent; users should have knowledge of its compatibility with materials. Use of HNO₃ on incompatible material has resulted in fires and explosions (in closed systems).

HNO_3 is also used at reprocessing plants to dissolve plutonium dioxide, fission products, sludge deposits, and residual contamination from system piping and components.

At the Eurochemic reprocessing facility, potassium permanganate (KMnO_4) was added to the HNO_3 , resulting in the most effective decontaminant of that major decontamination program.

Two similar processes used to decontaminate the cell of the acid recovery evaporator at the Tokai Reprocessing Facility in Japan were general treatment by HNO_3 , followed by a sodium hydroxide (NaOH) rinse, and decontamination of equipment bottoms using a three-stage process (i.e., AP, HNO_3 , and EDTA).

Sulfuric Acid

H_2SO_4 is an oxidizing agent used to a limited extent for removing deposits that do not contain calcium compounds.

This highly corrosive acid is used in dilute form with an inhibitor. The concentrated form has been used for removing organic deposits. H_2SO_4 has not been used extensively as a decontaminating solvent because the DFs are relatively small.

Phosphoric Acid

H_3PO_4 rapidly removes films from and decontaminates carbon steel surfaces. At 60–70 °C inhibited dilute (10%) H_3PO_4 solutions remove 95–99% of the contamination and all visible film in approximately 20 min. In practice, a ferrous phosphate film forms and is deposited on the treated area along with the contamination.

Diluted (15 vol. %) H_3PO_4 was used in decontaminating the BONUS reactor carbon steel and brass piping and components in preparation for entombment. The selection was based on a test program similar to that described for HCl. DFs between 5 and 37 experienced in laboratory tests were generally achieved during actual decontamination flushes. The carbon steel condensate system was passivated using ammonium hydroxide followed by a rust inhibiting rinse.

The use of phosphates is not recommended when the waste end product is glass.

4.4.4 Acid Solutions

Salts of various weak and strong acids can sometimes be used in place of the acids themselves, or as a more effective combination with various acids. The most commonly used salts are

- Sodium bisulphate: NaHSO_4
- Sodium sulfate: Na_2SO_4
- Ferric sulfate: $\text{Fe}_2(\text{SO}_4)_3$
- Ammonium oxalate: $\text{NH}_4\text{C}_2\text{O}_4$
- Ammonium citrate: $(\text{NH}_4)_2\text{HC}_6\text{H}_5\text{O}_7$
- Sodium fluoride: NaF

The salts can be used in combination with acids or acidic solutions to decontaminate metal surfaces. They work in a manner similar to the acid itself by dissolving or complexing the metal oxide surface, but they also provide free sodium and ammonium ions to replace contaminants at ion-exchange sites.

The salts are frequently used in combination with their parent acid and give a better DF than the acid alone. The salts are less corrosive than their parent acid and have fewer material compatibility problems, but are generally corrosive enough to require inhibitors. Their application as single agents is limited, with the exception of NaHSO_4 , which is often used alone for mild decontamination of carbon steel and aluminum.

The advantages of acid salts are that they increase the versatility of acid decontamination, produce less corrosive solutions, and are safer for personnel than the acids.

The disadvantages are that the salt solutions still present some corrosion considerations for both equipment and personnel, have limited application without addition of another acid to lower the pH of solution, and are slower acting than the acids.

4.4.5 Organic/Weak Acids

The use of weak (organic or inorganic) acids for decontamination is now widespread in the nuclear industry for nondecommissioning activities.

The most widely used weak acids include the following (in order of frequency of use):

- Oxalic acid: $\text{C}_2\text{H}_2\text{O}_4$
- Citric acid: $\text{C}_6\text{H}_8\text{O}_6$
- Sulfamic acid: HSO_3NH_2

The weak acids are generally used on metal surfaces and act by dissolving the metal oxide film and sequestering or solubilizing the metal ion. This sequestering or chelating property gives the organic acids a great advantage over the strong mineral acids.

The organic acids, also, are not as corrosive, are less toxic, and have few material compatibility problems. They contain no chloride or fluoride and thus can be used on stainless and high-alloy steels. Stainless steel is usually cleaned with organic acids, usually oxalic and citric. Plastics and other polymeric compounds can also be cleaned with organic acids.

The organic acids are used extensively on all metal surfaces where reuse or nondestructive cleaning is the objective. They may be used with or without inhibitors, depending on the acid and the conditions.

Oxalic, citric, and HSO_3NH_2 are the stronger acids and often are used with inhibitors. The organic acids may be mixed to get the full range of chelating abilities, or they may be matched to the specific surface and contaminant. Oxalic and citric acid mixtures have the greatest general use.

Oxidizing agents are often used with the acids to condition the metal so it may be solubilized. HSO_3NH_2 has the added benefit of being a solid that can be shipped and stored as a dry powder and mixed on-site. All of these organic acids are commercially available.

The advantages of the organic acids are their less corrosive nature, superior safety and handling characteristics, and double role in dissolving oxide films and sequestering the metal contaminant.

Some of the disadvantages are that they are more expensive than some of the strong acids; they react more slowly; although less corrosive than strong acids, they still have some material compatibility and personnel considerations; they can break down at high temperatures; and they require neutralization before treating in a radioactive waste system.

Several examples of the manner in which weak acids have been used are described in the following sections.

Oxalic Acid

Oxalic acid (OX) is effective for removing rust from iron. It is an excellent complexant for niobium (when present) and fission products. Oxalic acid was used at the Savannah River Plant in stainless steel heat exchangers.

