Thus, consider that \mathcal{S} is the sample space consisting of a certain number of events, the interpretation of which is left open for the moment. Assigned to each subset \mathcal{A} of \mathcal{S} , there exists a real number $P(\mathcal{A})$, called a probability, defined by the following three axioms (after A. Kolmogorov 1933):

AXIOM I (EXISTENCE): For every subset \mathcal{A} in \mathcal{S} , the respective probability exists and is nonnegative, i.e., $P(\mathcal{A}) \geq 0$.

AXIOM II (ADDITIVITY): For any two subsets \mathcal{A} and \mathcal{B} that are disjoint (i.e., $\mathcal{A} \cap \mathcal{B} = \emptyset$), the probability assigned to the union of \mathcal{A} and \mathcal{B} is the sum of the two corresponding probabilities, i.e., $P(\mathcal{A} \cup \mathcal{B}) = P(\mathcal{A}) + P(\mathcal{B})$.

AXIOM III (NORMALIZATION): The probability assigned to the entire sample space is one, i.e., $P(\mathcal{S}) = 1$; in other words, the certain event has unit probability.

Note that, the statements of the three axioms mentioned earlier are not entirely rigorous from the standpoint of pure mathematics, but suffice for the applications to nuclear engineering. Several useful properties of probabilities can be readily derived from the axiomatic definition introduced above:

$$\begin{aligned}
 P(\bar{\mathcal{A}}) &= 1 - P(\mathcal{A}), \text{ where } \bar{\mathcal{A}} \text{ is the complement of } \mathcal{A} \\
 P(\mathcal{A} \cup \bar{\mathcal{A}}) &= 1 \\
 0 &\leq P(\mathcal{A}) \leq 1 \\
 P(\emptyset) &= 0, \text{ but } P(\mathcal{A}) = 0 \text{ does NOT mean that } \mathcal{A} = \emptyset \\
 \text{If } \mathcal{A} &\subset \mathcal{B}, \text{ then } P(\mathcal{A}) \leq P(\mathcal{B}) \\
 P(\mathcal{A} \cup \mathcal{B}) &= P(\mathcal{A}) + P(\mathcal{B}) - P(\mathcal{A} \cap \mathcal{B})
 \end{aligned}$$

The last relation above is known as Poincaré’s theorem of probability addition. This theorem can be extended to any finite sequence of events $(\mathcal{E}_1, \mathcal{E}_2, \dots, \mathcal{E}_k)$ in a sample space \mathcal{S} , in which case it becomes

$$P\left(\bigcup_{i=1}^n \mathcal{E}_i\right) = \sum_{i=1}^n P(\mathcal{E}_i) - \sum_{i \neq j} P(\mathcal{E}_i \cap \mathcal{E}_j) + \sum_{i \neq j \neq k} P(\mathcal{E}_i \cap \mathcal{E}_j \cap \mathcal{E}_k) + \dots + (-1)^{n+1} P\left(\bigcap_{i=1}^n \mathcal{E}_i\right).$$

When the events $(\mathcal{E}_1, \mathcal{E}_2, \dots, \mathcal{E}_n)$ form a finite sequence of mutually exclusive events, the above expression reduces to

$$P\left(\bigcup_{i=1}^n \mathcal{E}_i\right) = \sum_{i=1}^n P(\mathcal{E}_i).$$

When extended to the infinite case $n \rightarrow \infty$, the above relation expresses one of the defining properties of the probability measure, which makes it possible to introduce the concept of probability function defined on an event space \mathcal{S} . Specifically, a function P is a probability function defined on \mathcal{S} if and only if it possesses the following properties:

$$\begin{aligned}
 P(\emptyset) &= 0, \quad \text{where } \emptyset \text{ is the null set,} \\
 P(\mathcal{S}) &= 1, \\
 0 &\leq P(\mathcal{E}) \leq 1, \quad \text{where } \mathcal{E} \text{ is any event in } \mathcal{S}, \\
 P\left(\bigcup_{i=1}^{\infty} \mathcal{E}_i\right) &= \sum_{i=1}^{\infty} P(\mathcal{E}_i),
 \end{aligned}$$

where $(\mathcal{E}_1, \mathcal{E}_2, \dots)$ is any sequence of mutually exclusive events in \mathcal{S} .

An additional concept of *conditional probability* is introduced in order to address conditions (implied or explicit) such as “What is the probability that event \mathcal{E}_2 occurs if it is known that event \mathcal{E}_1 has actually occurred?” The conditional probability $P(\mathcal{E}_2|\mathcal{E}_1)$ that event \mathcal{E}_2 occurs given the occurrence of \mathcal{E}_1 is defined as

$$P(\mathcal{E}_2|\mathcal{E}_1) \equiv \frac{P(\mathcal{E}_1 \cap \mathcal{E}_2)}{P(\mathcal{E}_1)}.$$

As can be seen from the definition introduced earlier, conditional probabilities also satisfy the axioms of probability. In particular, this definition implies that the usual probability

$P(\mathcal{E}_1)$ can itself be regarded as a conditional probability, because $P(\mathcal{E}_1) = P(\mathcal{E}_1|\mathcal{S})$ (i.e., $P(\mathcal{E}_1)$ is the conditional probability for \mathcal{E}_1 given \mathcal{S}). The definition of conditional probability can be extended to more than two events by partitioning the sample space \mathcal{S} into k mutually exclusive events $(\mathcal{E}_1, \mathcal{E}_2, \dots, \mathcal{E}_k)$, and by considering that $\mathcal{E} \subset \mathcal{S}$ is an arbitrary event in \mathcal{S} with $P(\mathcal{E}) > 0$. Then the probability that event \mathcal{E}_i occurs given the occurrence of \mathcal{E} , $P(\mathcal{E}_i|\mathcal{E})$ is expressed as

$$P(\mathcal{E}_i|\mathcal{E}) = \frac{P(\mathcal{E}|\mathcal{E}_i)P(\mathcal{E}_i)}{\sum_{j=1}^k P(\mathcal{E}|\mathcal{E}_j)P(\mathcal{E}_j)} \quad (i = 1, 2, \dots, k), \quad (\text{Bayes' theorem}),$$

where $P(\mathcal{E}|\mathcal{E}_i)$ denotes the probability that event \mathcal{E} occurs, given the occurrence of \mathcal{E}_i . The above relation is known as *Bayes' theorem*, and is of fundamental importance to practical applications of probability theory.

Two events, \mathcal{E}_1 and \mathcal{E}_2 , are *statistically independent* if $P(\mathcal{E}_2|\mathcal{E}_1) = P(\mathcal{E}_2)$. This means that the occurrence (or nonoccurrence) of \mathcal{E}_1 does not affect the occurrence of \mathcal{E}_2 . Note that, if \mathcal{E}_1 and \mathcal{E}_2 are statistically independent, then $P(\mathcal{E}_1\mathcal{E}_2) = P(\mathcal{E}_1)P(\mathcal{E}_2)$, $P(\mathcal{E}_1|\mathcal{E}_2) = P(\mathcal{E}_1)$, and also conversely.

The numerical representation of the elementary events \mathcal{E} in a set \mathcal{S} is accomplished by introducing a function, X , which operates on all events $\mathcal{E} \subset \mathcal{S}$ in such a way as to establish a particular correspondence between \mathcal{E} and the real number $x = X(\mathcal{E})$. The function X defined in this way is called a *random variable*. Note that, X itself is the random variable rather than the individual values $x = X(\mathcal{E})$, where X generates by operating on \mathcal{E} . Thus, although X has the characteristics of a “function” rather than those of a “variable,” the usual convention in probability theory and statistics is to call X a “random variable” rather than a “random function.” As is seen in the following section, there also exists “functions of random variables,” which may, or may not, be random themselves.

Random events $\mathcal{E} \subset \mathcal{S}$ that can be completely characterized by a single-dimensional random variable X are called single-variable events. The qualifier “single-dimensional” is omitted when it is apparent from the respective context. The concept of single-dimensional random variable, introduced to represent numerically a single-variable event, can be extended to a multi-variable event $\mathcal{E} \subset \mathcal{S}$. Thus, an n -variable event $\mathcal{E} \subset \mathcal{S}$ is represented numerically by establishing the correspondence $\mathbf{x} = \mathbf{X}(\mathcal{E})$, where $\mathbf{x} = (x_1, x_2, \dots, x_n)$ is a vector of real numbers and $\mathbf{X} = (X_1, X_2, \dots, X_n)$ is a multi-dimensional random variable (or random vector, for short) that takes on the specific values \mathbf{x} .

The dimensionality of a random number is defined by the dimensionality of the particular set of values $x = X(\mathcal{E})$, generated by the function X when operating on the events \mathcal{E} . By definition, *finite random variables* are those for which the set of values x obtainable from X operating on \mathcal{E} is in one-to-one correspondence with a finite set of integers. *Infinite discrete random variables* are those for which the set of values x obtainable from X operating on \mathcal{E} is in one-to-one correspondence with the infinite set of all integers. Unaccountable or *non-denumerable random variables* are those for which the set of values x obtainable from X operating on \mathcal{E} is in one-to-one correspondence with the infinite set of all real numbers.

The main interpretations of probability commonly encountered in data and model analysis are that of relative frequency (which is used, in particular, for assigning statistical errors to measurements) and that of subjective probability (which is used, in particular, to quantify systematic uncertainties). In data analysis, probability is more commonly interpreted as a limiting relative frequency. In this interpretation, the elements of the set \mathcal{S} correspond to the possible

outcomes of a measurement, assumed to be (at least hypothetically) repeatable. A subset \mathcal{E} of \mathcal{S} corresponds to the occurrence of any of the outcomes in the subset. Such a subset is called an event, which is said to occur if the outcome of a measurement is in the subset. A subset of \mathcal{S} consisting of only one element denotes an elementary outcome. The probability of an elementary outcome \mathcal{E} is defined as the fraction of times that \mathcal{E} occurs in the limit when the measurement is repeated many of times infinitely, namely:

$$P(\mathcal{E}) = \lim_{n \rightarrow \infty} \frac{\text{number of occurrences of outcome } \mathcal{E} \text{ in } n \text{ measurements}}{n}.$$

The probability for the occurrence of any one of several outcomes (i.e., for a nonelementary subset \mathcal{E}) is determined from the probabilities for individual elementary outcomes by using the addition rule provided by the axioms of probability. These individual probabilities correspond, in turn, to relative frequencies of occurrence. The relative frequency interpretation is consistent with the axioms of probability, because the fraction of occurrence is always greater than or equal to zero, the frequency of any outcome is the sum of the individual frequencies of the individual outcomes (as long as the set of individual outcomes is disjoint), and the measurement must, by definition, eventually yield some outcome (i.e., $P(\mathcal{S}) = 1$). Correspondingly, the conditional probability $P(\mathcal{E}_2|\mathcal{E}_1)$ represents the number of cases where both \mathcal{E}_2 and \mathcal{E}_1 occur divided by the number of cases in which \mathcal{E}_1 occurs, regardless of whether \mathcal{E}_2 occurs. In other words, $P(\mathcal{E}_2|\mathcal{E}_1)$ gives the frequency of \mathcal{E}_2 with the subset \mathcal{E}_1 taken as the sample space.

The concept of probability as a relative frequency becomes questionable when attempting to assign probabilities for very rare (or even uniquely occurring) phenomena (such as a core meltdown in a nuclear reactor). In such cases, probability must be considered as a mental construct to assist us in expressing a degree of belief, and the elements of the sample space are considered to correspond to hypotheses or propositions, i.e., statements that are either true or false; the sample space is often called the hypothesis space. This mental construct provides the premises of the so-called *subjective* or *Bayesian interpretation* of probability. In this interpretation, the probability associated with a cause or hypothesis \mathcal{A} is interpreted as a measure of degree of belief, namely:

$$P(\mathcal{A}) \equiv \text{a priori measure of the rational degree of belief} \\ \text{that } \mathcal{A} \text{ is the correct cause or hypothesis.}$$

The sample space \mathcal{S} must be constructed so that the elementary hypotheses are mutually exclusive, i.e., only one of them is true. A subset consisting of more than one hypothesis is true if any of the hypotheses in the subset is true. This means that the union of sets corresponds to the Boolean OR operation, while the intersection of sets corresponds to the Boolean AND operation. One of the hypotheses must necessarily be true, implying $P(\mathcal{S}) = 1$.

Since the statement “a measurement will yield a given outcome for a certain fraction of the time” can be regarded as a hypothesis, it follows that the framework of subjective probability includes the relative frequency interpretation. Furthermore, subjective probability can be associated with, for example, the value of an unknown constant; this association reflects one’s confidence that the value of the respective probability is contained within a certain fixed interval. This is in contrast with the frequency interpretation of probability, where the “probability for an unknown constant” is not meaningful, since it would be either zero or one, but one would not know which. For example, the mass of a physical quantity (e.g., neutron) may not be exactly known, but there is considerable evidence, in practice, that it lays between some upper and

lower limits of a given interval. In the frequency interpretation, the statement “the probability that the mass of the neutron lies within a given interval” is meaningless. By contrast, though, a subjective probability of 90% that the neutron mass is contained within the given interval is a meaningful reflection of one’s state of knowledge.

The use of subjective probability is closely related to Bayes’ theorem: in Bayesian statistics, the subset \mathcal{E}_2 appearing in the definition of conditional probability is interpreted as the hypothesis that “a certain theory is true,” while the subset \mathcal{E}_1 designates the hypothesis that “an experiment will yield a particular result (i.e., data).” In this interpretation, Bayes’ theorem takes on the form

$$P(\text{theory}|\text{data}) \propto P(\text{data}|\text{theory}) \cdot P(\text{theory}).$$

In the above expression of proportionality, $P(\text{theory})$ represents the prior probability that the theory is true, while the likelihood $P(\text{data}|\text{theory})$ expresses the probability of observing the data that were actually obtained under the assumption that the theory is true. The posterior probability, that the theory is correct after seeing the result of the experiment, is given by $P(\text{theory}|\text{data})$. Note that, the prior probability for the data, $P(\text{data})$, does not appear explicitly, so the above relation expresses a proportionality rather than an equality. Furthermore, Bayesian statistics provides no fundamental rule for assigning the prior probability to a theory. However, once a prior probability has been assigned, Bayesian statistics indicates how one’s degree of belief should change after obtaining additional information (e.g., experimental data).

7.2 Multivariate Probability Distributions

Consider that \mathcal{S} is a sample space in k -dimensions. As has been discussed in the previous section, if each random variable X_i ($i = 1, 2, \dots, k$) is a real-valued function defined on a domain \mathcal{N}_i (representing the i th dimension of \mathcal{S}), then (X_1, \dots, X_k) is a multivariate random variable or random vector. Furthermore, consider that each domain \mathcal{N}_i ($i = 1, 2, \dots, k$) is a discrete set, either finite or denumerably infinite (\mathcal{N}_i is usually the set of nonnegative integers or a subset thereof). Then, a probability function, $p(x_1, \dots, x_k)$, of the discrete random vector (X_1, \dots, X_k) is defined by requiring $p(x_1, \dots, x_k)$ to satisfy, for each value x_i taken on by X_i ($i = 1, 2, \dots, k$), the following properties:

1. $p(x_1, x_2, \dots, x_k) = P\{X_1 = x_1, X_2 = x_2, \dots, X_k = x_k\}$ and
2. $P\{\mathcal{A}\} = \sum_{(x_1, \dots, x_k) \in \mathcal{A}} p(x_1, \dots, x_k)$

for any subset \mathcal{A} of \mathcal{N} , where \mathcal{N} is the k -dimensional set whose i th component is \mathcal{N}_i ($i = 1, 2, \dots, k$) with $P\{\mathcal{N}\} = 1$.

Consider that \mathcal{A} is the set of all random vectors (X_1, \dots, X_k) such that $X_i \leq x_i$ ($i = 1, 2, \dots, k$). Then

$$P\{\mathcal{A}\} = P\{X_1 \leq x_1, X_2 \leq x_2, \dots, X_k \leq x_k\}$$

is called the cumulative distribution function (CDF) of (X_1, \dots, X_k) . The usual notation for the CDF of (X_1, \dots, X_k) is $F(x_1, \dots, x_k)$. Note that, the CDF is not a random variable; rather, it is a real numerical-valued function whose arguments represent compound events.

To define the probability density function (PDF) of a continuous random vector (X_1, \dots, X_k) , consider that (X_1, \dots, X_k) is a random vector whose i th component, X_i , is defined on the real line $(-\infty, \infty)$ or on a subset thereof. Suppose $p(x_1, \dots, x_k) > 0$ is a function such that for all $x_i \in [a_i, b_i]$ ($i = 1, 2, \dots, k$), the following properties hold:

1. $P\{a_1 < X_1 < b_1, \dots, a_k < X_k < b_k\} = \int_{a_k}^{b_k} \dots \int_{a_1}^{b_1} p(x_1, \dots, x_k) dx_1 \dots dx_k$ and if \mathcal{A} is any subset of k -dimensional intervals,
2. $P\{\mathcal{A}\} = \int_{(x_1, \dots, x_k) \in \mathcal{A}} \dots \int p(x_1, x_2, \dots, x_k) dx_1 dx_2 \dots dx_k$ then $p(x_1, \dots, x_k)$ is said to be a joint PDF of the continuous random vector (X_1, \dots, X_k) , if it is normalized to unity over its domain.

Consider that the set (x_1, \dots, x_k) represents a collection of random variables with a multivariate joint probability density $p(x_1, \dots, x_k) > 0$; then, the marginal probability density of x_i , denoted by $p_i(x_i)$, is defined as

$$p_i(x_i) = \int_{-\infty}^{\infty} dx_1 \dots \int_{-\infty}^{\infty} dx_{i-1} \int_{-\infty}^{\infty} dx_{i+1} \dots \int_{-\infty}^{\infty} p(x_1, x_2, \dots, x_k) dx_k.$$

Also, the conditional PDF $p(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_k | x_i)$ can be defined whenever $p_i(x_i) \neq 0$ by means of the expression

$$p(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_k | x_i) = p(x_1, \dots, x_k) / p_i(x_i).$$

The meaning of marginal and conditional probability can be illustrated by considering bivariate distributions. Thus, if (X, Y) is a discrete random vector whose joint probability function is $p(x, y)$, where X is defined over \mathcal{N}_1 and Y is defined over \mathcal{N}_2 , then the marginal probability distribution function (PDF) of X , $p_x(x)$, is defined as

$$p_x(x) = \sum_{y \in \mathcal{N}_2} p(x, y).$$

On the other hand, if (X, Y) is a continuous random vector whose joint PDF is $p(x, y)$, where X and Y are each defined over the domain $(-\infty, \infty)$, then the marginal PDF of X , $p_x(x)$, is defined by the integral

$$p_x(x) = \int_{-\infty}^{\infty} p(x, y) dy.$$

Consider that (X, Y) is a random vector (continuous or discrete) whose joint PDF is $p(x, y)$. The conditional PDF of y given $X = x$ (fixed), denoted by $h(y|x)$, is defined as

$$h(y|x) = \frac{p(x, y)}{p_x(x)},$$

where the domain of y may depend on x , and where $p_x(x)$ is the marginal PDF of X , with $p_x(x) > 0$.

Similarly, the conditional PDF, say $g(x|y)$, for x given y is

$$g(x|y) = \frac{p(x, y)}{p_y(y)} = \frac{p(x, y)}{\int p(x', y) dx'}.$$

Combining the last two definitions gives the following relationship between $g(x|y)$ and $h(y|x)$,

$$g(x|y) = \frac{h(y|x)p_x(x)}{p_y(y)},$$

which expresses *Bayes' theorem* for the case of continuous variables.

Consider that (X, Y) is a random vector whose joint PDF is $p(x, y)$. The random variables X and Y are called stochastically independent if and only if

$$p(x, y) = p_x(x)p_y(y)$$

over the entire domain of (X, Y) (i.e., for all x and y). From this definition and from Bayes' theorem, it follows that X and Y are independent iff $g(x|y) = p_x(x)$ over the entire domain of (X, Y) . Of course, this definition of stochastic independence can be generalized to random vectors.

For certain cases, the PDF of a function of random variables can be found by using integral transforms. In particular, Fourier transforms are well-suited for dealing with the PDF of sums of random variables, while Mellin transforms are well suited for dealing with PDF of products of random variables. For example, the PDF $f(z)$, of the sum $z = x + y$, where x and y are two independent random variables distributed according to $g(x)$ and $h(y)$, respectively, is obtained as

$$f(z) = \int_{-\infty}^{\infty} g(x)h(z-x) dx = \int_{-\infty}^{\infty} g(z-y)h(y) dy.$$

The function f in the above equation is actually the Fourier convolution of g and h , and is often written in the form $f = g \otimes h$.

On the other hand, the PDF, $f(z)$, of the product $z = xy$, where x and y are two random variables distributed according to $g(x)$ and $h(y)$, is given by

$$f(z) = \int_{-\infty}^{\infty} g(x)h(z/x) \frac{dx}{|x|} = \int_{-\infty}^{\infty} g(z/y)h(y) \frac{dy}{|y|},$$

where the second equivalent expression is obtained by reversing the order of integration. The function f defined above is actually the Mellin convolution of g and h , often written (also) in the convolution form $f = g \otimes h$. Taking the Mellin transform of the Mellin convolution of g and h , or taking the Fourier transform of the Fourier convolution of g and h , respectively, converts the respective convolution equations $f = g \otimes h$ into the respective products $\tilde{f} = \tilde{g} \cdot \tilde{h}$ of the transformed density functions. The actual PDF is subsequently obtained by finding the inverse transform of the respective \tilde{f} 's.

Consider that $\mathbf{x} = (x_1, \dots, x_n)$ and $\mathbf{y} = (y_1, \dots, y_n)$ are two distinct vector random variables that describe the same events. Consider, further, that the respective multivariate probability densities $p_x(\mathbf{x})$ and $p_y(\mathbf{y})$ are such that the mappings $y_i = y_i(x_1, \dots, x_n)$, ($i = 1, 2, \dots, n$), are continuous, one-to-one, and all partial derivatives $\partial y_i / \partial x_j$, ($i, j = 1, \dots, n$), exist. Then, the transformation from one PDF to the other is given by the relationship

$$p_y(\mathbf{y})|d\mathbf{y}| = p_x(\mathbf{x})|d\mathbf{x}| \quad \text{or} \quad p_x(\mathbf{x}) = |J|p_y(\mathbf{y}),$$

where $|J| \equiv \det |\partial y_i / \partial x_j|$, ($i, j = 1, \dots, n$), is the Jacobian of the respective transformation.

As an example of applying the above transformation, consider the linear transformation $\mathbf{y} = g(\mathbf{x}) = \mathbf{A}\mathbf{x} + \mathbf{b}$, where $\mathbf{A} \in \mathbb{R}^{n \times n}$ is non-singular, $\mathbf{b} \in \mathbb{R}^n$, and $\mathbf{x} \in \mathbb{R}^n$ is a normal random vector, $\mathbf{x} \sim N(\mu_x, \Sigma_x)$, i.e.,

$$p_x(\mathbf{x}) = \frac{1}{(2\pi)^{\frac{n}{2}} |\Sigma_x|^{\frac{1}{2}}} \exp[-(\mathbf{x} - \mu_x)^T \Sigma_x^{-1} (\mathbf{x} - \mu_x)].$$

It then follows that $|J| = |\mathbf{A}|$ and

$$\begin{aligned} p_y(\mathbf{y}) &= \frac{1}{|\mathbf{A}|} p_x(\mathbf{A}^{-1}(\mathbf{y} - \mathbf{b})) \\ &= \frac{1}{(2\pi)^{\frac{n}{2}} |\Sigma_x|^{\frac{1}{2}} |\mathbf{A}|} \exp[-[\mathbf{A}^{-1}(\mathbf{y} - \mathbf{b}) - \mu_x]^T \Sigma_x^{-1} [\mathbf{A}^{-1}(\mathbf{y} - \mathbf{b}) - \mu_x]]. \end{aligned}$$

The exponent above can be re-written as follows:

$$\begin{aligned} &[\mathbf{A}^{-1}(\mathbf{y} - \mathbf{b}) - \mu_x]^T \Sigma_x^{-1} [\mathbf{A}^{-1}(\mathbf{y} - \mathbf{b}) - \mu_x] \\ &= [\mathbf{A}^{-1}(\mathbf{y} - (\mathbf{A}\mu_x + \mathbf{b}))]^T \Sigma_x^{-1} [\mathbf{A}^{-1}(\mathbf{y} - (\mathbf{A}\mu_x + \mathbf{b}))] \\ &= (\mathbf{y} - \mu_y)^T \Sigma_y^{-1} (\mathbf{y} - \mu_y), \end{aligned}$$

where $\mu_y = \mathbf{A}\mu_x + \mathbf{b}$ and $\Sigma_y = \mathbf{A}\Sigma_x\mathbf{A}^T$. Since $|\Sigma_y| = |\mathbf{A}\Sigma_x\mathbf{A}^T| = |\mathbf{A}|^2 |\Sigma_x|$, it follows that $\mathbf{y} \sim N(\mathbf{A}\mu_x + \mathbf{b}, \mathbf{A}\Sigma_x\mathbf{A}^T)$, i.e.,

$$h(\mathbf{y}) = \frac{1}{(2\pi)^{\frac{n}{2}} |\Sigma_y|^{\frac{1}{2}}} \exp[-(\mathbf{y} - \mu_y)^T \Sigma_y^{-1} (\mathbf{y} - \mu_y)].$$

7.3 Expectations and Moments

Probabilities cannot be measured directly; they can be inferred from the results of observations or they can be postulated and (partially) verified through accumulated experience. In practice, though, certain random vectors tend to be more probable, so that most probability functions of practical interest tend to be localized. Therefore, the essential features regarding probability distributions of practical interest are measures of location and of dispersion. These measures are provided by the expectation and moments of the respective probability function. If the probability function is known, then these moments can be calculated directly through a process called statistical deduction. Otherwise, the respective moments must be estimated from experiments through a process called statistical inference.

Consider that $\mathbf{x} = (x_1, \dots, x_n)$ is a collection of random variables that represents the events in a space \mathcal{E} , and consider that S_x represents the n -dimensional space formed by all possible values of \mathbf{x} . The space S_x may encompass the entire range of real numbers (i.e., $-\infty < x_i < \infty$, $i = 1, \dots, n$) or a subset thereof. Furthermore, consider a real-valued function, $g(\mathbf{x})$, and a probability density, $p(\mathbf{x})$, both defined on S_x . Then, the expectation of $g(\mathbf{x})$, denoted as $E(g(\mathbf{x}))$, is defined as:

$$E(g(\mathbf{x})) \equiv \int_{S_x} g(\mathbf{x}) p(\mathbf{x}) d\mathbf{x}$$

if the condition of absolute convergence, $E(|g|) = \int_{\mathcal{S}_x} |g(\mathbf{x})| p(\mathbf{x}) d\mathbf{x} < \infty$ is satisfied. When x is discrete with the domain \mathcal{N} , the expectation of g is defined as

$$E(g(\mathbf{x})) = \sum_{\mathbf{x} \in \mathcal{N}} g(\mathbf{x}) p(\mathbf{x}), \quad \text{if } E(|g(\mathbf{x})|) < \infty.$$

In particular, the *moment of order k* about a point c is defined for a univariate probability function as

$$E((x - c)^k) \equiv \int_{\mathcal{S}_x} (x - c)^k p(x) dx,$$

where \mathcal{S}_x denotes the set of values of x for which $p(x)$ is defined, and the integral above is absolutely convergent. The zeroth-order moment is obtained by setting $k = 0$ in the above definition.

For a multivariate probability function, given a collection of n random-variables (x_1, \dots, x_n) and a set of constants (c_1, \dots, c_n) , the mixed moment of order k is defined as

$$E((x_1 - c_1)^{k_1}, \dots, (x_n - c_n)^{k_n}) \equiv \int_{\mathcal{S}_{x_1}} dx_1 \dots \int_{\mathcal{S}_{x_n}} dx_n (x_1 - c_1)^{k_1} \dots (x_n - c_n)^{k_n} p(x_1 \dots x_n).$$

The *zeroth-order moment* is obtained by setting $k_1 = \dots = k_n = 0$ (for multivariate probability) in the above definition. Since probability functions are required to be normalized, the zeroth moment is always equal to unity.

In particular, when $c = 0$ (for univariate probability) or when $c_1 = \dots = c_n = 0$ (for multivariate probability), the quantities defined as $\nu_k \equiv E(x^k)$, and, respectively, $\nu_{k_1 \dots k_n} \equiv E(x_1^{k_1} \dots x_n^{k_n})$ are called the *moments about the origin* (often also called *raw* or *crude moments*). If $\sum_{i=1, n} k_i = k$, then the moments of the form $\nu_{k_1 \dots k_n}$ are called the mixed raw moments of order k . For $k = 1$, these moments are called *mean values*, and are denoted as $m_o = \nu_1 = E(x)$ for univariate probability, and $m_{oi} \equiv \nu_{o \dots 1 \dots o} \equiv E(x_i)$, ($i = 1, \dots, n$), for multivariate probability, respectively. Note that, a “0” in the j th subscript position signifies that $k_j = 0$ for the particular raw moment in question, while a “1” in the i th subscript position indicates that $k_i = 1$ for the respective moment.

The moments about the mean or central moments are defined as $\mu_k \equiv E((x - m_o)^k)$, for univariate probability, and $\mu_{k_1 \dots k_n} \equiv E((x_1 - m_{o1})^{k_1} \dots (x_n - m_{on})^{k_n})$, for multivariate probability.

Furthermore, if $\sum_{i=1, n} k_i = k$, then the above moments are called the *mixed central moments* of order k . Note that the central moments vanish whenever one particular $k_i = 1$ and all other $k_j = 0$, i.e., $\mu_{o \dots 1 \dots o} = 0$. Note also that all even-power central moments of univariate probability functions (i.e., μ_k , for $k = \text{even}$) are nonnegative.

The central moments for $k = 2$ play very important roles in statistical theory and are therefore assigned special names. Thus, for univariate probability, the second moment, $\mu_2 \equiv E((x - m_o)^2)$, is called *variance* that is usually denoted as $\text{var}(x)$ or σ^2 . The positive square root of the variance is called the *standard deviation*, denoted as σ , and defined as

$$\sigma \equiv [\text{var}(x)]^{1/2} \equiv \mu_2^{1/2} \equiv [E((x - m_o)^2)]^{1/2}.$$

The terminology and notation used for univariate probability are also used for multivariate probability. In particular, the standard deviation of the i th component is defined as:

$$\mu_{o \dots 2 \dots o} \equiv \text{var}(x_i) \equiv \sigma_i^2 \equiv E((x_i - m_o)^2).$$

To simplify the notation, the subscripts accompanying the moments ν and μ for multivariate probability functions are usually dropped and alternative notation is used. For example, μ_{ii} is often employed to denote $\text{var}(x_i)$, and μ_{ij} signifies $E((x_i - m_{oi})(x_j - m_{oj}))$, ($i, j = 1, \dots, n$).

The raw and central moments are related to each other through the important relationship

$$\mu_k = \sum_{i=0}^k C_i^k (-1)^i \nu_{k-i} \nu_1^i \quad (k \geq 1),$$

where $C_i^k = k! / [(k-i)!i!]$ is the binomial coefficient. This formula is very useful for estimating central moments from sampling data, because, in practice, it is more convenient to estimate the raw moments directly from the data, and then derive the central moments by using the above equation.

7.4 Variance, Standard Deviation, Covariance, and Correlation

Since measurements never yield true values, it is necessary to introduce surrogate parameters to measure location and dispersion for the observed results. Practice indicates that location is best described by the mean value, while dispersion of observed results appears to be best described by the variance or standard deviation. In particular, the mean value can be interpreted as a locator of the center of gravity, whereas the variance is analogous to the moment of inertia (which linearly relates applied torque to induced angular acceleration in mechanics). Also very useful for the study of errors is the *Minimum Variance Theorem*, which states that: if c is a real constant and x is a random variable, then $\text{var}(x) \leq E((x - c)^2)$.

Henceforth, when we speak of *errors* in physical observations, they are to be interpreted as standard deviations. In short, errors are simply the measures of dispersion in the underlying probability functions that govern observational processes. The fractional relative error or coefficient of variation, f_x , is defined by $f_x = \sigma / |E(x)|$, when $E(x) \neq 0$. The reciprocal, $(1/f_x)$, is commonly called (particularly in engineering applications) the signal-to-noise ratio. Finally, the term percent error refers to the quantity $100 f_x$.

When the probability function is known and the respective mean and variance (or standard deviation) exist, they can be computed directly from their definitions. However, when the actual distribution is not known, it is considerably more difficult to interpret the knowledge of the mean and standard deviation in terms of confidence that they are representative of the distribution of measurements. The difficulty can be illustrated by considering a confidence indicator associated with the probability function p , $C_p(k\sigma)$, defined by means of the integral

$$C_p(k\sigma) \equiv \int_{m_o - k\sigma}^{m_o + k\sigma} p(x) dx,$$

where σ is the standard deviation and $k \geq 1$ is an integer. Since the probability density integrated over the entire underlying domain is normalized to unity, it follows that $C_p(k\sigma) < 1$ for all k . However, $C_p(k\sigma) \approx 1$ whenever $k \gg 1$. Thus, $C_p(k\sigma)$ can vary substantially in magnitude for different types of probability functions p , even for fixed values of σ and k . This result indicates that although the variance or standard deviation are useful parameters for measuring dispersion (error), knowledge of them alone does not provide an unambiguous measure of confidence

in a result, unless the probability family to which the distribution in question belongs is a priori known. Consequently, when an experiment involves several observational processes, each governed by a distinct law of probability, it is difficult to interpret overall errors (which consist of several components) in terms of confidence. However, the consequences are often mitigated in practice by a very important theorem of statistics, called the *central limit theorem*, which will be presented in the sequel.

For multivariate probability, the second-order central moments comprise not only the variances $\mu_{ii} = \text{var}(x_i) = E((x_i - m_{oi})^2)$, ($i = 1, \dots, n$), but also the moments $\mu_{ij} = E((x_i - m_{oi})(x_j - m_{oj}))$, ($i, j = 1, \dots, n$). These moments are called *covariances*, and the notation $\text{cov}(x_i, x_j) \equiv \mu_{ij}$ is often used. The collection of all second-order moments of a multivariate probability function involving n random variables forms an $n \times n$ matrix, denoted as \mathbf{V}_x , and called the variance-covariance matrix, or, simply, the covariance matrix. Since $\mu_{ij} = \mu_{ji}$ for all i and j , covariance matrices are symmetric.

Since covariance matrices are symmetric, an $n \times n$ matrix contains no more than $n + [n(n - 1/2)]$ distinct elements, comprising the off-diagonal covariances and the n variances along the diagonal. Often, therefore, only the diagonal and upper or lower triangular part of covariance and correlation matrices are listed in the literature. A formula often used in practical computations of covariances is obtained by rewriting the respective definition in the form

$$\text{cov}(x_i, x_j) = E(x_i x_j) - m_{oi} m_{oj}.$$

Note that, if any two random variables, x_i and x_j , in a collection of n random variables are independent, then $\text{cov}(x_i, x_j) = 0$. The converse of this statement is false, meaning that $\text{cov}(x_i, x_j) = 0$ does not necessarily imply that x_i and x_j are independent.

A very useful tool for practical applications is the so-called *scaling and translation theorem*, which states that if x_i and x_j are any two members of a collection of n random variables, then the following relations hold for the random variables $y_i = a_i x_i + b_i$ and $y_j = a_j x_j + b_j$:

$$\begin{aligned} E(y_i) &= a_i E(x_i) + b_i, & \text{var}(y_i) &= a_i^2 \text{var}(x_i), & (i = 1, \dots, n), \\ \text{cov}(y_i, y_j) &= a_i a_j \text{cov}(x_i, x_j), & (i, j = 1, \dots, n, i \neq j). \end{aligned}$$

The constants a_i and a_j are called *scaling* parameters, while the constants b_i and b_j are called *translation* parameters. The above relationships show that mean values are affected by both scaling and translation, while the variances and covariances are only affected by scaling. In particular, the above relationships can be used to establish the following theorem regarding the relationship between ordinary random variables x_i and their standard random variable counterparts $u_i = (x_i - m_{oi})/\sigma_i$, ($i = 1, \dots, n$): "the covariance matrix for the standard random variables $u_i = (x_i - m_{oi})/\sigma_i$ is the same as the correlation matrix for the random variables x_i ." In matrix form, if \mathbf{x} and \mathbf{y} are two random vectors of size n , and \mathbf{A} and \mathbf{B} are two $n \times n$ matrices, with $E(\mathbf{x}) = \boldsymbol{\mu}_x$ and $E(\mathbf{y}) = \boldsymbol{\mu}_y$, then

$$\begin{aligned} \text{Cov}(\mathbf{Ax}, \mathbf{By}) &= E[(\mathbf{Ax} - \mathbf{A}\boldsymbol{\mu}_x)(\mathbf{By} - \mathbf{B}\boldsymbol{\mu}_y)^T] = E[\mathbf{A}(\mathbf{x} - \boldsymbol{\mu}_x)(\mathbf{y} - \boldsymbol{\mu}_y)^T \mathbf{B}^T] \\ &= \mathbf{A}E[(\mathbf{x} - \boldsymbol{\mu}_x)(\mathbf{y} - \boldsymbol{\mu}_y)^T] \mathbf{B}^T = \mathbf{A} \text{Cov}(\mathbf{x}, \mathbf{y}) \mathbf{B}^T. \end{aligned}$$

When $\mu_{ii} > 0$, ($i = 1, \dots, n$), it is often convenient to use the quantities ρ_{ij} defined by the relationship

$$\rho_{ij} \equiv \mu_{ij} / (\mu_{ii} \mu_{jj})^{1/2}, \quad (i, j = 1, \dots, n),$$

and called *correlation coefficients* or, simply, *correlations*. The matrix obtained using the correlations, ρ_{ij} , is called the correlation matrix, and will be denoted as C_x .

Using the Cauchy–Schwartz inequality, it can be shown that the elements of V_x always satisfy the relationship

$$|\mu_{ij}| \leq (\mu_{ii}\mu_{jj})^{1/2} \quad (i, j = 1, n),$$

while the elements ρ_{ij} of the correlation matrix C_x satisfy the relationship

$$-1 \leq \rho_{ij} \leq 1.$$

In the context of covariance matrices, the Cauchy–Schwartz inequality provides an indicator of data consistency that is very useful to verify practical procedures for processing experimental information. Occasionally, practical procedures may generate covariance matrices with negative eigenvalues (thus violating the condition of positive-definitiveness), or with coefficients that would violate the Cauchy–Schwartz inequality; such matrices would, of course, be unsuitable for representing physical uncertainty. Although the mathematical definition of the variance only indicates that it must be nonnegative, the variance for physical quantities should in practice be positive, because it provides a mathematical basis for the representation of physical uncertainty. Since zero variance means no error, probability functions for which some of the random variables have zero variance are not realistic choices for the representation of physical phenomena, since such probability functions would indicate that some parameters were without error, which is never the case in practice. Furthermore, a situation where $\mu_{ii} < 0$ would imply an imaginary standard deviation (since $\sigma_i = \mu_{ii}^{1/2}$), which is clearly unrealistic. The reason for mentioning these points here is because, in practice, the elements of covariance matrices are very rarely obtained from direct evaluation of expectations, but are obtained by a variety of other methods, many of them ad hoc. Practical considerations also lead to the requirement that $|\rho_{ij}| < 1$, for $i \neq j$, but a presentation of the arguments underlying this requirement is beyond the purpose of this book. These and other constraints on covariance and correlation matrices lead to the conclusion that matrices which properly represent physical uncertainties are positive definite.

Denoting by $\Sigma \triangleq \text{diag}(\sigma_i)$, the diagonal matrix having the standard deviations σ_i on the main diagonal, it follows that the covariance matrix V_x and the correlation matrix C_x are related through the relation

$$C_x = \Sigma^{-1}V_x\Sigma^{-1}, \quad C_x = \text{Cor}(z), \quad \text{with } z = \Sigma^{-1}(x - \langle x \rangle).$$

The *conditional expectation* of x_1 given x_2 is defined as

$$E[x_1|x_2 = a] = \int_{-\infty}^{\infty} x_1 f(x_1, x_2 = a) dx_1.$$

As x_2 takes on different values in its domain, this conditional expectation will also take different values. Thus, the conditional expectation $E(x_1|x_2)$ is a function of the conditioning random variable, and hence is itself a random variable. Sometimes, the conditional expectation operator is distinguished by using the conditioning random variable as the subscript, thus

denoting $E(x_1|x_2)$ as $E_{x_2}(x_1)$. Note also that

$$\begin{aligned} E\{E_{x_2}(x_1)\} &= E\{E(x_1|x_2)\} = \int_{-\infty}^{\infty} \left[\int_{-\infty}^{\infty} x_1 f(x_1|x_2) dx_1 \right] f_2(x_2) dx_2 \\ &= \int_{-\infty}^{\infty} x_1 \left[\int_{-\infty}^{\infty} f(x_1|x_2) f_2(x_2) dx_2 \right] dx_1 \\ &= \int_{-\infty}^{\infty} x_1 f_1(x_1) dx_1 = E(x_1). \end{aligned}$$

Thus, the random variable $E_{x_2}(x_1)$ has the same expectation as x_1 ; the above relation is customarily called the *law of iterated expectations*. A useful particular result is the following: if $\mathbf{x} \in \mathbb{R}^n$ and $\mathbf{z} \in \mathbb{R}^m$ are jointly normal random vectors, with mean $\mathbf{m} = \begin{pmatrix} m_x \\ m_z \end{pmatrix}$ and covariance matrix $\Sigma = \begin{bmatrix} \Sigma_x & \Sigma_{xz} \\ \Sigma_{zx} & \Sigma_z \end{bmatrix}$, then the *conditional density* of $f(\mathbf{x}|\mathbf{z})$ of \mathbf{x} given \mathbf{z} is also normal with the *conditional mean* $\mu = E[\mathbf{x}|\mathbf{z}] = m_x + \Sigma_{xz}\Sigma_z^{-1}[\mathbf{z} - m_z]$ and the *conditional covariance* $\mathbf{A} = \text{Cov}(\mathbf{x}|\mathbf{z}) = \Sigma_x - \Sigma_{xz}\Sigma_z^{-1}\Sigma_{zx}$.

The determinant, $\det(\mathbf{V}_x)$, of the variance matrix is often referred to as the generalized variance, since it degenerates to a simple variance for univariate distributions. The probability distribution is called nondegenerate when $\det(\mathbf{V}_x) \neq 0$; when $\det(\mathbf{V}_x) = 0$, however, the distribution is called degenerate. Degeneracy is an indication that the information content of the set \mathbf{x} of random variable is less than rank n , or that the probability function is confined to a hyperspace of dimension lower than n . The determinant of a covariance matrix vanishes if there exist (one or more) linear relationships among the random variables of the set \mathbf{x} .

Since \mathbf{V}_x must be positive definite in order to provide a meaningful representation of uncertainty, it follows that $\det(\mathbf{V}_x) > 0$. Due to the properties of \mathbf{V}_x mentioned above, it also follows that

$$\det(\mathbf{V}_x) \leq \prod_{i=1,n} \text{var}(x_i) = \prod_{i=1,n} \sigma_i^2.$$

The equality in the above relation is reached only when \mathbf{V}_x is diagonal, i.e., when $\text{cov}(x_i, x_j) = 0$, ($i, j = 1, n, i \neq j$); in this case, $\det(\mathbf{V}_x)$ attains its maximum value, equal to the product of the respective variances. The determinant $\det(\mathbf{V}_x)$ is related to the determinant of the correlation matrix, $\det(\mathbf{C}_x)$, by the relationship

$$\det(\mathbf{V}_x) = \det(\mathbf{C}_x) \prod_{i=1,n} \sigma_i^2.$$

From above relations, it follows that $\det(\mathbf{C}_x) \leq 1$. It further follows that $\det(\mathbf{C}_x)$ attains its maximum value of unity only when $\text{cov}(x_i, x_j) = 0$, ($i, j = 1, n, i \neq j$). In practice, $\det(\mathbf{C}_x)$ is used as a measure of degeneracy of the multivariate probability function. In particular, the quantity $[\det(\mathbf{C}_x)]^{1/2}$ is called the scatter coefficient for the probability function. Note that $\det(\mathbf{C}_x) = 0$ when $\rho_{ij} = \rho_{ji} = 1$ for at least one pair (x_i, x_j) , with $i \neq j$.

Two random variables, x_i and x_j , with $i \neq j$, are called *fully-correlated* if $\text{cor}(x_i, x_j) = 1$; this situation arises if and only if the corresponding standard random variables u_i and u_j are identical, i.e., $u_i = u_j$. On the other hand, if $\text{cor}(x_i, x_j) = -1$, then x_i and x_j are *fully anti-correlated*, which can happen iff $u_i = -u_j$. Therefore, the statistical properties of fully correlated or fully anti-correlated random variables are identical, so that only one of them needs

to be considered, a fact reflected by the practice of referring to such random variables as being redundant.

In addition to covariance matrices, V_x , and their corresponding correlation matrices, C_x , a third matrix, called the *relative covariance matrix* or *fractional error matrix*, can also be defined when the elements of the covariance matrix satisfy the condition that $m_{oi} \neq 0$, ($i = 1, \dots, n$). This matrix is usually denoted as R_x and its elements $(R_x)_{ij} = \eta_{ij}$ are defined as $\eta_{ij} = \mu_{ij}/(m_{oi}m_{oj})$.

Moments of first and second order (i.e., means and covariance matrices) provide information regarding only the location and dispersion of probability distributions. Additional information on the nature of probability distributions is carried by the higher-order moments, although moments beyond fourth-order are seldom examined in practice. The nature of such information can be intuitively understood by considering the third- and fourth-order moments of univariate probability functions. For this purpose, it is the easiest to consider the respective reduced central moments, α_k , defined in terms of central moments and the standard deviation by the relationship $\alpha_k \equiv \mu_k/\sigma^k$. The reduced central moment α_3 is called the *skewness* of the probability distribution, because it measures quantitatively the departure of the probability distribution from symmetry (a symmetric distribution is characterized by the value $\alpha_3 = 0$). Thus, if $\alpha_3 < 0$, the distribution is skewed toward the left (i.e., it favors lower values of x relative to the mean), while $\alpha_3 > 0$ indicates a distribution skewed toward the right (i.e., it favors higher values of x relative to the mean). The reduced central moment α_4 measures the degree of sharpness in the peaking of a probability distribution and it is called *kurtosis*. Kurtosis is always nonnegative. The standard for comparison of kurtosis is the normal distribution (Gaussian) for which $\alpha_4 = 3$. Distributions with $\alpha_4 < 3$ are called *platykurtic* distributions. Those with $\alpha_4 = 3$ are called *mesokurtic* distributions. Finally, distributions with $\alpha_4 > 3$ are called *leptokurtic* distributions.

Very often in practice, the details of the distribution are unknown and only the mean and standard deviations can be estimated from the limited amount of information available. Even under such circumstances, it is still possible to make statements regarding confidence by relying on *Chebyshev's theorem*, which can be stated as follows. Consider that m_o and $\sigma > 0$ denote the mean value and standard deviation, respectively, of an otherwise unknown multivariate probability density p involving the random variable x . Furthermore, consider that P represents cumulative probability, C_p represents confidence, and $k \geq 1$ is a real constant (not necessarily an integer). Then, Chebyshev's theorem states that the following relationship holds:

$$C_p(k\sigma) = P(|x - m_o| \leq k\sigma) \geq 1 - (1/k^2).$$

Chebyshev's theorem is a weak law of statistics in that it provides an upper bound on the probability of a particular deviation ε . The actual probability of such a deviation (if the probability function were known in detail so that it could be precisely calculated) would always be smaller (implying greater confidence) than Chebyshev's limit. This important point is illustrated in [► Table 1](#), which presents probabilities for observing particular deviations, ε , from the mean when sampling from a normal distribution, and the corresponding bounds predicted by Chebyshev's theorem.

[► Table 1](#) clearly underscores the fact that normally distributed random variables are much more sharply localized with respect to the mean than indicated by Chebyshev's theorem.

■ **Table 1**
Probability of occurrence

Deviation σ	Normal distribution	Chebyshev's limit
$> \sigma$	< 0.3173	< 1.0
$> 2\sigma$	< 0.0455	< 0.25
$> 3\sigma$	< 0.00270	< 0.1111
$> 4\sigma$	< 0.0000634	< 0.0625
$> 5\sigma$	$< 5.73 \cdot 10^{-7}$	< 0.04
$> 6\sigma$	$< 2.0 \cdot 10^{-9}$	< 0.02778

The characteristic function $\phi_x(k)$ for a random variable x with PDF $p(x)$ is defined as the expectation value of e^{ikx} , namely

$$\phi_x(k) \equiv E(e^{ikx}) = \int_{-\infty}^{\infty} e^{ikx} p(x) dx.$$

The above definition is essentially the Fourier transform of the PDF; there is a one-to-one correspondence between the PDF and the characteristic function, so that knowledge of one is equivalent to knowledge of the other. The PDF, $p(x)$, is obtained from the inverse Fourier transform of the characteristic function $\phi_x(k)$, namely

$$p(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \phi_x(k) e^{-ikx} dk.$$

The moments of $p(x)$ can be obtained by differentiating the characteristic function $\phi_x(k)$ m times and evaluating the resulting expression at $k = 0$; this yields the relation

$$\left\{ \frac{d^m}{dk^m} \phi_x(k) \right\}_{k=0} = \left\{ \frac{d^m}{dk^m} \int e^{ikx} p(x) dx \right\}_{k=0} = i^m \int x^m p(x) dx = i^m \nu_m,$$

where $\nu_m = E(x^m)$ is the m th raw moment (about the origin) of x . For easy reference, ► [Table 2](#) lists characteristic functions for some commonly used probability functions.

Related to the characteristic function is the *moment generating function* (MGF), usually denoted by $M_x(t)$, and defined as the expectation of e^{tx} , namely:

$$M_x(t) = E(e^{tx}) = \int_{-\infty}^{\infty} e^{tx} p(x) dx,$$

where x is a random variable and t is a real number, $t \in \mathbb{R}$. Occasionally, t may be restricted to an interval subspace of the real line, say, $t \in (a, b) \subset \mathbb{R}$, but the interval (a, b) must necessarily contain the value $t = 0$. For convenience, one occasionally refers to t as a transform variable. The k th-derivative of $M_x(t)$ with respect to t , denoting as $M_x^{(k)}(t)$ has the property that $M_x^{(k)}(0) = E(x^k) = \nu_k$. Thus, if the expression of the MGF, $M_x(t)$, is known for a probability distribution of x , then all the raw moments of the respective distribution can be calculated

Table 2
Characteristic functions

Distribution	PDF	$\phi(k)$
Binomial	$p(x) = \frac{n!}{x!(n-x)!} s^x (1-s)^{n-x}$	$[s(e^{ik} - 1) + 1]^n$
Poisson	$p(x) = \frac{v^x}{x!} e^{-v}$	$\exp[v(e^{ik} - 1)]$
Uniform	$p(x) = \begin{cases} \frac{1}{\beta - \alpha}, & \alpha \leq x \leq \beta, \\ 0, & \text{otherwise} \end{cases}$	$\frac{e^{i\beta k} - e^{i\alpha k}}{(\beta - \alpha) ik}$
Exponential	$p(x) = \frac{1}{\xi} e^{-x/\xi}$	$\frac{1}{1 - ik\xi}$
Gaussian	$p(x) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(x-v)^2}{2\sigma^2}\right)$	$\exp\left(ivk - \frac{1}{2}\sigma^2 k^2\right)$
Chi-square	$p(x) = \frac{1}{2^{n/2}\Gamma(n/2)} x^{n/2-1} e^{-z/2}$	$(1 - 2ik)^{-n/2}$
Cauchy	$f(x) = \frac{1}{\pi} \frac{1}{1+x^2}$	$e^{- k }$

by taking derivatives of the MGF with respect to t and evaluating them at $t = 0$. Note also the following four theorems, which deal with random-variable translation and scaling:

1. If the MGF, $M_x(t)$, of the PDF of a random variable x exists, and if c is a constant, then $M_{x+c}(t) = e^{ct} M_x(t)$.
2. If the conditions of the preceding theorem apply, and if $m_o = v_1$ is the mean value, then the MGF, $M_{x-m_o}(t)$, is the generator of the central moments of the underlying probability function.
3. If the MGF, $M_x(t)$, of the PDF of a random variable x exists, and if c is a constant, then $M_{cx}(t) = M_x(ct)$.
4. The MGF for the PDF of a random variable x is related to the MGF of the PDF for the standard random variable $u = (x - m_o)/\sigma$ by the formula $M_u(t) = \exp(-m_o t/\sigma) M_x(t/\sigma)$.

The development of MGFs for probability functions of several random variables (random vectors) is analogous to the development for the univariate case. Thus, consider that $\mathbf{x} = (x_1, x_2, \dots, x_n)$ denotes a random vector with n components, where each $x_i \in \mathbb{R}$, ($i = 1, \dots, n$). Furthermore, consider that S_x represents the corresponding space of all such random vectors \mathbf{x} , and that $p(\mathbf{x})$ denotes the associated probability density. Then the multivariate MGF is defined as

$$M_x(\mathbf{t}) = E\left(\exp\left(\sum_{i=1}^n x_i t_i\right)\right) = \int_{S_x} \exp\left(\sum_{i=1}^n x_i t_i\right) p(\mathbf{x}) d\mathbf{x},$$

where the vector (t_1, t_2, \dots, t_n) has components t_i defined symmetrically around the origin $(0, 0, \dots, 0)$, namely $-t_{oi} < t_i < t_{oi}$, with $t_{oi} > 0$, ($i = 1, \dots, n$). Note that, MGFs for discrete

multivariate distributions are defined similarly as above, except that the multiple integrals are replaced by corresponding multiple sums.

The raw moments of multivariate probability functions can be generated from the partial derivatives of $M_x(t)$ with respect to the parameters t_i , ($i = 1, \dots, n$), evaluated at $t = 0$. For example,

$$m_{oi} = v_i = E(x_i) = [\partial M_x(t)/\partial t_i]_{t=0} \quad (i = 1, \dots, n),$$

$$E(x_i x_j) = [\partial^2 M_x(t)/\partial t_i \partial t_j]_{t=0} \quad (i, j = 1, \dots, n),$$

and so on. In particular, the elements of the covariance matrix V_x , ($i, j = 1, \dots, n$), can be readily generated by using the above relations, in conjunction with the relation

$$\text{cov}(x_i, x_j) = E[(x_i - m_{oi})(x_j - m_{oj})] = \mu_{ij} = E(x_i x_j) - m_{oi} m_{oj},$$

and using the convention $\text{var}(x_i) = \text{cov}(x_i, x_i)$, ($i = 1, \dots, n$).

7.5 Commonly Encountered Probability Distributions

This section presents the most important features of the probability distributions and density functions most commonly used for evaluation of data and models.

Degenerate distribution: Consider that x is a random variable which can assume only a single value, namely, $x = c$, where c is a real number. The distribution for x is called the degenerate distribution, and the corresponding probability density is given by $p(x) = \delta(x-c)$, where $-\infty \leq x \leq \infty$, and δ denotes the Dirac delta functional. The MGF for this distribution is $M_x(t) = e^{tc}$, ($t \in \mathbb{R}$), while the mean value is $m_o = c$, and the variance is $\mu_2 = 0$.

Discrete uniform distribution: Consider that x is a random variable, which can assume only the integer values $x = 1, \dots, n$. Each of these values carries equal probability. The distribution for x is called the discrete uniform distribution, and the corresponding probability is given by

$$p(x) = (1/n) \sum_{i=1, n} \delta(x - i) \quad \text{or} \quad p(x) = \begin{cases} 1/n, & (x = 1, 2, \dots, n), \\ 0, & \text{otherwise.} \end{cases}$$

The MGF for this distribution is

$$M_x(t) = [e^t(1 - e^{nt})]/[n(1 - e^t)], \quad (t \in \mathbb{R}).$$

Using either the above MGF or by direct calculations, the mean value of x is obtained as $m_o = (n + 1)/2$, while the variance of x is obtained as $\mu_2 = (n^2 - 1)/12$.

Continuous uniform distribution: Consider that x is a random variable, which can assume any real value in the nondegenerate (i.e., $a < b$) interval $I(a, b)$. The distribution for x is called the continuous uniform distribution, and the corresponding PDF is given by

$$p(x) = \begin{cases} 1/(b - a), & a \leq x < b; a, b \in \mathbb{R}, \\ 0, & \text{otherwise.} \end{cases}$$

The *MGF* for this distribution is

$$M_x(t) = \begin{cases} [(e^{tb} - e^{ta})/[(b-a)t]], & t \in \mathbb{R}, t \neq 0, \\ 1, & t = 0. \end{cases}$$

From the above *MGF*, the mean value is obtained as $m_o = (a + b)/2$, while the variance is obtained as $\mu_2 = (b - a)^2/12$. This distribution is employed wherever the range of a finite random variable is bounded and there is no a priori reason for favoring one value over another within that range. In practical applications, the continuous uniform distribution is often used in Monte Carlo analysis or computational methods, and as a prior for applying Bayes' theorem in the extreme situation when no information is available prior to performing an experiment.

Bernoulli distribution: Bernoulli trials are defined as random trials in which the outcomes can be represented by a random variable having only two values, say $x = 0$ and $x = 1$. Such a model can be applied to a random trial whose outcomes (events) are described by "yes or no," "on or off," "black or white," "success or failure," etc. Suppose that only one Bernoulli trial is performed, for which the probability of "success" ($x = 1$) is denoted by s , for $0 < s < 1$, while the probability of "failure" ($x = 0$) is $(1 - s)$. The probability distribution that describes this trial is called the Bernoulli distribution, and has the form

$$P(x) = \begin{cases} s^x(1-s)^{1-x}, & x = 0, 1, \\ 0, & \text{otherwise.} \end{cases}$$

The *MGF* for this distribution is given by

$$M_x(t) = se^t + 1 - s, \quad (t \in \mathbb{R}).$$

From the above *MGF*, the mean value is obtained as $m_o = s$, while the variance is obtained as $\mu_2 = s(1 - s)$. The Bernoulli distribution provides a basis for the binomial and related distributions.

Binomial and multinomial distributions: Consider a series of n independent trials or observations, each having two possible outcomes, usually referred to as "success" and "failure," respectively. Consider further that the probability for success takes on a constant value, s , and consider that the quantity of interest is the accumulated result of n such trials (as opposed to the outcome of just one trial). The set of n trials can thus be regarded as a single measurement characterized by a discrete random variable x , defined to be the total number of successes. Thus, the sample space is defined to be the set of possible values of x successes given n observations. If the measurement were repeated many times with n trials each time, the resulting values of x would occur with relative frequencies given by the binomial distribution, which is defined as

$$P(x) = \frac{n!}{x!(n-x)!} s^x(1-s)^{n-x}, \quad (x = 0, 1, \dots, n),$$

where x is the random variable, while n and s are parameters characterizing the binomial distribution. Note that the binomial distribution is symmetric for $s = 1/2$. The *MGF* is $M_x(t) = (se^t + 1 - s)^n$, ($t \in \mathbb{R}$). The mean value of x is given by $m_o = ns$, while the variance is given by $\mu_2 = ns(1 - s)$.

If the space \mathcal{E} of all possible simple events is partitioned in $m + 1$ (instead of just two, as was the case for the binomial distribution) compound events A_i , ($i = 1, \dots, m + 1$), the binomial

distribution can be generalized to the multinomial distribution by considering a set of nonnegative integer variables $(x_1, x_2, \dots, x_{m+1})$, satisfying the conditions $\sum_{i=1}^{m+1} x_i = n$, $\sum_{i=1}^{m+1} A_i = \mathcal{E}$, and $\sum_{i=1}^{m+1} s_i = 1$ (since one of the outcomes must ultimately be realized). Then, the multinomial distribution for the joint probability for x_1 outcomes of type 1, x_2 of type 2, etc. is given by

$$P(x_1, \dots, x_{m+1}) = \frac{n!}{x_1! \dots x_{m+1}!} s_1^{x_1} \dots s_{m+1}^{x_{m+1}}.$$

The MGF for this distribution is

$$M_{x_1 \dots x_{m+1}}(t_1, \dots, t_m) = \left(\sum_{i=1}^m s_i e^{t_i} + s_{m+1} \right)^n, \quad (t_i \in \mathbb{R}, i = 1, \dots, m).$$

The variances and covariances for this distribution are, respectively: $\mu_{ii} = \sigma_i^2 = ns_i(1 - s_i)$ for $i = j$, and $\mu_{ij} = -n s_i s_j$ for $i \neq j (i, j = 1, \dots, m + 1)$. Since μ_{ij} is negative (anti-correlated variables), it follows that, if in n trials, bin i contains a larger than average number of entries ($x_i > n s_i$), then the probability is increased that bin j will contain a smaller than average number of entries.

Geometric distribution: The geometric distribution is also based on the concept of a Bernoulli trial. Consider that s , $0 < s < 1$, is the probability that a particular Bernoulli trial is a success, while $1 - s$ is the corresponding probability of failure. Also, consider that x is a random variable that can assume the infinite set of integer values $(1, 2, \dots)$. The geometric distribution gives the probability that the first $x - 1$ trials will be failures, while the x^{th} trial will be a success. Therefore, the geometric distribution can be interpreted as the distribution of the “waiting time” for a success. The probability function characterizing the geometric distribution is

$$P(x) = s(1 - s)^{x-1}, \quad (x = 1, 2, \dots).$$

The MGF for this distribution is

$$M_x(t) = se^t / [1 - (1 - s)e^t], \quad (t < -\ln(1 - s)).$$

From the above MGF, the mean value is obtained as $m_o = (1/s)$, while the variance is obtained as $\mu_2 = (1 - s)/s^2$.

Negative binomial (Pascal) distribution: The negative binomial (Pascal) distribution also employs the concept of a Bernoulli trial. Thus, consider that s , $0 < s < 1$, is the probability of success in any single trial and $1 - s$ is the corresponding probability of failure. This time, though, the result of interest is the number of trials that are required in order for r successes to occur, ($r = 1, 2, \dots$). Note that at least r trials are needed in order to have r successes. Consider, therefore, that x is a random variable that represents the number of additional trials required (beyond r) before obtaining r successes, so that ($x = 0, 1, 2, \dots$). Then, the form of the Pascal probability distribution is

$$P(x) = C_{mx} s^r (1 - s)^n, \quad (x = 0, 1, 2, \dots),$$

where $m = x + r - 1$ and C_{mx} is the binomial coefficient. The MGF for the binomial distribution is $M_n(t) = [s/(1 - (1 - s)e^t)]^r$, ($t < -\ln(1 - s)$). The mean value for the Pascal distribution is $m_o = [r(1 - s)/s]$, while the variance is $\mu_2 = r(1 - s)/s^2$.

Poisson distribution: In the limit of many trials, as n becomes very large and the probability of success s becomes very small, but such that the product ns (i.e., the expectation value of the number of successes) remains equal to some finite value ν , the binomial distribution takes on the form

$$P(x) = \frac{\nu^x}{x!} e^{-\nu}, \quad (x = 0, 1, \dots),$$

which is called the Poisson distribution for the integer random variable x . The corresponding MGF is given by the expression $M_x(t) = \exp[\nu(e^t - 1)]$, ($t \in \mathbb{R}$). The expectation value of the Poisson random variable x is obtained as $m_o = \nu$, and the variance is $\mu_2 = \nu$. Although the Poisson variable x is discrete, it can be treated as a continuous variable if it is integrated over a range $\Delta x \gg 1$. An example of a Poisson random variable is the number of decays of a certain amount of radioactive material in a fixed time period, in the limit that the total number of possible decays (i.e., the total number of radioactive atoms) is very large and the probability for an individual decay within the time period is very small.

Exponential distribution: The exponential PDF, $p(x)$, of the continuous variable x ($0 \leq x < \infty$) is defined by

$$p(x) = \frac{1}{\xi} e^{-x/\xi},$$

where ξ is a real-valued parameter. The expectation value of x is $m_o = \xi$ and the variance of x is $\mu_2 = V(x) = \xi^2$. The MGF is

$$M_x(t) = \lambda/(\lambda - t), \quad \lambda \equiv 1/\xi, \quad (t \in \mathbb{R}, t < \lambda).$$

The exponential distribution is widely used in radioactivity applications and in equipment failure rate analysis. The failure rate is defined as the reciprocal of the mean time to failure, i.e., $\xi = 1/\lambda$. The quantity $R(t_o) = e^{-\lambda t_o}$ is usually denoted as the reliability (of the equipment) at time $t_o > 0$. It should not be surprising that the reliability of a piece of equipment should decline with age, and statistical experience has shown that this decline is well represented by the exponential distribution.

Gaussian distribution: Perhaps the single most important distribution in theoretical as well as in applied statistics is the Gaussian (or normal) PDF of the continuous random variable x (with $-\infty < x < \infty$), defined as

$$p(x) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(x - \nu)^2}{2\sigma^2}\right).$$

Note that, the Gaussian distribution has two parameters, ν and σ^2 , which are, by design, the mean, i.e., $E(x) = \nu$ and variance $V(x) = \sigma^2$. The MGF for the Gaussian distribution is $M_x(t) = \exp[\nu t + (\sigma^2 t^2/2)]$, ($t \in \mathbb{R}$).

The function

$$P(x) = \int_{-x}^x p(z) dz, \quad (x > 0),$$

with $p(z)$ given by the above Gaussian, represents the integrated probability of an event with $-x \leq z < x$, for the standard normal distribution. The first four derivatives of the MGF, $M_x(t)$, of the standard normal distribution are:

$$\begin{aligned} M_x^{(1)}(t) &= t \exp(t^2/2), & M_x^{(2)}(t) &= (1 + t^2) \exp(t^2/2), \\ M_x^{(3)}(t) &= (3t + t^3) \exp(t^2/2), & M_x^{(4)}(t) &= (3 + 6t^2 + t^4) \exp(t^2/2). \end{aligned}$$

Evaluating the above expressions at $t = 0$ yields:

$$\begin{aligned} M_x^{(1)}(0) &= v_1 = m_o = 0, & M_x^{(2)}(0) &= v_2 = \mu_2 = \sigma^2 = 1, \\ M_x^{(3)}(0) &= v_3 = \mu_3 = \alpha_3 = 0, & M_x^{(4)}(0) &= v_4 = \mu_4 = \alpha_4 = 3. \end{aligned}$$

Thus, a normal distribution is symmetric (since it has skewness $\alpha_3 = 0$) and is mesokurtic (since it has kurtosis $\alpha_4 = 3$). Furthermore, since $m_o = 0$ for all standard distributions, the respective raw and central moments are equal to each other. In particular, it can be shown that $\mu_{2k-1} = 0$, ($k = 1, 2, \dots$), which indicates that all the odd central moments of the normal distribution vanish. Furthermore, it can be shown that the even central moments are given by $\mu_{2k} = (1)(3) \dots (2k - 1) \sigma^{2k}$, ($k = 1, 2, \dots$). These results highlight the very important feature of the normal distribution that all its nonzero higher-order central moments can be expressed in terms of a single parameter, namely the standard deviation. This is one of several reasons why the Gaussian distribution is arguably the single most important PDF in statistics.

Another prominent practical role played by the Gaussian distribution is as a replacement for either the binomial distribution or the Poisson distribution. The circumstances under which such a replacement is possible are given by *DeMoivre–Laplace theorem* (given below without proof), which can be stated as follows: Consider the binomial distribution, denoted as $p_b(k)$, ($k = 1, \dots, n$) (n and s denote the usual parameters of the binomial distribution, while the subscript “b” denotes “binomial”), and consider that a and c are two nonnegative integers satisfying $a < c < n$. Furthermore, consider the standard normal distribution, denoted as $p_{sn}(x)$ (the subscript “sn” denotes “standard normal”). Finally, define the quantities α and β as

$$\alpha \equiv (a - ns - 0.5)/[ns(1 - s)]^{1/2} \quad \text{and} \quad \beta \equiv (c - ns + 0.5)/[ns(1 - s)]^{1/2}.$$

Then, for large n , the following relation holds

$$\sum_{k=a}^c p_b(k) \approx \int_{\alpha}^{\beta} p_{sn}(x) dx.$$

Thus, the DeMoivre–Laplace theorem indicates that the sum of the areas of contiguous histogram segments, representing discrete binomial probabilities, approximately equals the area under the corresponding continuous Gaussian curve spanning the same region. The binomial becomes increasingly symmetrical as $s \rightarrow 0.5$, so the approximation provided by the DeMoivre–Laplace theorem is accurate even for relatively small n , since the Gaussian is intrinsically symmetric. When $s \ll 1$, and n is so large that $\sigma^2 = ns(1 - s) = v(1 - v/n) \approx v$, even though $v \gg 1$, then the normal distribution can be shown to be a reasonably good approximation to both the corresponding Poisson distribution and to the binomial distribution (particularly when $x \approx v$).

Another very important role played by the Gaussian distribution is highlighted by the *Central Limit Theorem*, which essentially states that the sum of n independent continuous random variables x_i with means μ_i and variances σ_i^2 becomes a Gaussian random variable with mean $\mu = \sum_{i=1}^n \mu_i$ and variance $\sigma^2 = \sum_{i=1}^n \sigma_i^2$ in the limit that n approaches infinity. This statement holds under fairly general conditions, regardless of the form of the individual *PDFs* of the respective random variables x_i . The central limit theorem provides the formal justification for treating measurement errors as Gaussian random variables, as long as the total error is the sum of a large number of small contributions.

The behavior of certain distributions for limiting cases of their parameters can be investigated more readily by using characteristic or MGFs, rather than their *PDFs*. For example, taking the limit $s \rightarrow 0, n \rightarrow \infty$, with $v = sn$ (constant), in the characteristic function for the binomial distribution yields the characteristic function of the Poisson distribution:

$$\phi(k) = [s(e^{ik} - 1) + 1]^n = \left(\frac{v}{n}(e^{ik} - 1) + 1\right)^n \rightarrow \exp[v(e^{ik} - 1)].$$

Note also that a Poisson variable x with mean v becomes a Gaussian variable in the limit as $v \rightarrow \infty$. This fact can be shown as follows: although the Poisson variable x is discrete, when it becomes large, it can be treated as a continuous variable as long as it is integrated over an interval that is large compared to unity. Next, the Poisson variable x is transformed to the variable $z = (x - v)/\sqrt{v}$. The characteristic function of z is

$$\phi_z(k) = E(e^{ikz}) = E(e^{ikx/\sqrt{v}} e^{-ik\sqrt{v}}) = \phi_x\left(\frac{k}{\sqrt{v}}\right) e^{-ik\sqrt{v}},$$

where ϕ_x is the characteristic function of the Poisson distribution. Expanding the exponential term and taking the limit as $v \rightarrow \infty$ yields

$$\phi_z(k) = \exp[v(e^{ik/\sqrt{v}} - 1) - ik\sqrt{v}] \rightarrow \exp\left(-\frac{1}{2}k^2\right).$$

The last term on the right side of the above expression is the characteristic function for a Gaussian with zero mean and unit variance. Transforming back to the original Poisson variable x , one finds, therefore, that for large v , x follows a Gaussian distribution with mean and variance both equal to v .

Multivariate normal distribution: Consider that \mathbf{x} is a (column) vector of dimension n , with components $x_i \in \mathbb{R}$, ($i = 1, \dots, n$). Consider further that \mathbf{m}_0 is a (column) vector of constants with components denoted as $m_{0i} \in \mathbb{R}$, ($i = 1, \dots, n$). Finally, consider that \mathbf{V} is a real, symmetric, and positive definite $n \times n$ matrix with elements denoted by μ_{ij} , ($i, j = 1, \dots, n$). Then, the multivariate normal distribution for n variables is defined by the PDF

$$p(\mathbf{x}) = (2\pi)^{-n/2} [\det(\mathbf{V})]^{-1/2} \exp[-(1/2)(\mathbf{x} - \mathbf{m}_0)^+ \mathbf{V}^{-1}(\mathbf{x} - \mathbf{m}_0)],$$

where the superscript “+” denotes matrix transposition, and where \mathbf{V}^{-1} is the inverse of \mathbf{V} . The quantity $Q \equiv (\mathbf{x} - \mathbf{m}_0)^+ \mathbf{V}^{-1}(\mathbf{x} - \mathbf{m}_0)$ is called a multivariate quadratic form. The *MGF* is given by

$$M_x(t) = \exp[t^+ \mathbf{m}_0 + (1/2)t^+ \mathbf{V}^{-1}t], \quad (t_i \in \mathbb{R}; i = 1, \dots, n).$$

Note that \mathbf{m}_o is the mean vector, while \mathbf{V} is actually the covariance matrix for this distribution; note also that

$$E(x_i) = [\partial M_x(t)/\partial t_i]_{t=0} = m_{oi}, \quad E(x_i x_j) = [\partial^2 M_x(t)/\partial t_i \partial t_j]_{t=0} = m_{oi} m_{oj} + \mu_{ij}.$$

In particular, the Gaussian PDF for two random variables x_1 and x_2 becomes

$$p(x_1, x_2; m_{o1}, m_{o2}, \sigma_1, \sigma_2, \rho) = \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} \times \exp \left\{ -\frac{1}{2(1-\rho^2)} \left[\left(\frac{x_1 - m_{o1}}{\sigma_1} \right)^2 + \left(\frac{x_2 - m_{o2}}{\sigma_2} \right)^2 - 2\rho \left(\frac{x_1 - m_{o1}}{\sigma_1} \right) \left(\frac{x_2 - m_{o2}}{\sigma_2} \right) \right] \right\},$$

where $\rho = \text{cov}(x_1, x_2)/(\sigma_1\sigma_2)$ is the correlation coefficient.

The following properties of the multivariate normal distribution are often used in applications to data evaluation and analysis:

1. If \mathbf{x} is a normally distributed random vector of dimension n with corresponding mean vector \mathbf{m}_o and positive definite covariance matrix \mathbf{V} , and if \mathbf{A} is an $m \times n$ matrix of rank m , with $m \leq n$, then the m -dimensional random vector $\mathbf{y} = \mathbf{A}\mathbf{x}$ is also normally distributed, with a mean (vector) equal to $\mathbf{A}\mathbf{m}_o$ and a positive definite covariance matrix equal to $\mathbf{A}\mathbf{V}\mathbf{A}^+$.
2. If \mathbf{x} is a normally distributed random vector of dimension n , with corresponding mean vector \mathbf{m}_o and positive definite covariance matrix \mathbf{V} , and if \mathbf{A} is a nonsingular $n \times n$ matrix such that $\mathbf{A}^+\mathbf{V}^{-1}\mathbf{A} = \mathbf{I}$ (the diagonal unit matrix), then $\mathbf{y} = \mathbf{A}^{-1}(\mathbf{x} - \mathbf{m}_o)$ is a random vector with a zero mean vector, $\mathbf{0}$, and unit covariance matrix, \mathbf{I} . This linear transformation is the multivariate equivalent of the standard-variable transformation for the univariate Gaussian distribution.
3. If \mathbf{x} is a normally distributed random vector of dimension n with corresponding mean vector \mathbf{m}_o and positive definite covariance matrix \mathbf{V} , then the quadratic form $Q = (\mathbf{x} - \mathbf{m}_o)^+\mathbf{V}^{-1}(\mathbf{x} - \mathbf{m}_o)$ is a statistic distributed according to the chi-square distribution with n degrees of freedom.
4. If \mathbf{x} is a normally distributed vector with mean vector \mathbf{m}_o and covariance matrix \mathbf{V} , then the individual variables x_1, x_2, \dots, x_n are mutually independent iff all the elements μ_{ij} in \mathbf{V} are equal to zero for $i \neq j$.

Log-normal distribution: The random variable $x = e^y$, where y is a Gaussian random variable with mean μ and variance σ^2 , is distributed according to the log-normal distribution

$$p(x) = \frac{1}{\sqrt{2\pi\sigma^2}} \frac{1}{x} \exp \left(-\frac{(\log x - \mu)^2}{2\sigma^2} \right).$$

Since the log-normal and Gaussian distributions are closely connected to one another, they share many common properties. For example, the moments of the log-normal distribution can be obtained directly from those of the normal distribution, by noting that $E(x^k) = E(e^{ky}) = M_y(t)|_{t=k}$. Thus, the expectation value and variance, respectively, for the log-normal distribution are $E(x) = \exp(\mu + \frac{1}{2}\sigma^2)$, $V(x) = \exp(2\mu + \sigma^2)[\exp(\sigma^2) - 1]$.

Applying the central limit theorem to the variable $x = e^y$ shows that a variable x that stems from the product of n factors (i.e., $x = x_1 x_2 \dots x_n$) will follow a log-normal distribution in the

limit as $n \rightarrow \infty$. Therefore, the log-normal distribution is often used to model random errors which change a result by a multiplicative factor. Since the log-normal function is distributed over the range of positive real numbers, and has only two parameters, it is particularly useful for modeling nonnegative phenomena, such as analysis of incomes, classroom sizes, masses or sizes of biological organisms, evaluation of neutron cross sections, scattering of subatomic particles, etc.

Cauchy distribution: The Cauchy distribution is defined by the PDF

$$p(x) = (\lambda/\pi)[\lambda^2 + (x - \nu)^2]^{-1},$$

for $x \in \mathbb{R}$, $\nu \in \mathbb{R}$, and $\lambda \in \mathbb{R}(\lambda > 0)$. Although this distribution is normalized (i.e., the zeroth raw moment exists), the expectations that define the higher-order raw moments are divergent. Mathematical difficulties can be alleviated, however, by confining the analysis to the vicinity of $x = \nu$; if needed, this distribution can be arbitrarily truncated.

Gamma distribution: Consider that x is a nonnegative real variable ($x \in \mathbb{R}$, $x > 0$), and α and β are positive real constants ($\alpha \in \mathbb{R}$, $\alpha > 0$; $\beta \in \mathbb{R}$, $\beta > 0$). Then the PDF for the gamma distribution is defined as

$$p(x) = x^{\alpha-1} e^{-(x/\beta)} / [\beta^\alpha \Gamma(\alpha)].$$

The *MGF* for the gamma distribution is

$$M_x(t) = 1/(1 - \beta t)^\alpha, \quad (t \in \mathbb{R}, t < 1/\beta),$$

while the mean value and variance are $m_o = \alpha\beta$ and $\mu_2 = \alpha\beta^2$, respectively. Note that when $\alpha = 1$ and $\beta = 1/\lambda$, the gamma distribution reduces to the exponential distribution.

Beta distribution: Consider that x is a real variable in the range $0 \leq x \leq 1$, and α and β are positive real parameters ($\alpha \in \mathbb{R}$, $\alpha > 0$; $\beta \in \mathbb{R}$, $\beta > 0$). The PDF for the beta distribution is defined as

$$p(x) = \{\Gamma(\alpha + \beta)/[\Gamma(\alpha)\Gamma(\beta)]\}x^{\alpha-1}(1-x)^{\beta-1}.$$

Since the *MGF* for the beta distribution is inconvenient to use, it is easier to derive the mean value and the variance; this yields $m_o = \alpha/(\alpha + \beta)$ and $\mu_2 = \alpha\beta/[(\alpha + \beta)^2(\alpha + \beta + 1)]$. The beta distribution is often used for weighting probabilities along the unit interval.

Student's t-distribution: The t-distribution was discovered by W. Gosset (who published it under the pseudonym "Student"). It arises when considering the quotient of two random variables. For x a real variable ($x \in \mathbb{R}$), the probability density for the t-distribution is defined as

$$p(x) = \Gamma[(n+1)/2][1 + (x^2/n)]^{-(n+1)/2} / [(n\pi)^{1/2}\Gamma(n/2)], \quad (n = 1, 2, 3, \dots).$$

The t-distribution function does not have an *MGF*. However, certain moments do exist: the mean value is $m_o = 0$, for $n > 1$, and the variance is $\mu_2 = n/(n-2)$, for $n > 2$. Note that, the conditions $n > 1$ and $n > 2$ for the existence of the mean value and variance, respectively, arise from the fact that the t-distribution for $n = 1$ is equivalent to the Cauchy distribution for $\nu = 0$ and $\lambda = 1$.

F-distribution: Just as the t-distribution, the F-distribution also arises when considering the quotient of two random variables; its probability density is given by

$$p(x) = (n/m)^{n/2} \Gamma[(n+m)/2] x^{(n/2)-1} / \{ \Gamma(n/2) \Gamma(m/2) [1 + (nx/m)]^{(n+m)/2} \},$$

where $x \in \mathbb{R}, x > 0$, and the parameters m and n are positive integers called degrees of freedom. The MGF for the F-distribution does not exist, but the mean value is $m_o = m/(m-2)$, for $m > 2$, and the variance is

$$\mu_2 = m^2(2m+2n-4)/[n(m-2)^2(m-4)], \quad \text{for } m > 4.$$

Few-parameter distribution and Pearson's equation: Pearson made the remarkable discovery that the differential equation $(dp/dx) = p(x)(d-x)/(a+bx+cx^2)$ yields several of the univariate PDFs considered in the foregoing, e.g.:

- The normal distribution if $a > 0, b = c = 0$, while d is arbitrary
- The exponential distribution if $a = c = d = 0, b > 0$
- The gamma distribution if $a = c = 0, b > 0$, and $d > -b$
- The beta distribution if $a = 0, b = -c$, and $d > 1 - b$

Chi-square χ^2 -distribution: The χ^2 (chi-square) distribution of the continuous variable x ($0 \leq x < \infty$) is defined as

$$p(x) = \frac{1}{2^{n/2} \Gamma(n/2)} x^{n/2-1} e^{-x/2}, \quad (n = 1, 2, \dots),$$

where the parameter n is the number of degrees of freedom. The mean value and variance of x are given by $m_o = n$ and $\mu_2 = 2n$, respectively.

The χ^2 -distribution is related to the sum of squares of normally distributed variables: given N independent Gaussian random variables x_i with known mean μ_i and variance σ_i^2 , the random variable $x = \sum_{i=1}^N (x_i - \mu_i)^2 / \sigma_i^2$ is distributed according to the χ^2 -distribution with N degrees of freedom. More generally, if the random variables x_i are not independent but are described by an N -dimensional Gaussian PDF, then the random variable $Q = (\mathbf{x} - \boldsymbol{\mu})^+ \mathbf{V}^{-1} (\mathbf{x} - \boldsymbol{\mu})$ also obeys a χ^2 -distribution with N degrees of freedom. Random variables following the χ^2 -distribution play an important role in tests of goodness-of-fit, as highlighted, for example, by the method of least squares.

7.6 Central Limit Theorem

Consider that (x_1, x_2, \dots, x_n) is a random sample of the parent random variable x , whose MGF $M_x(t)$ exists in a range $-t_o < t < t_o$, $t_o > 0$, around $t = 0$. This requirement implies that the mean value m_o and $\text{var}(x) = \sigma^2$ both exist, while the sample average is $\xi_n = (\sum_{i=1}^n x_i) / n$. Note that, the MGF of ξ_n is $M_{\xi_n}(t) = [M_x(t/n)]^n$. Furthermore, define $z_n \equiv (\xi_n - m_o) / (\sigma / n^{1/2})$ to be the reduced random-variable equivalent of ξ_n . Then, the central limit theorem states that z_n , ξ_n , and $n\xi_n$ are all asymptotically normal in the limit as $n \rightarrow \infty$.

The conditions stated in the preceding theorem are more restrictive than they need to be; in particular, the condition that (x_1, x_2, \dots, x_n) be equally distributed can be eliminated. The

least restrictive necessary and sufficient condition for the validity of the central limit theorem is the *Lindeberg condition*, which states that if the sequence of random variables (x_1, x_2, \dots, x_n) is uniformly bounded (i.e., if there exists a positive real constant C such that $|x_i| < C$ for each x_i and all possible n) and the sequence is not degenerate, then the central limit theorem holds. In practice, the Lindeberg condition requires that the mean values and variances exist for each of these variables, and that the overall variance in the sum ξ_n of these random variables be not dominated by just a few of the components. Application of the central limit theorem to correlated random variables is still an open field of research in mathematical statistics.

Rather than specifying the conditions under which the central limit theorem holds exactly in the limit $n \rightarrow \infty$, in practice it is more important to know the extent to which the Gaussian approximation is valid for finite n . This is difficult to quantify exactly, but the rule of thumb is that the central limit theorem holds as long as the sum is built up of a large number of small contributions. Discrepancies arise if, for example, the distributions of the individual terms have long tails, so that occasional large values make up a large part of the sum. Such contributions lead to “non-Gaussian” tails in the sum, which can significantly alter the probability to find values with large departures from the mean. In such cases, the main assumption underlying the central limit theorem, namely the assumption that the measured value of a quantity is a normally distributed variable centered about the mean value, breaks down. Since this assumption is often used when constructing a confidence interval, such intervals can be significantly underestimated if non-Gaussian tails are present. In particular, the relationship between the confidence level and the size of the interval will differ from the Gaussian prescription (i.e., 68.3% for a “ 1σ ” interval, 95.4% for “ 2σ ,” etc.). A better understanding of the non-Gaussian tails can often be obtained from a detailed Monte Carlo simulation of the individual variables making up the sum.

7.7 Statistical Estimation

In practice, the exact form of mathematical models and/or exact values of data are rarely, if ever, available. Rather, the available information comes in the form of observations, usually associated with a frequency distribution, which must be used, in turn, to estimate the mathematical form and/or the parameters describing the underlying probability distribution function. The use of observations to estimate the underlying features of probability functions forms the objective of a branch of mathematical sciences called statistics. Conceptually, therefore, the objective of statistical estimation is to estimate the parameters $(\theta_1, \dots, \theta_k)$ that describe a particular statistical model, by using observations, x_n , of a frequency function $f(x; \theta_1, \dots, \theta_k)$. Furthermore, this statistical estimation process must provide reasonable assurance that the model based on these estimates will fit the observed data within acceptable limits. Furthermore, the statistical estimates obtained from observational data must be consistent, unbiased, and efficient. Therefore, the science of statistics embodies both inductive and deductive reasoning, encompassing procedures for estimating parameters from incomplete knowledge and for refining prior knowledge by consistently incorporating additional information. Hence, the solution to practical problems requires a synergetic use of the various interpretations of probability, including the axiomatic, frequency, and Bayesian interpretations and methodologies.

Consider that x represents a random variable that describes events in a certain event space. For simplicity, the symbol x will be used in this section to represent both the random variable and a typical value; a distinction between these two uses will be made only when necessary to avoid confusion. Thus, x is considered to be described by a probability density $p(x)$, with a

mean value $E(x) = m_o$ and $\text{var}(x) = \sigma^2$. Without loss of generality, x can be considered to be continuous, taking values in an uncountably infinite space \mathcal{S}_x ; the statistical formalisms to be developed in the following can be similarly developed for finite or countably infinite random variables.

In both classical and Bayesian statistics, the estimation procedures are applied to samples of data. A sample, \mathbf{x}_s , of size n is defined as a collection of n equally distributed random variables (x_1, x_2, \dots, x_n) ; each x_i is associated with the same event space and has the same probability density, $p_i(x_i) = p(x_i)$. The random variable x , which each x_i resembles, is usually called the parent random variable. Each sampling step corresponds to the selection of a sample; thus, the first step selects sample 1, which corresponds to x_1 , while the last step (the n th-step) selects sample n , which corresponds to x_n . The selection of values x_i is called a *sampling process*, and the result of this process is the n -tuple of values $\mathbf{x}_s \equiv (x_1, x_2, \dots, x_n)$. If the sampling is random (i.e., the selection of each x_i is unaffected by the selection of all other x_j , $j \neq i$), then the collection of random variables can be treated as a random vector $\mathbf{x}_s \equiv (x_1, x_2, \dots, x_n)$ distributed according to the multivariate probability density $p(x_1, x_2, \dots, x_n) = p(x_1)p(x_2) \dots p(x_n)$. For random sampling, the components x_i are uncorrelated (i.e., the covariance matrix is diagonal), and have mean values $E(x_i) = m_o$ and variances $\text{var}(x_i) = E[(x_i - m_o)^2] = \sigma^2$, identical to the mean value and standard deviation of the parent distribution x .

A function $\Theta(x_1, \dots, x_n)$ that acts only on the sample random variables (and, possibly, on well-defined constants) is called a *statistic*. An *estimator*, $T = \Theta(x_1, \dots, x_n)$, is a statistic specifically employed to provide estimated values for a particular, true yet unknown, constant value T_o of the underlying probability distribution for the parent variable x ; the function Θ is called the *estimation rule*. Since this rule is designed to provide specific values of T that are meant to approximate the constant T_o , the estimator T is called a *point estimator*. The process of selecting estimators is not unique, so the criteria used for particular selections are very important, since they determine the properties of the resulting estimated values for the parameters of the chosen model.

An *estimator* T of a physical quantity T_o is called *consistent* if it approaches the true value T_o of that quantity (i.e., it converges in probability to T_o) as the number of observations x_n of T_o increases: $T(x_1, \dots, x_n) \xrightarrow{n \rightarrow \infty} T_o$. An *estimator* T of T_o is called *unbiased* if its expectation is equal to the true value of the estimated quantity: $E(T) = T_o$. The bias $B(T, T_o)$ of an estimator is defined as $B(T, T_o) \equiv E(T) - T_o$. If $B(T, T_o) > 0$, then T tends to overestimate T_o ; if $B(T, T_o) < 0$, then T tends to underestimate T_o . The quantity $E[(T - T_o)^2]$ is called the *mean-squared error*.

If the estimator $T = \Theta(x_1, \dots, x_n)$ utilizes all the information in the sample that pertains to T_o , then the respective estimator is called a *sufficient estimator*. In practice, the choice of estimators is further limited by considering unbiased estimators, which, among all similar estimators, have the smallest variance. A consistent, unbiased, and minimum variance estimator is called an *efficient estimator*.

Intuitively, it would be expected that the smaller the variance of an unbiased estimator, the closer the estimator is to the respective parameter value. This intuitive expectation is indeed correct. For example, $T(x_1, x_2, \dots, x_n) = \sum_{i=1}^n a_i x_i$, where the quantities a_i are constants, would be a *best linear unbiased estimator (BLUE)* of a parameter θ , if $T(x_1, \dots, x_n)$ is a linear unbiased estimator such that $\text{var}\{T(x_1, \dots, x_n)\} \leq \text{var}\{T'(x_1, \dots, x_n)\}$, where $T'(x_1, \dots, x_n)$ is any other linear unbiased estimator of θ .

The *sample moment of order k* , x_k^S , is the statistic defined as $x_k^S \equiv (1/n) \sum_{i=1}^n x_i^k$, ($k = 1, 2, \dots$). In this definition, the superscript “S” denotes “sample.” The *sample mean* value,

$x^S \equiv (1/n) \sum_{i=1}^n x_i$, is defined in the special case when $k=1$. Note that $E(x^S) = (1/n) \sum_{i=1}^n E(x_i) = (1/n)nE(x) = m_o$, which indicates that the expectation value, $E(x^S)$, of the sample mean is an unbiased estimator for the distribution mean value $E(x) = m_o$. It can also be shown that the variance of the sample mean, $\text{var}(x^S)$, is related to $\sigma^2 = \text{var}(x)$ by means of the relation $\text{var}(x^S) = \sigma^2/n = \text{var}(x)/n$.

The *sample central moment statistic of order k* is defined as $\mu_k^S \equiv (1/n) \sum_{i=1}^n (x_i - x^S)^k$, ($k = 2, 3, \dots$). In particular, the sample variance is defined by setting $k = 2$, to obtain: $\mu_2^S \equiv (1/n) \sum_{i=1}^n (x_i - x^S)^2$, while the sample standard deviation is calculated using the formula $SD(x^S) = \sqrt{(1/(n-1)) \sum_{i=1}^n (x_i - x^S)^2}$.

The properties of sampling distributions from a normally distributed parent random variable x are of particular practical importance due to the prominent practical and theoretical role played by the central limit theorem. Thus, consider a normally distributed parent random variable x , with mean m_o and variance σ^2 . Furthermore, consider a sample (x_1, x_2, \dots, x_n) with sample mean value x^S and sample variance μ_2^S , respectively. Then, the following theorems hold and are often used in practice:

1. The quantities x^S and μ_2^S are independent random variables; note that the converse also holds, namely, if x^S and μ_2^S are independent, then the distribution for x must be normal.
2. The random variable $(n\mu_2^S/\sigma^2)$ is distributed according to a chi-square distribution with $(n - 1)$ degrees of freedom.

If y is a random variable distributed according to a χ^2 -square distribution with n degrees of freedom, and z is distributed as a standard normal random variable, and y and z are independent, then the ratio random variable $r \equiv z/\sqrt{y/n}$ is distributed according to Student's t-distribution with n degrees of freedom. In particular, this theorem holds when r, y, z are random variables defined as $(n\mu_2^S/\sigma^2) \equiv y$, $(x^S - m_o)/\sigma \equiv z$, and $r \equiv z/\sqrt{y/n}$; the ratio r is frequently used in practice to measure the scatter of the actual data relative to the scatter that would be expected from the parent distribution with standard deviation σ .

If y is distributed according to a χ^2 -square distribution with n degrees of freedom, and w is distributed according to a χ^2 -square distribution with m degrees of freedom, and y and w are independent, then the ratio variable $R \equiv (w/m)/(y/n)$ is distributed according to an F-distribution with degrees of freedom m and n . It is important to note that the sample mean $x^S \equiv (1/n) \sum_{i=1}^n x_i$ is the BLUE for the mean $E(x) = m_o$ of the parent distribution.

A concept similar to the BLUE is the *maximum likelihood estimator (MLE)*, which can be introduced, for simplicity, by considering that a single parameter, say θ_o , is to be estimated from a random sample (x_1, x_2, \dots, x_n) of size n . Since each sample is selected independently, the conditional multivariate probability density for the observed sample data set (x_1, x_2, \dots, x_n) is

$$\prod_{i=1}^n p(x_i|\theta) \equiv L(x_1, \dots, x_n|\theta),$$

where $p(x_i|\theta)$ is the conditional probability density that the value x_i will be observed in a single trial. The function $L(x_1, \dots, x_n|\theta)$ is called the *likelihood function*. The *maximum-likelihood method* for estimating θ_o consists of finding the particular value, say $\hat{\theta} \equiv \hat{\theta}(x_1, \dots, x_n)$, which maximizes $L(x_1, \dots, x_n|\theta)$ for the observed data set (x_1, x_2, \dots, x_n) . Thus, the MLE, $\hat{\theta}$, of θ_o is found as the solution to the equation

$$\left. \frac{d \ln L(x_1, \dots, x_n|\theta)}{d\theta} \right|_{\theta=\hat{\theta}} = 0.$$

If the above equation admits multiple solutions, then the solution that yields the largest likelihood function $L(x_1, \dots, x_n | \theta)$ is defined to be the *MLE*. The maximum likelihood method sketched above can, of course, be extended to more than a single parameter θ_o . For a normally distributed sample (x_1, \dots, x_n) , the sample mean x^S is the *MLE* for the parent's distribution mean value, m_o , while the sample variance, μ_2^S , is the *MLE* for the variance σ^2 of the parent's distribution. Since, $E(\mu_2^S) \rightarrow \sigma^2$ as $n \rightarrow \infty$, the *MLE* estimate μ_2^S is consistent; however, the *MLE* estimate μ_2^S is biased. Multiplying μ_2^S with the correction factor $n/(n-1)$ yields the estimate $[n/(n-1)]\mu_2^S = [1/(n-1)] \sum_{i=1}^n (x_i - x^S)^2$, which deviates from the *MLE* value but, on the other hand, is both consistent and unbiased. In practice, a small deviation from the maximum of the likelihood function is less important than a potential bias in the estimate. The sample standard deviation is computed using the formula $SD(x^S) = \sqrt{\sum_{i=1}^n (x_i - x^S)^2 / n - 1}$. The quantity $\hat{V}_{xy} \equiv 1/(n-1) \sum_{i=1}^n (x_i - x^S)(y_i - y^S)$ is an unbiased estimator of the covariance V_{xy} of two random variables x and y of unknown mean.

In many practical instances when estimating a set of parameters $(\theta_1, \dots, \theta_k)$, a certain amount of relevant knowledge is already available prior to performing the experiment. Such a priori knowledge is usually available in the form of a regression (or fitting) model $y = f(x; \theta_1, \dots, \theta_k)$, a priori parameter values $\theta_a = (\theta_1^a, \dots, \theta_k^a)$, and corresponding a priori covariance matrix V_a (the letter "a" indicates a priori). In such instances, it is important to combine the a priori information consistently with the new information derived from the experimental data set (η_1, \dots, η_n) , of observations of y , with a covariance V . The most popular method to accomplish such a consistent combination of a priori with newly obtained information is the *generalized least-squares method*. For example, when the a priori information is uncorrelated with the current information, the least squares method yields the array of values $(\theta_1, \dots, \theta_k)$ obtained by satisfying the condition

$$\chi^2 = (\boldsymbol{\theta} - \boldsymbol{\theta}_a)^+ \mathbf{V}_a^{-1} (\boldsymbol{\theta} - \boldsymbol{\theta}_a) + (\boldsymbol{\eta} - \mathbf{y})^+ \mathbf{V}^{-1} (\boldsymbol{\eta} - \mathbf{y}) = \min.$$

The above expression can be generalized to include also the case when the prior information is correlated with the newly obtained information. The statistic χ^2 to be minimized follows a χ^2 -square distribution, and provides a very valuable index for testing the consistency of data and numerical solutions (if applicable) of the regression model $y = f(x; \theta_1, \dots, \theta_k)$.

The estimators of the form $T = \Theta(x_1, \dots, x_n)$ that have been discussed in the foregoing are specifically employed to provide estimated values for a particular, true yet unknown, value $T_o = \Theta(x_1^o, \dots, x_n^o)$ of the underlying probability distribution. Since the estimation rule Θ is designed to provide specific values of T for approximating T_o , the estimator T is called a *point estimator*. Once the estimator T has been obtained, it becomes of interest to determine by how much the estimator can change when measurements are repeatedly performed under the same conditions. This question is addressed by constructing the so-called *confidence interval* for the true value $T_o = \Theta(x_1^o, \dots, x_n^o)$ of the measured quantity. The confidence interval is an interval that contains, with a prescribed probability called the confidence probability, the true value of the measured quantity. This concept can be illustrated by considering that (x_1, \dots, x_n) is a set of random variables defining the sample of data under study, and θ_p is a fundamental parameter of the underlying distribution that produced the data. If it were now possible to introduce two statistics, say $\theta_1 = \Theta_1(x_1, \dots, x_n)$ and $\theta_2 = \Theta_2(x_1, \dots, x_n)$ which would guarantee that $P\{\theta_1 < \theta_p < \theta_2\} = \alpha$, then the interval $I(\theta_1, \theta_2)$ would be called the $100\alpha\%$ confidence interval. The procedure employed to determine an estimate of the confidence interval is called *interval estimation*. Note that a single experiment involving n samples would produce a single sample

of data, say (x_1, \dots, x_n) ; in turn, this sample would yield a single interval. Additional similar experiments would generate different data and, consequently, different intervals. However, if $I(\theta_1, \theta_2)$ is the $100\alpha\%$ confidence interval, then $100\alpha\%$ of all intervals that might be generated this way would contain the true value, θ_p , of the parameter in question.

There are several methods for constructing confidence intervals. Perhaps the simplest and the most general method for constructing confidence intervals is based on Chebyshev's theorem, although the intervals obtained by using Chebyshev's theorem are too large for practical purposes. When the distribution of the sample observations can be assumed to follow a normal distribution with sample mean x^S and known standard deviation σ , then the confidence interval which would contain the true value, θ_p , of the parameter in question is constructed based on the expression

$$P\left\{|x^S - \theta_p| \leq z_\alpha \frac{\sigma}{\sqrt{n}}\right\} = \alpha,$$

where z_α is the quantile of the normalized Gaussian distribution corresponding to the selected confidence probability α . In practice, however, the sample standard deviation is rarely known; only its estimate, $SD(x^S)$, can be calculated. In such case, the confidence intervals are constructed based on Student's t-distribution, which is the distribution of the random quantity $t \equiv x^S - \theta_p / SD(x^S)$, where $SD(x^S)$ is the sample standard deviation. The confidence interval $[x^S - t_q SD(x^S), x^S + t_q SD(x^S)]$ corresponds to the probability $P\{|x^S - \theta_p| \leq t_q SD(x^S)\} = \alpha$, where t_q is the q -percent point of Student's t-distribution with $(n - 1)$ degrees of freedom and significance level $q \equiv (1 - \alpha)$. The significance level, q , should be consistent with the significance level adopted for verifying the normality of the sample. Although it is possible to verify the admissibility of the hypothesis that the observations are described by a normal distribution (and therefore verify the hypothesis that Student's t-distribution is admissible), in practice, however, confidence intervals are directly constructed based on Student's t-distribution without verifying its admissibility. The observation that this procedure works in practice indirectly confirms the tacit assumption that the truncated distributions usually obeyed by experimental data are often even narrower than normal distributions. In practice, the confidence probability is usually set equal to 0.95.

Confidence intervals for the standard deviation can also be constructed by using the χ^2 -distribution. The confidence interval thus constructed has the limits $(\sqrt{n-1}/\chi_L)SD(x^S)$ and $(\sqrt{n-1}/\chi_U)SD(x^S)$ for the probability

$$P\left\{\left(\frac{\sqrt{n-1}}{\chi_L}\right)SD(x^S) < \sigma < \left(\frac{\sqrt{n-1}}{\chi_U}\right)SD(x^S)\right\} = \alpha,$$

where χ_U^2 and χ_L^2 are found from tables, with χ_U^2 corresponding to $(1+\alpha)/2$, and χ_L^2 corresponding to $(1-\alpha)/2$. Note that the purpose of a confidence interval is to obtain a set of values which, despite sampling variations, yields a reasonable range of values for the estimated parameter, based on the data available. Thus, a confidence interval is an interval estimator of the parameter under investigation.

Another context in which inferences are made about parameters is the test of hypotheses. A *statistical hypothesis* is an assumption about the distribution (frequency function) of a

random variable. If the frequency function involves parameters, then the hypothesis can be an assumption concerning the respective parameters. A test of hypothesis is a rule by which the sample space is divided into two regions: the region in which the hypothesis is accepted and the region in which the hypothesis is rejected. A statistical hypothesis that is being tested is termed the null hypothesis, and is usually denoted by H_0 . In general, the alternative hypothesis is the complement of the null hypothesis. Rejection of the null hypothesis H_0 when it is true is called *type I error*. The size of type I error is the probability of rejecting H_0 when it is true. Acceptance of H_0 when it is false is called *type II error*. The size of type II error is the probability of accepting H_0 when it is false. The sizes of type I and type II errors are usually termed α and β , respectively. By definition, the *power of a test* is $1 - \beta$. The concept of power of a test is used to choose between (among) two or more procedures in testing a given null hypothesis, in that the test with the greater power, i.e., the smaller value of β (if one exists), is chosen. Occasionally, the power of a test depends on the value of the specific alternative when H_0 is not true; in such cases, a “most powerful” test does not exist. Tests that are “most powerful” against all alternatives are called *uniformly most powerful tests*.

7.8 Stationary Random Sequence and White Noise

Let $\mathbf{x} = \{x_0, x_1, x_2, x_3, \dots\}$ be a sequence of (scalar) random variables (also called a *time series*). Let $p(x_t)$ be the PDF of x_t for $t = 0, 1, 2, \dots$. In general, $p(x_t)$ may vary with time t . Then $E(x_t) = \mu_t = \int_{\mathbb{R}} x_t p(x_t) dx_t$ is the mean of x_t , while

$$E[(x_t - \mu_t)(x_{t-j} - \mu_{t-j})] = \gamma_{t,j} = \int_{\mathbb{R}} \int_{\mathbb{R}} (x_t - \mu_t)(x_{t-j} - \mu_{t-j}) p(x_t, x_{t-j}) dx_t dx_{t-j},$$

where $p(x_t, x_{t-j})$ is the joint density of x_t and x_{t-j} , is the covariance between x_t and x_{t-j} . The sequence x is said to be *weakly (or second-order) stationary* if $E(x_t) \equiv \mu$ and the mean and the covariance are *independent* of t , i.e., $E[(x_t - \mu_t)(x_{t-j} - \mu_{t-j})] = \gamma_j$. If $\gamma_j \equiv 0$ for $j \neq 0$, then the sequence x is *uncorrelated*. A weakly stationary random sequence that is uncorrelated is called a *stationary white noise*. In addition, if each of the elements x_t of the sequence has a common normal distribution, e.g., $N(0, \sigma^2)$ then the respective sequence is called *Gaussian white noise*. All of these notions carry over to sequences of random vectors.

8 Fourier Transforms

8.1 Fourier Transforms of Continuous Functions

Consider a function $g : \mathbb{R} \rightarrow \mathbb{R}$ which is piecewise smooth and absolutely integrable, i.e., $\int_{-\infty}^{\infty} |g(t)| dt < \infty$. The (direct or forward) *continuous time Fourier transform* $G(f)$ of a function $g(t)$ is a function $G : \mathbb{R} \rightarrow \mathbb{R}$ defined by $G(f) = F[g(t)] = \int_{-\infty}^{\infty} g(t) e^{-i2\pi ft} dt$, f is called the *rotational frequency* and $\omega = 2\pi f$ is called the *angular frequency*. The *inverse transform* of $G(f)$ is defined by $g(t) = F^{-1}[G(f)] = 1/2\pi \int_{-\infty}^{\infty} G(f) e^{i2\pi ft} df$. $G(f)$ is customarily called the *spectral representation* of $g(t)$. Note that $g(t)$ and $G(f)$ are two equivalent but different representations of the same function because

$$g(t) = F^{-1}[G(f)] = F^{-1}[F(g(t))] \quad \text{and} \quad G(f) = F[g(t)] = F[F^{-1}(G(f))].$$

8.2 Properties of Fourier Transform

1. *Linearity:* $F[ag(t) + bh(t)] = aF[g(t)] + bF[h(t)]$, for any two piecewise smooth and absolutely integrable functions $g(t)$ and $h(t)$ are, and any two real constants a and b .
2. *Shifting property:* $F[g(t - \tau)] = e^{-i2\pi f\tau} F[g(t)]$, for any real τ .
3. *Stretching property:* $F[g(at)] = \frac{1}{|a|} G\left(\frac{f}{a}\right)$, any nonzero real constant a .
4. *Derivative of a function:* $F\left[\frac{dg(t)}{dt}\right] = i2\pi fG(f)$.
5. *Integral of a function:* $F\left[\int_{-\infty}^t g(\tau)d\tau\right] = \frac{G(f)}{i2\pi f}$.
6. *Parseval's theorem:* $\int_{-\infty}^{\infty} |g(t)|^2 dt = \int_{-\infty}^{\infty} \|G(f)\|^2 df$, which signifies that the *total energy* is the same in both the representations.
7. *Time reversal property:* $F[g(-t)] = \int_{-\infty}^{\infty} g(-t)e^{-i2\pi ft} dt = G(-f)$.
8. *Convolution theorem:* the integral $(g * h)(t) = \int_{-\infty}^{\infty} g(r)h(t-r)dr$ is defined as the convolution of $g(t)$ and $h(t)$, and is denoted by $(g * h)(t)$. The convolution is commutative [$g * h = h * g$], associative [$g * (h * f) = (g * h) * f$], and distributive [$g * (f + h) = (g * f) + (g * h)$]; note that $F[g * h] = F(g)F(h)$.

8.3 Fourier Transform of Discrete Functions

The real-valued function $g = \{g_n\} = \{\dots, g_{-2}, g_{-1}, g_0, g_1, g_2, \dots\}$ is absolutely summable if $\sum_{n=-\infty}^{\infty} |g_n| < \infty$. The *discrete time Fourier transform* $G(f)$ of g is defined by $G(f) = \sum_{n=-\infty}^{\infty} g_n e^{-i2\pi fn}$. Note that, $G(f)$ is periodic with period = 1, i.e., $G(f + 1) = G(f)$.

Discrete convolution theorem: The (discrete) convolution of two sequences $g = \{g_n\}$ and $h = \{h_n\}$ is a sequence $s = \{s_n\}$, denoted by $s = g * h$, where $s_n = \sum_{k=-\infty}^{\infty} g_k h_{n-k}$. Note that

$$\begin{aligned} S(f) &= \sum_{n=-\infty}^{\infty} s_n e^{-i2\pi fn} = \sum_{n=-\infty}^{\infty} \left(\sum_{k=-\infty}^{\infty} g_k h_{n-k} \right) e^{-i2\pi fn} \\ &= \sum_{r=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} g_k h_r e^{-i2\pi f(k+r)} \\ &= \sum_{r=-\infty}^{\infty} h_r e^{-i2\pi fr} \sum_{k=-\infty}^{\infty} g_k e^{-i2\pi fk} \\ &= H(f)G(f) = G(f)H(f). \end{aligned}$$

8.4 Fourier Series

Functions in one dimension: A sequence of functions $\{g_k(x)\}_{k=0}^{\infty}$ is a (pair-wise) *orthogonal system* if $\langle g_m, g_n \rangle = 0$, for $m \neq n$, and $\|g_n\|^2 = \lambda_n^2 > 0$, for all m . If $\lambda_n = 1$, then $\{g_k(x)\}_{k=0}^{\infty}$ is called an *orthonormal system*. The inner product is defined as $\langle f, g \rangle = \int_a^b f(x)g(x)dx$ and the *norm* is defined as $\|f\| = \langle f, f \rangle = \int_a^b f^2(x)dx > 0$.

Fourier series expansion: Given an orthogonal system $\{g_k(x)\}_{k=0}^{\infty}$ over the interval $[a, b]$, any piecewise continuous function $f(x)$ over $[a, b]$ can be represented by the (formal) series,

called the *Fourier series* of $f(x)$, $f(x) = \sum_{k=0}^{\infty} c_k g_k(x)$, where the *Fourier coefficients* c_k are obtained from the integral $c_k = \frac{1}{\|g_k\|} \int_a^b f(x) g_k(x) dx$.

Least squares property: Consider that $\{g_k\}_{k=0}^{\infty}$ is an orthogonal system over $[a, b]$, and consider that the finite linear combination $\sum_{k=0}^N a_k g_k(x)$ with arbitrary coefficients a_0, a_1, \dots, a_N denotes an approximation of $f(x)$ over $[a, b]$. Then the norm of the error $[f(x) - \sum_{k=0}^N a_k g_k(x)]$ is a minimum exactly when $a_k = c_k = \frac{1}{\|g_k\|} \int_a^b f(x) g_k(x) dx$, i.e., $\|f(x) - \sum_{k=0}^N c_k g_k(x)\| \leq \|f(x) - \sum_{k=0}^N a_k g_k(x)\|$, for any arbitrary set of coefficients a_0, a_1, \dots, a_N .

Functions in two dimensions: The system $\{g_k(x, y)\}_{k=0}^{\infty}$ is *orthogonal* over a rectangle $[a, b] \times [c, d]$ in \mathbb{R}^2 , $a < b$ and $c < d$, if

1. $\langle g_m, g_n \rangle = \int_c^d \int_a^b g_m(x, y) g_n(x, y) dx dy = 0$ for $m \neq n$.
2. $\|g_m\|^2 = \langle g_m, g_m \rangle = \int_c^d \int_a^b g_m^2(x, y) dx dy > 0$ for all m .

When $\|g_k\| = 1$ for all k , then $\{g_k(x, y)\}$ is called an *orthonormal system*.

Fourier series expansion: A piecewise continuous function $f(x, y)$ over $[a, b] \times [c, d]$ can be expanded in the Fourier series $f(x, y) = \sum_{k=0}^{\infty} c_k g_k(x, y)$, where $c_k = \frac{1}{\|g_k\|^2} \int_c^d \int_a^b f(x, y) g_k(x, y) dx dy$ are the respective Fourier coefficients.

If $\{g_k(x)\}_{k=0}^{\infty}$ and $\{h_j(y)\}_{j=0}^{\infty}$ are two orthogonal systems over the one-dimensional intervals $[a, b]$ and $[c, d]$, respectively, then the product system $\{g_i(x)h_j(y)\}_{0 \leq i < \infty \text{ and } 0 \leq j < \infty}$ is an orthogonal system over $[a, b] \times [c, d]$. In particular, the system

$$\{\cos mx \cos ny, \cos mx \sin ny, \sin mx \cos ny, \sin mx \sin ny, |0 \leq m < \infty, 0 \leq n < \infty\}$$

is orthogonal over $[-\pi, \pi] \times [-\pi, \pi]$. Hence, any piecewise continuous function $f(x)$ over $[a, b] \times [c, d]$ can be expressed in a *double Fourier Series* as

$$f(x, y) = \sum_{m,n} \lambda_{mn} [A_{mn} \cos mx \cos ny + B_{mn} \sin mx \cos ny + C_{mn} \cos mx \sin ny + D_{mn} \sin mx \sin ny],$$

where

$$\lambda_{mn} = \begin{cases} \frac{1}{4}, & \text{if } m = 0, n = 0, \\ \frac{1}{2}, & \text{if } m = 0, n \neq 0, \text{ or } m \neq 0, n = 0, \\ 1 & \text{if } m \neq 0, n \neq 0, \end{cases}$$

$$A_{mn} = \frac{1}{\pi^2} \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} f(x, y) \cos mx \cos ny dx dy,$$

$$B_{mn} = \frac{1}{\pi^2} \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} f(x, y) \sin mx \cos ny dx dy,$$

$$C_{mn} = \frac{1}{\pi^2} \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} f(x, y) \cos mx \sin ny dx dy,$$

$$D_{mn} = \frac{1}{\pi^2} \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} f(x, y) \sin mx \sin ny dx dy.$$

Abstract: The *transport equation* is introduced to describe a population of neutral particles such as neutrons or photons, in a close domain, under steady-state (i.e., stationary) conditions. Its derivation is based on the principle of *particle conservation*. The transport equation describes the statistical behavior of a large population of particles. The exact number of particles per unit volume is continuously varying with time, even at steady-state conditions. Under steady-state conditions, the number density of particles oscillates about an average value related to the solution of the steady-state transport equation. A solution of the transport equation is required in many fields of nuclear engineering, notably in *reactor physics*, in *safety and criticality*, and in *radiation shielding and protection*. We review legacy approaches for solving the steady-state transport equation, namely, the method of spherical harmonics, the collision probability method, the discrete ordinates method, and the method of characteristics. The full-core calculation consists of solving a simplified transport equation, either the diffusion equation or the simplified P_n equation.

1 The Steady-State Boltzmann Equation

We first introduce the fundamental quantities used in the context of the transport equation. We use an approach of *statistical mechanics* in which each particle is moving in a six-dimensional *phase space* made of three positions and three velocity coordinate axes. The position of a single particle is identified by a set of seven quantities as follows:

- Three position coordinates $\mathbf{r} = x \mathbf{i} + y \mathbf{j} + z \mathbf{k}$
- Three velocity coordinates. We use the velocity module $V_n \equiv |\mathbf{V}_n|$ with $\mathbf{V}_n = d\mathbf{r}/dt$ and the two components of the direction $\mathbf{\Omega} \equiv \mathbf{V}_n/V_n$
- The time t , used in transient situations, when the steady-state hypothesis is not valid

A population of particles is represented by a distribution, the *population density* $n(\mathbf{r}, V_n, \mathbf{\Omega}, t)$ such that $n(\mathbf{r}, V_n, \mathbf{\Omega}, t) d^3r dV_n d^2\Omega$ is the number of particles, at time t , in the volume element d^3r surrounding point \mathbf{r} , in the velocity element dV_n surrounding V_n , and in the solid angle element $d^2\Omega$ surrounding $\mathbf{\Omega}$. We note that $n(\mathbf{r}, V_n, \mathbf{\Omega}, t)$ is a distribution with respect to variables \mathbf{r} , V_n , and $\mathbf{\Omega}$. It is a function of t .

The dependent variable used in reactor physics is the *particle flux*. The *angular flux* is a distribution related to the population density and is defined as

$$\phi(\mathbf{r}, V_n, \mathbf{\Omega}, t) \equiv V_n n(\mathbf{r}, V_n, \mathbf{\Omega}, t). \quad (1)$$

It is more convenient to use angular flux as the dependent variable of the transport equation. The angular flux has no precise physical significance; it is a mathematical definition. However, the probability for a particle to collide depends on each of the factors n and V_n . Increasing the number of particles in one cubic centimeter volume makes it more likely that one of them will collide. Increasing the particle speed increases the number of visits in the one cubic centimeter volume each second.

The angular flux defined in (1) gives the maximum information about the population of particles. In many applications a more global representation is preferred. The *integrated flux* is obtained by performing a distribution reduction on variable $\mathbf{\Omega}$, so that

$$\phi(\mathbf{r}, V_n, t) = \int_{4\pi} d^2\Omega \phi(\mathbf{r}, V_n, \mathbf{\Omega}, t), \quad (2)$$

where we have used the same symbol to represent the two distributions.

In physical terms, the integrated flux is the total distance traveled in one second by all the particles in the one cubic centimeter volume, as it is obtained by multiplying the number of particles in that cubic centimeter by the speed of each one. This is equivalent to the total length of all the particle tracks laid down in one cubic centimeter in one second.

The integrated flux may be written with the particle energy E or lethargy u as independent variable, replacing V_n . The change of variables can be performed, so that

$$E = \frac{1}{2} m V_n^2 \quad \text{and} \quad u = \ln \frac{E_0}{E}, \quad (3)$$

where m is the mass of a particle and E_0 is the maximum energy of a particle, so that

$$\phi(\mathbf{r}, E, t) = \frac{1}{m V_n} \phi(\mathbf{r}, V_n, t), \quad 0 < E \leq E_0 \quad (4)$$

and

$$\phi(\mathbf{r}, u, t) = E \phi(\mathbf{r}, E, t), \quad 0 \leq u < \infty. \quad (5)$$

We now define the *angular current*, another fundamental distribution. In  Fig. 1, we present an element of surface d^2S with a unit normal vector \mathbf{N} located on point \mathbf{r} .

The number of particles crossing d^2S in  Fig. 1 is

$$d^3n = n(\mathbf{r}, V_n, \Omega, t) [d^2S (V_n dt) \Omega \cdot \mathbf{N}]. \quad (6)$$

The angular current $\mathbf{J}(\mathbf{r}, V_n, \Omega, t)$ is a vector defined in such a way that

$$\frac{d^3n}{d^2S dt} = \mathbf{J}(\mathbf{r}, V_n, \Omega, t) \cdot \mathbf{N} \quad (7)$$

so that

$$\mathbf{J}(\mathbf{r}, V_n, \Omega, t) = \Omega \phi(\mathbf{r}, V_n, \Omega, t). \quad (8)$$

 Figure 1

Definition of the particle current. The number d^3n of particles, of velocity V_n and direction Ω , crossing d^2S during an element of time dt is equal to the number of particles located in the represented slanted cylinder

In similarity with the integrated flux, we can define the *integrated current* as

$$J(\mathbf{r}, V_n, t) = \int_{4\pi} d^2\Omega J(\mathbf{r}, V_n, \Omega, t) = \int_{4\pi} d^2\Omega \Omega \phi(\mathbf{r}, V_n, \Omega, t). \tag{9}$$

The angular current is positive if the particle crosses d^2S in the direction of \mathbf{N} , and negative otherwise. We can also define the *outgoing current* J^+ and *incoming current* J^- by integrating the angular current over outgoing and incoming directions, respectively. We write

$$J^+(\mathbf{r}, V_n, t) = \int_{\Omega \cdot \mathbf{N} > 0} d^2\Omega (\Omega \cdot \mathbf{N}) \phi(\mathbf{r}, V_n, \Omega, t) \tag{10}$$

and

$$J^-(\mathbf{r}, V_n, t) = - \int_{\Omega \cdot \mathbf{N} < 0} d^2\Omega (\Omega \cdot \mathbf{N}) \phi(\mathbf{r}, V_n, \Omega, t) \tag{11}$$

so that

$$J(\mathbf{r}, V_n, t) \cdot \mathbf{N} = J^+(\mathbf{r}, V_n, t) - J^-(\mathbf{r}, V_n, t). \tag{12}$$

The velocity vector V_n of the particle is pointing in the direction of the solid angle Ω , as depicted in  Fig. 2, so that

$$V_n = V_n \Omega, \tag{13}$$

where

$$V_n = |V_n| \quad \text{and} \quad |\Omega| = 1. \tag{14}$$

 **Figure 2**
 Definition of the solid angle. The direction of a moving particle in a three-dimensional (3D) domain is represented by its *solid angle*, a unit vector pointing in the direction of the particle

The solid angle Ω is defined in terms of its three *direction cosines*, μ , η , and ξ , using

$$\Omega = \mu \mathbf{i} + \eta \mathbf{j} + \xi \mathbf{k} \quad (15)$$

with the constraint

$$\mu^2 + \eta^2 + \xi^2 = 1, \quad (16)$$

where the symbols \mathbf{i} , \mathbf{j} , and \mathbf{k} are used to denote the unit vectors in the x -, y -, and z -direction, respectively.

Here, we have used the x -axis as the *principal axis* to define the *colatitude* or *polar angle* $\psi = \cos^{-1} \mu$ and the *azimuth* ϕ . The definition domain is $0 \leq \psi \leq \pi$ for the colatitude and $0 \leq \phi \leq 2\pi$ for the azimuth. On a case-by-case basis, any other axis can be used. The last two direction cosines are written in terms of the azimuthal angle ϕ using

$$\eta = \sqrt{1 - \mu^2} \cos \phi \quad \text{and} \quad \xi = \sqrt{1 - \mu^2} \sin \phi. \quad (17)$$

An increase in ψ by $d\psi$ and in ϕ by $d\phi$ sweeps out the area $d^2\Omega$ on a unit sphere. The solid angle encompassed by a range of directions is defined as the area swept out on the surface of a sphere divided by the square of the radius of the sphere. Thus, the differential solid angle associated with solid angle Ω is

$$d^2\Omega = \sin \psi \, d\psi \, d\phi. \quad (18)$$

The solid angle is a dimensionless quantity. Nevertheless, to avoid confusion when referring to a directional distribution function, units of steradians, abbreviated sr, are attributed to the solid angle.

In reactor physics, many quantities are continuous and bounded distributions of the particle direction cosine μ or solid angle Ω . In the first case, such a quantity is written as $f(\mu)$ and can be approximated in terms of an L -order *Legendre polynomial* expansion using

$$f(\mu) = \sum_{\ell=0}^L \frac{2\ell+1}{2} f_{\ell} P_{\ell}(\mu), \quad (19)$$

where the ℓ th order coefficient is obtained using

$$f_{\ell} = \int_{-1}^1 d\mu P_{\ell}(\mu) f(\mu). \quad (20)$$

The Legendre polynomials are defined by the relations

$$P_0(\mu) = 1, \quad P_1(\mu) = \mu \quad (21)$$

and

$$P_{\ell+1}(\mu) = \frac{1}{\ell+1} [(2\ell+1)\mu P_{\ell}(\mu) - \ell P_{\ell-1}(\mu)] \quad \text{if } \ell \geq 1. \quad (22)$$

In the more general case, a bounded distribution of the particle solid angle is written as $f(\Omega)$ and can be approximated in terms of an L -order *real spherical harmonics* expansion using

$$f(\Omega) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{m=-\ell}^{\ell} f_{\ell}^m R_{\ell}^m(\Omega), \quad (23)$$

where $R_{\ell}^m(\Omega)$ is a real spherical harmonics component, a distribution of the solid angle Ω .

The first component μ of the solid angle is the cosine of the polar angle and ϕ represents the azimuthal angle. These components are expressed in terms of the associated Legendre functions $P_\ell^{m_l}(\mu)$ using

$$R_\ell^m(\Omega) = \sqrt{(2 - \delta_{m,0}) \frac{(\ell - |m|)!}{(\ell + |m|)!}} P_\ell^{|m|}(\mu) \mathcal{T}_m(\phi), \quad (24)$$

where $P_\ell^m(\mu)$ is defined in terms of the ℓ th-order Legendre polynomial $P_\ell(\mu)$ as

$$P_\ell^m(\mu) = (1 - \mu^2)^{m/2} \frac{d^m}{d\mu^m} P_\ell(\mu), \quad m \geq 0 \quad (25)$$

and where

$$\mathcal{T}_m(\phi) = \begin{cases} \cos m\phi & \text{if } m \geq 0, \\ \sin |m|\phi & \text{otherwise.} \end{cases} \quad (26)$$

Note that we have used the Ferrer definition of the associated Legendre functions $P_\ell^m(\mu)$, in which the factor $(-1)^m$ is absent. They can be obtained using the following Matlab script:

```
function f=plgndr(l,m,x)
% return the Ferrer definition of the associated Legendre function.
% function f=plgndr(l,m,x)
% (c) 2008 Alain Hebert, Ecole Polytechnique de Montreal
if m < 0
    error('bad arguments in plgndr 1')
elseif m > l
    error('bad arguments in plgndr 2')
elseif abs(x) > 1.
    error('bad arguments in plgndr 3')
end
pmm=1.;
if m > 0, pmm=prod(1:2:2*m)*sqrt((1.-x).*(1.+x)).^m; end
if l == m
    f=pmm;
else
    pmmp1=(2*m+1)*x.*pmm;
    if l == m+1
        f=pmmp1;
    else
        for ll=m+2:l
            pll=((2*ll-1)*x.*pmmp1-(ll+m-1)*pmm)/(ll-m);
            pmm=pmmp1; pmmp1=pll;
        end
        f=pll;
    end
end
```

The Ferrer definition helps to simplify low-order angular expansions since

$$\mathbf{\Omega} = \begin{pmatrix} \frac{\mu}{\sqrt{1-\mu^2}} \cos \phi \\ \sqrt{1-\mu^2} \cos \phi \\ \sqrt{1-\mu^2} \sin \phi \end{pmatrix} = \begin{pmatrix} R_1^0(\mathbf{\Omega}) \\ R_1^1(\mathbf{\Omega}) \\ R_1^{-1}(\mathbf{\Omega}) \end{pmatrix}. \quad (27)$$

Real spherical harmonics are to be preferred to classical ones because they permit us to eliminate imaginary components in 3D problems. The trigonometric functions, associated Legendre functions, and real spherical harmonics obey the following orthonormal conditions:

$$\int_{-\pi}^{\pi} d\phi \mathcal{T}_m(\phi) \mathcal{T}_{m'}(\phi) = \pi (1 + \delta_{m,0}) \delta_{m,m'}, \quad (28)$$

$$\int_{-1}^1 d\mu P_\ell^m(\mu) P_{\ell'}^m(\mu) = \frac{2(\ell+m)!}{(2\ell+1)(\ell-m)!} \delta_{\ell,\ell'} \quad (29)$$

and

$$\int_{4\pi} d^2\Omega R_\ell^m(\mathbf{\Omega}) R_{\ell'}^{m'}(\mathbf{\Omega}) = \frac{4\pi}{2\ell+1} \delta_{\ell,\ell'} \delta_{m,m'} \quad (30)$$

with $d^2\Omega = d\mu d\phi$, so that the components of the source distribution are written as

$$f_\ell^m = \int_{4\pi} d^2\Omega R_\ell^m(\mathbf{\Omega}) f(\mathbf{\Omega}). \quad (31)$$

In the previous relations, we have introduced the integral over 4π to represent an integration over all possible directions. This integral is defined as

$$\int_{4\pi} d^2\Omega f(\mathbf{\Omega}) \equiv \int_{-1}^1 d\mu \int_0^{2\pi} d\phi f(\mu, \phi). \quad (32)$$

The real spherical harmonics satisfy the *addition theorem* which can be written in terms of two different solid angles, $\mathbf{\Omega}$ and $\mathbf{\Omega}'$, as

$$P_\ell(\mathbf{\Omega} \cdot \mathbf{\Omega}') = \sum_{m=-\ell}^{\ell} R_\ell^m(\mathbf{\Omega}) R_\ell^m(\mathbf{\Omega}'), \quad \ell \geq 0. \quad (33)$$

The real spherical harmonics can be written as polynomials in direction cosines as follows:

$$R_0^0 = 1, \quad (34)$$

$$R_1^{-1} = \xi, \quad R_1^0 = \mu, \quad R_1^1 = \eta, \quad (35)$$

$$R_2^{-2} = \sqrt{3} \eta \xi, \quad R_2^{-1} = \sqrt{3} \mu \xi, \quad R_2^0 = \frac{1}{2}(3\mu^2 - 1),$$

$$R_2^1 = \sqrt{3} \mu \eta, \quad R_2^2 = \frac{\sqrt{3}}{2}(\eta^2 - \xi^2), \quad (36)$$

$$\begin{aligned}
R_3^{-3} &= \sqrt{\frac{5}{8}} \xi(3\eta^2 - \xi^2), & R_3^{-2} &= \sqrt{15} \mu \xi \eta, & R_3^{-1} &= \sqrt{\frac{3}{8}} \xi(5\mu^2 - 1), \\
R_3^0 &= \frac{1}{2} \mu(5\mu^2 - 3), & R_3^1 &= \sqrt{\frac{3}{8}} \eta(5\mu^2 - 1), & R_3^2 &= \sqrt{\frac{15}{4}} \mu(\eta^2 - \xi^2), \\
R_3^3 &= \sqrt{\frac{5}{8}} \eta(\eta^2 - 3\xi^2).
\end{aligned} \tag{37}$$

Another common approximation consists in developing the angular flux in spherical harmonics. We are using the standard closure condition, assuming that the $(L + 1)$ th Legendre coefficients of the angular flux are zero at all spatial points. The angular flux is expanded as

$$\phi(\mathbf{r}, V_n, \mathbf{\Omega}, t) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{m=-\ell}^{\ell} \phi_{\ell}^m(\mathbf{r}, V_n, t) R_{\ell}^m(\mathbf{\Omega}), \tag{38}$$

where the real spherical harmonics $R_{\ell}^m(\mathbf{\Omega})$ are defined in (24). The summation over index ℓ in (38) corresponds to the more general case of a three-dimensional (3D) geometry. In one-dimensional (1D) slab and spherical geometries, only the $m = 0$ value is required, due to symmetry reasons. In 1D cylindrical geometry, only $0 \leq m \leq \ell$ values with $m + \ell$ even are required. In 2D geometries defined in the x - y plane, only even $m + \ell$ values are required.

There are important relations between the spherical harmonic moments of the angular flux and the integrated flux and current values. We can show that

$$\phi(\mathbf{r}, V_n, t) = \phi_0^0(\mathbf{r}, V_n, t) \tag{39}$$

and that

$$\mathbf{J}(\mathbf{r}, V_n, t) = \phi_1^0(\mathbf{r}, V_n, t) \mathbf{i} + \phi_1^1(\mathbf{r}, V_n, t) \mathbf{j} + \phi_1^{-1}(\mathbf{r}, V_n, t) \mathbf{k}. \tag{40}$$

However, (40) is only consistent with the Ferrer definition of the associated Legendre polynomials.

Equation (38) can be truncated after the $\ell = 1$ component, leading to the *linearly anisotropic flux approximation*. We write

$$\begin{aligned}
\phi(\mathbf{r}, V_n, \mathbf{\Omega}, t) &= \frac{1}{4\pi} \left[\phi_0^0(\mathbf{r}, V_n, t) + 3 \sum_{m=-1}^1 \phi_1^m(\mathbf{r}, V_n, t) R_1^m(\mathbf{\Omega}) \right] \\
&= \frac{1}{4\pi} [\phi(\mathbf{r}, V_n, t) + 3 \mathbf{\Omega} \cdot \mathbf{J}(\mathbf{r}, V_n, t)].
\end{aligned} \tag{41}$$

Analytical expressions for $J^+(\mathbf{r}, V_n, t)$ and $J^-(\mathbf{r}, V_n, t)$ can be found in the special case of the linearly anisotropic flux approximation. We substitute (41) into (10) and set $\mathbf{N} = \mathbf{i}$ with $\mathbf{\Omega} = \mu \mathbf{i} + \sqrt{1 - \mu^2} \cos \omega \mathbf{j} + \sqrt{1 - \mu^2} \sin \omega \mathbf{k}$, so that

$$\begin{aligned}
J^+(\mathbf{r}, V_n, t) &= \frac{1}{4\pi} \int_{\mathbf{\Omega} \cdot \mathbf{N} > 0} d^2 \Omega (\mathbf{\Omega} \cdot \mathbf{N}) [\phi(\mathbf{r}, V_n, t) + 3 \mathbf{\Omega} \cdot \mathbf{J}(\mathbf{r}, V_n, t)] \\
&= \frac{1}{4\pi} \int_0^1 d\mu \mu \int_0^{2\pi} d\omega [\phi(\mathbf{r}, V_n, t) + 3\mu J_x(\mathbf{r}, V_n, t) \\
&\quad + 3\sqrt{1 - \mu^2} \cos \omega J_y(\mathbf{r}, V_n, t) + 3\sqrt{1 - \mu^2} \sin \omega J_z(\mathbf{r}, V_n, t)] \\
&= \frac{1}{4} \phi(\mathbf{r}, V_n, t) + \frac{1}{2} \mathbf{J}(\mathbf{r}, V_n, t) \cdot \mathbf{N}.
\end{aligned}$$

Similarly, we can show that

$$J^-(\mathbf{r}, V_n, t) = \frac{1}{4} \phi(\mathbf{r}, V_n, t) - \frac{1}{2} \mathbf{J}(\mathbf{r}, V_n, t) \cdot \mathbf{N} \quad (42)$$

and

$$\phi(\mathbf{r}, V_n, t) = 2 [J^-(\mathbf{r}, V_n, t) + J^+(\mathbf{r}, V_n, t)]. \quad (43)$$

1.1 The Integro-Differential Form of the Transport Equation

The Boltzmann equation is obtained as the phase-space balance relation for the neutral particles located in a control volume. The absence of particle-particle interactions produces a linear form of the *Boltzmann equation*. In steady-state conditions, it is written (Hébert 2009) as

$$\Omega \cdot \nabla \phi(\mathbf{r}, V_n, \Omega) + \Sigma(\mathbf{r}, V_n) \phi(\mathbf{r}, V_n, \Omega) = Q(\mathbf{r}, V_n, \Omega). \quad (44)$$

The source density can be written in a spherical harmonic expansion similar to (38) as

$$Q(\mathbf{r}, V_n, \Omega) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{m=-\ell}^{\ell} Q_{\ell}^m(\mathbf{r}, V_n) R_{\ell}^m(\Omega), \quad (45)$$

where the value of L is smaller or equal to the value used in (38).

1.2 The Characteristic Form of the Transport Equation

The characteristic form of the transport equation corresponds to an integration of the *streaming operator* $\Omega \cdot \nabla \phi$ over the *characteristic*, a straight line direction Ω is corresponding to the particle trajectory. At each time of its motion, the particle is assumed to be at distance s from a reference position \mathbf{r} on its characteristic, so that its actual position is $\mathbf{r} + s \Omega$. The streaming operator can be transformed using a derivation in series. We first write

$$\frac{d}{ds} = \frac{dx}{ds} \frac{\partial}{\partial x} + \frac{dy}{ds} \frac{\partial}{\partial y} + \frac{dz}{ds} \frac{\partial}{\partial z} \quad (46)$$

with

$$ds \Omega = d\mathbf{r} = dx \mathbf{i} + dy \mathbf{j} + dz \mathbf{k}. \quad (47)$$

Taking the dot product of (47) with \mathbf{i} , we obtain $ds \Omega \cdot \mathbf{i} = dx$. Similarly, $ds \Omega \cdot \mathbf{j} = dy$ and $ds \Omega \cdot \mathbf{k} = dz$. After substitution into (46), we obtain

$$\frac{d}{ds} = (\Omega \cdot \mathbf{i}) \frac{\partial}{\partial x} + (\Omega \cdot \mathbf{j}) \frac{\partial}{\partial y} + (\Omega \cdot \mathbf{k}) \frac{\partial}{\partial z} = \Omega \cdot \nabla. \quad (48)$$

Substituting (48) into (44), we obtain the backward *characteristic form of the transport equation* as

$$\frac{d}{ds} \phi(\mathbf{r} + s \Omega, V_n, \Omega) + \Sigma(\mathbf{r} + s \Omega, V_n) \phi(\mathbf{r} + s \Omega, V_n, \Omega) = Q(\mathbf{r} + s \Omega, V_n, \Omega). \quad (49)$$

Equation (49) can also be written in the forward form as

$$-\frac{d}{ds}\phi(\mathbf{r}-s\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega}) + \Sigma(\mathbf{r}-s\boldsymbol{\Omega}, V_n)\phi(\mathbf{r}-s\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega}) = Q(\mathbf{r}-s\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega}). \quad (50)$$

1.3 The Integral Form of the Transport Equation

The integral transport equation is obtained by integrating the angular flux along its characteristic, for a given value of the source density $Q(\mathbf{r}, V_n, \boldsymbol{\Omega})$. We first introduce an integrating factor $e^{-\tau(s, V_n)}$ where the *optical path* is defined as a function of the macroscopic total cross-section $\Sigma(\mathbf{r}, V_n)$ using

$$\tau(s, V_n) = \int_0^s ds' \Sigma(\mathbf{r}-s'\boldsymbol{\Omega}, V_n). \quad (51)$$

We next compute the following relation:

$$\begin{aligned} \frac{d}{ds} \left[e^{-\tau(s, V_n)} \phi(\mathbf{r}-s\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega}) \right] &= e^{-\tau(s, V_n)} \left[-\Sigma(\mathbf{r}-s\boldsymbol{\Omega}, V_n) \phi(\mathbf{r}-s\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega}) \right. \\ &\quad \left. + \frac{d}{ds} \phi(\mathbf{r}-s\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega}) \right], \end{aligned} \quad (52)$$

where we used the identity

$$\frac{d}{ds} \int_0^s ds' g(s') = g(s).$$

Substitution of (50) into (52) leads to

$$-\frac{d}{ds} \left[e^{-\tau(s, V_n)} \phi(\mathbf{r}-s\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega}) \right] = e^{-\tau(s, V_n)} Q(\mathbf{r}-s\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega}). \quad (53)$$

Equation (53) can be integrated between 0 and ∞ , so that

$$-\int_0^\infty ds \frac{d}{ds} \left[e^{-\tau(s, V_n)} \phi(\mathbf{r}-s\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega}) \right] = \int_0^\infty ds e^{-\tau(s, V_n)} Q(\mathbf{r}-s\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega}) \quad (54)$$

or

$$\phi(\mathbf{r}, V_n, \boldsymbol{\Omega}) = \int_0^\infty ds e^{-\tau(s, V_n)} Q(\mathbf{r}-s\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega}). \quad (55)$$

Equation (55) is the integral form of the transport equation for the infinite-domain case.

The path of the particle between points \mathbf{r}' and \mathbf{r} is depicted in  Fig. 3.

If the domain is finite, it is possible to integrate only over the s values corresponding to a value of \mathbf{r}' inside the domain. In this case, the integral form of the transport equation is written as

$$\phi(\mathbf{r}, V_n, \boldsymbol{\Omega}) = e^{-\tau(b, V_n)} \phi(\mathbf{r}-b\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega}) + \int_0^b ds e^{-\tau(s, V_n)} Q(\mathbf{r}-s\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega}), \quad (56)$$

where $\phi(\mathbf{r}-b\boldsymbol{\Omega}, V_n, \boldsymbol{\Omega})$ can be assimilated to a boundary flux.

The integral form of the transport equation is generally limited to isotropic sources in the laboratory (LAB) frame of reference, so that

$$Q(\mathbf{r}, V_n, \boldsymbol{\Omega}) = \frac{1}{4\pi} Q(\mathbf{r}, V_n). \quad (57)$$

■ Figure 3

Characteristic of the particle between two positions. A particle from source $Q(r', V_n, \Omega)$ will travel with an exponential attenuation factor in direction Ω and contribute to the flux at point r

1.4 Boundary and Continuity Conditions

The domain V where the particles move may be surrounded by a boundary ∂V where *boundary conditions* are imposed. We also introduce $N(\mathbf{r}_s)$, the outward normal at $\mathbf{r}_s \in \partial V$. Solution of the transport equation in V requires the knowledge of the angular flux $\phi(\mathbf{r}_s, V_n, \Omega)$ for $\Omega \cdot N(\mathbf{r}_s) < 0$.

The *albedo boundary condition* is used to relate the incoming flux with the known outgoing flux. This condition is written as

$$\phi(\mathbf{r}_s, V_n, \Omega) = \beta \phi(\mathbf{r}_s, V_n, \Omega') \quad (58)$$

with $\Omega \cdot N(\mathbf{r}_s) < 0$, the solid angle Ω' representing the direction of the outgoing particle. The albedo β is equal to zero and one for a vacuum and reflective boundary condition, respectively. Intermediate values can also be used. *Specular reflection* corresponds to the case where

$$\Omega \cdot N(\mathbf{r}_s) = -\Omega' \cdot N(\mathbf{r}_s) \quad \text{and} \quad (\Omega \times \Omega') \cdot N(\mathbf{r}_s) = 0. \quad (59)$$

The *white boundary condition* is a reflective condition where all particles striking the boundary turn back to V with an isotropic angular distribution. In this case,

$$\phi(\mathbf{r}_s, V_n, \Omega) = \beta \frac{\int_{\Omega' \cdot N(\mathbf{r}_s) > 0} d^2 \Omega' [\Omega' \cdot N(\mathbf{r}_s)] \phi(\mathbf{r}_s, V_n, \Omega')}{\int_{\Omega' \cdot N(\mathbf{r}_s) > 0} d^2 \Omega' [\Omega' \cdot N(\mathbf{r}_s)]} \quad (60)$$

with $\Omega \cdot N(\mathbf{r}_s) < 0$ and where β is the albedo, defined as before. Equation (60) simplifies to

$$\phi(\mathbf{r}_s, V_n, \Omega) = \frac{\beta}{\pi} \int_{\Omega' \cdot N(\mathbf{r}_s) > 0} d^2 \Omega' [\Omega' \cdot N(\mathbf{r}_s)] \phi(\mathbf{r}_s, V_n, \Omega') \quad (61)$$

with $\Omega \cdot N(\mathbf{r}_s) < 0$.

The *periodic boundary condition* corresponds to the case where the flux on one boundary is equal to the flux on another parallel boundary in a periodic lattice grid. In this case,

$$\phi(\mathbf{r}_s, V_n, \Omega) = \phi(\mathbf{r}_s + \Delta \mathbf{r}, V_n, \Omega), \quad (62)$$

where $\Delta \mathbf{r}$ is the lattice pitch.

The *zero-flux boundary condition* corresponds to the absence of particles on ∂V . This condition is nonphysical as particles are continuously leaving the domain V , producing a nonzero number density on ∂V . The vacuum boundary condition must always be preferred to represent an external boundary. In cases where a zero-flux boundary condition must be applied, it is obtained by setting to zero all *even moments* of the spherical harmonic expansion of ϕ as

$$\phi_\ell^m(\mathbf{r}_s, V_n) = 0 \quad \text{with } \ell \text{ even.} \quad (63)$$

Inside the domain V , the angular flux $\phi(\mathbf{r}, V_n, \mathbf{\Omega})$ must be continuous across all internal interfaces in the direction $\mathbf{\Omega}$ of the moving particle. Discontinuities along $\mathbf{\Omega}$ can occur only if the source density contains Dirac delta contributions. The continuity condition is not required along directions which are not parallel to the path of travel.

1.5 The Steady-State Source Density

In reactor physics, the neutral particles are neutrons and the source density is a multiplicative source of secondary fission, scattering, and (n, xn) secondary neutrons. Expressions for the source density are given in steady-state and transient conditions. The steady-state source density is used in both lattice and static full-core calculations. The transient source density is only meaningful for full-core calculations. In the following developments, the energy variable $E = mV_n^2/2$ is used as a replacement for the neutron velocity V_n as independent variable.

In the case of a multiplying medium with neutrons, the differential form of the steady-state transport equation is given by (44) as

$$\mathbf{\Omega} \cdot \nabla \phi(\mathbf{r}, E, \mathbf{\Omega}) + \Sigma(\mathbf{r}, E) \phi(\mathbf{r}, E, \mathbf{\Omega}) = Q(\mathbf{r}, E, \mathbf{\Omega}). \quad (64)$$

Assuming that the fission reactions are isotropic in the LAB, the steady-state source density is written as

$$Q(\mathbf{r}, E, \mathbf{\Omega}) = \int_{4\pi} d^2\Omega' \int_0^\infty dE' \Sigma_s(\mathbf{r}, E \leftarrow E', \mathbf{\Omega} \leftarrow \mathbf{\Omega}') \phi(\mathbf{r}, E', \mathbf{\Omega}') + \frac{1}{4\pi K_{\text{eff}}} Q^{\text{fiss}}(\mathbf{r}, E), \quad (65)$$

where

$\Sigma_s(\mathbf{r}, E \leftarrow E', \mathbf{\Omega} \leftarrow \mathbf{\Omega}')$ = macroscopic differential-scattering cross-section taking into account diffusion *and* (n, xn) reactions.

K_{eff} = *effective multiplication factor*. If the sum of absorption and leakage rates does not equal the production rate of new-fission neutrons, the steady-state condition is lost. K_{eff} is the factor used to divide the fission sources in order to maintain the steady-state condition.

$Q^{\text{fiss}}(\mathbf{r}, E)$ = isotropic fission sources.

In isotropic media, the scattering cross-section is only a function of the scattering angle, so that (65) can be rewritten as

$$Q(\mathbf{r}, E, \mathbf{\Omega}) = \frac{1}{2\pi} \int_{4\pi} d^2\Omega' \int_0^\infty dE' \Sigma_s(\mathbf{r}, E \leftarrow E', \mathbf{\Omega} \cdot \mathbf{\Omega}') \phi(\mathbf{r}, E', \mathbf{\Omega}') + \frac{1}{4\pi K_{\text{eff}}} Q^{\text{fiss}}(\mathbf{r}, E). \quad (66)$$

In this case, it is convenient to expand the scattering cross-section in terms of Legendre polynomials as

$$\Sigma_s(\mathbf{r}, E \leftarrow E', \boldsymbol{\Omega} \cdot \boldsymbol{\Omega}') = \sum_{\ell=0}^L \frac{2\ell+1}{2} \Sigma_{s,\ell}(\mathbf{r}, E \leftarrow E') P_\ell(\boldsymbol{\Omega} \cdot \boldsymbol{\Omega}'), \quad (67)$$

where L is the scattering order of the medium where the neutron is moving. $L = 0$ and $L = 1$ correspond to *isotropic scattering* and to *linearly anisotropic scattering* in the LAB, respectively. The Legendre coefficients $\Sigma_{s,\ell}(E \leftarrow E')$ are defined as

$$\Sigma_{s,\ell}(E \leftarrow E') = \int_{-1}^1 d\mu \Sigma_s(E \leftarrow E', \mu) P_\ell(\mu). \quad (68)$$

Using the addition theorem of spherical harmonics (see (33)), it is possible to rewrite the scattering source of (66) in terms of the spherical harmonics components of the flux as

$$Q(\mathbf{r}, E, \boldsymbol{\Omega}) = \int_0^\infty dE' \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \Sigma_{s,\ell}(\mathbf{r}, E \leftarrow E') \sum_{m=-\ell}^{\ell} R_\ell^m(\boldsymbol{\Omega}) \phi_\ell^m(\mathbf{r}, E') + \frac{1}{4\pi K_{\text{eff}}} Q^{\text{fiss}}(\mathbf{r}, E), \quad (69)$$

where

$$\phi_\ell^m(\mathbf{r}, E) = \int_{4\pi} d^2\Omega R_\ell^m(\boldsymbol{\Omega}) \phi(\mathbf{r}, E, \boldsymbol{\Omega}). \quad (70)$$

We assume that the isotropic fission source is independent of the energy of the incident neutron. For each fissionable nuclide i , the energy of emitted neutrons is distributed according to a probability density known as *fission spectrum* $\chi_i(E)$. The quantity $\chi_i(E) dE$ is the probability for an emitted neutron to have an energy equal to E (within a dE interval) in the LAB. As expected, the normalization is

$$\int_0^\infty dE \chi_i(E) = 1. \quad (71)$$

The isotropic fission source is written as

$$Q^{\text{fiss}}(\mathbf{r}, E) = \sum_{j=1}^{j^{\text{fiss}}} \chi_j(E) \int_0^\infty dE' \nu_{\Sigma_{f,j}}(\mathbf{r}, E') \phi(\mathbf{r}, E'), \quad (72)$$

where j^{fiss} is the total number of fissionable isotopes and $\nu_{\Sigma_{f,j}}(\mathbf{r}, E)$ is the number of emitted neutrons per fission times the macroscopic fission cross-section of the j th-fissionable isotope.

Substitution of (72) into (69) gives the complete expression of a multiplicative source in reactor physics:

$$\begin{aligned} Q(\mathbf{r}, E, \boldsymbol{\Omega}) &= \int_0^\infty dE' \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \Sigma_{s,\ell}(\mathbf{r}, E \leftarrow E') \sum_{m=-\ell}^{\ell} R_\ell^m(\boldsymbol{\Omega}) \phi_\ell^m(\mathbf{r}, E') \\ &+ \frac{1}{4\pi K_{\text{eff}}} \sum_{j=1}^{j^{\text{fiss}}} \chi_j(E) \int_0^\infty dE' \nu_{\Sigma_{f,j}}(\mathbf{r}, E') \phi(\mathbf{r}, E'), \end{aligned} \quad (73)$$

where $\phi(\mathbf{r}, E) \equiv \phi_0^0(\mathbf{r}, E)$.

Substitution of (73) into (64) leads to the singular form of the transport equation. This is an *eigenproblem* featuring a number of properties as follows:

- The neutron flux ϕ appears in each term, so that $\phi = 0$ is a trivial solution. A set of nontrivial solutions (also called *eigensolutions*) exists for some discrete values of K_{eff} . We clearly obtain an *eigenvalue* problem, with K_{eff} as the eigenvalue and ϕ as the eigenvector. The *fundamental solution* corresponds to the maximum possible value of K_{eff} and is the only eigensolution with a physical meaning.
- Only the flux distribution of the fundamental solution is almost positive everywhere in the domain. The other eigensolutions are the harmonics of the flux and are partly positive and partly negative.
- The flux distributions of each eigensolution can be arbitrarily normalized. If $\phi(\mathbf{r}, E)$ is a nontrivial solution, then $C\phi(\mathbf{r}, E)$ is also a nontrivial solution for any nonzero value of the constant C . The value of the normalization constant C is generally computed from the thermal power P of the reactor using

$$\int_0^\infty dE \int_V d^3r H(\mathbf{r}, E) \phi(\mathbf{r}, E) = P, \quad (74)$$

where V is the volume of the reactor and $H(\mathbf{r}, E)$ is the *power factor* giving the recoverable energy in terms of the flux.

- It is possible to define a mathematical *adjoint problem* with the same eigenvalues as the original problem.

A multiplicative domain with $K_{\text{eff}} > 1$ is said to be overcritical because its flux level will increase with time if we remove the eigenvalue. Similarly, a multiplicative domain with $K_{\text{eff}} < 1$ is said to be undercritical.

Each term of the steady-state transport equation is an operator for which an adjoint operator can be found. The general rules for creating the adjoint of an operator are

1. Transpose the matrix operators.
2. Change the sign of odd-parity differential operators.
3. Interchange the arguments of the kernels of integral operators.

Using these rules, the adjoint of (64) is written as

$$-\mathbf{\Omega} \cdot \nabla \phi^*(\mathbf{r}, E, \mathbf{\Omega}) + \Sigma(\mathbf{r}, E) \phi^*(\mathbf{r}, E, \mathbf{\Omega}) = Q^*(\mathbf{r}, E, \mathbf{\Omega}), \quad (75)$$

where the adjoint source density is

$$Q^*(\mathbf{r}, E, \mathbf{\Omega}) = \int_0^\infty dE' \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \Sigma_{s,\ell}(\mathbf{r}, E' \leftarrow E) \sum_{m=-\ell}^{\ell} R_{\ell}^m(\mathbf{\Omega}) \phi_{\ell}^{*m}(\mathbf{r}, E') + \frac{1}{4\pi K_{\text{eff}}} \sum_{j=1}^{j_{\text{fiss}}} \nu \Sigma_{f,j}(\mathbf{r}, E) \int_0^\infty dE' \chi_j(E') \phi^*(\mathbf{r}, E'). \quad (76)$$

A close inspection of (76) reveals that the adjoint flux is a *function* of E . The adjoint flux cannot be a distribution of E because the term $\chi_j(E') \phi^*(\mathbf{r}, E')$ in (76) cannot involve the product of two distributions of E' . In some textbooks, the adjoint flux is referred to as the *importance function*.

The adjoint flux solution is generally normalized to an arbitrary value as

$$\int_0^\infty dE \int_V d^3r \phi^*(\mathbf{r}, E) = 1. \quad (77)$$

The adjoint transport equation is also an eigenvalue problem. Its eigenvalues are the same as those of the original transport equation. Each eigenvalue, such as the K_{eff} in (73) or (76), can be expressed in terms of the corresponding eigenvectors $\phi(\mathbf{r}, E)$ and $\phi^*(\mathbf{r}, E)$ using the *Rayleigh ratio*:

$$K_{\text{eff}} = \frac{\sum_{j=1}^{\text{fiss}} \int_0^\infty dE' \chi_j(E') \phi^*(\mathbf{r}, E') \int_0^\infty dE \nu \Sigma_{f,j}(\mathbf{r}, E) \phi(\mathbf{r}, E)}{\int_0^\infty dE' \phi^*(\mathbf{r}, E') \left[\Sigma(\mathbf{r}, E') \phi(\mathbf{r}, E') - \int_0^\infty dE \Sigma_{s,0}(\mathbf{r}, E' \leftarrow E) \phi(\mathbf{r}, E) \right]}. \quad (78)$$

The interest of the Rayleigh ratio is that it is stationary with respect to a small variation $\delta\Sigma$ of the cross-section terms. The first-order variation δK_{eff} corresponding to such a variation in cross-sections can be written in terms of ϕ , ϕ^* , Σ , and $\delta\Sigma$, *without* using $\delta\phi$ or $\delta\phi^*$. This observation is at the origin of the *perturbation theory*.

1.6 The Transport Correction

The transport equation is frequently solved by assuming the isotropy of the scattering sources in the LAB. This approximation is generally not valid but can be mitigated by performing a *transport correction* on the cross-sections appearing in the transport equation.

The basic principle is to add a forward-peaked component in the Legendre expansion of the differential-scattering cross-section. This additional component takes the form of a Dirac delta term in (67) as

$$\Sigma_s(\mathbf{r}, E \leftarrow E', \mu) = \sum_{\ell=0}^L \frac{2\ell+1}{2} \bar{\Sigma}_{s,\ell}(\mathbf{r}, E \leftarrow E') P_\ell(\mu) + \Delta\Sigma_{\text{tr}}(\mathbf{r}, E \leftarrow E') \delta(\mu-1), \quad (79)$$

where $\bar{\Sigma}_{s,\ell}(\mathbf{r}, E' \leftarrow E)$ is a modified Legendre coefficient and $\Delta\Sigma_{\text{tr}}(\mathbf{r}, E' \leftarrow E)$ is the additional coefficient multiplying the Dirac delta term. These coefficients are computed so as to preserve the Legendre moments of (68). We write

$$\int_{-1}^1 d\mu \Sigma_s(\mathbf{r}, E \leftarrow E', \mu) P_\ell(\mu) = \Sigma_{s,\ell}(\mathbf{r}, E \leftarrow E') \quad (80)$$

for $0 \leq \ell \leq L+1$. Substituting (79) into (80) and using the relation $P_\ell(1) = 1$, we obtain

$$\bar{\Sigma}_{s,\ell}(\mathbf{r}, E \leftarrow E') + \Delta\Sigma_{\text{tr}}(\mathbf{r}, E' \leftarrow E) = \Sigma_{s,\ell}(\mathbf{r}, E \leftarrow E') \quad \text{if } 0 \leq \ell \leq L \quad (81)$$

and

$$\Delta\Sigma_{\text{tr}}(\mathbf{r}, E' \leftarrow E) = \Sigma_{s,L+1}(\mathbf{r}, E \leftarrow E'). \quad (82)$$

Writing $L = 0$, (79) and (82) reduce to

$$\begin{aligned} \Sigma_s(\mathbf{r}, E \leftarrow E', \mu) = & \frac{1}{2} \left[\Sigma_{s,0}(\mathbf{r}, E \leftarrow E') - \Sigma_{s,1}(\mathbf{r}, E \leftarrow E') \right] \\ & + \Sigma_{s,1}(\mathbf{r}, E \leftarrow E') \delta(\mu-1) \end{aligned} \quad (83)$$

so that the substitution of (83) into the steady-state transport equation (64) leads to

$$\mathbf{\Omega} \cdot \nabla \phi(\mathbf{r}, E, \mathbf{\Omega}) + \Sigma(\mathbf{r}, E) \phi(\mathbf{r}, E, \mathbf{\Omega}) - \int_0^\infty dE' \Sigma_{s,1}(\mathbf{r}, E \leftarrow E') \phi(\mathbf{r}, E', \mathbf{\Omega}) = \bar{Q}(\mathbf{r}, E, \mathbf{\Omega}), \quad (84)$$

where the transport-corrected steady-state source density is now given by

$$\begin{aligned} \bar{Q}(\mathbf{r}, E, \mathbf{\Omega}) = & \frac{1}{4\pi} \int_0^\infty dE' [\Sigma_{s,0}(\mathbf{r}, E \leftarrow E') - \Sigma_{s,1}(\mathbf{r}, E \leftarrow E')] \phi(\mathbf{r}, E') \\ & + \frac{1}{4\pi K_{\text{eff}}} \sum_{j=1}^{j_{\text{fiss}}} \chi_j(E) \int_0^\infty dE' \nu \Sigma_{f,j}(\mathbf{r}, E') \phi(\mathbf{r}, E'). \end{aligned} \quad (85)$$

Another approximation is required to simplify the LHS of (84). Two alternative approaches can be used as follows:

- The *micro-reversibility* approximation (MRA) is valid in the thermal energy domain where the neutrons are in quasi-equilibrium with the nucleus. This approximation can be written as

$$\Sigma_{s,1}(\mathbf{r}, E \leftarrow E') \phi(\mathbf{r}, E', \mathbf{\Omega}) = \Sigma_{s,1}(\mathbf{r}, E' \leftarrow E) \phi(\mathbf{r}, E, \mathbf{\Omega}). \quad (86)$$

- The *one-over-E* weighting approximation (OEWA) consists of introducing a weighting function $W(E', E)$, so that

$$\Sigma_{s,1}(\mathbf{r}, E \leftarrow E') \phi(\mathbf{r}, E', \mathbf{\Omega}) = \Sigma_{s,1}(\mathbf{r}, E \leftarrow E') \phi(\mathbf{r}, E, \mathbf{\Omega}) W(E', E), \quad (87)$$

where $W(E', E)$ is given in terms of the neutron energy as

$$W(E', E) = \frac{E}{E'}. \quad (88)$$

In principle, the OEWA is more accurate than the MRA at neutron energies > 4 eV. However, it is common in reactor physics to perform an MRA-based transport correction over the complete energy spectrum.

Substitution of (86) or (87) in (84) leads to

$$\mathbf{\Omega} \cdot \nabla \phi(\mathbf{r}, E, \mathbf{\Omega}) + \bar{\Sigma}(\mathbf{r}, E) \phi(\mathbf{r}, E, \mathbf{\Omega}) = \bar{Q}(\mathbf{r}, E, \mathbf{\Omega}), \quad (89)$$

where the transport-corrected macroscopic cross-section is written as

$$\bar{\Sigma}(\mathbf{r}, E) = \Sigma(\mathbf{r}, E) - \Delta\Sigma_{\text{tr}}(\mathbf{r}, E) \quad (90)$$

with

$$\Delta\Sigma_{\text{tr}}(\mathbf{r}, E) = \begin{cases} \int_0^\infty dE' \Sigma_{s,1}(\mathbf{r}, E' \leftarrow E) & \text{if MRA,} \\ \int_0^\infty dE' W(E', E) \Sigma_{s,1}(\mathbf{r}, E \leftarrow E') & \text{if OEWA.} \end{cases} \quad (91)$$

The transport-corrected steady-state source density can also be simplified, so that

$$\begin{aligned} \bar{Q}(\mathbf{r}, E, \Omega) = & \frac{1}{4\pi} \int_0^\infty dE' \bar{\Sigma}_{s,0}(\mathbf{r}, E \leftarrow E') \phi(\mathbf{r}, E') \\ & + \frac{1}{4\pi K_{\text{eff}}} \sum_{j=1}^{j_{\text{fiss}}} \chi_j(E) \int_0^\infty dE' \nu \Sigma_{f,j}(\mathbf{r}, E') \phi(\mathbf{r}, E'), \end{aligned} \quad (92)$$

where the P_0 transport-corrected component of the differential scattering cross-section is now written as

$$\bar{\Sigma}_{s,0}(\mathbf{r}, E \leftarrow E') = \Sigma_{s,0}(\mathbf{r}, E \leftarrow E') - \delta(E' - E) \Delta \Sigma_{\text{tr}}(\mathbf{r}, E). \quad (93)$$

The transport [equation \(89\)](#) with the transport-corrected source density [\(92\)](#) is as easy to solve as the transport equation for an isotropic collision in the LAB, but includes a correction for anisotropic scattering effects. This technique of transport correction is very useful with the integral form of the transport equation, as presented in [\(55\)](#) and [\(56\)](#), as these equations are otherwise limited to isotropic scattering in the LAB. In this case, the optical path defined in [\(51\)](#) is computed using the transport corrected total cross-section defined in [\(90\)](#). Lattice calculations are generally performed this way.

1.7 Multigroup Discretization

The numerical solution of the transport equation is greatly facilitated by using a *multigroup discretization* in energy. This approach consists in dividing the energy domain in a set of G *energy groups* inside which the neutrons are assumed to behave as one-speed particles and to take averages of all energy-dependent quantities over these groups. This procedure is also named *energy condensation*.

It is advantageous to define the groups in terms of the lethargy variable. As neutron energy approaches the thermal-energy range, the number of collisions required to slow down increases and the average energy loss per collision decreases. Conversely, the average gain in lethargy per collision is almost constant over the complete energy range. We are going to assume constant cross-sections in each group. The definition of the lethargy limits is made after close inspection of the cross-section behavior of all major isotopes present in the reactor, including the position of the resolved resonances. The cross-sections of low-energy resonances (such as the 0.3 eV resonance of ^{239}Pu) must be precisely discretized with a sufficient number of groups; and other resolved resonances must be enclosed in an energy group, in order to avoid numerical problems.

Multigroup discretization may be performed in many instances of the global computational scheme. The first energy condensation occurs in the GROUPR module, during the NJOY-processing step. Energy condensation of continuous-energy cross-sections produces multigroup cross-sections defined over the energy structure of the cross-section library, typically with $50 \leq G \leq 400$. The next energy condensation occurs in the lattice code, in order to produce cross-sections defined over the energy structure of the reactor calculation with $2 \leq G \leq 8$. In some cases, the lattice code uses a *multilevel energy representation* and performs two energy condensations: the first toward an intermediate energy structure with $20 \leq G \leq 35$ and the second toward the energy structure of the reactor calculation. The values of G actually used after each condensation step are carefully chosen by the computational scheme specialists.

The reference energy E_0 used to define the lethargy $u = \ln(E_0/E)$ is generally taken above 10 MeV in order to correspond to the maximum energy of neutrons in a nuclear reactor. The lethargy is zero for the neutrons of energy E_0 and increases as neutrons slow down. We divide the energy domain $0 \leq E \leq E_0$ into G groups W_g , so that

$$W_g = \{u; u_{g-1} \leq u < u_g\} = \{E; E_g < E \leq E_{g-1}\}, \quad g = 1, G,$$

where $u_g = \ln(E_0/E_g)$ and $u_0 = 0$.

Before proceeding with energy condensation, we shall define the average $\langle X \rangle_g$ of a function or of a distribution $X(E)$ over group g . The following definition is used:

$$\langle X \rangle_g = \int_{u_{g-1}}^{u_g} du X(u) = \int_{E_g}^{E_{g-1}} dE X(E) \quad (94)$$

if $X(E)$ is a distribution, and

$$\langle X \rangle_g = \frac{1}{u_g - u_{g-1}} \int_{u_{g-1}}^{u_g} du X(u) = \frac{1}{\ln(E_{g-1}/E_g)} \int_{E_g}^{E_{g-1}} \frac{dE}{E} X(E) \quad (95)$$

if $X(E)$ is a function.

The group-averaged values of the flux, cross-section, differential cross-section, and source density are, therefore, defined as

$$\phi_g(\mathbf{r}, \boldsymbol{\Omega}) \equiv \langle \phi(\mathbf{r}, \boldsymbol{\Omega}) \rangle_g = \int_{u_{g-1}}^{u_g} du \phi(\mathbf{r}, u, \boldsymbol{\Omega}), \quad (96)$$

$$\phi_g(\mathbf{r}) \equiv \langle \phi(\mathbf{r}) \rangle_g = \int_{u_{g-1}}^{u_g} du \phi(\mathbf{r}, u), \quad (97)$$

$$\langle \Sigma(\mathbf{r}) \phi(\mathbf{r}) \rangle_g = \int_{u_{g-1}}^{u_g} du \Sigma(\mathbf{r}, u) \phi(\mathbf{r}, u), \quad (98)$$

$$\langle \Sigma_{s,\ell}(\mathbf{r}) \phi(\mathbf{r}) \rangle_{g \leftarrow h} = \int_{u_{g-1}}^{u_g} du \int_{u_{h-1}}^{u_h} du' \Sigma_{s,\ell}(\mathbf{r}, u \leftarrow u') \phi(\mathbf{r}, u') \quad (99)$$

and

$$\langle Q(\mathbf{r}, \boldsymbol{\Omega}) \rangle_g = \int_{u_{g-1}}^{u_g} du Q(\mathbf{r}, u, \boldsymbol{\Omega}). \quad (100)$$

The angular and integrated *multigroup flux* components are defined as $\phi_g(\mathbf{r}, \boldsymbol{\Omega}) \equiv \langle \phi(\mathbf{r}, \boldsymbol{\Omega}) \rangle_g$ and $\phi_g(\mathbf{r}) \equiv \langle \phi(\mathbf{r}) \rangle_g$. The *multigroup cross-section* components are defined in such a way as to preserve the values of the reaction rates. We write

$$\Sigma_g(\mathbf{r}) = \frac{1}{\phi_g(\mathbf{r})} \langle \Sigma(\mathbf{r}) \phi(\mathbf{r}) \rangle_g, \quad (101)$$

$$\Sigma_{s,\ell,g \leftarrow h}(\mathbf{r}) = \frac{1}{\phi_h(\mathbf{r})} \langle \Sigma_{s,\ell}(\mathbf{r}) \phi(\mathbf{r}) \rangle_{g \leftarrow h}, \quad (102)$$

and

$$v\Sigma_{f,j,g}(\mathbf{r}) = \frac{1}{\phi_g(\mathbf{r})} \langle v\Sigma_{f,j}(\mathbf{r}) \phi(\mathbf{r}) \rangle_g. \quad (103)$$

The multigroup transport correction obtained by energy condensation of (91) leads to

$$\Delta\Sigma_{\text{tr},g}(\mathbf{r}) = \begin{cases} \sum_{h=1}^G \Sigma_{s,1,h\leftarrow g}(\mathbf{r}) & \text{if MRA,} \\ \sum_{h=1}^G W_{gh} \Sigma_{s,1,g\leftarrow h}(\mathbf{r}) & \text{if OEWA.} \end{cases} \quad (104)$$

The multigroup transport-corrected cross-sections are obtained by energy condensation of (90) and (93). The multigroup transport-corrected macroscopic cross-section is written as

$$\bar{\Sigma}_g(\mathbf{r}) = \Sigma_g(\mathbf{r}) - \Delta\Sigma_{\text{tr},g}(\mathbf{r}) \quad (105)$$

and the multigroup P_0 transport-corrected component of the differential-scattering cross-section is written as

$$\bar{\Sigma}_{s,0,g\leftarrow h}(\mathbf{r}) = \Sigma_{s,0,g\leftarrow h}(\mathbf{r}) - \delta_{gh} \Delta\Sigma_{\text{tr},g}(\mathbf{r}), \quad (106)$$

where δ_{gh} is the Kronecker delta function and where

$$W_{gh} = \frac{\int_{E_g}^{E_{g-1}} \frac{dE}{E}}{\int_{E_h}^{E_{h-1}} \frac{dE}{E}} = \frac{u_g - u_{g-1}}{u_h - u_{h-1}}. \quad (107)$$

The transport equation for neutrons can be written in multigroup form, leading to a set of G -coupled integro-differential equations. We will now present the steady-state transport equations.

The multigroup and differential form of the steady-state transport equation in group g is written as

$$\boldsymbol{\Omega} \cdot \nabla \phi_g(\mathbf{r}, \boldsymbol{\Omega}) + \Sigma_g(\mathbf{r}) \phi_g(\mathbf{r}, \boldsymbol{\Omega}) = Q_g(\mathbf{r}, \boldsymbol{\Omega}), \quad (108)$$

where $1 \leq g \leq G$. The multigroup source density is

$$Q_g(\mathbf{r}, \boldsymbol{\Omega}) = \sum_{h=1}^G \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \Sigma_{s,\ell,g\leftarrow h}(\mathbf{r}) \sum_{m=-\ell}^{\ell} R_{\ell}^m(\boldsymbol{\Omega}) \phi_{\ell,h}^m(\mathbf{r}) + \frac{1}{4\pi K_{\text{eff}}} \sum_{j=1}^{J^{\text{fiss}}} \chi_{j,g} \sum_{h=1}^G \nu \Sigma_{f,j,h}(\mathbf{r}) \phi_h(\mathbf{r}) \quad (109)$$

and the average fission spectrum in group g is

$$\chi_{j,g} \equiv \langle \chi_j \rangle_g = \int_{u_{g-1}}^{u_g} du \chi_j(u). \quad (110)$$

It is always possible to perform a transport correction on the transport equation, whatever its form. This operation will only be illustrated in the case of (108). The substitution of (105) and (106) into (108) leads to a differential-transport equation with a first-order transport correction as

$$\boldsymbol{\Omega} \cdot \nabla \phi_g(\mathbf{r}, \boldsymbol{\Omega}) + \bar{\Sigma}_g(\mathbf{r}) \phi_g(\mathbf{r}, \boldsymbol{\Omega}) = Q_g(\mathbf{r}, \boldsymbol{\Omega}) - \frac{1}{4\pi} \Delta\Sigma_{\text{tr},g}(\mathbf{r}) \phi_g(\mathbf{r}). \quad (111)$$

The characteristic form of (108), without transport correction, is

$$\frac{d}{ds} \phi_g(\mathbf{r} + s \boldsymbol{\Omega}, \boldsymbol{\Omega}) + \Sigma_g(\mathbf{r} + s \boldsymbol{\Omega}) \phi_g(\mathbf{r} + s \boldsymbol{\Omega}, \boldsymbol{\Omega}) = Q_g(\mathbf{r} + s \boldsymbol{\Omega}, \boldsymbol{\Omega}) \quad (112)$$

and the integral infinite-domain form is

$$\phi_g(\mathbf{r}, \boldsymbol{\Omega}) = \int_0^\infty ds e^{-\tau_g(s)} Q_g(\mathbf{r} - s \boldsymbol{\Omega}, \boldsymbol{\Omega}) \quad (113)$$

or, in the case of a finite domain,

$$\phi_g(\mathbf{r}, \boldsymbol{\Omega}) = e^{-\tau_g(b)} \phi_g(\mathbf{r} - b \boldsymbol{\Omega}, \boldsymbol{\Omega}) + \int_0^b ds e^{-\tau_g(s)} Q_g(\mathbf{r} - s \boldsymbol{\Omega}, \boldsymbol{\Omega}), \quad (114)$$

where the optical path in group g is

$$\tau_g(s) = \int_0^s ds' \Sigma_g(\mathbf{r} - s' \boldsymbol{\Omega}). \quad (115)$$

We have obtained an eigenproblem taking the form of a set of coupled differential equations. This problem is not self-adjoint, due to slowing-down effects. The corresponding adjoint equation is written in terms of the multigroup *adjoint flux* $\phi_g^*(\mathbf{r}, \boldsymbol{\Omega}) \equiv \langle \phi^*(\mathbf{r}, \boldsymbol{\Omega}) \rangle_g$ and $\phi_g^*(\mathbf{r}) \equiv \langle \phi^*(\mathbf{r}) \rangle_g$. At this point, an important distinction must be made. The adjoint flux is a *function* of energy, *not* a distribution. It is therefore defined as

$$\phi_g^*(\mathbf{r}, \boldsymbol{\Omega}) \equiv \langle \phi^*(\mathbf{r}, \boldsymbol{\Omega}) \rangle_g = \frac{1}{u_g - u_{g-1}} \int_{u_{g-1}}^{u_g} du \phi^*(\mathbf{r}, u, \boldsymbol{\Omega}), \quad (116)$$

and

$$\phi_g^*(\mathbf{r}) \equiv \langle \phi^*(\mathbf{r}) \rangle_g = \frac{1}{u_g - u_{g-1}} \int_{u_{g-1}}^{u_g} du \phi^*(\mathbf{r}, u). \quad (117)$$

The adjoint, multigroup, and differential form of the steady-state transport equation in group g is written as

$$-\boldsymbol{\Omega} \cdot \nabla \phi_g^*(\mathbf{r}, \boldsymbol{\Omega}) + \Sigma_g(\mathbf{r}) \phi_g^*(\mathbf{r}, \boldsymbol{\Omega}) = Q_g^*(\mathbf{r}, \boldsymbol{\Omega}), \quad (118)$$

where $1 \leq g \leq G$. The adjoint multigroup source density is

$$\begin{aligned} Q_g^*(\mathbf{r}, \boldsymbol{\Omega}) &= \sum_{h=1}^G \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \Sigma_{s,\ell,h \leftarrow g}(\mathbf{r}) \sum_{m=-\ell}^{\ell} R_{\ell}^m(\boldsymbol{\Omega}) \phi_{\ell,h}^{*m}(\mathbf{r}) \\ &+ \frac{1}{4\pi K_{\text{eff}}} \sum_{j=1}^{j_{\text{fiss}}} \nu \Sigma_{f,j,g}(\mathbf{r}) \sum_{h=1}^G \chi_{j,h} \phi_h^*(\mathbf{r}). \end{aligned} \quad (119)$$

Different approaches can be used to solve the transport equation for neutral particles. The most accurate, and most expensive, technique is the *Monte-Carlo method*. Many millions of particle histories are simulated based on a sequence of random numbers. The simulation of each particle takes into account its interactions with an accurate representation of the geometric domain, using a continuous-energy or multigroup representation of the cross-sections.

The second class of approaches comprises *deterministic-solution* techniques. These approaches do not use any random-number generator. They are based on the application of numerical analysis techniques to the transport equation, either in differential (see (44)), characteristic (see (49)), or integral (see (56)) form. The particle flux is used as a dependent variable and the transport equation is solved with its boundary conditions. A multigroup representation of the cross-sections is generally imposed. The deterministic approaches are based on many approximations related to their energetic and spatial discretization and to the limitation of the angular representation. They are used in legacy lattice and full-core codes such as Dragon and Trivac (Marleau et al. 1992; Hébert 1987).