The process consisted of filling the system with water, adding a corrosion inhibitor (2.6 g/l ferric sulfate), steam heating to 70 °C, adding oxalic acid to 2 wt. %, and recirculating the mixture. The system was then drained, water-rinsed, and neutralized with 50% potassium hydroxide. The system was drained and rinsed again with water. DFs of 3–20 were achieved. At temperatures of about 90 °C, the oxalic acid reacted with the stainless steel to form a highly insoluble ferrous oxalate film. Subsequent treatment with sulfuric and HNO₃ was necessary to remove the precipitate.

This acid is used as the second step with AP (alkaline permanganate) preconditioning, but because of the precipitate it is not of significant interest.

Problems may occur during evaporation when using oxalic acid because of the formation of crystals.

Oxalate Peroxide

Oxalate peroxide (OPP) is an oxidizing agent consisting of a mixture of oxalic acid and hydrogen peroxide. It is used for the simultaneous dissolution of UO₂ and the defilming and decontamination of metals.

The oxalic acid decontaminates the surface, and the hydrogen peroxide enhances the decontamination and passivates the steel by its oxidative action. However, the peroxide destroys the oxalic acid, preventing reuse of the solvent. The decontamination is fast enough to be effective before the oxalic acid is destroyed.

Hydrogen peroxide acts as a carbon-steel cleaner in concentrations up to 0.2 M H₂O₂ and then as a passivator at concentrations above 1.0 M H₂O₂. In tests at ORNL, carbon and stainless steels heated to about 200 °C and treated with OPP (pH = 4) exhibited DFs of 100–1,000 or more.

Citric Acid

A mixture of citric (0.2 M) and oxalic (0.3 M) acids with a corrosive inhibitor is used as a reducing agent. This process is very effective for decontaminating stainless steel in a two-step process following alkaline permanganate (AP). A typical procedure consists of the following steps:

- Circulate AP for 2 h at 105 °C
- Water-rinse until the (MnO₄)⁻¹ is completely removed and pH is less than 10
- Circulate dilute (10%) mixture for 2 h at room temperature
- Circulate mixture until the conductivity of the rinse water is less than 50 μmho

The citrate ions are added to complex the iron ions and inhibit the formation of any precipitate.

The dilute mixture neutralizes traces of residual NaOH (from AP) and dissolves any MnO₂ (by reduction to Mn⁺²). This dilute rinse may be eliminated for simple systems without dead-legs or crud traps. The process is not very effective unless preceded by the AP flush.

Sulfamic Acid

HSO₃NH₂ with an inhibitor is an effective decontaminant for carbon-steel components, providing good DFs with low corrosion rates. Redeposition or film formation does not occur.

Because it is a less reactive reagent, longer contact times may be necessary than with other reagents. HSO_3NH_2 has not been used extensively in decontaminating reactor carbon-steel systems, but it is acknowledged to be an effective decontaminant.

4.4.6 Alkaline Solutions

Caustic compounds are used for decontamination both by themselves and in solutions with compounds. The primary alkaline salts are:

- Potassium hydroxide: KOH
- Sodium hydroxide: NaOH
- Sodium carbonate: Na_2CO_3
- Trisodium phosphate: Na_3PO_4
- Ammonium carbonate: $(\text{NH}_4)_2\text{CO}_3$

Alkaline salts (i.e., bases) are used to remove grease and oil films, to neutralize acids, as surface passivators, to remove paint and other coatings, as a rust remover for mild steel, as a solvent for species that are soluble at high pH, and as a means of providing the right chemical environment for other agents. As a degreaser, they are normally mixed with detergents, and most commercial detergents contain mild caustic compounds.

The strong bases (KOH, NaOH) are frequently mixed in solutions with oxidizing agents (KMnO_4 and potassium metaperiodate KIO_4) and a reducing agent (NaH_4PO_2), which are not stable in acid solutions. Alkaline permanganate (NaOH and KMnO_4) is a very widely used decontaminating agent for metal surfaces, especially as a first conditioning step for stainless steel. Some important species like iodine are more soluble in alkaline solutions and can be effectively washed from the surface.

The aggressiveness with which these compounds act on paints, coatings, and films and can be controlled by using the strong bases (KOH, NaOH) for harsh attack or the weak bases for milder conditions. The alkaline solution softens the paint so that it can be removed by mechanical means. This process is often preferable to completely dissolving the paint because that may contaminate the surface under it. Alkaline solutions may be used on all nonporous surfaces, except aluminum and magnesium, which react to strong bases.

The advantages of using alkaline solutions are that they are cheap, are easy to store, have fewer material problems than acids, and can be applied in the form of gels for ceilings and walls. The disadvantages include their long reaction time and their destructive effect on aluminum. In addition, the bases are safety hazards: workers can be burned if they come into contact with them.

4.4.7 Complexing Agents

A complexing agent is a chemical species that forms a stable complex with a metal ion in two different manners. Those that are preferential form complexes with certain ions and are called sequestering agents. Chelating agents are complexing agents that bind the metal at two or more locations.

The most common complexing agents used in decontamination are the following:

- EDTA and the monoacid HEDTA
- Organic acids

- Sodium or ammonium salts of the organic acids
- Nitrilotriacetic acid (NTA)

The complexing agents solubilize certain metal ions and prevent their redeposition out of solution. This is most important since metal ions have a strong affinity for bare metal surfaces.

Complexing agents are used with solutions of detergents, acids, or oxidizing agents to dramatically increase the DFs. The ability of the agent to sequester metal ions depends on the specific ion, its oxidation state, and the solution pH.

EDTA works best with most ions, but it is expensive, and its pH range is too high for strong acid solutions used to attack metal oxide layers.