The Monte-Carlo method is used to study difficult or nonstandard situations and to validate the deterministic results, principally in the lattice-calculation step. The design- and operation-related calculations are generally deterministic. The remaining sections of this chapter are devoted to a description of standard deterministic solution approaches.

2 The First-Order Streaming Operator

We now study the behavior of the first-order streaming operator $\Omega \cdot \nabla \phi(\mathbf{r}, \Omega)$ in different geometries. The energy is not represented as an independent variable, in order to simplify the notation. The streaming operator actually represents the rate of change of the angular flux along the streaming path of the particle, in the direction of its motion Ω . Two coordinate systems can be used to express this term. The position \mathbf{r} of the particle is defined in a Cartesian, cylindrical or spherical coordinate system consistent with the type of geometry being analyzed. The direction of the particle is a solid-angle Ω defined in an *angular-direction coordinate system* that is moving with the particle. Ω is, therefore, defined in terms of its direction cosines in this moving coordinate system using

$$\Omega = \mu \mathbf{e}_\mu + \eta \mathbf{e}_\eta + \xi \mathbf{e}_\xi \quad \text{with} \quad \mu^2 + \eta^2 + \xi^2 = 1. \quad (120)$$

2.1 Cartesian Coordinate System

The 3D Cartesian coordinate system is shown in  Fig. 4. The particle is located at position (x, y, z) , corresponding to the origin of the angular-direction coordinate system. The three axes of the angular-direction coordinate system, denoted as $\mathbf{e}_x = \mathbf{i}$, $\mathbf{e}_y = \mathbf{j}$, and $\mathbf{e}_z = \mathbf{k}$, are parallel to the X , Y , and Z axes of the Cartesian system.

The direction Ω of the particle is uniquely defined by the direction cosine μ of the polar angle Ψ and by the azimuthal angle ϕ . The first-order streaming operator is, therefore, a distribution of x , y , z , μ , and ϕ . Consequently, it can be written as

$$\Omega \cdot \nabla = \frac{d}{ds} = \frac{dx}{ds} \frac{\partial}{\partial x} + \frac{dy}{ds} \frac{\partial}{\partial y} + \frac{dz}{ds} \frac{\partial}{\partial z} + \frac{d\mu}{ds} \frac{\partial}{\partial \mu} + \frac{d\phi}{ds} \frac{\partial}{\partial \phi}, \quad (121)$$

where ds is a differential element of the particle path in direction Ω . Here, we have

$$\frac{dx}{ds} = \mu, \quad \frac{dy}{ds} = \eta, \quad \frac{dz}{ds} = \xi, \quad \text{and} \quad \frac{d\mu}{ds} = \frac{d\phi}{ds} = 0 \quad (122)$$

Figure 4
Cartesian coordinate system

so that

$$\mathbf{\Omega} \cdot \nabla = \mu \frac{\partial}{\partial x} + \eta \frac{\partial}{\partial y} + \xi \frac{\partial}{\partial z}. \quad (123)$$

In the particular case of 1D x -oriented slab geometry, the flux and source density are independent of y , z , and of the azimuthal angle ϕ . The source density components with $m \neq 0$ vanish, so that (45) is written as

$$Q(\mathbf{r}, \mathbf{\Omega}) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} Q_{\ell}(\mathbf{r}) R_{\ell,0}(\mathbf{\Omega}) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} Q_{\ell}(\mathbf{r}) P_{\ell}(\mu), \quad (124)$$

where $P_{\ell}(\mu)$ is the ℓ -order Legendre polynomial. The source density is reduced by integration over the azimuthal angle, using $Q(\mathbf{r}, \mathbf{\Omega}) d^3r d^2\Omega = Q(x, \mu) dx d\mu$, $d^3r = dx dy dz$, and $d^2\Omega = d\mu d\phi$. We obtain

$$Q(x, \mu) = \sum_{\ell=0}^L \frac{2\ell+1}{2} Q_{\ell}(x) P_{\ell}(\mu) \quad (125)$$

so that using the streaming operator (123), the first-order form of the linear Boltzmann equation (44) in slab geometry is written as

$$\left[\mu \frac{\partial}{\partial x} + \Sigma(x) \right] \phi(x, \mu) = \sum_{\ell=0}^L \frac{2\ell+1}{2} Q_{\ell}(x) P_{\ell}(\mu). \quad (126)$$

Another useful geometry is the 2D Cartesian geometry defined on the (x, y) plane. It is convenient to represent the angular variation of the flux using the direction cosine ξ and the

azimuthal angle ω , as represented in  Fig. 4. In this case, the flux and the source density are independent of z and are symmetric with respect to the direction cosine ξ , so that

$$\phi(x, y, \xi, \omega) = \phi(x, y, -\xi, \omega) \quad \text{and} \quad Q(x, y, \xi, \omega) = Q(x, y, -\xi, \omega). \quad (127)$$

In this case, the source density components with odd values of $\ell + m$ vanish, so that (45) is written as

$$Q(x, y, \Omega) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{\substack{m=-\ell \\ \ell+m \text{ even}}}^{\ell} Q_{\ell}^m(x, y) R_{\ell}^m(\Omega) \quad (128)$$

and the first-order form of the linear Boltzmann equation (44) in Cartesian 2D geometry is written as

$$\begin{aligned} & \left[\sqrt{1-\xi^2} \cos \omega \frac{\partial}{\partial x} + \sqrt{1-\xi^2} \sin \omega \frac{\partial}{\partial y} + \Sigma(x, y) \right] \phi(x, y, \xi, \omega) \\ & = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{\substack{m=-\ell \\ \ell+m \text{ even}}}^{\ell} Q_{\ell}^m(x, y) R_{\ell}^m(\xi, \omega), \end{aligned} \quad (129)$$

where

$$R_{\ell}^m(\xi, \omega) = \sqrt{(2-\delta_{m,0}) \frac{(\ell-|m|)!}{(\ell+|m|)!}} P_{\ell}^{|m|}(\xi) \mathcal{T}_m(\omega). \quad (130)$$

2.2 Cylindrical Coordinate System

The 3D cylindrical coordinate system is shown in  Fig. 5. The particle is located at position (ρ, θ, z) , corresponding to the origin of the angular-direction coordinate system. The three axes of the angular-direction coordinate system, denoted as \mathbf{e}_{ρ} , \mathbf{e}_{θ} , and \mathbf{e}_z , are defined in such a way that \mathbf{e}_{ρ} is colinear with the projection of \mathbf{r} on the XY plane and that \mathbf{e}_z is parallel to the Z axis.

The direction Ω of the particle is uniquely defined by the direction cosine ξ of the polar angle and by the azimuthal angle ω . The first-order streaming operator is, therefore, a distribution of ρ , θ , z , ξ , and ω . Consequently, it can be written as

$$\Omega \cdot \nabla = \frac{d}{ds} = \frac{d\rho}{ds} \frac{\partial}{\partial \rho} + \frac{d\theta}{ds} \frac{\partial}{\partial \theta} + \frac{dz}{ds} \frac{\partial}{\partial z} + \frac{d\xi}{ds} \frac{\partial}{\partial \xi} + \frac{d\omega}{ds} \frac{\partial}{\partial \omega}, \quad (131)$$

where

$$\frac{d\rho}{ds} = \mu, \quad \frac{d\theta}{ds} = \frac{\eta}{\rho}, \quad \frac{dz}{ds} = \xi \quad \text{and} \quad \frac{d\mu}{ds} = 0. \quad (132)$$

The term $d\omega/ds$ is not zero because the particle direction changes as the particle moves. This phenomenon, called *angular redistribution*, is specific to curvilinear geometries. The angular redistribution term is computed with the help of  Fig. 6, representing the projection of the particle path on the $\mathbf{e}_{\rho}-\mathbf{e}_{\theta}$ plane.

Figure 5
Cylindrical coordinate system

Figure 6
Angular redistribution of particles in cylindrical geometry

We see that

$$\frac{d\omega}{ds} = -\frac{1}{\rho} \sqrt{1-\xi^2} \sin \omega = -\frac{\eta}{\rho}, \tag{133}$$

where the negative sign indicates that the azimuthal angle ω decreases as the particle goes forward. The first-order streaming operator in cylindrical geometry is obtained after substituting (132) and (133) into (131) as

$$\mathbf{\Omega} \cdot \nabla = \mu \frac{\partial}{\partial \rho} + \frac{\eta}{\rho} \frac{\partial}{\partial \theta} + \xi \frac{\partial}{\partial z} - \frac{\eta}{\rho} \frac{\partial}{\partial \omega}. \tag{134}$$

When this operator is applied on the angular flux, the terms can be rearranged in a form that facilitates the representation of particle conservation as

$$\Omega \cdot \nabla \phi = \frac{\mu}{\rho} \frac{\partial}{\partial \rho} (\rho \phi) + \frac{\eta}{\rho} \frac{\partial \phi}{\partial \theta} + \xi \frac{\partial \phi}{\partial z} - \frac{1}{\rho} \frac{\partial}{\partial \omega} (\eta \phi). \quad (135)$$

The angular flux and source are distributions of the solid angle only through direction cosine ξ and azimuthal angle ω . The angular flux and source vary parametrically with μ and η through relations

$$\mu = \sqrt{1 - \xi^2} \cos \omega \quad \text{and} \quad \eta = \sqrt{1 - \xi^2} \sin \omega. \quad (136)$$

Equations (136) can also be used to show that $\partial \eta / \partial \omega = \mu$ and to transform (134) into (135).

In the particular case of a 1D cylindrical geometry, the flux and source density are independent of θ , z and are symmetric with respect to both the direction cosine ξ and azimuthal angle ω , so that

$$\begin{aligned} \phi(\rho, \xi, \omega) &= \phi(\rho, \xi, -\omega), & Q(\rho, \xi, \omega) &= Q(\rho, \xi, -\omega), \\ \phi(\rho, \xi, \omega) &= \phi(\rho, -\xi, \omega), & \text{and} & \quad Q(\rho, \xi, \omega) = Q(\rho, -\xi, \omega). \end{aligned} \quad (137)$$

Under these conditions, the source density components with $m < 0$ and with odd values of $m + \ell$ vanish, so that (45) is written as

$$Q(\rho, \Omega) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{\substack{m=0 \\ \ell+m \text{ even}}}^{\ell} Q_{\ell}^m(\rho) R_{\ell}^m(\Omega) \quad (138)$$

and the first-order form of the linear Boltzmann equation (44) in cylindrical 1D geometry is written as

$$\begin{aligned} &\mu \frac{\partial}{\partial \rho} \phi(\rho, \xi, \omega) - \frac{\eta}{\rho} \frac{\partial}{\partial \omega} \phi(\rho, \xi, \omega) + \Sigma(\rho) \phi(\rho, \xi, \omega) \\ &= \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{\substack{m=0 \\ \ell+m \text{ even}}}^{\ell} Q_{\ell}^m(\rho) R_{\ell}^m(\xi, \omega), \end{aligned} \quad (139)$$

where

$$R_{\ell}^m(\xi, \omega) = \sqrt{(2 - \delta_{m,0})} \frac{(\ell - m)!}{(\ell + m)!} P_{\ell}^m(\xi) \cos m\omega. \quad (140)$$

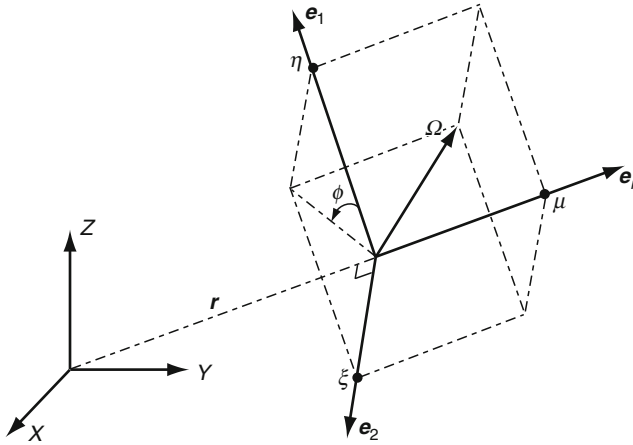

The conservative form of (139) is written as

$$\begin{aligned} &\frac{\mu}{\rho} \frac{\partial}{\partial \rho} [\rho \phi(\rho, \xi, \omega)] - \frac{1}{\rho} \frac{\partial}{\partial \omega} [\eta \phi(\rho, \xi, \omega)] + \Sigma(\rho) \phi(\rho, \xi, \omega) \\ &= \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{\substack{m=0 \\ \ell+m \text{ even}}}^{\ell} Q_{\ell}^m(\rho) R_{\ell}^m(\xi, \omega), \end{aligned} \quad (141)$$

where it can be shown that

$$\int_{4\pi} d^2 \Omega \frac{\partial}{\partial \omega} [\eta \phi(\rho, \xi, \omega)] = 0. \quad (142)$$

2.3 Spherical Coordinate System

The 3D spherical coordinate system is shown in  Fig. 7. The particle is located at the origin of the angular-direction coordinate system. The three axes of the angular-direction coordinate system, denoted as \mathbf{e}_r , \mathbf{e}_1 , and \mathbf{e}_2 , are defined in such a way that \mathbf{e}_r is colinear with the position vector of the particle.

The direction Ω of the particle is uniquely defined by the direction cosine μ of the polar angle and by the azimuthal angle ϕ . For 1D spheres, the first-order streaming operator is only a distribution of r and μ so that it can be written as

$$\Omega \cdot \nabla = \frac{d}{ds} = \frac{dr}{ds} \frac{\partial}{\partial r} + \frac{d\mu}{ds} \frac{\partial}{\partial \mu}, \quad (143)$$

where $dr/ds = \mu$ and where the angular redistribution term $d\mu/ds$ is evaluated using an expression similar to (133). Writing $\mu = \cos \theta$, we can show that $r d\theta = -ds \sin \theta$ and

$$\frac{d\mu}{ds} = \frac{\sin^2 \theta}{r} = \frac{1 - \mu^2}{r} \quad (144)$$

so that

$$\Omega \cdot \nabla = \mu \frac{\partial}{\partial r} + \frac{1 - \mu^2}{r} \frac{\partial}{\partial \mu}. \quad (145)$$

When this operator is applied on the angular flux, the terms can be rearranged in a form that facilitates the representation of particle conservation as

$$\Omega \cdot \nabla \phi = \frac{\mu}{r^2} \frac{\partial}{\partial r} (r^2 \phi) + \frac{1}{r} \frac{\partial}{\partial \mu} [(1 - \mu^2) \phi]. \quad (146)$$

 Figure 7
Spherical coordinate system

In the particular case of a 1D spherical geometry, the flux and source density are only dependent upon r and μ , so that the source density components with $m \neq 0$ vanish. In this case, (45) is written as

$$Q(r, \mu) = \sum_{\ell=0}^L \frac{2\ell+1}{2} Q_{\ell}(r) P_{\ell}(\mu) \quad (147)$$

so that using the streaming operator (145), the first-order form of the linear Boltzmann equation (44) in 1D spherical geometry is written as

$$\mu \frac{\partial}{\partial r} \phi(r, \mu) + \frac{1-\mu^2}{r} \frac{\partial}{\partial \mu} \phi(r, \mu) + \Sigma(r) \phi(r, \mu) = \sum_{\ell=0}^L \frac{2\ell+1}{2} Q_{\ell}(r) P_{\ell}(\mu). \quad (148)$$

The conservative form of this equation is

$$\frac{\mu}{r^2} \frac{\partial}{\partial r} [r^2 \phi(r, \mu)] + \frac{1}{r} \frac{\partial}{\partial \mu} [(1-\mu^2) \phi(r, \mu)] + \Sigma(r) \phi(r, \mu) = \sum_{\ell=0}^L \frac{2\ell+1}{2} Q_{\ell}(r) P_{\ell}(\mu). \quad (149)$$

3 The Spherical Harmonics Method

The spherical harmonics, or P_n method, is a discretization of the differential form of the transport equation. The angular flux is represented as a limited development in real spherical harmonics, as defined in (24). This approach is by far the oldest way to solve transport equations and was used by astrophysicists at the beginning of the twentieth century (Eddington 1926). More recently, this approach was used in neutron-transport theory and has been called the P_n method (Gelbard 1968; Lewis and Miller 1984). A closely-related approximation is based on the solution of the *simplified P_n equation*, leading to an efficient solution technique that can be used for full-core calculations (Gelbard 1960).

We have chosen a *weighted residual* derivation of the relations between values of the particle flux defined at specific points of the spatial domain. A presentation of modern spherical harmonics approximations, based on variational principles and consistent with this text, can be found in Hébert (2006).

It is useful to recall the one-speed steady-state transport (108) as

$$\boldsymbol{\Omega} \cdot \nabla \phi(\mathbf{r}, \boldsymbol{\Omega}) + \Sigma(\mathbf{r}) \phi(\mathbf{r}, \boldsymbol{\Omega}) = Q(\mathbf{r}, \boldsymbol{\Omega}), \quad (150)$$

where the group index g is omitted to simplify the notation.

The spherical harmonics method is based on the expansion of $\phi(\mathbf{r}, \boldsymbol{\Omega})$ and $Q(\mathbf{r}, \boldsymbol{\Omega})$ in spherical harmonics. The expansions are truncated after a few terms, leading to the so-called P_n method. We write

$$\phi(\mathbf{r}, \boldsymbol{\Omega}) = \sum_{\ell=0}^n \frac{2\ell+1}{4\pi} \sum_{m=-\ell}^{\ell} \phi_{\ell}^m(\mathbf{r}) R_{\ell}^m(\boldsymbol{\Omega}) \quad (151)$$

and

$$Q(\mathbf{r}, \boldsymbol{\Omega}) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{m=-\ell}^{\ell} Q_{\ell}^m(\mathbf{r}) R_{\ell}^m(\boldsymbol{\Omega}), \quad (152)$$

where n is odd and $L \leq n$. The within-group scattering component can be made explicit in (152), leading to

$$Q(\mathbf{r}, \boldsymbol{\Omega}) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{m=-\ell}^{\ell} [\Sigma_{w,\ell}(\mathbf{r}) \phi_{\ell}^m(\mathbf{r}) + Q_{\ell}^{\circ m}(\mathbf{r})] R_{\ell}^m(\boldsymbol{\Omega}), \quad (153)$$

where $\Sigma_{w,\ell}(\mathbf{r})$ is the macroscopic within-group scattering cross section and $Q_{\ell}^{\circ m}(\mathbf{r})$ is the out-of-group source density.

It is possible to use symmetry properties of specific geometries to reduce the number of components in (151)–(153). This will be the subject of the following sub-sections.

3.1 The P_n Method in 1D Slab Geometry

3.1.1 Discretization in Angle

The P_n method will first be studied for the simple case of a 1D x -oriented slab geometry. In this case, the flux and source density are independent of y , z , and of the azimuthal angle. The flux and source density components with $m \neq 0$ vanishes, so that the angular variation of the flux is only a function of the direction cosine μ . The flux components can be developed using the first $n+1$ Legendre polynomials, n being an odd number. Equation (150) simplifies to (126), so that

$$\left[\mu \frac{\partial}{\partial x} + \Sigma(x) \right] \phi(x, \mu) = Q(x, \mu), \quad (154)$$

where (151) and (152) are now written

$$\phi(x, \mu) = \sum_{\ell=0}^n \frac{2\ell+1}{2} \phi_{\ell}(x) P_{\ell}(\mu) \quad \text{and} \quad Q(x, \mu) = \sum_{\ell=0}^L \frac{2\ell+1}{2} Q_{\ell}(x) P_{\ell}(\mu), \quad (155)$$

where $L \leq n$, so that the components of the flux are written as

$$\phi_{\ell}(x) = \int_{-1}^1 d\mu P_{\ell}(\mu) \phi(x, \mu) \quad (156)$$

with the scalar flux and current given by $\phi_0(x)$ and $\phi_1(x)$, respectively.

We next substitute (155) into (154), multiply by $P_{\ell}(\mu)$, integrate from -1 to $+1$, and use the orthogonality and recurrence relations for the Legendre polynomials. Recurrence relations were previously introduced as (21) and (22). The result is

$$\frac{\ell}{2\ell+1} \frac{d}{dx} \phi_{\ell-1}(x) + \frac{\ell+1}{2\ell+1} \frac{d}{dx} \phi_{\ell+1}(x) + \Sigma(x) \phi_{\ell}(x) = Q_{\ell}(x). \quad (157)$$

3.1.2 Boundary Conditions

A boundary condition with a specular reflection on surface x_- is imposed as a symmetry in direction cosine μ as

$$\phi(x_-, \mu) = \phi(x_-, -\mu) \quad (158)$$

so that the odd moments of the flux are set to zero at point x_- .

There is no straightforward way to represent a vacuum boundary condition. If the domain is bounded on the left by vacuum, then

$$\phi(x_-, \mu) = 0 \quad \text{if } \mu > 0. \quad (159)$$

No sum of Legendre polynomials can fulfill (159) exactly. We are limited to use an approximation in which this condition is projected on the polynomial basis, as proposed by Marshak. Another well-known approximation was proposed by Mark, but will not be considered until we introduce the *discrete ordinate*, or S_n , method in [Sect. 5](#). A Marshak boundary condition on the left boundary x_- is written as

$$\int_0^1 d\mu \phi(x_-, \mu) P_\ell(\mu) = \sum_{m=0}^n \frac{2m+1}{2} \phi_m(x_-) \int_0^1 d\mu P_\ell(\mu) P_m(\mu) = 0, \quad (160)$$

where ℓ is odd and $1 \leq \ell \leq n$.

[Equation \(160\)](#) can be generalized by introducing an albedo β^- representing the fraction of outgoing particles undergoing specular reflection. The revised condition is

$$\begin{aligned} & \sum_{m=0}^n (2m+1) \phi_m(x_-) \int_0^1 d\mu P_\ell(\mu) P_m(\mu) \\ &= -\beta^- \sum_{m=0}^n (2m+1) \phi_m(x_-) \int_{-1}^0 d\mu P_\ell(\mu) P_m(\mu), \end{aligned} \quad (161)$$

where ℓ is odd and $1 \leq \ell \leq n$. This equation can be rewritten as

$$(1 + \beta^-) \phi_\ell(x_-) + (1 - \beta^-) \sum_{\substack{m=0 \\ m \text{ even}}}^{n-1} \mathcal{M}_{\ell,m} \phi_m(x_-) = 0, \quad (162)$$

where ℓ is odd, $1 \leq \ell \leq n$, and where the Marshak coefficients $\mathcal{M}_{\ell,m}$ are given in [Table 1](#). They are defined as

$$\mathcal{M}_{\ell,m} = (2m+1) \int_0^1 d\mu P_\ell(\mu) P_m(\mu). \quad (163)$$

■ **Table 1**

Marshak coefficients in slab geometry

ℓ	$m = 0$	$m = 2$	$m = 4$	$m = 6$	$m = 8$
1	0.5	0.625	-0.1875	0.101562	-0.066406
3	-0.125	0.625	0.632812	-0.203125	0.116211
5	0.0625	-0.195312	0.632812	0.634766	-0.207520
7	-0.039063	0.109375	-0.205078	0.634765	0.635528
9	0.027344	-0.073242	0.118652	-0.208283	0.635528

The Marshak coefficients in slab geometry can be obtained with the following Matlab script:

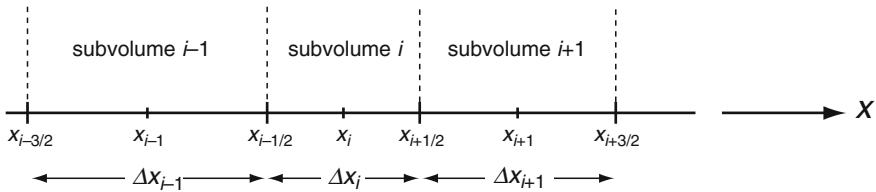

```
function f=pnmars (l, m)
% return the Marshak boundary coefficients in slab geometry. These
% coefficients are specific to the left boundary.
% function f=pnmars (l, m)
% (c) 2008 Alain Hebert, Ecole Polytechnique de Montreal
if mod (l, 2) == 0
    error('odd first index expected')
end
zgksi=[ 0.00529953837 0.0277124941 0.0671843886 0.122297794 ...
0.191061884 0.270991623 0.359198213 0.452493757 0.547506273 ...
0.640801787 0.729008377 0.808938146 0.877702236 0.932815611 ...
0.972287536 0.994700432 ];
wgksi=[ 0.01357623 0.0311267618 0.047579255 0.0623144843 ...
0.0747979954 0.0845782608 0.0913017094 0.0947253034 0.0947253034 ...
0.0913017094 0.0845782608 0.0747979954 0.0623144843 0.047579255 ...
0.0311267618 0.01357623 ];
f=(2*m+1)*sum(wgksi(:).*plgndr(l,0,zgksi(:)).*plgndr(m,0,zgksi(:)));
```

Similarly, a Marshak condition on the right boundary at x_+ would be written as

$$(1 + \beta^+) \phi_\ell(x_+) - (1 - \beta^+) \sum_{\substack{m=0 \\ m \text{ even}}}^{n-1} \mathcal{M}_{\ell,m} \phi_m(x_+) = 0, \quad (164)$$

where ℓ is odd and $1 \leq \ell \leq n$.

3.1.3 Difference Relations

A *first-order numerical solution* of the spherical harmonics equations requires the application of finite-difference discretization to every order ℓ of (157), resulting in a symmetric linear system of $n + 1$ coupled relations. The domain is divided into subvolumes, or *elements*, with constant cross-sections, as depicted in  Fig. 8.

The odd-parity variables are discretized over mesh-centered coordinates (x_{i-1}, x_i, x_{i+1}) and the even-parity variables are discretized over interface coordinates $(x_{i-1/2}, x_{i+1/2}, x_{i+3/2})$.

 **Figure 8**
Spatial discretization for slab geometry

We define the corresponding volumes as

$$\Delta x_i = x_{i+1/2} - x_{i-1/2}. \quad (165)$$

Let us now consider the spherical harmonics-discretized relations for even indices ℓ . First consider the case where surface $i + 1/2$ is not a boundary. The finite-difference relations can be applied in many different ways, leading to linear-order accuracy. The specific relations selected here have been selected to enforce consistency with the *diamond differencing scheme* of the discrete ordinates method presented in [5.2](#).

We first consider even-parity indices ℓ . The approximation consists in writing (157) at x_i and x_{i+1} , using the average of even-parity variables on these points. We write

$$\begin{aligned} \ell \frac{d}{dx} \phi_{\ell-1,i}^- + (\ell + 1) \frac{d}{dx} \phi_{\ell+1,i}^- + \frac{2\ell + 1}{2} \Sigma_i (\phi_{\ell,i-1/2}^+ + \phi_{\ell,i+1/2}^+) \\ = \frac{2\ell + 1}{2} (Q_{\ell,i-1/2}^+ + Q_{\ell,i+1/2}^+) \end{aligned} \quad (166)$$

and

$$\begin{aligned} \ell \frac{d}{dx} \phi_{\ell-1,i+1}^- + (\ell + 1) \frac{d}{dx} \phi_{\ell+1,i+1}^- + \frac{2\ell + 1}{2} \Sigma_{i+1} (\phi_{\ell,i+1/2}^+ + \phi_{\ell,i+3/2}^+) \\ = \frac{2\ell + 1}{2} (Q_{\ell,i+1/2}^+ + Q_{\ell,i+3/2}^+) \end{aligned} \quad (167)$$

together with the finite difference relations

$$\frac{d}{dx} \phi_{\ell\mp 1,i}^- = \frac{\phi_{\ell\mp 1,i+1/2}^- - \phi_{\ell\mp 1,i}^-}{\Delta x_i/2}$$

and

$$\frac{d}{dx} \phi_{\ell\mp 1,i+1}^- = \frac{\phi_{\ell\mp 1,i+1}^- - \phi_{\ell\mp 1,i+1/2}^-}{\Delta x_{i+1/2}}, \quad (168)$$

so that

$$\begin{aligned} \ell (\phi_{\ell-1,i+1}^- - \phi_{\ell-1,i}^-) + (\ell + 1) (\phi_{\ell+1,i+1}^- - \phi_{\ell+1,i}^-) \\ + (2\ell + 1) \frac{\Delta x_i}{4} (\Sigma_i \phi_{\ell,i-1/2}^+ - Q_{\ell,i-1/2}^+) + (2\ell + 1) \frac{\Delta x_i}{4} (\Sigma_i \phi_{\ell,i+1/2}^+ - Q_{\ell,i+1/2}^+) \\ + (2\ell + 1) \frac{\Delta x_{i+1}}{4} (\Sigma_{i+1} \phi_{\ell,i+1/2}^+ - Q_{\ell,i+1/2}^+) \\ + (2\ell + 1) \frac{\Delta x_{i+1}}{4} (\Sigma_{i+1} \phi_{\ell,i+3/2}^+ - Q_{\ell,i+3/2}^+) = 0, \end{aligned} \quad (169)$$

where $1 \leq i \leq I$.

Similarly, the left- and right-boundary relations are obtained using difference relations. The derivative of odd-parity variables at $x_{1/2}$ are written with the help of (162) as

$$\frac{d}{dx} \phi_{\ell\mp 1,1}^- = \frac{\phi_{\ell\mp 1,1}^- - \phi_{\ell\mp 1,1/2}^-}{\Delta x_{1/2}} = \frac{2}{\Delta x_1} \left(\phi_{\ell\mp 1,1}^- + \frac{1 - \beta^-}{1 + \beta^-} \sum_{\substack{m=0 \\ m \text{ even}}}^{n-1} \mathcal{M}_{\ell\mp 1,m} \phi_{m,1/2}^+ \right). \quad (170)$$

The left- and right-boundary relations are finally written as

$$\begin{aligned} \ell \phi_{\ell-1,1}^- + (\ell+1) \phi_{\ell+1,1}^- + (2\ell+1) \frac{\Delta x_1}{4} (\Sigma_1 \phi_{\ell,1/2}^+ - Q_{\ell,1/2}^+) + (2\ell+1) \frac{\Delta x_1}{4} (\Sigma_1 \phi_{\ell,3/2}^+ - Q_{\ell,3/2}^+) \\ + (2\ell+1) \frac{1-\beta^-}{1+\beta^-} \sum_{\substack{m=0 \\ m \text{ even}}}^{n-1} \hat{\mathcal{M}}_{\ell,m} \phi_{m,1/2}^+ = 0 \end{aligned} \quad (171)$$

and

$$\begin{aligned} -\ell \phi_{\ell-1,I}^- - (\ell+1) \phi_{\ell+1,I}^- + (2\ell+1) \frac{\Delta x_I}{4} (\Sigma_I \phi_{\ell,I-1/2}^+ - Q_{\ell,I-1/2}^+) \\ + (2\ell+1) \frac{\Delta x_I}{4} (\Sigma_I \phi_{\ell,I+1/2}^+ - Q_{\ell,I+1/2}^+) \\ + (2\ell+1) \frac{1-\beta^+}{1+\beta^+} \sum_{\substack{m=0 \\ m \text{ even}}}^{n-1} \hat{\mathcal{M}}_{\ell,m} \phi_{m,I+1/2}^+ = 0, \end{aligned} \quad (172)$$

where

$$\hat{\mathcal{M}}_{\ell,m} = (2m+1) \int_0^1 d\mu \mu P_\ell(\mu) P_m(\mu) = \frac{1}{2\ell+1} [\ell \mathcal{M}_{\ell-1,m} + (\ell+1) \mathcal{M}_{\ell+1,m}]. \quad (173)$$

Finally, the spherical harmonics-discretized relations for odd-parity indices ℓ are obtained by integrating (157) between $x_{i-1/2}$ and $x_{i+1/2}$ and by assuming that $\phi_{\ell,i}^-$ is equal to the averaged value over subvolume i . We obtain

$$\begin{aligned} -\ell (\phi_{\ell-1,i+1/2}^+ - \phi_{\ell-1,i-1/2}^+) - (\ell+1) (\phi_{\ell+1,i+1/2}^+ - \phi_{\ell+1,i-1/2}^+) - (2\ell+1) \Delta x_i \Sigma_i \phi_{\ell,i}^- \\ = -(2\ell+1) \Delta x_i Q_{\ell,i}^-, \end{aligned} \quad (174)$$

where $1 \leq i \leq I$.

Equations (169)–(174) are the difference equations corresponding to the discretized transport equation in 1D slab geometry. They are solved iteratively, taking two successive Legendre orders at each iteration. The scattering reduction is done in a straightforward way, by extracting the within-group scattering rates from $Q_{\ell,i\pm 1/2}^+$ and $Q_{\ell,i}^-$.

3.2 The P_n Method in 1D Cylindrical Geometry

3.2.1 Discretization in Angle

Due to specific symmetries, the flux is a function of the radius ρ , of the direction cosine ξ , of the azimuthal angle ω , and can be developed in terms of the even $\ell + m$ positive components of an expansion in spherical harmonics, where $1 \leq \ell \leq n$, n being an odd number. Equation (150) simplifies to (139) which can be rewritten, with the help of (136), as

$$\sqrt{1-\xi^2} \cos \omega \frac{\partial}{\partial \rho} \phi(\rho, \xi, \omega) - \frac{\sqrt{1-\xi^2} \sin \omega}{\rho} \frac{\partial}{\partial \omega} \phi(\rho, \xi, \omega) + \Sigma(\rho) \phi(\rho, \xi, \omega) = Q(\rho, \xi, \omega), \quad (175)$$

where the angular source is expanded at order $L \leq n$. The spherical harmonic expansions are written as

$$\phi(\rho, \xi, \omega) = \sum_{\ell=0}^n \frac{2\ell+1}{4\pi} \sum_{\substack{m=0 \\ \ell+m \text{ even}}}^{\ell} \phi_{\ell}^m(\rho) R_{\ell}^m(\xi, \omega) \quad (176)$$

and

$$Q(\rho, \xi, \omega) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{\substack{m=0 \\ \ell+m \text{ even}}}^{\ell} Q_{\ell}^m(\rho) R_{\ell}^m(\xi, \omega) \quad (177)$$

so that the components of the flux are written as

$$\phi_{\ell}^m(\rho) = \int_{-1}^1 d\xi \int_{-\pi}^{\pi} d\omega R_{\ell}^m(\xi, \omega) \phi(\rho, \xi, \omega) \quad (178)$$

with the scalar flux and current given by $\phi_0^0(\rho)$ and $\phi_1^1(\rho)$, respectively.

We next substitute (176) into (175), multiply by $\rho R_{\ell'}^m(\xi, \omega)$, integrate over 4π , and use the orthogonality relation (30). The result is

$$\begin{aligned} & \mathcal{A}_{\ell}^m \left[\rho \frac{d}{d\rho} - (m-1) \right] \phi_{\ell-1}^{m-1}(\rho) + \mathcal{B}_{\ell}^m \left[\rho \frac{d}{d\rho} - (m-1) \right] \phi_{\ell+1}^{m-1}(\rho) \\ & + \mathcal{C}_{\ell}^m \left[\rho \frac{d}{d\rho} + (m+1) \right] \phi_{\ell-1}^{m+1}(\rho) + \mathcal{D}_{\ell}^m \left[\rho \frac{d}{d\rho} + (m+1) \right] \phi_{\ell+1}^{m+1}(\rho) \\ & + \rho \Sigma(\rho) \phi_{\ell}^m(\rho) = \rho Q_{\ell}^m(\rho), \end{aligned} \quad (179)$$

where we used the following relations:

$$\begin{aligned} & \frac{2\ell'+1}{4\pi} \int_{-1}^1 d\xi \sqrt{1-\xi^2} \int_{-\pi}^{\pi} d\omega \cos \omega R_{\ell}^m(\xi, \omega) R_{\ell'}^m(\xi, \omega) \\ & = \mathcal{A}_{\ell}^m \delta_{\ell', \ell-1} \delta_{m', m-1} + \mathcal{B}_{\ell}^m \delta_{\ell', \ell+1} \delta_{m', m-1} + \mathcal{C}_{\ell}^m \delta_{\ell', \ell-1} \delta_{m', m+1} \\ & + \mathcal{D}_{\ell}^m \delta_{\ell', \ell+1} \delta_{m', m+1}, \end{aligned} \quad (180)$$

$$\begin{aligned} & \frac{2\ell'+1}{4\pi} \int_{-1}^1 d\xi \sqrt{1-\xi^2} \int_{-\pi}^{\pi} d\omega \sin \omega R_{\ell}^m(\xi, \omega) \frac{\partial}{\partial \omega} R_{\ell'}^m(\xi, \omega) \\ & = (m-1) \mathcal{A}_{\ell}^m \delta_{\ell', \ell-1} \delta_{m', m-1} + (m-1) \mathcal{B}_{\ell}^m \delta_{\ell', \ell+1} \delta_{m', m-1} \\ & - (m+1) \mathcal{C}_{\ell}^m \delta_{\ell', \ell-1} \delta_{m', m+1} - (m+1) \mathcal{D}_{\ell}^m \delta_{\ell', \ell+1} \delta_{m', m+1} \end{aligned} \quad (181)$$

and

$$\begin{aligned} & \frac{2\ell'+1}{4\pi} \int_{-1}^1 d\xi \sqrt{1-\xi^2} \int_{-\pi}^{\pi} d\omega \sin \omega \left(\frac{\partial}{\partial \omega} R_{\ell}^m(\xi, \omega) \right) R_{\ell'}^m(\xi, \omega) \\ & = -m \mathcal{A}_{\ell}^m \delta_{\ell', \ell-1} \delta_{m', m-1} - m \mathcal{B}_{\ell}^m \delta_{\ell', \ell+1} \delta_{m', m-1} \\ & + m \mathcal{C}_{\ell}^m \delta_{\ell', \ell-1} \delta_{m', m+1} + m \mathcal{D}_{\ell}^m \delta_{\ell', \ell+1} \delta_{m', m+1} \end{aligned} \quad (182)$$

with the definitions:

$$\begin{aligned}
 \mathcal{A}_\ell^m &= \frac{1}{2(2\ell+1)} \sqrt{(1-\delta_{m,0})(1+\delta_{m,1})(\ell+m)(\ell+m-1)}, \\
 \mathcal{B}_\ell^m &= -\frac{1}{2(2\ell+1)} \sqrt{(1-\delta_{m,0})(1+\delta_{m,1})(\ell-m+1)(\ell-m+2)}, \\
 \mathcal{C}_\ell^m &= -\frac{1}{2(2\ell+1)} \sqrt{(1+\delta_{m,0})(\ell-m)(\ell-m-1)}, \\
 \mathcal{D}_\ell^m &= \frac{1}{2(2\ell+1)} \sqrt{(1+\delta_{m,0})(\ell+m+1)(\ell+m+2)}.
 \end{aligned} \tag{183}$$

These coefficients were obtained using the following identities:

$$\begin{aligned}
 &\int_{-1}^1 d\xi \sqrt{1-\xi^2} P_\ell^m(\xi) P_{\ell'}^{m+1}(\xi) \\
 &= \frac{2}{2\ell+1} \left[\frac{(\ell+m+2)!}{(2\ell+3)(\ell-m)!} \delta_{\ell,\ell'-1} - \frac{(\ell+m)!}{(2\ell-1)(\ell-m-2)!} \delta_{\ell,\ell'+1} \right],
 \end{aligned} \tag{184}$$

$$\begin{aligned}
 &\int_{-1}^1 d\xi \sqrt{1-\xi^2} P_\ell^m(\xi) P_{\ell'}^{m-1}(\xi) \\
 &= \frac{2(\ell+m)!}{(2\ell+1)(\ell-m)!} \left[\frac{1}{2\ell-1} \delta_{\ell,\ell'+1} - \frac{1}{2\ell+3} \delta_{\ell,\ell'-1} \right],
 \end{aligned} \tag{185}$$

$$\int_{-\pi}^{\pi} d\phi \cos \phi \cos m\phi \cos m'\phi = \frac{\pi}{2} [(1+\delta_{m,0})\delta_{m,m'-1} + (1+\delta_{m',0})\delta_{m,m'+1}] \tag{186}$$

and

$$\int_{-\pi}^{\pi} d\phi \sin \phi \cos m\phi \sin m'\phi = \frac{\pi}{2} [(1+\delta_{m,0})\delta_{m,m'-1} - \delta_{m,m'+1}] \quad \text{where } m' > 0. \tag{187}$$

3.2.2 Boundary Conditions

The $\rho = \rho_- \equiv 0$ condition is set by forcing the flux to be an even function of ζ at the origin. Consequently, all components of the flux with an odd value of ℓ are forced to zero.

The external boundary condition of a 1D cylindrical geometry is introduced by choosing an albedo β^+ set to zero for representing a voided boundary, or set to one for representing reflection of particles. The voided boundary condition is similar to the Marshak condition used for 1D slab geometry. The inward flux, written as

$$\phi(\rho_+, \xi, \omega) = 0 \quad \text{if } \pi/2 < \omega < 3\pi/2 \tag{188}$$

is projected onto a space of trial functions. Such a boundary condition is useful in criticality problems for computing the critical radius of tubes. The more general albedo boundary condition is written as

$$(1+\beta^+) \phi_\ell^m(\rho_+) - (1-\beta^+) \sum_{\substack{\ell'=0 \\ \ell' \text{ even}}}^{n-1} \sum_{\substack{m'=0 \\ m' \text{ even}}}^{\ell'} \mathcal{M}_{\ell,\ell'}^{m,m'} \phi_{\ell'}^{m'}(\rho_+) = 0, \tag{189}$$

where ℓ and m are odd integers, $1 \leq \ell \leq n$ and $1 \leq m \leq \ell$. The cylindrical-geometry Marshak coefficients are defined as

$$\mathcal{M}_{\ell, \ell'}^{m, m'} = \frac{2\ell' + 1}{2\pi} \int_{-1}^1 d\xi \int_{-\pi/2}^{\pi/2} d\omega R_{\ell}^m(\xi, \omega) R_{\ell'}^{m'}(\xi, \omega). \quad (190)$$

They can be obtained using the following Matlab script:

```
function f=pncmar (l1,l2,m1,m2)
% return the Marshak boundary coefficients in 1D tube geometry.
% function f=pncmar (l1,l2,m1,m2)
% (c) 2008 Alain Hebert, Ecole Polytechnique de Montreal
if mod(l1,2) == 0
    error('odd legendre order expected.')
elseif mod(m1,2) == 0
    error('odd azimuthal order expected.')
end

Implementing the reflecting-boundary condition is less straightforward. Such a condition is useful in the context of the *Wigner–Seitz approximation* for lattice calculations in reactor physics. An elementary cell of a nuclear reactor can be represented with a reflecting rectangular or hexagonal boundary. The Wigner–Seitz approximation consists of replacing the exact boundary with an *equivalent cylindrical boundary*, as shown in  Fig. 9, taking care to conserve the amount of moderator present in the cell.

However, a specular boundary condition cannot be used with Wigner–Seitz approximation, because a neutron incident on the boundary would be reflected in such a way that its path could not intersect the fuel element without being scattered. The correct condition in this case is the

Figure 9
Wigner-Seitz boundary approximation

white boundary condition in which the particles are reflected back, on the cylindrical boundary, with an isotropic angular distribution in the radial plane. Such a condition can be represented by forcing to zero the components of the incoming odd-parity fluxes with $m = 1$ and by treating the remaining components with a vacuum boundary condition.

3.2.3 Difference Relations

Equation (179) with the Marshak-boundary condition (189) can be discretized in ρ by replacing the differential terms with difference relations, taking care to preserve the symmetry of the resulting matrices. The odd-parity variables are discretized over mesh-centered coordinates $(\rho_{i-1}, \rho_i, \rho_{i+1})$ and the even-parity variables are discretized over interface coordinates $(\rho_{i-1/2}, \rho_{i+1/2}, \rho_{i+3/2})$. We also define

$$\Delta\rho_i = \rho_{i+1/2} - \rho_{i-1/2}, \quad \rho_i = \frac{1}{2}(\rho_{i-1/2} + \rho_{i+1/2}), \quad \text{and} \quad V_i = 2\pi \rho_i \Delta\rho_i. \quad (191)$$

We first consider even-parity indices ℓ and m in the case where surface $i + 1/2$ is not a boundary. The approximation consists in writing (179) at ρ_i and ρ_{i+1} , using the average of even-parity variables on these points. We write

$$\begin{aligned} & \mathcal{A}_\ell^m \left[\frac{d}{d\rho} (\rho \phi_{\ell-1,i}^{-,m-1}) - m \phi_{\ell-1,i}^{-,m-1} \right] + \mathcal{B}_\ell^m \left[\frac{d}{d\rho} (\rho \phi_{\ell+1,i}^{-,m-1}) - m \phi_{\ell+1,i}^{-,m-1} \right] \\ & + \mathcal{C}_\ell^m \left[\frac{d}{d\rho} (\rho \phi_{\ell-1,i}^{-,m+1}) + m \phi_{\ell-1,i}^{-,m+1} \right] + \mathcal{D}_\ell^m \left[\frac{d}{d\rho} (\rho \phi_{\ell+1,i}^{-,m+1}) + m \phi_{\ell+1,i}^{-,m+1} \right] \\ & + \frac{\Sigma_i \rho_i}{2} (\phi_{\ell,i-1/2}^{+,m} + \phi_{\ell,i+1/2}^{+,m}) = \frac{\rho_i}{2} (Q_{\ell,i-1/2}^{+,m} + Q_{\ell,i+1/2}^{+,m}) \end{aligned} \quad (192)$$

and

$$\begin{aligned} & \mathcal{A}_\ell^m \left[\frac{d}{d\rho} (\rho \phi_{\ell-1,i+1}^{-,m-1}) - m \phi_{\ell-1,i+1}^{-,m-1} \right] + \mathcal{B}_\ell^m \left[\frac{d}{d\rho} (\rho \phi_{\ell+1,i+1}^{-,m-1}) - m \phi_{\ell+1,i+1}^{-,m-1} \right] \\ & + \mathcal{C}_\ell^m \left[\frac{d}{d\rho} (\rho \phi_{\ell-1,i+1}^{-,m+1}) + m \phi_{\ell-1,i+1}^{-,m+1} \right] + \mathcal{D}_\ell^m \left[\frac{d}{d\rho} (\rho \phi_{\ell+1,i+1}^{-,m+1}) + m \phi_{\ell+1,i+1}^{-,m+1} \right] \\ & + \frac{\Sigma_{i+1} \rho_{i+1}}{2} (\phi_{\ell,i+1/2}^{+,m} + \phi_{\ell,i+3/2}^{+,m}) = \frac{\rho_{i+1}}{2} (Q_{\ell,i+1/2}^{+,m} + Q_{\ell,i+3/2}^{+,m}) \end{aligned} \quad (193)$$

together with the finite difference relations

$$\frac{d}{d\rho}(\rho \phi_{\ell\mp 1, i}^{-, m\mp 1}) = \frac{\rho_{i+1/2} \phi_{\ell\mp 1, i+1/2}^{-, m\mp 1} - \rho_i \phi_{\ell\mp 1, i}^{-, m\mp 1}}{\Delta\rho_i/2} \quad (194)$$

and

$$\frac{d}{d\rho}(\rho \phi_{\ell\mp 1, i+1}^{-, m\mp 1}) = \frac{\rho_{i+1} \phi_{\ell\mp 1, i+1}^{-, m\mp 1} - \rho_{i+1/2} \phi_{\ell\mp 1, i+1/2}^{-, m\mp 1}}{\Delta\rho_{i+1/2}}, \quad (195)$$

so that

$$\begin{aligned} & 2\pi\mathcal{A}_\ell^m \left[(\rho_{i+1} \phi_{\ell-1, i+1}^{-, m-1} - \rho_i \phi_{\ell-1, i}^{-, m-1}) - \frac{m}{2} (\Delta\rho_i \phi_{\ell-1, i}^{-, m-1} + \Delta\rho_{i+1} \phi_{\ell-1, i+1}^{-, m-1}) \right] \\ & + 2\pi\mathcal{B}_\ell^m \left[(\rho_{i+1} \phi_{\ell+1, i+1}^{-, m-1} - \rho_i \phi_{\ell+1, i}^{-, m-1}) - \frac{m}{2} (\Delta\rho_i \phi_{\ell+1, i}^{-, m-1} + \Delta\rho_{i+1} \phi_{\ell+1, i+1}^{-, m-1}) \right] \\ & + 2\pi\mathcal{C}_\ell^m \left[(\rho_{i+1} \phi_{\ell-1, i+1}^{-, m+1} - \rho_i \phi_{\ell-1, i}^{-, m+1}) + \frac{m}{2} (\Delta\rho_i \phi_{\ell-1, i}^{-, m+1} + \Delta\rho_{i+1} \phi_{\ell-1, i+1}^{-, m+1}) \right] \\ & + 2\pi\mathcal{D}_\ell^m \left[(\rho_{i+1} \phi_{\ell+1, i+1}^{-, m+1} - \rho_i \phi_{\ell+1, i}^{-, m+1}) + \frac{m}{2} (\Delta\rho_i \phi_{\ell+1, i}^{-, m+1} + \Delta\rho_{i+1} \phi_{\ell+1, i+1}^{-, m+1}) \right] \\ & + \frac{V_i}{4} (\Sigma_i \phi_{\ell, i-1/2}^{+, m} - Q_{\ell, i-1/2}^{+, m}) + \frac{V_i}{4} (\Sigma_i \phi_{\ell, i+1/2}^{+, m} - Q_{\ell, i+1/2}^{+, m}) \\ & + \frac{V_{i+1}}{4} (\Sigma_{i+1} \phi_{\ell, i+1/2}^{+, m} - Q_{\ell, i+1/2}^{+, m}) + \frac{V_{i+1}}{4} (\Sigma_{i+1} \phi_{\ell, i+3/2}^{+, m} - Q_{\ell, i+3/2}^{+, m}) = 0, \quad (196) \end{aligned}$$

where ℓ and m are even integers and $1 \leq i < I$.

Let us now consider the case where $\rho_{I+1/2}$ is the outer boundary. The derivative of odd-parity variables at $\rho_{I+1/2}$ is written with the help of (189) as

$$\begin{aligned} \frac{d}{d\rho}(\rho \phi_{\ell\mp 1, I}^{-, m\mp 1}) &= \frac{\rho_{I+1/2} \phi_{\ell\mp 1, I+1/2}^{-, m\mp 1} - \rho_I \phi_{\ell\mp 1, I}^{-, m\mp 1}}{\Delta\rho_I/2} \\ &= \frac{2}{\Delta\rho_I} \left(\rho_+ \frac{1 - \beta^+}{1 + \beta^+} \sum_{\substack{\ell'=0 \\ \ell' \text{ even}}}^{n-1} \sum_{\substack{m'=0 \\ m' \text{ even}}}^{\ell'} \mathcal{M}_{\ell\mp 1, \ell'}^{m\mp 1, m'} \phi_{\ell', I+1/2}^{+, m'} - \rho_I \phi_{\ell\mp 1, I}^{-, m\mp 1} \right) \quad (197) \end{aligned}$$

so that

$$\begin{aligned} & 2\pi\mathcal{A}_\ell^m \left[-\rho_I \phi_{\ell-1, I}^{-, m-1} - \frac{m}{2} \Delta\rho_I \phi_{\ell-1, I}^{-, m-1} \right] + 2\pi\mathcal{B}_\ell^m \left[-\rho_I \phi_{\ell+1, I}^{-, m-1} - \frac{m}{2} \Delta\rho_I \phi_{\ell+1, I}^{-, m-1} \right] \\ & + 2\pi\mathcal{C}_\ell^m \left[-\rho_I \phi_{\ell-1, I}^{-, m+1} + \frac{m}{2} \Delta\rho_I \phi_{\ell-1, I}^{-, m+1} \right] + 2\pi\mathcal{D}_\ell^m \left[-\rho_I \phi_{\ell+1, I}^{-, m+1} + \frac{m}{2} \Delta\rho_I \phi_{\ell+1, I}^{-, m+1} \right] \\ & + \frac{V_I}{4} (\Sigma_I \phi_{\ell, I-1/2}^{+, m} - Q_{\ell, I-1/2}^{+, m}) + \frac{V_I}{4} (\Sigma_I \phi_{\ell, I+1/2}^{+, m} - Q_{\ell, I+1/2}^{+, m}) \\ & + 2\pi\rho_+ \frac{1 - \beta^+}{1 + \beta^+} \sum_{\substack{\ell'=0 \\ \ell' \text{ even}}}^{n-1} \sum_{\substack{m'=0 \\ m' \text{ even}}}^{\ell'} \mathcal{M}_{\ell, \ell'}^{m, m'} \phi_{\ell', I+1/2}^{+, m'} = 0 \quad (198) \end{aligned}$$

if ℓ and m are even, where $\rho_+ \equiv \rho_{I+1/2}$ and

$$\begin{aligned} \mathcal{M}_{\ell,\ell'}^{m,m'} &= \frac{2\ell'+1}{2\pi} \int_{-1}^1 d\xi \sqrt{1-\xi^2} \int_{-\pi/2}^{\pi/2} d\omega \cos \omega R_\ell^m(\xi, \omega) R_{\ell'}^{m'}(\xi, \omega) \\ &= \mathcal{A}_\ell^m \mathcal{M}_{\ell-1,\ell'}^{m-1,m'} + \mathcal{B}_\ell^m \mathcal{M}_{\ell+1,\ell'}^{m-1,m'} + \mathcal{C}_\ell^m \mathcal{M}_{\ell-1,\ell'}^{m+1,m'} + \mathcal{D}_\ell^m \mathcal{M}_{\ell+1,\ell'}^{m+1,m'}. \end{aligned} \quad (199)$$

Finally, the spherical harmonics-discretized relations for odd-parity indices ℓ and m are obtained by integrating (179) between $\rho_{i-1/2}$ and $\rho_{i+1/2}$ and by assuming that $\phi_{\ell,i}^{-,m}$ is equal to the averaged value over subvolume i . We obtain

$$\begin{aligned} &-2\pi \mathcal{A}_\ell^m \left[\rho_i (\phi_{\ell-1,i+1/2}^{+,m-1} - \phi_{\ell-1,i-1/2}^{+,m-1}) - \frac{m-1}{2} \Delta \rho_i (\phi_{\ell-1,i-1/2}^{+,m-1} + \phi_{\ell-1,i+1/2}^{+,m-1}) \right] \\ &-2\pi \mathcal{B}_\ell^m \left[\rho_i (\phi_{\ell+1,i+1/2}^{+,m-1} - \phi_{\ell+1,i-1/2}^{+,m-1}) - \frac{m-1}{2} \Delta \rho_i (\phi_{\ell+1,i-1/2}^{+,m-1} + \phi_{\ell+1,i+1/2}^{+,m-1}) \right] \\ &-2\pi \mathcal{C}_\ell^m \left[\rho_i (\phi_{\ell-1,i+1/2}^{+,m+1} - \phi_{\ell-1,i-1/2}^{+,m+1}) + \frac{m+1}{2} \Delta \rho_i (\phi_{\ell-1,i-1/2}^{+,m+1} + \phi_{\ell-1,i+1/2}^{+,m+1}) \right] \\ &-2\pi \mathcal{D}_\ell^m \left[\rho_i (\phi_{\ell+1,i+1/2}^{+,m+1} - \phi_{\ell+1,i-1/2}^{+,m+1}) + \frac{m+1}{2} \Delta \rho_i (\phi_{\ell+1,i-1/2}^{+,m+1} + \phi_{\ell+1,i+1/2}^{+,m+1}) \right], \\ &-V_i \Sigma_i \phi_{\ell,i}^{-,m} = -V_i Q_{\ell,i}^{-,m}, \end{aligned} \quad (200)$$

where ℓ and m are odd integers and $1 \leq i \leq I$.

3.3 The P_n Method in 1D Spherical Geometry

3.3.1 Discretization in Angle

The P_n method will be studied for the simple case of a 1D spherical geometry. In this case, the angular variation of the flux is only a function of the direction cosine μ and can be developed using the first $n + 1$ Legendre polynomials, n being an odd number. Equation (150) simplifies to (148), so that

$$\mu \frac{\partial}{\partial r} \phi(r, \mu) + \frac{1-\mu^2}{r} \frac{\partial}{\partial \mu} \phi(r, \mu) + \Sigma(r) \phi(r, \mu) = Q(r, \mu), \quad (201)$$

where the angular source is expanded at order $L \leq n$. The spherical harmonic expansions are written as

$$\phi(r, \mu) = \sum_{\ell=0}^n \frac{2\ell+1}{2} \phi_\ell(r) P_\ell(\mu) \quad \text{and} \quad Q(r, \mu) = \sum_{\ell=0}^L \frac{2\ell+1}{2} Q_\ell(r) P_\ell(\mu) \quad (202)$$

so that the components of the flux are written as

$$\phi_\ell(r) = \int_{-1}^1 d\mu P_\ell(\mu) \phi(r, \mu) \quad (203)$$

with the scalar flux and current given by $\phi_0(r)$ and $\phi_1(r)$, respectively.

We next substitute (202) into (201), multiply by $P_{\ell'}(\mu)$, integrate from -1 to $+1$, and use the orthogonality and recurrence relation for Legendre polynomials. The result is

$$\begin{aligned} \frac{\ell}{2\ell+1} \left[r \frac{\partial}{\partial r} - (\ell-1) \right] \phi_{\ell-1}(r) + \frac{\ell+1}{2\ell+1} \left[r \frac{\partial}{\partial r} + (\ell+2) \right] \phi_{\ell+1}(r) \\ + r \Sigma(r) \phi_{\ell}(r) = r Q_{\ell}(r). \end{aligned} \quad (204)$$

3.3.2 Boundary Conditions

The boundary conditions are similar to those in cylindrical 1D geometry. The $r = r_- \equiv 0$ condition is set by forcing the flux to be an even function of μ at the origin. Consequently, all components of the flux with an odd value of ℓ are forced to zero.

Vacuum and general albedo (β^+) boundary conditions at $r = r_+$, on the external surface, are set using the Marshak coefficients already introduced for slab geometry in [3.1](#).

A *white-boundary condition* can be applied at $r = r_+$, in which case the particles are reflected back with an isotropic angular distribution. Such a condition can be represented by forcing to zero the component of the incoming odd-parity fluxes with $\ell = 1$ and by treating the remaining components with a vacuum-boundary condition.

3.3.3 Difference Relations

Equations (204) with the Marshak-boundary condition (164) can be discretized in r by replacing the differential terms with difference relations, taking care to preserve the symmetry of the resulting matrices. The odd-parity variables are discretized over mesh-centered coordinates (r_{i-1} , r_i , r_{i+1}) and the even-parity variables are discretized over interface coordinates ($r_{i-1/2}$, $r_{i+1/2}$, $r_{i+3/2}$).

We first consider even-parity indices ℓ in the case where surface $i + 1/2$ is not a boundary. The finite difference approximation is set as before, leading to

$$\begin{aligned} 4\pi\ell \left(\bar{r}_{i+1}^2 \phi_{\ell-1,i+1}^- - \bar{r}_i^2 \phi_{\ell-1,i}^- \right) + 4\pi(\ell+1) \left(\bar{r}_{i+1}^2 \phi_{\ell+1,i+1}^- - \bar{r}_i^2 \phi_{\ell+1,i}^- \right) \\ - 4\pi\ell(\ell+1) \left(\mathcal{B}_i \phi_{\ell-1,i}^- + \mathcal{A}_{i+1} \phi_{\ell-1,i+1}^- - \mathcal{B}_i \phi_{\ell+1,i}^- - \mathcal{A}_{i+1} \phi_{\ell+1,i+1}^- \right) \\ + 4\pi r_i^2 \Delta r_i \sum_{p=0}^1 \left[\mathcal{R}_{p,1} + \frac{2\Delta r_i}{r_i} \mathcal{R}_{p,1}^s + \left(\frac{\Delta r_i}{r_i} \right)^2 \mathcal{R}_{p,1}^{ss} \right] \left(\Sigma_i \phi_{\ell,i-1/2+p}^+ - Q_{\ell,i-1/2+p}^+ \right) \\ + 4\pi r_{i+1}^2 \Delta r_{i+1} \sum_{p=0}^1 \left[\mathcal{R}_{p,0} + \frac{2\Delta r_{i+1}}{r_{i+1}} \mathcal{R}_{p,0}^s + \left(\frac{\Delta r_{i+1}}{r_{i+1}} \right)^2 \mathcal{R}_{p,0}^{ss} \right] \\ \times \left(\Sigma_{i+1} \phi_{\ell,i+1/2+p}^+ - Q_{\ell,i+1/2+p}^+ \right) = 0, \end{aligned} \quad (205)$$

where ℓ is even and $1 \leq i \leq I$. The geometric coefficients are defined as

$$\begin{aligned} \Delta r_i &= r_{i+1/2} - r_{i-1/2}, \\ r_i &= \frac{1}{2} (r_{i-1/2} + r_{i+1/2}), \end{aligned}$$

$$\tilde{r}_i^2 = \frac{1}{3} (r_{i-1/2} r_{i-1/2} + r_{i-1/2} r_{i+1/2} + r_{i+1/2} r_{i+1/2}),$$

$$V_i = 4\pi \tilde{r}_i^2 \Delta r_i,$$

$$\mathcal{A}_i = \Delta r_i \left(\frac{r_{i-1/2}}{3} + \frac{r_{i+1/2}}{6} \right),$$

and

$$\mathcal{B}_i = \Delta r_i \left(\frac{r_{i-1/2}}{6} + \frac{r_{i+1/2}}{3} \right). \quad (206)$$

The mass-matrix components $\mathcal{R}_{p,q}$, $\mathcal{R}_{p,q}^s$, and $\mathcal{R}_{p,q}^{ss}$ are defined as (Hébert 2005)

$$\mathbf{R} = \begin{bmatrix} 1/4 & 1/4 \\ 1/4 & 1/4 \end{bmatrix}, \quad \mathbf{R}^s = \begin{bmatrix} -5/144 & -1/144 \\ -1/144 & 7/144 \end{bmatrix}$$

and

$$\mathbf{R}^{ss} = \begin{bmatrix} 1/108 & 1/54 \\ 1/54 & 1/27 \end{bmatrix}. \quad (207)$$

Let us now consider the case where $r_{I+1/2}$ is the outer boundary. In this case, the even-parity difference relation is written as

$$\begin{aligned} & -4\pi\ell \tilde{r}_I^2 \phi_{\ell-1,I}^- - 4\pi(\ell+1) \tilde{r}_I^2 \phi_{\ell+1,I}^- + 4\pi\mathcal{B}_I \ell(\ell+1) (\phi_{\ell-1,I}^- - \phi_{\ell+1,I}^-) \\ & + 4\pi r_I^2 \Delta r_I \sum_{p=0}^1 \left[\mathcal{R}_{p,1} + \frac{2\Delta r_I}{r_I} \mathcal{R}_{p,1}^s + \left(\frac{\Delta r_I}{r_I} \right)^2 \mathcal{R}_{p,1}^{ss} \right] (\Sigma_I \phi_{\ell,I-1/2+p}^+ - Q_{\ell,I-1/2+p}^+) \\ & + (2\ell+1) 4\pi r_+^2 \frac{1-\beta^+}{1+\beta^+} \sum_{\substack{m=0 \\ m \text{ even}}}^{n-1} \hat{\mathcal{M}}_{m,\ell} \phi_{m,I+1/2}^+ = 0 \quad \text{where } \ell \text{ is even.} \end{aligned} \quad (208)$$

Finally, the spherical harmonics-discretized relations for odd-parity indices ℓ are obtained by integrating (204) between $r_{i-1/2}$, and $r_{i+1/2}$, and by assuming that $\phi_{\ell,i}^-$ is equal to the averaged value over subvolume i . We obtain

$$\begin{aligned} & -4\pi \tilde{r}_i^2 \ell (\phi_{\ell-1,i+1/2}^+ - \phi_{\ell-1,i-1/2}^+) - 4\pi \tilde{r}_i^2 (\ell+1) (\phi_{\ell+1,i+1/2}^+ - \phi_{\ell+1,i-1/2}^+) \\ & + 4\pi [\ell(\ell-1) (\mathcal{A}_i \phi_{\ell-1,i-1/2}^+ + \mathcal{B}_i \phi_{\ell-1,i+1/2}^+) \\ & - (\ell+1)(\ell+2) (\mathcal{A}_i \phi_{\ell+1,i-1/2}^+ + \mathcal{B}_i \phi_{\ell+1,i+1/2}^+)] - (2\ell+1) V_i \Sigma_i \phi_{\ell,i}^- \\ & = - (2\ell+1) V_i Q_{\ell,i}^-, \end{aligned} \quad (209)$$

where ℓ is odd and $1 \leq i \leq I$.

3.4 The Simplified P_n Method in 2D Cartesian Geometry

Application of the spherical harmonics method in 2D and 3D cases produces a linear system with complicated couplings between the discretized unknowns in space and angle. For this reason, the discrete-ordinates method of [Sect. 5](#) is generally a more practical choice. The SP_n method, on the other hand, is based on an expansion of the angular flux in an incomplete basis of orthogonal functions, and its discretization produces a linear system with a simplified structure that can be solved effectively in 2D and 3D cases. A few important facts must be understood concerning the use of SP_n methods:

- The SP_1 method is equivalent to the P_1 method in 1D, 2D, and 3D cases. Assuming $L = 0$ in these cases produces an approximation that is equivalent to the diffusion approximation of [Sect. 7](#).
- The SP_n method is equivalent to the P_n method in 1D, for all values of n .
- Using an incomplete basis does not guarantee the convergence of the numerical results as n increases in 2D and 3D cases. However, SP_3 or SP_5 results have proven to be more accurate than SP_1 results in many situations, leading to production codes with improved accuracy when compared with the diffusion approximation.

3.4.1 Discretization in Angle

The SP_n is *not* based on a spherical harmonics expansion. This approach is an heuristics presented in the original work of Gelbard (1960). We start with the 1D slab-geometry P_n equations, obtained in [3.1.1](#). These equations are written as

$$\frac{\ell}{2\ell+1} \frac{d}{dx} \phi_{\ell-1}(x) + \frac{\ell+1}{2\ell+1} \frac{d}{dx} \phi_{\ell+1}(x) + \Sigma(x) \phi_{\ell}(x) = Q_{\ell}(x), \quad (210)$$

where $\phi_{\ell}(x)$ is the ℓ th Legendre moment of the angular flux, $\Sigma(x)$ is the macroscopic total cross-section, and $Q_{\ell}(x)$ is the ℓ th Legendre moment of the angular source. These equations are written for $0 \leq \ell \leq n$. The closure relation consists to assume that $\phi_{n+1}(x)$ is identically zero.

The Gelbard approach to obtain the SP_n equations is based on the following procedure:

1. Replace the operator d/dx in (210) for even ℓ with the divergence operator.
2. Replace the operator d/dx in (210) for odd ℓ with the gradient operator.

Carrying out this procedure, we obtain

$$\frac{\ell}{2\ell+1} \nabla \cdot \Phi_{\ell-1}(\mathbf{r}) + \frac{\ell+1}{2\ell+1} \nabla \cdot \Phi_{\ell+1}(\mathbf{r}) + \Sigma(\mathbf{r}) \phi_{\ell}(\mathbf{r}) = Q_{\ell}(\mathbf{r}) \quad (211)$$

if $0 \leq \ell \leq n-1$ and ℓ is even, and

$$\frac{\ell}{2\ell+1} \nabla \phi_{\ell-1}(\mathbf{r}) + \frac{\ell+1}{2\ell+1} \nabla \phi_{\ell+1}(\mathbf{r}) + \Sigma(\mathbf{r}) \Phi_{\ell}(\mathbf{r}) = Q_{\ell}(\mathbf{r}) \quad (212)$$

if $1 \leq \ell \leq n$ and ℓ is odd.

Similarly, the albedo boundary condition of (162) can be generalized to the SP_n method by writing

$$(1 + \beta(\mathbf{r})) \Phi_\ell(\mathbf{r}) \cdot \mathbf{N}(\mathbf{r}) - (1 - \beta(\mathbf{r})) \sum_{\substack{m=0 \\ m \text{ even}}}^{n-1} \mathcal{M}_{\ell,m} \phi_m(\mathbf{r}) = 0 \quad \text{if } \mathbf{r} \in \partial V_\beta, \quad (213)$$

where ℓ is an odd integer, ∂V_β is the boundary with an albedo condition, $\beta(\mathbf{r})$ is the albedo, and $\mathbf{N}(\mathbf{r})$ is an outgoing normal unit vector.

Equations (211) and (212) are the differential formulation of the SP_n method. The scalar even-parity flux $\phi_\ell(\mathbf{r})$ and vector odd-parity flux $\Phi_\ell(\mathbf{r})$ are the dependent variables of this equation system.

3.4.2 Difference Relations

The Cartesian domain is discretized in an $I \times J$ grid of rectangular subvolumes. The odd-parity variables are discretized over mesh-centered coordinates, so that $\phi_{i,j}^- \equiv \phi^-(x_i, y_j)$. The even-parity variables are defined over the surfaces surrounding subvolumes, so that $\phi_{i\mp 1/2, j}^+ \equiv \phi^+(x_{i\mp 1/2}, y_j)$ and $\phi_{i, j\mp 1/2}^+ \equiv \phi^+(x_i, y_{j\mp 1/2})$. We define the corresponding mesh widths and volumes as

$$\Delta x_i = x_{i+1/2} - x_{i-1/2}, \quad \Delta y_j = y_{j+1/2} - y_{j-1/2}, \quad \text{and} \quad V_{i,j} = \Delta x_i \Delta y_j. \quad (214)$$

The difference relations are obtained by similarity with the slab-geometry derivation of [3.1](#), so that 2D Cartesian results are identical to 1D slab results in cases where $I = 1$ or $J = 1$. Let us first consider the difference relation, for even-parity values of ℓ , in the case where surface $i + 1/2$ is not a boundary. We obtain

$$\begin{aligned} \Delta y_j \frac{\ell}{2\ell+1} (\phi_{\ell-1, i+1, j}^- - \phi_{\ell-1, i, j}^-) + \Delta y_j \frac{\ell+1}{2\ell+1} (\phi_{\ell+1, i+1, j}^- - \phi_{\ell+1, i, j}^-) \\ + \frac{V_{i,j}}{4} (\Sigma_{i,j} \phi_{\ell, i-1/2, j}^+ - Q_{\ell, i-1/2, j}^+) + \frac{V_{i,j}}{4} (\Sigma_{i,j} \phi_{\ell, i+1/2, j}^+ - Q_{\ell, i+1/2, j}^+) \\ + \frac{V_{i+1, j}}{4} (\Sigma_{i+1, j} \phi_{\ell, i+1/2, j}^+ - Q_{\ell, i+1/2, j}^+) + \frac{V_{i+1, j}}{4} (\Sigma_{i+1, j} \phi_{\ell, i+3/2, j}^+ - Q_{\ell, i+3/2, j}^+) = 0, \end{aligned} \quad (215)$$

where ℓ is even, $1 \leq i < I$ and $1 \leq j < J$.

We next consider the case where surface $j + 1/2$ is not a boundary. We obtain

$$\begin{aligned} \Delta x_i \frac{\ell}{2\ell+1} (\phi_{\ell-1, i, j+1}^- - \phi_{\ell-1, i, j}^-) + \Delta x_i \frac{\ell+1}{2\ell+1} (\phi_{\ell+1, i, j+1}^- - \phi_{\ell+1, i, j}^-) \\ + \frac{V_{i,j}}{4} (\Sigma_{i,j} \phi_{\ell, i, j-1/2}^+ - Q_{\ell, i, j-1/2}^+) + \frac{V_{i,j}}{4} (\Sigma_{i,j} \phi_{\ell, i, j+1/2}^+ - Q_{\ell, i, j+1/2}^+) \\ + \frac{V_{i, j+1}}{4} (\Sigma_{i, j+1} \phi_{\ell, i, j+1/2}^+ - Q_{\ell, i, j+1/2}^+) + \frac{V_{i, j+1}}{4} (\Sigma_{i, j+1} \phi_{\ell, i, j+3/2}^+ - Q_{\ell, i, j+3/2}^+) = 0, \end{aligned} \quad (216)$$

where ℓ is even, $1 \leq i < I$ and $1 \leq j < J$.

Let us now consider the case where the external right boundary, located at $x_{I+1/2}$, has an albedo condition. The difference equation is written as

$$\begin{aligned}
 & -\frac{\ell}{2\ell+1} \Delta y_j \phi_{\ell-1,I,j}^- - \frac{\ell+1}{2\ell+1} \Delta y_j \phi_{\ell+1,I,j}^- + \frac{V_{i,j}}{4} (\Sigma_{I,j} \phi_{\ell,I-1/2,j}^+ - Q_{\ell,I-1/2,j}^+) \\
 & + \frac{V_{i,j}}{4} (\Sigma_{I,j} \phi_{\ell,I+1/2,j}^+ - Q_{\ell,I+1/2,j}^+) + \Delta y_j \frac{1-\beta^+}{1+\beta^+} \sum_{\substack{\ell'=0 \\ \ell' \text{ even}}}^{n-1} \mathcal{M}_{\ell,\ell'} \phi_{\ell',I+1/2,j}^+ = 0, \quad (217)
 \end{aligned}$$

where ℓ is even and $1 \leq j < J$.

Finally, the spherical harmonics-discretized relations for odd-parity indices ℓ are obtained by integrating (212) over subvolume $\{i, j\}$ and by assuming that $\phi_{\ell-1,j}^-$ is equal to the averaged value over this subvolume. We obtain

$$\begin{aligned}
 & -\frac{\ell}{2\ell+1} \Delta y_j (\phi_{\ell-1,i+1/2,j}^+ - \phi_{\ell-1,i-1/2,j}^+) - \frac{\ell+1}{2\ell+1} \Delta y_j (\phi_{\ell+1,i+1/2,j}^+ - \phi_{\ell+1,i-1/2,j}^+) \\
 & -\frac{\ell}{2\ell+1} \Delta x_i (\phi_{\ell-1,i,j+1/2}^+ - \phi_{\ell-1,i,j-1/2}^+) - \frac{\ell+1}{2\ell+1} \Delta x_i (\phi_{\ell+1,i,j+1/2}^+ - \phi_{\ell+1,i,j-1/2}^+) \\
 & -V_{i,j} \Sigma_{i,j} \phi_{\ell,i,j}^- = -V_{i,j} Q_{\ell,i,j}^-, \quad (218)
 \end{aligned}$$

where ℓ is odd, $1 \leq i \leq I$ and $1 \leq j \leq J$.

4 The Collision Probability Method

The *collision probability* (CP) method results from the spatial discretization of the integral transport equation in multigroup form, assuming isotropic particle sources (Carlvik 1965). For a problem containing I regions, this approach produces an $I \times I$ matrix in each energy group. This method is preferred for treating general unstructured meshes and few-region problems. Collision probabilities can be defined over an infinite domain (such as a lattice of identical cells or assemblies) or over a finite (or *open*) domain D surrounded by a surface ∂D . The formalism of the first case is simpler but brings some difficulties related to the practical evaluation of the CPs. It will be examined first. The second case requires that *boundary conditions* be added to close the domain.

Let us first integrate (113) over the solid angles to directly obtain the integrated flux $\phi_g(\mathbf{r})$ as

$$\phi_g(\mathbf{r}) = \int_{4\pi} d^2\Omega \phi_g(\mathbf{r}, \Omega) = \frac{1}{4\pi} \int_{4\pi} d^2\Omega \int_0^\infty ds e^{-\tau_g(s)} Q_g(\mathbf{r} - s\Omega), \quad (219)$$

where the optical path $\tau_g(s)$ is given by (115).

We now introduce the change of variable $\mathbf{r}' = \mathbf{r} - s\Omega$ with $d^3r' = s^2 d^2\Omega ds$. We obtain

$$\phi_g(\mathbf{r}) = \frac{1}{4\pi} \int_\infty^\infty d^3r' \frac{e^{-\tau_g(s)}}{s^2} Q_g(\mathbf{r}') \quad (220)$$

with $s = |\mathbf{r} - \mathbf{r}'|$.

This form of transport equation is generally used to represent an infinite lattice of identical (or *unit*) cells or assemblies, repeating themselves by symmetric- or periodic-boundary conditions. We next perform a partition of the *unit cell* or assembly into regions V_i . We also use the

symbol V_i^∞ to represent the infinite set of regions V_i belonging to all the cells or assemblies in the lattice. We also suppose that the sources of secondary neutrons are uniform and equal to $Q_{i,g}$ on each region V_i . After multiplication by $\Sigma_g(\mathbf{r})$ and integration over each region V_i , (220) can be written as

$$\int_{V_j} d^3r \Sigma_g(\mathbf{r}) \phi_g(\mathbf{r}) = \frac{1}{4\pi} \int_{V_j} d^3r \Sigma_g(\mathbf{r}) \sum_i Q_{i,g} \int_{V_i^\infty} d^3r' \frac{e^{-\tau_g(s)}}{s^2}, \quad (221)$$

where

$$Q_{i,g} = \sum_h \Sigma_{s0,i,g \leftarrow h} \phi_{i,h} + \frac{1}{K_{\text{eff}}} Q_{i,g}^{\text{fiss}}. \quad (222)$$

The fission source in (222) is defined as

$$Q_{i,g}^{\text{fiss}} = \sum_{j=1}^{\text{fiss}} \chi_{j,g} \sum_h \nu \Sigma_{f,j,h} \phi_{i,h}, \quad (223)$$

where j is a fissionable isotope index, $\chi_{j,g}$ is the fission spectrum of isotope j , and $\Sigma_{f,j,h}$ is the macroscopic fission cross-section of isotope j for neutrons in group h .

Equation (221) simplifies to

$$V_j \Sigma_{j,g} \phi_{j,g} = \sum_i Q_{i,g} V_i P_{ij,g}, \quad (224)$$

where

$$\phi_{j,g} = \frac{1}{V_j} \int_{V_j} d^3r \phi_g(\mathbf{r}), \quad (225)$$

$$\Sigma_{j,g} = \frac{1}{V_j \phi_{j,g}} \int_{V_j} d^3r \Sigma_g(\mathbf{r}) \phi_g(\mathbf{r}) \quad (226)$$

and

$$P_{ij,g} = \frac{1}{4\pi V_i} \int_{V_i^\infty} d^3r' \int_{V_j} d^3r \Sigma_g(\mathbf{r}) \frac{e^{-\tau_g(s)}}{s^2}. \quad (227)$$

The *collision probability* $P_{ij,g}$ is the probability for a neutron born uniformly and isotropically in *any* of the regions V_i of the lattice to undergo its first collision in region V_j of a unit cell or assembly.

If the total cross-section $\Sigma_g(\mathbf{r})$ is constant and equal to $\Sigma_{j,g}$ in region V_j , *reduced* CPs can be defined from (227) as

$$P_{ij,g} = \frac{P_{ij,g}}{\Sigma_{j,g}} = \frac{1}{4\pi V_i} \int_{V_i^\infty} d^3r' \int_{V_j} d^3r \frac{e^{-\tau_g(s)}}{s^2}. \quad (228)$$

Reduced CPs generally remain finite in the limit where $\Sigma_{j,g}$ tends to zero. This ensures the correct behavior of the collision probability theory in cases where some regions of the lattice are voided.

Other interesting properties of CPs are the *reciprocity* and *conservation* properties, which can be written as

$$p_{ij,g} V_i = p_{ji,g} V_j \quad (229)$$

and

$$\sum_j P_{ij,g} \Sigma_{j,g} = 1, \quad \forall i. \quad (230)$$

Using the reciprocity property, (224) can be further simplified to

$$\phi_{i,g} = \sum_j Q_{j,g} P_{ij,g}. \quad (231)$$

The CP method generally proceeds in three steps as follows:

1. A *tracking* process is applied over the lattice geometry to span a sufficiently large number of neutron trajectories. In a 2D domain, the tracking parameters are the number of azimuthal angles and the number of parallel tracks per centimeter. The tracking process is dependent on the energy index g only if the domain is infinite (i.e., if boundary conditions are not used) and if the tracks are not cyclic in the lattice.
2. A numerical integration process is required to compute the CPs, using tracking information and knowledge of the macroscopic total cross-sections in each region. This integration should be done for each energy group, but the process is completely parallelizable as there is no interaction between the groups. Parallelization is greatly facilitated in cases where the same tracking file is used for all the energy groups.
3. Once the CPs are known, the integrated flux can be computed from (222) to (231).

Collision probability techniques can also be applied to the case of a domain D surrounded by a surface ∂D . In this case, the free path lengths are restricted to finite lengths defined inside ∂D and (114) is used as the basic integral transport equation. Infinite lattices can still be described by incorporating *reflective* or *periodic* boundary conditions over ∂D .

4.1 The Interface Current Method

Another important category of collision probability techniques is the *interface current* (IC) methods (Sanchez and McCormick 1982). In this case, a unit assembly is subdivided into cells and CP matrices are computed for each uncoupled cell. The detailed flux can then be reconstructed from the knowledge of interface currents surrounding each cell.

In each point \mathbf{r}_s of the surface ∂V surrounding a cell, the outgoing angular flux can be expressed as a double P_n expansion as

$$\phi^+(\mathbf{r}_s, \boldsymbol{\Omega}) = \frac{1}{4\pi} \sum_{\rho} \phi_{\rho}^+(\mathbf{r}_s) \psi_{\rho}(\boldsymbol{\Omega}, \mathbf{N}^+), \quad \text{where } \boldsymbol{\Omega} \cdot \mathbf{N}^+ > 0, \quad (232)$$

where \mathbf{N}^+ is a unit-outgoing vector, normal to ∂V , and located at point \mathbf{r}_s . In this section, we do not show the group g dependence of the various physical quantities. This will help to lighten the mathematical notation.

The base functions are chosen so as to satisfy the following orthogonality condition:

$$\int_{\boldsymbol{\Omega} \cdot \mathbf{N} > 0} d^2\boldsymbol{\Omega} (\boldsymbol{\Omega} \cdot \mathbf{N}) \psi_{\nu}(\boldsymbol{\Omega}, \mathbf{N}) \psi_{\rho}(\boldsymbol{\Omega}, \mathbf{N}) = \pi \delta_{\nu\rho}, \quad (233)$$

where $\delta_{\nu\rho}$ is the delta Kronecker function.

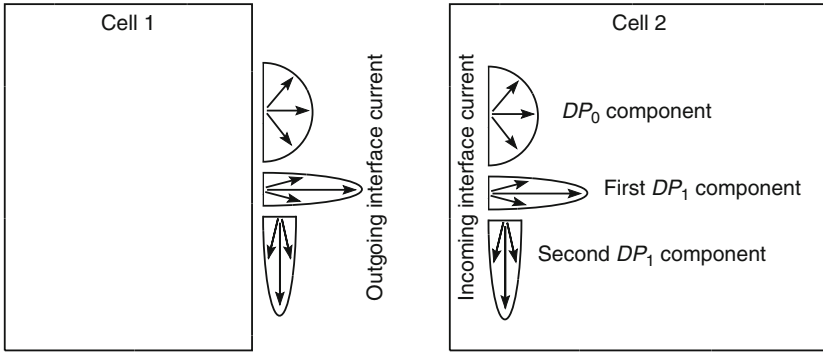

Figure 10
The interface current method

In 2D cases, the base functions corresponding to a double P_1 expansion are illustrated in **Fig. 10** and are obtained as

$$\begin{aligned}
 \psi_0(\mathbf{\Omega}, \mathbf{N}) &= 1 \quad (DP_0 \text{ component}), \\
 \psi_1(\mathbf{\Omega}, \mathbf{N}) &= 3\sqrt{2} (\mathbf{\Omega} \cdot \mathbf{N}) - 2\sqrt{2} \quad (\text{first } DP_1 \text{ component}), \\
 \psi_2(\mathbf{\Omega}, \mathbf{N}) &= 2 (\mathbf{\Omega} \cdot \mathbf{N}_\perp) \quad (\text{second } DP_1 \text{ component}),
 \end{aligned}
 \tag{234}$$

where \mathbf{N}_\perp is a unit vector perpendicular to \mathbf{N} and located in the 2D plane.

The neutron balance equation is ensured by using the same expansion for the outgoing angular flux in a cell and for the incoming angular flux in the neighboring cell. Using \mathbf{N}^- as the incoming unit normal vector in the neighboring cell, we write

$$\varphi^-(\mathbf{r}_s, \mathbf{\Omega}) = \frac{1}{4\pi} \sum_{\rho} \varphi_{\rho}^-(\mathbf{r}_s) \psi_{\rho}(\mathbf{\Omega}, \mathbf{N}^-), \quad \text{where } \mathbf{\Omega} \cdot \mathbf{N}^- > 0.
 \tag{235}$$

Another usual approximation consists in assuming that the expansion coefficients $\varphi_{\rho}^+(\mathbf{r}_s)$ and $\varphi_{\rho}^-(\mathbf{r}_s)$ are uniform along each side of the cell. They are taken equal to $\varphi_{\rho, \alpha}^+$ and $\varphi_{\rho, \alpha}^-$ on surface S_{α} . Uniform- DP_0 and Uniform- DP_1 are the two usual IC approximations.

A cell may contain one or several regions defining the fuel, clad, and coolant. A CP method is used to compute the response matrices of each cell. The following matrices are computed:

- p_{ij} = reduced CP for a neutron born uniformly and isotropically in region i to have its first collision in region j without leaving the cell.
- $P_{S_{\alpha}j}^{(\rho)}$ = reduced CP for a neutron entering from surface S_{α} uniformly and with an angular distribution $\psi_{\rho}(\mathbf{\Omega}, \mathbf{N}^-)$ to have its first collision in region j without leaving the cell.
- $P_{iS_{\beta}}^{(v)}$ = escape probability for a neutron born uniformly and isotropically in region i to leave the cell by surface S_{β} with an angular distribution $\psi_{\nu}(\mathbf{\Omega}, \mathbf{N}^+)$.
- $P_{S_{\alpha}S_{\beta}}^{(\rho\nu)}$ = transmission probability for a neutron entering from surface S_{α} uniformly and with an angular distribution $\psi_{\rho}(\mathbf{\Omega}, \mathbf{N}^-)$ to leave the cell by surface S_{β} , with an angular distribution $\psi_{\nu}(\mathbf{\Omega}, \mathbf{N}^+)$.

The reduced collision probability component p_{ij} is given by an equation similar to (228), taking care to replace the integration over V_i^∞ by an integration over the unique volume V_i in the cell being processed. We write

$$p_{ij} = \frac{P_{ij}}{\Sigma_j} = \frac{1}{4\pi V_i} \int_{V_i} d^3 r' \int_{V_j} d^3 r \frac{e^{-\tau(s)}}{s^2}. \quad (236)$$

The $p_{S_\alpha j}^{(\rho)}$ components are defined as

$$p_{S_\alpha j}^{(\rho)} = \frac{P_{S_\alpha j}^{(\rho)}}{\Sigma_j} = \frac{1}{\pi S_\alpha} \int_{S_\alpha} d^2 r'_s \int_{V_j} d^3 r (\mathbf{\Omega} \cdot \mathbf{N}^-) \psi_\rho(\mathbf{\Omega}, \mathbf{N}^-) \frac{e^{-\tau(s)}}{s^2} \quad (237)$$

and the other CP components are defined as

$$P_{iS_\beta}^{(\nu)} = \frac{1}{4\pi V_i} \int_{V_i} d^3 r' \int_{S_\beta} d^2 r_s (\mathbf{\Omega} \cdot \mathbf{N}^+) \psi_\nu(\mathbf{\Omega}, \mathbf{N}^+) \frac{e^{-\tau(s)}}{s^2} \quad (238)$$

and

$$P_{S_\alpha S_\beta}^{(\rho\nu)} = \frac{1}{\pi S_\alpha} \int_{S_\alpha} d^2 r'_s \int_{S_\beta} d^2 r_s (\mathbf{\Omega} \cdot \mathbf{N}^-) (\mathbf{\Omega} \cdot \mathbf{N}^+) \psi_\rho(\mathbf{\Omega}, \mathbf{N}^-) \psi_\nu(\mathbf{\Omega}, \mathbf{N}^+) \frac{e^{-\tau(s)}}{s^2}. \quad (239)$$

Again, these probabilities satisfy reciprocity relations written as

$$p_{ij} V_i = p_{ji} V_j, \quad p_{S_\alpha i}^{(\rho)} = \frac{4V_i}{S_\alpha} P_{iS_\alpha}^{(\rho)} \quad (240)$$

and

$$P_{S_\alpha S_\beta}^{(\rho\nu)} S_\alpha = P_{S_\beta S_\alpha}^{(\nu\rho)} S_\beta \quad (241)$$

and conservation relations written as

$$\sum_\beta P_{iS_\beta}^{(0)} + \sum_j p_{ij} \Sigma_j = 1, \quad \forall i \quad (242)$$

and

$$\sum_\beta P_{S_\alpha S_\beta}^{(00)} + \sum_j P_{S_\alpha j}^{(0)} \Sigma_j = 1, \quad \forall \alpha. \quad (243)$$

The flux equation for neutrons in each group can be cast into a response-matrix form where the unknowns are the averaged integrated flux ϕ_i in region i and the uniform components of the angular fluxes along surface S_α (related to the *interface currents*). We obtain

$$\begin{aligned} \phi_i &= \sum_\beta \sum_\nu \varphi_{\nu, \beta}^- P_{iS_\beta}^{(\nu)} + \sum_j Q_j p_{ij}, \\ \varphi_{\rho, \alpha}^+ &= \sum_\beta \sum_\nu \varphi_{\nu, \beta}^- P_{S_\alpha S_\beta}^{(\rho\nu)} + \sum_j Q_j p_{S_\alpha j}^{(\rho)}, \end{aligned} \quad (244)$$

where Q_j is the scattering and fission sources in region j .

Finally, a purely geometric equation is required to connect the outgoing and incoming angular fluxes, $\varphi_{\rho,\alpha}^+$ and $\varphi_{\nu,\beta}^-$. This relation is written as

$$\varphi_{\rho,\beta}^- = \sum_{\alpha} A_{\alpha,\beta}^{(\rho)} \varphi_{\rho,\alpha}^+. \quad (245)$$

The complete set of (244) and (245) form a closed system that can be solved iteratively. Another technique consists in simplifying the outgoing and incoming angular fluxes and transforming this coupled system into a simple matrix equation similar to (231).

4.2 Scattering-Reduced Matrices and Power Iteration

The within-group scattering term is first included on the left-hand side of (231) to obtain

$$\phi_{i,g} - \sum_j p_{ij,g} \Sigma_{s0,j,g \leftarrow g} \phi_{j,g} = \sum_j Q_{j,g}^{\diamond} p_{ij,g}, \quad (246)$$

where $Q_{i,g}^{\diamond}$ includes the fission sources and the diffusion sources from all groups except group g . It is obtained from (222) as

$$Q_{i,g}^{\diamond} = \sum_{h \neq g} \Sigma_{s0,i,g \leftarrow h} \phi_{i,h} + \frac{1}{K_{\text{eff}}} Q_{i,g}^{\text{fiss}}. \quad (247)$$

Equation (246) can be written in matrix form as

$$\Phi_g = \mathbb{W}_g \mathbf{Q}_g^{\diamond}, \quad (248)$$

where $\Phi_g = \{\phi_{i,g}; \forall i\}$ and $\mathbf{Q}_g^{\diamond} = \{Q_{i,g}^{\diamond}; \forall i\}$.

The \mathbb{W}_g matrix is the scattering-reduced collision probability matrix and is used in the power iteration of the lattice code. It is defined as

$$\mathbb{W}_g = [\mathbb{I} - \mathbb{P}_g \mathbb{S}_{s0,g \leftarrow g}]^{-1} \mathbb{P}_g, \quad (249)$$

where \mathbb{I} is the identity matrix, $\mathbb{P}_g = \{p_{ij,g}; \forall i \text{ and } j\}$ and $\mathbb{S}_{s0,g \leftarrow g} = \text{diag}\{\Sigma_{s0,i,g \leftarrow g}; \forall i\}$.

Two iterative processes are generally superimposed on these monoenergetic flux solution methods. First, the inner process iterates over the diffusion up-scattering sources until an adequate multigroup thermal flux distribution is obtained. This iteration process is accelerated using two different techniques. The rebalancing technique produces a group-dependent factor which restores the exact multigroup flux distribution homogenized over all regions. Then the variational acceleration technique is used to compute an over-relaxation factor to be used at the next iteration. The outer (or *power*) iteration process is over the eigenvalue and is not required for fixed source problems. It is generally not accelerated in a lattice code and consists in computing neutron flux at outer iteration $k + 1$ from source at iteration k , using

$$\Phi_g^{(k+1)} = \mathbb{W}_g \mathbf{Q}_g^{\diamond(k)}. \quad (250)$$

The critical parameter (K_{eff}) is then adjusted at the end of each power iteration.

4.3 Slab Geometry

The CP formulation in one-dimensional (1D) slab geometry makes possible the analytical integration of (55) or (56) with respect to some dependent variables. We will first consider the case of a geometry made of an infinite lattice of identical unit cells. Each unit cell is made of a succession of I regions, each of volume V_i with $1 \leq i \leq I$. The reference unit cell is defined in $x_{1/2} \leq x \leq x_{I+1/2}$ and the reference region i is defined in $x_{i-1/2} \leq x \leq x_{i+1/2}$. We will represent as \mathcal{C}_i the infinite set of all instances of region i , repeating itself by translation of the unit cell.

Equation (228) is the expression of a CP component in the infinite domain case. It can be rewritten in a more convenient form. We use the relations $\mathbf{r} = \mathbf{r}' + s \boldsymbol{\Omega}$ and $d^3 r = s^2 d^2 \Omega ds$, so that

$$p_{ij} = \frac{1}{4\pi V_i} \int_{V_i^\infty} d^3 r' \int_{4\pi} d^2 \Omega \int_{\mathcal{I}_j} ds e^{-\tau(s)}, \quad (251)$$

where we have omitted the energy group index in order to simplify the equations. The quantity \mathcal{I}_j is the set of points belonging simultaneously to

- The half straight line of origin \mathbf{r} and direction $-\boldsymbol{\Omega}$
- A single instance of volume V_j

We also define the direction $\boldsymbol{\Omega}$ of the particle in terms of the colatitude θ and azimuth ε using $\boldsymbol{\Omega} = \cos \theta \mathbf{i} + \sin \theta \cos \varepsilon \mathbf{j} + \sin \theta \sin \varepsilon \mathbf{k}$. With this definition and with the help of Fig. 11, we can write

$$\begin{aligned} d^2 \Omega &= d\theta d\varepsilon \sin \theta, \\ \ell(\rho) &= \tau(s) |\cos \theta|, \\ dx &= ds |\cos \theta|, \end{aligned} \quad (252)$$

where ρ is a positive number representing the projection of s on the x -axis. The material properties are independent of ε so that the integration in this variable can be performed analytically. Equation (251) can be simplified as

$$p_{ij} = \frac{1}{2 \Delta x_i} \sum_{i' \in \mathcal{C}_i} \int_{x_{i'-1/2}}^{x_{i'+1/2}} dx' \int_0^{\pi/2} d\theta \tan \theta \int_{x_{j-1/2}}^{x_{j+1/2}} dx e^{-\frac{|\ell(x',x)|}{\cos \theta}}, \quad (253)$$

Figure 11
Spatial discretization for slab geometry

where

$$\Delta x_i = V_i = x_{i+1/2} - x_{i-1/2} \tag{254}$$

and $\ell(x', x) = -\ell(x, x')$ is the projected optical path $\ell(\rho)$ defined between points x' and x as

$$\ell(x', x) = \int_{x'}^x dx'' \Sigma(x'') \tag{255}$$

so that $\ell(x', x_{j+1/2}) = \ell(x', x_{j-1/2}) + \Delta x_j \Sigma_j$.

Summation over V_i^∞ includes instances of V_i belonging to all unit cells of the lattice. The presence of neighboring cells will be taken into account in a specular way, using the *periodic boundary condition* introduced in **1.4. Equation (253)** can be rewritten so as to explicitly represent all contributions from other cells. A unit-cell optical path ℓ_{cell} is defined as

$$\ell_{\text{cell}} = \int_{x_{1/2}}^{x_{I+1/2}} dx' \Sigma(x') \tag{256}$$

so that

$$p_{ij} = \frac{1}{2 \Delta x_i} \sum_{m=0}^{\infty} \int_{x_{i-1/2}}^{x_{i+1/2}} dx' \int_0^{\pi/2} d\theta \tan \theta \int_{x_{j-1/2}}^{x_{j+1/2}} dx \left[e^{-\frac{m \ell_{\text{cell}} + \ell(x', x)}{\cos \theta}} + e^{-\frac{(m+1) \ell_{\text{cell}} - \ell(x', x)}{\cos \theta}} \right], \tag{257}$$

where $1 \leq i < j \leq I$ and

$$p_{ii} = \frac{1}{2 \Delta x_i} \sum_{m=0}^{\infty} \int_{x_{i-1/2}}^{x_{i+1/2}} dx' \int_0^{\pi/2} d\theta \tan \theta \left\{ \int_{x_{i-1/2}}^{x'} dx \left[e^{-\frac{m \ell_{\text{cell}} + \ell(x, x')}{\cos \theta}} + e^{-\frac{(m+1) \ell_{\text{cell}} - \ell(x, x')}{\cos \theta}} \right] + \int_{x'}^{x_{i+1/2}} dx \left[e^{-\frac{m \ell_{\text{cell}} + \ell(x', x)}{\cos \theta}} + e^{-\frac{(m+1) \ell_{\text{cell}} - \ell(x', x)}{\cos \theta}} \right] \right\}, \tag{258}$$

where $1 \leq i \leq I$.

In the case where the domain is not a lattice made of repeating unit cells, (257) must be modified accordingly. If the domain is a set of I regions surrounded by vacuum left- and right-boundary conditions, the CP components are simply

$$p_{ij} = \frac{1}{2 \Delta x_i} \int_{x_{i-1/2}}^{x_{i+1/2}} dx' \int_0^{\pi/2} d\theta \tan \theta \int_{x_{j-1/2}}^{x_{j+1/2}} dx e^{-\frac{|\ell(x', x)|}{\cos \theta}}, \quad \text{where } 1 \leq i \leq j \leq I, \tag{259}$$

and the conservation (230) is no longer valid. Whether (257) or (259) is used, the values of p_{ij} with $i > j$ are computed using the reciprocity (229).

The Kavenoky method is presented as a numerical technique for obtaining the values of the CP components in slab geometry (Kavenoky 1969). We will limit ourselves to (257), (258), and (259), although other boundary conditions were treated in Kavenoky (1969). The principle of this method is to keep the sum over n in (257) and (258) and to introduce *exponential functions* $E_n(x)$, with $n \geq 1$, defined as

$$E_n(x) = \int_0^1 du u^{n-2} e^{-x/u} = \int_1^\infty du u^{-n} e^{-xu}. \tag{260}$$

■ **Figure 12**
Exponential functions

Exponential functions are depicted in [Fig. 12](#). They can be evaluated efficiently using the Matlab script `taben` of Hébert (2009).

The exponential functions satisfy the following two relations:

$$\int_x^{x'} du E_n(u) = E_{n+1}(x) - E_{n+1}(x') \quad (261)$$

and

$$E_n(x) = -\frac{d}{dx} E_{n+1}(x) \quad (262)$$

so that the Taylor expansion of $E_3(x)$ is

$$E_3(x) = E_3(x_0) - E_2(x_0)(x - x_0) + \frac{1}{2}E_1(x_0)(x - x_0)^2 + \mathcal{O}(x - x_0)^3. \quad (263)$$

Integration of (257) in θ leads to

$$p_{ij} = \frac{1}{2\Delta x_i} \sum_{m=0}^{\infty} \int_{x_{i-1/2}}^{x_{i+1/2}} dx' \int_{x_{j-1/2}}^{x_{j+1/2}} dx \{E_1[m \ell_{\text{cell}} + \ell(x', x)] + E_1[(m+1)\ell_{\text{cell}} - \ell(x', x)]\} \quad (264)$$

if $i \leq j$ and

$$\begin{aligned}
 p_{ii} = & \frac{1}{2 \Delta x_i} \sum_{m=0}^{\infty} \int_{x_{i-1/2}}^{x_{i+1/2}} dx' \left\{ \int_{x_{i-1/2}}^{x'} dx \{E_1[m \ell_{\text{cell}} + \ell(x, x')]\right. \\
 & + E_1[(m+1) \ell_{\text{cell}} - \ell(x, x')]\} \\
 & + \left. \int_{x'}^{x_{i+1/2}} dx \{E_1[m \ell_{\text{cell}} + \ell(x', x)] + E_1[(m+1) \ell_{\text{cell}} - \ell(x', x)]\} \right\}. \quad (265)
 \end{aligned}$$

Equations (264) and (265) involve two types of spatial integration which can be written in functional form as

$$\mathcal{R}_{ij,m} \{\pm \ell\} = \frac{1}{2} \int_{x_{i-1/2}}^{x_{i+1/2}} dx' \int_{x_{j-1/2}}^{x_{j+1/2}} dx E_1[m \ell_{\text{cell}} \pm \ell(x', x)], \quad \text{where } i < j \quad (266)$$

and

$$\begin{aligned}
 \mathcal{R}_{ii,m} \{\pm \ell\} = & \frac{1}{2} \int_{x_{i-1/2}}^{x_{i+1/2}} dx' \left\{ \int_{x_{i-1/2}}^{x'} dx E_1[m \ell_{\text{cell}} \pm \ell(x, x')]\right. \\
 & + \left. \int_{x'}^{x_{i+1/2}} dx E_1[m \ell_{\text{cell}} \pm \ell(x', x)] \right\} \quad (267)
 \end{aligned}$$

so that

$$p_{ij} = \frac{1}{\Delta x_i} \sum_{m=0}^{\infty} \mathcal{R}_{ij,m} \{\ell\} + \mathcal{R}_{ij,m+1} \{-\ell\}, \quad \text{where } i \leq j. \quad (268)$$

Similarly, (259) reduces to

$$p_{ij} = \frac{1}{\Delta x_i} \mathcal{R}_{ij,0} \{\ell\}, \quad \text{where } i \leq j. \quad (269)$$

The collision probabilities defined in (268) represent an infinite lattice and are normalized as

$$\sum_{j=1}^I p_{ij} \Sigma_j = 1, \quad \forall i. \quad (270)$$

In contrast, the collision probabilities defined in (269) have boundary leakage and are, therefore, *not* normalized to unity.

We will now find analytical reductions for functionals $\mathcal{R}_{ij,m} \{\pm \ell\}$ and use them to evaluate the CP components in slab geometry. Using (261), it is possible to perform a first integration and obtain

$$\begin{aligned}
 & \int_{x_{i-1/2}}^{x_{i+1/2}} dx E_n[f(x, x')] \\
 = & \begin{cases} \pm \frac{1}{\Sigma_i} \{E_{n+1}[f(x_{i+1/2}, x')] - E_{n+1}[f(x_{i-1/2}, x')]\} & \text{if } \Sigma_i \neq 0, \\ \Delta x_i E_n[f(x_{i-1/2}, x')] & \text{otherwise} \end{cases} \quad (271)
 \end{aligned}$$

and

$$\int_{x_{j-1/2}}^{x_{j+1/2}} dx E_n [f(x', x)] = \begin{cases} \mp \frac{1}{\Sigma_j} \{E_{n+1}[f(x', x_{j+1/2})] - E_{n+1}[f(x', x_{j-1/2})]\} & \text{if } \Sigma_j \neq 0, \\ \Delta x_j E_n [f(x', x_{j-1/2})] & \text{otherwise,} \end{cases} \quad (272)$$

where the upper sign is used if $f \equiv m\ell_{\text{cell}} + \ell$ and the lower sign is used if $f \equiv m\ell_{\text{cell}} - \ell$.

Integration in x' is next performed, leading to the following relations:

(a) $i < j$, $\Sigma_i \neq 0$ and $\Sigma_j \neq 0$:

$$\mathcal{R}_{ij,m} \{\pm \ell\} = \frac{1}{2\Sigma_i \Sigma_j} \{E_3[m\ell_{\text{cell}} \pm \ell(x_{i+1/2}, x_{j-1/2})] - E_3[m\ell_{\text{cell}} \pm \ell(x_{i+1/2}, x_{j+1/2})] + E_3[m\ell_{\text{cell}} \pm \ell(x_{i-1/2}, x_{j+1/2})] - E_3[m\ell_{\text{cell}} \pm \ell(x_{i-1/2}, x_{j-1/2})]\}. \quad (273)$$

(b) $i < j$, $\Sigma_i = 0$ and $\Sigma_j \neq 0$:

$$\mathcal{R}_{ij,m} \{\pm \ell\} = \pm \frac{\Delta x_i}{2\Sigma_j} \{E_2[m\ell_{\text{cell}} \pm \ell(x_{i-1/2}, x_{j-1/2})] - E_2[m\ell_{\text{cell}} \pm \ell(x_{i-1/2}, x_{j+1/2})]\}. \quad (274)$$

(c) $i < j$, $\Sigma_i \neq 0$ and $\Sigma_j = 0$:

$$\mathcal{R}_{ij,m} \{\pm \ell\} = \pm \frac{\Delta x_j}{2\Sigma_i} \{E_2[m\ell_{\text{cell}} \pm \ell(x_{i+1/2}, x_{j-1/2})] - E_2[m\ell_{\text{cell}} \pm \ell(x_{i-1/2}, x_{j-1/2})]\}. \quad (275)$$

(d) $i < j$ and $\Sigma_i = \Sigma_j = 0$:

$$\mathcal{R}_{ij,m} \{\pm \ell\} = \frac{\Delta x_i \Delta x_j}{2} E_1[m\ell_{\text{cell}} \pm \ell(x_{i-1/2}, x_{j-1/2})]. \quad (276)$$

(e) $i = j$ and $\Sigma_i \neq 0$:

$$\mathcal{R}_{ii,m} \{\pm \ell\} = \pm \frac{\Delta x_i E_2[m\ell_{\text{cell}}]}{\Sigma_i} - \frac{1}{\Sigma_i^2} \{E_3[m\ell_{\text{cell}}] - E_3[m\ell_{\text{cell}} \pm \ell(x_{i-1/2}, x_{i+1/2})]\}. \quad (277)$$

(f) $i = j$ and $\Sigma_i = 0$:

$$\mathcal{R}_{ii,m} \{\pm \ell\} = \frac{E_1[m\ell_{\text{cell}}] \Delta x_i^2}{2}. \quad (278)$$

The above relations are implemented in Matlab using the following two scripts:

```
function f=rif_f(sg,tau0,sigi,sigj,segmenti,segmentj)
% function f=rif_f(sg,tau0,sigi,sigj,segmenti,segmentj)
% (c) 2006 Alain Hebert, Ecole Polytechnique de Montreal
```

```

if sigi == 0 && sigj == 0
    f=0.5*(taben(3,tau0)-taben(3,tau0+sg*sigi*segmenti)- ...
        taben(3,tau0+sg*sigj*segmentj)+ ...
        taben(3,tau0+sg*sigi*segmenti+sg*sigj*segmentj))/(sigi*sigj) ;
elseif sigi == 0 && sigj == 0
    f=sg*0.5*segmenti*(taben(2,tau0)-taben(2,tau0+sg*sigj*segmentj))/sigj ;
elseif sigi == 0 && sigj == 0
    f=sg*0.5*segmentj*(taben(2,tau0)-taben(2,tau0+sg*sigi*segmenti))/sigi ;
else
    f=0.5*segmenti*segmentj*taben(1,tau0) ;
end

```

and

```

function f=rri_f(sg,tau0,sigi,segmenti)
% function f=rri_f(sg,tau0,sigi,segmenti)
% (c) 2006 Alain Hebert, Ecole Polytechnique de Montreal
if sigi == 0
    f=sg*segmenti*taben(2,tau0)/sigi- ...
        (taben(3,tau0)-taben(3,tau0+sg*sigi*segmenti))/sigi^2 ;
else
    f=0.5*segmenti^2*taben(1,tau0) ;
end

```

In the case where $m = 0$, (278) reduces to $\mathcal{R}_{ii,0}\{\ell\} = \infty$. This singularity has no effect on the solution of the transport equation because region i is voided and $\mathcal{R}_{ii,0}\{\ell\}$ is multiplied by a zero cross-section value. The value of the neutron flux in region i remains finite in this case. In all other cases, the reduced collision probability components remain finite as a cross-section is set to zero. All the collision probability components with $i > j$ are computed using the reciprocity (229).

4.4 Cylindrical 1D Geometry

We will now study the case of a 2D geometry defined in the x - y plane and homogenous along the z -axis. A cylinder or tube of infinite length is an example of such a geometry. In this case, it is possible to analytically integrate (228) or (236)–(239) along the axial angle θ , as depicted in  Fig. 13.

The direction of the particle is $\Omega = \sin \theta \cos \varepsilon i + \sin \theta \sin \varepsilon j + \cos \theta k$. Integration over θ is possible by taking the projection of each particle free path on the x - y plane. We write

$$\begin{aligned}
 d^2\Omega &= d\theta d\varepsilon \sin \theta, \\
 \tau(\rho) &= \tau(s) \sin \theta, \\
 d\rho &= ds \sin \theta,
 \end{aligned} \tag{279}$$

where ρ is the projection of s on the x - y plane.

■ Figure 13

Projection of a particle trajectory on the x - y plane. Angle θ is used to define the direction cosine of the particle relative to the z -axis

For reasons that will be explained later, we will limit ourselves to the integration of (236), defined on the domain of a unique unit cell. As before, we use the relations $\mathbf{r} = \mathbf{r}' + s \boldsymbol{\Omega}$ and $d^3 r = s^2 d^2 \Omega ds$ and obtain an equation similar to (251) as follows:

$$p_{ij} = \frac{1}{4\pi V_i} \int_{V_i} d^3 r' \int_{4\pi} d^2 \Omega \int_{\mathcal{I}_j} ds e^{-\tau(s)}, \quad (280)$$

where the quantity \mathcal{I}_j is the set of points belonging simultaneously

- To the half straight line of origin \mathbf{r} and direction $-\boldsymbol{\Omega}$
- To volume V_j of the unit cell

With the help of ► Fig. 13, (280) can be rewritten as

$$p_{ij} = \frac{1}{4\pi V_i} \int_0^{2\pi} d\epsilon \int_{V_i} d^2 r' \int_0^\pi d\theta \int_{\mathcal{I}_j} d\rho e^{-\frac{\tau(\rho)}{\sin \theta}}, \quad (281)$$

where V_i now represents a surface in the x - y plane and \mathcal{I}_j is the set of points belonging simultaneously

- To the half straight line of origin \mathbf{r}' and direction ϵ
- To surface V_j of the unit cell

Equation (281) can be simplified by introducing the *Bickley functions* $Ki_n(x)$, with $n \geq 1$, defined as

$$Ki_n(x) = \int_0^{\pi/2} d\theta \sin^{n-1} \theta e^{-\frac{x}{\sin \theta}} = \int_0^{\pi/2} d\theta \cos^{n-1} \theta e^{-\frac{x}{\cos \theta}} \quad (282)$$

and depicted in ► Fig. 14. They can be evaluated using the Matlab script `aki_n` of Hébert (2009).

Figure 14
Bickley functions

The following equations present the relationships between Bickley functions of different orders:

$$\int_x^{x'} du \text{Ki}_n(u) = \text{Ki}_{n+1}(x) - \text{Ki}_{n+1}(x'), \tag{283}$$

$$\frac{d}{dx} \text{Ki}_n(x) = -\text{Ki}_{n-1}(x) \tag{284}$$

so that the Taylor expansion of $\text{Ki}_3(x)$ is

$$\text{Ki}_3(x) = \text{Ki}_3(x_0) - \text{Ki}_2(x_0)(x - x_0) + \frac{1}{2} \text{Ki}_1(x_0)(x - x_0)^2 + \mathcal{O}(x - x_0)^3 \tag{285}$$

and

$$n \text{Ki}_{n+1}(x) = (n - 1) \text{Ki}_{n-1}(x) + x [\text{Ki}_{n-2}(x) - \text{Ki}_n(x)]. \tag{286}$$

We obtain

$$p_{ij} = \frac{1}{2\pi V_i} \int_0^{2\pi} d\varepsilon \int_{V_i} d^2r' \int_{\mathcal{I}_j} d\rho \text{Ki}_1[\tau(\rho)]. \tag{287}$$

Sets of integration lines, referred to as *tracks*, are drawn over the complete domain. Each set is characterized by a given angle ε and contains parallel tracks covering the domain. Tracks in a set can be separated by a constant distance Δh or can be placed at optimal locations, as depicted in **Fig. 15a** and **b**, respectively. Each track is used forward and backward, corresponding to angles ε and $-\varepsilon$. The track generation procedure is described in Appendices **Section 1** and **Section 2**.

In the case of convex volumes i and j , as depicted in **Fig. 16**, (287) can be rewritten as

$$p_{ij} = \frac{1}{2\pi V_i} \int_0^{2\pi} d\varepsilon \int_{h_{\min}}^{h_{\max}} dh \int_0^{\ell_i} d\ell' \int_0^{\ell_j} d\ell \text{Ki}_1(\tau_{ij} + \Sigma_i \ell' + \Sigma_j \ell) \quad \text{if } i \neq j, \tag{288}$$

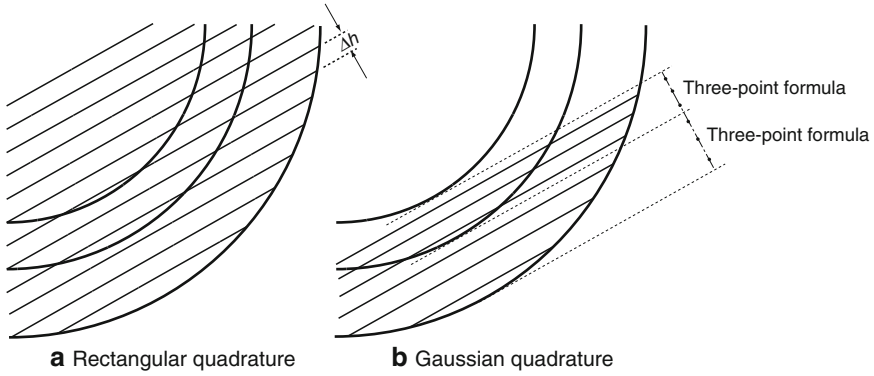

Figure 15 Tracking a 1D cylindrical geometry (a) Rectangular quadrature and (b) Gaussian quadrature

Figure 16 Integration of collision probabilities in 2D x-y geometry

where τ_{ij} is the optical path of the materials between regions i and j and

$$p_{ii} = \frac{1}{2\pi V_i} \int_0^{2\pi} d\epsilon \int_{h_{\min}}^{h_{\max}} dh \int_0^{\ell_i} d\ell' \int_{\ell'}^{\ell_i} d\ell \text{Ki}_1[\Sigma_i(\ell - \ell')]. \quad (289)$$

In the case of 1D cylindrical geometry, the tracks are identical for any value of the angle ϵ . However, the tubular volumes are concave, causing extra terms to appear. The corresponding geometry is depicted in Fig. 17. Two tracks are represented, both contributing to collision probability components p_{ij} with $i < j$ and p_{ii} . Track ① corresponds to the integration domain where region i is concave and track ② corresponds to the integration domain where it is convex. In this figure, τ_{ij} and τ_{ii} are the optical paths of the materials located between the regions i and j or between two instances of region i .

Figure 17
 Integration of collision probabilities in 1D cylindrical geometry

In this case, (287) can be rewritten as

$$\begin{aligned}
 p_{ij} = \frac{2}{V_i} \left\{ \int_0^{r_{i-1/2}} dh \int_0^{\ell_i} d\ell' \int_0^{\ell_j} d\ell \left[\text{Ki}_1[(\tau_{ij} + \tau_{ii} + \Sigma_i \ell_i) + \Sigma_i \ell' + \Sigma_j \ell] \right. \right. \\
 \left. \left. + \text{Ki}_1(\tau_{ij} + \Sigma_i \ell' + \Sigma_j \ell) \right] \right. \\
 \left. + \int_{r_{i-1/2}}^{r_{i+1/2}} dh \int_0^{\ell_i} d\ell' \int_0^{\ell_j} d\ell \text{Ki}_1(\tau_{ij} + \Sigma_i \ell' + \Sigma_j \ell) \right\} \quad \text{if } i < j, \quad (290)
 \end{aligned}$$

where $r_{i\pm 1/2}$ are the radii bounding region i and

$$\begin{aligned}
 p_{ii} = \frac{2}{V_i} \left\{ \int_0^{r_{i-1/2}} dh \int_0^{\ell_i} d\ell' \left[2 \int_{\ell'}^{\ell_i} d\ell \text{Ki}_1[\Sigma_i (\ell - \ell')] + \int_0^{\ell_i} d\ell \text{Ki}_1[\tau_{ii} + \Sigma_i (\ell' + \ell)] \right] \right. \\
 \left. + \int_{r_{i-1/2}}^{r_{i+1/2}} dh \int_0^{\ell_i} d\ell' \int_{\ell'}^{\ell_i} d\ell \text{Ki}_1[\Sigma_i (\ell - \ell')] \right\}, \quad (291)
 \end{aligned}$$

where the first and second terms of (290) and (291) are the contributions from tracks ① and ②, respectively. All the collision probability components with $i > j$ are computed using the reciprocity (229).

These equations can be simplified by introducing the following definitions:

$$C_{ij}(\tau_0) = \int_0^{\ell_i} d\ell' \int_0^{\ell_j} d\ell \text{Ki}_1(\tau_0 + \Sigma_i \ell' + \Sigma_j \ell) \quad (292)$$

and

$$\mathcal{D}_i = \int_0^{\ell_i} d\ell' \int_{\ell'}^{\ell_i} d\ell \text{Ki}_1[\Sigma_i(\ell - \ell')] \quad (293)$$

so that

$$p_{ij} = \frac{2}{V_i} \left\{ \int_0^{r_{i-1/2}} dh [C_{ij}(\tau_{ij} + \tau_{ii} + \Sigma_i \ell_i) + C_{ij}(\tau_{ij})] + \int_{r_{i-1/2}}^{r_{i+1/2}} dh C_{ij}(\tau_{ij}) \right\} \quad \text{if } i < j \quad (294)$$

and

$$p_{ii} = \frac{2}{V_i} \left\{ \int_0^{r_{i-1/2}} dh [2\mathcal{D}_i + C_{ii}(\tau_{ii})] + \int_{r_{i-1/2}}^{r_{i+1/2}} dh \mathcal{D}_i \right\}. \quad (295)$$

Integration in ℓ and ℓ' is performed next, leading to the following relations:

(a) $\Sigma_i \neq 0$ and $\Sigma_j \neq 0$:

$$C_{ij}(\tau_0) = \frac{1}{\Sigma_i \Sigma_j} [\text{Ki}_3(\tau_0) - \text{Ki}_3(\tau_0 + \Sigma_i \ell_i) - \text{Ki}_3(\tau_0 + \Sigma_j \ell_j) + \text{Ki}_3(\tau_0 + \Sigma_i \ell_i + \Sigma_j \ell_j)]. \quad (296)$$

(b) $\Sigma_i = 0$ and $\Sigma_j \neq 0$:

$$C_{ij}(\tau_0) = \frac{\ell_i}{\Sigma_j} [\text{Ki}_2(\tau_0) - \text{Ki}_2(\tau_0 + \Sigma_j \ell_j)]. \quad (297)$$

(c) $\Sigma_i \neq 0$ and $\Sigma_j = 0$:

$$C_{ij}(\tau_0) = \frac{\ell_j}{\Sigma_i} [\text{Ki}_2(\tau_0) - \text{Ki}_2(\tau_0 + \Sigma_i \ell_i)]. \quad (298)$$

(d) $\Sigma_i = \Sigma_j = 0$:

$$C_{ij}(\tau_0) = \ell_i \ell_j \text{Ki}_1(\tau_0). \quad (299)$$

(e) $\Sigma_i \neq 0$:

$$\mathcal{D}_i = \frac{\ell_i}{\Sigma_i} - \frac{1}{\Sigma_i^2} [\text{Ki}_3(0) - \text{Ki}_3(\Sigma_i \ell_i)]. \quad (300)$$

(f) $\Sigma_i = 0$:

$$\mathcal{D}_i = \frac{\pi \ell_i^2}{4}. \quad (301)$$

The above relations are implemented in Matlab using the following two scripts:

```
function f=cij_f(tau0,sigi,sigj,segmenti,segmentj)
% function f=cij_f(tau0,sigi,sigj,segmenti,segmentj)
% (c) 2006 Alain Hebert, Ecole Polytechnique de Montreal
if sigi ~= 0 && sigj ~= 0
    f=(akin(3,tau0)-akin(3,tau0+sigi*segmenti)-akin(3,tau0+sigj*segmentj)+ ...
        akin(3,tau0+sigi*segmenti+sigj*segmentj))/(sigi*sigj);
```

```

elseif sigi == 0 && sigj ~ = 0
    f=(akin(2,tau0)-akin(2,tau0+sigj*segmentj))*segmenti/sigj ;
elseif sigi ~ = 0 && sigj == 0
    f=(akin(2,tau0)-akin(2,tau0+sigi*segmenti))*segmentj/sigi ;
else
    f=akin(1,tau0)*segmenti*segmentj ;
end

```

and

```

function f=di_f(sig,segment)
% function f=di_f(sig,segment)
% (c) 2006 Alain Hebert, Ecole Polytechnique de Montreal
if sig ~ = 0
    f=segment/sig-(akin(3,0)-akin(3,sig*segment))/sig^2 ;
else
    f=pi*segment^2/4 ;
end

```

The external-boundary condition of a 1D cylindrical geometry is introduced by choosing an albedo β^+ set to zero for representing a voided boundary, or set to one for representing reflection of particles. The voided-boundary condition is similar to the vacuum condition used for 1D slab geometry. Such a boundary condition is useful in criticality problems for computing the critical radius of tubes. On the other hand, the reflecting boundary condition is implemented in the context of the *Wigner–Seitz approximation* for lattice calculations in reactor physics. As introduced in [▶ 3.2](#), the Wigner–Seitz approximation consists of replacing the exact boundary with an *equivalent cylindrical boundary*, as shown in [▶ Fig. 18](#), taking care to conserve the amount of moderator present in the cell. The correct condition in this case is the *white-boundary condition* in which the particles are reflected back, on the cylindrical boundary, with an isotropic angular distribution in the radial plane.

We present two cylinderization techniques on the unit cell of [▶ Fig. 18](#). The square boundary of side a must be replaced by a cylindrical boundary of radius R^* . Moreover, all

■ **Figure 18**
Wigner–Seitz boundary approximation

cross-sections Σ_x in the outer-most region must be replaced by cross-sections Σ_x^* . The *Wigner cylinderization* consists in preserving the volume of the outermost region. We write

$$R^* = \sqrt{\frac{a^2}{\pi}} \quad \text{and} \quad \Sigma_x^* = \Sigma_x. \quad (302)$$

The *Askew cylinderization* consists in preserving the outer surface of the unit cell and modifying the number density of the nuclei present in the outermost region. We write

$$R^* = \frac{2a}{\pi} \quad \text{and} \quad \Sigma_x^* = \frac{a^2 - \pi R^2}{\pi[(R^*)^2 - R^2]} \Sigma_x. \quad (303)$$

The application of a white-boundary condition is based on the transformation of the reduced collision probability matrix $\mathbb{P} = \{p_{ij}, i = 1, I \text{ and } j = 1, I\}$ corresponding to a vacuum-boundary condition. We first compute the *escape probability* vector $\mathbf{P}_{iS} = \{P_{iS}, i = 1, I\}$, a column vector whose components are obtained from

$$P_{iS} = 1 - \sum_{j=1}^I p_{ij} \Sigma_j \quad (304)$$

representing the probability for a neutron born in region i to escape from the unit cell without collision.

We define P_{Si} as the probability for a neutron, entering the unit cell through its boundary with an isotropic angular distribution, to first collide in region i . It is possible to show that

$$p_{Si} = \frac{P_{Si}}{\Sigma_i} = \frac{4V_i}{S} P_{iS}, \quad (305)$$

where S is the surface of the boundary.

The *transmission probability* P_{SS} is, therefore, given as

$$P_{SS} = 1 - \sum_{i=1}^I p_{Si} \Sigma_i. \quad (306)$$

The reduced-collision probability matrix $\tilde{\mathbb{P}} = \{\tilde{p}_{ij}, i = 1, I \text{ and } j = 1, I\}$ corresponding to a white-boundary condition can now be obtained using

$$\tilde{\mathbb{P}} = \mathbb{P} + \frac{\beta^+}{1 - \beta^+ P_{SS}} \mathbf{P}_{iS} \mathbf{P}_{Sj}^\top. \quad (307)$$

The collision-probability matrix $\tilde{\mathbb{P}}$ can be scattering-reduced using (249) and used in the matrix-flux equation of (248).

4.5 Spherical 1D Geometry

Computing the tracking and collision probabilities in 1D spherical geometry is similar to the cylindrical geometry case. The tracking is obtained by the `sybt1d` procedure

of Appendices [Section 1](#) and [Section 2](#). Equation (287) is replaced by

$$p_{ij} = \frac{1}{V_i} \int_{V_i} d^3 r' \int_{\mathcal{I}_j} ds e^{-\tau(s)} \quad (308)$$

which can be rewritten as

$$p_{ij} = \frac{2\pi}{V_i} \left\{ \int_0^{r_{i-1/2}} dh h \int_0^{\ell_i} d\ell' \int_0^{\ell_j} d\ell \left[e^{-[(\tau_{ij} + \tau_{ii} + \Sigma_i \ell_i) + \Sigma_i \ell' + \Sigma_j \ell]} + e^{-(\tau_{ij} + \Sigma_i \ell' + \Sigma_j \ell)} \right] \right. \\ \left. + \int_{r_{i-1/2}}^{r_{i+1/2}} dh h \int_0^{\ell_i} d\ell' \int_0^{\ell_j} d\ell e^{-(\tau_{ij} + \Sigma_i \ell' + \Sigma_j \ell)} \right\} \quad \text{if } i < j, \quad (309)$$

where $r_{i\pm 1/2}$ are the radii-bounding region i and

$$p_{ii} = \frac{2\pi}{V_i} \left\{ \int_0^{r_{i-1/2}} dh h \int_0^{\ell_i} d\ell' \left[2 \int_{\ell'}^{\ell_i} d\ell e^{-[\Sigma_i (\ell - \ell')]} + \int_0^{\ell_i} d\ell e^{-[\tau_{ii} + \Sigma_i (\ell' + \ell)]} \right] \right. \\ \left. + \int_{r_{i-1/2}}^{r_{i+1/2}} dh h \int_0^{\ell_i} d\ell' \int_{\ell'}^{\ell_i} d\ell e^{-[\Sigma_i (\ell - \ell')]} \right\}, \quad (310)$$

where the first- and second terms of (309) and (310) are the contributions from tracks ① and ②, respectively. All the collision probability components with $i > j$ are computed using the reciprocity (229).

These equations can be simplified by introducing the following definitions:

$$C_{ij}(\tau_0) = \int_0^{\ell_i} d\ell' \int_0^{\ell_j} d\ell e^{-(\tau_0 + \Sigma_i \ell' + \Sigma_j \ell)} \quad (311)$$

and

$$\mathcal{D}_i = \int_0^{\ell_i} d\ell' \int_{\ell'}^{\ell_i} d\ell e^{-\Sigma_i (\ell - \ell')} \quad (312)$$

so that

$$p_{ij} = \frac{2\pi}{V_i} \left\{ \int_0^{r_{i-1/2}} dh h [C_{ij}(\tau_{ij} + \tau_{ii} + \Sigma_i \ell_i) + C_{ij}(\tau_{ij})] + \int_{r_{i-1/2}}^{r_{i+1/2}} dh h C_{ij}(\tau_{ij}) \right\} \quad (313)$$

if $i < j$, and

$$p_{ii} = \frac{2\pi}{V_i} \left\{ \int_0^{r_{i-1/2}} dh h [2\mathcal{D}_i + C_{ii}(\tau_{ii})] + \int_{r_{i-1/2}}^{r_{i+1/2}} dh h \mathcal{D}_i \right\}. \quad (314)$$

Integration in ℓ and ℓ' is performed next, leading to the following relations:

(a) $\Sigma_i \neq 0$ and $\Sigma_j \neq 0$:

$$C_{ij}(\tau_0) = \frac{1}{\Sigma_i \Sigma_j} \left[e^{-\tau_0} - e^{-(\tau_0 + \Sigma_i \ell_i)} - e^{-(\tau_0 + \Sigma_j \ell_j)} + e^{-(\tau_0 + \Sigma_i \ell_i + \Sigma_j \ell_j)} \right]. \quad (315)$$

(b) $\Sigma_i = 0$ and $\Sigma_j \neq 0$:

$$C_{ij}(\tau_0) = \frac{\ell_i}{\Sigma_j} \left[e^{-\tau_0} - e^{-(\tau_0 + \Sigma_j \ell_j)} \right]. \quad (316)$$

(c) $\Sigma_i \neq 0$ and $\Sigma_j = 0$:

$$C_{ij}(\tau_0) = \frac{\ell_j}{\Sigma_i} \left[e^{-\tau_0} - e^{-(\tau_0 + \Sigma_i \ell_i)} \right]. \quad (317)$$

(d) $\Sigma_i = \Sigma_j = 0$:

$$C_{ij}(\tau_0) = \ell_i \ell_j e^{-\tau_0}. \quad (318)$$

(e) $\Sigma_i \neq 0$:

$$D_i = \frac{\ell_i}{\Sigma_i} - \frac{1}{\Sigma_i^2} \left[1 - e^{-\Sigma_i \ell_i} \right]. \quad (319)$$

(f) $\Sigma_i = 0$:

$$D_i = \frac{\ell_i^2}{2}. \quad (320)$$

4.6 Unstructured 2D Finite Geometry

The calculation of collision, escape, and transmission probabilities in unstructured 2D geometry is based on the generalization of (288) and (289) to concave volumes (Hébert 1981). In the general unstructured 2D case, the tracks are no longer identical for different values of the azimuthal angle ε . The integration domain for computing the collision probabilities can be either an infinite lattice or a finite geometry V surrounded by an external boundary ∂V . The former case is similar to the approach introduced in [4.3](#) and is beyond the level of this handbook. However, the calculation of collision probabilities in finite-geometry cases will be studied in detail.

We have chosen to present the *square pincell* geometry as an illustration of the more general unstructured 2D geometry. This simplified geometry is illustrated in [Fig. 19](#).

The approach used for this simple pincell geometry can be generalized to more complex 2D unstructured geometries, such as the BASALA assembly, depicted in [Fig. 20](#). This assembly

■ Figure 19

2D square pincell geometry. This geometry is among the simplest type of unstructured 2D finite geometry that can be processed using a tracking approach

Figure 20
2D BASALA geometry

represents an experimental setup for studying mixed-oxide recycling in boiling water reactors (BWR) (Le Tellier et al. 2008). The tracking procedure presented in Appendices Section 3 and Section 4 can be generalized to these types of geometries, but the complexity of the corresponding tracking algorithms is far beyond the level of this handbook.

Sets of tracks are drawn over the complete 2D domain. Each set is characterized by a given angle ε and contains parallel tracks covering the domain. Tracks in a set can be separated by a constant distance Δh or can be placed at optimal locations, as depicted in Fig. 21a and b, respectively. Each track is used forward and backward, corresponding to angles ε and $-\varepsilon$. The track-generation procedure is described in Appendices Section 3 and Section 4 for the particular case of a 2D square pincell.

In the case of convex volumes i and j , a collision-probability component is given by (288) and (289) as

$$p_{ij} = \frac{1}{2\pi V_i} \int_0^{2\pi} d\varepsilon \int_{h_{\min}}^{h_{\max}} dh \int_0^{\ell_i} d\ell' \int_0^{\ell_j} d\ell \text{Ki}_1(\tau_{ij} + \Sigma_i \ell' + \Sigma_j \ell) \quad \text{if } i \neq j, \quad (321)$$

where τ_{ij} is the optical path of the materials between regions i and j and

$$p_{ii} = \frac{1}{2\pi V_i} \int_0^{2\pi} d\varepsilon \int_{h_{\min}}^{h_{\max}} dh \int_0^{\ell_i} d\ell' \int_{\ell'}^{\ell_i} d\ell \text{Ki}_1[\Sigma_i (\ell - \ell')]. \quad (322)$$

Figure 21
Tracking a 2D pincell geometry (a) Rectangular quadrature and (b) Gaussian quadrature

Figure 22
Integration of escape probabilities in 2D x - y geometry

Similarly, escape and transmission probability components are obtained after integration of (238) and (239) as

$$P_{iS_\beta} = \frac{1}{2\pi V_i} \int_0^{2\pi} d\varepsilon \int_{h_{\min}}^{h_{\max}} dh \int_0^{\ell_i} d\ell \text{Ki}_2(\tau_{i\beta} + \Sigma_i \ell), \quad (323)$$

where $\tau_{i\beta}$ is the optical path between region i and surface S_β , as depicted in Fig. 22, and

$$P_{S_\alpha S_\beta} = \frac{2}{\pi S_\alpha} \int_0^{2\pi} d\varepsilon \int_{h_{\min}}^{h_{\max}} dh \text{Ki}_3(\tau_{\alpha\beta}). \quad (324)$$

These equations can be simplified by introducing (294) and (295), together with the following definition:

$$\mathcal{E}_i(\tau_0) = \int_0^{\ell_i} d\ell \text{Ki}_2(\tau_0 + \Sigma_j \ell), \quad (325)$$

where $\tau_{\alpha\beta}$ is the optical path between surface S_α and surface S_β , so that

$$p_{ij} = \frac{1}{2\pi V_i} \int_0^{2\pi} d\varepsilon \int_{h_{\min}}^{h_{\max}} dh \mathcal{C}_{ij}(\tau_{ij}) \quad \text{if } i \neq j, \quad (326)$$

$$p_{ii} = \frac{1}{2\pi V_i} \int_0^{2\pi} d\varepsilon \int_{h_{\min}}^{h_{\max}} dh \mathcal{D}_i \quad (327)$$

and

$$P_{iS_\beta} = \frac{1}{2\pi V_i} \int_0^{2\pi} d\varepsilon \int_{h_{\min}}^{h_{\max}} dh \mathcal{E}_i(\tau_{i\beta}). \quad (328)$$

The analytical reduction of (294) and (295) is given in (296)–(301). Analytical reduction of $\mathcal{E}_i(\tau_0)$ leads to the following relations:

(a) $\Sigma_i \neq 0$:

$$\mathcal{E}_i(\tau_0) = \frac{1}{\Sigma_i} [\text{Ki}_3(\tau_0) - \text{Ki}_3(\tau_0 + \Sigma_i \ell_i)]. \quad (329)$$

(b) $\Sigma_i = 0$:

$$\mathcal{E}_i(\tau_0) = \ell_i \text{Ki}_2(\tau_0). \quad (330)$$

The above relations are implemented in Matlab using the following script:

```
function f=ei_f(tau0,sig,segment)
% function f=ei_f(tau0,sig,segment)
% (c) 2008 Alain Hebert, Ecole Polytechnique de Montreal
if sig ~= 0
    f=(akin(3,tau0)-akin(3,tau0+sig*segment))/sig;
else
    f=segment*akin(2,tau0);
end
```

The algorithm for computing p_{ij} , P_{iS_β} , and $P_{S_\alpha S_\beta}$ is greatly simplified by the definition of a symmetric matrix \mathbb{T} of order $\Lambda + I$, where Λ is the total number of surfaces and I is the total number of volumes. The components of \mathbb{T} are defined as

$$t_{\alpha,\beta} = \frac{S_\alpha}{4} P_{S_\alpha S_\beta}, \quad t_{\Lambda+i,\beta} = V_i P_{iS_\beta} \quad \text{and} \quad t_{\Lambda+i,\Lambda+j} = V_i p_{ij}. \quad (331)$$

Unstructured geometries may contain concave volumes, causing additional terms to appear in (321)–(324). These terms exist even for the simple pincell geometry of  Fig. 19. A straightforward way to present the integration algorithm of (321)–(324) in the presence of concave volumes is to provide a Matlab script implementing their practical evaluation. The simplicity of this script is remarkable. Matrix \mathbb{T} is obtained using the tracking information of the 2D geometry and the array of macroscopic total cross-sections in each region as input. This script follows:

```

function tij=tij_2d(track,sigt)
% integration of the collision, escape and transmission probabilities
% in unstructured finite 2D geometry.
% function tij=tij_2d(track,sigt)
% (c) 2009 Alain Hebert, Ecole Polytechnique de Montreal
indpos=@(i,j) max(i,j).*(max(i,j)-1)./2+min(i,j);

            jrs=jrs+nsurf ; iij=indpos(irt,jrs) ;
            if irt <= nsurf
                tij(iij)=tij(iij)+wei*ei_f(tau0,sig3,seg3) ;
            else
                wi3=cij_f(tau0,sig1,sig3,seg1,seg3) ;
                if jrs == irt, wi3=2.0*wi3 ; end
                tij(iij)=tij(iij)+wei*wi3 ;
            end
            tau0=tau0+seg3*sig3 ;
        end
        iij=indpos(irt,jsurf) ;
        if irt <= nsurf
            wi3=akin(3,tau0) ;
            if isurf == jsurf, wi3=2.0*wi3 ; end
            tij(iij)=tij(iij)+wei*wi3 ;
        else
            tij(iij)=tij(iij)+wei*ei_f(tau0,sig1,seg1) ;
        end
        seg1=seg2 ; sig1=sig2 ;
    end
    iij=indpos(irs,jsurf) ; tij(iij)=tij(iij)+wei*ei_f(0.0,sig1,seg1) ;
    k=k+km ;
end
tij(:)=tij(:).*track(5)^2 ;

```

Script `tij_2d` implements the core algorithm for computing the \mathbb{T} matrix corresponding to finite 2D unstructured geometries. The symmetric matrix \mathbb{T} is returned in triangular storage mode. The tracking script `sybt2d` of Appendices [Section 3](#) and [Section 4](#) is limited to pincell geometries, but the \mathbb{T} integration script `tij_2d` is general, as long as the geometry domain is

finite. The script calls functions `cij_f`, `di_f` and `ei_f`, the former two defined in [4.4](#). We also note that these three functions do not deal with situations where the cross-section values are small and approach zero. A production implementation should take this possibility into consideration using power series. Finally, it is worth noting that the evaluation of functions `akin` is time consuming. Typical production implementations generally rely on piecewise linear or quadratic fits to evaluate these functions.

There is no guarantee that the collision, escape, and transmission probability matrices obtained that way are conservative. Conservation relations can be forced using a consistent normalization of the collision probability matrices. Many normalization techniques are available, but the approach promoted by Villarino (1992) is highly recommended.

The Villarino–Stamm’ler normalization is based on the symmetric matrix \mathbb{T} defined by (331) and on the definition of two vectors defined as

$$\mathbf{s} = \text{col}\{(1; \alpha = 1, \Lambda), (\Sigma_i; i = 1, I)\}$$

and

$$\mathbf{g} = \text{col}\{(S_\alpha/4; \alpha = 1, \Lambda), (V_i; i = 1, I)\}. \quad (332)$$

Using this definition, reciprocity (240) and (241) are satisfied if matrix \mathbb{T} remains symmetric. Conservation (242) and (243) are written as

$$\mathbb{T} \mathbf{s} = \mathbf{g}. \quad (333)$$

Conservation relations are imposed *a posteriori* by computing a normalized matrix $\hat{\mathbb{T}}$ preserving its symmetry and satisfying (333). The additive normalization proposed by Villarino and Stamm’ler consists in finding a set of $\Lambda + I$ factors z_ℓ defined in such a way that

$$\tilde{t}_{\ell m} = (z_\ell + z_m) t_{\ell m}, \quad \ell, m = 1, \Lambda + I. \quad (334)$$

Substitution of (334) into (333) leads to

$$z_\ell \sum_m t_{\ell m} s_m + \sum_m z_m t_{\ell m} s_m = \sum_m \left[\delta_{\ell m} \sum_k t_{\ell k} s_k + t_{\ell m} s_m \right] z_m = g_\ell, \quad \ell = 1, \Lambda + I. \quad (335)$$

A fixed-point iteration for solving this linear equation can be written as

$$z_\ell^{(n+1)} = \frac{g_\ell - \left[\sum_{m < \ell} t_{\ell m} s_m z_m^{(n+1)} + \sum_{m > \ell} t_{\ell m} s_m z_m^{(n)} \right]}{t_{\ell \ell} s_\ell + \sum_m t_{\ell m} s_m}, \quad (336)$$

where $\ell = 1, \Lambda + I$, and where n is the iteration index.

Fixed-point iterations are initialized using $z_\ell^{(0)} = 1/2; \forall \ell$. Convergence can be accelerated by using a residue-minimizing approach.

The final assembly step consists in introducing albedo-boundary conditions to our unstructured finite geometry. A *white-boundary condition*, similar to the condition presented at the end of [4.4](#), can be implemented in a straightforward way. The normalized $\hat{\mathbb{T}}$ matrix can be transformed into collision, escape, and transmission probabilities using (331). The resulting matrices

are defined as

$$\mathbb{P}_{\text{vv}} = \{p_{ij}; i = 1, I \text{ and } j = 1, I\}, \quad \mathbb{P}_{\text{vS}} = \{P_{iS_\alpha}; i = 1, I \text{ and } \beta = 1, \Lambda\},$$

$$\mathbb{P}_{\text{Sv}} = \{P_{S_\alpha j}; \alpha = 1, \Lambda \text{ and } j = 1, I\}$$

and

$$\mathbb{P}_{\text{SS}} = \{P_{S_\alpha S_\beta}; \alpha = 1, \Lambda \text{ and } \beta = 1, \Lambda\}. \quad (337)$$

The flux and outgoing boundary current values are related to incoming boundary current and source values using (244). They are written in matrix form as

$$\begin{aligned} \Phi &= \mathbb{P}_{\text{vS}} J^- + \mathbb{P}_{\text{vv}} Q, \\ J^+ &= \mathbb{P}_{\text{SS}} J^- + \mathbb{P}_{\text{Sv}} Q, \end{aligned} \quad (338)$$

where $J^+ = \{\varphi_{0,\alpha}^+; \alpha = 1, \Lambda\}$, $J^- = \{\varphi_{0,\beta}^-; \beta = 1, \Lambda\}$, $Q = \{Q_i; i = 1, I\}$, and $\Phi = \{\phi_j; j = 1, I\}$.

A white-boundary condition is set by assigning unit albedos ($\beta_\alpha = 1$) on each boundary surface. A geometric equation can be written in terms of albedo values β_α as

$$\mathbb{A} = \text{diag}\{\beta_\alpha; \alpha = 1, \Lambda\} \quad (339)$$

and used to relate outgoing and incoming boundary currents using

$$J^- = \mathbb{A} J^+. \quad (340)$$

Combining (338) and (340) leads to a standard collision probability matrix equation, written as

$$\Phi = \hat{\mathbb{P}}_{\text{vv}} Q, \quad (341)$$

where the *closed* collision probability matrix is given as

$$\hat{\mathbb{P}}_{\text{vv}} = \mathbb{P}_{\text{vv}} \hat{\mathbb{P}}_{\text{SS}} \mathbb{P}_{\text{Sv}}, \quad (342)$$

where

$$\hat{\mathbb{P}}_{\text{SS}} = \mathbb{A} (\mathbb{I} - \mathbb{P}_{\text{SS}} \mathbb{A})^{-1}. \quad (343)$$

The complete assembly sequence implementing the collision-probability method in unstructured 2D finite geometry can be summarized as follows:

1. A tracking file is produced after analysis of the geometry. This approach is presented in **► Sects. 3** and **► 4** for the particular case of a 2D square pincell. The same tracking can usually be used in all energy groups.
2. The diagonal matrix \mathbb{T} is obtained by integration of the tracking using the algorithm of script `t i j _ 2 d`. This operation must be repeated in every energy group.
3. The \mathbb{T} matrix is normalized using the Villarino–Stamm’ler method.
4. A *closed*-reduced collision probability matrix is computed using (342) and (343).
5. The scattering-reduced collision probability matrix \mathbb{W} is computed using (249).

5 The Discrete Ordinates Method

The discrete ordinates method, also called the S_N method, is a discretization of the differential form of the transport equation. The angular flux is discretized according to discrete values and the particle flux is solved along each angular base point. This method is the evolution of an approach used in radiation transfer theory for stellar atmospheres (Chandrasekhar 1960). It was later adapted in reactor physics by Carlson and Bell (1958).

The basic difference relations of the S_N method are obtained from the straightforward discretization of the one-speed Boltzmann equation, evaluated at specific angles. The number of angles is a function of N , an even integer. Different relations are obtained, depending on the geometry. In each case, a fixed-point iterative strategy will emerge from the difference relations. However, powerful preconditioners and acceleration strategies will be required to ensure convergence in many practical cases.

5.1 Quadrature Sets in the Method of Discrete Ordinates

The discrete ordinate, or S_N method, is based on the discretization of the angular variable Ω as a set of discrete directions Ω_n defined in terms of specific-direction cosines. The direction cosines are chosen so as to integrate polynomials in direction cosines with maximum accuracy. Moreover, the S_N method must be consistent with diffusion theory, even at low N values. Different quadrature sets are used, depending on the type of geometry.

In 1D slab and spherical geometries, the transport equation is a function of only one direction cosine μ . In this case, a N -point Gauss-Legendre quadrature is generally used. This quadrature is written as

$$\int_{-1}^1 d\mu f(\mu) \simeq \sum_{n=1}^N \mathcal{W}_n f(\mu_n), \quad (344)$$

where the weights \mathcal{W}_n and base points μ_n are those of the classical Gauss-Legendre quadrature. This quadrature is known to be exact for polynomial functions $f(\mu)$ of degree equal or less than $2N - 1$, so that

$$\int_{-1}^1 d\mu \mu^k = \sum_{n=1}^N \mathcal{W}_n \mu_n^k = \begin{cases} \frac{2}{k+1} & \text{if } k \text{ is even,} \\ 0 & \text{if } k \text{ is odd,} \end{cases} \quad \forall 0 \leq k \leq 2N - 1. \quad (345)$$

In the more general case where the transport equation is a function of all the direction cosines, a two-dimensional quadrature is required to approximate integrals in angular variables. The S_N quadrature over the positive octant is written as

$$\frac{2}{\pi} \int_0^1 d\mu \int_0^{\pi/2} d\phi f(\mu, \eta, \xi) \simeq \sum_{n=1}^M \mathcal{W}_n f(\mu_n, \eta_n, \xi_n), \quad (346)$$

where $\eta = \sqrt{1 - \mu^2} \cos \phi$, $\xi = \sqrt{1 - \mu^2} \sin \phi$, and $M = N(N + 2)/8$. A solid angle is associated to each direction Ω_n , so that

$$\mathcal{W}_n = \frac{1}{4\pi} \int_{\Omega_n} d^2\Omega \quad (347)$$

with

$$\sum_{n=1}^M \mathcal{W}_n = 1. \quad (348)$$

In this case, it is generally recommended to use a two-dimensional quadrature where the base points are selected on the unit sphere in such a way as to preserve the symmetry of the eight octants with respect to $\pi/2$ rotations. This approach leads to the *level-symmetric* quadratures as represented in  Fig. 23. The projection of the base points on each Cartesian axis leads to the same set of N -direction cosine values. This choice reduces the number of degrees of freedom for the positioning of base points. It can be shown that the set of direction cosine values on each axis is represented by

$$\mu_p^2 = \mu_1^2 + (p-1) \frac{2(1-3\mu_1^2)}{N-2}, \quad 1 \leq p \leq \frac{N}{2}, \quad (349)$$

where μ_1 is the projection of the first base point in the interval $0 < \mu_1^2 \leq 1/3$. The choice of μ_1 is arbitrary, except in S_2 case where the only available value is $\mu_1^2 = 1/3$. For μ_1 small, the base points are located near the limits of the $[0, 1]$ interval and are concentrated around the Cartesian axis. If the value of μ_1 is close to $1/\sqrt{3}$, the base points are located around the middle direction of each octant.

Weights associated with each base point a subject to symmetry constraints. For $N = 2$, there is only one direction per octant and one corresponding weight. For $N = 4$, the three directions

 Figure 23

S_6 level-symmetric quadrature

per octant must share the same weight, for symmetry reasons. In general, for all orders $N \geq 6$, the symmetry imposes equal weights for all directions belonging to a set of positions invariant with respect to $\pi/2$ rotations. For low values of N , the number of distinct weights per octant is equal to

$$N_w = 1 + \frac{N(N + 8) - 1}{48}. \tag{350}$$

► *Figure 24* represents the level-symmetric weight configuration for one octant showing base points of equal weight. Considering the free choice for μ_1 , the total number of degrees of freedom for a level-symmetric quadrature is $N_w + 1$. These degrees of freedom can be used in many ways to try to satisfy as many even-moments of direction cosines as possible. There is no need to include odd-moment conditions since these are automatically satisfied by level-symmetric quadrature sets when the integral is performed over 4π solid angles. Depending on the choice of even-moment conditions, different level-symmetric quadrature sets are obtained.

A first set of level-symmetric quadratures has been proposed in Carlson (1971) so as to integrate a polynomial function in direction cosines with maximum accuracy. These quadratures are represented in ► *Table 2*. They are exact for integrating the following polynomials for low values of k and ℓ :

$$\frac{2}{\pi} \int_0^1 d\mu \int_0^{\pi/2} d\phi \mu^k \eta^\ell = \sum_{m=1}^M \mathcal{W}_m \mu_m^k \eta_m^\ell = \begin{cases} \frac{1}{k+1} & \text{if } \ell = 0, \\ \frac{1}{k+\ell+1} \prod_{i=1, \text{ odd}}^{\ell-1} \frac{i}{k+i} & \text{if } \ell \geq 2, \end{cases} \tag{351}$$

where k and ℓ are even integers. Quadratures in ► *Table 2* are exact for $k + \ell \leq N$ if $N \leq 6$, for $k \leq 12$ ($\ell = 0$) and $k + \ell \leq 8$ if $N = 8$, for $k \leq 20$ ($\ell = 0$) and $k + \ell \leq 10$ if $N = 12$, and for $k \leq 30$ ($\ell = 0$) and $k + \ell \leq 14$ if $N = 16$.

Jenal et al. (1977) proposes a root-mean square approach for obtaining the quadrature sets in such a way that polynomials (351) are integrated exactly for all values of k and ℓ with

^a The weights are normalized to 1 in one octant

$0 \leq k + \ell < N$. In this work, the first base point is always taken equal to

$$\mu_1 = \frac{1}{\sqrt{3(N-1)}}. \quad (352)$$

It is possible to gain one order of accuracy by choosing the optimal value of μ_1 . The quadrature sets given in [Table 3](#) can integrate polynomials (351) exactly for all values of k and ℓ such that $0 \leq k + \ell \leq N$. An S_N quadrature is therefore able to integrate the spherical harmonics orthogonality in (30) exactly up to order of $\ell = N/2$.

Finally, [Table 4](#) reproduces quadrature sets used in the discrete ordinates code SNOW (Gunther and Kinnebrock 1973). They are given only for historical reasons.

In the particular case of cylindrical 1D geometry, two variables (ξ and ω) are required to determine the direction of the particle. The previous level-symmetric quadratures are consistent with this geometry. However, it is recommended to use the combination of a Gauss–Legendre and Gauss–Chebychev quadrature with the main axis (ξ) parallel to the cylinder axis and the μ axis joining the position of the particle with the cylinder axis, as shown in [Fig. 25](#).

The corresponding S_N quadrature is defined in terms of integer indices p and q as

$$\mu_{p,q} = \sqrt{1 - \xi_p^2} \cos \omega_{p,q} \quad \text{with} \quad 1 \leq p \leq \frac{N}{2} \quad \text{and} \quad 1 \leq q \leq N - 2p + 2, \quad (353)$$

where the values ξ_p are the positive base points of a Gauss–Legendre quadrature and where

$$\omega_{p,q} = \frac{\pi}{2} \left(1 - \frac{N - 2q - 2p + 3}{N - 2p + 2} \right). \quad (354)$$

The corresponding weights of the S_N quadrature are given in terms of the Gauss–Legendre weights \mathcal{W}_p using

$$\mathcal{W}_{p,q} = \frac{\pi \mathcal{W}_p}{N - 2p + 2}. \quad (355)$$

Table 4
Level-symmetric S_N quadratures used in code SNOW

Level	μ_1	Distinct weights		
S_2	0.5773503	1.0		
S_4	0.3333333	0.3333333		
S_6	0.2581989	0.1608612	0.1724721	
S_8	0.2182179	0.1066008	0.1011727	0.0731616

The weights \mathcal{W}_p are normalized to one so that $\mathcal{W}_{p,q}$ is normalized to the solid angle of an octant as

$$\sum_{p=1}^{N/2} \mathcal{W}_p = 1, \quad \sum_{p=1}^{N/2} \sum_{q=1}^{N-2p+2} \mathcal{W}_{p,q} = \pi. \tag{356}$$

A set of $N/2$ zero-weight points is also defined in a direction where the angular redistribution term of the Boltzmann equation vanishes. These points are set at $\omega = \pi$, so that

$$\tilde{\mu}_p \equiv \mu_{p,N-2p+(5/2)} = -\sqrt{1 - \xi_p^2}. \tag{357}$$

Figure 25
 S_6 Gauss–Chebyshev quadrature

Product quadratures can also be used in 1D cylindrical geometry. They are defined in such a way that $\mu_{p,q}$ and $\omega_{p,q}$ can be set as the product of an index p value with an index q value. The product of a Gauss–Legendre and a Gauss–Chebyshev quadrature is defined as

$$\mu_{p,q} = \sqrt{1 - \xi_p^2} \cos \omega_q \quad \text{with } 1 \leq p \leq \frac{N}{2} \quad \text{and } 1 \leq q \leq N, \tag{358}$$

where the values ξ_p are the positive base points of a Gauss–Legendre quadrature and where

$$\omega_q = \frac{\pi}{2} \left(1 - \frac{N - 2q + 1}{N} \right). \tag{359}$$

The corresponding weights of the S_N quadrature are given in terms of the Gauss–Legendre weights \mathcal{W}_p using

$$\mathcal{W}_{p,q} = \frac{\pi \mathcal{W}_p}{N}. \tag{360}$$

The weights \mathcal{W}_p are normalized to one so that $\mathcal{W}_{p,q}$ is normalized to the solid angle of an octant as

$$\sum_{p=1}^{N/2} \mathcal{W}_p = 1, \quad \sum_{p=1}^{N/2} \sum_{q=1}^N \mathcal{W}_{p,q} = \pi. \tag{361}$$

As before, a set of $N/2$ zero-weight points are set at $\omega = \pi$. These points are written as

$$\tilde{\mu}_p \equiv \mu_{p,N+(1/2)} = -\sqrt{1 - \xi_p^2}. \tag{362}$$

5.2 The Difference Relations in 1D Slab Geometry

The first-order form of the linear Boltzmann equation in 1D slab geometry is given in (126). The base points μ_n and weights \mathcal{W}_n are those of an N -point Gauss–Legendre quadrature. After discretization of the direction cosine, we obtain

$$\left[\mu_n \frac{\partial}{\partial x} + \Sigma(x) \right] \phi_n(x) = \sum_{\ell=0}^L \frac{2\ell+1}{2} Q_\ell(x) P_\ell(\mu_n), \quad n = 1, N, \tag{363}$$

where $\phi_n(x) \equiv \phi(x, \mu_n)$. The Legendre moments of the flux are given in terms of the S_N components using

$$\phi_\ell(x) = \sum_{n=1}^N \mathcal{W}_n \phi_n(x) P_\ell(\mu_n), \quad 0 \leq \ell \leq L. \tag{364}$$

The domain is divided in submeshes with constant cross-sections, as depicted in Fig. 26. The mesh-edge and mesh-centered values of the flux are given as $\phi_{n,i\pm 1/2}$ and $\phi_{n,i}$, respectively. The size of submesh i is given by

$$\Delta x_i = x_{i+1/2} - x_{i-1/2}. \tag{365}$$

The next step of the discretization procedure is to integrate (363) over each sub-mesh to obtain the following balance relation:

$$\mu_n \left(\phi_{n,i+1/2} - \phi_{n,i-1/2} \right) + \Delta x_i \Sigma_i \phi_{n,i} = \Delta x_i Q_{n,i}, \quad n = 1, N. \tag{366}$$

Using (125), the source components are defined as

$$Q_{n,i} = \sum_{\ell=0}^L \frac{2\ell+1}{2} Q_{\ell,i} P_\ell(\mu_n) \tag{367}$$

and where the mesh-centered values are given by

$$\phi_{n,i} = \frac{1}{\Delta x_i} \int_{x_{i-1/2}}^{x_{i+1/2}} dx \phi_n(x) \quad \text{and} \quad Q_{\ell,i} = \frac{1}{\Delta x_i} \int_{x_{i-1/2}}^{x_{i+1/2}} dx Q_\ell(x). \tag{368}$$

Equation (366) is an exact relation resulting from integration of (363) over each submesh. We will assume that the incoming left-hand side mesh-edge flux $\phi_{n,i-1/2}$ is known for $\mu_n > 0$

Figure 26
Spatial discretization for slab geometry

and that the incoming right-hand side mesh-edge flux $\phi_{n,i+1/2}$ is known for $\mu_n < 0$. Using these known values, it is possible to compute the outgoing fluxes in each direction, providing that an auxiliary relation is introduced to close the system. One of the most common auxiliary equations is the *diamond-differencing scheme* written as

$$\phi_{n,i} = \frac{1}{2} (\phi_{n,i-1/2} + \phi_{n,i+1/2}). \quad (369)$$

An inner iteration is initiated by assuming incoming fluxes at one boundary and proceeds by computing the other mesh-edge and mesh-centered fluxes recursively using

$$\begin{aligned} \phi_{n,i-1/2} = 2\phi_{n,i} - \phi_{n,i+1/2} & \quad \text{with } \phi_{n,i} = \frac{\Delta x_i Q_{n,i} - 2\mu_n \phi_{n,i+1/2}}{\Delta x_i \Sigma_i - 2\mu_n} & \text{if } \mu_n < 0, \\ \phi_{n,i+1/2} = 2\phi_{n,i} - \phi_{n,i-1/2} & \quad \text{with } \phi_{n,i} = \frac{\Delta x_i Q_{n,i} + 2\mu_n \phi_{n,i-1/2}}{\Delta x_i \Sigma_i + 2\mu_n} & \text{if } \mu_n > 0. \end{aligned} \quad (370)$$

The procedure generally starts from a vacuum boundary if one exists. A linear shooting approach can be used in other cases, in order to match the boundary incoming and outgoing fluxes at the starting boundary. At the end of each inner iteration, we have obtained matching boundary fluxes for a given set of sources $Q_{\ell,i}$. Inner iterations are required because the scattering rate components in $Q_{\ell,i}$ are generally a function of the flux moments $\phi_{\ell,i}$. Note that outer iterations are also required for convergence to the eigenvalue in criticality cases.

At the end of each inner iteration, the Legendre moments of the flux are computed using (364). These values are used to compute the Legendre moments $Q_{\ell,i}$ of the source for the next iteration.

Combining (370), we eliminate edge-mesh fluxes and obtain

$$\phi_{n,i \mp 1/2} = \frac{2\Delta x_i Q_{n,i} + (2|\mu_n| - \Delta x_i \Sigma_i) \phi_{n,i \pm 1/2}}{\Delta x_i \Sigma_i + 2|\mu_n|}. \quad (371)$$

The resulting mesh-averaged flux becomes negative if the numerator becomes negative. The condition for positive flux $\phi_{n,i}$ is

$$(2|\mu_n| - \Delta x_i \Sigma_i) \phi_{n,i \pm 1/2} < 2\Delta x_i Q_{n,i}. \quad (372)$$

This relation must be valid even for zero sources. The positive flux condition becomes

$$\Delta x_i \Sigma_i < 2|\mu_n|. \quad (373)$$

Negative fluxes can be generated if $\Delta x_i \Sigma_i$ is large or if some values of the base points μ_n are small. They are likely to occur when the mesh sizes are large, in high cross-section zones or with high-order angular quadratures.

There is an equivalence between a spherical harmonics solution of order $N-1$, as presented in [3.1](#), and the S_N solution of a 1D slab geometry. We observe that any discrepancy between the two numerical solutions is only due to the Marshak versus Mark treatment of vacuum-boundary conditions. Infinite lattice solutions are identical.

5.3 The Difference Relations in 1D Cylindrical Geometry

The first-order form of the linear Boltzmann equation in 1D cylindrical geometry is given in (141). After integration over the angular subdomain surrounding direction Ω_n , we obtain

$$\begin{aligned} & \frac{1}{\rho} \int_{\Omega_n} d^2\Omega \mu \frac{\partial}{\partial \rho} [\rho \phi(\rho, \xi, \omega)] - \frac{1}{\rho} \int_{\Omega_n} d^2\Omega \frac{\partial}{\partial \omega} [\eta \phi(\rho, \xi, \omega)] \\ & + \Sigma(\rho) \int_{\Omega_n} d^2\Omega \phi(\rho, \xi, \omega) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{\substack{m=0 \\ \ell+m \text{ even}}}^{\ell} Q_{\ell}^m(\rho) \int_{\Omega_n} d^2\Omega R_{\ell}^m(\xi, \omega). \end{aligned} \quad (374)$$

In cylindrical geometry, the direction Ω_n is defined in terms of base points ξ_p and $\omega_{p,q}$. The integration must be done over two octants with $N/2$ axial levels in interval $0 \leq \xi \leq 1$. Each axial level contains $2\mathcal{F}(p)$ base points in interval $0 \leq \omega_{p,q} \leq \pi$, with

$$\mathcal{F}(p) = \begin{cases} N/2 & \text{for a product quadrature,} \\ (N/2) - p + 1 & \text{otherwise,} \end{cases} \quad \text{with } 1 \leq p \leq \frac{N}{2} \quad (375)$$

so that the total number of positive-weight discrete directions is equal to $N^2/4$ for a product quadrature and equal to $N(N+2)/4$ otherwise.

The integrals in (374) can be evaluated as

$$\int_{\Omega_n} d^2\Omega \mu \frac{\partial}{\partial \rho} [\rho \phi(\rho, \xi, \omega)] = \mathcal{W}_{p,q} \mu_{p,q} \frac{\partial}{\partial \rho} [\rho \phi(\rho, \xi_p, \omega_{p,q})], \quad (376)$$

$$\begin{aligned} \int_{\Omega_n} d^2\Omega \frac{\partial}{\partial \omega} [\eta \phi(\rho, \xi, \omega)] &= \mathcal{W}_p [\eta_{p,q+1/2} \phi(\rho, \xi_p, \omega_{p,q+1/2}) \\ &\quad - \eta_{p,q-1/2} \phi(\rho, \xi_p, \omega_{p,q-1/2})], \end{aligned} \quad (377)$$

$$\int_{\Omega_n} d^2\Omega \phi(\rho, \xi, \omega) = \mathcal{W}_{p,q} \phi(\rho, \xi_p, \omega_{p,q}) \quad (378)$$

and

$$\int_{\Omega_n} d^2\Omega R_{\ell}^m(\xi, \omega) = \mathcal{W}_{p,q} R_{\ell}^m(\xi_p, \omega_{p,q}). \quad (379)$$

We now present the approach proposed by Alcouffe and O'Dell to compute the $\eta_{p,q\pm 1/2}$ values (Alcouffe and O'Dell 1986). For each level ξ_p , the first value η lies on the ξ - μ plane and is therefore zero. These values correspond to the zero-weight points in  Fig. 25. We can write

$$\eta_{p,2\mathcal{F}(p)+(1/2)} = 0 \quad \text{with } 1 \leq p \leq \frac{N}{2}. \quad (380)$$

The other values of $\eta_{p,q\pm 1/2}$ are obtained in such a way as to preserve the constant flux in a case where an infinite, homogenous, and nonabsorbing medium contains a population

of particles, in the absence of sources. In this case, $\phi(\rho, \xi, \omega) = C$, a constant, and (374) reduces to

$$\mathcal{W}_{p,q} \mu_{p,q} C - \mathcal{W}_p (\eta_{p,q+1/2} C - \eta_{p,q-1/2} C) = 0 \quad (381)$$

so that the $\eta_{p,q\pm 1/2}$ values can be computed recursively using

$$\eta_{p,q+1/2} = \eta_{p,q-1/2} + \frac{\mathcal{W}_{p,q}}{\mathcal{W}_p} \mu_{p,q}. \quad (382)$$

Defining $\alpha_{p,q\pm 1/2} = \mathcal{W}_p \eta_{p,q\pm 1/2}$, the recurrence relation simplifies to

$$\alpha_{p,q+1/2} = \alpha_{p,q-1/2} + \mathcal{W}_{p,q} \mu_{p,q}. \quad (383)$$

Equation (374) can therefore be rewritten as

$$\begin{aligned} \mu_{p,q} \frac{\partial}{\partial \rho} [\rho \phi_{p,q}(\rho)] - \frac{1}{\mathcal{W}_{p,q}} [\alpha_{p,q+1/2} \phi_{p,q+1/2}(\rho) - \alpha_{p,q-1/2} \phi_{p,q-1/2}(\rho)] \\ + \rho \Sigma(\rho) \phi_{p,q}(\rho) = \rho \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{\substack{m=0 \\ \ell+m \text{ even}}}^{\ell} Q_{\ell}^m(\rho) R_{\ell}^m(\xi_p, \omega_{p,q}), \end{aligned} \quad (384)$$

where $\phi_{p,q}(\rho) \equiv \phi(\rho, \xi_p, \omega_{p,q})$. The spherical harmonics moments of the flux are given in terms of its S_N components using

$$\phi_{\ell}^m(\rho) = 4 \sum_{p=1}^{N/2} \sum_{q=1}^{2\mathcal{F}(p)} \mathcal{W}_{p,q} \phi_{p,q}(\rho) R_{\ell}^m(\xi_p, \omega_{p,q}), \quad (385)$$

with $0 \leq \ell \leq L$ and $0 \leq m \leq \ell$ with $\ell + m$ even.

The domain is divided in submeshes with constant cross-sections, with $\rho_{1/2} = 0$. The mesh-edge and mesh-centered values of the flux are given as $\phi_{p,q,i\pm 1/2}$ and $\phi_{p,q,i}$, respectively. The volume and surfaces of submesh i are given by

$$V_i = \pi (\rho_{i+1/2}^2 - \rho_{i-1/2}^2) \quad \text{and} \quad S_{i\pm 1/2} = 2\pi \rho_{i\pm 1/2} \quad (386)$$

with $\Delta S_i = S_{i+1/2} - S_{i-1/2}$.

The next step of the discretization procedure is to integrate (384) over each submesh to obtain the following balance relation:

$$\begin{aligned} \mu_{p,q} (S_{i+1/2} \phi_{p,q,i+1/2} - S_{i-1/2} \phi_{p,q,i-1/2}) - \frac{\Delta S_i}{\mathcal{W}_{p,q}} (\alpha_{p,q+1/2} \phi_{p,q+1/2,i} \\ - \alpha_{p,q-1/2} \phi_{p,q-1/2,i}) + V_i \Sigma_i \phi_{p,q,i} = V_i Q_{p,q,i}, \end{aligned} \quad (387)$$

where $1 \leq p \leq N/2$ and $1 \leq q \leq 2\mathcal{F}(p)$. Using (138), the source components are defined as

$$Q_{p,q,i} = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{\substack{m=0 \\ \ell+m \text{ even}}}^{\ell} Q_{\ell,i}^m R_{\ell}^m(\xi_p, \omega_{p,q}) \quad (388)$$

and the mesh-centered values are given by

$$\phi_{p,q,i} = \frac{2\pi}{V_i} \int_{\rho_{i-1/2}}^{\rho_{i+1/2}} d\rho \rho \phi_{p,q}(\rho) \quad \text{and} \quad Q_{\ell,i}^m = \frac{2\pi}{V_i} \int_{\rho_{i-1/2}}^{\rho_{i+1/2}} d\rho \rho Q_{\ell}^m(\rho). \quad (389)$$

In this case, the *diamond-differencing scheme* is written as

$$\phi_{p,q,i} = \frac{1}{2} (\phi_{p,q,i-1/2} + \phi_{p,q,i+1/2}) = \frac{1}{2} (\phi_{p,q-1/2,i} + \phi_{p,q+1/2,i}). \quad (390)$$

We first need knowledge of mesh-centered values of the flux $\phi_{p,1/2,i}$ over the zero-weight points, in order to initialize the recursive solution procedure. We observe that these directions correspond to particles entering the external surface and moving toward the central axis, for discrete values of ξ . The angular redistribution term vanishes on these points so that (139) simplifies to

$$\mu \frac{\partial}{\partial \rho} \phi(\rho, \xi, \pi) + \Sigma(\rho) \phi(\rho, \xi, \pi) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{\substack{m=0 \\ \ell+m \text{ even}}}^{\ell} Q_{\ell}^m(\rho) R_{\ell}^m(\xi, \pi), \quad (391)$$

where $\omega = \pi$ since the particle is moving toward the central axis. Discretization of (391) leads to

$$2\pi\tilde{\mu}_p (\tilde{\phi}_{p,i+1/2} - \tilde{\phi}_{p,i-1/2}) + \Delta S_i \Sigma_i \tilde{\phi}_{p,i} = \Delta S_i \tilde{Q}_{p,i}, \quad (392)$$

where $\tilde{\phi}_{p,i} \equiv \phi_{p,2\mathcal{F}(p)+(1/2),i}$ and $\tilde{Q}_{p,i} \equiv Q_{p,2\mathcal{F}(p)+(1/2),i}$.

The average flux $\tilde{\phi}_{p,i}$ is given in terms of the right-hand side components as

$$\tilde{\phi}_{p,i} = \frac{\Delta S_i \tilde{Q}_{p,i} - 4\pi\tilde{\mu}_p \tilde{\phi}_{p,i+1/2}}{\Delta S_i \Sigma_i - 4\pi\tilde{\mu}_p}, \quad \tilde{\mu}_p < 0, \quad (393)$$

and the corresponding angular edge values are

$$\tilde{\phi}_{p,i-1/2} = 2\tilde{\phi}_{p,i} - \tilde{\phi}_{p,i+1/2}. \quad (394)$$

At completion of this initialization sweep, the angular edge values are discarded and the mesh-centered values $\tilde{\phi}_{p,i}$ are kept.

The finite-weight points are next processed, taking into account the angular redistribution term. In this case, the average flux $\phi_{p,q,i}$ is given in terms of the right-hand side components as

$$\begin{aligned} \phi_{p,q,i} = & \frac{V_i Q_{p,q,i} - \mu_{p,q} (S_{i-1/2} + S_{i+1/2}) \phi_{p,q,i+1/2}}{V_i \Sigma_i - 2\mu_{p,q} S_{i-1/2} + 2\Delta S_i \alpha_{p,q-1/2} / \mathcal{W}_{p,q}} \\ & + \frac{\Delta S_i (\alpha_{p,q-1/2} + \alpha_{p,q+1/2}) \phi_{p,q+1/2,i} / \mathcal{W}_{p,q}}{V_i \Sigma_i - 2\mu_{p,q} S_{i-1/2} + 2\Delta S_i \alpha_{p,q-1/2} / \mathcal{W}_{p,q}} \end{aligned} \quad (395)$$

if $\mu_{p,q} < 0$. The corresponding edge values are

$$\phi_{p,q,i-1/2} = 2\phi_{p,q,i} - \phi_{p,q,i+1/2} \quad \text{and} \quad \phi_{p,q+1/2,i} = 2\phi_{p,q,i} - \phi_{p,q-1/2,i}. \quad (396)$$

Moreover, the average flux $\phi_{p,q,i}$ is given in terms of the left-hand side components as

$$\begin{aligned} \phi_{p,q,i} = & \frac{V_i Q_{p,q,i} + \mu_{p,q} (S_{i-1/2} + S_{i+1/2}) \phi_{p,q,i-1/2}}{V_i \Sigma_i + 2\mu_{p,q} S_{i+1/2} + 2\Delta S_i \alpha_{p,q-1/2} / \mathcal{W}_{p,q}} \\ & + \frac{\Delta S_i (\alpha_{p,q-1/2} + \alpha_{p,q+1/2}) \phi_{p,q+1/2,i} / \mathcal{W}_{p,q}}{V_i \Sigma_i + 2\mu_{p,q} S_{i+1/2} + 2\Delta S_i \alpha_{p,q-1/2} / \mathcal{W}_{p,q}} \end{aligned} \quad (397)$$

if $\mu_{p,q} > 0$. The corresponding edge values are

$$\phi_{p,q,i+1/2} = 2\phi_{p,q,i} - \phi_{p,q,i-1/2} \quad \text{and} \quad \phi_{p,q+1/2,i} = 2\phi_{p,q,i} - \phi_{p,q-1/2,i}. \quad (398)$$

Equations (396) and (398) are used to iterate the flux for particles moving toward the central axis and the external surface, respectively.

The sweep strategy is represented in  Fig. 27 for a fixed ξ level. The iteration is started by assuming a fixed incoming current (either zero or positive) on the external boundary at ρ_I , for all negative (entering) μ values. These points correspond to symbol \otimes in  Fig. 27. The initialization sweep corresponds to the line with $\omega = \pi$ and is indicated by symbol \circ . Using the same incoming current at all angles leads to the *white-boundary condition*, currently used with cylindrical geometry. Next, for each remaining negative μ direction, we perform a backward sweep (from ρ_I to ρ_1) immediately followed by a forward sweep (from ρ_1 to ρ_I) in the corresponding positive μ direction. The complete inner iteration terminates when the flux is available over each point in  Fig. 27, for all ξ levels.

At the end of each inner iteration, the spherical harmonics moments of the flux are computed using mesh-centered values of the flux in (385). These values are used to compute the spherical harmonics moments $Q_{m,i}^{\ell}$ of the source for the next iteration. The outgoing current

 Figure 27

Sweep strategy for one-dimensional cylindrical geometry

on the external boundary is also computed using mesh-edge values of the boundary flux with

$$J^+ = 4 \sum_{p=1}^{N/2} \sum_{q=1}^{(N/2)-p+1} \mathcal{W}_{p,q} \mu_{p,q} \phi_{p,q,I+1/2}. \quad (399)$$

The boundary flux used to start an elementary sweep is a function of the incoming current $J^- = \beta J^+$ using

$$\phi_{p,q,I+1/2} = \frac{J^-}{4 \sum_{p'=1}^{N/2} \sum_{q'=1}^{(N/2)-p'+1} \mathcal{W}_{p',q'} \mu_{p',q'}} \quad \forall p \text{ and } q, \quad (400)$$

where the denominator is a normalization constant used to ensure particle conservation in cases where the albedo β is set to one. Equation (399) corresponds to a white-boundary condition.

A vacuum-boundary condition is represented by setting $J^- = 0$. In this case, a single pair of backward and forward sweeps is sufficient to compute J^+ and complete a single inner iteration. A reflective ($\beta = 1$) or general albedo-boundary condition involves finding the incoming current matching the outgoing current. This operation can be done with a *shooting method* involving two pairs of backward–forward sweeps. The first pair is performed with $J_{\bar{a}}^- = 0$ and leads to a corresponding value of $J_{\bar{a}}^+$. The second pair is performed with $J_{\bar{b}}^- = 1$ and leads to a corresponding value of $J_{\bar{b}}^+$. Using the linear characteristic of the transport operator, one can obtain the correct value of J^- as

$$J^- = \frac{\beta J_{\bar{a}}^+}{1 + \beta (J_{\bar{a}}^+ - J_{\bar{b}}^+)}. \quad (401)$$

5.4 The Difference Relations in 1D Spherical Geometry

The first-order form of the linear Boltzmann equation in 1D spherical geometry is given in (149). After integration over the angular subdomain, we obtain

$$\begin{aligned} & \frac{1}{r^2} \int_{\mu_{n-1/2}}^{\mu_{n+1/2}} d\mu \mu \frac{\partial}{\partial r} [r^2 \phi(r, \mu)] + \frac{1}{r} \int_{\mu_{n-1/2}}^{\mu_{n+1/2}} d\mu \frac{\partial}{\partial \mu} [(1 - \mu^2) \phi(r, \mu)] \\ & + \Sigma(r) \int_{\mu_{n-1/2}}^{\mu_{n+1/2}} d\mu \phi(r, \mu) = \sum_{\ell=0}^L \frac{2\ell + 1}{2} Q_{\ell}(r) \int_{\mu_{n-1/2}}^{\mu_{n+1/2}} d\mu P_{\ell}(\mu). \end{aligned} \quad (402)$$

In spherical geometry, the base points μ_n and weights \mathcal{W}_n are those of an N -point Gauss–Legendre quadrature.

The integrals in (402) can be evaluated as

$$\int_{\mu_{n-1/2}}^{\mu_{n+1/2}} d\mu \mu \frac{\partial}{\partial r} [r^2 \phi(r, \mu)] = \mathcal{W}_n \mu_n \frac{\partial}{\partial r} [r^2 \phi(r, \mu_n)], \quad (403)$$

$$\int_{\mu_{m-1/2}}^{\mu_{m+1/2}} d\mu \frac{\partial}{\partial \mu} [(1 - \mu^2) \phi(r, \mu)] = [\alpha_{m+1/2} \phi(r, \mu_{m+1/2}) - \alpha_{m-1/2} \phi(r, \mu_{m-1/2})], \quad (404)$$

$$\int_{\mu_{m-1/2}}^{\mu_{m+1/2}} d\mu \phi(r, \mu) = \mathcal{W}_n \phi(r, \mu_n) \quad (405)$$

and

$$\int_{\mu_{m-1/2}}^{\mu_{m+1/2}} d\mu P_\ell(\mu) = \mathcal{W}_n P_\ell(\mu_n). \quad (406)$$

We now present the approach to compute the $\alpha_{n\pm 1/2}$ values. The first value α is equal to $1 - (-1)^2 = 0$. The other values of $\alpha_{n\pm 1/2}$ are obtained in such a way as to preserve the constant flux in a case where an infinite, homogeneous and nonabsorbing medium contains a population of particles, in the absence of sources. In this case, $\phi(r, \mu) = C$, a constant, and (402) reduces to

$$2\mathcal{W}_n \mu_n C + (\alpha_{n+1/2} C - \alpha_{n-1/2} C) = 0 \quad (407)$$

so that the $\alpha_{n\pm 1/2}$ values can be computed recursively using

$$\alpha_{n+1/2} = \alpha_{n-1/2} - 2\mathcal{W}_n \mu_n. \quad (408)$$

Equation (402) can therefore be rewritten as

$$\begin{aligned} \mu_n \frac{\partial}{\partial r} [r^2 \phi_n(r)] + \frac{r}{\mathcal{W}_n} [\alpha_{n+1/2} \phi_{n+1/2}(r) - \alpha_{n-1/2} \phi_{n-1/2}(r)] + r^2 \Sigma(r) \phi_n(r) \\ = r^2 \sum_{\ell=0}^L \frac{2\ell+1}{2} Q_\ell(r) P_\ell(\mu_n), \quad n = 1, N, \end{aligned} \quad (409)$$

where $\phi_n(r) \equiv \phi(r, \mu_n)$. The Legendre moments of the flux are given in terms of its S_N components using

$$\phi_\ell(r) = \sum_{n=1}^N \mathcal{W}_n \phi_n(r) P_\ell(\mu_n) \quad \text{with } 0 \leq \ell \leq L. \quad (410)$$

The domain is divided in submeshes with constant cross-sections, with $r_{1/2} = 0$. The mesh-edge and mesh-centered values of the flux are given as $\phi_{n,i\pm 1/2}$ and $\phi_{n,i}$, respectively. The volume and surfaces of submesh i are given by

$$V_i = \frac{4\pi}{3} (r_{i+1/2}^3 - r_{i-1/2}^3) \quad \text{and} \quad S_{i\pm 1/2} = 4\pi r_{i\pm 1/2}^2 \quad (411)$$

with $\Delta S_i = S_{i+1/2} - S_{i-1/2}$.

The next step of the discretization procedure is to integrate (409) over each submesh to obtain the following balance relation:

$$\begin{aligned} \mu_n (S_{i+1/2} \phi_{n,i+1/2} - S_{i-1/2} \phi_{n,i-1/2}) + \frac{\Delta S_i}{2\mathcal{W}_n} [\alpha_{n+1/2} \phi_{n+1/2,i} - \alpha_{n-1/2} \phi_{n-1/2,i}] \\ + V_i \Sigma_i \phi_{n,i} = V_i Q_{n,i}, \end{aligned} \quad (412)$$

where $1 \leq n \leq N$. Using (147), the source components are defined as

$$Q_{n,i} = \sum_{\ell=0}^L \frac{2\ell+1}{2} Q_{\ell,i} P_{\ell}(\mu_n) \quad (413)$$

and the mesh-centered values are given by

$$\phi_{n,i} = \frac{4\pi}{V_i} \int_{\rho_{i-1/2}}^{r_{i+1/2}} dr r^2 \phi_n(r) \quad \text{and} \quad Q_{\ell,i} = \frac{4\pi}{V_i} \int_{r_{i-1/2}}^{r_{i+1/2}} dr r^2 Q_{\ell}(r). \quad (414)$$

In this case, the *diamond differencing scheme* is written as

$$\phi_{n,i} = \frac{1}{2} (\phi_{n,i-1/2} + \phi_{n,i+1/2}) = \frac{1}{2} (\phi_{n-1/2,i} + \phi_{n+1/2,i}). \quad (415)$$

We first need knowledge of mesh-centered values of the flux $\phi_{1/2,i}$ over the zero-weight points, in order to initialize the recursive-solution procedure. We observe that these directions correspond to particles entering the external surface and moving toward the central axis with $\mu = -1$. The angular redistribution term vanishes on these points so that (148) simplifies to

$$-\frac{\partial}{\partial r} \phi_{-1/2}(r) + \Sigma(r) \phi_{-1/2}(r) = \sum_{\ell=0}^L \frac{2\ell+1}{2} Q_{\ell}(r) P_{\ell}(-1). \quad (416)$$

Discretization of (416) leads to

$$-(\tilde{\phi}_{i+1/2} - \tilde{\phi}_{i-1/2}) + \Delta r_i \Sigma_i \tilde{\phi}_i = \Delta r_i \tilde{Q}_i, \quad (417)$$

where $\tilde{\phi}_i \equiv \phi_{1/2,i}$, $\tilde{Q}_i \equiv Q_{1/2,i}$, and $\Delta r_i = r_{i+1/2} - r_{i-1/2}$.

The average flux $\tilde{\phi}_i$ is given in terms of the right-hand side components as

$$\tilde{\phi}_i = \frac{\Delta r_i \tilde{Q}_i + 2\tilde{\phi}_{i+1/2}}{\Delta r_i \Sigma_i + 2}, \quad (418)$$

and the corresponding angular edge values are

$$\tilde{\phi}_{i-1/2} = 2\tilde{\phi}_i - \tilde{\phi}_{i+1/2}. \quad (419)$$

At completion of this initialization sweep, the angular edge values are thrown away and the mesh-centered values $\phi_{1/2,i}$ are kept.

The finite-weight points are processed next, taking into account the angular redistribution term. In this case, the average flux $\phi_{n,i}$ is given in terms of the right-hand side components as

$$\phi_{n,i} = \frac{V_i Q_{n,i} - \mu_n (S_{i-1/2} + S_{i+1/2}) \phi_{n,i+1/2} + \Delta S_i (\alpha_{n-1/2} + \alpha_{n+1/2}) \phi_{n-1/2,i} / 2\mathcal{W}_n}{V_i \Sigma_i - 2\mu_n S_{i-1/2} + \Delta S_i \alpha_{n+1/2} / \mathcal{W}_n} \quad (420)$$

if $\mu_n < 0$. The corresponding edge values are

$$\phi_{n,i-1/2} = 2\phi_{n,i} - \phi_{n,i+1/2} \quad \text{and} \quad \phi_{n+1/2,i} = 2\phi_{n,i} - \phi_{n-1/2,i}. \quad (421)$$

Moreover, the average flux $\phi_{n,i}$ is given in terms of the left-hand side components as

$$\phi_{n,i} = \frac{V_i Q_{n,i} + \mu_n (S_{i-1/2} + S_{i+1/2}) \phi_{n,i-1/2} + \Delta S_i (\alpha_{n-1/2} + \alpha_{n+1/2}) \phi_{n-1/2,i} / 2 \mathcal{W}_n}{V_i \Sigma_i + 2\mu_n S_{i+1/2} + \Delta S_i \alpha_{n+1/2} / \mathcal{W}_n} \quad (422)$$

if $\mu_n > 0$. The corresponding edge values are

$$\phi_{n,i+1/2} = 2\phi_{n,i} - \phi_{n,i-1/2} \quad \text{and} \quad \phi_{n+1/2,i} = 2\phi_{n,i} - \phi_{n-1/2,i}. \quad (423)$$

Equations (421) and (423) are used to iterate the flux for particles moving toward the central axis and the external surface, respectively. The sweep strategy is identical to the one used in the cylindrical 1D case. At the end of each inner iteration, the Legendre moments of the flux are computed using (410). These values are used to compute the Legendre moments $Q_{\ell,i}$ of the source for the next iteration.

5.5 The Difference Relations in 2D Cartesian Geometry

The first-order form of the linear Boltzmann equation in 2D Cartesian geometry is given in (129). The direction Ω_n is defined in terms of base points μ_n and η_n . The integration must be done over four octants, using $N(N+2)/2$ discrete directions, corresponding to a level-symmetric quadrature. After discretization of the direction cosines, we obtain

$$\left[\mu_n \frac{\partial}{\partial x} + \eta_n \frac{\partial}{\partial y} + \Sigma(x, y) \right] \phi_n(x, y) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{\substack{m=-\ell \\ \ell+m \text{ even}}}^{\ell} Q_{\ell}^m(x, y) R_{\ell}^m(\Omega_n), \quad (424)$$

$n = 1, N(N+2)/2$, where $\phi_n(x, y) \equiv \phi(x, y, \mu_n, \eta_n)$. The spherical harmonics moments of the flux are given in terms of the S_N components using

$$\phi_{\ell}^m(x, y) = 2 \sum_{n=1}^{N(N+2)/2} \mathcal{W}_n \phi_n(x, y) R_{\ell}^m(\mu_n, \eta_n, \xi_n). \quad (425)$$

The domain is divided in rectangular submeshes $\{i, j\}$ with constant cross-sections. The x -directed mesh-edge and mesh-centered values of the flux are given as $\phi_{n,i\pm 1/2,j}$ and $\phi_{n,i,j}$, respectively. Similar definitions are used along the y -axis. The dimensions of each sub-mesh are

$$\Delta x_i = x_{i+1/2} - x_{i-1/2} \quad \text{and} \quad \Delta y_j = y_{j+1/2} - y_{j-1/2} \quad (426)$$

corresponding to a volume $V_{i,j} = \Delta x_i \Delta y_j$.

The next step of the discretization procedure is to integrate (424) over each submesh to obtain the following balance relation:

$$\frac{\mu_n}{\Delta x_i} (\phi_{n,i+1/2,j} - \phi_{n,i-1/2,j}) + \frac{\eta_n}{\Delta y_j} (\phi_{n,i,j+1/2} - \phi_{n,i,j-1/2}) + \Sigma_{i,j} \phi_{n,i,j} = Q_{n,i,j}, \quad (427)$$

where $n = 1, N(N+2)/2$. Using (128), the source components are defined as

$$Q_{n,i,j} = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{\substack{m=-\ell \\ \ell+m \text{ even}}}^{\ell} Q_{\ell,i,j}^m R_{\ell}^m(\mu_n, \eta_n, \xi_n) \quad (428)$$

and where the mesh-centered values are given by

$$\phi_{n,i,j} = \frac{1}{V_{i,j}} \int_{x_{i-1/2}}^{x_{i+1/2}} dx \int_{y_{j-1/2}}^{y_{j+1/2}} dy \phi_n(x, y) \quad (429)$$

and

$$Q_{\ell,i,j}^m = \frac{1}{V_{i,j}} \int_{x_{i-1/2}}^{x_{i+1/2}} dx \int_{y_{j-1/2}}^{y_{j+1/2}} dy Q_{\ell}^m(x, y). \quad (430)$$

Equation (427) is an exact relation between one mesh-centered and four mesh-edge flux values. Assuming two mesh-edge values, two supplementary equations are required to obtain the other three values. Again, *diamond-differencing scheme* relations are written as

$$\phi_{n,i,j} = \frac{1}{2} (\phi_{n,i-1/2,j} + \phi_{n,i+1/2,j}) = \frac{1}{2} (\phi_{n,i,j-1/2} + \phi_{n,i,j+1/2}). \quad (431)$$

The flux values are computed by following the particle path. The sweep strategy can be described using generic relations. We first define

$$\begin{aligned} \phi_{n,i-,j} &= \begin{cases} \phi_{n,i-1/2,j} & \text{if } \mu > 0, \\ \phi_{n,i+1/2,j} & \text{if } \mu < 0, \end{cases} & \phi_{n,i+,j} &= \begin{cases} \phi_{n,i+1/2,j} & \text{if } \mu > 0, \\ \phi_{n,i-1/2,j} & \text{if } \mu < 0, \end{cases} \\ \phi_{n,i,j-} &= \begin{cases} \phi_{n,i,j-1/2} & \text{if } \eta > 0, \\ \phi_{n,i,j+1/2} & \text{if } \eta < 0, \end{cases} & \phi_{n,i,j+} &= \begin{cases} \phi_{n,i,j+1/2} & \text{if } \eta > 0, \\ \phi_{n,i,j-1/2} & \text{if } \eta < 0, \end{cases} \end{aligned} \quad (432)$$

so that the sweep relations are

$$\phi_{n,i,j} = \frac{Q_{n,i,j} + (2|\mu_n|/\Delta x_i) \phi_{n,i-,j} + (2|\eta_n|/\Delta y_j) \phi_{n,i,j-}}{\Sigma_{i,j} + (2|\mu_n|/\Delta x_i) + (2|\eta_n|/\Delta y_j)} \quad (433)$$

with

$$\phi_{n,i+,j} = 2\phi_{n,i,j} - \phi_{n,i-,j} \quad \text{and} \quad \phi_{n,i,j+} = 2\phi_{n,i,j} - \phi_{n,i,j-}. \quad (434)$$

The sweep relations can be solved without iterations, provided that the angular flux is known on the domain boundary. The numerical approximation of the flux $\phi_{n,i,j}$ in each mesh, for a given angle Ω_n , is computed from the known components of the source $Q_{n,i,j}$ and from the incoming fluxes $\phi_{n,i-,j}$ and $\phi_{n,i,j-}$ using (433). The outgoing flux components $\phi_{n,i+,j}$ and $\phi_{n,i,j+}$ are computed from (434). The outgoing flux from a cell is the incoming flux of the following mesh in the direction of the traveling particle.

The spatial swapping starts from the boundary meshes where the angular flux is known and proceeds forward in the direction of the particle, as depicted in  Fig. 28. We selected sides $X+$ and $Y+$ as starting boundaries, so that we expect that any vacuum-boundary condition shall be assigned to these two sides in priority. The particles are next assumed to reflect on $X-$ and $Y-$ boundaries (possibly with an albedo condition) and pursue their path toward the $X+$ and $Y+$ boundaries. If a nonvacuum boundary condition is assigned on $X+$ or $Y+$ boundaries, initial flux components are assumed to initiate the spatial swapping on these surfaces. These initial values are taken as equal to one or are recovered from the last inner iteration. No shooting approach is used in 2D Cartesian geometry, so that we need to keep the S_N boundary fluxes $\phi_{n,i+,j}$ and $\phi_{n,i,j+}$ on $X+$ and $Y+$ in the unknown vector, in addition to the spherical harmonic moments $\phi_{\ell,i,j}^m$ inside the domain.

■ Figure 28

Cartesian 2D spatial swapping. The spatial swapping start from the boundary meshes where the angular flux is known and proceed forward in the direction of the particle

At the end of each inner iteration, the spherical harmonics moments of the flux are computed using mesh-centered values of the flux in (425). These values are used to compute the spherical harmonic moments $Q_{m,i,j}^\ell$ of the source for the next iteration.

The above procedure can be generalized to higher spatial discretization orders. The *diamond-differencing scheme* can be written at quadratic and cubic orders for Cartesian approximations (Hébert 2006).

As pointed out in an important paper by Lathrop, the discrete ordinates method in 2D and 3D suffers from a limitation called *ray effect* (Lathrop 1968). The ray effect is an oscillation of the flux distribution about its exact value that can be observed in cases with very little scattering and localized sources. This is caused by the discretization of the angular variable over precise directions Ω_n , producing a numerical solution which is represented as a sum of delta distributions in angle although the exact solution is a continuous distribution in angle. Ray effects do not occur in 1D geometries, since even a plane source produces uncollided neutrons traveling in all $\mu > 0$ and $\mu < 0$ directions (Lewis and Miller 1984). The most straightforward approach to reduce ray effects is to simply increase the order of the discrete ordinates approximation, at the cost of increased CPU resources.

5.6 Synthetic Acceleration

The particle source distribution $Q(\mathbf{r}, \Omega)$ appearing in the right-hand side of the transport equation is written in terms of the within-group scattering-reaction rate using

$$Q(\mathbf{r}, \Omega_n) = \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{m=-\ell}^{\ell} [\Sigma_{w,\ell}(\mathbf{r}) \phi_l^m(\mathbf{r}) + Q_\ell^{\diamond m}(\mathbf{r})] R_\ell^m(\Omega_n), \quad (435)$$

where $\Sigma_{w,\ell}(\mathbf{r})$ is the ℓ th Legendre moment of the macroscopic within-group scattering cross-section, $\phi_l^m(\mathbf{r})$ is a spherical harmonic component of the flux, and $Q_\ell^{\diamond m}(\mathbf{r})$ is a spherical harmonic component of the source representing other contributions such as fission and out-of-group scattering rates. Scattering source iterations are always required with the discrete

ordinates method because the flux component $\phi_l^m(\mathbf{r})$ is obtained in terms of the dependent variable using (425). Introducing an iteration index (κ), the basic *scattering source iterative scheme* is written as

$$\begin{aligned} & \Omega \cdot \nabla \phi^{(\kappa+1)}(\mathbf{r}, \Omega) + \Sigma(\mathbf{r}) \phi^{(\kappa+1)}(\mathbf{r}, \Omega) \\ &= \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{m=-\ell}^{\ell} \left[\Sigma_{w,\ell}(\mathbf{r}) \phi_l^{m,(\kappa)}(\mathbf{r}) + Q_{\ell}^{\diamond m}(\mathbf{r}) \right] R_{\ell}^m(\Omega), \end{aligned} \quad (436)$$

where $\phi_l^{m,(\kappa)}(\mathbf{r})$ are the spherical harmonic flux component computed from the S_N components of the flux obtained at the (κ)th iteration.

As pointed out in Alcouffe (1977), the fixed-point convergence of (436) becomes difficult when the scattering ratio approaches one, a situation that occurs in the presence of purely scattering media. In this case, Alcouffe proposed a preconditioning known as *synthetic acceleration*, based on the following scheme:

$$\begin{aligned} & \Omega \cdot \nabla \phi^{(\kappa+1/2)}(\mathbf{r}, \Omega) + \Sigma(\mathbf{r}) \phi^{(\kappa+1/2)}(\mathbf{r}, \Omega) \\ &= \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{m=-\ell}^{\ell} \left[\Sigma_{w,\ell}(\mathbf{r}) \phi_l^{m,(\kappa)}(\mathbf{r}) + Q_{\ell}^{\diamond m}(\mathbf{r}) \right] R_{\ell}^m(\Omega), \end{aligned} \quad (437)$$

$$\begin{aligned} & \Omega \cdot \nabla \delta \phi^{(\kappa+1/2)}(\mathbf{r}, \Omega) + \Sigma(\mathbf{r}) \delta \phi^{(\kappa+1/2)}(\mathbf{r}, \Omega) \\ & - \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{m=-\ell}^{\ell} \Sigma_{w,\ell}(\mathbf{r}) \delta \phi_l^{m,(\kappa+1/2)}(\mathbf{r}) R_{\ell}^m(\Omega) \\ &= \sum_{\ell=0}^L \frac{2\ell+1}{4\pi} \sum_{m=-\ell}^{\ell} \Sigma_{w,\ell}(\mathbf{r}) \left[\phi_l^{m,(\kappa+1/2)}(\mathbf{r}) - \phi_l^{m,(\kappa)}(\mathbf{r}) \right] R_{\ell}^m(\Omega) \end{aligned} \quad (438)$$

and

$$\phi^{(\kappa+1)}(\mathbf{r}, \Omega) = \phi^{(\kappa+1/2)}(\mathbf{r}, \Omega) + \delta \phi^{(\kappa+1/2)}(\mathbf{r}, \Omega). \quad (439)$$

The above scheme leads to the converged solution of the within-group transport equation in only one iteration, provided that (438) can be solved. This fact can be easily demonstrated by adding (437) and (438) and by canceling the term in $\phi_l^{m,(\kappa)}(\mathbf{r})$. However, (438) is just as difficult to solve as the original transport equation itself. The approach proposed by Alcouffe is to replace (438) by a form of the transport equation that is simpler to solve. He proposed to use a compatible *diffusion equation*, leading to the *diffusion-synthetic acceleration* (DSA) scheme. In his work, (438) is replaced by

$$\begin{aligned} & -\nabla \cdot \frac{1}{3\Sigma(\mathbf{r})} \nabla \delta \phi^{(\kappa+1/2)}(\mathbf{r}) + [\Sigma(\mathbf{r}) - \Sigma_{w,0}(\mathbf{r})] \delta \phi^{(\kappa+1/2)}(\mathbf{r}) \\ &= \Sigma_{w,0}(\mathbf{r}) \left[\phi_0^{0,(\kappa+1/2)}(\mathbf{r}) - \phi_0^{0,(\kappa)}(\mathbf{r}) \right]. \end{aligned} \quad (440)$$

The spherical harmonic flux component with $m = \ell = 0$ at iteration ($\kappa + 1$) are set as

$$\phi_0^{0,(\kappa+1)}(\mathbf{r}) = \phi_0^{0,(\kappa+1/2)}(\mathbf{r}) + \delta \phi^{(\kappa+1/2)}(\mathbf{r}). \quad (441)$$

Alcouffe also pointed out that not any discretization scheme can be used to solve (440). Only specific differentiation approaches are compatible with the diamond-differencing scheme used to solve (437). A compatible diffusion approximation consists in setting $L = 0$ in (438) and using a Raviart-Thomas discretization of the P_1 spherical harmonic equations with Gauss-Legendre integration of the mass matrices, as explained in Hébert (2006). This type of discretization has the greatest compatibility with the diamond-differencing scheme.

Specific attention should be made to the S_N boundary fluxes used to represent nonvacuum boundary conditions in Cartesian 2D geometry. These components of the unknown vector must be accelerated using a relation similar to (441). The solution of the DSA equation is evaluated on each boundary point \mathbf{r}_s and is applied isotropically on each angular component n using

$$\phi_n^{(\kappa+1)}(\mathbf{r}_s) = \phi_n^{(\kappa+1/2)}(\mathbf{r}_s) + \frac{1}{4\pi} \delta\phi^{(\kappa+1/2)}(\mathbf{r}_s). \quad (442)$$

It is important to note that the above synthetic acceleration scheme is equivalent to a preconditioning of the nonaccelerated scheme in (436). We first recognize that (438) or (440) can be written in matrix-operator form as

$$\mathbb{D} \delta\Phi^{(\kappa+1/2)} = \mathbb{E}(\Phi^{(\kappa+1/2)} - \Phi^{(\kappa)}), \quad (443)$$

where Φ (or $\delta\Phi$) is a column vector containing all the spherical harmonic components of the flux (or of the flux increments) in the domain. Equations (437) and (443) can be rewritten in matrix-operator form as

$$\begin{aligned} \Phi^{(\kappa+1/2)} &= \mathbb{W} \Phi^{(\kappa)} + \mathbf{S}, \\ \Phi^{(\kappa+1)} &= \Phi^{(\kappa)} + \mathbb{M}(\Phi^{(\kappa+1/2)} - \Phi^{(\kappa)}) \end{aligned} \quad (444)$$

so that

$$\Phi^{(\kappa+1)} = \Phi^{(\kappa)} + \mathbb{M}(\mathbf{S} - \mathbb{A}\Phi^{(\kappa)}), \quad (445)$$

where

$$\mathbb{M} = \mathbb{I} + \mathbb{D}^{-1} \mathbb{E} \quad \text{and} \quad \mathbb{A} = \mathbb{I} - \mathbb{W}. \quad (446)$$

Equation (445) is a standard preconditioned fixed-point recursion. Setting $\mathbb{M} = \mathbb{I}$ reduces the preconditioned form to the nonaccelerated scheme in (436). This form is compatible with an acceleration procedure based on the minimization of its residual. The *Livolant acceleration* and GMRES(m) methods are efficient acceleration procedures based on this principle. The Livolant method is the simplest approach, requiring minimal storage resources. The GMRES(m) is more efficient at reducing the total number of iterations but relies on sophisticated orthogonalization processes (Saad and Schultz Kelley 1986; 1995).

6 The Method of Characteristics

The method of characteristics (MOC) solves the characteristic form of the transport equation by following the straight neutron paths of the neutral particle as it moves across the complete domain (Askew 1972). This approach is based on an iterative calculation of the particle flux by

solving the transport equation over tracks crossing the complete domain. The MOC is generally applied to the multigroup form of the transport equation and to spatial domains made of regions with piecewise-uniform nuclear properties. The scalar flux per region and energy group is constructed by collecting all mean angular fluxes in terms of the entering angular flux and the source inside the region. Interestingly, the MOC has the capability to use the same tracking information as the collision probability method.

The MOC offers an alternative to the collision probability (CP) method in order to overcome its two main limitations: (1) the CP method produces full square matrices of order equal to the number of regions in the domain, and (2) the CP method is limited to isotropic sources in the LAB. In particular, the MOC is to be preferred in cases where the number of regions exceeds a few hundred.

The application of the MOC to reactor physics was first reported by Askew (1972), followed by a first-production implementation, known as the CACTUS module of WIMS-E (Halsall 1980). CACTUS is based on the concept of *cyclic tracking* where the characteristics are infinite in length and periodic with respect to the lattice. The same idea of periodic characteristics has also been implemented in the MOCC module of DRAGON V3 (Roy 1998) and MCCG module of DRAGON V4 (Le Tellier and Hébert 2006).

Another class of characteristic solvers is based on the explicit representation of boundary conditions and on the use of finite-length characteristics. This class of solvers is noticeably faster than those based on the cyclic-tracking approach and is used in production lattice calculations. The most widely known implementations are those of codes CASMO-4 Knott and Edenius (1993) and MCCG3D (Suslov 1993). Similar techniques were subsequently implemented in codes APOLLO2 (Sanchez and Chetaine 2000) and DRAGON (Wu and Roy 2003). We have chosen to present this approach in the upcoming subsections.

Our presentation of the MOC follows the terminology and the guidelines proposed by Roy (1998). Many technical details have been recovered from Le Tellier (2006).

6.1 The MOC Integration Strategy

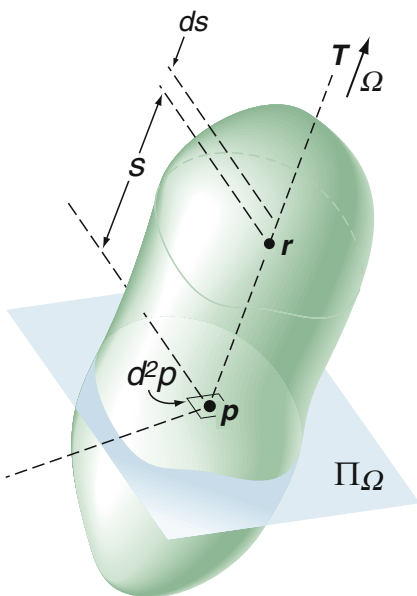

The backward *characteristic form of the transport equation* was obtained as (49) in 1.2. The one-speed and steady-state form of this equation is written as

$$\frac{d}{ds} \phi(\mathbf{r} + s \boldsymbol{\Omega}, \boldsymbol{\Omega}) + \Sigma(\mathbf{r} + s \boldsymbol{\Omega}) \phi(\mathbf{r} + s \boldsymbol{\Omega}, \boldsymbol{\Omega}) = Q(\mathbf{r} + s \boldsymbol{\Omega}, \boldsymbol{\Omega}) \quad (447)$$

where \mathbf{r} is the starting point of the particle, s is the distance traveled by the particle on its characteristic, $\boldsymbol{\Omega}$ is the direction of the characteristic, $\Sigma(\mathbf{r})$ is the value of the macroscopic total cross-section at \mathbf{r} , $\phi(\mathbf{r}, \boldsymbol{\Omega})$ is the particle angular flux at \mathbf{r} , and $Q(\mathbf{r}, \boldsymbol{\Omega})$ is the fixed source at \mathbf{r} .

The spatial integration domain is partitioned into regions of volume $\{V_i; i = 1, I\}$, each of them characterized by uniform nuclear properties and surrounded by boundary surfaces $\{S_\alpha; \alpha = 1, \Lambda\}$. The MOC is based on the discretization of (447) along each path of the particle and on the integration of the flux contributions using spatial integrals of the form

$$\begin{aligned} V_i \phi_i &= \int_{V_i} d^3 r \int_{4\pi} d^2 \Omega \phi(\mathbf{r}, \boldsymbol{\Omega}) \\ &= \int_Y d^4 T \int_{-\infty}^{\infty} ds \chi_{V_i}(T, s) \phi(\mathbf{p} + s \boldsymbol{\Omega}, \boldsymbol{\Omega}) \end{aligned} \quad (448)$$

where ϕ_i is the average flux in region i and $Y = \{T\}$ is the tracking domain. A single characteristic T is determined by its orientation Ω and its starting point p defined on a reference plane Π_Ω perpendicular to T , as depicted in  Fig. 29. The characteristics are selected in domain $Y = 4\pi \times \Pi_\Omega$ which is characterized by an order-four differential $d^4 T = d^2 \Omega d^2 p$. The local coordinate s defines the distance of point r with respect to plane Π_Ω . Finally, the characteristic function $\chi_{V_i}(T, s)$ is equal to 1 if point $p + s\Omega$ of characteristic T is located inside V_i , and zero otherwise.

The MOC requires knowledge of region indices N_k and segment lengths ℓ_k describing the overlapping of characteristic T with the domain. This information is written as $\{N_k, \ell_k; k = 1, K\}$, where K is the total number of regions crossed by T . It is important to note that segment lengths ℓ_k are *always* defined in 3D, even for prismatic 2D geometries. The intersection points of a characteristic with the region boundaries, and the corresponding angular flux on these boundaries, are written as

$$\mathbf{r}_{k+1} = \mathbf{r}_k + \ell_k \Omega, \quad k = 1, K \quad (449)$$

and

$$\phi_k(T) = \phi(\mathbf{r}_k, \Omega), \quad k = 1, K + 1. \quad (450)$$

The average flux over each segment is defined as

$$\bar{\phi}_k(T) = \frac{1}{\ell_k(T)} \int_0^{\ell_k(T)} ds \phi(\mathbf{r}_k + s \Omega, \Omega), \quad k = 1, K. \quad (451)$$

 **Figure 29**
Spatial integration domain

Using this relation, it is possible to rewrite (448) as

$$V_i \phi_i = \int_Y d^4 T \sum_k \delta_{iN_k} \ell_k(\mathbf{T}) \bar{\phi}_k(\mathbf{T}), \quad (452)$$

where δ_{ij} is the Kronecker delta function and where the summation over k is performed over all the existing indices. All the characteristics \mathbf{T} are spanned in (452), but only those that effectively cross region i contribute to the integral.

Using the same approach that leads to (452), the volume of region i is written as

$$4\pi V_i = \int_Y d^4 T \sum_k \delta_{iN_k} \ell_k(\mathbf{T}). \quad (453)$$

The MOC equations also use the average fixed source over each segment, defined as

$$\bar{Q}_k(\mathbf{T}) = \frac{1}{\ell_k(\mathbf{T})} \int_0^{\ell_k(\mathbf{T})} ds Q(\mathbf{r}_k + s \boldsymbol{\Omega}, \boldsymbol{\Omega}), \quad k = 1, K. \quad (454)$$

Based on (449), \mathbf{r}_1 and \mathbf{r}_{K+1} are the incoming and outgoing boundary points for \mathbf{T} . The incoming (-) and outgoing (+) boundary currents are given as

$$\begin{aligned} \frac{S_\alpha}{4} \varphi_\alpha^- &= - \int_{\partial D_\alpha} d^2 r_\alpha \int_{\boldsymbol{\Omega} \cdot \mathbf{N}_\alpha < 0} d^2 \boldsymbol{\Omega} (\boldsymbol{\Omega} \cdot \mathbf{N}_\alpha) \phi(\mathbf{r}_\alpha, \boldsymbol{\Omega}), \\ \frac{S_\beta}{4} \varphi_\beta^+ &= \int_{\partial D_\beta} d^2 r_\beta \int_{\boldsymbol{\Omega} \cdot \mathbf{N}_\beta > 0} d^2 \boldsymbol{\Omega} (\boldsymbol{\Omega} \cdot \mathbf{N}_\beta) \phi(\mathbf{r}_\beta, \boldsymbol{\Omega}), \end{aligned} \quad (455)$$

where \mathbf{r}_α is a point of the domain boundary ∂D_α and \mathbf{N}_α is an outgoing unit normal vector at that point. The corresponding MOC integrals are written

$$\begin{aligned} \frac{S_\alpha}{4} \varphi_\alpha^- &= - \int_Y d^4 T \chi_\alpha(\mathbf{T}, \mathbf{r}_1) \phi_1(\mathbf{T}), \\ \frac{S_\beta}{4} \varphi_\beta^+ &= \int_Y d^4 T \chi_\beta(\mathbf{T}, \mathbf{r}_{K+1}) \phi_{K+1}(\mathbf{T}), \end{aligned} \quad (456)$$

where the characteristic function $\chi_\alpha(\mathbf{T}, \mathbf{r})$ is equal to 1 if point \mathbf{r} of characteristic \mathbf{T} is located on surface ∂D_α , and zero otherwise.

Using the same approach that leads to (456), the values of surfaces α and β are written as

$$\pi S_\alpha = \int_Y d^4 T \chi_\alpha(\mathbf{T}, \mathbf{r}_1) \quad \text{and} \quad \pi S_\beta = \int_Y d^4 T \chi_\beta(\mathbf{T}, \mathbf{r}_{K+1}). \quad (457)$$

The MOC is similar to a discrete ordinates approach in the way the integrals in $d^4 T$ are handled. These integrals are systematically replaced by weighted summations of the form

$$\int_Y d^4 T f(\mathbf{T}) \simeq 4\pi \sum_{m=1}^M \omega_m f(\mathbf{T}_m), \quad (458)$$

where M is the number of discrete characteristic. The discrete characteristic \mathbf{T}_m and weights ω_m are recovered from a collision probability-type tracking, but defined in 3D.

Each characteristic T_m is associated with another one of opposite direction. In the practical implementation of the MOC, only characteristics with $\Omega > 0$ are computed and stored, so that every available characteristic travels two ways, back and forth.

These numerical quadratures can also be applied to the evaluation of volumes and surfaces, using (453) and (457), respectively. These approximate values are used as a denominator to normalize the MOC quadratures, leading to the following values of ϕ_i , φ_α^- and φ_β^+ :

$$\frac{\phi_i}{4\pi} = \frac{\sum_{m=1}^M \omega_m \sum_k \delta_{iN_k} \ell_k(T_m) \bar{\phi}_k(T_m)}{\sum_{m=1}^M \omega_m \sum_k \delta_{iN_k} \ell_k(T_m)} \quad (459)$$

and

$$\begin{aligned} \frac{\varphi_\alpha^-}{4\pi} &= -\frac{\sum_{m=1}^M \omega_m \chi_\alpha(T_m, \mathbf{r}_1) \phi_1(T_m)}{\sum_{m=1}^M \omega_m \chi_\alpha(T_m, \mathbf{r}_1)}, \\ \frac{\varphi_\beta^+}{4\pi} &= \frac{\sum_{m=1}^M \omega_m \chi_\beta(T_m, \mathbf{r}_{K+1}) \phi_{K+1}(T_m)}{\sum_{m=1}^M \omega_m \chi_\beta(T_m, \mathbf{r}_{K+1})}. \end{aligned} \quad (460)$$

Integration of the characteristics (447) requires a hypothesis concerning the spatial variation of the fixed source along each characteristic T . The *step-characteristic* (SC) *scheme* is a widely used approximation written as

$$Q(\mathbf{r}_k + s \mathbf{\Omega}, \mathbf{\Omega}) = Q_{N_k}(\mathbf{\Omega}); \quad \forall s \in [0, \ell_k]. \quad (461)$$

The SC scheme is prevalent for the following reasons: (1) The SC scheme is *positive*, leading to positive values for $Q_i(\mathbf{\Omega})$, $\phi_k(T)$, and $\bar{\phi}_k(T)$. (2) The SC scheme leads to a number of unknowns equal to the number of regions plus the number of boundary surfaces; more advanced schemes may require storing an amount of information proportional to the tracking. (3) The SC scheme has the same level of approximation as the collision probability method. (4) The SC scheme is conservative.

Introduction of the SC scheme in the characteristics in (447) and integration of the resulting equation over a single segment ℓ_k leads to the following analytical solution for the segment-boundary and segment-averaged fluxes:

$$\begin{aligned} \phi_{k+1}(T) &= \mathcal{A}_k(T) \phi_k(T) + \mathcal{B}_k(T) Q_{N_k}(\mathbf{\Omega}), \\ \bar{\phi}_k(T) &= \frac{1}{\ell_k} [\mathcal{B}_k(T) \phi_k(T) + \mathcal{C}_k(T) Q_{N_k}(\mathbf{\Omega})], \end{aligned} \quad (462)$$

where the SC coefficients are written as,

(a) $\Sigma_{N_k} \neq 0$:

$$\begin{aligned}\mathcal{A}_k(\mathbf{T}) &= e^{-\tau_k(\mathbf{T})}, \\ \mathcal{B}_k(\mathbf{T}) &= \frac{1}{\Sigma_{N_k}} \left(1 - e^{-\tau_k(\mathbf{T})}\right), \\ \mathcal{C}_k(\mathbf{T}) &= \frac{\ell_k(\mathbf{T})}{\Sigma_{N_k}} \left(1 - \frac{1 - e^{-\tau_k(\mathbf{T})}}{\tau_k(\mathbf{T})}\right),\end{aligned}\quad (463)$$

(b) $\Sigma_{N_k} = 0$:

$$\mathcal{A}_k(\mathbf{T}) = 1, \quad \mathcal{B}_k(\mathbf{T}) = \ell_k(\mathbf{T}), \quad \text{and} \quad \mathcal{C}_k(\mathbf{T}) = \frac{\ell_k(\mathbf{T})^2}{2}.\quad (464)$$

Equation (463) use the optical paths $\tau_k(\mathbf{T})$ defined as

$$\tau_k(\mathbf{T}) = \Sigma_{N_k} \ell_k(\mathbf{T}).\quad (465)$$

In the case of an isotropic source in the LAB, (462) is rewritten as

$$\begin{aligned}\phi_{k+1}(\mathbf{T}) &= \mathcal{A}_k(\mathbf{T}) \phi_k(\mathbf{T}) + \frac{1}{4\pi} \mathcal{B}_k(\mathbf{T}) Q_{N_k}, \\ \bar{\phi}_k(\mathbf{T}) &= \frac{1}{\ell_k} \left[\mathcal{B}_k(\mathbf{T}) \phi_k(\mathbf{T}) + \frac{1}{4\pi} \mathcal{C}_k(\mathbf{T}) Q_{N_k} \right],\end{aligned}\quad (466)$$

where Q_i is written in terms of fission, out-of-group scattering and/or fixed sources Q_i^\diamond , and macroscopic within-group scattering cross-sections $\Sigma_{w,i}$ using

$$Q_i = Q_i^\diamond + \Sigma_{w,i} \phi_i.\quad (467)$$

Substitution of (466b) into (459) leads to

$$\phi_i = \mathcal{P}_{ii} Q_i + 4\pi \frac{\sum_{m=1}^M \omega_m \sum_k \delta_{iN_k} \mathcal{B}_k(\mathbf{T}_m) \phi_k(\mathbf{T}_m)}{\sum_{m=1}^M \omega_m \sum_k \delta_{iN_k} \ell_k(\mathbf{T}_m)},\quad (468)$$

where we defined the *self-collision factor* \mathcal{P}_{ii} as

$$\mathcal{P}_{ii} = \frac{\sum_{m=1}^M \omega_m \sum_k \delta_{iN_k} \mathcal{C}_k(\mathbf{T}_m)}{\sum_{m=1}^M \omega_m \sum_k \delta_{iN_k} \ell_k(\mathbf{T}_m)}.\quad (469)$$

The self-collision factor should not be confused with the collision probability component p_{ii} introduced in [Sect. 4](#). The self-collision factor is computed using only the particle paths that are not intercepting regions with indices other than i . All the self-collision factors can be computed in the assembly phase of the transport calculation, outside the scattering iterations.

The MOC integration strategy can be further simplified by performing a partial scattering reduction based on (467). It is written as

$$\begin{aligned} \phi_i &= \frac{1}{1 - \sum_{w,i} \mathcal{P}_{ii}} \left[\mathcal{P}_{ii} Q_i^\diamond + 4\pi \frac{\sum_{m=1}^M \omega_m \sum_k \delta_{iN_k} \mathcal{B}_k(\mathbf{T}_m) \phi_k(\mathbf{T}_m)}{\sum_{m=1}^M \omega_m \sum_k \delta_{iN_k} \ell_k(\mathbf{T}_m)} \right], \\ \phi_\alpha^- &= -4\pi \frac{\sum_{m=1}^M \omega_m \chi_\alpha(\mathbf{T}_m, \mathbf{r}_1) \phi_1(\mathbf{T}_m)}{\sum_{m=1}^M \omega_m \chi_\alpha(\mathbf{T}_m, \mathbf{r}_1)}, \\ \phi_\beta^+ &= 4\pi \frac{\sum_{m=1}^M \omega_m \chi_\beta(\mathbf{T}_m, \mathbf{r}_{K+1}) \phi_{K+1}(\mathbf{T}_m)}{\sum_{m=1}^M \omega_m \chi_\beta(\mathbf{T}_m, \mathbf{r}_{K+1})}, \end{aligned} \quad (470)$$

where the swapping relations are simplified to

$$\phi_{k+1}(\mathbf{T}) = \mathcal{A}_k(\mathbf{T}) \phi_k(\mathbf{T}) + \frac{1}{4\pi} \mathcal{B}_k(\mathbf{T}) Q_{N_k}. \quad (471)$$

This approach based on self-collision factors is referred to as the *source isolation method* in (Le Tellier 2006). It can be generalized to anisotropic cases by introducing angular-dependent self-collision factors.

There is one more issue of the MOC that is worth mentioning. It is possible to replace the SC scheme with a *diamond-differencing scheme* similar to (369). Using this relation, the average flux on a track segment is assumed to be

$$\bar{\phi}_k(\mathbf{T}) = \frac{1}{2} [\phi_k(\mathbf{T}) + \phi_{k+1}(\mathbf{T})]. \quad (472)$$

The diamond-differencing (DD) scheme leads to the same (462) with the corresponding coefficients now written as

$$\begin{aligned} \mathcal{A}_k(\mathbf{T}) &= \frac{2 - \tau_k(\mathbf{T})}{2 + \tau_k(\mathbf{T})}, \\ \mathcal{B}_k(\mathbf{T}) &= \frac{2\ell_k(\mathbf{T})}{2 + \tau_k(\mathbf{T})}, \\ \mathcal{C}_k(\mathbf{T}) &= \frac{\ell_k(\mathbf{T})^2}{2 + \tau_k(\mathbf{T})}. \end{aligned} \quad (473)$$

As pointed out by Suslov, the DD scheme can be obtained from the SC scheme by performing a Padé approximation of the exponential function (Suslov 1997). Suslov has shown that the DD scheme is related to the linear characteristic (LC) scheme, based on the assumption that the angular flux varies linearly in each region. Assuming that the slope of the fixed sources is proportional to the slope of the flux, the LC scheme reduces to the DD scheme. Consequently, the DD scheme has numerical properties that make it more accurate than the SC scheme in many practical situations. Another successful linear scheme is the linear surface characteristic (LSC) scheme proposed by Santandrea and Mosca (2006).

6.2 Unstructured 2D Finite Geometry

Let us consider an unstructured finite geometry in the x - y plane, infinite and uniform along the z -axis. This type of geometry is commonly used in lattice codes. The projection on the x - y plane is performed as depicted in **Fig. 30**. The direction of the particle is $\Omega = \sin \theta \cos \varepsilon \mathbf{i} + \sin \theta \sin \varepsilon \mathbf{j} + \cos \theta \mathbf{k}$. Integration over θ is possible by taking the projection of each particle free path on the x - y plane. The differential element $d^4 T$ is written as

$$d^4 T = d^2 p d^2 \Omega = dr (\sin \theta dr) (\sin \theta d\varepsilon) d\theta. \quad (474)$$

Defining $\mu = \cos \theta$ and $d^2 T_{xy} = dr d\varepsilon$, (474) can be rewritten as

$$d^4 T = d^2 T_{xy} \sin^2 \theta d\theta dz. \quad (475)$$

The tracking domain $Y_{xy} = \{T_{xy}\}$ is now defined in the x - y plane. The discrete tracking information $\{T_{xy,m}; m = 1, M\}$ is computed using the *same* tracking operator available with the collision probability method in unstructured 2D finite geometry. A useful example of 2D tracking is presented in Appendices **Sects. 3** and **4** for the particular case of a square pincell geometry.

The 3D track lengths corresponding to the tabulated segments are given as

$$\ell_k(T) = \frac{\ell_k(T_{xy})}{\sin \theta} \quad (476)$$

so that (452) and (456) are now written as

$$V_i \phi_i = 2 \int_{Y_{xy}} d^2 T \sum_k \delta_{iN_k} \ell_k(T_{xy}) \int_0^{\pi/2} d\theta \sin \theta \check{\phi}_k(T) \quad (477)$$

Figure 30

Projection of a particle trajectory on the x - y plane. The polar angle θ is used to define the direction cosine of the particle relative to the z -axis

and

$$\begin{aligned}\frac{S_\alpha}{4} \varphi_\alpha^- &= -2 \int_{Y_{xy}} d^2 T \chi_\alpha(\mathbf{T}_{xy}, \mathbf{r}_1) \int_0^{\pi/2} d\theta \sin^2 \theta \phi_1(\mathbf{T}), \\ \frac{S_\beta}{4} \varphi_\beta^+ &= 2 \int_{Y_{xy}} d^2 T \chi_\beta(\mathbf{T}_{xy}, \mathbf{r}_{K+1}) \int_0^{\pi/2} d\theta \sin^2 \theta \phi_{K+1}(\mathbf{T}).\end{aligned}\quad (478)$$

Leonard and McDaniel (1995) introduced *optimized polar quadratures* for the MOC, in such a way as to generate numerical results close to those obtained via the collision probability method with isotropic scattering. They proposed approaches to obtain quadratures that optimize the integration of *Bickley functions*, as defined in (282). Later, the two-base point Leonard–McDaniel optimized polar quadratures were generalized to three and four base points in Le Tellier and Hébert (2008). These quadratures are written as

$$\int_0^{\pi/2} d\theta \sin \theta f\left(\frac{1}{\sin \theta}\right) \simeq \sum_{\lambda=1}^L \mathcal{W}_\lambda f(z_\lambda), \quad (479)$$

where θ is the polar angle depicted in  Fig. 30. Using this quadrature, the $Ki_3(x)$ function is approximated as

$$Ki_3(x) = \int_0^{\pi/2} d\theta \sin^2 \theta e^{-\frac{x}{\sin \theta}} \simeq \sum_{\lambda=1}^L \mathcal{W}_\lambda e^{z_\lambda x}. \quad (480)$$

The Leonard–McDaniel-optimized polar quadratures can be recovered from the following Matlab script:

```
function [zmu,wzmu]=lmcd(nmu)
% set the Leonard-McDaniel quadrature base points and weights
% function [zmu,wzmu]=lmcd(nmu)
% (c) 2008 Alain Hebert, Ecole Polytechnique de Montreal
if nmu == 2
    zmu=[1.15511584 3.65419436 ]; wzmu=[ 0.744970262 0.03816792 ];
elseif nmu == 3
    zmu=[ 1.12178171 2.52822733 10.0188332 ];
    wzmu=[ 0.707642138 0.0745818987 0.00175868778 ];
elseif nmu == 4
    zmu=[ 1.10098934 2.15439725 6.02394629 23.7072144 ];
    wzmu=[ 0.677962959 0.10134203 0.00533553911 0.000130677523 ];
else
    error('invalid number of base points.')
end
```

where variables K , z_λ , and \mathcal{W}_λ are represented by Matlab variables `nmu`, `zmu`, and `wzmu`, respectively. Errors observed in the (480) evaluation are plotted in  Fig. 31. Other optimized polar quadratures are presented in Le Tellier and Hébert (2008) for situations with source anisotropy.

Figure 31 Error of the Leonard–McDaniel quadratures for evaluating $Ki_3(x)$ functions

Using the polar quadrature of (479), (470) are now rewritten as

$$\begin{aligned} \phi_i &= \frac{1}{1 - \sum_{w,i} \mathcal{P}_{ii}} \left[\mathcal{P}_{ii} Q_i^\diamond + 4\pi \frac{\sum_{m=1}^M \omega_m \sum_k \delta_{iN_k} \sum_{\lambda=1}^L \mathcal{W}_\lambda \mathcal{B}_k(\mathbf{T}_m) \phi_k(\mathbf{T}_m)}{\sum_{m=1}^M \omega_m \sum_k \delta_{iN_k} \sum_{\lambda=1}^L \mathcal{W}_\lambda \ell_k(\mathbf{T}_m)} \right], \\ \phi_\alpha^- &= -4\pi \frac{\sum_{m=1}^M \omega_m \chi_\alpha(\mathbf{T}_m, \mathbf{r}_1) \sum_{\lambda=1}^L \mathcal{W}_\lambda \phi_1(\mathbf{T}_m)}{\sum_{m=1}^M \omega_m \chi_\alpha(\mathbf{T}_m, \mathbf{r}_1) \sum_{\lambda=1}^L \mathcal{W}_\lambda}, \\ \phi_\beta^+ &= 4\pi \frac{\sum_{m=1}^M \omega_m \chi_\beta(\mathbf{T}_m, \mathbf{r}_{K+1}) \sum_{\lambda=1}^L \mathcal{W}_\lambda \phi_{K+1}(\mathbf{T}_m)}{\sum_{m=1}^M \omega_m \chi_\beta(\mathbf{T}_m, \mathbf{r}_{K+1}) \sum_{\lambda=1}^L \mathcal{W}_\lambda}, \end{aligned} \tag{481}$$

where the self-collision factors are now written as

$$\mathcal{P}_{ii} = \frac{\sum_{m=1}^M \omega_m \sum_k \delta_{iN_k} \sum_{\lambda=1}^L \mathcal{W}_\lambda \mathcal{C}_k(\mathbf{T}_m)}{\sum_{m=1}^M \omega_m \sum_k \delta_{iN_k} \sum_{\lambda=1}^L \mathcal{W}_\lambda \ell_k(\mathbf{T}_m)}, \tag{482}$$

and where

$$\ell_k(\mathbf{T}_m) = z_\lambda \ell_k(\mathbf{T}_{xy,m}). \tag{483}$$

The self-collision factors \mathcal{P}_{ii} are not a function of the fluxes or sources. They are computed during the assembly phase of the calculation using the algorithm reproduced in Matlab script `mcppii`. The tracking in `track` is produced using the script `sybt2d` of Appendix Section 3 for a square pincell. The script parameters are defined as

`track`=tracking information,
`sig`=array of size `nreg` containing the macroscopic total cross-sections,
`nmu`=order of the optimized polar quadrature, and
`pii`=array of size `nreg` containing the self-collision factors.

The script `mcgp ii` is written as

```
function pii=mcgp ii(track,sigt,nmu)
% compute the pii components for source isolation with the MOC.
% function pii=mcgp ii(track,sigt,nmu)
% (c) 2008 Alain Hebert, Ecole Polytechnique de Montreal
nreg=track(2); nbtr=track(4);
[zmu,wzmu]=lmcd(nmu);
k=5+track(1)+track(2)+2*track(3);
volnum=zeros(nreg,1); pii=zeros(nreg,1);
for iline=1:nbtr
    weitf=track(k+4); km=track(k+5); kgar=k+5; k=k+5+km;
    nom=track(kgar+1:kgar+km); htf=track(k+1:k+km); h=zeros(1,km);
    for imu=1:nmu
        ww=weitf*wzmu(imu); h(:)=htf(:).*zmu(imu);
        b=mcgscs(nom,h,sigt);
        for i=1:km
            nomi=nom(i);
            volnum(nomi)=volnum(nomi)+h(i)*ww;
            pii(nomi)=pii(nomi)+b(2,i)*ww;
        end
    end
    k=k+km;
end
pii=pii./volnum;
```

where the script `mcgscs` is implemented as

```
function b=mcgscs(nom,h,xst)
% calculate coefficients of a track for the characteristics integration.
% step-characteristic scheme with exact exponential calls.
% function b=mcgscs(nom,h,xst)
% (c) 2008 Alain Hebert, Ecole Polytechnique de Montreal
km=length(h); b=zeros(2,km);
for i=1:km
    nomi=nom(i);
    if xst(nomi) == 0.
        b(1,i)=h(i);
        b(2,i)=0.5*h(i)^2;
```

```

else
    b(1,i)=(1.-exp(-h(i)*xst(nomi)))/xst(nomi);
    b(2,i)=(h(i)-b(1,i))/xst(nomi);
end
end
end

```

The basic algorithm for computing the fluxes and interface current in the innermost scattering iteration is reproduced in Matlab script `mcgsis`. The script parameters are defined as

`phi` = dependent variables. The first `nsurf` components of column array `phi` contain the interface currents and the following `nreg` components contain the fluxes ϕ_i in each region.

`q` = source array. The array `q` of length `nreg` contains Q_i^\diamond , the fission, out-of-group scattering, and/or fixed sources.

`track` = tracking information.

`sigt` = array of size `nreg` containing the macroscopic total cross-sections.

`sigw` = array of size `nreg` containing the macroscopic within-group scattering cross-sections.

`pii` = self-collision factors as computed by script `mcgpii`.

`nmu` = order of the optimized polar quadrature.

The script `mcgsis` is written as

```

function phi=mcgsis(phi,q,track,sigt,sigw,pii,nmu)
% single MOC scattering iteration with source isolation
% function phi=mcgsis(phi,q,track,sigt,sigw,pii,nmu)
% (c) 2008 Alain Hebert, Ecole Polytechnique de Montreal
    nsurf=track(1); nreg=track(2); nbtr=track(4);
    s=q+phi.*[ones(1,nsurf) sigw]';
    [zmu,wzmu]=lmcd(nmu);
%--
%      flux calculation
%--
    k=5+track(1)+track(2)+2*track(3);
    volsur=zeros(nsurf+nreg,1); phi=zeros(nsurf+nreg,1);
    for iline=1:nbtr
        isurf=track(k+2); jsurf=track(k+3); weitf=track(k+4); km=track(k+5);
        kgar=k+5; k=k+5+km;
        nom=track(kgar+1:kgar+km); htf=track(k+1:k+km); h=zeros(1,km);
        for imu=1:nmu
            ww=weitf*wzmu(imu); h(:)=htf(:).*zmu(imu);
            b=mcgscs(nom,h,sigt);
            rp=s(isurf); rm=s(jsurf);
            for i=1:km
                nomi=nom(i);
                volsur(nsurf+nomi)=volsur(nsurf+nomi)+2.*h(i)*ww;
            end
        end
    end
end

```

```

    phi(nsurf+nomi)=phi(nsurf+nomi)+b(1,i)*rp*ww ;
    rp=rp+b(1,i)*(s(nsurf+nomi)-sigt(nomi)*rp);
end
for i=km:-1:1
    nomi=nom(i) ;
    phi(nsurf+nomi)=phi(nsurf+nomi)+b(1,i)*rm*ww ;
    rm=rm+b(1,i)*(s(nsurf+nomi)-sigt(nomi)*rm) ;
end
phi(jsurf)=phi(jsurf)+rp*ww ; phi(isurf)=phi(isurf)+rm*ww ;
volsur(jsurf)=volsur(jsurf)+ww ; volsur(isurf)=volsur(isurf)+ww ;
end
k=k+km ;
end
phi=phi./volsur ;
unk=phi(nsurf+1:nsurf+nreg)+pii.*q(nsurf+1:nsurf+nreg) ;
phi(nsurf+1:nsurf+nreg)=unk./(ones(nreg,1)-pii.*sigw') ;

```

The largest fraction of CPU resources required to execute the MOC algorithm is spent in script `mcgscs` and in the two inner loops of script `mcgsls`. These few lines of code must be highly optimized to ensure a good performance for production calculations. The `mcgscs` script requires the evaluation of $\exp(x)$ and $\mathcal{B}_k(T)$ functions. It is recommended to compute these functions from piecewise linear or parabolic fits instead of using the hardwired $\exp(x)$ operator of the CPU.

It is possible to analytically integrate the MOC equations in polar angle θ , leading to a version of the MOC written in terms of $Ki_3(x)$ functions instead of exponentials. Such a method leads to numerical results equivalent to those obtained with a polar quadrature, as L goes to infinity. However, Bickley functions do not satisfy the same properties as exponentials, so that $Ki_3(x+y) \neq Ki_3(x)Ki_3(y)$. Consequently, the practical implementation of a script similar to `mcgsls` would require the addition of an inner loop of the form “for $j=i-1:-1:1$ ” and “for $j=i+1:km$ ” inside the “for $i=1:km$ ” and “for $i=km:-1:1$ ” loops, respectively. The extra loops make this MOC inefficient if too many tracks have a number of segments greater than K .

Once the MOC single-iteration capability is implemented, the complete scattering iteration can be set using a fixed-point iterative approach. A free-iteration fixed-point approach would be implemented as

```
[phi err iter]=free(phi,q,'mcgsls',errtol,maxit,track,sigt,sigw,pii,nmu)
```

where the Matlab script `free` is programmed as

```

function [x, error, iter] = free(x, b, atv, errtol, maxit, varargin)
% free-iteration linear equation solver
% function [x, error, total_iters] = free(x0, b, atv, errtol, maxit, varargin)
% input parameters:
% x    initial iterate

```

```

% b   right-hand side
% atv character name of a matrix-vector product routine returning x+(b-Ax)
%     when x is input. The format for atv is "function x = atv(x,b,p1,p2,...)"
%     where p1 and p2 are optional parameters
% errtol relative residual reduction factor
% maxit maximum number of iterations
% varargin optional parameters (p1,p2,...) for atv
% output parameters:
% x     solution of the linear system
% error vector of residual norms for the history of the iteration
% iter  number of iterations
% (c) 2007 Alain Hebert, Ecole Polytechnique de Montreal
errtol=errtol*norm(b);
error=[];
rho=Inf;
iter=0;
while((rho > errtol) && (iter < maxit))
    iter=iter+1;
    r=feval(atv,x,b,varargin)-x;
    rho=norm(r); error=[error;rho];
    x=x+r;
end

```

6.3 The Algebraic Collapsing Acceleration

The algebraic collapsing acceleration (ACA) method was introduced by Suslov as a general technique for the acceleration of the MOC in 2D and 3D (see Suslov 1993; Le Tellier and Hébert 2007). The core of the ACA is the solution of a simplified transport equation, referred to as the ACA operator, leading to even-parity fluxes similar to those obtained with the diffusion theory. The discretization process is based on a weighted summation of all trajectories over the global angular domain. The resulting sparse matrix system, of order $\Lambda + I$, can be scattering reduced and solved for the even-parity flux and boundary currents. The solution of the sparse matrix system requires only small computer resources and is therefore a good candidate for synthetic acceleration. The scattering iteration of the MOC is preconditioned with the ACA operator using the synthetic acceleration approach already presented in [5.5](#).

Other types of simplified transport equations have been used within a synthetic acceleration approach, leading to competing acceleration strategies. The asymptotic synthetic acceleration (ASA) and DP_1 acceleration methods, based on the interface current formalism of [4.1](#), are alternative approaches proposed in Sanchez and Chetaine (2000), Santandrea and Sanchez (2002) and Santandrea and Sanchez (2005). A presentation of ASA and DP_1 strategies is outside the scope of this handbook.

The ACA operator is based on a set of relations between the isotropic flux and boundary currents on a single track. Each of these relations is expected to couple an unknown with its

two neighbors, leading to a tridiagonal matrix system for the single-track unknown numbering. The contribution of all tracks T_m and the introduction of the global unknown numbering lead to a sparse matrix system that can be solved using sparse matrix algebra techniques.

We first obtain the tridiagonal matrix system for a single-track T . Any function of the position s can be written in terms of even- and odd-parity functions, defined as

$$f^s(T, s) = \frac{1}{2} [f(T, s) + f(-T, s)] \quad \text{and} \quad f^a(T, s) = \frac{1}{2} [f(T, s) - f(-T, s)]. \quad (484)$$

The k th segment on track T is located between positions s_k and s_{k+1} . Using (462), the segment-boundary and segment-averaged flux are related as

$$\bar{\phi}_k(T) = \frac{1 + \alpha(T)}{2} \phi_{k+1}(T) + \frac{1 - \alpha(T)}{2} \phi_k(T), \quad (485)$$

$$\bar{\phi}_k(-T) = \frac{1 - \alpha(T)}{2} \phi_{k+1}(-T) + \frac{1 + \alpha(T)}{2} \phi_k(-T), \quad (486)$$

where $k = 1, K$. The coefficient $\alpha_k(T)$ is written in terms of the SC or DD coefficients as

$$\alpha(T) = \frac{2}{1 - \mathcal{A}(T)} - \frac{2}{\tau_k(T)} - 1 \quad (487)$$

with the asymptotic limit

$$\lim_{\tau_k \rightarrow 0} \alpha(T) = 0. \quad (488)$$

Equation (486) is substituted into (484), leading to a first set of flux relations:

$$\bar{\phi}_k^s(T) = \frac{1}{2} [\phi_{k+1}^s(T) + \phi_k^s(T) + \alpha(T) (\phi_{k+1}^a(T) - \phi_k^a(T))], \quad (489)$$

$$\bar{\phi}_k^a(T) = \frac{1}{2} [\phi_{k+1}^a(T) + \phi_k^a(T) + \alpha(T) (\phi_{k+1}^s(T) - \phi_k^s(T))]. \quad (490)$$

A second set of flux equations can now be obtained. The integration of the characteristics in (447) over the k th segment leads to

$$\phi_{k+1}(T) - \phi_k(T) + \tau_k(T) \bar{\phi}_k(T) = \frac{\ell_k(T)}{4\pi} Q_{N_k}, \quad (491)$$

where we assumed an isotropic source. Equation (490) can be rewritten in terms of $-T$, leading to its even- and odd-parity formulation. We have obtained

$$\phi_{k+1}^a(T) - \phi_k^a(T) + \tau_k(T) \bar{\phi}_k^s(T) = \frac{\ell_k(T)}{4\pi} Q_{N_k}, \quad (492)$$

$$\phi_{k+1}^s(T) - \phi_k^s(T) + \tau_k(T) \bar{\phi}_k^a(T) = 0. \quad (493)$$

Substitution of (490) into (493) leads to

$$\phi_{k+1}^s(T) = \phi_k^s(T) - \frac{\tau_k(T)}{2 + \tau_k(T) \alpha_k(T)} (\phi_k^a(T) + \phi_{k+1}^a(T)). \quad (494)$$

Substitution of (494) and (489) into (492) leads to

$$\phi_k^s(\mathbf{T}) = \zeta_k(\mathbf{T}) \phi_k^a(\mathbf{T}) + (1 - \tilde{b}_k(\mathbf{T})) \bar{\phi}_k^s(\mathbf{T}) + b_k(\mathbf{T}) \frac{Q_{N_k}}{4\pi}, \quad (495)$$

where

$$\zeta_k(\mathbf{T}) = \frac{\tau_k(\mathbf{T})}{2 + \tau_k(\mathbf{T}) \alpha_k(\mathbf{T})}, \quad b_k(\mathbf{T}) = \frac{\ell_k(\mathbf{T})}{2} (\zeta_k(\mathbf{T}) - \alpha_k(\mathbf{T})) \quad (496)$$

and

$$\tilde{b}_k(\mathbf{T}) = b_k(\mathbf{T}) \Sigma_{N_k}. \quad (497)$$

Similarly, we can show that

$$\phi_{k+1}^s(\mathbf{T}) = -\zeta_k(\mathbf{T}) \phi_{k+1}^a(\mathbf{T}) + (1 - \tilde{b}_k(\mathbf{T})) \bar{\phi}_k^s(\mathbf{T}) + b_k(\mathbf{T}) \frac{Q_{N_k}}{4\pi}. \quad (498)$$

We combine (495) for segment k with (498) for segment $k - 1$, so that

$$\begin{aligned} \phi_k^a(\mathbf{T}) = & \frac{1}{\zeta_{k-1}(\mathbf{T}) + \zeta_k(\mathbf{T})} \left[(1 - \tilde{b}_{k-1}(\mathbf{T})) \bar{\phi}_{k-1}^s(\mathbf{T}) - (1 - \tilde{b}_k(\mathbf{T})) \bar{\phi}_k^s(\mathbf{T}) \right. \\ & \left. + \left(b_{k-1}(\mathbf{T}) \frac{Q_{N_{k-1}}}{4\pi} - b_k(\mathbf{T}) \frac{Q_{N_k}}{4\pi} \right) \right]. \end{aligned} \quad (499)$$

Next, we combine (495) for segment $k + 1$ with (498) for segment k , so that

$$\begin{aligned} \phi_{k+1}^a(\mathbf{T}) = & \frac{1}{\zeta_k(\mathbf{T}) + \zeta_{k+1}(\mathbf{T})} \left[(1 - \tilde{b}_k(\mathbf{T})) \bar{\phi}_k^s(\mathbf{T}) - (1 - \tilde{b}_{k+1}(\mathbf{T})) \bar{\phi}_{k+1}^s(\mathbf{T}) \right. \\ & \left. + \left(b_k(\mathbf{T}) \frac{Q_{N_k}}{4\pi} - b_{k+1}(\mathbf{T}) \frac{Q_{N_{k+1}}}{4\pi} \right) \right]. \end{aligned} \quad (500)$$

Finally, the boundary conditions can be written in terms of fixed incoming currents \mathcal{J}_1^- and \mathcal{J}_{K+1}^- , and of albedo values β_1 and β_{K+1} at each end of track \mathbf{T} . They are written as

$$\phi_1(\mathbf{T}) = \mathcal{J}_1^-(\mathbf{T}) + \beta_1 \phi_1(-\mathbf{T}') \quad \text{and} \quad \phi_{K+1}(-\mathbf{T}) = \mathcal{J}_{K+1}^-(-\mathbf{T}) + \beta_{K+1} \phi_{K+1}(\mathbf{T}'), \quad (501)$$

where \mathbf{T}' is the *mirror image* track corresponding to a specular reflection of track \mathbf{T} on the boundary. Here, we will assume $\mathbf{T}' \equiv \mathbf{T}$ which is consistent with the hypothesis of a *white-boundary condition*. The weighted summation approach of the ACA naturally leads to white-boundary conditions. The even- and odd-parity boundary fluxes are therefore written as

$$\phi_1^a(\mathbf{T}) = \frac{1}{2} [\mathcal{J}_1^-(\mathbf{T}) - (1 - \beta_1) \phi_1(-\mathbf{T})], \quad (502)$$

$$\phi_{K+1}^a(\mathbf{T}) = \frac{1}{2} [-\mathcal{J}_{K+1}^-(-\mathbf{T}) + (1 - \beta_{K+1}) \phi_{K+1}(\mathbf{T})] \quad (503)$$

and

$$\phi_1^s(\mathbf{T}) = \frac{1}{2} [\mathcal{J}_1^-(\mathbf{T}) + (1 + \beta_1) \phi_1(-\mathbf{T})], \quad (504)$$

$$\phi_{K+1}^s(\mathbf{T}) = \frac{1}{2} [\mathcal{J}_{K+1}^-(\mathbf{T}) + (1 + \beta_{K+1}) \phi_{K+1}(\mathbf{T})]. \quad (505)$$

Substitution of (499), (500), (502), and (503) into (492) leads to K ACA relations, one for each segment of \mathbf{T} . Two relations are still missing to close our linear system. The first is obtained by combining (495) for segment 1 with (502) and (504). The second is obtained by combining (498) for segment K with (503) and (505).

The ACA linear system is written in terms of global unknown numbering for the flux, outgoing boundary current, and source components. We are representing the starting and ending surfaces of \mathbf{T} as α_{st} and α_{end} , respectively. The relation between the local and global numbering is set as

$$\phi_1(-\mathbf{T}) = \frac{1}{4\pi} \varphi_{\alpha_{st}}^+, \quad \phi_{K+1}(\mathbf{T}) = \frac{1}{4\pi} \varphi_{\alpha_{end}}^+, \quad \text{and} \quad \mathcal{J}_1^-(\mathbf{T}) = \frac{1}{4\pi} J_{\alpha_{st}}^-, \quad (506)$$

$$\mathcal{J}_{K+1}^-(\mathbf{T}) = \frac{1}{4\pi} J_{\alpha_{end}}^- \quad \text{and} \quad \bar{\phi}_k^s(\mathbf{T}) = \frac{1}{4\pi} \phi_{N_k}. \quad (507)$$

The complete linear system for a single track \mathbf{T}_m is made of $2 + K$ relations. The dependence of parameters on \mathbf{T}_m has been removed to simplify the notation. The ACA linear system is written as

$$\frac{1}{2} [1 + \beta_{\alpha_{st}} + \zeta_1(1 - \beta_{\alpha_{st}})] \varphi_{\alpha_{st}}^+ - (1 - \bar{b}_1) \phi_{N_1} = -\frac{1}{2} (1 - \zeta_1) J_{\alpha_{st}}^- + b_1 Q_{N_1} \quad (508)$$

$$\frac{1}{2} [1 + \beta_{\alpha_{end}} + \zeta_K(1 - \beta_{\alpha_{end}})] \varphi_{\alpha_{end}}^+ - (1 - \bar{b}_K) \phi_{N_K} = -\frac{1}{2} (1 - \zeta_K) J_{\alpha_{end}}^- + b_K Q_{N_K}. \quad (509)$$

If $K = 1$:

$$\frac{1}{2} (1 - \beta_{\alpha_{st}}) \varphi_{\alpha_{st}}^+ + \tau_1 \phi_{N_1} + \frac{1}{2} (1 - \beta_{\alpha_{end}}) \varphi_{\alpha_{end}}^+ = \frac{1}{2} J_{\alpha_{st}}^- + \ell_1 Q_{N_1} + \frac{1}{2} J_{\alpha_{end}}^- \quad (510)$$

If $K > 1$:

$$\begin{aligned} & \frac{1}{2} (1 - \beta_{\alpha_{st}}) \varphi_{\alpha_{st}}^+ + \left(\frac{1 - \bar{b}_1}{\zeta_1 + \zeta_2} + \tau_1 \right) \phi_{N_1} - \frac{1 - \bar{b}_2}{\zeta_1 + \zeta_2} \phi_{N_2} \\ & = \frac{1}{2} J_{\alpha_{st}}^- - \left(\frac{b_1}{\zeta_1 + \zeta_2} - \ell_1 \right) Q_{N_1} + \frac{b_2}{\zeta_1 + \zeta_2} Q_{N_2}, \end{aligned} \quad (511)$$

$$\begin{aligned} & - \frac{1 - \bar{b}_{k-1}}{\zeta_{k-1} + \zeta_k} \phi_{N_{k-1}} + \left[\left(\frac{1}{\zeta_{k-1} + \zeta_k} + \frac{1}{\zeta_k + \zeta_{k+1}} \right) (1 - \bar{b}_k) + \tau_k \right] \phi_{N_k} \\ & - \frac{1 - \bar{b}_{k+1}}{\zeta_k + \zeta_{k+1}} \phi_{N_{k+1}} = \frac{b_{k-1}}{\zeta_{k-1} + \zeta_k} Q_{N_{k-1}} - \left[\left(\frac{1}{\zeta_{k-1} + \zeta_k} + \frac{1}{\zeta_k + \zeta_{k+1}} \right) b_k - \ell_k \right] Q_{N_k} \\ & + \frac{b_{k+1}}{\zeta_k + \zeta_{k+1}} Q_{N_{k+1}}, \quad k = 1, K - 1 \end{aligned} \quad (512)$$

and

$$\begin{aligned}
 & -\frac{1-\tilde{b}_{K-1}}{\zeta_{K-1}+\zeta_K}\phi_{N_{K-1}}+\left(\frac{1-\tilde{b}_K}{\zeta_{K-1}+\zeta_K}+\tau_K\right)\phi_{N_K}+\frac{1}{2}(1-\beta_{\alpha_{\text{end}}})\varphi_{\alpha_{\text{end}}}^+ \\
 & =\frac{b_{K-1}}{\zeta_{K-1}+\zeta_K}Q_{N_{K-1}}-\left(\frac{b_K}{\zeta_{K-1}+\zeta_K}-\ell_K\right)Q_{N_K}+\frac{1}{2}J_{\alpha_{\text{end}}}^-.
 \end{aligned} \tag{513}$$

Equations (508) to (513) can be obtained for a single-track T_m and written as

$$\mathbb{A}_m \Phi_m = \mathbb{B}_m \mathbf{Q}_m, \tag{514}$$

where the first Λ components of Φ_m and \mathbf{Q}_m are related to boundary surfaces and the following I components are related to regions. The coefficients of the above linear system are computed for *each* track T_m . The source components are written in terms of \mathbf{Q}_m^\diamond (fission, out-of-group scattering, and/or fixed sources) and in terms of within-group scattering sources, so that

$$\mathbf{Q}_m = \mathbf{Q}_m^\diamond + \mathbb{S} \Phi_m, \tag{515}$$

where $\mathbb{S} = \text{diag}\{0; \alpha = 1, \Lambda \text{ and } \Sigma_{w,i}; i = 1, I\}$ is a diagonal matrix containing the macroscopic within-group scattering cross-sections in each region. The first Λ diagonal terms of \mathbb{S} are set to zero.

The linear system (514) is equivalent to the MOC solution on a single track. The ACA approximation comes from the weighted summation of all individual \mathbb{A}_m and \mathbb{B}_m matrices, assuming the isotropy of flux and boundary currents. Individual matrices are weighted with the ω_m -values of (458) and summed as

$$\mathbb{A} = \sum_m \omega_m \mathbb{A}_m \quad \text{and} \quad \mathbb{B} = \sum_m \omega_m \mathbb{B}_m, \tag{516}$$

so that the ACA approximation leads to a unique sparse matrix system written as

$$\mathbb{A} \Phi = \mathbb{B} \mathbf{Q} = \mathbb{B} (\mathbf{Q}^\diamond + \mathbb{S} \Phi). \tag{517}$$

A scattering reduction can be performed on (517), so that

$$\Phi = \tilde{\mathbb{A}}^{-1} \mathbb{B} \mathbf{Q}^\diamond, \tag{518}$$

where the scattering-reduced matrix $\tilde{\mathbb{A}}$ is defined as

$$\tilde{\mathbb{A}} = \mathbb{A} - \mathbb{B} \mathbb{S}. \tag{519}$$

Equation (518) is the ACA discretization of the one-speed transport equation for neutral particles. It can be used to obtain an approximate solution of the flux and outgoing boundary currents as required in our synthetic acceleration method.

The synthetic ACA is implemented in three phases:

1. The sparsity graph of matrices $\tilde{\mathbb{A}}$ and \mathbb{B} is only a function of the tracking. It is independent of the particle energy and can therefore be obtained at the end of the tracking operation.

Obtaining the sparsity graph at this point greatly reduces the CPU resources required to construct matrices $\tilde{\mathbb{A}}$ and \mathbb{B} in production calculations. This phase is omitted in our simple Matlab implementation.

2. The construction of matrices $\tilde{\mathbb{A}}$ and \mathbb{B} in sparse storage mode and their incomplete factorization is performed in the assembly phase of the calculation, just after the calculation of the self-collision factors \mathcal{P}_{ii} .

This construction of matrices \mathbb{A} and \mathbb{B} can be implemented in Matlab using the script `mcgaca` taking as input the tracking (`track`), the macroscopic total cross sections (`sigt`), the polar quadrature order (`nmu`), and the albedo (`beta`). The programming of this script is left as an exercise for the reader. Scattering reduction of matrix \mathbb{A} is performed next, using the macroscopic within-group scattering cross-sections (`sigw`). Then, an incomplete LU factorization of matrix $\tilde{\mathbb{A}}$ is performed in such a way as to avoid any fill-in. These operations are set in Matlab as

```
pii=mcgpri(track,sigt,nmu);
beta=1.0; [A B]=mcgaca(track,sigt,nmu,beta);
A=sparse(A-B*diag([zeros(nsurf,1); sigw']));
[L1 U1]=luinc(A,'0');
```

3. An ACA-preconditioned scattering iteration can be set, using information already available from the assembly phase. The preconditioning operations are based on Eqs. (437) to (439). This step makes use of incomplete LU factors obtained previously and the solution of (518) is based on the *Bi-CGSTAB* algorithm (see Kelley 1995). It is possible to combine the ACA preconditioning with Livolant or GMRES(m) acceleration in order to further reduce the number of scattering iterations. We are using a special version of script `gmres_m`, as implemented in (Hébert 2009). Here, our Matlab prototype is based on ACA preconditioning together with GMRES(m) convergence of the scattering iterations:

```
phi=[zeros(track(1),1); ones(track(2),1)];
errtol=1.e-10; maxit=300;
[phi err iter]=gmres_m(phi,q,'mcgsis_aca',errtol,nstart,maxit, ...
    track,sigt,sigw,pii,nmu,A,B,L1,U1);
```

where a single-scattering iteration of the preconditioned MOC is implemented as

```
function phi=mcgsis_aca(phi,q,track,sigt,sigw,pii,nmu,A,B,L1,U1)
% single MOC scattering iteration with source isolation and ACA
% function phi=mcgsis_aca(phi,q,track,sigt,sigw,pii,nmu,A,B,L1,U1)
% (c) 2008 Alain Hebert, Ecole Polytechnique de Montreal
nsurf=track(1);
phi_half=mcgsis(phi,q,track,sigt,sigw,pii,nmu);
qaca=(phi_half - phi).*[ones(1,nsurf),sigw]';
[delta_phi flag]=bicgstab(A,B*qaca,1e-6,20,L1,U1);
phi=phi_half+delta_phi;
```

7 The Steady-State Diffusion Equation

In the previous sections, we have studied the notions of neutron cross-section, reaction rates, and neutron flux. The calculation of the energy-dependent neutron flux in each reactor region is required to obtain reaction rates in general and thermal reactor power in particular. Thermal reactor power is a measure of the *recoverable energy* production rate due to decay and neutron-induced reactions, the fission reaction being the most important source of energy release. As explained in the previous sections, neutron-induced reaction rates can be computed from knowledge of the *neutron flux* distribution, the solution of the *transport equation* for neutrons.

The geometric complexity of most nuclear reactors prevents the detailed solution of the neutron transport equation on the full-core geometry. Moreover, the resonant behavior in the energy of many cross-sections introduces another level of complexity along the energy independent variable. The computation of full-core reaction rates is generally the result of a *two-level computational scheme* based on the observation that the reactor is an assembly of unit cells or assemblies organized in a Cartesian or hexagonal lattice layout. The unit cell of a CANDU reactor is composed of the fuel bundle, pressure tube, calandria tube, and moderator zone. The unit assembly of a pressurized water reactor (PWR) is composed of the fuel assembly (generally a 15×15 or 17×17 assembly), including the control poisons and the interstitial light water. The unit cells or assemblies present in the reactor are supposed to be similar, only differing by a set of *global* or *local parameters*. These parameters generally include a measure of the fuel burnup (expressed in MW-day/tons of initial heavy isotopes), the fuel temperature, the coolant density and/or temperature, and any other parameter having an effect on the nuclear properties.

The first level of our computational scheme is the *lattice calculation*. Such a calculation is performed for *every* combination of global and local parameters that are likely to occur. The lattice calculation involves the solution of the steady-state transport equation over the unit cell or assembly, using a few hundred energy groups, as depicted in  Fig. 32. The dependent variable of this calculation is the neutron flux in each energy group, written as $\phi_g(\mathbf{r})$, with $1 \leq g \leq G$. The steady-state condition requires an exact balance between neutron loss and production. If this condition is not fulfilled, the production rate is divided by an adjustment factor, the *effective multiplication factor* K_{eff} , defined as

$$K_{\text{eff}} = \frac{\text{production rate by fission}}{\text{absorption rate} + \text{leakage rate}}. \quad (520)$$

In general, the steady-state condition $K_{\text{eff}} = 1$ is obtained by adjusting the *buckling* B^2 of the lattice calculation. The selected parameter used to force steady-state conditions is the *eigenvalue* of the calculation. At the end of a lattice calculation, the homogenized and condensed information is stored in the *reactor database*.

The second level of our computational scheme is the *full-core calculation*, aimed at producing the neutron flux and reaction rates over the complete reactor. This calculation is an assembly of homogenized cells or assemblies whose condensed nuclear properties are recovered from the reactor database. The homogenized cells or assemblies are generally arranged over a regular Cartesian or hexagonal mesh, so that the transport equation can be solved using standard numerical analysis techniques such as the *finite-difference* or *finite-element method* (FEM).

The full-core calculation consists of solving a simplified transport equation, either the *diffusion equation* or the *simplified P_n equation*, already presented in [3.4](#). This solution can be performed either in transient or steady-state conditions, in which case it can also be depicted by [Fig. 32](#), using a small number of energy groups (generally, $G = 2$ is sufficient). A steady-state full-core calculation generally uses the effective multiplication factor K_{eff} as eigenvalue. Another possible choice of eigenvalue is to select a poison concentration or the position of a reactivity device.

Full-core calculations offer the possibility of accurately representing the reactor boundary. A correct representation of neutron leakage will be possible, as neutrons effectively escape the reactor domain through its boundary. Consequently, 3D full-core calculations do not need a leakage model.

We will first investigate the steady-state solution of the transport equation over the complete reactor domain. The neutron balance over any control domain in energy group g will be written as

$$\text{Leakage rate} + \text{Collision rate} = \text{Sources}$$

or, in symbolic form, as

$$\nabla \cdot \mathbf{J}_g(\mathbf{r}) + \Sigma_g(\mathbf{r})\phi_g(\mathbf{r}) = Q_g(\mathbf{r}), \quad (521)$$

where $\mathbf{J}_g(\mathbf{r})$ is the *neutronic current*, as defined by (9). The definition of the neutronic current involves the introduction of an arbitrary surface whose unit normal vector is set to \mathbf{N} . The scalar product of the neutronic current with \mathbf{N} is equal to the net number of neutrons crossing the arbitrary surface per unit surface and time.

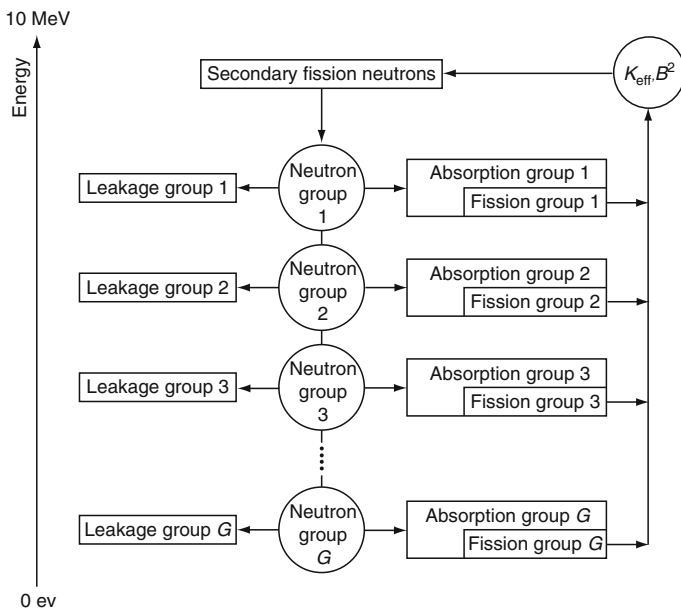

Figure 32
G-energy group transport calculation

The neutronic sources $Q_g(\mathbf{r})$ represent the production of secondary neutrons from scattering (including neutrons from (n,xn) reactions) and fission reactions. This term is written as

$$Q_g(\mathbf{r}) = \sum_{h=1}^G \Sigma_{g \leftarrow h}(\mathbf{r}) \phi_h(\mathbf{r}) + \frac{\chi_g(\mathbf{r})}{K_{\text{eff}}} \sum_{h=1}^G \nu \Sigma_{fh}(\mathbf{r}) \phi_h(\mathbf{r}), \tag{522}$$

where

- G = total number of energy groups
- $\Sigma_{g \leftarrow h}(\mathbf{r})$ = macroscopic-scattering cross-section from group h toward group g
- $\chi_g(\mathbf{r})$ = fission spectrum in group g
- $\nu \Sigma_{fh}(\mathbf{r})$ = product of the macroscopic fission cross-section by the average number of neutrons emitted per fission in group h

In the particular case where $G = 2$, as depicted in Fig. 33, two approximations will be made:

- A neutron cannot be accelerated from group 2 (thermal) toward group 1 (fast)
- All the secondary neutrons from fission are produced in group 1

The approximations are written as

$$\Sigma_{1 \leftarrow 2}(\mathbf{r}) = 0, \quad \chi_1(\mathbf{r}) = 1, \quad \text{and} \quad \chi_2(\mathbf{r}) = 0. \tag{523}$$

Using these approximations, the sources $Q_g(\mathbf{r})$ simplify to

$$\begin{aligned} Q_1(\mathbf{r}) &= \Sigma_{1 \leftarrow 1}(\mathbf{r}) \phi_1(\mathbf{r}) + \frac{1}{K_{\text{eff}}} [\nu \Sigma_{f1}(\mathbf{r}) \phi_1(\mathbf{r}) + \nu \Sigma_{f2}(\mathbf{r}) \phi_2(\mathbf{r})], \\ Q_2(\mathbf{r}) &= \Sigma_{2 \leftarrow 1}(\mathbf{r}) \phi_1(\mathbf{r}) + \Sigma_{2 \leftarrow 2}(\mathbf{r}) \phi_2(\mathbf{r}). \end{aligned} \tag{524}$$

We have obtained a balance equation for a steady-state reactor, corresponding to the situation where the leakage and absorption rates are exactly equal to the production rate of new neutrons, at all times, in each energy group. In this case, the effective multiplication factor K_{eff} is an artifact (or an *eigenvalue*) that satisfies this equality. This factor is expected to be

Figure 33 Two-group full-core calculation. This multigroup approximation is frequently used in full-core production calculations

close to one for a reactor in a nominal situation. An additional term can be added to the transport equation to represent transient behavior of the reactor in cases where the equality is not met.

Equation (521) must be solved on the scale of the complete reactor, correctly taking into account the position of its boundaries. Its solution requires additional information to relate the neutron flux and current. Two approaches are possible to obtain this information:

- Use a spherical harmonics (P_n) or discrete ordinate (S_N) approach, as proposed in Sects. 3 or 5. A legacy alternative is to use a variant of the P_n method based on the *simplified P_n equation*, as presented in 3.4. Gelbard (1960)
- Relate the neutron current to the gradient of the neutron flux using the *Fick law*.

This second choice will lead to the *diffusion equation*, used in this section.

7.1 The Fick Law

The *neutron diffusion equation* can be readily obtained by introducing the Fick law into (521). The Fick law is a heuristic relation between the neutron current and the gradient of the neutron flux, translating the fact that neutrons have a tendency to migrate from regions where they are more numerous to regions where they are less. This relation is known to be acceptable on the scale of the complete reactor, but not at the level of lattice calculations where it breaks down. It is written as

$$\mathbf{J}_g(\mathbf{r}) = -\mathbb{D}_g(\mathbf{r})\nabla\phi_g(\mathbf{r}), \quad (525)$$

where $\mathbb{D}_g(\mathbf{r})$ is a 3×3 diagonal tensor containing *directional diffusion coefficients*. Nondirectional diffusion coefficients are generally sufficient to represent streaming effects in the lattice. In this case, the three diagonal components are simply set to the same value. Directional diffusion coefficients are more closely related to the B_1 *heterogeneous streaming* effect occurring when long streaming channels or planes are open in the reactor. The unit of the diffusion coefficient is the centimeter (cm).

Substituting (525) into (521), we get

$$-\nabla \cdot \mathbb{D}_g(\mathbf{r})\nabla\phi_g(\mathbf{r}) + \Sigma_g(\mathbf{r})\phi_g(\mathbf{r}) = Q_g(\mathbf{r}). \quad (526)$$

The next step consists in subtracting the within-group scattering rate from both sides of (526). We obtain the one-speed neutron diffusion equation as

$$-\nabla \cdot \mathbb{D}_g(\mathbf{r})\nabla\phi_g(\mathbf{r}) + \Sigma_{rg}(\mathbf{r})\phi_g(\mathbf{r}) = Q_g^\diamond(\mathbf{r}), \quad (527)$$

where $\Sigma_{rg}(\mathbf{r}) = \Sigma_g(\mathbf{r}) - \Sigma_{g\leftarrow g}(\mathbf{r})$ is the *removal cross section* and where $Q_g^\diamond(\mathbf{r})$ is written as

$$Q_g^\diamond(\mathbf{r}) = \sum_{\substack{h=1 \\ h \neq g}}^G \Sigma_{g\leftarrow h}(\mathbf{r}) \phi_h(\mathbf{r}) + \frac{\chi_g(\mathbf{r})}{K_{\text{eff}}} \sum_{h=1}^G \nu \Sigma_{fh}(\mathbf{r}) \phi_h(\mathbf{r}). \quad (528)$$

In the two-energy group case ($G = 2$), (528) simplifies to

$$\begin{aligned} Q_1^\circ(\mathbf{r}) &= \frac{1}{K_{\text{eff}}} [v\Sigma_{f1}(\mathbf{r})\phi_1(\mathbf{r}) + v\Sigma_{f2}(\mathbf{r})\phi_2(\mathbf{r})], \\ Q_2^\circ(\mathbf{r}) &= \Sigma_{2\leftarrow 1}(\mathbf{r})\phi_1(\mathbf{r}). \end{aligned} \quad (529)$$

The neutron diffusion equation can be solved analytically in academic cases or using standard numerical analysis techniques such as the *finite difference* or *finite-element method*.

Substituting the source term from (528) into (527), we get the multigroup form of the steady-state neutron diffusion equation:

$$-\nabla \cdot \mathbb{D}_g(\mathbf{r})\nabla\phi_g(\mathbf{r}) + \Sigma_{rg}(\mathbf{r})\phi_g(\mathbf{r}) = \sum_{\substack{h=1 \\ h \neq g}}^G \Sigma_{g\leftarrow h}(\mathbf{r})\phi_h(\mathbf{r}) + \frac{\chi_g(\mathbf{r})}{\lambda} \sum_{h=1}^G v\Sigma_{fh}(\mathbf{r})\phi_h(\mathbf{r}). \quad (530)$$

Equation (530) is an *eigenproblem*, whose solution behaves in a typical way:

- A trivial solution of (530) is $\phi_g(\mathbf{r}) = 0, \forall \mathbf{r}$. Many nontrivial solutions of (530) exist for different eigenvalues λ . The largest eigenvalue in absolute value corresponds to the *fundamental solution* of the eigenproblem and is equal to the *effective multiplication factor* K_{eff} of the reactor. Only the fundamental solution has a physical meaning. The *eigenspectrum* of (530) is the set of all its eigenvalues (including K_{eff}).
- Only the fundamental solution can lead to a positive neutron flux $\phi_g(\mathbf{r})$ over the reactor domain. The other solutions are called *neutron flux harmonics* and lead to oscillating values of the flux, sometime positive, sometime negative. The knowledge of these harmonics is useful in some stability analysis as they correspond to natural excitation modes of the reactor.
- Every solution of (530) can be renormalized with an arbitrary normalization constant. If $\phi_g(\mathbf{r})$ is a solution, then $C\phi_g(\mathbf{r})$ is also a solution for any value of constant C . The normalization constant is generally computed from the knowledge of the reactor power using

$$\sum_{g=1}^G \int_V d^3r H_g(\mathbf{r})\phi_g(\mathbf{r}) = P, \quad (531)$$

where V is the volume of the reactor, $H_g(\mathbf{r})$ is the *H-factor*, and P is the power of the reactor. The H-factor permits the computation of the recoverable energy produced by the reactor.

- It is possible to find a *mathematical adjoint* to (530). This adjoint equation has the same *eigenspectrum* as (530).

The mathematical adjoint of (530) is obtained by permuting primary and secondary group indices. It is written as

$$-\nabla \cdot \mathbb{D}_g(\mathbf{r})\nabla\phi_g^*(\mathbf{r}) + \Sigma_{rg}(\mathbf{r})\phi_g^*(\mathbf{r}) = \sum_{\substack{h=1 \\ h \neq g}}^G \Sigma_{h\leftarrow g}(\mathbf{r})\phi_h^*(\mathbf{r}) + \frac{v\Sigma_{fg}(\mathbf{r})}{\lambda} \sum_{h=1}^G \chi_h(\mathbf{r})\phi_h^*(\mathbf{r}), \quad (532)$$

where $\phi_g^*(\mathbf{r})$ is the adjoint flux or adjoint-flux harmonics. The particular case with $G = 1$ is said to be *self-adjoint* as it corresponds to the case where $\phi_g^*(\mathbf{r}) = \phi_g(\mathbf{r})$. The adjoint flux can also be renormalized with an arbitrary normalization constant. It is generally normalized using the following arbitrary relation:

$$\sum_{g=1}^G \int_V d^3r \chi_g(\mathbf{r})\phi_g^*(\mathbf{r}) = 1. \quad (533)$$

7.2 Continuity and Boundary Conditions

The neutron flux is a continuous distribution of \mathbf{r} and the neutron current must be continuous across any imaginary surface (of unit normal \mathbf{N}) placed at any point of the reactor. Let's first imagine an infinite plane placed at abscissa x_0 . The flux continuity condition at this point is written as

$$\phi_g(x_0^-, y, z) = \phi_g(x_0^+, y, z) \quad \forall y \text{ and } z. \quad (534)$$

The neutron current continuity condition is written after introducing the unit normal $\mathbf{N} = (1, 0, 0)$, perpendicular to the infinite plane. We write

$$\mathbf{J}_g(x_0^-, y, z) \cdot \mathbf{N} = \mathbf{J}_g(x_0^+, y, z) \cdot \mathbf{N} \quad \forall y \text{ and } z. \quad (535)$$

Using the Fick law from (525), we obtain

$$-\mathbb{D}_g(x_0^-, y, z) \nabla \phi_g(x_0^-, y, z) \cdot \mathbf{N} = -\mathbb{D}_g(x_0^+, y, z) \nabla \phi_g(x_0^+, y, z) \cdot \mathbf{N} \quad \forall y \text{ and } z \quad (536)$$

or with the help of the first diagonal component $D_{x,g}(x, y, z)$ in $\mathbb{D}_g(x, y, z)$,

$$D_{x,g}(x_0^-, y, z) \left. \frac{d}{dx} \phi_g(x, y, z) \right|_{x=x_0^-} = D_{x,g}(x_0^+, y, z) \left. \frac{d}{dx} \phi_g(x, y, z) \right|_{x=x_0^+} \quad \forall y \text{ and } z. \quad (537)$$

Equation (537) clearly indicates that the neutron flux gradient is discontinuous at each point of the domain where the diffusion coefficient is discontinuous.

Boundary conditions must be applied at each point of the spatial domain boundary ∂V . We will identify the real boundaries and the symmetry boundaries, as depicted in  Fig. 34.

The most straightforward way to represent a real boundary is to set a *zero-flux boundary condition* on it. In this case, we simply write

$$\phi_g(\mathbf{r}) = 0 \quad \text{if } \mathbf{r} \in \partial W_i, \quad (538)$$

 Figure 34

Spatial domain with symmetries. The spatial boundary generally includes the complete reactor with its reflector, but it may happen that symmetries exist so that the domain may correspond to a fraction of the complete reactor

where ∂W_i is the fraction of ∂V where the zero-flux condition is applied. However, this condition is not fully satisfactory, as it assumes the *absence* of neutrons on ∂W_i . It would be more exact to assume a *zero-incoming current condition* translating the fact that neutrons can escape from the real boundary but cannot be reflected back. Such a condition can be seen as a particular case of the more general *albedo-boundary condition*.

To implement this condition, we first identify the incoming and outgoing net currents using

$$\mathbf{J}_g(\mathbf{r}) \cdot \mathbf{N}(\mathbf{r}) = J_g^+(\mathbf{r}) - J_g^-(\mathbf{r}) \quad \text{if } \mathbf{r} \in \partial W_i, \quad (539)$$

where $\mathbf{N}(\mathbf{r})$ is a unit vector, located at \mathbf{r} , normal to ∂W_i , and pointing in the outgoing direction, as depicted in  Fig. 35.

The *albedo* at \mathbf{r} is defined by the relation

$$\beta_g(\mathbf{r}) = \frac{J_g^-(\mathbf{r})}{J_g^+(\mathbf{r})} \quad \text{if } \mathbf{r} \in \partial W_i. \quad (540)$$

In general, we use the same albedo in all energy groups. The most usual values are $\beta(\mathbf{r}) = 0$ to represent a *zero-incoming current condition* and $\beta(\mathbf{r}) = 1$ to represent a symmetry condition. However, any positive value of $\beta(\mathbf{r})$ can be set at a boundary.

We have shown in  Sect. 1 that the incoming and outgoing net currents can be obtained from the neutron current and flux distributions provided the angular flux is represented by a limited P_1 expansion. In this case, we recall (42) and (43) as

$$J_g^-(\mathbf{r}) = \frac{1}{4} \phi_g(\mathbf{r}) - \frac{1}{2} \mathbf{J}_g(\mathbf{r}) \cdot \mathbf{N}(\mathbf{r})$$

and

$$J_g^+(\mathbf{r}) = \frac{1}{4} \phi_g(\mathbf{r}) + \frac{1}{2} \mathbf{J}_g(\mathbf{r}) \cdot \mathbf{N}(\mathbf{r}). \quad (541)$$

Substituting (541) into (540) and using the Fick law (525), we obtain the *albedo boundary condition* as

$$\mathbb{D}_g(\mathbf{r}) \nabla \phi_g(\mathbf{r}) \cdot \mathbf{N}(\mathbf{r}) + \frac{1 - \beta(\mathbf{r})}{2(1 + \beta(\mathbf{r}))} \phi_g(\mathbf{r}) = 0 \quad \text{if } \mathbf{r} \in \partial W_i, \quad (542)$$

where ∂W_i is the fraction of ∂V where the albedo-boundary condition is applied.

 **Figure 35**
Definition of incoming and outgoing net currents

The zero-incoming current condition ($J_g^-(\mathbf{r}) = 0$) is obtained by setting $\beta(\mathbf{r}) = 0$. However, it can be shown that the Fick law and the P_1 approximation used in [Sect. 1](#) introduce an error that can be reduced by using a value of $\beta(\mathbf{r})$ slightly above zero. It is sometimes recommended to represent the zero-incoming current condition using the value $\beta(\mathbf{r}) = 0.031758$.

Another particular case is the symmetry condition obtained by setting the albedo to value $\beta(\mathbf{r}) = 1$. In this case, (542) reduces to

$$\nabla \phi_g(\mathbf{r}) \cdot \mathbf{N}(\mathbf{r}) = 0 \quad \text{if } \mathbf{r} \in \partial W_i. \quad (543)$$

7.3 The Finite Homogenous Reactor

We will now study the particular case of a homogenous and finite reactor surrounded by zero-flux or symmetry-boundary conditions, represented by (538) and (543), respectively. We will also use nondirectional diffusion coefficients. With all these simplifications, it is now possible to obtain an analytical solution for the diffusion equation, whatever the form of the reactor or the number of energy groups. This analytic solution is similar to the relations obtained with a homogenous fundamental mode approximation. In this case, the nuclear properties of the reactor are independent of space and (530) simplifies to

$$-D_g \nabla^2 \phi_g(\mathbf{r}) + \Sigma_{rg} \phi_g(\mathbf{r}) = \sum_{\substack{h=1 \\ h \neq g}}^G \Sigma_{g \leftarrow h} \phi_h(\mathbf{r}) + \frac{\chi_g}{K_{\text{eff}}} \sum_{h=1}^G \nu \Sigma_{fh} \phi_h(\mathbf{r}). \quad (544)$$

It is possible to factorize the flux according to

$$\phi_g(\mathbf{r}) = \psi(\mathbf{r}) \varphi_g. \quad (545)$$

Substituting (545) into (544), we obtain

$$-\frac{\nabla^2 \psi(\mathbf{r})}{\psi(\mathbf{r})} = -\frac{\Sigma_{rg}}{D_g} + \frac{1}{D_g \varphi_g} \left\{ \sum_{\substack{h=1 \\ h \neq g}}^G \Sigma_{g \leftarrow h} \varphi_h + \frac{\chi_g}{K_{\text{eff}}} \sum_{h=1}^G \nu \Sigma_{fh} \varphi_h \right\}. \quad (546)$$

We note that the left side of (546) is independent of the neutron energy, whereas its right side is independent of the position in the reactor. This fact is only possible if each side of (546) is itself equal to the same constant. The choice of this constant is arbitrary, and any real number can be selected. Here, by analogy to the fundamental mode approximation, this constant was set equal to B^2 , the *buckling* of the reactor. We therefore obtain two independent equations as

$$\nabla^2 \psi(\mathbf{r}) + B^2 \psi(\mathbf{r}) = 0 \quad (547)$$

and

$$[D_g B^2 + \Sigma_{rg}] \varphi_g = \sum_{\substack{h=1 \\ h \neq g}}^G \Sigma_{g \leftarrow h} \varphi_h + \frac{\chi_g}{K_{\text{eff}}} \sum_{h=1}^G \nu \Sigma_{fh} \varphi_h. \quad (548)$$

Equation (547) is a Laplace equation, an eigenproblem whose eigenvalue is the buckling B^2 . Its solution is a function of the shape and size of the reactor and of the boundary conditions. Substituting the factorization (545) in the boundary conditions (538) and (543), we get

- Zero-flux-boundary condition:

$$\psi(\mathbf{r}) = 0 \quad \text{if } \mathbf{r} \in \partial W_i \quad (549)$$

- Symmetry-boundary condition:

$$\nabla\psi(\mathbf{r}) \cdot \mathbf{N}(\mathbf{r}) = 0 \quad \text{if } \mathbf{r} \in \partial W_i. \quad (550)$$

Here, the more general albedo-boundary condition (542) cannot be factorized and cannot be used in this analytical solution technique of a finite homogenous reactor.

Equation (547) has many nontrivial solutions, each of them corresponding to an element of its eigenspectrum. Only the fundamental solution corresponds to a positive neutron flux everywhere in the domain.

The Laplace operator ∇^2 can be written in different ways, depending on the coordinate system selected to solve the problem. We will present the three most usual coordinate systems.

7.3.1 Cartesian Coordinate System

The Cartesian coordinate system is the most usual choice for real application problems. In this case, the Laplace operator is written as

$$\nabla^2\psi = \frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2} + \frac{\partial^2\psi}{\partial z^2}. \quad (551)$$

Let us consider a prismatic homogenous reactor of dimension $L_x \times L_y \times L_z$. In this case, the fundamental solution of (547) is

$$\psi(x, y, z) = C \sin \frac{\pi x}{L_x} \sin \frac{\pi y}{L_y} \sin \frac{\pi z}{L_z}. \quad (552)$$

The Cartesian domain is defined over $0 \leq x \leq L_x$, $0 \leq y \leq L_y$, and $0 < z < L_z$. A *zero-flux-boundary condition* is imposed on the surface of the domain. The normalization constant C is arbitrary as both (547) and (548) are eigenproblems.

The corresponding critical buckling is

$$B^2 = \left(\frac{\pi}{L_x}\right)^2 + \left(\frac{\pi}{L_y}\right)^2 + \left(\frac{\pi}{L_z}\right)^2. \quad (553)$$

7.3.2 Spherical Coordinate System

The spherical coordinate system is depicted in  Fig. 36. In this case, the Laplace operator is written as

$$\nabla^2\psi = \frac{1}{r^2 \sin \theta} \left[\sin \theta \frac{\partial}{\partial r} \left(r^2 \frac{\partial \psi}{\partial r} \right) + \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial \psi}{\partial \theta} \right) + \frac{1}{\sin \theta} \frac{\partial^2 \psi}{\partial \varepsilon^2} \right]. \quad (554)$$

■ **Figure 36**
Definition of the spherical coordinate system

The fundamental solution of (547) represents the neutron flux in a spherical reactor of radius R . A *zero-flux-boundary condition* is imposed at $r = R$ (i.e., $\psi(R) = 0$). The fundamental solution is written as

$$\psi(r) = \frac{C}{r} \sin \frac{\pi r}{R} \quad (555)$$

with the critical buckling equal to

$$B^2 = \left(\frac{\pi}{R}\right)^2. \quad (556)$$

7.3.3 Cylindrical Coordinate System

The cylindrical coordinate system is depicted in ► Fig. 37. In this case, the Laplace operator is written as

$$\nabla^2 \psi = \frac{1}{\rho} \left[\frac{\partial}{\partial \rho} \left(\rho \frac{\partial \psi}{\partial \rho} \right) + \frac{1}{\rho} \frac{\partial^2 \psi}{\partial \varepsilon^2} + \rho \frac{\partial^2 \psi}{\partial z^2} \right]. \quad (557)$$

The fundamental solution of (547) represents the neutron flux in a cylindrical reactor of radius R and height L_z . The spatial domain is defined as $0 \leq \rho \leq R$ and $0 \leq z \leq L_z$. A *zero-flux-boundary condition* is imposed on the surface of the domain. The fundamental solution is

$$\psi(\rho, z) = C J_0 \left(\frac{2.405 \rho}{R} \right) \sin \frac{\pi z}{L_z} \quad (558)$$

with the critical buckling equal to

$$B^2 = \left(\frac{2.405}{R}\right)^2 + \left(\frac{\pi}{L_z}\right)^2, \quad (559)$$

where $J_0(x)$ is a zeroth-order ordinary Bessel function, such as $J_0(2.405) = 0$.

Figure 37 Definition of the cylindrical coordinate system

7.4 The Heterogenous 1D Slab Reactor

The one-dimensional (1D) heterogenous reactor configurations correspond to the case where the neutron flux is a function of a unique spatial variable. These cases can be solved analytically, whatever the type of conditions imposed at boundaries. These academic cases are useful to validate solutions based on numerical analysis techniques. Here, we are limiting our investigations to a 1D Cartesian domain made from the assembly of many infinite slabs.

In this case, the nuclear properties of the reactor are only a function of the independent variable x . Equation (530) simplifies to

$$-\frac{d}{dx} D_g(x) \frac{d\phi_g}{dx} + \Sigma_{rg}(x) \phi_g(x) = Q_g^\diamond(x), \tag{560}$$

where

$$Q_g^\diamond(x) = \sum_{\substack{h=1 \\ h \neq g}}^G \Sigma_{g \leftarrow h}(x) \phi_h(x) + \frac{\chi_g(x)}{K_{\text{eff}}} \sum_{h=1}^G \nu \Sigma_{fh}(x) \phi_h(x). \tag{561}$$

The boundary conditions are either a zero-flux condition ($\phi_g(x) = 0$) or an albedo condition written as

$$\mp D_g(x) \frac{d\phi_g}{dx} + \frac{1 - \beta(x)}{2(1 + \beta(x))} \phi_g(x) = 0, \tag{562}$$

where the sign “-” or “+” is used for a left ($x = x_{l/2}$) or a right boundary ($x = x_{l+1/2}$), respectively.

Each slab is assumed to be homogenous, so that the corresponding nuclear properties $D_g(x)$, $\Sigma_{rg}(x)$, $\Sigma_{g \leftarrow h}(x)$, $\chi_g(x)$, and $\nu \Sigma_{fh}(x)$ are piecewise continuous. As shown in Fig. 38, the reactor domain is divided into I regions of indices $1 \leq i \leq I$, in such a way that the nuclear properties in region i are constant and equal to $D_{g,i}$, $\Sigma_{rg,i}$, $\Sigma_{g \leftarrow h,i}$, $\chi_{g,i}$, and $\nu \Sigma_{fh,i}$.

■ Figure 38

Definition of the regions in 1D slab geometry

Equation (560) can be written in such a way as to be valid in region i as

$$-D_{g,i} \frac{d^2 \phi_g}{dx^2} + \Sigma_{rg,i} \phi_g(x) = Q_g^\diamond(x), \quad (563)$$

where

$$Q_g^\diamond(x) = \sum_{\substack{h=1 \\ h \neq g}}^G \Sigma_{g \leftarrow h,i} \phi_h(x) + \frac{\chi_{g,i}}{K_{\text{eff}}} \sum_{h=1}^G v \Sigma_{fh,i} \phi_h(x) \quad (564)$$

if $x_{i-1/2} < x < x_{i+1/2}$.

At this point, we introduce the analytical solution approach for (563). It is based on a *linear transformation technique*, valid only for multigroup 1D problems. Equation (563) is first rewritten in matrix form as

$$\frac{d^2}{dx^2} \Phi(x) + \mathbb{F}_i \Phi(x) = \mathbf{0} \quad \text{if } x_{i-1/2} < x < x_{i+1/2} \quad (565)$$

with

$$\Phi(x) = \begin{pmatrix} \phi_1(x) \\ \vdots \\ \phi_G(x) \end{pmatrix} \quad (566)$$

and

$$\mathbb{F}_i = \begin{pmatrix} f_{11,i} & f_{12,i} & \cdots & f_{1G,i} \\ f_{21,i} & f_{22,i} & \cdots & f_{2G,i} \\ \vdots & \vdots & \ddots & \vdots \\ f_{G1,i} & f_{G2,i} & \cdots & f_{GG,i} \end{pmatrix}, \quad (567)$$

where the components $f_{gh,i}$ of this matrix are written as

$$f_{gh,i} = \frac{1}{D_{g,i}} \left[-\Sigma_{rg,i} \delta_{gh} + \Sigma_{g \leftarrow h,i} (1 - \delta_{gh}) + \frac{\chi_{g,i}}{K_{\text{eff}}} v \Sigma_{fh,i} \right]. \quad (568)$$

The next step consists in finding all eigenvectors $\mathbf{t}_{\ell,i}$ of matrix \mathbb{F}_i with the associated eigenvalues $\lambda_{\ell,i}$. We build a matrix \mathbb{T}_i whose columns are the eigenvectors of \mathbb{F}_i . This matrix is written as

$$\mathbb{T}_i = (\mathbf{t}_{1,i} \quad \mathbf{t}_{2,i} \quad \cdots \quad \mathbf{t}_{G,i}) \quad (569)$$

so that

$$\mathbb{F}_i \mathbb{T}_i = \mathbb{T}_i \text{diag}(\lambda_{\ell,i}). \quad (570)$$

The linear transformation technique used to solve (560) is based on the introduction of an unknown vector $\Psi(x)$ defined as

$$\Phi(x) = \mathbb{T}_i \Psi(x) = \begin{pmatrix} t_{11,i} & t_{12,i} & \dots & t_{1G,i} \\ t_{21,i} & t_{22,i} & \dots & t_{2G,i} \\ \vdots & \vdots & \ddots & \vdots \\ t_{G1,i} & t_{G2,i} & \dots & t_{GG,i} \end{pmatrix} \begin{pmatrix} \psi_1(x) \\ \psi_2(x) \\ \vdots \\ \psi_G(x) \end{pmatrix} \quad (571)$$

and to its substitution in (565). We obtain

$$\frac{d^2}{dx^2} \mathbb{T}_i \Psi(x) + \mathbb{F}_i \mathbb{T}_i \Psi(x) = \mathbf{0} \quad \text{if } x_{i-1/2} < x < x_{i+1/2}. \quad (572)$$

We next left-multiply each side of (572) by $[\mathbb{T}_i]^{-1}$ and use (570) to obtain

$$\frac{d^2}{dx^2} \Psi(x) + \text{diag}(\lambda_{\ell,i}) \Psi(x) = \mathbf{0} \quad \text{if } x_{i-1/2} < x < x_{i+1/2}. \quad (573)$$

Equation (573) is similar to (565) with the difference that all the energy groups are uncoupled. Its resolution is reduced to the solution of G one-speed problems. In each energy group g , we assume an analytical solution of the form

$$\psi_g(x) = \begin{cases} A_{g,i} \cos(\sqrt{\lambda_{g,i}} x) + B_{g,i} \sin(\sqrt{\lambda_{g,i}} x) & \text{if } \lambda_{g,i} \geq 0, \\ C_{g,i} \cosh(\sqrt{-\lambda_{g,i}} x) + E_{g,i} \sinh(\sqrt{-\lambda_{g,i}} x) & \text{otherwise,} \end{cases} \quad (574)$$

if $x_{i-1/2} < x < x_{i+1/2}$.

The analytical expression of the flux $\phi_g(x)$ is obtained after substitution of (574) into (571) as

$$\phi_g(x) = \sum_{h=1}^G t_{gh,i} \psi_h(x) \quad \text{if } x_{i-1/2} < x < x_{i+1/2}. \quad (575)$$

The final step consists of coupling together the analytical solutions of each region i and applying the boundary conditions. If region $i-1$ exists (i.e., if the left side of region i is not a boundary), the solution obeys the continuity relations (534) and (537), so that

$$\phi_g(x_{i-1/2}^-) = \phi_g(x_{i-1/2}^+) \quad (576)$$

and

$$D_{g,i-1} \phi_g'(x_{i-1/2}^-) = D_{g,i} \phi_g'(x_{i-1/2}^+), \quad (577)$$

where we defined $\phi'_g(x_{i-1/2}^-) = (d\phi_g/dx)|_{x=x_{i-1/2}^-}$. Similarly, if region $i + 1$ exists, we write

$$\phi_g(x_{i+1/2}^-) = \phi_g(x_{i+1/2}^+) \quad (578)$$

and

$$D_{g,i} \phi'_g(x_{i+1/2}^-) = D_{g,i+1} \phi'_g(x_{i+1/2}^+). \quad (579)$$

The boundary conditions are imposed in the same way, by forcing the value of $\phi_g(x)$ or $\phi'_g(x)$ on a boundary abscissa.

An analytical solution of (563) with its continuity and boundary conditions can always be found, with a computational effort increasing with the number of energy groups and regions. We will now apply this analytical technique to a simple two-region problem.

7.4.1 Two-Region Example

We now apply the linear transformation technique to the one-speed, two-region problem depicted in  Fig. 39. In this case, (563) simplifies to

$$-D_i \frac{d^2\phi}{dx^2} + \Sigma_{r,i} \phi(x) = \frac{1}{K_{\text{eff}}} \nu \Sigma_{f,i} \phi(x) \quad \text{if } x_{i-1/2} < x < x_{i+1/2}. \quad (580)$$

We assume an analytical solution of the form

$$\phi(x) = \begin{cases} A_{11} \cos(\kappa_1 x) + A_{21} \sin(\kappa_1 x), & \text{if } 0 \leq x \leq \frac{1}{2}; \\ A_{12} \cos(\kappa_2 x) + A_{22} \sin(\kappa_2 x), & \text{if } \frac{1}{2} \leq x \leq 1, \end{cases} \quad (581)$$

so that

$$\phi'(x) = \begin{cases} -A_{11} \kappa_1 \sin(\kappa_1 x) + A_{21} \kappa_1 \cos(\kappa_1 x), & \text{if } 0 \leq x \leq \frac{1}{2}, \\ -A_{12} \kappa_2 \sin(\kappa_2 x) + A_{22} \kappa_2 \cos(\kappa_2 x), & \text{if } \frac{1}{2} \leq x \leq 1 \end{cases} \quad (582)$$

 Figure 39

Two-region 1D slab reactor

and

$$\frac{d^2\phi}{dx^2} = \begin{cases} -A_{11} \kappa_1^2 \cos(\kappa_1 x) - A_{21} \kappa_1^2 \sin(\kappa_1 x), & \text{if } 0 \leq x \leq \frac{1}{2}, \\ -A_{12} \kappa_2^2 \cos(\kappa_2 x) - A_{22} \kappa_2^2 \sin(\kappa_2 x), & \text{if } \frac{1}{2} \leq x \leq 1. \end{cases} \quad (583)$$

The left zero-flux boundary condition is written as

$$\phi(0) = A_{11} = 0. \quad (584)$$

The continuity conditions at $x = \frac{1}{2}$ are written as

$$A_{11} \cos\left(\frac{\kappa_1}{2}\right) + A_{21} \sin\left(\frac{\kappa_1}{2}\right) = A_{12} \cos\left(\frac{\kappa_2}{2}\right) + A_{22} \sin\left(\frac{\kappa_2}{2}\right) \quad (585)$$

and

$$\begin{aligned} & -A_{11} \kappa_1 D_1 \sin\left(\frac{\kappa_1}{2}\right) + A_{21} \kappa_1 D_1 \cos\left(\frac{\kappa_1}{2}\right) \\ & = -A_{12} \kappa_2 D_2 \sin\left(\frac{\kappa_2}{2}\right) + A_{22} \kappa_2 D_2 \cos\left(\frac{\kappa_2}{2}\right). \end{aligned} \quad (586)$$

Finally, the right-symmetry-boundary condition is written as

$$-A_{12} \kappa_2 \sin(\kappa_2) + A_{22} \kappa_2 \cos(\kappa_2) = 0$$

so that

$$A_{22} = A_{12} \tan(\kappa_2). \quad (587)$$

Substituting (584) and (587) into (585) and (586), we find the following matrix equation:

$$\begin{pmatrix} \sin\left(\frac{\kappa_1}{2}\right) & -\frac{1}{\cos(\kappa_2)} \cos\left(\frac{\kappa_2}{2}\right) \\ \kappa_1 D_1 \cos\left(\frac{\kappa_1}{2}\right) & -\frac{\kappa_2 D_2}{\cos(\kappa_2)} \sin\left(\frac{\kappa_2}{2}\right) \end{pmatrix} \begin{pmatrix} A_{21} \\ A_{12} \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}. \quad (588)$$

Equation (588) has a nontrivial solution only if its determinant is zero. We write

$$\det \begin{pmatrix} \sin\left(\frac{\kappa_1}{2}\right) & -\frac{1}{\cos(\kappa_2)} \cos\left(\frac{\kappa_2}{2}\right) \\ \kappa_1 D_1 \cos\left(\frac{\kappa_1}{2}\right) & -\frac{\kappa_2 D_2}{\cos(\kappa_2)} \sin\left(\frac{\kappa_2}{2}\right) \end{pmatrix} = 0 \quad (589)$$

so that the resulting characteristic equation is a nonlinear relation in κ_1 and κ_2 , written as

$$\tan\left(\frac{\kappa_1}{2}\right) \tan\left(\frac{\kappa_2}{2}\right) = \frac{\kappa_1 D_1}{\kappa_2 D_2}. \quad (590)$$

Substituting (581) and (583) into (580), we find the expressions of κ_1 and κ_2 as

$$\kappa_1 = \sqrt{\frac{v\Sigma_{f,1} - K_{\text{eff}}\Sigma_{r,1}}{K_{\text{eff}}D_1}} \quad \text{and} \quad \kappa_2 = \sqrt{\frac{v\Sigma_{f,2} - K_{\text{eff}}\Sigma_{r,2}}{K_{\text{eff}}D_2}}. \quad (591)$$

Combining (590) and (591), we obtain the nonlinear expression of the effective multiplication factor K_{eff} as

$$\tan\left(\frac{1}{2}\sqrt{\frac{\nu\Sigma_{f,1} - K_{\text{eff}}\Sigma_{r,1}}{K_{\text{eff}}D_1}}\right)\tan\left(\frac{1}{2}\sqrt{\frac{\nu\Sigma_{f,2} - K_{\text{eff}}\Sigma_{r,2}}{K_{\text{eff}}D_2}}\right) = \sqrt{\frac{D_1(\nu\Sigma_{f,1} - K_{\text{eff}}\Sigma_{r,1})}{D_2(\nu\Sigma_{f,2} - K_{\text{eff}}\Sigma_{r,2})}}. \quad (592)$$

The effective multiplication factor is obtained by solving (592) using a numerical technique for the solution of a nonlinear equation with one unknown. Knowledge of K_{eff} permits the computation of κ_1 and κ_2 , and the determination of the analytical expression of the neutron flux $\phi(x)$, the eigenvector corresponding to K_{eff} . Its value is

$$\phi(x) = \begin{cases} A_{21} \sin(\kappa_1 x), & \text{if } 0 \leq x \leq \frac{1}{2}, \\ A_{21} \frac{\sin\left(\frac{\kappa_1}{2}\right)}{\cos\left(\frac{\kappa_2}{2}\right)} \cos[\kappa_2(1-x)], & \text{if } \frac{1}{2} \leq x \leq 1. \end{cases} \quad (593)$$

The neutron flux can be renormalized to the power of the reactor by adjusting the remaining constant A_{21} .

8 Discretization of the Neutron Diffusion Equation

We refer to as *discretization* the technique we use to transform an algebraic operator, similar to those present in a differential equation, into a matrix operator. A discretization of the neutron diffusion equation allows its transformation into a matrix system that can be solved by standard numerical analysis techniques. A variety of different discretization techniques exists and many techniques, at first view different, produce *identical* matrix systems. A discretization technique is characterized by the following criteria:

- A discretization technique is said to be *consistent* if the discretization of a *Laplace operator* $\nabla^2\phi(\mathbf{r})$ produces a symmetric, positive-definite- and diagonally dominant matrix. Consistent discretization techniques are generally based on polynomial approximation of the dependent variable (here, the neutron flux) in each region. Each homogeneous region of the reactor can be subdivided into subregions in order to increase the number of piecewise polynomials. This operation is called *sub-meshing*. Moreover, a numerical solution of a consistent discretization technique must tend to the exact solution of the differential problem
 - As the number of subregions increases to infinity, for a given order of the polynomial basis,
 - As the polynomial order of the polynomial basis increases to infinity, for a given number of subregions.

The criterion relative to the symmetry of the matrix operator is important to ensure that the discretization of an adjoint differential equation, similar to (532), leads to the transposed matrix operator obtained from the discretization of the direct differential equation ((530)

in this case). Moreover, the positive-definite and diagonally dominant criteria ensure the success of the standard numerical analysis techniques used to solve the matrix system.

- Discretization techniques can be derived from the *differential formulation* of the neutron diffusion equation by replacing the dependent variable with *Taylor's expansions* or by using a *weighted residual approach*. They can also be obtained from a *variational formulation* by finding a *stationary point* of an ad-hoc functional. In this case, the choice of the functional is arbitrary, the only condition being that the *Euler equations* of the functional must be identical to the neutron diffusion equation with its continuity and boundary conditions. The variational approach and the FEM are presented in [▶ 8.3](#) and [▶ 8.4](#).
- A discretization technique can be *primal* if it belongs to the family of *mesh-corner-finite differences*, or *dual* if it belongs to the family of *mesh-centered finite differences*. A discretization technique can be simultaneously primal and dual; this property is called *primal-dual agreement* and is a characteristic of *superconvergent* approximations (Hébert 2005).

Both mesh-corner and mesh-centered techniques are consistent discretization approaches that can be obtained from the differential formulation of the neutron diffusion equation. These two basic formulations are presented in [▶ 8.1](#) and [▶ 8.2](#).

8.1 Mesh-Corner Finite Differences

The 1D Cartesian mesh-corner finite-difference formulation can be derived from the differential formulation of the neutron diffusion equation. This approach consists of replacing the flux derivative terms in (560) and (562) by finite-difference relations written in terms of the neutron flux values at specific abscissa points. These finite-difference relations can be obtained from the Taylor expansion of the neutron flux between successive points.

The choice of the abscissa points where the neutron flux is explicitly calculated determines the type of finite-difference approximation. In its mesh-corner formulation, these points are chosen on the boundary between subregions and are numbered as depicted in [▶ Fig. 38](#). We will use Taylor expansions to represent the flux at points $x_{i-3/2}$ and $x_{i+1/2}$ in terms of the flux at point $x_{i-1/2}$, so that

$$\phi(x_{i-3/2}) = \phi(x_{i-1/2}) - \Delta x_{i-1} \phi'(x_{i-1/2}^-) + \frac{1}{2} \Delta x_{i-1}^2 \phi''(x_{i-1/2}^-) \quad (594)$$

and

$$\phi(x_{i+1/2}) = \phi(x_{i-1/2}) + \Delta x_i \phi'(x_{i-1/2}^+) + \frac{1}{2} \Delta x_i^2 \phi''(x_{i-1/2}^+), \quad (595)$$

where the energy group index was omitted, in order to simplify the notation.

Care must be taken to correctly represent the discontinuous behavior of the first derivative of the neutron flux at material discontinuities. The neutron current continuity condition at $x_{i-1/2}$ causes a discontinuity in the first derivative of the neutron flux at this point. This relation is written as

$$D_{i-1} \phi'(x_{i-1/2}^-) = D_i \phi'(x_{i-1/2}^+). \quad (596)$$

We multiply (594) and (595) by $D_{i-1}/\Delta x_{i-1}$ and $D_i/\Delta x_i$, respectively, add the resulting relations, and introduce (596). We obtain

$$\begin{aligned} & \frac{1}{2} \left[\Delta x_{i-1} D_{i-1} \phi''(x_{i-1/2}^-) + \Delta x_i D_i \phi''(x_{i-1/2}^+) \right] \\ &= \frac{D_i}{\Delta x_i} \left[\phi(x_{i+1/2}) - \phi(x_{i-1/2}) \right] - \frac{D_{i-1}}{\Delta x_{i-1}} \left[\phi(x_{i-1/2}) - \phi(x_{i-3/2}) \right]. \end{aligned} \quad (597)$$

Equation (597) is used as a finite-difference relation valid for the internal points. We also need relations valid on the left- and right-boundary points where an *albedo boundary condition* is imposed. In this case, a Taylor expansion is written as

$$\phi(x_{3/2}) = \phi(x_{1/2}) + \Delta x_1 \phi'(x_{1/2}) + \frac{1}{2} \Delta x_1^2 \phi''(x_{1/2}) \quad (598)$$

for the left boundary and

$$\phi(x_{I-1/2}) = \phi(x_{I+1/2}) - \Delta x_I \phi'(x_{I+1/2}) + \frac{1}{2} \Delta x_I^2 \phi''(x_{I+1/2}) \quad (599)$$

for the right boundary. We multiply these two relations by $D_1/\Delta x_1$ and $D_I/\Delta x_I$, respectively, and introduce (562). We obtain

$$\frac{1}{2} \Delta x_1 D_1 \phi''(x_{1/2}) = \frac{D_1}{\Delta x_1} \left[\phi(x_{3/2}) - \phi(x_{1/2}) \right] - \frac{1}{2} \frac{1 - \beta_-}{1 + \beta_-} \phi(x_{1/2}) \quad (600)$$

and

$$\frac{1}{2} \Delta x_I D_I \phi''(x_{I+1/2}) = \frac{D_I}{\Delta x_I} \left[\phi(x_{I-1/2}) - \phi(x_{I+1/2}) \right] - \frac{1}{2} \frac{1 - \beta_+}{1 + \beta_+} \phi(x_{I+1/2}), \quad (601)$$

where β_- and β_+ are the left- and right-domain albedos, respectively.

Our Taylor expansions are truncated after the term in Δx_i^2 . Consequently, the difference relations (597), (600), and (601) are accurate only to the second order in Δx_i^2 . *This order is the smallest one that leads to a consistent discretization of the diffusion equation.* This choice will limit the accuracy of the discretization process in terms of the selected mesh Δx_i^2 .

The final step of our discretization process consists in substituting the finite difference relations into the differential equation, that is, into the neutron diffusion equation. On both sides of point $x_{i-1/2}$, the nuclear properties are uniform, so that the neutron diffusion equation reduces to

$$-D_{i-1} \phi''(x_{i-1/2}^-) + \Sigma_{r,i-1} \phi(x_{i-1/2}) = Q_{i-1}^\diamond$$

and

$$-D_i \phi''(x_{i-1/2}^+) + \Sigma_{r,i} \phi(x_{i-1/2}) = Q_i^\diamond, \quad (602)$$

where the flat-source approximation leading to constant terms Q_{i-1}^\diamond and Q_i^\diamond is compatible with the truncation order of the Taylor series. A higher truncation order would have required spatially dependent neutron sources in the right term.

We multiply each of (602) with Δx_{i-1} and Δx_i , respectively, and we add the resulting relations. Introducing the finite-difference relations (597), (600), and (601), we obtain

- In mesh points internal to the domain:

$$\begin{aligned} & \frac{D_i}{\Delta x_i} [\phi_{i+1/2} - \phi_{i-1/2}] - \frac{D_{i-1}}{\Delta x_{i-1}} [\phi_{i-1/2} - \phi_{i-3/2}] \\ &= \frac{1}{2} \phi_{i-1/2} [\Delta x_i \Sigma_{r,i} + \Delta x_{i-1} \Sigma_{r,i-1}] - \frac{1}{2} [\Delta x_i Q_i^\diamond + \Delta x_{i-1} Q_{i-1}^\diamond], \end{aligned} \quad (603)$$

where we used the notation $\phi_{i-1/2} = \phi(x_{i-1/2})$.

- On zero-flux-boundary points:

$$\phi_{1/2} = 0 \quad \text{or} \quad \phi_{I+1/2} = 0. \quad (604)$$

- On the left-boundary point, assuming an *albedo-boundary condition*:

$$\frac{D_I}{\Delta x_1} [\phi_{3/2} - \phi_{1/2}] - \frac{1}{2} \frac{1 - \beta_-}{1 + \beta_-} \phi_{1/2} = \frac{1}{2} \Delta x_1 \Sigma_{r,1} \phi_{1/2} - \frac{1}{2} \Delta x_1 Q_1^\diamond. \quad (605)$$

- On the right-boundary point, assuming an *albedo-boundary condition*:

$$\frac{D_I}{\Delta x_I} [\phi_{I-1/2} - \phi_{I+1/2}] - \frac{1}{2} \frac{1 - \beta_+}{1 + \beta_+} \phi_{I+1/2} = \frac{1}{2} \Delta x_I \Sigma_{r,I} \phi_{I+1/2} - \frac{1}{2} \Delta x_I Q_I^\diamond. \quad (606)$$

The discretization process involves the transformation of (560) with its continuity and boundary conditions into a matrix system whose unknown vector, denoted Φ , is a set of neutron flux values selected at specific abscissa:

$$\Phi = \begin{pmatrix} \phi_{1/2} \\ \phi_{3/2} \\ \vdots \\ \phi_{I+1/2} \end{pmatrix}. \quad (607)$$

The matrix system is written as

$$\mathbb{A} \Phi = \mathbf{Q}, \quad (608)$$

where coefficient matrix \mathbb{A} and source vector \mathbf{Q} components correspond to the various terms of (603) to (606). Matrix \mathbb{A} is symmetric, positive definite, and diagonally dominant.

The numerical solution of (608) is greatly simplified by the particular structure of matrix \mathbb{A} . All its components are located in a *tridiagonal structure*, each component $\phi_{i-1/2}$ being related only to its two closest neighbors, $\phi_{i-3/2}$ and $\phi_{i+1/2}$. The wide acceptance of the mesh-corner finite-difference method is due to the observation that similar tridiagonal layouts are observed with two- and three-dimensional domains.

8.2 Mesh-Centered Finite Differences

The mesh-centered finite-difference method is an alternative to the mesh-corner finite-difference method frequently implemented in production codes for solving the neutron diffusion equation. It basically offers the same accuracy and the same advantages as the mesh-corner finite-difference method. However, the discretization errors originating from these two types of finite-difference methods are often of opposite sign: an overestimation of a power peak with one method is often associated with an underestimation with the other method. A careful mathematical study of this phenomenon reveals that the mesh-corner and mesh-centered finite-difference methods are the *Euler equations* of *primal* and *dual* variational formulations, respectively (Hébert 1993).

The mesh-centered finite-difference relations can be obtained in many different ways. We are presenting the simplest approach, which consists in assuming that the average neutron flux in a subregion is equal to the neutron flux at the center of this subregion. We consider the subregion surrounding the abscissa point x_i and write the neutron flux at this point, using  Fig. 38 to define the other abscissa values. We obtain

$$\phi_i = \phi(x_i) = \frac{1}{\Delta x_i} \int_{x_{i-1/2}}^{x_{i+1/2}} dx \phi(x). \quad (609)$$

The next step consists in integrating (563) over each subregion, so that

$$-D_i \int_{x_{i-1/2}}^{x_{i+1/2}} dx \frac{d^2 \phi}{dx^2} + \Sigma_{r,i} \int_{x_{i-1/2}}^{x_{i+1/2}} dx \phi(x) = \Delta x_i Q_i^\diamond, \quad (610)$$

where we assumed that neutron sources $Q^\diamond(x)$ are uniform and equal to Q_i^\diamond over subregion i .

The first term on the left can be integrated analytically. Introducing (609), we get

$$-D_i [\phi'(x_{i+1/2}^-) - \phi'(x_{i-1/2}^+)] + \Delta x_i \Sigma_{r,i} \phi(x_i) = \Delta x_i Q_i^\diamond. \quad (611)$$

The differential terms of (611) are replaced with finite-difference relations. These relations can be obtained from the following two Taylor expansions:

$$\phi(x_{i-1}) = \phi(x_{i-1/2}) - \frac{\Delta x_{i-1}}{2} \phi'(x_{i-1/2}^-) \quad (612)$$

and

$$\phi(x_i) = \phi(x_{i-1/2}) + \frac{\Delta x_i}{2} \phi'(x_{i-1/2}^+). \quad (613)$$

We also remember the neutron-current continuity condition at point $x_{i-1/2}$. This condition is written as

$$D_{i-1} \phi'(x_{i-1/2}^-) = D_i \phi'(x_{i-1/2}^+). \quad (614)$$

We multiply (612) and (613) by $D_{i-1}/\Delta x_{i-1}$ and $D_i/\Delta x_i$, respectively, and add these relations in such a way as to eliminate the derivatives of the flux with the help of (614). We obtain

$$\phi(x_{i-1/2}) = \frac{\Delta x_i D_{i-1} \phi(x_{i-1}) + \Delta x_{i-1} D_i \phi(x_i)}{\Delta x_i D_{i-1} + \Delta x_{i-1} D_i}. \quad (615)$$

After substitution of (615) into (613), we obtain our first mesh-centered finite-difference relation as

$$\phi' (x_{i-1/2}^+) = 2D_{i-1} \frac{\phi(x_i) - \phi(x_{i-1})}{\Delta x_i D_{i-1} + \Delta x_{i-1} D_i}. \quad (616)$$

Using a similar approach, we obtain a second mesh-centered finite-difference relation as

$$\phi' (x_{i+1/2}^-) = 2D_{i+1} \frac{\phi(x_{i+1}) - \phi(x_i)}{\Delta x_{i+1} D_i + \Delta x_i D_{i+1}}. \quad (617)$$

Let us now consider the case where the left-most surface is characterized by a *zero-flux boundary condition*. Setting $\phi(x_{1/2}) = 0$ in (613) leads to the corresponding finite-difference relation. It is written as

$$\phi' (x_{1/2}^+) = \frac{2}{\Delta x_1} \phi(x_1). \quad (618)$$

Similarly, if the left-most surface is characterized by an *albedo-boundary condition*, we combine (562) and (613) to obtain

$$\phi' (x_{1/2}^+) = \frac{2(1 - \beta_-)}{4D_1(1 + \beta_-) + \Delta x_1(1 - \beta_-)} \phi(x_1). \quad (619)$$

The substitution of finite-difference (616) to (619) into (611) leads to the complete set of mesh-centered finite-difference relations. A specific relation is written for each of the following situations:

- The subregion i is internal to the domain:

$$\begin{aligned} & 2 \left[D_i D_{i+1} \frac{\phi_{i+1} - \phi_i}{\Delta x_{i+1} D_i + \Delta x_i D_{i+1}} - D_i D_{i-1} \frac{\phi_i - \phi_{i-1}}{\Delta x_i D_{i-1} + \Delta x_{i-1} D_i} \right] \\ & = \Delta x_i \Sigma_{r,i} \phi_i - \Delta x_i Q_i^\diamond. \end{aligned} \quad (620)$$

- The left surface of subregion $i = 1$ is characterized by a zero-flux-boundary condition:

$$2 \left[D_1 D_2 \frac{\phi_2 - \phi_1}{\Delta x_2 D_1 + \Delta x_1 D_2} - \frac{D_1}{\Delta x_1} \phi_1 \right] = \Delta x_1 \Sigma_{r,1} \phi_1 - \Delta x_1 Q_1^\diamond. \quad (621)$$

- The left surface of subregion $i = 1$ is characterized by an albedo-boundary condition:

$$\begin{aligned} & 2 \left[D_1 D_2 \frac{\phi_2 - \phi_1}{\Delta x_2 D_1 + \Delta x_1 D_2} - \frac{D_1(1 - \beta_-)}{4D_1(1 + \beta_-) + \Delta x_1(1 - \beta_-)} \phi_1 \right] \\ & = \Delta x_1 \Sigma_{r,1} \phi_1 - \Delta x_1 Q_1^\diamond \end{aligned} \quad (622)$$

- The right surface of subregion $i = I$ is characterized by a zero-flux-boundary condition:

$$2 \left[-\frac{D_I}{\Delta x_I} \phi_I - D_I D_{I-1} \frac{\phi_I - \phi_{I-1}}{\Delta x_I D_{I-1} + \Delta x_{I-1} D_I} \right] = \Delta x_I \Sigma_{r,I} \phi_I - \Delta x_I Q_I^\diamond. \quad (623)$$

- The right surface of subregion $i = I$ is characterized by an albedo-boundary condition:

$$2 \left[-\frac{D_I(1 - \beta_+)}{4D_I(1 + \beta_+) + \Delta x_I(1 - \beta_+)} \phi_I - D_I D_{I-1} \frac{\phi_I - \phi_{I-1}}{\Delta x_I D_{I-1} + \Delta x_{I-1} D_I} \right] = \Delta x_I \Sigma_{r,I} \phi_I - \Delta x_I Q_I^\diamond \quad (624)$$

The matrix system produced by the mesh-centered finite-difference method is similar and has the same numerical properties as the matrix system produced by the mesh-corner finite-difference method. The principal distinction comes from the fact that the unknown vector is the set of all mesh-centered neutron flux values. It is written as

$$\Phi = \begin{pmatrix} \phi_1 \\ \phi_2 \\ \vdots \\ \phi_I \end{pmatrix}. \quad (625)$$

As before, the matrix system is written as

$$\mathbb{A} \Phi = \mathbf{Q}, \quad (626)$$

where coefficient matrix \mathbb{A} and source vector \mathbf{Q} components correspond to the various terms of Eqs. (620) to (624). Matrix \mathbb{A} is symmetric, positive definite, and diagonally dominant.

The spatial discretization order of the mesh-centered finite-difference method can be increased beyond the linear order presented in this text, leading to the *nodal collocation method* Hébert (1987).

8.3 A Primal Variational Formulation

It is possible to rewrite the diffusion equation (527), together with its continuity and boundary conditions, into a *variational formulation* that is mathematically equivalent. This approach is also known as the *Rayleigh–Ritz method* and provides a means to obtain approximate solutions to a differential equation by finding a stationary point of a related functional. Many variational formulations exist, but we will restrict ourselves to the kind based on the *one-speed primal functional*. This formulation enables us to obtain a solution for (527) inside a space of basic functions. The *Sobolev space* is the most general space that can be used. It is a vector space of functions $f(\mathbf{r})$ defined over domain V and bounded in the Sobolev sense. Elements of the Sobolev space $W_1(V)$ are L^2 -integrable over domain V and possess first derivatives that are also L^2 -integrable over domain V . Functions that are elements of $W_1(V)$ are therefore continuous over V . We write

$$W_1(V) = \left\{ f(\mathbf{r}); f(\mathbf{r}) \in L^2(V) \text{ and } \nabla f(\mathbf{r}) \in [L^2(V)]^3 \right\}, \quad (627)$$

where $L^2(V)$ is the set of functions defined over domain V , whose quadratic norm is bounded, so that

$$L^2(V) = \left\{ f(\mathbf{r}); \sqrt{\int_V d^3r [f(\mathbf{r})]^2} < \infty \right\}. \quad (628)$$

The elements of $W_1(V)$ are functions with less-restrictive continuity requirements than those imposed on the solution of (527). For example, it is possible to choose basis functions that do not satisfy (536). In this sense, a variational formulation is a *weak formulation*.

It is also possible to choose basis functions within a subset of $W_1(V)$. For example, a primal formulation restricts the choice to the set $\mathcal{D}(V)$ of functions that vanish over ∂V_0 , the domain boundary where a zero-flux condition is imposed. It is also possible to restrict ourselves to piecewise polynomial functions, leading to the *Lagrangian FEM*. Use of a primal variational formulation together with the Lagrangian FEM was first reported by Semenza (1972).

A variational formulation makes it possible to solve (527) by seeking a stationary point of a corresponding functional. The one-speed primal functional is written as

$$\begin{aligned} \mathcal{F} \{ \phi(\mathbf{r}) \} = & \frac{1}{2} \int_V d^3r \{ D(\mathbf{r}) \nabla \phi(\mathbf{r}) \cdot \nabla \phi(\mathbf{r}) + \Sigma_r(\mathbf{r}) [\phi(\mathbf{r})]^2 \\ & - 2\phi(\mathbf{r}) Q^\circ(\mathbf{r}) \} + \frac{1}{2} \int_{\partial V_\beta} d^2r \frac{1-\beta(\mathbf{r})}{2+\beta(\mathbf{r})} [\phi(\mathbf{r})]^2, \end{aligned} \quad (629)$$

where $\phi(\mathbf{r}) \in W_1(V) \cap \mathcal{D}(V)$, $\beta(\mathbf{r})$ is the albedo, and ∂V_β is the fraction of ∂V where the *albedo-boundary condition* is applied, so that $\partial V = \partial V_0 \cup \partial V_\beta$. We have suppressed the group index g in order to simplify the notation.

A stationary point of this functional is defined by the relation

$$\delta_{\delta\phi} \mathcal{F} \{ \phi(\mathbf{r}) \} = \lim_{\varepsilon \rightarrow 0} \left\{ \frac{d}{d\varepsilon} \mathcal{F} \{ \phi(\mathbf{r}) + \varepsilon \delta\phi(\mathbf{r}) \} \right\} = 0, \quad (630)$$

where $\delta\phi(\mathbf{r})$ is an arbitrary element of vector space $W_1(V) \cap \mathcal{D}(V)$. We thus obtain

$$\begin{aligned} \int_V d^3r \{ D(\mathbf{r}) \nabla \delta\phi(\mathbf{r}) \cdot \nabla \phi(\mathbf{r}) + \Sigma_r(\mathbf{r}) \delta\phi(\mathbf{r}) \phi(\mathbf{r}) \\ - \delta\phi(\mathbf{r}) Q^\circ(\mathbf{r}) \} + \int_{\partial V_\beta} d^2r \frac{1-\beta(\mathbf{r})}{2+\beta(\mathbf{r})} \delta\phi(\mathbf{r}) \phi(\mathbf{r}) = 0 \end{aligned} \quad (631)$$

$\forall \delta\phi(\mathbf{r}) \in W_1(V) \cap \mathcal{D}(V)$.

We divide the total reactor volume V into a set of subvolumes $\{V_i; i = 1, N\}$ over which constant diffusion coefficient $\{D_i; i = 1, N\}$ and constant removal cross-sections $\{\Sigma_{r,i}; i = 1, N\}$ are defined. Moreover, $\nabla\phi(\mathbf{r})$ and $\nabla\delta\phi(\mathbf{r})$ are assumed continuous inside each subvolume V_i . With the help of \blacktriangleright Fig. 40, we also define $\{\partial V_i; i = 1, N\}$ as surfaces surrounding each subvolume and $\mathbf{N}_i(\mathbf{r})$ as the normal unit vector pointing out of ∂V_i at \mathbf{r} . We note from \blacktriangleright Fig. 40 that $\mathbf{N}_i(\mathbf{r}) = -\mathbf{N}_j(\mathbf{r})$.

Figure 40

Variational formulation in diffusion theory

Let us now apply the Gauss divergence theorem over subvolume V_i , so that

$$\begin{aligned} \int_{V_i} d^3r D(\mathbf{r}) \nabla \delta \phi(\mathbf{r}) \cdot \nabla \phi(\mathbf{r}) &= - \int_{V_i} d^3r \delta \phi(\mathbf{r}) \nabla \cdot D(\mathbf{r}) \nabla \phi(\mathbf{r}) \\ &+ \int_{\partial V_i} d^2r \delta \phi(\mathbf{r}) D(\mathbf{r}_-) \nabla \phi(\mathbf{r}_-) \cdot \mathbf{N}_i(\mathbf{r}); \quad i = 1, N. \end{aligned} \quad (632)$$

We separate each surface ∂V_i into three parts, as

$$\partial V_i = \partial W_i + \partial V_{\beta,i} + \partial V_{0,i}, \quad (633)$$

where ∂W_i is the part of ∂V_i internal to domain V . Surfaces $\partial V_{\beta,i}$ and $\partial V_{0,i}$ are the part of ∂V_i belonging to ∂V_β and ∂V_0 , respectively.

Substituting (632) into (631), we obtain

$$\begin{aligned} \sum_{i=1}^N \int_{V_i} d^3r \delta \phi(\mathbf{r}) \left[- \nabla \cdot D(\mathbf{r}) \nabla \phi(\mathbf{r}) + \Sigma_r(\mathbf{r}) \phi(\mathbf{r}) - Q^\circ(\mathbf{r}) \right] \\ + \int_{\partial W_i} d^2r \delta \phi(\mathbf{r}) D(\mathbf{r}_-) \nabla \phi(\mathbf{r}_-) \cdot \mathbf{N}_i(\mathbf{r}) \\ + \int_{\partial V_{\beta,i}} d^2r \left[D(\mathbf{r}) \nabla \phi(\mathbf{r}) \cdot \mathbf{N}_i(\mathbf{r}) + \frac{1-\beta(\mathbf{r})}{2(1+\beta(\mathbf{r}))} \phi(\mathbf{r}) \right] = 0 \end{aligned} \quad (634)$$

$\forall \delta \phi(\mathbf{r}) \in W_1(V) \cap \mathcal{D}(V)$.

Hence $\phi(\mathbf{r})$ is a stationary point of functional (629) for all arbitrary variations $\delta \phi(\mathbf{r}) \in W_1(V) \cap \mathcal{D}(V)$ if, and only if,

$$- \nabla \cdot D(\mathbf{r}) \nabla \phi(\mathbf{r}) + \Sigma_r(\mathbf{r}) \phi(\mathbf{r}) = Q^\circ(\mathbf{r}), \quad \mathbf{r} \in V, \quad (635)$$

$$\sum_{i=1}^N \delta_i(\mathbf{r}) D_i \nabla \phi(\mathbf{r}_-) \cdot \mathbf{N}_i(\mathbf{r}) = 0 \quad (636)$$

with

$$\delta_i(\mathbf{r}) = \begin{cases} 1, & \text{if } \mathbf{r} \in \delta W_i, \\ 0, & \text{otherwise,} \end{cases} \quad (637)$$

and

$$D(\mathbf{r}) \nabla \phi(\mathbf{r}) \cdot \mathbf{N}(\mathbf{r}) + \frac{1}{2} \frac{1 - \beta(\mathbf{r})}{1 + \beta(\mathbf{r})} \phi(\mathbf{r}) = 0, \quad \mathbf{r} \in \partial V_\beta. \tag{638}$$

We have obtained the *Euler equations* of functional (629). Equation (635) is none other than the diffusion (527). Equation (636) is the current continuity condition for the particles inside the domain. Lastly, (638) is the *albedo-boundary condition* (542). In conclusion, a function $\phi(\mathbf{r})$ corresponding to a stationary point of functional (629) will respect current continuity and albedo-boundary conditions in addition to satisfying the diffusion equation. Conditions satisfied as a stationary point of a functional are said to be *natural conditions*. Conditions imposed on the trial functions, such as flux continuity or zero-flux boundary conditions, are said to be *essential conditions*.

8.4 The Lagrangian Finite-Element Method

The FEM is used for finding approximate solutions of partial differential equations. It is based on an expansion of the dependent variable(s), the particle flux in our case, into a linear combination of polynomial *trial functions* defined over subvolumes. The trial function space must be chosen so as to ensure that improvement in the numerical approximation occurs with an increase in the number I of subvolumes *and/or* with the degree K of the polynomial trial functions. The trial functions are known a priori and the corresponding coefficients can be found using a *weighted residual approach* or a *variational formulation* as introduced in [8.3](#). We have chosen to present the latter approach, as it brings two important benefits: (1) the intrinsic symmetry of the one-speed diffusion equation is always preserved by the discretization process and (2) the boundary conditions are introduced in a consistent way.

The polynomial basis $\{u_m(\mathbf{r}); m = 1, M\}$ with $u_m(\mathbf{r}) \in W_1(V) \cap \mathcal{D}(V)$ is used to span the neutron flux $\phi(\mathbf{r})$ and flux variation $\delta\phi(\mathbf{r})$ over V , according to

$$\phi(\mathbf{r}) = \sum_{m=1}^M \phi_m u_m(\mathbf{r}) \quad \text{and} \quad \delta\phi(\mathbf{r}) = \sum_{m=1}^M \delta\phi_m u_m(\mathbf{r}), \tag{639}$$

where the set of *variational coefficients* $\{\phi_m; m = 1, M\}$ represents the unknown vector or the numerical solution to be obtained by the FEM.

The FEM can be applied to various types and forms of subvolumes or *elements*. Cartesian and hexagonal elements are the most widely used in reactor physics for full-core calculations. A Cartesian domain is first partitioned into rectangular parallelepipeds over which the nuclear properties are assumed to be uniform. A polynomial basis is defined over each element by using full tensorial products of 1D polynomials up to a given order. In the case of a primal variational formulation, as introduced in [8.3](#), Lagrange polynomials are chosen as polynomial basis in order to satisfy the requirement that $u_m(\mathbf{r}) \in W_1(V) \cap \mathcal{D}(V)$.

We will consider a 1D Cartesian domain with I subvolumes, as depicted in [Fig. 38](#). Trial functions in space are transformed from the global coordinate x defined over element i with $x_{i-1/2} \leq x \leq x_{i+1/2}$ to local coordinate u defined over the unit domain, with $-1/2 \leq u \leq 1/2$. The following change of variable will be used:

$$u = \frac{1}{\Delta x_i} \left[x - \frac{1}{2} (x_{i-1/2} + x_{i+1/2}) \right], \tag{640}$$

where

$$\Delta x_i = x_{i+1/2} - x_{i-1/2}. \quad (641)$$

The polynomial trial functions are written as

$$u_m(x) = \sum_{i=1}^I \sum_{k=0}^K \delta_{i,k}^m L_k(u), \quad m = 1, M, \quad (642)$$

where I is the total number of elements and $\delta_{i,k}^m$ is the finite-element delta function, equal to 1 if the local unknown k in element i corresponds to the global unknown m , and 0 otherwise. Each element i serves as support for a local basis of order- K Lagrange polynomials. These polynomials are defined so as to preserve the continuity of the global trial functions, as required by our primal variational formulation.

- Linear Lagrange polynomials ($K = 1$): This local basis contains two linear Lagrange polynomials in 1D, defined for local base points $u_0 = -1/2$ and $u_1 = 1/2$. They are written as

$$L_0(u) = \frac{1}{2} - u \quad \text{and} \quad L_1(u) = \frac{1}{2} + u \quad (643)$$

so that $L_0(-1/2) = L_1(1/2) = 1$ and $L_0(1/2) = L_1(-1/2) = 0$.

In this case, the variational coefficients ϕ_m are the flux values at abscissas $x_{i-1/2}$ and $x_{i+1/2}$. Continuity of the trial functions is preserved if each coefficient ϕ_m , corresponding to an internal mesh, is shared by two elements. This condition is reached by using the correct values of the finite-element delta function. For example, if a domain has left- and right-albedo boundary conditions, then $\delta_{i,k}^m$ is defined as

$$\delta_{i,k}^m = \begin{cases} 1, & \text{if } m = i + k, \\ 0, & \text{otherwise.} \end{cases} \quad (644)$$

Similarly, if a domain has left- and right *zero-flux-boundary conditions*, then $\delta_{i,k}^m$ is defined as

$$\delta_{i,k}^m = \begin{cases} 0, & \text{if } i = 1 \text{ and } k = 0, \\ 0, & \text{if } i = I \text{ and } k = 1, \\ 1, & \text{if } m = i + k - 1, \\ 0, & \text{otherwise.} \end{cases} \quad (645)$$

- Parabolic Lagrange polynomials ($K = 2$): This local basis contains three parabolic Lagrange polynomials in 1D. They are written as

$$L_0(u) = -\frac{1}{8} - u + \frac{5u^2}{2}, \quad L_1(u) = \frac{5}{4} - 5u^2, \quad \text{and} \quad L_2(u) = -\frac{1}{8} + u + \frac{5u^2}{2}. \quad (646)$$

Again, the continuity of trial functions will be satisfied if some coefficients ϕ_m are shared by two elements. For example, if a domain has left- and right-albedo boundary conditions, then $\delta_{i,k}^m$ is defined as

$$\delta_{i,k}^m = \begin{cases} 1, & \text{if } m = 2i + k - 1, \\ 0, & \text{otherwise.} \end{cases} \quad (647)$$

Similarly, if a domain has left- and right zero-flux-boundary conditions, then $\delta_{i,k}^m$ is defined as

$$\delta_{i,k}^m = \begin{cases} 0, & \text{if } i = 1 \text{ and } k = 0, \\ 0, & \text{if } i = I \text{ and } k = 2, \\ 1, & \text{if } m = 2i + k - 2, \\ 0, & \text{otherwise.} \end{cases} \tag{648}$$

- Cubic Lagrange polynomials ($K=3$): This local basis contains four parabolic Lagrange polynomials in 1D. They are written as

$$\begin{aligned} L_0(u) &= -\frac{1}{8} + \frac{3u}{4} + \frac{5u^2}{2} - 7u^3, & L_1(u) &= \frac{5}{8} - \frac{5\sqrt{7}u}{4} - \frac{5u^2}{2} + 5\sqrt{7}u^3, \\ L_2(u) &= \frac{5}{8} + \frac{5\sqrt{7}u}{4} - \frac{5u^2}{2} - 5\sqrt{7}u^3, & \text{and } L_3(u) &= -\frac{1}{8} - \frac{3u}{4} + \frac{5u^2}{2} + 7u^3. \end{aligned} \tag{649}$$

Again, the continuity of trial functions will be satisfied if some coefficients ϕ_m are shared by two elements. For example, if a domain has left- and right-albedo-boundary conditions, then $\delta_{i,k}^m$ is defined as

$$\delta_{i,k}^m = \begin{cases} 1, & \text{if } m = 3i + k - 2, \\ 0, & \text{otherwise.} \end{cases} \tag{650}$$

Similarly, if a domain has left- and right-zero-flux-boundary conditions, then $\delta_{i,k}^m$ is defined as

$$\delta_{i,k}^m = \begin{cases} 0, & \text{if } i = 1 \text{ and } k = 0, \\ 0, & \text{if } i = I \text{ and } k = 3, \\ 1, & \text{if } m = 3i + k - 3, \\ 0, & \text{otherwise.} \end{cases} \tag{651}$$

Having defined our space of polynomial trial functions, we need to find the variational coefficients corresponding to the solution of the diffusion equation. Using the variational approach introduced in [8.3](#), we first rewrite (631) for the particular case of a Cartesian 1D domain. We have

$$\begin{aligned} \sum_{i=1}^I \int_{x_{i-1/2}}^{x_{i+1/2}} dx [D_i \nabla \delta \phi(x) \cdot \nabla \phi(x) + \Sigma_{r,i} \delta \phi(x) \phi(x) - \delta \phi(x) Q^\circ(x)] \\ + \mathcal{B}_- \delta \phi(x_{1/2}) \phi(x_{1/2}) + \mathcal{B}_+ \delta \phi(x_{I+1/2}) \phi(x_{I+1/2}) = 0 \end{aligned} \tag{652}$$

$\forall \delta \phi(x) \in W_1(V) \cap \mathcal{D}(V)$. The two boundary terms \mathcal{B}_- and \mathcal{B}_+ are defined as

$$\mathcal{B}_- = \begin{cases} \frac{1}{2} \frac{1 - \beta_-}{1 + \beta_-}, & \text{if the domain has a left-albedo condition,} \\ 0, & \text{otherwise.} \end{cases} \tag{653}$$

and

$$\mathcal{B}_+ = \begin{cases} \frac{1}{2} \frac{1 - \beta_+}{1 + \beta_+}, & \text{if the domain has a right-albedo condition,} \\ 0, & \text{otherwise.} \end{cases} \tag{654}$$

We next define a linear product and two different types of bilinear products:

$$\langle Q^\diamond u_m \rangle = \sum_{i=1}^I \int_{x_{i-1/2}}^{x_{i+1/2}} dx Q^\diamond(x) u_m(x), \quad (655)$$

$$\langle \nabla u_m, D \nabla u_n \rangle = \sum_{i=1}^I \int_{x_{i-1/2}}^{x_{i+1/2}} dx D_i \nabla u_m(x) \cdot \nabla u_n(x) \quad (656)$$

and

$$\langle u_m, \Sigma u_n \rangle = \sum_{i=1}^I \int_{x_{i-1/2}}^{x_{i+1/2}} dx \Sigma_i u_m(x) u_n(x). \quad (657)$$

These bilinear products can be expressed for a Lagrangian FEM as

$$\langle \nabla u_m, D \nabla u_n \rangle = \sum_{i=1}^I \frac{D_i}{\Delta x_i} \sum_{k=0}^K \sum_{\ell=0}^K \delta_{i,k}^m \delta_{i,\ell}^n Q_{k,\ell} \quad (658)$$

and

$$\langle u_m, \Sigma u_n \rangle = \sum_{i=1}^I \Delta x_i \Sigma_i \sum_{k=0}^K \sum_{\ell=0}^K \delta_{i,k}^m \delta_{i,\ell}^n M_{k,\ell}. \quad (659)$$

Substitution of (655) to (657) into (652) leads to the discretized linear system, corresponding to the one-speed neutron diffusion equation. We write

$$\left\{ \sum_{m=1}^M \phi_m [\langle \nabla u_m, D \nabla u_n \rangle + \langle u_m, \Sigma_r u_n \rangle] \right\} + \phi_1 \mathcal{B}_- \delta_{n,1} + \phi_M \mathcal{B}_+ \delta_{n,M} = \langle Q^\diamond u_n \rangle, \quad (660)$$

where $n = 1, M$.

System (660) is a linear matrix system of the form $\mathbb{A} \Phi = \mathbf{Q}$ where the coefficient matrix \mathbb{A} is symmetric, positive definite, and diagonally dominant. Its resolution can be performed using standard numerical techniques.

Equations (658) and (659) are written in terms of the FEM *mass matrix* $\{M_{k,\ell}, k = 0, K \text{ and } \ell = 0, K\}$ and *stiffness matrix* $\{Q_{k,\ell}, k = 0, K \text{ and } \ell = 0, K\}$, defined as

$$M_{k,\ell} = \int_{-1/2}^{1/2} du L_k(u) L_\ell(u) \quad (661)$$

and

$$Q_{k,\ell} = \int_{-1/2}^{1/2} du \frac{d}{du} L_k(u) \frac{d}{du} L_\ell(u). \quad (662)$$

These unit matrices can be integrated analytically, leading to

- Linear Lagrange polynomials ($K = 1$):

$$\mathbb{M}_1 = \begin{bmatrix} \frac{1}{3} & \frac{1}{6} \\ \frac{1}{6} & \frac{1}{3} \end{bmatrix} \quad \text{and} \quad \mathbb{Q}_1 = \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}. \quad (663)$$

- Parabolic Lagrange polynomials ($K = 2$):

$$\mathbb{M}_2 = \begin{bmatrix} \frac{1}{8} & 0 & -\frac{1}{24} \\ 0 & \frac{5}{6} & 0 \\ -\frac{1}{24} & 0 & \frac{1}{8} \end{bmatrix} \quad \text{and} \quad \mathbb{Q}_2 = \begin{bmatrix} \frac{37}{12} & -\frac{25}{6} & \frac{13}{12} \\ -\frac{25}{6} & \frac{25}{3} & -\frac{25}{6} \\ \frac{13}{12} & -\frac{25}{6} & \frac{37}{12} \end{bmatrix}. \quad (664)$$

- Cubic Lagrange polynomials ($K = 3$):

$$\mathbb{M}_3 = \begin{bmatrix} \frac{1}{15} & 0 & 0 & \frac{1}{60} \\ 0 & \frac{5}{12} & 0 & 0 \\ 0 & 0 & \frac{5}{12} & 0 \\ \frac{1}{60} & 0 & 0 & \frac{1}{15} \end{bmatrix} \quad (665)$$

and

$$\mathbb{Q}_3 = \begin{bmatrix} \frac{83}{15} & -\frac{21\sqrt{7}+25}{12} & \frac{21\sqrt{7}-25}{12} & -\frac{41}{30} \\ -\frac{21\sqrt{7}+25}{12} & \frac{65}{6} & -\frac{20}{3} & \frac{21\sqrt{7}-25}{12} \\ \frac{21\sqrt{7}-25}{12} & -\frac{20}{3} & \frac{65}{6} & -\frac{21\sqrt{7}+25}{12} \\ -\frac{41}{30} & \frac{21\sqrt{7}-25}{12} & -\frac{21\sqrt{7}+25}{12} & \frac{83}{15} \end{bmatrix}. \quad (666)$$

We have presented the FEM in its simplest implementation. The Lagrangian formulation can be modified by using numerical integration to obtain the mass and stiffness matrices of (661) and (662). Using a *Gauss–Lobatto quadrature* with linear Lagrange polynomials produces a numerical solution that is equivalent to the mesh-corner finite-difference method of [8.1](#). Using a *Gauss–Legendre quadrature* leads to *superconvergent* approximations. Discretization of 2D and 3D domains with a Lagrangian FEM produces a matrix system that is not compatible with the alternating direction implicit (ADI) method. This incompatibility is due to the off-diagonal term present in the mass matrices of (663) to (665). This off-diagonal term can be suppressed by using a Gauss–Lobatto quadrature, leading to the primal finite-element approximations of the TRIVAC code (Hébert 1987).

The *Raviart–Thomas (1977) finite element* method introduces an important class of approximations, based on a *mixed-dual variational formulation*. These methods have been applied to the solution of the neutron diffusion equation in 3D Cartesian and hexagonal domains in Hébert (1993) and Hébert (2008), respectively. A linear Raviart–Thomas FEM, with Gauss–Lobatto integration of the unit matrices, is equivalent to the mesh-centered finite-difference method of [8.2](#). All Raviart–Thomas FEMs produce approximations that are compatible with the ADI method and with the TRIVAC code.

8.5 The Analytic Nodal Method in 2D Cartesian Geometry

The 2D Cartesian heterogeneous-reactor configurations correspond to the case where the neutron flux is a function of two spatial variables. These cases cannot be solved analytically and the analytic nodal method (ANM) is an attempt to find the solution with the *smallest possible approximation*. Here, we are limiting our investigations to a 2D Cartesian domain made from the assembly of many x – y rectangular nodes which are infinite in the z direction.

In this case, the nuclear properties of the reactor are only a function of the independent variables x and y . Equation (530) simplifies to

$$\begin{aligned} & -\frac{\partial}{\partial x} D_g(x, y) \frac{\partial \phi_g}{\partial x} - \frac{\partial}{\partial y} D_g(x, y) \frac{\partial \phi_g}{\partial y} + \Sigma_{rg}(x, y) \phi_g(x, y) = Q_g^\circ(x, y) \\ & = \sum_{\substack{h=1 \\ h \neq g}}^G \Sigma_{g \leftarrow h}(x, y) \phi_h(x, y) + \frac{\chi_g(x, y)}{K_{\text{eff}}} \sum_{h=1}^G v \Sigma_{fh}(x, y) \phi_h(x, y). \end{aligned} \quad (667)$$

Each node is assumed to be homogenous, so that the corresponding nuclear properties $D_g(x, y)$, $\Sigma_{rg}(x, y)$, $\Sigma_{g \leftarrow h}(x, y)$, $\chi_g(x, y)$, and $v \Sigma_{fh}(x, y)$ are piecewise continuous. As shown in Fig. 41, the reactor domain is divided into $I \times J$ regions of indices $1 \leq i \leq I$ and $1 \leq j \leq J$, in such a way that the nuclear properties in region i, j are constant and equal to $D_{g,i,j}$, $\Sigma_{rg,i,j}$, $\Sigma_{g \leftarrow h,i,j}$, $\chi_{g,i,j}$, and $v \Sigma_{fh,i,j}$.

The linear transformation technique of 7.4 is applied on each node, leading to the linear transformation $G \times G$ matrix $\mathbb{T}_{i,j}$ and to a set of G eigenvalues $\lambda_{\ell,i,j}$. The transformation process is repeated for each node, leading to $I \times J$ matrix equations written as

$$\frac{\partial^2}{\partial x^2} \Psi(x, y) + \frac{\partial^2}{\partial y^2} \Psi(x, y) + \text{diag}(\lambda_{\ell,i,j}) \Psi(x, y) = \mathbf{0} \quad (668)$$

if $x_{i-1/2} < x < x_{i+1/2}$ and $y_{j-1/2} < y < y_{j+1/2}$. Each equation is uncoupled in energy, and can be written as G differential equations of the form

$$\frac{\partial^2}{\partial x^2} \psi_g(x, y) + \frac{\partial^2}{\partial y^2} \psi_g(x, y) + \lambda_{g,i,j} \psi_g(x, y) = 0, \quad g = 1, G. \quad (669)$$

Figure 41

Definition of the regions in 2D Cartesian geometry

Unfortunately, it is impossible to find the analytical solution of (669) because its dependent variable $\psi_g(x, y)$ is generally not separable. The ANM is based on *transverse integration* of (669). Transverse integration along the Y -axis leads to

$$\int_{y_{j-1/2}}^{y_{j+1/2}} dy \frac{\partial^2}{\partial x^2} \psi_g(x, y) + \int_{y_{j-1/2}}^{y_{j+1/2}} dy \frac{\partial^2}{\partial y^2} \psi_g(x, y) + \lambda_{g,i,j} \int_{y_{j-1/2}}^{y_{j+1/2}} dy \psi_g(x, y) = 0, \quad (670)$$

which can be rewritten as

$$\frac{\partial^2}{\partial x^2} \psi_{g,j}^y(x) + \lambda_{g,i,j} \psi_{g,j}^y(x) = \frac{1}{\Delta y_j} \mathcal{F}_{g,j}^y(x), \quad (671)$$

where $\Delta y_j = y_{j+1/2} - y_{j-1/2}$,

$$\psi_{g,j}^y(x) = \frac{1}{\Delta y_j} \int_{y_{j-1/2}}^{y_{j+1/2}} dy \psi_g(x, y) \quad (672)$$

and where we introduced the X -directed *transverse-leakage* term as

$$\mathcal{F}_{g,j}^y(x) = - \int_{y_{j-1/2}}^{y_{j+1/2}} dy \frac{\partial^2}{\partial y^2} \psi_g(x, y) = - \left. \frac{\partial}{\partial y} \psi_g(x, y) \right|_{y_{j-1/2}}^{y_{j+1/2}}. \quad (673)$$

Similarly, the transverse integration along the X -axis leads to

$$\frac{\partial^2}{\partial y^2} \psi_{g,i}^x(y) + \lambda_{g,i,j} \psi_{g,i}^x(y) = \frac{1}{\Delta x_i} \mathcal{F}_{g,i}^x(y), \quad (674)$$

where $\Delta x_i = x_{i+1/2} - x_{i-1/2}$,

$$\psi_{g,i}^x(y) = \frac{1}{\Delta x_i} \int_{x_{i-1/2}}^{x_{i+1/2}} dx \psi_g(x, y) \quad (675)$$

and where we introduced the Y -directed *transverse-leakage* term as

$$\mathcal{F}_{g,i}^x(y) = - \int_{x_{i-1/2}}^{x_{i+1/2}} dx \frac{\partial^2}{\partial x^2} \psi_g(x, y) = - \left. \frac{\partial}{\partial x} \psi_g(x, y) \right|_{x_{i-1/2}}^{x_{i+1/2}}. \quad (676)$$

Equations (671) and (674) can be solved analytically, provided that the x and y variation of the transverse-leakage terms $\mathcal{F}_{g,j}^y(x)$ and $\mathcal{F}_{g,i}^x(y)$ are known. This is where we introduce the *unique* approximation of the ANM. Many possibilities exist to predict this variation, and have been investigated in the 1970s. Shober (1976) initially assumed that the transverse leakages and the 1D fluxes had the same shape. He wrote

$$\begin{aligned} \mathcal{F}_{g,j}^y(x) &= B_{g,i,j}^y \psi_{g,j}^y(x), \\ \mathcal{F}_{g,i}^x(y) &= B_{g,i,j}^x \psi_{g,i}^x(y). \end{aligned} \quad (677)$$

This *buckling*-type approximation would be exact if the dependent-variable $\psi_g(x, y)$ were spatially separable within node (i, j) . However, Shober found that the use of the buckling

approximation led to large errors in highly nonseparable cases. As an alternative to the buckling approximation, Shober proposed to use a *flat leakage approximation* in which the transverse-leakage shape is spatially flat over each node, leading to

$$\begin{aligned}\mathcal{F}_{g,j}^y(x) &= \bar{\mathcal{F}}_{g,i,j}^y = \mathcal{J}_{g,i}^x(y_{j+1/2}) - \mathcal{J}_{g,i}^x(y_{j-1/2}), \\ \mathcal{F}_{g,i}^x(y) &= \bar{\mathcal{F}}_{g,i,j}^x = \mathcal{J}_{g,j}^y(x_{i+1/2}) - \mathcal{J}_{g,j}^y(x_{i-1/2}),\end{aligned}\quad (678)$$

where the *transformed currents* are defined as

$$\mathcal{J}_{g,j}^y(x) \equiv -\frac{\partial}{\partial x} \psi_{g,j}^y(x) \quad \text{and} \quad \mathcal{J}_{g,i}^x(y) \equiv -\frac{\partial}{\partial y} \psi_{g,i}^x(y). \quad (679)$$

Later, Smith introduced a *quadratic-leakage approximation* in the ANM, leading to the version that is now currently used in legacy codes (Smith 1979). The expansion coefficients of the leakage fit are calculated by assuming that the quadratic polynomial extends over the two neighboring nodes and satisfies the average leakages in the central and two neighboring nodes. The quadratic leakage fit does not rely on the diffusion equation itself and can only be justified if the transverse leakages vary smoothly across the three nodes. Such an approximation can be constructed for node (i, j) , in the X -direction, using $\bar{F}_{g,i-1,j}^y$, $\bar{F}_{g,i,j}^y$ and $\bar{F}_{g,i+1,j}^y$, the transverse-leakage terms *without* linear transformation. In his thesis, Smith developed the ANM with a quadratic leakage approximation in two-group, 3D-Cartesian geometry. In this handbook, we will restrict ourselves to the flat-leakage approximation in G -group, 2D-Cartesian geometry.

Under these conditions, (671) is rewritten as

$$\frac{\partial^2}{\partial x^2} \psi_{g,j}^y(x) + \lambda_{g,i,j} \psi_{g,j}^y(x) = \frac{1}{\Delta y_j} [\mathcal{J}_{g,i}^x(y_{j+1/2}) - \mathcal{J}_{g,i}^x(y_{j-1/2})]. \quad (680)$$

Integration of (680) over node (i, j) leads to the transformed *nodal balance equation*, written as

$$\begin{aligned}\bar{\psi}_{g,i,j} &= \frac{1}{\Delta x_i \lambda_{g,i,j}} [\mathcal{J}_{g,j}^y(x_{i+1/2}) - \mathcal{J}_{g,j}^y(x_{i-1/2})] \\ &+ \frac{1}{\Delta y_j \lambda_{g,i,j}} [\mathcal{J}_{g,i}^x(y_{j+1/2}) - \mathcal{J}_{g,i}^x(y_{j-1/2})].\end{aligned}\quad (681)$$

Let us first consider the case where $\lambda_{g,i,j} \geq 0$. In energy group g and in node (i, j) , (680) has an analytical solution of the form

$$\begin{aligned}\psi_{g,j}^y(x) &= \frac{1}{\Delta y_j \lambda_{g,i,j}} [\mathcal{J}_{g,i}^x(y_{j+1/2}) - \mathcal{J}_{g,i}^x(y_{j-1/2})] \\ &+ A_{g,i,j} \cos(\sqrt{\lambda_{g,i,j}} x) + B_{g,i,j} \sin(\sqrt{\lambda_{g,i,j}} x)\end{aligned}\quad (682)$$

if $x_{i-1/2} < x < x_{i+1/2}$.

Integrating (682) over the node leads to

$$\begin{aligned}\bar{\psi}_{g,i,j} &= \frac{1}{\Delta y_j \lambda_{g,i,j}} [\mathcal{J}_{g,i}^x(y_{j+1/2}) - \mathcal{J}_{g,i}^x(y_{j-1/2})] + \frac{A_{g,i,j}}{\Delta x_i \sqrt{\lambda_{g,i,j}}} \sin(\sqrt{\lambda_{g,i,j}} x) \Big|_{x_{i-1/2}}^{x_{i+1/2}} \\ &- \frac{B_{g,i,j}}{\Delta x_i \sqrt{\lambda_{g,i,j}}} \cos(\sqrt{\lambda_{g,i,j}} x) \Big|_{x_{i-1/2}}^{x_{i+1/2}}.\end{aligned}\quad (683)$$

Differentiating (682) over the node leads to

$$\mathcal{J}_{g,j}^y(x) = A_{g,i,j} \sqrt{\lambda_{g,i,j}} \sin(\sqrt{\lambda_{g,i,j}} x) - B_{g,i,j} \sqrt{\lambda_{g,i,j}} \cos(\sqrt{\lambda_{g,i,j}} x). \quad (684)$$

Equations (682) to (684) can be rewritten, if $\lambda_{g,i,j} \leq 0$, as

$$\begin{aligned} \psi_{g,j}^y(x) &= \frac{1}{\Delta y_j \lambda_{g,i,j}} [\mathcal{J}_{g,i}^x(y_{j+1/2}) - \mathcal{J}_{g,i}^x(y_{j-1/2})] \\ &\quad + C_{g,i,j} \cosh(\sqrt{-\lambda_{g,i,j}} x) + E_{g,i,j} \sinh(\sqrt{-\lambda_{g,i,j}} x), \end{aligned} \quad (685)$$

$$\begin{aligned} \bar{\psi}_{g,i,j} &= \frac{1}{\Delta y_j \lambda_{g,i,j}} [\mathcal{J}_{g,i}^x(y_{j+1/2}) - \mathcal{J}_{g,i}^x(y_{j-1/2})] \\ &\quad + \frac{C_{g,i,j}}{\Delta x_i \sqrt{-\lambda_{g,i,j}}} \sinh(\sqrt{-\lambda_{g,i,j}} x) \Big|_{x_{i-1/2}}^{x_{i+1/2}} \\ &\quad + \frac{E_{g,i,j}}{\Delta x_i \sqrt{-\lambda_{g,i,j}}} \cosh(\sqrt{-\lambda_{g,i,j}} x) \Big|_{x_{i-1/2}}^{x_{i+1/2}} \end{aligned} \quad (686)$$

and

$$\mathcal{J}_{g,j}^y(x) = -C_{g,i,j} \sqrt{-\lambda_{g,i,j}} \sin h(\sqrt{-\lambda_{g,i,j}} x) - E_{g,i,j} \sqrt{-\lambda_{g,i,j}} \cos h(\sqrt{-\lambda_{g,i,j}} x). \quad (687)$$

To proceed further, we need to rewrite Eqs. (682) to (687) in matrix algebra. We define

$$\begin{aligned} \Psi_j^y(x) &= \{\psi_{g,j}^y(x), g = 1, G\}, \\ \bar{\Psi}_{i,j} &= \{\bar{\psi}_{g,i,j}, g = 1, G\}, \\ \mathcal{J}_j^y(x) &= \{\mathcal{J}_{g,j}^y(x), g = 1, G\}, \\ \mathcal{J}_i^x(y) &= \{\mathcal{J}_{g,i}^x(y), g = 1, G\}, \\ \mathbf{A}_{i,j} &= \{A_{g,i,j}, g = 1, G\}, \\ \mathbf{B}_{i,j} &= \{B_{g,i,j}, g = 1, G\} \end{aligned}$$

so that the above equations can be cast into

$$\begin{bmatrix} \bar{\Psi}_{i,j} \\ \mathcal{J}_j^y(x_{i-1/2}) \end{bmatrix} = \mathbb{M}_{i,j}^- \begin{bmatrix} \mathbf{A}_{i,j} \\ \mathbf{B}_{i,j} \end{bmatrix} + \begin{bmatrix} -\mathbb{Y}_{i,j} & \mathbb{Y}_{i,j} \\ \mathbb{O} & \mathbb{O} \end{bmatrix} \begin{bmatrix} \mathcal{J}_i^x(y_{j-1/2}) \\ \mathcal{J}_i^x(y_{j+1/2}) \end{bmatrix}, \quad (688)$$

$$\begin{bmatrix} \bar{\Psi}_{i,j} \\ \mathcal{J}_j^y(x_{i+1/2}) \end{bmatrix} = \mathbb{M}_{i,j}^+ \begin{bmatrix} \mathbf{A}_{i,j} \\ \mathbf{B}_{i,j} \end{bmatrix} + \begin{bmatrix} -\mathbb{Y}_{i,j} & \mathbb{Y}_{i,j} \\ \mathbb{O} & \mathbb{O} \end{bmatrix} \begin{bmatrix} \mathcal{J}_i^x(y_{j-1/2}) \\ \mathcal{J}_i^x(y_{j+1/2}) \end{bmatrix}, \quad (689)$$

$$\Psi_j^y(x_{i-1/2}) = \mathbb{N}_{i,j}^- \begin{bmatrix} \mathbf{A}_{i,j} \\ \mathbf{B}_{i,j} \end{bmatrix} + \begin{bmatrix} -\mathbb{Y}_{i,j} & \mathbb{Y}_{i,j} \\ \mathbb{O} & \mathbb{O} \end{bmatrix} \begin{bmatrix} \mathcal{J}_i^x(y_{j-1/2}) \\ \mathcal{J}_i^x(y_{j+1/2}) \end{bmatrix} \quad (690)$$

and

$$\Psi_j^y(x_{i+1/2}) = \mathbb{N}_{i,j}^+ \begin{bmatrix} \mathbf{A}_{i,j} \\ \mathbf{B}_{i,j} \end{bmatrix} + \begin{bmatrix} -\mathbb{Y}_{i,j} & \mathbb{Y}_{i,j} \\ \mathbb{O} & \mathbb{O} \end{bmatrix} \begin{bmatrix} \mathcal{J}_i^x(y_{j-1/2}) \\ \mathcal{J}_i^x(y_{j+1/2}) \end{bmatrix}, \quad (691)$$

where $\mathbb{M}_{i,j}^\mp$ are two $2G \times 2G$ matrices, $\mathbb{N}_{i,j}^\mp$ are two $G \times 2G$ matrices, and $\mathbb{Y}_{i,j}$ is a $G \times G$ matrix whose coefficients are recovered from (682) to (687). Coefficients $\mathbf{A}_{i,j}$ and $\mathbf{B}_{i,j}$ from (690) can be eliminated using (688) and coefficients $\mathbf{A}_{i,j}$ and $\mathbf{B}_{i,j}$ from (691) can be eliminated using (689). The resulting equations can be cast into

$$\Psi_j^y(x_{i-1/2}) = \mathbb{P}_{i,j} \begin{bmatrix} \tilde{\Psi}_{i,j} \\ \mathcal{J}_j^y(x_{i-1/2}) \\ \mathcal{J}_i^x(y_{j-1/2}) \\ \mathcal{J}_i^x(y_{j+1/2}) \end{bmatrix} \quad \text{and} \quad \Psi_j^y(x_{i+1/2}) = \mathbb{Q}_{i,j} \begin{bmatrix} \tilde{\Psi}_{i,j} \\ \mathcal{J}_j^y(x_{i+1/2}) \\ \mathcal{J}_i^x(y_{j-1/2}) \\ \mathcal{J}_i^x(y_{j+1/2}) \end{bmatrix}, \quad (692)$$

where $\mathbb{P}_{i,j}$ and $\mathbb{Q}_{i,j}$ are two $G \times 4G$ matrices.

The transformed nodal balance equation (681) can be written in matrix form as

$$\tilde{\Psi}_{i,j} = [-\mathbb{X}_{i,j} \quad \mathbb{X}_{i,j}] \begin{bmatrix} \mathcal{J}_j^y(x_{i-1/2}) \\ \mathcal{J}_j^y(x_{i+1/2}) \end{bmatrix} + [-\mathbb{Y}_{i,j} \quad \mathbb{Y}_{i,j}] \begin{bmatrix} \mathcal{J}_i^x(y_{j-1/2}) \\ \mathcal{J}_i^x(y_{j+1/2}) \end{bmatrix}. \quad (693)$$

Finally, the linear transformation can be inverted, with the help of the following definitions:

$$\begin{aligned} \Phi_j^y(x) &= \{ \phi_{g,j}^y(x); \quad g = 1, G \} = \mathbb{T}_{i,j} \Psi_j^y(x), \\ \tilde{\Phi}_{i,j} &= \{ \tilde{\phi}_{g,i,j}^y; \quad g = 1, G \} = \mathbb{T}_{i,j} \tilde{\Psi}_{i,j}, \\ J_j^y(x) &= \left\{ -D_{g,i,j} \frac{d}{dx} \phi_{g,j}^y(x); \quad g = 1, G \right\} = \text{diag}(D_{g,i,j}) \mathbb{T}_{i,j} \mathcal{J}_j^y(x), \\ S_{i,j} &= \mathbb{T}_{i,j}^{-1} \text{diag}(D_{g,i,j})^{-1}. \end{aligned}$$

We can show that

$$\Phi_j^y(x_{i-1/2}) = \mathbb{L}_{i,j} \begin{bmatrix} \tilde{\Phi}_{i,j} \\ J_j^y(x_{i-1/2}) \\ J_i^x(y_{j-1/2}) \\ J_i^x(y_{j+1/2}) \end{bmatrix} \quad \text{and} \quad \Phi_j^y(x_{i+1/2}) = \mathbb{R}_{i,j} \begin{bmatrix} \tilde{\Phi}_{i,j} \\ J_j^y(x_{i+1/2}) \\ J_i^x(y_{j-1/2}) \\ J_i^x(y_{j+1/2}) \end{bmatrix}, \quad (694)$$

where

$$\mathbb{L}_{i,j} = \mathbb{T}_{i,j} \mathbb{P}_{i,j} \begin{bmatrix} \mathbb{T}_{i,j}^{-1} & \mathbb{O} & \mathbb{O} & \mathbb{O} \\ \mathbb{O} & \mathbb{S}_{i,j} & \mathbb{O} & \mathbb{O} \\ \mathbb{O} & \mathbb{O} & \mathbb{S}_{i,j} & \mathbb{O} \\ \mathbb{O} & \mathbb{O} & \mathbb{O} & \mathbb{S}_{i,j} \end{bmatrix} \quad (695)$$

and

$$\mathbb{R}_{i,j} = \mathbb{T}_{i,j} \mathbb{Q}_{i,j} \begin{bmatrix} \mathbb{T}_{i,j}^{-1} & \mathbb{O} & \mathbb{O} & \mathbb{O} \\ \mathbb{O} & \mathbb{S}_{i,j} & \mathbb{O} & \mathbb{O} \\ \mathbb{O} & \mathbb{O} & \mathbb{S}_{i,j} & \mathbb{O} \\ \mathbb{O} & \mathbb{O} & \mathbb{O} & \mathbb{S}_{i,j} \end{bmatrix}. \quad (696)$$

The X-directed ANM-coupling relations are therefore written by imposing the flux continuity on $x_{i-1/2}$ as

$$\mathbb{R}_{i-1,j} \begin{bmatrix} \tilde{\Phi}_{i-1,j} \\ J_j^y(x_{i-1/2}) \\ J_{i-1}^x(y_{j-1/2}) \\ J_{i-1}^x(y_{j+1/2}) \end{bmatrix} = \mathbb{L}_{i,j} \begin{bmatrix} \tilde{\Phi}_{i,j} \\ J_j^y(x_{i-1/2}) \\ J_i^x(y_{j-1/2}) \\ J_i^x(y_{j+1/2}) \end{bmatrix}. \quad (697)$$

The nodal balance equation can be written in terms of nontransformed variables as

$$\bar{\Phi}_{i,j} = \mathbb{B}_{i,j} \begin{bmatrix} J_j^y(x_{i-1/2}) \\ J_j^y(x_{i+1/2}) \end{bmatrix} + \mathbb{C}_{i,j} \begin{bmatrix} J_i^x(y_{j-1/2}) \\ J_i^x(y_{j+1/2}) \end{bmatrix}, \quad (698)$$

where

$$\mathbb{B}_{i,j} = \mathbb{T}_{i,j} \begin{bmatrix} -\mathbb{X}_{i,j} & \mathbb{X}_{i,j} \\ \mathbb{O} & \mathbb{S}_{i,j} \end{bmatrix} \quad (699)$$

and

$$\mathbb{C}_{i,j} = \mathbb{T}_{i,j} \begin{bmatrix} -\mathbb{Y}_{i,j} & \mathbb{Y}_{i,j} \\ \mathbb{O} & \mathbb{S}_{i,j} \end{bmatrix}. \quad (700)$$

Relations (697) are used together with the Y -directed ANM-coupling relations and with the nodal balance equation (698) to build the global matrix system.

Calculation of matrices $\mathbb{L}_{i,j}$, $\mathbb{R}_{i,j}$, $\mathbb{B}_{i,j}$, and $\mathbb{C}_{i,j}$ for each node represents the core of the ANM. These matrices are a function of the G -group cross-sections and diffusion coefficients, of the node size *and* of the effective multiplication factor K_{eff} . They must be updated during the power iteration, as K_{eff} changes. A straightforward way to present the core of the ANM is to provide a Matlab script implementing the linear transformation and the calculation of the nodal-coupling matrices for a single node. The script parameters are defined as

keff = effective multiplication factor,
 xm = value of $x_{i-1/2}$ (cm),
 xp = value of $x_{i+1/2}$ (cm),
 dely = node size Δy_j along the Y -axis (cm),
 diff = diffusion-coefficient array of size G (cm),
 sigr = macroscopic removal cross-section array of size G (cm^{-1}),
 chi = fission-spectrum array of size G ,
 nusigf = ν times the macroscopic-fission cross-section array of size G (cm^{-1}),
 [L, R, B] = nodal-coupling matrices,

The script `anm_coupling_2D` follows:

```
function [L, R, B] = anm_coupling_2D(keff, xm, xp, dely, diff, sigr, chi, ...
    nusigf)
% Compute the 2D ANM coupling matrices for a single node. Flat transverse
% leakage approximation.
% function [L, R, B] = anm_coupling_2D(keff, xm, xp, dely, diff, sigr, ...
%     chi, nusigf)
% (c) 2008 Alain Hebert, Ecole Polytechnique de Montreal
G=size(diff,2);
F=inv(diag(diff))*(chi*nusigf/keff-sigr); [T,Lambda]=eig(F);
delx=xp-xm;
Mm=zeros(2*G,2*G); Mp=zeros(2*G,2*G); Nm=zeros(G,2*G); Np=zeros(G,2*G);
B=zeros(G,2*G); Y=zeros(G,G);
```

```

```

Equations (694) are written in a convenient form to introduce a *zero-flux-* or *albedo-boundary condition* on the left or right boundary. The relation between the surfacic flux and current, required to implement an albedo-boundary condition, is obtained directly from (542). We also note that the above Matlab script does not deal with situations where $\lambda_{g,i,j}$ approaches zero. A production implementation should take this possibility into consideration.

The ANM unknowns are the average fluxes on the node volumes and the average net currents on the node surfaces. This choice of unknowns is a characteristic of *dual discretization* approaches such as the *mesh-centered finite-difference* method of ▶ 8.2 or the *Raviart-Thomas finite-element* technique of Hébert (1993). The ANM belongs to the family of dual-discretization approaches.

The ANM in 2D leads to a matrix system of order approximately equal to $3GN$ where G is the number of energy groups and N is the number of nodes. About one-third of the system equations are nodal-balance relations and the remaining equations corresponds to X - or Y -directed nodal-coupling relations.

Appendix: Tracking of 1D and 2D Geometries

1 Tracking of 1D Cylindrical and Spherical Geometries

The tracking of 1D cylindrical and spherical geometries is similar and can be generated with the same algorithm. A Matlab script `f=sybt1d(rad,lg sph,ngauss)` is presented to produce a tracking object in these cases. **Figure 42** presents an example with $I = 2$ regions and $K = 2$ tracks per regions. Tracks ① and ② have two segments, identified as ℓ_1 and ℓ_2 . Tracks ③ and ④ have only one segment, identified as ℓ_2 . Each track is making an angle ϕ with respect to the outgoing normal vector.

The purpose of the tracking object is to permit the numerical evaluation of the integrals in a collision probability approach or with the MOC. A K -point Gauss-Jacobi quadrature is used as follows:

$$\int_{r_1}^{r_2} dh f[\ell(h)] = \frac{1}{2} \sum_{k=1}^K w_k f[\ell(h_k)], \tag{701}$$

where r_1 and r_2 are the integration limits, corresponding to consecutive radii of the geometry. The Matlab-tracking object is a 2D-cell array containing $I \times K$ elements, one per track. The i index refers to the tracks located in $r_{i-1/2} < h < r_{i+1/2}$. The (i, j) -th cell is also a cell array containing three elements:

- The weight w_k of the track
- The product $w_k \cos \phi$
- A 1D array of dimension $I - i + 1$ containing the track segments

The Matlab script uses three arguments: a 1D array of dimension I containing the radii (the 0.0 radius is not given), a logical variable set to `false` in cylindrical geometry or `true`

Figure 42
Tracking in 1D cylindrical and spherical geometries

in spherical geometry, and the number of Gauss–Jacobi points. The script is implemented as follows:

```
function f=sybt1d(rad, lgsph, ngauss)
% produce a Gauss-Jacobi tracking in 1D curvilinear geometry
% function f=sybt1d(rad, lgsph, ngauss)
% (c) 2005 Alain Hebert, Ecole Polytechnique de Montreal
    npij=size(rad,2);
    if ngauss == 1
        alp=.6666666667; pwr=.5;
    elseif ngauss == 2
        alp=[.3550510257, .8449489743]; pwr=[.1819586183, .3180413817];
    elseif ngauss == 3
        alp=[.2123405382, .5905331356, .9114120405];
        pwr=[.0698269799, .2292411064, .2009319137];
    elseif ngauss == 4
        alp=[.1397598643, .4164095676, .7231569864, .9428958039];
        pwr=[.0311809710, .1298475476, .2034645680, .1355069134];
    elseif ngauss == 5
        alp=[.0985350858, .3045357266, .5620251898, .8019865821, .9601901429];
        pwr=[.0157479145, .0739088701, .1463869871, .1671746381, .0967815902];
    elseif ngauss == 6
        alp=[.0730543287, .2307661380, .4413284812, .6630153097, .8519214003, ...
            .9706835728];
        pwr=[.0087383018, .0439551656, .0986611509, .1407925538, .1355424972, ...
            .0723103307];
    else
        error('invalid number of Gauss-Jacobi points.')
    end
    rik1=0;
    for ik=1:npij
        rik2=rad(ik);
        rd=rik2-rik1;
        for il=1:ngauss
            r=rik2-rd*alp(il)^2;
            aux=4*rd*pwr(il);
            if lgsph
                aux=aux*r*pi;
            end
            ct1=0.;
            z=zeros(1,npij-ik+1);
            for i=ik:npij;
                ct2=sqrt(rad(i)^2-r^2);
                z(i-ik+1)=ct2-ct1;
                ct1=ct2;
            end
            cell {1} = aux;
        end
    end
end
```

```

cell {2} = aux*ct2/rad(npj);
cell {3} = z;
f {ik,il} = cell;
end
rik1=rik2;
end

```

Using this script, the four tracks of [Fig. 42](#) are obtained using

```

rad=[0.075 0.15];
track=sybt1d(rad,false,2);

```

The ℓ_1 -segment length of track ② is

```
l2=track{1,2} {3} (1)
```

leading to $l_2 = 0.07186585$. Any length $\text{track}\{ik, il\} \{3\} (1)$ corresponding to a segment that crosses the h -axis must be multiplied by 2, as depicted in [Fig. 17](#).

This tracking can be used to compute the p_{11} component of an infinite cylinder of radius R and cross-section Σ surrounded by a vacuum-boundary condition. According to (295), this component is

$$p_{11} = \frac{2}{\pi R^2} \int_0^R dh \left\{ \frac{\ell(h)}{\Sigma} - \frac{1}{\Sigma^2} [\text{Ki}_3(0) - \text{Ki}_3(\Sigma \ell(h))] \right\} \quad \text{if } \Sigma \neq 0 \quad (702)$$

and

$$p_{11} = \frac{1}{2R^2} \int_0^R dh \ell(h)^2 = \frac{4R}{3} \quad \text{if } \Sigma = 0. \quad (703)$$

The following script will perform a numerical integration of p_{11} in a 1D cylindrical tube of radius rad and macroscopic total cross-section sigt :

```

function f=p11_cyl(rad,sigt)
% compute the p11 component in 1D cylindrical geometry
track=sybt1d(rad,false,5);
val=0;
for i=1:5
    segment=2*track{1,i} {3} (1);
    if sigt == 0
        d=segment/sigt-(akin(3,0)-akin(3,sigt*segment))/sigt^2;
    else
        d=pi*segment^2/4;
    end
    val=val+track{1,i} {1} *d;
end
f=val/(pi*rad^2);

```

where $\text{akin}(n, x)$ is a script used to compute $Ki_n(x)$.

Similarly, the following script will perform a numerical integration of p_{11} in a 1D spherical sphere of radius rad and macroscopic total cross-section sigt :

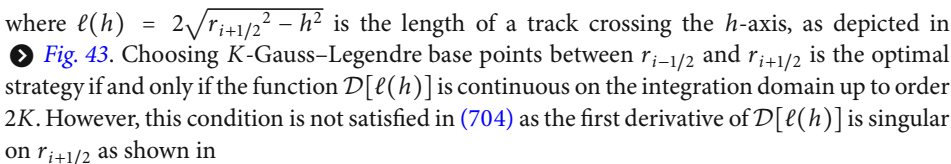

```
function f=p11_sphere(rad,sigt)
% compute the p11 component in 1D spherical geometry
track=sybt1d(rad,true,5);
val=0;
for i=1:5
    segment=2*track{1,i}{3}(1);
    if sigt == 0
        d=segment/sigt*(1-exp(-sigt*segment))/sigt^2;
    else
        d=segment^2/2;
    end
    val=val+track{1,i}{1}*d;
end
f=val/(4*pi*rad^3/3);
```

2 The Theory Behind sybt1d

The tracking strategy consists in drawing K tracks (Matlab variable `ngauss`) in each subdomain $r_{i-1/2} < h < r_{i+1/2}$. It is important to find the optimal location for these tracks, in order to keep the total number of tracks in the complete domain as low as possible. Such an optimization strategy helps to reduce round-off errors in the collision probability or characteristics calculation.

We will concentrate our investigation on the second term of components p_{ii} in (295), which can be written as

$$I = \int_{r_{i-1/2}}^{r_{i+1/2}} dh \mathcal{D}[\ell(h)], \quad (704)$$

where $\ell(h) = 2\sqrt{r_{i+1/2}^2 - h^2}$ is the length of a track crossing the h -axis, as depicted in  **Fig. 43**. Choosing K -Gauss-Legendre base points between $r_{i-1/2}$ and $r_{i+1/2}$ is the optimal strategy if and only if the function $\mathcal{D}[\ell(h)]$ is continuous on the integration domain up to order $2K$. However, this condition is not satisfied in (704) as the first derivative of $\mathcal{D}[\ell(h)]$ is singular on $r_{i+1/2}$ as shown in

$$\frac{d\mathcal{D}}{dh} = \frac{d\mathcal{D}}{d\ell} \frac{d\ell}{dh} = \frac{d\mathcal{D}}{d\ell} \frac{-2h}{\sqrt{r_{i+1/2}^2 - h^2}}. \quad (705)$$

This singularity is purely geometric and is not related to the presence of Bickley or exponential functions that may appear in $\mathcal{D}[\ell(h)]$. The behavior of the singularity was studied in the sixties by Carlvik (1965) and Kavenoky (1969) in the context of the collision probability method in 1D cylindrical and spherical geometry. The proposed solution is to remove the singularity by performing a change of variable in (704).

Figure 43 The Flurig scheme allows to take into account the singularity of tracks tangent to a circular arc

The *Flurig scheme* is a change of variable of the form $y = \sqrt{r_{i+1/2} - h}$, so that (704) is rewritten as

$$I = 2 \int_0^{\sqrt{r_{i+1/2} - r_{i-1/2}}} dy y \mathcal{D}[\ell(r_{i+1/2} - y^2)]. \tag{706}$$

With this transformation, the first derivative of the integrand is

$$\frac{d\mathcal{D}}{dy} = \frac{d\mathcal{D}}{d\ell} \frac{d\ell}{dh} \frac{dh}{dy} = \frac{d\mathcal{D}}{d\ell} \frac{-2h}{\sqrt{r_{i+1/2}^2 - h^2}} (-2\sqrt{r_{i+1/2} - h}) \tag{707}$$

so that

$$\lim_{h \rightarrow r_{i+1/2}} \frac{d\mathcal{D}}{dy} = 2\sqrt{2r_{i+1/2}} \left. \frac{d\mathcal{D}}{d\ell} \right|_{h=r_{i+1/2}}. \tag{708}$$

There is no singularity in the integral of (706) and an efficient Gauss–Legendre quadrature can be used to determine its value. However, it is possible to gain one more order of accuracy by using a Gauss–Jacobi quadrature where the factor y is taken into account implicitly, as proposed in Article 25.4.33 of Abramowitz and Stegun (1970).

A second change of variable is made in order to transform the support $0 \leq y \leq \sqrt{r_{i+1/2} - r_{i-1/2}}$ into a normalized support $0 \leq u \leq 1$. We define

$$u = \frac{y}{\sqrt{r_{i+1/2} - r_{i-1/2}}} \tag{709}$$

so that

$$\begin{aligned} I &= 2(r_{i+1/2} - r_{i-1/2}) \int_0^1 du u \mathcal{D}[\ell(r_{i+1/2} - (r_{i+1/2} - r_{i-1/2}) u^2)] \\ &= 2(r_{i+1/2} - r_{i-1/2}) \sum_{k=1}^K \omega_k \mathcal{D}[\ell(r_{i+1/2} - (r_{i+1/2} - r_{i-1/2}) u_k^2)], \end{aligned} \tag{710}$$

where $\{\omega_k, u_k; k = 1, K\}$ are the weights and base points of a Gauss–Jacobi quadrature.

3 Tracking of 2D Square Pincell Geometries

The tracking of unstructured 2D geometries is performed using a *tracking operator*, leading to a *tracking file* containing straight-line particle trajectories spread over the complete domain. The complexity of this operator increases with the complexity of the geometry, so that general algorithms involve large production softwares. Here, we have chosen to define a specification for a general-purpose tracking file and to present a Matlab script for generating this file in the particular case of a 2D-square *pincell* geometry. This geometry features one-eighth symmetry with concentric annuli not crossing the external perimeter, as depicted in  Fig. 19. This simple geometry is sufficient to introduce solution algorithms of the particle-transport equation based on the method of collision probabilities or on the MOC.

A general-purpose tracking file can be implemented as a binary sequential file. It is described using the following Fortran instructions:

```
WRITE (IUNIT)  NSURF, NREG, NANGLE, NBTRK, FNORM
WRITE (IUNIT)  (SURF ( I ), I=1, NSURF) , (VOL ( I ), I=1, NREG)
WRITE (IUNIT)  (SINANG ( I ), I=1, NANGLE) , (COSANG ( I ), I=1, NANGLE)
DO  ITRK=1, NBTRK
  WRITE (IUNIT)  IANGL, ISURF, JSURF, WEIGHT, NSEG
  WRITE (IUNIT)  (NRSEG ( I ), I=1, NSEG)
  WRITE (IUNIT)  (SEGLN ( I ), I=1, NSEG)
ENDDO
```

where

IUNIT = Fortran unit associated with this sequential binary file

NSURF = number of surfaces surrounding the geometry

NREG = number of regions in the geometry

NANGLE = number of trajectory angles

NBTRK = number of trajectories (tracks) in tracking file

FNORM = angular normalization factor

SURF = perimeter length of each surface

VOL = volume of each region

SINANG = sine of trajectory angles

COSANG = cosine of trajectory angles

IANGL = angle index for this track ($1 \leq \text{IANGL} \leq \text{NANGLE}$)

ISURF = entering surface index for this track ($1 \leq \text{ISURF} \leq \text{NSURF}$)

JSURF = exit surface index for this track ($1 \leq \text{JSURF} \leq \text{NSURF}$)

WEIGHT = weight for this track

NSEG = number of regions crossed by this track. If a single region is crossed many times, NSEG must be increased accordingly.

NRSEG = indices of the regions crossed by this track ($1 \leq \text{NRSEG} (I) \leq \text{NREG}$)

SEGLN = segment lengths corresponding to each region crossed by this track.

We have implemented a simple Matlab script to generate the tracking information for a 2D square pincell. The Matlab script `track=sybt2d(a, rad, nangle, ngauss)` stores this information in a Matlab array `track` instead of using a sequential binary file. Variables `nangle` and `ngauss` (≤ 6) are the number of trajectory angles in $(0, \pi/4)$ and the number of Gauss-Jacobi points in each subdomain, respectively. A partial tracking is first

computed on the subdomain depicted in  Fig. 44 and is unfolded to cover the full pincell geometry. The script is implemented as follows:

```
function track=sybt2d(a,rad,nangle,ngauss)
% produce a Gauss-Jacobi tracking in 2D square pincell geometry
% function track=sybt2d(a,rad,nangle,ngauss)

The tracking algorithm of script `sybt2d` originates from Appendix A in Hébert (1981). The I regions (Matlab variable `npj`) of the 2D square pincell are numbered from center toward perimeter. Their volumes are computed as

$$\begin{aligned}
 V_i &= \pi R_{i+1}^2 - \pi R_i^2, \quad i = 1, I - 1 \\
 V_I &= a^2 - \pi R_I^2,
 \end{aligned} \tag{711}$$

where a is the side length and where R_i and R_{i+1} are the internal and external radii of region i , respectively. The first radius is set as $R_1 = 0$. The geometry is homogenous if $I = 1$.

The tracking information is used for the numerical integration of functions $F_{S_\alpha, S_\beta} \{f_i(x, \varepsilon)\}$ defined as

$$F_{3,2} \{f_i(x, \varepsilon)\} = \frac{1}{\pi} \int_0^a dx \int_0^{\pi/4} d\varepsilon \sin \varepsilon f_i(x, \varepsilon) \tag{712}$$

Figure 44
Integration domain for a 2D square pincell

and

$$F_{3,4}\{f_i(x, \varepsilon)\} = F_{1,2}\{f_i(x, \varepsilon)\} = \frac{1}{\pi} \int_0^a dx \int_{\varepsilon^*}^{\pi/2} d\varepsilon \sin \varepsilon f_i(x, \varepsilon), \quad (713)$$

where

$$\varepsilon^* = \tan^{-1} \frac{a}{a-x}. \quad (714)$$

The transmission probability matrix P_{S_α, S_β} of a square pincell is a 4×4 matrix that can be computed using (712) and (713). The angular integration domain is illustrated in Fig. 44, taking care of the pincell symmetries. A simple Matlab script can be used to obtain this matrix as a function of the tracking and of the macroscopic total cross-sections sigt in each region:

```
function pss=sybpss(track,sigt)
% integration of transmission probabilities. The tracks are computed by
% sybt2d.
% function pss=sybpss(track,sigt)
% (c) 2008 Alain Hebert, Ecole Polytechnique de Montreal

    pop=sum(sigt(track(kgar+1:kgar+km)).*track(k+km:-1:k+1));
```

```

    tij(ind)=tij(ind)+akin(3,pop)*z1 ; k=k+km ;
end
pss=zeros(nsurf,nsurf) ;
for i=1:nsurf
    pss(i,1:nsurf)=tij(indpos(i,1:nsurf)).*(4.*track(5)^2/surfa(i)) ;
end

```

4 The Theory Behind sybt2d

The practical evaluation of (712) and (713) first involves the permutation of variables x and ε . The angular domain between 0 and $\pi/2$ is divided into J equidistant values (Matlab variable `nanngle`), with J even. We write

$$\varepsilon_j = \frac{\pi}{2J} (j - 1/2), \quad j = 1, J, \quad (715)$$

$$\Delta\varepsilon_j = \frac{\pi}{2J}, \quad j = 1, J. \quad (716)$$

For each angle ε_j , we trace a set of parallel trajectories, each of them made of m individual segments, with $1 \leq m \leq 2I-1$. The global integration domain is next subdivided into subdomains where all the trajectories have the same number of segments. In each subdomain, K trajectories (Matlab variable `ngauss`) are set according to the Flurig scheme presented in [Sect. 2](#). The set $\{\Delta s_k; k = 1, K\}$ contains the perpendicular distances associated with the K trajectories for angle ε_j in a given subdomain. The corresponding distances on the X -axis are therefore written as

$$\Delta x_k = \frac{\Delta s_k}{\sin \varepsilon_k}, \quad k = 1, K \quad (717)$$

so that the trajectory weights, corresponding to Fortran variable `WEIGHT`, are computed as a function of spacings Δs_k using

$$\omega_k = \frac{\Delta s_k}{2J}. \quad (718)$$

We can now rewrite (712) and (713) in their discretized form as

$$F_{3,2}\{f_i(x, \varepsilon)\} = \sum_{j=1}^{J/2} \sum_{k \in D_{3,2}} \omega_k f_i(x_k, \varepsilon_j) \quad (719)$$

and

$$F_{3,4}\{f_i(x, \varepsilon)\} = F_{1,2}\{f_i(x, \varepsilon)\} = \sum_{j \in C_{3,4}} \sum_{k \in D_{3,4}} \omega_k f_i(x_k, \varepsilon_j), \quad (720)$$

where

$$D_{3,2} = \{k \mid x_k > a - a \tan \varepsilon_j\}, \tag{721}$$

$$D_{3,4} = \{k \mid x_k < a - a \tan \varepsilon_j\} \tag{722}$$

and

$$C_{3,4} = \{j \mid \varepsilon_j > \pi/4\}. \tag{723}$$

The segment lengths $X_i(x, \varepsilon)$ depicted in **Fig. 45** are obtained using the following two trigonometric formulas:

$$\begin{aligned} d &= \frac{a}{2} \cos \varepsilon_j + \left(x_k - \frac{a}{2}\right) \sin \varepsilon_j, \\ c &= \left[\frac{a}{2} \sin \varepsilon_j - \left(x_k - \frac{a}{2}\right) \cos \varepsilon_j\right] - \sqrt{R^2 - d^2}. \end{aligned} \tag{724}$$

A spatial subdomain E_i is depicted in gray in **Fig. 46**, corresponding to an angle ε_j . It is possible to use the tracking to obtain a numerical approximation W_i of this volume, as

$$W_i = \sum_{k \in E} \Delta s_k X_i(x_k, \varepsilon_j), \quad i = 1, I. \tag{725}$$

Subdomain E_i is bounded by two straight lines set at distances d_1 and d_2 from the pincell center, as depicted in **Fig. 46**. We also define an area $G_i(d)$, with $1 \leq i \leq I$, as

$$G_i(d) = \begin{cases} R_i^2 + \cos^{-1} \frac{d}{R_i} - d\sqrt{R_i^2 - d^2} & \text{if } 0 \leq d \leq R_i, \\ 0 & \text{otherwise.} \end{cases} \tag{726}$$

The exact value of subvolume W_i is given in terms of these areas as

$$\begin{aligned} W_1^+ &= G_2(d_1) - G_2(d_2), \\ W_i^+ &= G_{i+1}(d_1) - G_{i+1}(d_2) - \sum_{\ell=1}^{i-1} W_\ell^+; \quad i = 2, I-1 \end{aligned} \tag{727}$$

Figure 45
Interception of a trajectory with pincell geometry

■ Figure 46

Calculation of subvolume W_i^+ (in gray in the figure)

and

$$W_i^+ = \begin{cases} \frac{1}{2} \tan \varepsilon_j [(a - x_1)^2 - (a - x_2)^2] - \sum_{\ell=1}^{I-1} W_\ell^+, & \text{if } x_1 > a - a \tan \varepsilon_j, \\ b(x_2 - x_1) - \sum_{\ell=1}^{I-1} W_\ell^+, & \text{if } x_2 < a - a \tan \varepsilon_j. \end{cases} \quad (728)$$

The numerical value W_i of the subvolume evaluated from the tracking is different from its analytical value W_i^+ , due to discretization error during the integration process. This error is expected to become smaller as the number of trajectories increases, i.e., as Matlab variables `nangle` and `ngauss` increase. However, increasing the size of the tracking has undesirable effects:

- The CPU time required to compute the collision probabilities or to solve the characteristics equations increases strongly with the size of the tracking. Moreover, large domains can lead to tracking sizes exceeding the limits of the computer.
- As the number of tracks increases, the collision probability components (or the solution of the characteristics equations) are obtained as the summation of increments that become smaller and smaller. Consequently, numerical instabilities are likely to produce oscillations in the transport calculation.

Two remedies exist to increase the accuracy of the integration process using small tracking files. The first remedy is the *Flurig scheme* and is already incorporated into Matlab script `sybt2d`. This approach is very efficient but breaks down in complex 2D geometries due to its inherent difficulty in isolating each subdomain E_i .

A second remedy consists in normalizing the segment lengths $X_i(x_k, \varepsilon_j)$ in such a way that (725) leads to exact volumes, whatever the size of the tracking. It is important to perform segment normalization one angle ε_j at a time. Our Matlab script `sybt2d` performs an improved normalization that preserves the exact volumes W_i^+ for each angle ε_j and for each

subdomain E_i . This normalization is written as

$$\tilde{X}_i(x_k, \varepsilon_j) = \frac{W_i^+}{W_i} X_i(x_k, \varepsilon_j), \quad k \in E_i. \quad (729)$$

It is also possible to normalize the angular integral values. The idea here is to multiply the angular summations by the factor e_1^2 chosen in such a way that

$$e_1^2 \left[\frac{\pi}{2J} \sum_{j=1}^J \sin \varepsilon_j \right] = \int_0^{\pi/2} d\varepsilon \sin \varepsilon = 1. \quad (730)$$

An angular normalization factor e_1 is written in position `track(5)` of the Matlab tracking (Fortran variable `FNORM`), defined as

$$e_1 = \frac{1}{\sqrt{\frac{\pi}{2J} \sum_{j=1}^J \sin \varepsilon_j}}. \quad (731)$$

Abstract: This chapter presents a detailed description of the elements that comprise a lattice physics code. Lattice physics codes are used to generate cross section data for nodal codes, where the nodal codes are used to model the coupled neutronics and thermal-hydraulics behavior of the entire reactor core during steady state and transient operation. Lattice physics codes analyze axial segments of fuel assemblies, referred to as *lattices*, to determine the detailed spatial and spectral distribution of neutrons and photons across the segment. Once the flux distribution is known, the cross sections can be condensed and homogenized into the structure needed by the nodal code. The nodal code then pieces the various lattices together to construct the various fuel assemblies in the reactor core. This chapter is split into individual sections representing the major pieces of a lattice physics code. ➤ [Section 1](#) presents a general overview of the computational scheme used for a typical lattice physics code (*Knott*). The remaining sections of this chapter are used to describe the major pieces in detail. ➤ [Section 2](#) describes the contents of the cross section library that accompanies a lattice physics code (*Yamamoto*). ➤ [Section 3](#) discusses the various resonance treatments used in lattice physics calculations (*Yamamoto*). ➤ [Section 4](#) describes a method for removing cross section energy detail without sacrificing too much accuracy (*Knott*). ➤ [Section 5](#) describes the fine-mesh transport calculation on the heterogeneous lattice geometry (*Knott*). ➤ [Section 6](#) discusses the burnup calculation (*Yamamoto*). ➤ [Section 7](#) describes some of the details of a typical case matrix (*Knott*), and ➤ [Sect. 8](#) discusses some of the edits that are provided by the lattice physics code (*Knott*). This chapter provides the interested reader with a broad understanding of a typical lattice physics code.

1 Overview

1.1 Introduction

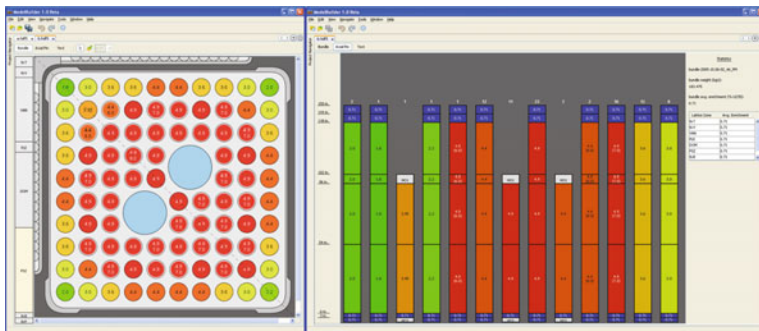

Our primary interest in reactor analysis is to be able to model day-to-day steady state operation of the reactor core, or to model brief periods of time during which the reactor is experiencing some sort of operational transient due to an unexpected insertion or removal of reactivity. Such analyses are performed using a three-dimensional nodal code with thermal-hydraulic feedback. The nodal code models the entire reactor core as a collection of homogeneous prisms, referred to as *nodes*. The nodes are homogeneous in the sense that the material cross sections, used to represent the neutronic properties of the fuel, are constant and there is no geometry detail within a node, such as the explicit representation of fuel pins, guide tubes, or control rods. In other words, everything gets smeared together. A model of a full-sized reactor core will use anywhere from 15,000 to 20,000 nodes. Material cross sections for a node have traditionally been represented by just two energy groups – a fast group typically above 0.625 eV and a thermal group typically below 0.625 eV – although current nodal codes have begun to expand on this number. The material cross sections for a node are obtained from tables generated by a *lattice physics code*. The lattice physics code is used to perform a very detailed neutronic analysis on each unique axial portion of a fuel design, where the characteristics of the fuel might change due to changes in geometry or materials from the surrounding elevations. We refer to these unique axial zones as *lattices*, two of which are illustrated in ➤ [Fig. 1](#). A typical fuel bundle may contain seven or eight different axial zones. This is illustrated in ➤ [Fig. 2](#) for a boiling water reactor (BWR) bundle design, where the panel on the left shows the radial distribution of pin enrichments in the bundle design and the panel on the right shows the axial zoning of each

■ Figure 1
Lattices within homogeneous nodes

of the unique pin types that have been included in the design. In this example, of the 92 fuel pins contained in the bundle design, 13 happen to be unique, differing from each other either in enrichment, burnable absorber content (i.e., Gadolinium mixed into the Uranium fuel pellet), or height. Several pins in the bundle are referred to as part-length rods and span only a portion of the total height of the assembly. The lattice physics code analyses each zone at various snap shots in time (i.e., burnup) and at different core conditions to create tables of homogenized two-group cross sections, which are needed by the nodal code. The collection of cases analyzed to create the tables is referred to as the *case matrix*. The nodal code then interpolates the tables between snap shots to determine the characteristics of the fuel at each specific core elevation, for a given reactor condition. The challenge is to come up with a scheme for the lattice physics code that can accurately reduce the continuous energy raw cross section data for the strongly heterogeneous fuel assembly into a single, homogenized material in two representative energy groups that can be used by the nodal code to produce accurate results.

To create the homogenized, two-group cross sections for each lattice, the lattice physics code needs to calculate an accurate flux distribution in energy and space for the heterogeneous problem. It will then use this flux distribution to spatially and spectrally homogenize the lattice. The main difference between various lattice physics codes in use today is the way in which they go about determining the flux.

■ Figure 2

Panels showing the radial and axial enrichment distribution of pins in a BWR bundle

Ideally, the flux distribution in the lattice would be determined by solving the transport equation in the exact geometry of the lattice using continuous energy cross sections, the way a Monte Carlo code might. But because of time constraints, such a calculation is outside the realm of today's design requirements, where thousands of lattice physics calculations are needed to fully functionalize a single fuel design's characteristics. To this end, the calculational scheme within a lattice physics code is intended to reduce the overall computation time without sacrificing too much accuracy.

In this chapter, we will describe the concept of the lattice physics code. The details of the scheme that will be discussed follow the path outlined in ► Fig. 3. The lattice physics code draws upon many of the topics discussed in other chapters of this handbook, so it provides a nice way of tying many of the topics together. Application to BWR fuel designs are used as examples. Concepts developed to analyze a BWR fuel design can be extended directly to pressurized water reactor (PWR) fuel designs.

1.2 Brief History

In the early days (i.e., late 1950s and early 1960s), the method for analyzing a reactor core consisted of a series of simplistic calculations performed using separate pieces of software that formed a calculational chain. Each piece of software in the chain served a specific purpose and results from one piece of software were used to feed the next piece of software in the chain. The procedure began by calculating a spatially independent fast flux spectrum above 0.625 eV, such as the one generated on a grid of 54 energy groups using the MUFT code (Bohl et al. 1957). The companion thermal flux spectrum below 0.625 eV was generated on a grid of 172 energy groups using the SOFOCATE code (Amster and Suarez 1957). The 0.625 eV energy was used as the thermal cut-off, above which up-scattering effects were neglected. Both MUFT and SOFOCATE were dimensionless codes that simply supplied a general flux spectrum for a given material.

The flux spectrum from the MUFT–SOFOCATE analysis was used to collapse cross sections to a very small number of groups – typically 4. Using the four-group energy structure, a one-dimensional cylindrical pin-cell calculation was performed using the THERMOS code

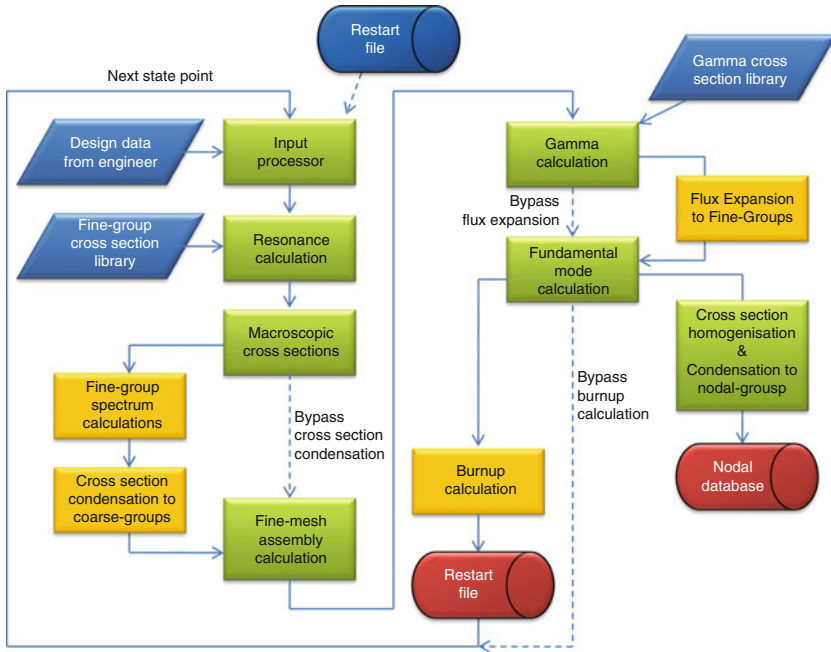

Figure 3
Typical lattice physics calculation scheme

(Honeck 1961). The pin-cell calculation provided representative flux spectrums for the fuel, clad, and coolant regions of the reactor. The flux in the fuel region from the THERMOS pin-cell calculation was passed to a burnup code, such as LEOPARD (Barry 1963), which performed the depletion analysis on selected isotopes. The whole process was very crude by today's standards and offered little in the way of accuracy.

The development of lattice physics codes for reactor analysis began in the mid-1960s with the introduction of WIMS (Winfrith Improved Multigroup Scheme) at Winfrith in the UK (Askew et al. 1966a). The concept gathered all the processes for generating few-group cross section data into a modular collection of software that automated many of the tasks in a systematic fashion, thereby relieving the engineer of a great deal of tedious data transfer and manipulation. But the major evolutionary step was to add a two-dimensional calculation, which analyzed a fuel assembly at a specific elevation. (It should be noted here that the lattice physics code models each lattice as being infinitely tall; i.e., there are no boundaries along the z -axis. This is what we refer to as a two-dimensional problem, i.e., boundaries along two axes.) This two-dimensional calculation provided a way of explicitly capturing the response of each pin due to the influence of its neighbors (other fuel pins, absorber rods, water rods, channel box walls, water gaps, etc.). The original WIMS code provided a framework for research in reactor analysis and could be applied to a very wide range of problems, such as gas-cooled reactors of the Magnox and AGR types that are prevalent in the UK. In the early 1970s, a special version of WIMS was released, LWRWIMS (Fayers et al. 1972), which was streamlined for analyzing light water reactor (LWR) fuel designs. These first versions of WIMS made use of gross approximations at all stages of the

calculational scheme in order to reduce execution time and memory requirements to a manageable level. For LWR analysis, the standard way of determining the flux at the lattice level was based on a few-group diffusion calculation applied to a coarse Cartesian grid.

In the 1970s and early 1980s, a series of lattice physics codes were developed in the Scandinavian countries. These included CASMO (Ahlin and Edenius 1977), CPM (Ahlin and Edenius 1978), and PHOENIX (Stamm'ler 1992). These codes, together with LWRWIMS, the General Electric/Toshiba code TGBLA (Yamamoto et al. 1984), the Combustion Engineering code DIT (Jonsson and Loretz 1991), and the Cadarache code APOLLO (Hoffman et al. 1973), provided a stable platform for LWR lattice physics analysis throughout the 1980s. Most codes were very similar in concept, but differed in detail. All employed significant approximations in order to reduce execution time to a manageable level. However, the newer codes had begun to introduce transport effects into the lattice calculation. Throughout the 1990s, CPM and DIT faded from routine use. During the same period of time, drastic improvements in computer architecture allowed for significant improvements in accuracy in CASMO (CASMO-4 (Knott et al. 1995)), APOLLO (APOLLO-2 (Sanchez et al. 1988)), and the development of HELIOS (Casal et al. 1991). Most lattice physics codes in production use today share many of the ideas from these codes.

The content of this chapter relies heavily on experiences from the development of CASMO-4, LANCER02 (Knott and Wehlage 2007), and AEGIS (Sugimura et al. 2007). When appropriate, deviations from the approaches in these codes are discussed.

1.3 Cross Section Library

The first step in building a lattice physics code is to create an energy group-dependent cross section library. This is our first approximation – that we assume we can accurately represent cross sections over a range of energies using constant values as opposed to point-wise data. The number of energy groups needed and the location of the group boundaries are determined by the lattice physics code's range of application. For example, analysis on mixed-oxide fuel requires different energy detail than does analysis on Uranium-oxide fuel; analysis on fast reactors requires different energy detail than does analysis on thermal reactors; analysis on light water reactors requires different energy detail than does analysis on heavy water reactors, and so on. From the early WIMS days through the 1980s, the cross section libraries associated with production-level lattice physics codes were limited to 100 energy groups or fewer. The original WIMS library contained 69 energy groups (Taubman 1975) and many early lattice physics codes replicated that structure. In the early 1990s, HELIOS was released with a master library containing 190 energy groups, although this group structure was rarely used for analysis. Instead, a smaller library with 35 groups was routinely utilized. Today, it is common for libraries to contain hundreds of energy groups (Rhodes 2009). The more energy groups contained in the library, the more time consuming the analysis becomes. In [▶ 1.5](#) – and in much more detail in [▶ Sect. 4](#) – we will discuss the ways of reducing this computational burden.

In addition to determining the energy group structure of the cross section library, it is also necessary to determine the isotopes that will be carried in the library. Not all isotopes need to be included in the library. For instance, deuterium data might only be required if the lattice physics code is going to be applied to heavy water reactor analysis; graphite data might only be required if the lattice physics code is going to be applied to gas-cooled reactors and so on. The number of isotopes included in the library is primarily dictated by the depletion chains that will be solved during the burnup calculation and by the fission products that will be treated explicitly.

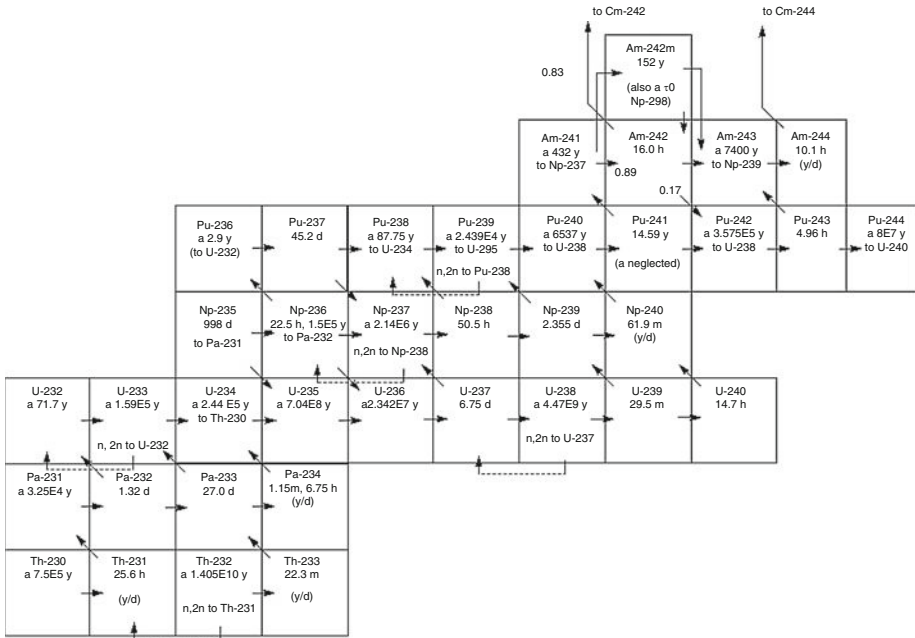

Figure 4
Typical actinide chain

Figure 4 contains an example of the lower portion of the actinide chain modeled in a typical lattice physics code (Rhodes 2009). In order to model this burnup chain, data for every isotope in the chain would need to be contained in the cross section library, although an exception can be made for the extremely short-lived isotopes (i.e., those isotopes that decay within a matter of minutes). Early libraries typically linearized the depletion chains in order to reduce the computational burden and memory requirements (Stamm’ler and Abbate 1983). In addition, only the most important fission products were modeled explicitly in the library. The fission products that were not modeled explicitly were rolled up into a couple of pseudo isotopes, typically one pseudo isotope for all the slowly saturating fission products and one pseudo isotope for all the non-saturating fission products. The total number of isotopes contained in the early libraries was often limited to 100. Today, it is common practice to include several hundred isotopes in a library and to solve the depletion chains explicitly in their matrix representation (Knott and Wehlage 2007); (Rhodes 2009). Section 2 is devoted to a discussion on the cross section library associated with a lattice physics code.

Creation of a multigroup cross section library for a lattice physics code begins with the code that processes the continuous energy cross section data. In the case of the ENDF/B data, the major processing code is NJOY (MacFarlane and Muir 1994a). To create a group-wise library from the continuous energy point-wise data, NJOY must have a flux spectrum with which to combine point-wise data over an energy range,

$$\sigma_x^g = \frac{\int_E^{E+\Delta E} \sigma_x(E)\phi(E)dE}{\int_E^{E+\Delta E} \phi(E)dE} \tag{1}$$

where x is a reaction type (e.g., fission, capture); g is an energy group over the energy interval ΔE ; $\sigma_x(E)$ is the microscopic cross section at energy point E ; and $\phi(E)$ is the flux spectrum used to weigh the continuous energy cross section over the energy interval from E to $E + \Delta E$.

The flux contained in (1) is meant to represent the spectrum found in a typical LWR. Unfortunately, NJOY does not contain the capability of solving the transport equation for a specific flux spectrum. Instead, NJOY contains a couple of options that can be selected to generate an estimate to the true flux found in an LWR. The options available in NJOY assume that the flux behaves as defined by the following expression,

$$\phi(E) \propto \frac{1/E}{\sigma_{t,iso}(E) + \sigma_0} \quad (2)$$

where $\sigma_{t,iso}(E)$ is the microscopic total cross section for the isotope under consideration, iso ; and σ_0 is the microscopic background cross section, which represents the scattering strength of all isotopes in the system other than isotope of interest, iso . In this context, the term *system* refers to the material mixture plus anything else in the immediate vicinity that can contribute to scattering, such as moderator surrounding a fuel pellet. Equation (2) is often referred to as the Bondarenko model based on the narrow resonance (NR) approximation (Lamarsh 1972). If possible, group boundaries in the cross section library should be chosen such that results are insensitive to the flux from (2) used to generate the library.

For each isotope containing resonances, NJOY creates a base cross section set at a base temperature (e.g., 300 K), for infinitely dilute conditions by setting σ_0 equal to a very large value (e.g., 10^{10}) in (2). In this context, the term *infinitely dilute* refers to a system in which the background cross section (i.e., the scattering strength of all the other isotopes in the material and surrounding environment) is so large as to render the presence of the resonance absorber unrecognizable. That is, scattering is the dominant process even at resonance energies.

Once the base set of cross sections are generated, NJOY can create correction factors to the infinitely dilute values to account for changes in the cross sections caused by different temperatures and different background cross sections. We will refer to these tables as the f -tables, $f(T, \sigma_0)$. When the lattice physics code obtains microscopic cross sections from the cross section library, the code reads the infinitely dilute values and enters the f -tables to obtain the appropriate correction factor as a function of temperature and microscopic background cross section,

$$\sigma_{x,iso}^g = \sigma_{x,iso}^g(300 \text{ K}, \infty) \cdot f_{x,iso}^g(T, \sigma_0) \quad (3)$$

Interpolation in the f -tables is performed as a quadratic function of the square root of the fuel temperature, $\sqrt{T_f}$, and the logarithm of the microscopic background cross section, $\log(\sigma_0)$. Self-shielded data for each resonance absorber are generated at many different temperatures between 300 and 2,500 K, and at many different background cross section conditions between 10 barns and 10^{10} barns.

In a lattice physics code, the fuel temperature is typically set to a specific value by the user, removing all ambiguity for that particular parameter. The various microscopic background cross sections for the resonance absorbers in the bundle, however, are not obvious and must be determined by the code. If the calculated microscopic background cross section for a particular isotope is incorrect, the lattice physics code will enter the f -tables in the wrong location and pick up the wrong cross sections for the resonance region. This introduces a certain amount of error into the analysis, so it becomes very important that the lattice physics code have a way of accurately calculating the background cross section for each material in the fuel assembly.

1.4 Entering the Resonance Tables

1.4.1 Determining Microscopic Background Cross Sections

To calculate a proper *microscopic* background cross section for each isotope in a material mixture, we begin by determining the *macroscopic* background cross section for the system as a whole and then back-out the microscopic contribution for each isotope.

The calculation of a macroscopic background cross section for a system, Σ_0 , can be separated into two contributions: (1) a volume component, Σ_p ; and (2) a surface component, Σ_e (Wigner et al. 1955). That is, $\Sigma_0 = \Sigma_p + \Sigma_e$.

Volume Component

The volume component, Σ_p , accounts for neutrons that are scattered into a resonance energy by the material mixture (i.e., not the moderator). It is calculated in a very straightforward way as the sum of the potential scattering cross sections for all isotopes in the mixture (hence the use of the subscript p for potential),

$$\Sigma_p = \sum_{iso} N_{iso} \sigma_{p,iso} \quad (4)$$

where N_{iso} is the number density for isotope iso ; and $\sigma_{p,iso}$ is the microscopic potential scattering cross section for isotope iso . The potential scattering cross section is energy-independent and represents the forces that act upon a neutron as it moves in or near the nucleus of an atom. It is a function only of the effective scattering radius of the nucleus, which depends on the way in which the different wavelengths of the incident neutron (e.g., s -wave, p -wave) interact with the target nucleus. The effective scattering radius of each isotope is obtained from the ENDF/B files and the potential scattering cross section is then calculated as $\sigma_{p,iso} = 4\pi R_{0,iso}^2$, where $R_{0,iso}$ is the effective scattering radius of the nuclide.

Surface Component

The surface component, Σ_e , accounts for neutrons that escape the fuel material and are scattered into a resonance energy by the surrounding moderator (hence the use of the subscript e for escape). They are then free to reenter the material, where they may be absorbed. It is the solution to this component that has been studied extensively since the 1960s.

There are many different ways to estimate the contribution from the surface component and different lattice physics codes address it using different approximations. For an isolated fuel pellet, the surface component may be grossly approximated using the Wigner rational expression (Wigner et al. 1955), where a macroscopic escape cross section is expressed as the inverse of the mean chord length for a simple convex body,

$$\Sigma_e = \left(\frac{4V}{S} \right)^{-1} = \frac{1}{2r} \quad (5)$$

In (5), V refers to the volume of the fuel pellet; S refers to the surface area of the pellet; and r is the pellet radius.

The Wigner rational expression is a surprisingly good approximation under certain circumstances. For modern LWR fuel designs, though, the escape cross section calculated using the

Wigner approximation can be in error by far more than is tolerable for the accuracy we desire. Hence, few lattice physics codes rely on the Wigner approximation. Those that do must augment the approximation with a correction factor to produce acceptable results. When this method is chosen, the correction factor is usually determined from a Monte Carlo analysis. ▶ [Section 3](#) is devoted to a thorough description of resonance approximations in lattice physics codes.

For an array of tightly packed fuel pins, such as those in a fuel assembly, some neutrons may escape from one pellet and suffer their first collision in a neighboring pellet rather than in the surrounding moderator. This shadowing effect changes the escape cross section of the isolated pellet and can be taken into account through the use of a Dancoff factor, Γ , and applied to the escape cross section (Carlvik [1966b](#))

$$\Sigma_0 = \Sigma_p + \Gamma \Sigma_e \quad (6)$$

A detailed description of Dancoff factors is included in ▶ [Sect. 3](#).

For each isotope in the fuel mixture, the associated microscopic background cross section is calculated as

$$\sigma_{0,iso} = \frac{\Sigma_0}{N_{iso}} - \sigma_{p,iso} \quad (7)$$

The microscopic background cross section from (7) is used to enter the resonance tables and obtain the appropriate cross sections for each isotope in each fuel mixture in the lattice.

1.4.2 Resonance Interference Effects

Resonance interference refers to the way in which cross section resonances from one nuclide affect resonance absorption or scattering in another nuclide when multiple resonance absorbers exist in the same fuel mixture. During creation of the cross section library, resonance interference effects were neglected. That is, microscopic cross sections for each isotope in the library were created as if none of the resonances from any of the other isotopes existed. In practice, such a condition will never exist since all LWR fuel consists of several Uranium isotopes and/or Plutonium isotopes – all of which contain many resonances over a wide range of energies. In addition, many major fission products contain large resonances. The presence of the additional resonances will exaggerate the spectral flux dips and change the results when using (1). In lattice physics codes, resonance interference effects between different resonance absorbers in the same material mixture can be taken into account through a separate calculation that determines a resonance interference correction factor to the NJOY-generated cross sections (Williams [1983](#); Wehlage [2005](#)).

For this model, a separate ultrafine-group cross section library is utilized that contains tens of thousands of group-wise data points with equal lethargy widths in the resolved resonance energy range from about 40 eV to 10 keV, or possibly even extended up to 100 keV. The narrow resonance (NR) approximation is used to generate a flux spectrum for each resonance absorber in isolation, ϕ_{iso}^u , and a separate flux spectrum for the material mixture as a whole, ϕ_{Mix}^u . Here, u represents the ultrafine-group energy structure. The narrow resonance approximation assumes that the energy lost by a neutron suffering a scattering collision is large compared to the width of a resonance. Under such circumstances, it is unlikely that a neutron will experience more than a single collision within any resonance peak and the neutron is, therefore, somewhat unlikely to be absorbed by a resonance absorber. This approximation tends to be very good for all neutron

energies above 40 eV. Below 40 eV, it is important that the energy group structure of the lattice physics cross section library contains enough detail such that the group-wise cross sections are not strongly shielded.

The ultrafine-group flux for each isotope, ϕ_{iso}^u , and for the material mixture as a whole, ϕ_{Mix}^u , can be described by the following expressions:

$$\phi_{iso}^u = \frac{1/E^u}{\Sigma_{t,iso}^u + \Sigma_0} \quad (8)$$

$$\phi_{Mix}^u = \frac{1/E^u}{\Sigma_{t,Mix}^u + \Sigma_0} \quad (9)$$

where the only difference between (8) and (9) is in the value for the total cross section in the denominator. $\Sigma_{t,iso}^u$ is the ultrafine-group total cross section for isotope *iso*; and $\Sigma_{t,Mix}^u$ is the ultrafine-group total cross section for the material mixture as a whole.

Equations (8) and (9) may be solved directly using the macroscopic background cross section for the material mixture, Σ_0 , from (6). The fluxes from (8) are used to create parallel sets of cross sections, in the energy group structure of the lattice physics cross section library, for each individual resonance absorber,

$$\sigma_{x,iso}^g = \frac{\sum_{u \in g} \sigma_x^u \phi_{iso}^u}{\sum_{u \in g} \phi_{iso}^u} \quad (10)$$

And the flux from (9) is used to create cross sections for the material mixture as a whole,

$$\sigma_{x,Mix}^g = \frac{\sum_{u \in g} \sigma_x^u \phi_{Mix}^u}{\sum_{u \in g} \phi_{Mix}^u} \quad (11)$$

where *x* is the reaction type; *iso* is a resonance absorber; *g* is the energy group structure of the lattice physics cross section library; and *u* is the energy group structure of the ultrafine-group cross section library. Resonance interference correction factors are then calculated as the ratio of (11) to (10),

$$\text{RIF}_{x,iso}^g = \frac{\sigma_{x,Mix}^g}{\sigma_{x,iso}^g} \quad (12)$$

and are applied to the cross sections from the lattice physics library,

$$\sigma_{x,iso}^g = \sigma_{x,iso}^g(300 \text{ K}, \infty) \cdot f_{x,iso}^g(T, \sigma_0) \cdot \text{RIF}_{x,iso}^g \quad (13)$$

RIFs for capture, fission, and elastic scattering cross sections for each major resonance absorber in any material mixture should be calculated. In most cases, the effect of the resonance interference calculation on the results from the lattice physics code is small and serves to basically fine-tune any reactivity coefficients that rely on spectrum hardening effects. A more thorough description of resonance interference effects is contained in [Sect. 3](#).

1.5 Condensation Scheme

Once microscopic cross sections have been obtained from the cross section library and the macroscopic cross sections for each material region in the problem have been created, the lattice physics code is ready to determine the flux distribution throughout the lattice. Solution to the steady state Boltzmann transport equation in the energy group structure of the cross section library is usually supported by modern lattice physics codes, but the calculation is often too time consuming for production-level analysis, where several thousand state points are analyzed to generate nodal cross section data for a single bundle design.

One common approach for reducing execution time to a reasonable level is to condense the cross sections from the energy group structure of the library to a smaller, more manageable energy group structure. When doing this, it is imperative that accuracy is maintained by the smaller cross section set, so an adequate condensation scheme is very important.

HELIOS addressed this issue by performing a single calculation on a generic LWR lattice in the energy group structure of the master cross section library (Casal et al. 1991). The lattice-averaged flux from the reference calculation was then used to condense the entire master cross section library from the fine-group structure (190 groups) into a smaller energy group structure (~35 groups). The smaller library was then used in all production-level analyses without any further condensation. Since the condensation scheme was applied to the microscopic cross sections, the resonance tables (i.e., f -tables) had to be condensed, as well.

CASMO-4 used a different approach (Knott et al. 1995). The cross section library for CASMO-4 contained 70 energy groups and at the beginning of each individual case the code performed a series of calculations in the energy group structure of the library in order to generate a unique condensation spectrum for each different material region of the problem. Macroscopic cross sections for each material region in the problem were condensed from 70-groups to a much smaller group structure, which depended on the type of problem being analyzed, but in general was kept below a dozen energy groups. The approach in LANCER02 is very similar (Knott and Wehlage 2007). The LANCER02 cross section library contains 118 energy groups (or a 190 group library for mixed oxide analysis) and the flux from the condensation scheme is used to collapse macroscopic cross sections to approximately 25 energy groups. The approaches in both CASMO-4 and LANCER02 are based on the scheme described in Knott (1991). This scheme will be described in this chapter.

The condensation scheme in CASMO-4 and LANCER02 consists of a two-step process involving, first, a series of one-dimensional pin-cell calculations and, second, a fast two-dimensional coupling calculation, as illustrated in  Fig. 5. Both calculations could be performed in the energy group structure of the cross section library. An alternative approach would be to perform the coupling calculation in an intermediate energy group structure, somewhere between the fine-group structure of the library and the broad-group structure of the assembly fine-mesh transport solution, in order to reduce execution time even further. Either approach is acceptable, keeping in mind that the level of accuracy used at this stage of the computational scheme will affect the number of energy groups that must be maintained for the assembly fine-mesh transport solution.

In contrast to the two-step approach, CASMO-5 has removed the coupling calculation from the condensation scheme and relies solely on the pin-cell calculations to generate a condensation flux. The lattice physics code AEGIS contains no condensation scheme and performs the assembly fine-mesh transport calculation in the energy group structure of the cross section

■ **Figure 5**
Progression of condensation scheme

library. This is the approach taken for ultimate accuracy, although at the price of a much longer run time.

1.5.1 Pin-Cell Calculations

For the series of one-dimensional pin-cell calculations in the CASMO-4 and LANCER02 condensation scheme, the flux in the system is determined by solving the integral form of the transport equation using the method of collision probabilities (CP). The CP method is ideal for physically small systems containing a small number of mesh. Each pin cell in the lattice – including water rods and vanish locations (i.e., locations above the top of part-length fuel rods) – should take part in its own unique pin-cell calculation. The square coolant region of each cell can be cylindricalized by preserving volume. This converts the two-dimensional nature of the square cell into a one-dimensional problem, where the flux can be determined very rapidly without significantly affecting accuracy. A buffer zone, made up of average fuel and moderator material, can be added to the outside of each cell to help drive the flux across inert pins (e.g., water rods, control rods) and pins containing strong absorbers (e.g., gadolinium, erbium). The system can be represented as a fixed source problem, where the fission spectrum can be used as the neutron source and can be placed in the buffer zone. This helps to facilitate a speedy convergence to the transport solution.

The scalar flux is determined by solving the following integral equation (the derivation of which is presented in detail in [Sect. 4](#)),

$$\phi(\vec{r}_i, E) = \int_{-\infty}^0 Q(\vec{r}_j, E) \cdot T(\vec{r}_j \rightarrow \vec{r}_i, E) \cdot dV_j \quad (14)$$

where $Q(\vec{r}_j, E)$ is the total neutron source in mesh j ; $\phi(\vec{r}_i, E)$ is the scalar flux in mesh i ; and $T(\vec{r}_j \rightarrow \vec{r}_i, E)$ is the first-flight transmission probability of neutrons from mesh j to mesh i , given by the expression

$$T(\vec{r}_j \rightarrow \vec{r}_i, E) = \frac{e^{-\tau(\vec{r}_i - \vec{r}_j, E)}}{4\pi |\vec{r}_i - \vec{r}_j|^2} \quad (15)$$

In order to arrive at the expression for the scalar flux in (14), the source term was assumed to be isotropic. Such an assumption necessitates the use of transport-corrected cross sections in order to account for anisotropic scattering effects. The transport-correction is derived by expanding the scattering kernel using spherical harmonics and keeping only the first two terms. This leads us to the diffusion equations for the scalar flux, ϕ_0^g , and current, ϕ_1^g , and the corresponding definition for the diffusion coefficient

$$D^g = \frac{1/3}{\Sigma_{t1}^g - \sum \Sigma_{s1}^{g' \rightarrow g} \left(\phi_1^{g'} / \phi_1^g \right)} \quad (16)$$

The denominator in (16) represents the definition for the transport cross section, which is a function of the ratio of currents in various energy groups. Unfortunately, we do not know the currents in our problem a priori and we are forced to make the assumption that the current-induced scattering of neutrons into an energy group is equal to the current-induced scattering of neutrons out of the energy group,

$$\sum_{g'} \Sigma_{s1}^{g' \rightarrow g} \phi_1^{g'} \approx \sum_{g'} \Sigma_{s1}^{g \rightarrow g'} \phi_1^g \quad (17)$$

This is a fair assumption when scattering is the dominant reaction and relatively little neutron absorption is taking place. It is a poor assumption when absorption is the dominant reaction.

From (17) it follows that,

$$\Sigma_{tr}^g = \Sigma_t^g - \sum_{g'} \Sigma_{s1}^{g \rightarrow g'} = \Sigma_t^g - \Sigma_{s1}^g \quad (18)$$

which is our definition for the transport cross section. In (18), Σ_t^g is the total cross section in group g ; and Σ_{s1}^g is the first moment to the total scattering cross section in group g . The transport cross section can be created internally from the total cross section and the first moment to the scattering cross section, both of which should be contained in the cross section library.

Specular reflection boundary conditions are used on the outside of the one-dimensional pin-cell geometry to simulate perfect reflection in the square coolant system (i.e., Weiner-Seitz cell).

1.5.2 Coupling Calculation

The solution to the CP equation yields a flux distribution in each region of each pin cell in the energy group structure of the cross section library. This flux distribution is generated without considering the true surroundings of each pin cell (water gaps, water rods, strong absorber pins, control blades, etc.). Before condensing cross sections to a smaller energy group structure, the

fluxes from the one-dimensional pin-cell calculations should be updated to account for the effects on the energy distribution from the surrounding components of the lattice. This can be accomplished by performing a two-dimensional coupling calculation on the entire lattice using a simplified geometry and a simplified solution to the transport equation.

Since this coupling calculation will use a simplified geometry of the lattice, all solutions techniques to the Boltzmann transport equation are viable. At this stage of the calculational scheme, speed is of essence. A very good choice for the two-dimensional coupling calculation is one that solves the integral transport equation using a response matrix (RM) method based on simplified transmission probabilities. In this method, each pin cell is homogenized into an equivalent material set of cross sections using the fluxes from the corresponding one-dimensional pin-cell calculation. Cells are coupled to each other via surface currents, which are assumed to be isotropically distributed in angle and spatially constant along a given cell surface. The equations representing the scalar flux and outward-directed current are, respectively,

$$\phi_I^g = T_{I \leftarrow I}^g Q_I^g V_I + 4 \sum_s T_{I \leftarrow s}^g J_{s, in}^g A_s \quad (19)$$

$$J_{I, out}^g = T_{s \leftarrow I}^g Q_I^g V_I + \sum_{s'} T_{I \leftarrow s'}^g J_{s', in}^g A_{s'} \quad (20)$$

where I represents a spatial mesh, such as an homogenized pin cell; s represents a surface to mesh I ; the T 's are transmission probabilities between volumes and/or surfaces; V represents the volume of mesh I ; and A represents the surface area of surface s . Outward-directed currents from one mesh become the inward-directed currents to the neighboring mesh. The calculation of transmission probabilities will be discussed in [Sect. 4](#).

Following the two-dimensional RM calculation, the energy distribution of neutrons from each one-dimensional pin-cell calculation is updated,

$$\tilde{\phi}_i^g = \phi_i^g \cdot \frac{\phi_I^g V_I}{\sum_{i \in I} \phi_i^g V_i} \quad (21)$$

Fluxes for the surrounding regions of the lattice – channel box wall, water gaps, etc. – are obtained directly from the RM solution. Fluxes for the various regions of a control blade can be obtained from a special series of pin-cell calculations performed on each absorber tube in a control blade and updated with the flux from the RM solution. [Equation \(21\)](#) represents the flux for each material region of the problem that will be used to condense the macroscopic cross sections. The final energy group structure for the two-dimensional assembly transport calculation depends on the accuracy of the condensation scheme, the energy group boundaries in the cross section library, and the types of problems to be analyzed by the lattice physics code.

Today, many lattice physics codes are attempting to move away from cross section condensation and rely solely on solving the fine-mesh transport problem in the energy group structure of the cross section library. Although this approach produces the most accurate solution possible, it is still far too time consuming for a lattice physics code used at a fuel vendor, where millions of lattice calculations must be performed each year in order to support reload core design work. Because of this, the need for a suitable condensation scheme will not go away anytime soon.

[Section 4](#) is devoted to a thorough description of the condensation scheme used in CASMO-4 and LANCER02.

1.6 Assembly Fine-Mesh Transport Calculation

Due to severe heterogeneities present in most modern bundle designs, the final two-dimensional lattice calculation (in the condensed energy group structure if a condensation scheme is employed) should be performed by modeling the lattice in its true geometry. This need renders many solution techniques obsolete due to the complex geometries of LWR fuel designs (cylinders arranged in square arrays, surrounded by channels with partial arcs, etc.). The most feasible techniques are those that solve the integral form of the transport equation. These techniques include the method of collision probabilities (CP) and its current coupling derivatives; the method of characteristics (MoC), and Monte Carlo methods. Monte Carlo methods are far too time consuming when detailed flux tallies in small regions are required, such as those needed for providing the means to solve the depletion chains in fuel pellets. For this reason, we will abandon the idea of using Monte Carlo techniques directly and focus on the other two possibilities.

1.6.1 The CCCP Method

The CP method is an outstanding choice for small problems, such as one-dimensional pin cells. However, because execution times and memory requirements increase with the square of the number of mesh, the straightforward CP method is a very poor choice for large problems, such as full-size lattices. One way around this is to decouple cells and connect them via surface currents, as we did for the coupling calculation in the condensation scheme. This is the approach used for the assembly fine-mesh transport calculation in HELIOS and derivatives thereof. In order to do this, however, an assumption must be made about the distribution of the current in both angle and space as it leaves or enters a cell. Such an assumption will introduce a certain error into the solution, which will manifest itself around cells containing strong absorbers (control rods, control blades, absorber pins, fuel pins containing Gadolinium, etc.). This is highly undesirable for lattice physics code modeling LWR assemblies, since all of the above-mentioned absorbers are present, to some degree, in every assembly design. In addition, anisotropic scattering effects are nearly impossible to model explicitly in the CP method and we are forced to rely solely on transport-corrected cross sections, which tend to be more than adequate for single assembly calculations using perfectly reflective boundary conditions.

The transmission probabilities method used in the first release of HELIOS is referred to as the CCCP method (Current Coupling of the space elements, which are internally treated by collision probabilities (Casal et al. 1991)). It is a method that has since been employed in other lattice physics codes, such as LANCER01 (Azekura et al. 2003) and PARAGON (Ouisloumen et al. 2001). The premise is to perform a very detailed transport solution within a cell, which for fuel pins is made up of the fuel pellet, cladding, and coolant, and possibly including the initial expansion gap between the pellet and the cladding. The surface of each cell is split into multiple regions and a separate current is calculated for each unique region of the surface, as illustrated in  Fig. 6 where each surface has been split in half. This provides a means for modeling spatial changes in the surface current. In the original HELIOS work, the angular distribution of the current is represented using the quadrature used to model neutron transport within the cell: that is, which ever quadrature is used to integrate the collision probabilities within the cell, the same is also used to subdivide the current as it leaves one cell and enters the neighboring cell.

Figure 6
Outward directed currents split along a cell surface

The surface coupling is performed at different polar levels as well as different azimuthal angles, producing a current that can be anisotropic in all directions.

The coupled multigroup equations to be solved are

$$\sum_i^g \varphi_i^g V_i = \sum_{n,m,l} \Gamma_{nml \rightarrow i}^g J_{nml}^{-g} A_{nm} + \sum_j P_{j \rightarrow i}^g \sum_{g'} \left(\Sigma_j^{g' \rightarrow g} + \frac{\chi_j^g}{\lambda} \nu \Sigma_{f,j}^{g'} \right) \varphi_j^{g'} V_j \quad (22)$$

$$J_{nml}^{+,g} = \sum_j P_{j \rightarrow nml}^g \sum_{g'} \left(\Sigma_j^{g' \rightarrow g} + \frac{\chi_j^g}{\lambda} \nu \Sigma_{f,j}^{g'} \right) \varphi_j^{g'} V_j + \sum_{n',m',l'} \Gamma_{n',m',l' \rightarrow nml}^g J_{n',m',l'}^{-g} A_{n'm'} \quad (23)$$

where $J_{nml}^{\pm,g}$ is the out-going/in-coming current from/to the cell in group g , through surface segment m , of cell boundary n , in direction l ; φ_i^g is the neutron flux in group g , mesh i of the cell; $P_{j \rightarrow i}^g$ is the probability for a neutron emitted in group g , mesh j , to suffer its first collision in mesh i ; $P_{j \rightarrow nml}^g$ is the probability for a neutron emitted in group g , mesh j , to leave the cell through segment m of node boundary n in directional l ; $\Gamma_{n',m',l' \rightarrow i}^g$ is the probability for a neutron in group g , in-coming through segment m' , of cell surface n' , in directional l' , to suffer its first collision in mesh i ; $\Gamma_{n',m',l' \rightarrow nml}^g$ is the probability for a neutron in group g , in-coming through segment m' ; cell surface n' ; in directional l' , to leave the cell through segment m of cell surface n in directional l ; A_{nm} is the area of segment m of surface n ; V_i is the volume of mesh i ; $\Sigma_i^g, \nu \Sigma_{f,i}^g, \Sigma_i^{g' \rightarrow g}$ are the macroscopic neutron cross sections in group g , mesh i ; χ_j^g is the fission neutron spectrum in mesh j ; and λ is the neutron multiplication factor.

Ray tracing is used to calculate collision probabilities between mesh within a given cell. The various regions of a cell (e.g., fuel, clad, and coolant) are subdivided further into flat source/flat flux mesh and the collision probabilities are used to redistribute the neutrons between the various mesh of a cell, based on the neutron source distribution in the mesh layout and the neutron current distribution across cell surfaces.

This whole effort is implemented in order to reduce the number of coupled mesh in the CP matrix. In a typical LWR lattice, there may be 5,000 mesh needed to accurately capture the physics of the problem using flat source regions. For a straightforward CP solution, this would require inverting a $5,000 \times 5,000$ matrix for every energy group – a rather daunting task even by today’s standards. By decoupling cells from the CP solution, the problem is reduced to a collection of much smaller “mini” CP matrices – one for each cell in the problem (on the order of a couple of hundreds). The size of each mini CP matrix is on the order of 40×40 , except in cells containing fuel pellets with multiple depletion rings, where the mini CP matrix can be as large as 100×100 – still a much more manageable size compared to $5,000 \times 5,000$. The method still suffers from the approximation imposed by coupling cells via currents.

1.6.2 The Method of Characteristics

In contrast to the drawbacks associated with the method of collision probabilities and Monte Carlo methods, the method of characteristics has few drawbacks. Execution times and memory requirements increase linearly with the angular and spatial detail of the problem; the accuracy of the method can be virtually precise – assuming enough angular detail is used and the spatial mesh are small enough and the method can accommodate explicit modeling of anisotropic scattering, if needed. Additionally, the method is relatively simple to implement, compared with other methods.

The method of characteristics was originally introduced into WIMS in the early 1980s as the CACTUS module (Halsall 1980). That first incarnation of the method saw limited success, though, due to memory requirements and limitations in computers of the day. The first serious application in a commercial lattice physics code was introduced into CASMO-4 in the early 1990s, at a time when workstations had progressed to the point where memory was no longer a major issue (although it remained a minor issue for many more years to come). Since then, the method has found widespread use in other lattice physics codes, including a reawakening in WIMS and additional applications in DRAGON (Marleau et al. 1994), AEGIS (Sugimura et al. 2007), LANCER02 (Knott and Wehlage 2007), APOLLO-2 (Masiello et al. 2009), and most ironically HELIOS-2 (Wemple et al. 2008).

The MoC implemented in CASMO-4 and LANCER02 is the most basic of all the characteristic methods and is a direct derivative of the CACTUS module, first proposed by Askew in the 1970s (Askew 1972). The multigroup equation to be solved is the characteristic form of the Boltzmann equation,

$$\frac{d\Phi_{m,i}^G}{ds_m} + \Sigma_{tr,i}^G \Phi_{m,i}^G = Q_{m,i}^G \quad (24)$$

where s_m is a streaming track across a mesh at angle Ω_m ; $\Phi_{m,i}^G$ is the angular flux in direction Ω_m , across mesh i , in energy group G ; and $Q_{m,i}^G$ is the corresponding angular source, which can be calculated using transport-corrected cross sections or can be modeled using anisotropic scattering effects explicitly.

To solve the characteristic equation, streaming tracks are traced over the problem geometry at a number of different angles. Each angle has associated with it a weight, and each track has associated with it a width. Solution to the characteristics equation, in terms of the angular flux, is obtained along streaming rays and is of the form

$$\Phi_{m,i}^G(s_m) = \Phi_{m,i}^G(0)e^{-\Sigma_{tr,i}^G s_m} + \frac{Q_{m,i}^G}{\Sigma_{tr,i}^G}(1 - e^{-\Sigma_{tr,i}^G s_m}) \quad (25)$$

where the source across a mesh is considered constant (i.e., flat source approximation).

The scalar flux for a given mesh is calculated by integrating the angular flux along all streaming tracks that cross the mesh, and integrating over all directions of motion,

$$\phi_i^G = \int_{4\pi} \bar{\Phi}_i^G(\Omega) d\Omega = 4\pi \sum_m \bar{\Phi}_{m,i}^G \omega_m \quad (26)$$

where ω_m is the weight associated with each direction of motion and the average angular flux in a specific direction across a given mesh, $\bar{\Phi}_{m,i}^G$, is obtained from

$$\bar{\Phi}_{m,i}^G = \frac{\sum_k \bar{\Phi}_{m,k,i}^G \cdot s_{m,k,i} \cdot \delta A_m}{\sum_k s_{m,k,i} \cdot \delta A_m} \quad (27)$$

In (27), δA_m is the separation between parallel streaming tracks; $s_{m,k,i}$ is the length of the streaming track crossing mesh i ; and k represents the different streaming tracks that cross mesh i in direction Ω_m . To obtain an expression for the average value of the angular flux along a streaming track, $\bar{\Phi}_{m,k,i}^G$, (25) is integrated along track k , in direction Ω_m , crossing mesh i , and divided by the length of the track,

$$\bar{\Phi}_{m,k,i}^G = \frac{\int_0^{s_{m,k,i}} \Phi_{m,k,i}^G(s') ds'}{\int_0^{s_{m,k,i}} ds'} \quad (28)$$

Solution to the characteristic equation reduces to finding the intersections between rays and mesh boundaries and calculating the angular flux between intersections. The final solution to the equation produces a very detailed, very accurate flux distribution throughout the lattice (in the condensed energy group structure, if a condensation scheme is employed).

Due to its prominence in lattice physics,  Sect. 5 is devoted to a thorough description of the method of characteristics as applied to the two-dimensional fine-mesh lattice calculation.

1.7 Fundamental Mode Calculation

The fine-mesh assembly calculation assumes perfect reflection on all surfaces of the bundle. In this way, there are no neutrons leaking into or out of the system. However, the data generated by the lattice physics code will be used in a nodal code to model an entire reactor core and, within the reactor core, there are almost always neutrons leaking into or out of each node in the system. To be consistent with the way in which the nodal cross sections are to be used, the lattice physics code should somehow account for neutron leakage at the assembly level.

Leakage effects can be included in an ad hoc way by performing a buckling calculation on the system. The leakage calculation typically involves solving the fundamental mode equation in the diffusion approximation for the material buckling of the system,

$$\bar{\Sigma}_r^g \Psi^g + B_m^2 \bar{D}^g \Psi^g = \sum_{g' \neq g} \bar{\Sigma}_s^{g' \rightarrow g} \Psi^{g'} + \chi^g \quad (29)$$

where the lattice-averaged diffusion coefficient, \bar{D}^g , is calculated as

$$\bar{D}^g = \frac{1}{3 \bar{\Sigma}_{tr}^g} \quad (30)$$

The lattice-averaged removal cross section, $\bar{\Sigma}_r^g$ is calculated as

$$\bar{\Sigma}_r^g = \bar{\Sigma}_{tr}^g - \bar{\Sigma}_s^{g \rightarrow g} \quad (31)$$

and the lattice-averaged cross sections are calculated by volume and flux weighting the cross sections from the various regions of the problem,

$$\bar{\Sigma}_x^g = \frac{\sum_i \Sigma_{x,i}^g \phi_i'^g V_i}{\sum_i \phi_i'^g V_i} \quad (32)$$

In (32), x is a reaction type and $\phi_i'^g$ is the MoC flux distribution expanded back to the energy group structure of the cross section library,

$$\phi_i'^g = \bar{\phi}_i^g \cdot \frac{\phi_i^G}{\sum_{g \in G} \bar{\phi}_i^g} \quad (33)$$

To create a lattice-averaged fission spectrum using the averaging technique represented in (32), $\bar{\chi}^g$, the summation should include only the fuel regions in the lattice.

The flux distribution in (33) has been expanded back to the energy group structure of the cross section library in order to more accurately account for leakage effects in the fast energy group range, where the majority of neutron leakage occurs. In (33), $\bar{\phi}_i^g$ is the condensation flux from (21), and ϕ_i^G is the flux from the broad-group MoC calculation, given by (26).

Equation (27) assumes that the flux has been normalized such that a single absorption occurs in the system, $\sum_g (\bar{\Sigma}_a^g + \bar{D}^g B_m^2) \Psi^g = 1$. The multiplication factor of the system is then calculated from

$$k_{eff} = \sum_g \nu \bar{\Sigma}_f^g \Psi^g \quad (34)$$

The material buckling is adjusted until $k_{eff} = 1.0$. That is, an initial calculation is performed by setting $B_m^2 = 0$. This reproduces the infinite lattice multiplication factor. Next, a second calculation is performed by setting the buckling to a very small positive value, for example, $B_m^2 = 10^{-6}$. The multiplication factors from the first two calculations are used to extrapolate the buckling value to a new value and the corresponding multiplication factor is calculated using

(34). This process continues until a multiplication factor sufficiently close to unity is obtained (i.e., $|k_{eff} - 1| < 0.00001$). This produces the flux spectrum for a critical system and the expanded flux distribution from the MoC solution is adjusted to account for leakage effects,

$$\phi_i''^g = \phi_i'^g \cdot \frac{\Psi^g \cdot \sum_i V_i}{\sum_i \phi_i'^g V_i} \quad (35)$$

Equation (35) represents the final flux distribution for the lattice. The leakage flux can be used to create the nodal data and to deplete the burnable isotopes in the fuel. We also need the adjoint flux in order to accurately generate nodal kinetics data for the effective delayed neutron fraction, β_{eff}^m , and the prompt neutron lifetime, l_p ,

$$\beta_{eff}^d = \frac{\sum_{iso} \left[\sum_g \beta_{iso}^d \chi_d^g \Psi^{\dagger g} \cdot \sum_g \nu \sigma_{f,iso}^g N_{iso} \Psi^g \right]}{\sum_g \chi^g \Psi^{\dagger g} \cdot \sum_g \nu \Sigma_f^g \Psi^g} \quad (36)$$

$$l_p = \frac{\sum_g \frac{1}{v^g} \Psi^{\dagger g} \Psi^g}{\sum_g \chi^g \Psi^{\dagger g} \cdot \sum_g \nu \Sigma_f^g \Psi^g} \quad (37)$$

where the outer summation in (36) is over all isotopes in the fuel and d represents a delayed neutron group.

The adjoint flux is obtained by solving the adjoint to the fundamental mode equation,

$$\Sigma_r^g \Psi^{\dagger g} = \sum_{g' \neq g} \Sigma_s^{g \rightarrow g'} \Psi^{\dagger g'} + \nu \Sigma_f^g \quad (38)$$

where the removal cross section now contains the leakage term

$$\bar{\Sigma}_r^g = \bar{\Sigma}_{tr}^g - \bar{\Sigma}_s^{g \rightarrow g} - B_m^2 \bar{D}^g \quad (39)$$

In this derivation, the spatial component of the adjoint flux is assumed to be equivalent to the spatial component of the forward flux and only the energy distribution of the adjoint flux is assumed to differ from that of the forward flux. This is a very good assumption when there is no spatial leakage explicitly modeled in the system, as is the case for our lattice physics calculations.

1.8 Gamma Transport Calculation

The gamma transport calculation is used to generate a detailed rod-by-rod gamma energy deposition that can be used to determine the gamma heating contribution to the total power distribution. The calculation can also provide a gamma detector response for reactors that contain a gamma TIP (Traversing Incore Probe) system or that use gamma thermometers as a stationary detector system. In BWRs, the detector tube is located in the corner of the lattice that is diagonally opposite to the corner in which the control blade resides.

The gamma transport calculation can be performed using the same computational module as that used to solve the neutron transport problem. Steady state gamma sources are calculated for each region of the lattice in the energy group structure of the accompanying gamma library. The gamma calculation is a fixed source calculation, where the sum of prompt and delayed gamma sources, due to neutron capture and fission, are given by the following expressions:

$$q_{\text{capture}}^y = \sum_g N_{\text{iso}} \sigma_{\text{capture},\text{iso}}^g V_i \phi_i''^g q_{\text{capture},\text{iso}}^g \chi_{\text{capture},\text{iso}}^{g \rightarrow y} \quad (40)$$

$$q_{\text{fission}}^y = q_{\text{fission},\text{iso}}^y \chi_{\text{fission},\text{iso}}^y \sum_g N_{\text{iso}} \sigma_{\text{fission},\text{iso}}^g V_i \phi_i''^g \quad (41)$$

Here, $q_{\text{capture},\text{iso}}^g$ is the gamma energy (in MeV/fission) released by neutron capture in isotope iso , neutron energy group g ; $q_{\text{fission},\text{iso}}^y$ is the total gamma energy (in MeV/fission) released through fission in isotope iso ; $\chi_{\text{capture},\text{iso}}^{g \rightarrow y}$ is the gamma spectrum that distributes the energy released from neutron capture in neutron energy group g , isotope iso , to gamma energy group y ; $\chi_{\text{fission},\text{iso}}^y$ is the gamma spectrum that distributes the energy released from fission in isotope iso ; $\sigma_{\text{capture},\text{iso}}^g$ and $\sigma_{\text{fission},\text{iso}}^g$ are the gamma microscopic cross sections; V_i is the volume of material region i ; and $\phi_i''^g$ is the neutron flux in material region i , neutron energy group g obtained from (35). The total fixed source in each region of the problem is the sum of (40) and (41).

The gamma transport calculation can use the same geometry and angular detail to solve the transport equation as is used to determine the neutron flux distribution. There is no condensation applied to the gamma cross sections and the flux is determined in the energy group structure of the gamma library. Typical gamma libraries contain no more than a couple of dozen energy groups.

For lattice physics codes based on the MoC, the equation to be solved is (25), where the total fixed source per mesh, i , is given by

$$q_i^y = q_{\text{capture},i}^y + q_{\text{fission},i}^y + \sum_{y'} \Sigma_{s,i}^{y' \rightarrow y} \phi_i^{y'} \quad (42)$$

In (42), $\Sigma_{s,i}^{y' \rightarrow y}$ is the macroscopic gamma scattering cross section. From (42), the isotropic angular source needed in (25) is calculated as $Q_{m,i}^y = q_i^y / 4\pi$, m being the angular direction.

Gamma energy deposition in each unique material region of the lattice is calculated by using the converged gamma fluxes and macroscopic energy deposition cross sections,

$$E_i = \sum_y \Sigma_{e,i}^y V_i \phi_i^y \quad (43)$$

where the energy deposition cross section, $\Sigma_{e,i}^y$, accounts for contributions from the photoelectric effect, pair production, and Compton scattering.

The detector response is defined as the energy deposited to the detector and normalized to the lattice power level. A good approximation for the energy deposition cross section for the detector is to use the value for Fe. The equation for calculating the gamma detector response is given by

$$R = \frac{\sum_y \sigma_{e,\text{Fe}}^y \Phi_{\text{DET}}^y}{P} \quad (44)$$

where ϕ_{DET}^γ is the gamma flux at the location of the detector tube and $\sigma_{e,\text{Fe}}^\gamma$ is the microscopic gamma energy deposition cross section for some representative material, for example, Fe. P is the lattice power level, in MeV.

1.9 Power Distribution Calculation

The power generated in a fuel rod is the sum of energy from gamma and beta decay, as well as kinetic energy from fission. The various contributions to the power can be calculated from the following relationships;

Kinetic energy:

$$E_{\text{kinetic}} = \sum_{\text{iso}} q_{\text{fission,iso}} \sum_i \sum_g N_{\text{iso},i} \sigma_{f,\text{iso},i}^g V_i \phi_i^g \quad (45)$$

Total gamma energy:

$$E_\gamma = \sum_i \sum_\gamma \Sigma_{e,i}^\gamma V_i \phi_i^\gamma \quad (46)$$

Beta energy due to capture (a very minor contributor):

$$E_{\beta,i} = \sum_{\text{iso}} q_{\beta,\text{iso}} \sum_i \sum_g N_{\text{iso},i} \sigma_{a,\text{iso},i}^g V_i \phi_i^g \quad (47)$$

Neutron slowing down:

$$E_{\text{SD},i} = \sum_{\text{iso}} \sum_i \sum_g \sum_{g' > g} N_{\text{iso},i} \sigma_{s,\text{iso},i}^{g' \rightarrow g} V_i \phi_i^g \cdot (\bar{E}^g - \bar{E}^{g'}) \quad (48)$$

where i is a material region; g is a neutron energy group; and γ is a gamma energy group. The microscopic neutron cross sections per isotope are for fission, σ_f^g , absorption, σ_a^g , and scattering, $\sigma_s^{g \rightarrow g'}$. \bar{E}^g is the average energy per neutron group. The summations for i are over all mesh in a specific fuel region.

1.10 Burnup Calculation

The last step of the lattice physics calculation is to determine the change in fuel isotopics over a specified period of time, referred to as a *burnup step*. The equation to be solved is the first-order differential equation of the type (Knott and Wehlage 2007)

$$\begin{aligned} \frac{dN_{\text{iso}}}{dt} = & \sum_{\text{iso}'} u_{\text{iso},\text{iso}'} \lambda_{\text{iso}'} N_{\text{iso}'} + \sum_{\text{iso}'} v_{\text{iso},\text{iso}'} \left(\sum_g \sigma_{c,\text{iso}'}^g \phi''^g N_{\text{iso}'} \right) \\ & + \sum_{\text{iso}'} w_{\text{iso},\text{iso}'} \left(\sum_g \sigma_{(n,2n),\text{iso}'}^g \phi''^g N_{\text{iso}'} \right) + \sum_{\text{iso}'} \gamma_{\text{iso},\text{iso}'} \left(\sum_g \sigma_{f,\text{iso}'}^g \phi''^g N_{\text{iso}'} \right) \\ & - \left\{ \lambda_{\text{iso}} + \left(\sum_g \sigma_{a,\text{iso}}^g \phi''^g \right) + \left(\sum_g \sigma_{(n,2n),\text{iso}}^g \phi''^g \right) \right\} \cdot N_{\text{iso}} \quad (49) \end{aligned}$$

where $\mathbf{u}_{iso,iso'}$, $\mathbf{v}_{iso,iso'}$, $\mathbf{w}_{iso,iso'}$ are branching ratios for decay, neutron capture, and (n, 2n) reactions, respectively; λ_{iso} is the decay constant; $\gamma_{iso,iso'}$ is the fission yield; and ϕ''^g is the flux distribution from (35). The symbols iso and iso' in (49) represent different isotopes. Equation (49) has a solution of the form

$$N_{iso}(\Delta t) - N_{iso}(0) = (Q - \tilde{\lambda}_{iso}N_{iso}(0)) \frac{(1 - e^{-\tilde{\lambda}_{iso}\Delta t})}{\tilde{\lambda}_{iso}} \quad (50)$$

where the effective decay constant, $\tilde{\lambda}_{iso}$, is equal to

$$\tilde{\lambda}_{iso} = \lambda_{iso} + \left(\sum_g \sigma_{a,iso}^g \phi''^g \right) + \left(\sum_g \sigma_{n2n,iso}^g \phi''^g \right) \quad (51)$$

and the production term, Q , is assumed constant over a small time interval, Δt .

The analytical solution to (49) can be obtained using a fourth order Runge–Kutta–Gill numerical algorithm for the predictor step, or by several other methods. **► Section 6** is devoted to a detailed description of the burnup solution in lattice physics codes.

1.11 Edits

Results from the lattice physics code to the corresponding three-dimensional nodal code are produced in two distinct categories: (1) cross sections that have been condensed and homogenized to represent the characteristics of the entire lattice, and (2) form factors that represent pin-by-pin distributions across the lattice.

The condensed and homogenized cross sections can be created by flux and volume weighting cross sections from every region of the lattice

$$\Sigma_x^h = \frac{\sum_i \sum_{g \in h} \Sigma_{x,i}^g V_i \phi_i''^g}{\sum_i \sum_{g \in h} V_i \phi_i''^g} \quad (52)$$

where x is a reaction type, such as absorption, fission, etc.; the flux, $\phi_i''^g$, includes leakage and is obtained from (35), and h represents the energy group structure of the nodal code, which has commonly been defined as two energy groups with the boundary between the fast and thermal groups at 0.625 eV, although there is some variation to this within the industry.

Form factors typically take the form of a two-dimensional normalized distribution. These factors can represent many physical properties from the lattice calculation, such as a pin-by-pin power distribution, multiple pin-by-pin isotopic distributions, and a pin-by-pin exposure distribution etc. The form factors are usually normalized to an average value of unity with a corresponding scaling factor that is passed to the nodal code. The nodal code can then superimpose the pin-by-pin shape from the lattice physics calculation onto the intra-nodal flux shape. For a more accurate super-positioning, form factors can be broken into individual pieces for each nodal energy group. For instance, the pin-by-pin power distribution can be broken into a fast group distribution and a thermal group distribution before being edited by the lattice physics code. Fast group distributions tend to be fairly flat across the assembly, while thermal group distributions tend to vary significantly from one pin location to another, especially in BWR assemblies.

Along with the form factors, the lattice physics code must also edit surface fluxes, surface currents, and assembly discontinuity factors. These data are used to transfer information about the heterogeneous assembly that would otherwise be lost from the homogeneous cross sections. The surface currents and surface fluxes are used in conjunction with the 2-D form factors in reconstructing the various pin distributions across the node.

Discontinuity factors are used by nodal codes to preserve surface currents from the lattice physics calculation. For a lattice calculation using reflective boundary conditions, the discontinuity factors are defined as

$$DF_S^h = \frac{\sum_{s \in S} \sum_{g \in h} A_s \psi_s^g}{\bar{\phi}^h} \quad (53)$$

where S is a specific surface of the assembly (north, south, etc.) and s are all the mesh that lie along that surface; A_s are the various surface areas that lie along the assembly surface, S ; ψ_s^g are the scalar fluxes lying along the assembly surface (i.e., the heterogeneous flux); $\bar{\phi}^h$ is the assembly homogeneous flux, and h is the nodal energy group structure. The homogeneous flux is the average flux across the assembly that would be produced by the homogenized cross sections,

$$\bar{\phi}^h = \frac{\sum_i \sum_{g \in h} V_i \phi_i^g}{\sum_i V_i} \quad (54)$$

where the heterogeneous fluxes are those obtained prior to the fundamental mode calculation.

Several parameters commonly edited by a lattice physics code are discussed in [Sect. 8](#).

1.12 Summary

This section has provided an overview of the calculational scheme used for a typical lattice physics code. The remainder of this chapter is devoted to describing, in depth, many of the features mentioned in this overview section. We will concentrate our discussions on methods that are considered to be somewhat current in lattice physics computations. The reader is directed to (Stamm'ler and Abbate 1983) for an in-depth discussion of legacy methods in lattice physics computations.

2 Cross Section Library

2.1 Objective

Various data for nuclear reactions are necessary for lattice physics computations, for example, fission, capture, absorption, scattering, $(n, 2n)$, and fission spectrum. The typical energy range considered in lattice physics computations ranges from 20 MeV down to 10^{-5} eV – from fast to thermal neutrons. The sources of these nuclear data are evaluated in nuclear data files such as ENDF, JEFF, and JENDL. These nuclear data files are collected for general-purpose utilization and thus contain highly detailed information on cross section data, for example, continuous energy (or “point-wise”) cross section data can be reconstructed from them. They contain cross

sections not only for neutrons but also for other particles, for example, electrons and photons. Covariance data that represent the uncertainty of cross section data are also included for some nuclides. A detailed description of a nuclear data file is, however, far beyond the scope of this section, but can be found in [▶ Chap. 4](#).

In principle, since a nuclear data file contains “everything,” it can be directly used in lattice physics computations. Such direct utilization of a nuclear data file, however, is not very efficient, for the following reasons:

First, since a nuclear data file is designed for general-purpose utilization, from the viewpoint of lattice physics computations, it contains much excess data. For example, the neutron fission cross section is sometimes classified according to the probability of fission. The inelastic scattering cross sections for different levels are tabulated independently. However, because such detailed classification is not necessary in common lattice physics computations appropriate data preprocessing becomes necessary.

Second, a nuclear data file adopts various formulae to describe the complicated behavior of cross sections, for example, the single and multilevel Bright Wigner and the Rich–Moore formulae used in the resonance peak. With some processing, these data can be used to reconstruct point-wise (or “continuous”) cross sections. The reconstructed point-wise cross sections are discrete (cross sections are given at discrete energy points), but have sufficient resolution to accurately reproduce the original continuous cross sections for nuclides. Since medium-to-heavy nuclides have many resolved resonances, a detailed description of these resonances is necessary. Consequently, for many nuclides, the typical number of energy points for point-wise cross sections ranges from several dozen to several hundred thousand. The reconstruction of a cross section requires considerable computation time, as discussed in [▶ Chap. 4](#). Furthermore, a great deal of memory is necessary when point-wise cross sections are directly used in lattice physics computations. As the above points make clear, preprocessing of cross sections is both necessary and useful.

What is much needed, then, is a dedicated database for the processed cross sections of various nuclides. In fact, a lattice physics code has its own dedicated cross section database, which is usually called a cross section library. We must note here that the source of cross sections (e.g., ENDF) is called a nuclear data file. The distinctions between a cross section library and cross section file can be confusing, and will be clarified in this section.

Since lattice physics computations are usually carried out in multiple groups (typically, several dozen to a few hundred groups), the number of energy groups in a cross section library is chosen to suit the calculation. A detailed discussion on the number of energy groups and the energy group structure is given in [▶ Sect. 2.2](#).

The major objective of a lattice physics computation is to provide a set of cross sections for successive core analysis. Therefore, a portion of the cross section data in a nuclear data file is not necessary in lattice computations. In [▶ Sect. 2.3](#), some typical cross sections used in lattice physics computation will be discussed.

Various processing steps are necessary for the preparation of a cross section library, and nuclear data processing codes are used for this purpose. A general-purpose cross section processing code (e.g., NJOY) and a dedicated post-processing code for library tabulation are commonly used to prepare a cross section library. Though a detailed discussion of nuclear data processing codes is presented in [▶ Chap. 4](#), a brief discussion that is relevant to cross section library preparation is offered in [▶ Sect. 2.4](#).

Since numerous data are necessary for cross section data, the methods of tabulation for cross section data are essential for their efficient storage and usage. [▶ Section 2.5](#) addresses some

key considerations on the tabulation of cross section data, and the structure and contents of a cross section library.

2.2 Choice of Energy Group Structure

The number of energy groups in a cross section library has a significant impact on lattice physics computations from two important points of view, namely, accuracy and computation time. And expectedly, there exists a trade-off between these two parameters. When the number of energy groups is small, the computation time will be short but the accuracy of the calculations might be insufficient. On the other hand, a large number of energy groups can be favorable in terms of accuracy, yet can be impractical due to the long computation time required. If we are to mitigate these contradictions, then the choice of energy group structure becomes crucial. There are two areas in which we can influence this: the number of energy groups, and their structure. We should note that some resonance calculation methods (the subgroup method, and ultrafine energy group calculation) may require a dedicated energy group structure. This topic will be discussed in [Sect. 3](#).

For typical light water reactors, anywhere from several dozen to a few hundred energy groups are adopted in a cross section library used in lattice physics computations. As a general trend, the number of energy groups used in the most recent lattice physics codes is increasing. This is due to improvements in storage capacity, and the higher processing speed of the affordable computers used for production calculations.

As discussed above, a larger number of energy groups allows for a more detailed representation of the energetic behavior of the neutron spectrum, which in turn can be applied with improved accuracy to a wider range of fuel assembly designs. Though the number of energy groups is quite important, the structure of the energy groups is crucial as well. These two factors are strongly interdependent, that is, the number of energy groups depends on the energy group structure, and vice versa.

The choice of an energy group structure is quite difficult. In general, this choice requires that four important physical phenomena in the reactor must be taken into account. The first of these is the generation of fission neutrons in the fast energy range. The second is the slowing down and diffusion of neutrons in the fast to resonance energy range. The third is the resonance absorption, and the final factor is the thermalization of neutrons in the thermal energy range. In order to appropriately incorporate these four phenomena, the energy range of a cross section library is typically divided into three parts: fast, resonance, and thermal regions. The fast range (typically 20 MeV to 10 keV) is usually divided into groups of equal lethargy width to capture the fission, slowing down, and diffusion phenomena. We must note that a sufficiently high upper energy boundary (20 MeV) is important in order to accurately capture an $(n, 2n)$ reaction.

In the resonance energy range (typically 10 keV to 1 eV), the widths of the energy groups should be small when a cross section shows rapid variations in energy, that is, in the resonance region. However, when all the resonances of all nuclides are explicitly taken into account, the energy group structure will be very fine, that is, comparable to point-wise energy groups (a few hundred thousand). From this point of view, the choice of energy group structure also depends on resonance calculation methods, which will be discussed in [Sect. 3](#).

For accurate resonance calculations, the significant resonance peaks should generally be located in the center of the energy group. Since the “significant” resonance depends on the

dominant nuclides appearing in lattice physics computations, it inherently depends on the given type of target reactor. In the case of light water reactor analyses, the first priority is given to major resonances of ^{238}U , and then those of ^{235}U and plutonium isotopes. However, care should also be taken for intermediate weight nuclides such as Fe and Ni, which are important as structural materials. These nuclides also have many resonances in the medium-to-high energy range, and accurate consideration of these resonances is very important, especially for PWR, in which baffle plates or heavy reflectors are made of stainless steel.

The thermal energy range (typically 1 to 10^{-5} eV) is divided into groups of equal lethargy or equal energy width to capture the Maxwell energy distribution of thermal neutrons. Special care must be taken at the boundary of resonance and thermal energy regions, which is usually called the thermal cut-off energy. In the typical thermal energy range, neutron up-scatter, which is caused by the thermal vibration of the nucleolus, is considered through up-scattering cross sections. Therefore, the thermal cut-off energy is set in order to cover the up-scattering effect. In light water reactor analysis, a few electronvolts (eV) is usually sufficient. In the case of graphite-moderated reactors, however, a higher thermal cut-off energy (~ 4 eV) is necessary, due to the greater up-scattering by graphite.

Up-scattering may also pose a challenge in the treatment of resonances at low energy around the thermal cut-off energy. Two issues may need to be addressed for resonance treatment at low energy. The first is the preparation of effective cross sections. In the usual resonance calculations, the neutron slowing down equation is solved from a higher to a lower energy without consideration of up-scattering. By using the neutron spectrum obtained by the neutron slowing down equation, effective cross sections can be evaluated; the effect of up-scattering on the neutron spectrum (and thus on effective cross sections) is therefore not taken into account. Next, many cross section libraries do not have a self-shielding table to evaluate effective cross sections in the thermal energy range, since resonances appear in the epithermal – resonance (i.e., higher than thermal) energy range. Therefore, when large resonances in the thermal energy range have a considerable impact on calculation results, their treatment should be carefully considered. A typical example of such resonances is the giant resonance of ^{240}Pu around 1 eV shown in  [Fig. 7](#).

In many cross section libraries for light water reactor analyses, the above resonance is treated by a fine energy group structure around 1 eV, as will be described later. In the following section, the principal energy group structures used in light water reactor analyses are briefly introduced.

2.2.1 WIMS 69 Groups

The 69 group energy structure of WIMS, which is designed for light water reactor analysis, is shown in  [Table 1](#) (Askew et al. 1966; WIMS-D/4 2000). The WIMS energy group structure and those derived from it (e.g., 70 energy groups used in CASMO) have been widely used not only in academic investigations, but also for production calculations for light water reactors.

The WIMS library is divided into three parts: fast, resonance, and thermal energy ranges. The fast energy range (10 MeV to 9.118 keV) has 14 groups with an equal lethargy width of 0.5. This structure is selected to capture neutron slowing down and diffusion in the fast energy range, and the fast fission of ^{238}U . The resonance energy range (9.118 keV to 4 eV) is divided into 13 groups. The lethargy width in the resonance energy range is basically 0.5, but several energy boundaries are adjusted in order to put important resonances close to the center of groups. For

Figure 7
Large resonance of ^{240}Pu around the thermal cut-off energy

example, large resonances of ^{238}U located at 6.7, 20, and 33 eV are included in the 27th group (9.877 – 4.0 eV), 25th group (27.7 – 15.698 eV), and 24th group (48.052 – 27.7 eV), respectively.

A considerable number of energy groups are devoted to the description of the large resonance of ^{240}Pu at 1.0 eV. Since this large resonance is located near the thermal cut-off energy and is affected by thermal up-scattering, it is handled by fine energy discretization, rather than the utilization of a self-shielding table. The approximately 0.02 eV energy mesh is assigned near 1.0 eV. In the preparation of a self-shielding table, slowing down calculations are carried out in a very fine energy group structure, as described in [Sect. 3](#). This slowing down calculation is carried out without consideration of thermal up-scattering, so the utilization of a self-shielding table for resonances below the thermal cut-off energy should be carefully performed.

The thermal energy range is divided into 42 groups, which allows for a detailed description of the Maxwell spectrum of thermal neutrons. We must note that a fine energy mesh is also assigned around 0.3 eV, in which there is a broad resonance of ^{239}Pu .

2.2.2 XMAS 172 Groups

The XMAS 172 group structure is also designed for light water reactor analysis (Sartori 1990; Santamarina et al. 2004). Therefore, the XMAS 172 group structure has features similar to those in WIMS 69 groups, for example, fine energy discretization around 1 eV, an energy boundary suitable for large resonances of ^{238}U at low energy. In fact, the XMAS group structure is derived from the WIMS 69 and APOLLO1 99 group structures.

This energy group structure was developed in France and is widely used in light water reactor analyses, particularly in European countries. Since the XMAS group structure has more detailed energy discretization than the WIMS structure, the XMAS group structure can be applied to more generic applications. For example, the XMAS group structure is more suitable for MOX or high burnup fuel analyses, since spectrum variations and resonance absorption by higher plutonium (^{242}Pu) and minor actinides can be taken into account more precisely. In order to accurately consider an (n, 2n) reaction that plays an important part in the burnup

calculation of heavy nuclides, the upper boundary of the energy groups is increased to 20 MeV. The energy group structure of XMAS is shown in [▶ Table 2](#).

2.2.3 SHEM 281 Groups

The SHEM 281 group structure was designed to overcome certain potential deficiencies in the XMAS group structure (Hfaïdedh and Santamarina 2005; Hebert and Santamarina 2008). The SHEM group structure is especially designed to avoid the resonance overlap effect among different nuclides. The resonances of major nuclides (heavy nuclides, fission products, structural

Δu : lethargy width.

material nuclides, and burnable nuclides) are treated in different energy groups as much as possible up to 23 eV. The descriptions of slowing down and resonance scattering in coolant and structural material (^{16}O , ^{23}Na , ^{27}Al , ^{56}Fe , ^{58}Ni , and ^{55}Mn) are improved. Threshold reactions such as the inelastic scattering of ^{238}U and fission (1 – 0.1 MeV) are considered in the design of a library structure. Though the number of the energy group is increased (from 172 to 281), it offers higher calculation accuracy than conventional energy group structures. Since the maximum lethargy width in the SHEM structure is less than 0.2 in the slowing down energy region, it is applicable not only to LWR, but also to fast reactors.

The energy group structure of SHEM is shown in [▶ Table 3](#).

2.2.4 Other Energy Group Structures

Looking at recent improvements in cross section libraries, we find an increased number of energy groups in the resonance region. For example, in the latest version of CASMO, resonances in the low-energy ranges (<10 eV) are divided into fine energy groups in which a self-shielding table is not necessary. As a result, the number of energy groups in the cross section library

■ Table 3

Δu : lethargy width.

reaches approximately 600 (Rhodes et al. 2006). Such fine groups are being used in production calculation due to the ongoing improvements in the capacity of affordable computers.

Another energy group structure sometimes used in lattice physics computation is that of so-called ultrafine energy groups (MC** 2-2 1999; Ishiguro 1974; Tsuchihashi et al. 1982; Williams et al. 2005; Huria and Ouislomen 2008; Sugimura and Yamamoto 2007). A very fine energy group structure is used in an ultrafine group's spectrum calculation in which resolved resonances are explicitly treated without self-shielding factors. Unfortunately, since the number of energy groups reaches from several thousand to several dozens of thousands, the preparation of an explicit scattering matrix becomes difficult on account of the storage it requires. To overcome this obstacle, a one-dimensional cross section (e.g., absorption, fission, capture, and elastic scattering) is stored in a cross section library. Neutron slowing down is evaluated from slowing down calculations that assume elastic scattering. A more detailed discussion of this will be provided in [▶ Sect. 3](#).

2.3 Cross Sections Used in Lattice Physics Computations

Various cross sections are used in lattice physics computations. The following cross sections are usually necessary.

Total cross section: A total cross section is necessary for transport calculations in order to obtain neutron spatial distribution. In the principal lattice physics codes, transport-corrected (P0) cross sections are used instead of explicit treatment of anisotropic scattering.

Capture cross section: A capture cross section is necessary for burnup calculations.

Fission cross section: A fission cross section is necessary for burnup calculations as well as pin-power distribution calculations.

Production cross section: A production cross section, which is the product of a fission cross section and the average number of neutrons released per fission, is used in transport calculations to evaluate the reactivity of the fuel assembly.

Absorption cross section: For many nuclides, an absorption cross section can be obtained by the summation of the capture and fission cross sections. However, especially for light nuclides, other reactions may play significant role in neutron absorption. For example, most of the absorption reaction for ^{10}B is (n, α) . Therefore, the absorption cross section should be treated independently from the capture and fission reactions. In lattice physics computations, the absorption cross section is used to evaluate the reactivity of the fuel assembly. Neutron emission reactions other than fission may be considered as absorption cross sections, as described below.

$(n, 2n)$ cross section: This reaction is important both in burnup calculation and in its contribution to reactivity. Since an $(n, 2n)$ reaction increases the number of neutrons, its contribution to reactivity is positive. Note that an $(n, 3n)$ reaction has a similar effect, but has a smaller impact than an $(n, 2n)$ reaction since the cross section of $(n, 3n)$ has a higher threshold energy and is smaller than that of $(n, 2n)$. It is for this reason that in many lattice physics codes, only an $(n, 2n)$ reaction is considered. In order to rigorously incorporate an $(n, 2n)$ reaction, a dedicated treatment that is similar to fission is necessary. Many transport codes, however, do not incorporate the capability of such treatment. Therefore, an $(n, 2n)$ cross section is usually subtracted from the absorption cross section since the “net neutron emission” in an $(n, 2n)$ reaction is one (one absorption, two emissions). This apparently has a positive effect on reactivity. In this simplified treatment, the neutron emission spectrum is disregarded, and emitted neutrons are assumed to have the same energy as the absorbed neutron. When an $(n, 3n)$ reaction is taken into account,

twice the $(n, 3n)$ cross section is subtracted from the absorption cross section. As described in [2.2](#), since $(n, 2n)$ is a threshold reaction, the upper limit of an energy group in a cross section library is important –20 MeV is necessary in order to accurately incorporate an $(n, 2n)$ reaction. *Scattering cross section:* A scattering cross section is treated in matrix form. Though other reactions (e.g., fission) do not have anisotropy on the angular distribution of emitted neutrons, the elastic scattering reaction has considerable anisotropy. This anisotropy on the scattering reaction is expanded by the Legendre functions of the scattering angle. Not just the isotropic (P0) component of a scattering matrix, but also higher-order anisotropic components (P1, P2, and so on) can be considered. Light nuclides (e.g., hydrogen) have greater anisotropy since the neutrons are scattered in a more forward direction by these nuclides. Since the anisotropic scattering of hydrogen, which is a major nuclide in LWRs, has a large impact on neutron leakage from the core, this effect must be taken into account.

Anisotropic scattering may be explicitly taken into account when the transport calculation module in a lattice physics code has such capability. In fact, the method of characteristics, which is commonly used in the most recent lattice physics codes, can account for anisotropic scattering, though larger memory and longer computation time are required. However, the anisotropic component of a scattering matrix is also approximately taken into account by the transport-corrected total cross section (transport cross section), with a P0 scattering cross section. When we use the transport-corrected cross section, the self-scattering cross section is also modified to maintain balance in the cross section. Described in more detail, the difference between the total and transport-corrected cross sections is subtracted from the self-scattering cross section.

The effect of anisotropic scattering becomes more important when the angular distribution of the neutron flux is far from isotropic. Since neutron absorption in MOX fuel is much greater than that in UO₂ fuel, the angular distribution of the neutron flux is more anisotropic. The effect of anisotropic scattering therefore becomes more important in MOX fuel analysis.

Another consideration in this regard is the order of anisotropic scattering that should be taken into account. Higher-order anisotropic scattering gives more accurate results, but requires more memory because of the higher-order scattering matrix. In a typical light water reactor analysis, the incorporation of P1 scattering gives fair results. When up to P3 components are taken into account, it gives an almost converged result on the treatment of anisotropic scattering. Note that when transport-corrected scattering is used, up to P1 component is commonly taken into account.

Fission spectrum: Fission spectra are slightly different in each fissionable nuclide, as each fissionable nuclide has an independent fission spectrum. Furthermore, strictly speaking, a given fission spectrum also depends upon the incident neutron energy. In common lattice physics computations, however, such rigorous treatment is not necessary, and an approximate treatment can be applied, as will be described later.

Gamma cross sections: In fission and the successive decays of fission products, many photons (gamma rays) are emitted. The gamma ray plays an important role in the distribution of power in a reactor core since considerable energy (heat) is deposited due to the scattering and absorption of gamma rays. Since the mean free path of a gamma ray is larger than that of typical neutrons, gamma ray “removes” heat from pellet as the form of its energy and releases it at other places. In this sense, a gamma ray “smears” heat generation in a core, which is why this effect is known as gamma smearing. The gamma-smearing effect is important for the accurate evaluation of heat distribution in a fuel assembly.

Table 4
Example of energy release per fission of ^{235}U

Form of released energy	MeV	Note
Kinetic energy of fission fragment	168	Heat deposit mainly in pellet
Prompt gamma ray	7	Gammer smearing
Kinetic energy of prompt neutrons	5	Possible heat deposit in moderator
Beta ray originated by decay of fission fragment	8	
Gamma ray originated by decay of fission fragment	7	Gammer smearing
Anti-neutrino	(12)	Cannot be recovered (escapes from reactor)
Gamma ray emitted by capture of fission neutron	3 ~ 12	Gammer smearing
Total	~ 202	

Source: Stacy (2001).

In many cases, the gamma-smearing effect flattens the power distribution in a core, but it may also increase pin-power for pellets with low power density. For example, the power density of a gadolinia-bearing fuel pellet is very low at the beginning of life (BOL) due to the extremely large absorption cross section of gadolinium isotopes. The gamma-smearing effect pushes up the pin-power of a gadolinia-bearing fuel rod at BOL.

Note that gamma smearing is also significant in a reflector that uses medium-heavy nuclides, such as stainless-steel reflectors in advanced type PWRs, and shielding fuel elements in fast breeder reactors. Gamma transport calculation is sometimes carried out to accurately estimate heat deposition by gamma rays. In this case, cross sections for the gamma rays are also necessary. The gamma production cross section is also necessary in order to estimate the gamma source.

Energy release per fission: The value of energy release per fission is not a “cross section,” but is a very important parameter in lattice physics computation, since it defines the normalization condition of the absolute value of neutron flux. Elementary textbooks on reactor physics tell us that the energy release per fission is approximately 200 MeV for ^{235}U . This is not incorrect, but we must be careful how we regard the breakdown of its contents. ▶ *Table 4* shows the breakdown of energy release by fission of ^{235}U . Since the energy balance due to fission and successive phenomena is complicated, one needs to be careful when setting values for energy release per fission.

2.4 Cross Section Processing

The source of nuclear data is an evaluated nuclear data file. In order to generate a cross section library for use in lattice physics computations, the processing of nuclear data files is necessary (Marcille and Mills 2003; Yamamoto et al. 2006; Yamamoto and Sugimura 2006). In general, nuclear data processing is divided into two parts. The first part is the generation of

general-purpose multigroup cross section data by a nuclear data processing code. The second part is the editing of cross section data into a suitable format of a lattice physics code. Some detailed description of these processes is presented below.

2.4.1 Generation of Multigroup Cross Section Data

As described before, nuclear data files such as ENDF/B, JEFF, and JENDL are not suitable for direct utilization in lattice physics codes (McLane 2001). Therefore, cross section processing codes are used to generate multigroup cross section data. Many lattice physics codes utilize the NJOY code, which is widely used not only in academia, but also in industry (MacFarlane and Muir 1994b). Though a detailed description of the NJOY code and the theoretical background of cross section processing are given in [Chaps. 1 and 4](#), a brief description of cross section processing is given in this section, with a focus on the preparation of a lattice physics code for a cross section library.

The common nuclear data processing scheme by NJOY is described as follows. The modules of NJOY used in processing are given along with brief descriptions of the outline of processing.

MODER

Since a nuclear data file is given in text format, it is converted to binary format in order to perform rapid input/output during cross section processing.

RECONR

Though the original cross section data is “continuous,” it is energetically discretized for processing. The point-wise cross section data, which accurately reproduces the original continuous cross section data with cross sections at discrete energy grid points, are reconstructed from an original nuclear data file. The accuracy of a reconstructed cross section is determined by the number of energy grid points, and the structure of their point-wise cross sections. In order to reduce the number of energy grid points while retaining accuracy, a dedicated algorithm is used to thin out the energy grid points. In general, grid points are chosen so that the accuracy of the interpolated cross section data satisfies the required tolerance given by the user. The number of grid points of a point-wise cross section may reach a few hundred thousand for heavy nuclides with many resonances. The reconstructed data is written to an intermediate (working) file in the PENDF (point-wise ENDF) format.

BROARDR

The point-wise cross section data are generated at a base temperature (typically room temperature) in RECONR. Cross sections, however, are temperature dependent. Thus, cross section data in the resonance region are broadened by considering the Doppler effect in BROARDR. Specific temperatures are given by users for consideration of the Doppler effect.

THERMR

A cross section in the thermal energy range (~ 4 eV) is created by considering the thermal vibration of the nucleolus. When the chemical binding of a molecule is taken into account (e.g., H in H₂O, D in D₂O, and graphite), $S(\alpha, \beta)$ data, which describe the secondary energy distribution

of a scattered neutron, are also necessary as an input file. The $S(\alpha, \beta)$ data are given as a part of the evaluated nuclear data file.

UNRESR

Multigroup cross section data in the unresolved resonance energy region is given as a function of the background cross sections given in the input data. A narrow resonance approximation is used to evaluate an effective multigroup cross section. The NJOY code provides another approach for the resonance treatment of an unresolved resonance region by PURR. The PURR module can provide a probability table in addition to a self-shielding table for multigroup cross sections. The probability table can be used through the subgroup method, which will be described in [Sect. 3](#).

GROUPR

Since the reconstructed data is “point-wise,” an adequate neutron spectrum is necessary in order to evaluate effective (average) multigroup cross sections. The GROUPR module provides the capability of evaluating the neutron spectrum with the reconstructed point-wise cross sections. Therefore, the present module is highly important in the generation of a multigroup cross section library for lattice physics codes. The GROUPR module provides two different ways to estimate the point-wise neutron spectrum. The first is a very quick, simple approach based on the narrow resonance approximation. In this approach, the neutron flux is simply expressed as

$$\phi(E) = \frac{C(E)}{\sigma_t(E) + \sigma_0} \quad (55)$$

where

- $\phi(E)$: neutron flux,
- $C(E)$: base spectrum function,
- $\sigma_t(E)$: microscopic total cross section of a nuclide,
- σ_0 : background cross section.

Note that the theoretical background for resonance calculation will be described in [Sect. 3](#). Since no slowing down calculation is carried out, the generation of a multigroup cross section takes place quite quickly. However, since (55) is based on a narrow resonance approximation, its accuracy is not sufficient for broad resonances that appear in the epithermal energy region, for example, resonance of ^{238}U at 6.7 eV. That said, the above approach is usually satisfactory for the high-energy region in which each resonance is narrow enough, compared to the energy width of neutron slowing down. Note that various options are provided as $C(E)$ in the GROUPR module, that is, $1/E$, fission spectrum $+1/E$, fission spectrum $+1/E + \text{Maxwell}$. A suitable base spectrum function would be preferable for the generation of a cross section library. The base spectrum function can also be given as input data. Therefore, a typical spectrum (e.g., cell average spectrum in the operating condition of light water reactors) can be used. Some sensitivity analyses of the base spectrum function are desirable before the preparation of a cross section library.

The second option is a direct numerical solution of the neutron slowing down equation. In the GROUPR module, the second option can be used for the resolved resonance energy range, and the following equation is usually solved:

$$(\sigma_t(E) + \sigma_0) \phi(E) = \int_E^{E/\alpha} \frac{\sigma_s(E') \phi(E')}{(1 - \alpha)E'} dE' + \int_E^{E/\alpha_0} \frac{\sigma_0 \phi(E')}{(1 - \alpha_0)E'} dE' \quad (56)$$

where

$$\alpha := \left(\frac{A-1}{A+1} \right)^2, \quad A \text{ is the relative mass of a nuclide to a neutron,}$$

$$\alpha_0 := \left(\frac{A_0-1}{A_0+1} \right)^2, \quad A_0 \text{ is the relative mass of a background nuclide to a neutron,}$$

$$\sigma_s(E): \text{ elastic scattering cross section.}$$

As commonly calculated, hydrogen is assumed as a background nuclide; thus α_0 is set at a very small value (e.g., 10^{-7}). When the mass effect of a moderator is taken into account as the lambda parameter, different A_0 values are used to solve (56). A detailed discussion of this issue will be presented in  Sect. 3.

Though the direct numerical solution of (56) is quite accurate, it may also be time consuming. The computation time depends on the number of points of reconstructed cross sections. In the case of heavy nuclides (e.g., ^{238}U and ^{239}Pu), the number of the reconstructed cross section point may reach a few hundred thousand. Since slowing down calculations are repeatedly carried out for different background cross sections (typically 10–20 different background cross sections for major resonance isotopes), and for different temperatures (typically several temperature points), the computation time needed to process a heavy nuclide may be more than several hours on a modern PC or Workstation.

The obtained effective multigroup cross sections are written into a file in a GENDF (group-wise ENDF) format. The GROUPT module has various options for the energy group structure. The major energy group structures are hardwired in the GROUPT module, for example, WIMS 69 groups and XMAS 172 groups. Of course, an arbitrary energy group structure can be also given for the GROUPT module.

MATXS

The multigroup cross section (GENDF) generated by GROUPT is converted to the MATXS format that can be used in some application codes. Since the MATXS format is versatile, it is useful for many lattice physics codes.

Other Modules

When gamma transport calculations are carried out in a lattice physics code, multigroup cross sections for gamma rays are necessary (Wemple et al. 2008; Mertyurek 2007). In this case, a KERMA (kinetic energy released in material) factor evaluation by the HEATR module, and gamma cross section evaluations by the GAMINR module, are necessary.

The NJOY code can provide a cross section library for the MCNP code, which is a continuous energy Monte Carlo code frequently used for the validation and verification of lattice physics codes. The ACER module is used for the preparation of an MCNP library. When a cross section library for MCNP is generated by the NJOY code and is used for verification, “consistent comparison” between a Monte Carlo code and a lattice physics code can be carried out. Such comparisons (verification and validation) yield rich information regarding the soundness of lattice physics codes.

A cross section library for the widely used lattice physics code WIMS, can be generated through the WIMSR module. Even if direct utilization of the WIMS code is not considered, the output of the WIMSR module provides an invaluable benchmark for a cross section library of

lattice physics codes. As discussed later, the post-processing of NJOY outputs is usually carried out to generate a cross section library of a lattice physics code. Certain aspects of this post-processing are highly complicated, for example, the processing of a fission matrix. Therefore, in order to check the correctness of edited multigroup cross section data, a comparison with the WIMSR output sometimes proves quite useful.

Some Notes on NJOY

The NJOY code is well maintained and is continuously updated with improvements and bug-fixes. These improvements and fixes can be downloaded from the Web site as a collection of patches, and can be applied to the NJOY code by a dedicated update system. The latest version has fewer flaws, and is thus recommended for use. Furthermore, there are various options as input data that are sometimes difficult to use. It is therefore highly recommended that calculation results be verified. A comparison with independent calculations (e.g., continuous energy Monte Carlo calculations) can provide a good means for such verification.

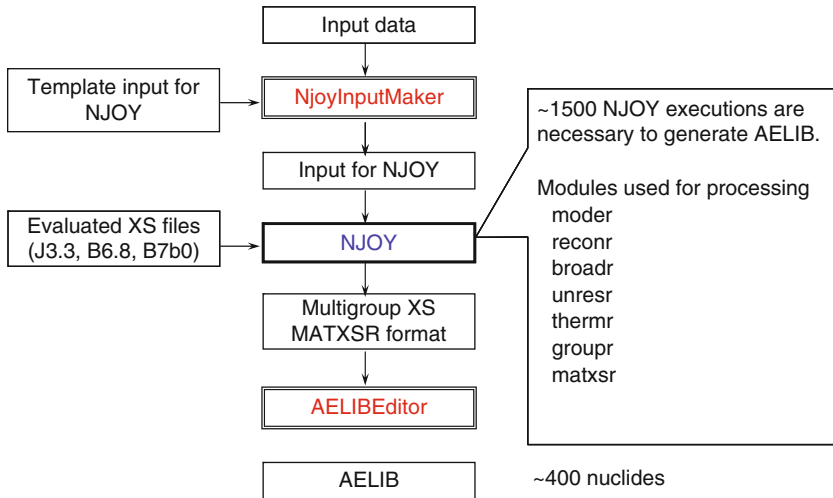

2.4.2 Execution Control of NJOY

In common lattice physics codes, more than a few hundred nuclides may be processed in order to generate a cross section library. When this processing is carried out manually, quality control for the generation of a cross section library becomes difficult. Therefore, a dedicated cross section generation system that automatically generates NJOY inputs and can manage subsequent post-processing steps with minimal user input is often developed and used.

In this section, the cross section library generation system of AELIB, which is a cross section library for the lattice physics code AEGIS, is described as an example (Yamamoto et al. 2006; Yamamoto and Sugimura 2006). A calculation flowchart of the system is shown in  Fig. 8. The NjoyInputMaker code generates input data for NJOY by using short user input that contains the following information:

- Nuclide identification name in AELIB
- Upper energy boundary of resolved energy range
- Potential scattering cross section
- Order of anisotropic scattering
- Temperature points
- Background cross section points

NjoyInputMaker automatically generates not only the input data but also the execution shell. The NJOY code is executed using the automatically generated shell. The calculation result of NJOY is dumped onto a file in the MATXS format. The AELIBEditor code performs post-processing of the NJOY results shown in the next section, and generates AELIB, which is a binary file of a particular format. The details of post-processing will be described in the next section. Note that the AELIBEditor code can generate AELIB not only from the NJOY result, but also from user input data. For example, some fission product nuclides that have a short half-life are defined as “dummy” nuclides with a zero cross section, that is, only decay is considered for these nuclides. In such a case, a zero cross section is given from an input file. Since an ideal nuclide that has a particular multigroup cross section can be defined, a multigroup benchmark calculation, in which a given cross section is used, can easily be performed. Note that using a

■ **Figure 8**
Example of automatic calculation flowchart of NJOY

common PC, it takes approximately two CPU days to generate an entire set of AELIB in which more than 400 nuclides are stored.

2.4.3 Post-Processing for Cross Section Library

The NJOY code can output a multigroup cross section in various formats (e.g., MATXS, WIMS, CCCC, and DTF). These output formats, however, may not be suitable for direct utilization as a cross section library of lattice physics codes. For example, while the MATXS format can be used for very general purposes, it may contain cross sections that are too detailed for lattice physics codes, such as a fission matrix. The WIMS format may require additional data for higher-order anisotropic scattering ($>P1$).

For the reasons given above, many lattice physics codes use their own (dedicated) formats in their cross section library – formats that are suitable for lattice physics computations. In order to generate such a cross section library, post-processing of the NJOY output becomes necessary. A description of post-processing of the MATXS format into a lattice physics code is given below as an example.

Absorption Cross Section

In the MATXS format, various reactions may be tabulated as neutron absorption reactions. However, in lattice physics computations, an absorption cross section is necessary for the neutron transport calculation. Therefore, various neutron absorption reactions are summed in order to obtain an absorption cross section:

$$\begin{aligned} \sigma_a = & \sigma(n, \gamma) + \sigma(n, f) + \sigma(n, p) + \sigma(n, d) + \sigma(n, t) + \sigma(n, \alpha) + \sigma(n, 2\alpha) + \dots \\ & - \sigma(n, 2n) - 2\sigma(n, 3n) - 3\sigma(n, 4n) \end{aligned} \quad (57)$$

The $(n, 2n)$ cross section is subtracted since its “net emission” of neutrons is 1, that is, “net absorption” is -1 . Similarly, the “net absorptions” for $(n, 3n)$ and $(n, 4n)$ reactions are -2 and -3 , respectively. By using (57), various neutron absorption reactions can be taken into account.

Nu-Value and Fission Spectrum

Energy distribution and the number of released neutrons in fission depend on the incident neutron energy. Therefore, in a nuclear data file, the fission cross sections of major fissionable nuclides are given not only as ordinary (total) fission cross sections, but also in the form of a fission matrix. In the MATXS format, a similar expression is used for the fission cross section. Unfortunately, the transport modules of many lattice physics codes cannot directly handle the fission matrix.

For a fission matrix, the fission neutron is evaluated by

$$f_g = \sum_{g'} \sigma_{f,g' \rightarrow g} \phi_{g'} + \chi_{d,g} \sum_{g'} \nu_{d,g'} \sigma_{f,g'} \phi_{g'} \quad (58)$$

where

f_g : fission neutrons appeared in group g ,

$\sigma_{f,g' \rightarrow g}$: fission matrix for prompt neutrons, whose incident and emission energy groups are g' and g , respectively,

$\phi_{g'}$: neutron flux of group g' ,

$\chi_{d,g}$: fission spectrum for delayed neutrons,

$\nu_{d,g}$: number of delayed neutrons per fission,

$\sigma_{f,g}$: (total) fission cross section (MT = 18 in the ENDF format).

However, many lattice physics codes evaluate fission neutrons as follows, since the dependence of fission spectra upon incident neutron energy is fairly minor:

$$f_g = \chi_g \sum_{g'} \nu_{g'} \sigma_{f,g'} \phi_{g'} \quad (59)$$

In order to fit the fission-related data in the MATXS format into ordinary representation, the following post-processing is carried out for a cross section library of lattice physics codes.

$$\chi_g = \frac{\sum_{g'} \sigma_{f,g' \rightarrow g} \phi_{g'} + \chi_{d,g} \sum_{g'} \nu_{d,g'} \sigma_{f,g'} \phi_{g'}}{\sum_g \sum_{g'} \sigma_{f,g' \rightarrow g} \phi_{g'} + \sum_{g'} \nu_{d,g'} \sigma_{f,g'} \phi_{g'}} \quad (60)$$

$$\nu_g = \frac{\sum_{g'} \sigma_{f,g' \rightarrow g}}{\sigma_{f,g}} + \nu_{d,g} \quad (61)$$

where

χ_g : fission spectrum for neutrons (including both prompt and delayed),

ν_g : number of neutrons per fission (including both prompt and delayed).

Equation (60) indicates that a neutron spectrum is necessary to evaluate the fission spectrum, that is, the fission spectrum depends on the neutron spectrum. However, the neutron spectrum is, of course, unknown during the preparation of the cross section library. Fortunately,

the fission spectrum is not strongly dependent on the neutron spectrum, so we can use a typical neutron spectrum for (60), for example, a cell average neutron spectrum in the operating condition of a typical LWR.

Scattering Matrix

In the MATXS format, various scattering cross sections are independently given as the matrix form. Therefore, these scattering matrixes should be summed up for utilization in lattice physics codes:

$$\begin{aligned} \sigma_{s,g' \rightarrow g} = & \sigma_{el,g' \rightarrow g} + \sigma_{n,2n,g' \rightarrow g} + \sigma_{n,3n,g' \rightarrow g} + \sigma_{n,4n,g' \rightarrow g} + \sigma_{n,n\alpha,g' \rightarrow g} + \sigma_{n,np,g' \rightarrow g} \\ & + \sigma_{n,nd,g' \rightarrow g} + \sigma_{n,nt,g' \rightarrow g} + \sum_i \sigma_{inel,i,g' \rightarrow g} + \sigma_{inel,c,g' \rightarrow g}, \end{aligned} \quad (62)$$

where

- $\sigma_{s,g' \rightarrow g}$: scattering cross section used for lattice physics computation,
- $\sigma_{el,g' \rightarrow g}$: elastic scattering cross section,
- $\sigma_{n,2n,g' \rightarrow g}$, $\sigma_{n,3n,g' \rightarrow g}$, $\sigma_{n,4n,g' \rightarrow g}$: (n, 2n) cross section, and so on,
- $\sigma_{n,n\alpha,g' \rightarrow g}$, $\sigma_{n,np,g' \rightarrow g}$, $\sigma_{n,nd,g' \rightarrow g}$, $\sigma_{n,nt,g' \rightarrow g}$: (n, n + α) cross section, and so on,
- $\sigma_{inel,i,g' \rightarrow g}$: inelastic cross section of *i*th level,
- $\sigma_{inel,c,g' \rightarrow g}$: inelastic cross section of continuous level.

Note that the above treatment is an approximation for (n, 2n) cross sections, and so on, since the “scattering” reaction changes only the energy of an incident neutron and does not affect the number of neutrons. Variations in the number of neutrons through (n, 2n), along with other reactions, are taken into account approximately through modification of the absorption cross section, in which the energy of the incident neutron does not change, as described in “Absorption cross section”. However, the impact of the present approximation is considered negligible, since the total reactivity effect of (n, 2n) and similar reactions are not of a significant degree.

Editing for Cross Section Library

Multiple NJOY calculation results are usually necessary to generate a complete cross section library for an isotope, since variations in temperatures and background cross sections must be taken into account. Furthermore, additional data (e.g., cross section identifiers, names of isotopes, and burnup-related data) may be supplemented by the input data. In order to gather and handle multiple NJOY outputs and fit the cross section data of NJOY outputs into a cross section library format of a lattice physics code, some post-editing is carried out at the end of the post-processing of cross sections.

2.5 Tabulation and Contents of Cross Section Library

The tabulation and contents of a cross section library are very important for utilization by lattice physics codes (Stammler and Abbate 1983; Okumura et al. 2007; Marleau et al. 2000; Hébert et al. 2000). This section provides some practical information on tabulation methods and the contents of a cross section library.

2.5.1 General File Format

Cross section data are stored in a cross section library. There are two approaches to the configuration of a file(s) for a cross section library.

The first approach is an “integrated” cross section library, that is, all cross sections and related data are stored in a file. For example, the WIMS code utilizes one file for a cross section library.

The second approach is an “indexed” cross section library. In this approach, there are two file types in regard to a cross section, that is, an index file and cross sections files. An index file indicates the correspondence between a cross section file and each nuclide and miscellaneous data. A cross section file contains cross sections for a nuclide, that is, each nuclide is stored in an independent file. The MCNP code adopts such a cross section configuration.

There are advantages and disadvantages to both approaches. From the point of view of the integrity of the cross section data, the “integrated” approach is better than the “indexed” approach, since part of the cross section library cannot be replaced. On the other hand, the “indexed” approach is better in terms of flexibility, since the replacement, removal, and addition of cross sections for a particular nuclide(s) are easily accomplished. During routine production calculations, such manipulations are not necessary. However, when research and development works, for example, the incorporation of new burnable absorbers and the adjustment of cross sections to obtain better prediction accuracy, are considered, such flexibility becomes invaluable. The “indexed” approach is also advantageous in the input of cross sections in lattice physics codes, since the nuclides used in the calculation can be read on a “demand-basis.”

The structure of cross section files for the “index” type cross section library is shown in

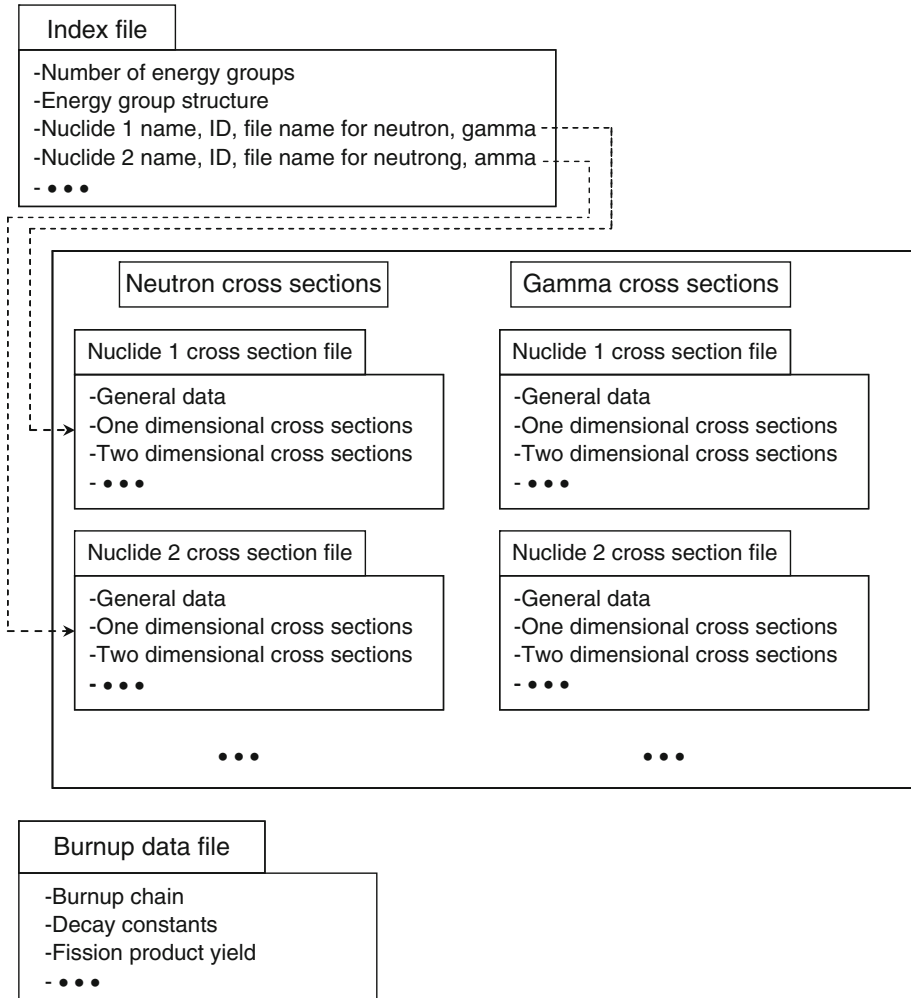

► [Fig. 9.](#)

Though the manipulation of many files requires a considerable effort for conventional main-frame computers, it is very easy for the modern Unix, Linux, or Windows operating systems. Many files can quite practically be treated and managed by a directory. If we consider the ongoing progress being made in the computer industry, the second approach, that is, the index-type cross section library, will be more suitable for future lattice physics codes. In this approach, a cross section library is no longer “a file,” but rather, is “a directory.” Note that burnup-related data may also be prepared by an independent file, since the selection of a burnup chain to be used in calculations is easily accomplished.

2.5.2 Nuclide Identifiers

Nuclide identifiers are very important for a lattice physics code since they are the bridge between users and the lattice physics codes. Nuclide identifiers should include the following information:

- Nuclide information (name of element, atomic number, and mass number)
- State of nuclide (ground/meta-stable)
- Fission product or not
- Chemical binding form (e.g., H in H₂O)
- Source of cross section data (e.g., ENDF/B-VII.0)
- Additional information (e.g., adjustment of cross section data)

■ **Figure 9**
Structure of cross section library ("index" type)

The identifiers can be a string of characters or digits. In conventional lattice physics codes, digits are usually used, for example, "92238" represents ^{238}U . However, when the above information is taken into account, the design of identifiers should be done quite carefully, especially from the viewpoint of extensibility.

Though identifiers based on digits are "computer friendly," they are not "user friendly." On the other hand, identifiers based on a string of characters are "user friendly" but are not "computer friendly." In order to resolve this contradiction, each nuclide can have two identifiers, that is, one consisting of a string of characters, and one of a string of digits. The character identifiers are used in input data, while the digit identifiers are used in the internal calculations of a lattice physics code.

Some nuclides play two roles in lattice physics computations. For example, ^{155}Gd is used as a burnable absorber, but it also appears as a fission product. The number density of ^{155}Gd in a burnable absorber is high, but that of the fission product is low. Therefore, though the self-shielding (resonance) effect of ^{155}Gd in a burnable absorber must be accurately accounted for, the resonance of ^{155}Gd as a fission product may be simply accounted for by assuming an appropriate (fixed) background cross section. Since the scattering matrix of ^{155}Gd as a fission product has a negligible impact from the point of view of neutronics, it may be truncated in a cross section library.

Furthermore, burnable absorber nuclides sometimes have a burnup chain that is independent of that of fission products. In such a case, though the same nuclides (^{155}Gd) appear as both a burnable absorber and fission product, they are considered as different nuclides from the viewpoint of the implementation of lattice physics codes. In order to distinguish “different” ^{155}Gd , different identifiers are necessary for the burnable absorber and fission product. We encounter a similar situation for other nuclides, for example, ^{109}Ag (control rod absorber and fission product), ^{103}Rh (Rh detector and fission product), and Zr (cladding and fission products).

2.5.3 Dependency of Cross Sections

Microscopic cross sections stored in a cross section library are usually dependent on the background cross section and temperature. In a given case, the mass effect of moderator nuclides may be taken into account (a detailed description of the mass effect will be given in [▶ Sect. 3](#)).

In order to account for these dependencies, multiple NJOY calculations are carried out for different calculation conditions (different temperatures and background cross sections). Some typical examples of temperatures and background cross sections used in the NJOY code are shown in [▶ Tables 5](#) and [▶ 6](#), respectively.

The temperatures for the major nuclides cover a range from room temperature (293 K) almost to the melting point of UO_2 (2,800 K). The maximum average pellet temperature of light water reactor fuel in a typical nominal operating condition is approximately 1,100 K. Higher temperatures (>1,100 K) are necessary for transient and accident analyses. Hydrogen has more detailed temperature grid points between 300 and 600 K, due to the considerable variation in scattering cross sections in the thermal energy region. For less important nuclides (e.g., fission product with small absorption) less detailed temperature grid points (or even one fixed temperature) can be applied in order to reduce the size of a cross section library with no loss of accuracy.

The grid points for a background cross section cover a range from infinite dilution (10^8 barn) to a fully shielded condition (10 or 1 barn). Dedicated grid points are assigned to ^{238}U since it is a dominant resonance absorber in many currently used reactor fuels. The grid points for ^{238}U have a fine resolution between 10–100 barn, since the typical background cross section for ^{238}U in light water reactor fuel pins is ~50 barn. Since the number densities of other nuclides (e.g., ^{235}U and ^{239}Pu) vary considerably during burnup, their background cross sections should also cover a wide range. For example, a background cross section for ^{235}U in typical UO_2 fuel is ~1,000 barn at beginning of life (BOL), but it increases up to ~5,000 barn at end of life (EOL), since the number density of ^{235}U reduces with burnup. In the case of ^{239}Pu , its background cross

Source: Marcille and Mills (2003).

section is very large (almost infinite dilution) at BOL, since the number density of ^{239}Pu is very small. At EOL, the background cross section is reduced to approximately several thousands barn due to buildup during burnup.

Due to a current limitation of the NJOY code, the number of background cross sections is limited to less than or equal to 10. When more detailed grid points for a background cross section are necessary, two NJOY executions and the coupling of their results in post-processing becomes necessary.

2.5.4 General Data

When the index file approach is adopted, we have two different files, that is, the index file, and the cross section file for each nuclide. The general data contained in the index file and cross section file are described as follows:

a. Index file

- Numbers of total, fast, and thermal energy groups (note that thermal groups have up-scattering)
- Energy boundaries
- Directory in which cross section files are stored
- Correspondence among name of nuclide (character string identifier), nuclide id (digit identifier), and file name that stores cross section data

b. Cross section file

- Name of nuclide (character string identifier)
- Nuclide id (digit identifier)
- Atomic number, mass number
- Atomic weight (in units of amu is useful for slowing down calculation)
- Number of energy groups
- Fissionable (yes/no)
- Scattering matrix (present/no)
- Upper boundary of resolved resonance range
- Potential scattering cross section
- IR (intermediate resonance) parameter, if necessary
- Energy released per fission
- Kinetic parameters (delayed neutron fraction and decay constant for delayed neutron precursor)
- Number of grid points for temperature
- Number of grid points for background cross section
- Number of grid points for moderator mass effect
- Grid points for temperature
- Grid points for background cross section
- Grid points for moderator mass
- Generation time and date
- Comments
- Others

2.5.5 One-Dimensional Data

In the cross section file for each nuclide, the following one-dimensional cross section data are tabulated:

- Total cross section
- Absorption cross section
- Fission cross section

- Production cross section (number of neutrons released by a fission multiplied by fission cross section)
- (n, 2n) cross section
- Capture cross section
- Fission spectrum
- Neutron source intensity (e.g., by spontaneous fission)
- Other parameters (e.g., (n, 3n), (n, γ), and so on, if necessary)

Additional parameters may be necessary if a lattice physics code adopts a particular resonance calculation method. When the subgroup method is used, the band cross sections and band probabilities are necessary. Almost continuous energy (point-wise) cross sections are necessary for the ultrafine group calculation method.

The above data are tabulated for each energy group, temperature, background cross section, and moderator mass. Since the volume of data is quite considerable and several elements of the above data are zero, compression of the above data is of practical importance. The following two approaches can be used to reduce data size.

Elimination of Zero Elements

For example, an (n, 2n) cross section has a nontrivial value for energy groups above 1 MeV. In other words, (n, 2n) cross sections are zero for most energy groups. Many nuclides are not fissionable; thus, fission, production cross sections, and the fission spectrum are zero for these nuclides. In order to eliminate the zero elements, the upper and bottom energy groups with significant values are stored with nonzero values between the (stored) upper and bottom energy groups. This approach is adopted in the MATXS format.

Storage of Variations in Cross Sections

Certain one-dimensional cross sections, for example, cross sections in the fast energy range, are insensitive to variations in temperature and background cross section. This means that almost identical cross sections are repeatedly tabulated for different temperatures and background cross sections. In such a case, the difference between cross sections from a base condition (e.g., room temperature and infinite dilution condition) will be zero when variations due to temperature and/or background cross section are considered, as follows:

$$\begin{aligned}\sigma(T, \sigma_0) &= \sigma(T_0, \sigma_{0,\infty}) + (\sigma(T, \sigma_0) - \sigma(T_0, \sigma_{0,\infty})) \\ &= \sigma(T_0, \sigma_{0,\infty}) + \Delta\sigma(T, \sigma_0)\end{aligned}\quad (63)$$

where

$\sigma(T, \sigma_0)$: effective microscopic cross section for temperature T and background cross section σ_0 ,

$\sigma(T_0, \sigma_{0,\infty})$: effective microscopic cross section for temperature T_0 and background cross section $\sigma_{0,\infty}$,

$\Delta\sigma(T, \sigma_0)$: difference of effective microscopic cross section,

T_0 : base temperature, for example, 293 K,

$\sigma_{0,\infty}$: background cross section for infinite dilute condition, for example, 10^8 barn.

Since the zero element of a cross section can be compressed by elimination, as discussed above, consideration through variation of a cross section is effective at reducing the volume of cross section data. The present method is also adopted in the MATXS format.

Reduction of Grid Points for Temperature/Background Cross Sections

For less important nuclides such as minor fission products, full tabulation of the cross sections for all temperatures/background cross sections is not necessary, since they have little impact on the calculation results. For these nuclides, a typical temperature (e.g., that of the operating condition) and background cross section (e.g., average value during burnup) can be used, instead of full tabulation of temperatures/background cross sections.

2.5.6 Two-Dimensional Data

Scattering matrixes for both isotropic component (P0) and anisotropic components are tabulated here. In light water reactor analysis, the transport-corrected total cross section, which considers anisotropic components up to P1, is usually used with acceptable results. However, for fuels with a steep angular flux distribution, an explicit anisotropic scattering calculation is desirable. Higher-order anisotropic scattering matrixes are necessary for such calculations. Several studies have demonstrated that anisotropic scattering up to a P3 component is sufficient for ordinary light water reactor core calculations. Therefore, anisotropic scattering up to P3 components for nuclides with large anisotropic scattering (light nuclides) and reflector materials (e.g., Fe, Ni, and Cr) would be included in the cross section data. For other materials, anisotropic scattering up to a P1 component is sufficient for lattice physics computation. Note that if sensitivity calculations on anisotropic scattering will be carried out, the order of anisotropic scattering in a cross section library should be higher.

Since the size of a scattering matrix is large, the compression of data is crucial. The techniques for one-dimensional cross sections described previously can also be applied to two-dimensional data, that is, scattering matrixes. Furthermore, scattering matrixes for nuclides with a small number density and small cross section (e.g., minor fission products) can be omitted, since the scattering matrix of such nuclides has a negligible impact on reactor physics parameters. This is another reason to provide independent nuclide identifiers for fission products. For example, the number density of ^{155}Gd used as a burnable absorber is high, so its scattering matrix should be explicitly taken into account. However, since the number density of ^{155}Gd as a fission product is small, its scattering matrix can be omitted. Therefore, we can have two different cross section files for ^{155}Gd : one that (for a burnable absorber) contains a scattering matrix, and one that does not.

2.5.7 Burnup-Related Data

For burnup-related data, the following information is necessary:

- Burnup chain (including branching ratio)
- Decay constant for each nuclide
- Yields for fission products

A burnup chain used in a lattice physics code would depend on the purpose of the analysis. Therefore, various burnup chains may be used with the same cross section library. Therefore, burnup-related data might be stored in a file that is independent of the cross section data. More detailed discussion on burnup chains will be presented in [▶ Sect. 6](#).

2.5.8 Gamma Cross Section Library

In order to evaluate detailed pin-wise energy deposition by gamma rays, a transport calculation of gamma rays is necessary. For such gamma transport calculation, the following data are necessary (Mertyurek 2007):

- Gamma energy released by a photonuclear reaction, mainly (n, γ)
- Gamma spectra of a photonuclear reaction (from neutron group n to gamma group g)
- Gamma energy released by a fission reaction
- Gamma spectra of a fission reaction (to gamma group g)
- Gamma total cross section
- Gamma absorption cross section
- Gamma scattering cross section (isotropic and anisotropic components)
- Energy deposition cross section from gamma

Since gamma cross sections have contents similar to those of neutron cross sections, a similar format for neutron cross sections can be used.

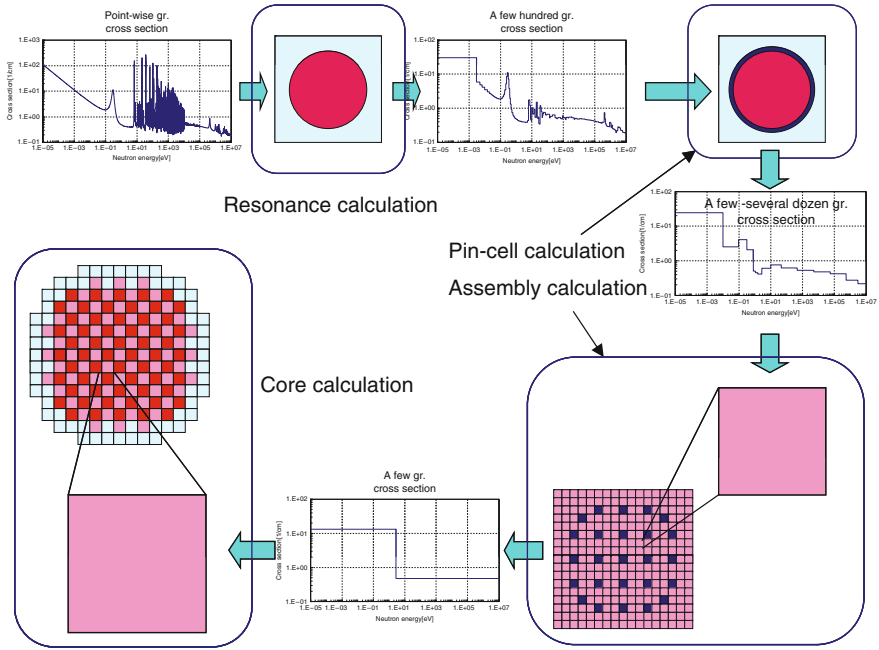

2.6 Summary

In [▶ Sect. 2](#), a detailed discussion of a cross section library for lattice physics code is provided. Though a cross section library is a crucial part of a lattice physics code, a description of its contents and preparation is rarely found in references. This section will be useful not only for the design and generation of a new cross section library, but also for an understanding of the contents and generation process of a current cross section library.

3 Resonance Treatment

3.1 Objective

All reactor physics calculations are carried out with cross sections. The actual cross-sectional data for each nuclide describe the very detailed (fine) energy structure, typically comprising several hundreds of thousands of energy points for major resonance nuclides. In fact, direct utilization of such ultrafine energy groups in lattice physics computations and subsequent core calculations is so time consuming as to be impractical, even on today's computers. For this reason, the fine energy structures of cross sections, especially in the resonance energy range, are condensed during lattice physics computations, as shown in [▶ Fig. 10](#). The first step in such energy condensation for cross sections is the resonance calculation. In this context, the resonance calculation is the “sole interface with the real world,” since the “actual” cross section

■ Figure 10

General calculation flow for core analysis

appears only in the resonance calculation, while only the condensed (i.e., artificial) cross sections are used in subsequent calculations. The consequence is that if the resonance calculation were inaccurate, subsequent calculations would be meaningless.

Since the resonance calculation is one of the most difficult and challenging part of reactor physics calculations, significant effort and study have been directed to the development of various innovative calculation methods. A complete review of these resonance calculation methods would, however, require an entire book, and hence, the discussion in ► 3.2 is limited to the major calculation methods being used in current lattice physics codes.

In the following subsection, the concept of an effective cross section is introduced, along with a discussion of the major resonance calculation methods used in current lattice physics codes (Weinberg and Wigner 1958; Dresner 1960; Goldstein and Cohen 1962; Rothenstein 1980; Stamm'ler and Abbate 1983; Rothenstein and Segev 1986; Cullen 1986; Kobayashi 1995; Hall-sall 1995; Loubiere et al. 1999; Hwang 2003; Reuss and Coste-Delclaux 2003; Hébert 2005b; Karthikeyan and Hébert 2008).

3.2 Effective Cross Sections

The Boltzmann transport equation in continuous energy is given as follows:

$$\vec{\Omega} \cdot \nabla \psi(\vec{r}, E, \vec{\Omega}) + \Sigma_t(\vec{r}, E) \psi(\vec{r}, E, \vec{\Omega}) = Q(\vec{r}, E, \vec{\Omega}) \quad (64)$$

In principle, (64) can be accurately solved with a very fine energy structure, but for the reasons discussed in the previous section, such treatment remains impractical. Thus, the Boltzmann transport equation in a multigroup form is usually used in lattice physics computations:

$$\vec{\Omega} \cdot \nabla \psi_g(\vec{r}, \vec{\Omega}) + \Sigma_{t,g}(\vec{r}, \vec{\Omega}) \psi_g(\vec{r}, \vec{\Omega}) = Q_g(\vec{r}, \vec{\Omega}) \quad (65)$$

With the following definition of a multigroup microscopic cross section, (64) and (65) are consistent.

$$\sigma_g(\vec{r}, \vec{\Omega}) = \frac{\int_{E_g}^{E_{g-1}} dE \sigma(E) \psi(\vec{r}, E, \vec{\Omega})}{\int_{E_g}^{E_{g-1}} dE \psi(\vec{r}, E, \vec{\Omega})} \quad (66)$$

It should be noted that the multigroup cross sections given in (66) is not a common expression since it depends not only on the location, but also on angle. Since neutron transport calculations in a lattice physics code assumes a constant cross section in a small spatial region (e.g., a fuel pellet), the spatially averaged cross section is necessary:

$$\sigma_{i,g}(\vec{\Omega}) \psi_{i,g}(\vec{\Omega}) V_i = \int_{V_i} d\vec{r} \sigma_g(\vec{r}, \vec{\Omega}) \psi_g(\vec{r}, \vec{\Omega}). \quad (67)$$

The cross section expressed in (67) still has angular dependence, which is not usually taken into account in the transport calculations in lattice physics codes. Therefore, the following definition is of practical value for microscopic cross sections in the multigroup neutron transport calculation:

$$\sigma_g(\vec{r}) = \frac{\int_{E_g}^{E_{g-1}} dE \sigma(E) \phi(\vec{r}, E)}{\int_{E_g}^{E_{g-1}} dE \phi(\vec{r}, E)} \quad (68)$$

where $\phi(\vec{r}, E)$ is the total (or scalar) flux, which is defined as

$$\phi(\vec{r}, E) = \int^{4\pi} \psi(\vec{r}, E, \vec{\Omega}) d\vec{\Omega}$$

The cross section given in (68) is called the effective cross section because it can effectively preserve the total reaction rate for the group. The group-wise definition of reaction leads also to scattering matrices for various angular moments. The scattering matrices are not covered in detail here though. It should be noted that detailed information regarding angular flux is implicitly taken into account.

The above discussion clarifies the fact that the essence of the resonance calculation is the energy collapsing and the spatial averaging (homogenization) that uses the detailed angular flux distribution to be obtained by solving (64). The above discussion also suggests a significant contradiction: the detailed angular fluxes used in (66) and (67) are, of course, unknown, since they are exactly what we would like to know. If the exact angular flux were known, the reactor physics calculation would have already been completed with ideal accuracy.

Herein lies the difficulty of the resonance calculation. We need to estimate the neutron flux distribution in a resonance region without a complete knowledge of the entire calculation system, such as a fuel assembly or a reactor core. In this sense, the resonance calculation methods must to a significant degree rely on approximations, which are considered valid from an engineering perspective.

3.3 Physics of Self-Shielding and Major Resonance Calculations

3.3.1 Physics of Self-Shielding

In the resonance energy range, the cross sections of many nuclides (especially heavy nuclides) exhibit a severely varying behavior. Since the peak of a resonance is often quite high, neutrons at the resonance peak energy are often easily absorbed by resonance nuclides. In such a case, the neutron flux also exhibits very complicated energetic behavior due to resonance absorption, as shown in [Fig. 11](#). Since the neutron absorption rate is obtained as a product of the microscopic cross section and the neutron flux, the dip in the neutron flux at a resonance peak reduces absorption at that peak. The resonance peak thus appears to be “energetically” shielded from neutrons around the resonance peak energy. For this reason, the reduction of neutron absorption around the resonance peak by the above mechanism is referred to as the energetic self-shielding effect. It is apparent that the energetic self-shielding effect appears not only in a heterogeneous geometry, but also in a homogeneous geometry, since the slowing down of the neutrons (energetic transport of neutrons) and absorption are the principal physical phenomena behind the energetic self-shielding effect.

There is another important shielding effect related to resonance absorption. In heterogeneous geometry, neutrons that flow from a moderator into a fuel (i.e., into the resonance region) are captured in the peripheral area, as shown in [Fig. 12](#). The neutron flux distribution thus shows a profound depression from the surface to the center part of the fuel near the resonance peak energy. The spatial variation in neutron absorption becomes very large in the resonance energy range due to the large resonance absorption cross section of fuel. This phenomenon is known as the spatial self-shielding effect, since the resonance material “shields” the inflow of neutrons, thus reducing the neutron absorption in the resonance material.

The essence of the resonance calculation is, in other words, the accurate evaluation of the energetic and spatial self-shielding effects in resonance material.

Figure 11

Neutron spectrum obtained by ultra-fine energy groups calculation

Figure 12
Space dependency of neutron spectrum in a fuel pellet

Even though there are various approaches to resonance calculations, they are generally classified into three categories: ultrafine energy group calculation, the equivalence theory, and the subgroup (or multiband) method.

3.3.2 Ultrafine Energy Group Calculation

The ultrafine energy group calculation is a quite simple and direct approach, in which neutron flux distribution (both energetic and spatial) is calculated with very fine energy groups (Ishiguro 1974; Tsuchihashi et al. 1982; Rothenstein et al. 1988; MC²-2 1999; Chiba 2003; Sugimura and Yamamoto 2007). In this approach, the effective multigroup cross section is evaluated with a very detailed neutron spectrum distribution, as shown in [Fig. 11](#), and since it is based on first principles, it clearly gives quite accurate, effective cross sections. We must recall, however, the necessity of the resonance calculation. If a neutron transport calculation in very fine energy groups can be carried out, a conventional resonance calculation is not necessary. Currently, the direct practical application of ultrafine energy group calculation is, however, limited to a pin cell or to small multicells, because of the enormous amount of computational resource required for the ultrafine group transport calculation.

3.3.3 Equivalence Theory

The second approach, that is, the equivalence theory, is a historical method that is widely used in current lattice physics codes (Weinberg and Wigner 1958; Dresner 1960; Goldstein and Cohen 1962; Bitelli et al. 1970; Chao and Martinez 1978; Chao et al. 1981; Stamm'ler and Abbate 1983; Rothenstein and Segev 1986; Cullen 1986). In this approach, the neutron escape probability from the fuel (resonance) material is approximated by a rational function of the total cross section of a resonance nuclide. With some additional assumptions, the neutron flux spectrum in a heterogeneous resonance region can be expressed as an analytic formula that is applicable to a homogeneous medium as well. During this derivation, the effect of heterogeneity is taken into account by the macroscopic escape cross section. The escape cross section plays the same role as the background cross section does in the self-shielding effect in a homogeneous system. The notion of escape and background cross sections will be addressed in more detail in [3.4](#) and [3.5](#). Therefore, an effective cross section can be tabulated with a background cross section

■ Figure 13

Effective cross section versus background cross section (^{238}U , 293 K, 6.16–7.52 eV)

(which may include the escape cross section) as an index, as shown in [▶ Fig. 13](#). Consequently, the effective cross sections in homogeneous and heterogeneous configurations will be the same if they have the same background cross sections. In this sense, the treatment of homogeneous and heterogeneous geometries is unified through the background cross section. In other words, the spatial self-shielding effect (captured by the escape cross section) and the energetic self-shielding effect (captured by the background cross section) are unified.

Though the equivalence theory offers a very simple and effective approach to resonance calculation, one must remember that it incorporates many approximations that are implicitly used. Therefore, the application of the equivalence theory is inherently limited to simple configurations, such as an isolated pin cell or regular lattices. Very heterogeneous geometries with complicated resonance material distribution require a more sophisticated approach.

3.3.4 Subgroup Method

The previous approach, the subgroup method, provides a calculation route that offers a compromise, by using a correlation between the neutron flux and the resonance cross section shown in [▶ Fig. 11](#) (Nikoleav et al. 1971; Levitt 1972; Cullen 1986). Generally speaking, neutron flux is inversely proportional to the macroscopic total cross section of a resonance material. This dynamic suggests that neutron energy groups would be subdivided not by the order of energy (the conventional approach), but by the magnitude of the cross section, as show in [▶ Fig. 14](#). When neutron energy groups are defined according to the magnitude of the cross section, the variations in neutron flux in a subdivided energy group will be smaller than those in a conventional subdivision, since the variation of the cross section (and thus that of the neutron flux) in a sub-energy group is smaller. The dependence of the effective cross section in each subgroup on a shielding condition (in the equivalence theory, on a background cross section) is clearly weaker, and it is this condition, which guarantees the robustness of the subgroup method. Although a very fine energy group structure is necessary in the ultrafine energy group calculation, a few subgroups within a conventional group offer high accuracy, which makes the subgroup method computationally efficient.

Figure 14
Concept of the subgroup method

The above discussion describes the concept of the subgroup method, in which the energy group structure in each subgroup is explicitly defined. In other words, all energy points are explicitly classified into corresponding subgroups. However, the subgroup method currently used in lattice physics codes does not have such an explicit energy group structure. Each subgroup is probabilistically defined in terms of its band probability and the corresponding band cross sections. The band probability and band cross sections are chosen to be independent of the self-shielding condition (i.e., the background cross section in the equivalence theory). Since each band does not have an explicit energy range, direct application of the current subgroup method is difficult when the shape of the cross section of a nuclide is different in each resonance region. The radial temperature distribution in a pellet poses just such a situation, since the shape of a cross section in a resonance energy range depends on the temperature, due to the Doppler effect. Furthermore, since the common subgroup method relies on the narrow resonance approximation that will be presented in the [3.4](#), its accuracy might be limited.

The advantages and disadvantages of the three major resonance calculation methods are summarized in [Table 7](#). This table suggests that there is no method of “last resort,” so the choice of a resonance calculation method greatly depends on the design concept of a given lattice physics code.

In the following subsection, the theoretical basis of the resonance calculation methods will be described. Beginning with the resonance theory in a homogeneous medium, the discussion is then extended to heterogeneous geometries.

3.4 Resonance Self-Shielding in a Homogeneous System (Dresner 1960; Rothenstein and Segev 1986; Cullen 1986)

3.4.1 Slowing Down of Neutrons in a Homogeneous System

In a homogeneous system, where the neutron flux is isotropic, the Boltzmann transport equation can be written as follows:

$$\Sigma_t(E)\phi(E) = \int_0^\infty \Sigma_s(E' \rightarrow E)\phi(E')dE' + \frac{\chi(E)}{k_{eff}} \int_0^\infty v\Sigma_f(E')\phi(E')dE' \quad (69)$$

■ Table 7

Advantages and disadvantages of the major resonance calculation methods

Methods	Advantages	Disadvantages
Equivalence theory	Simple	Inability to treat space-dependent resonance shielding
	Fast	Inability to treat complicated geometry Limited accuracy due to assumptions for simplification Inability to treat the resonance interference effect
Subgroup method	Reasonably accurate	Longer computation time than the equivalence theory
	Applicable to general geometry	Inability to treat temperature distribution Inability to treat resonance interference effect
Ultrafine group method	Accurate	Longer computation time and larger memory storage
	Applicable to general geometry Ability to treat resonance interference effect	Impractical for large system (e.g., a fuel assembly)

where

$\Sigma_t(E)$: macroscopic total cross section,
 $\Sigma_s(E' \rightarrow E)$: macroscopic scattering cross section,
 $\nu\Sigma_f(E)$: macroscopic production cross section,
 $\chi(E)$: fission spectrum,
 $\phi(E)$: scalar flux, and
 k_{eff} : k -effective.

In the resonance region (e.g., 1 eV–10 keV and 10–300 keV for the resolved and unresolved resonance energy ranges, respectively, for ^{238}U), fission neutrons can be neglected, and elastic scattering is the dominant mechanism for the slowing down of neutrons. Under these assumptions, (69) can be simplified into

$$\left(\sum_k N_k \sigma_{t,k}(E) \right) \phi(E) = \sum_k \frac{1}{1 - \alpha_k} \int_E^{E/\alpha_k} N_k \sigma_{s,k}(E') \phi(E') \frac{dE'}{E'} \quad (70)$$

where

$\sigma_{t,k}(E')$: microscopic total cross section of nuclide k ,
 $\sigma_{s,k}(E')$: microscopic elastic scattering of nuclide k ,
 $\phi(E)$: total (scalar) neutron flux, and
 $\alpha_k = \left(\frac{A-1}{A+1} \right)^2$ when A is the atomic mass in atomic mass units (amu).

If a material is a pure scatterer that consists of a single nuclide, (70) becomes

$$N_k \sigma_{t,k}(E) \phi(E) = \frac{1}{1 - \alpha_k} \int_E^{E/\alpha_k} N_k \sigma_{t,k}(E') \phi(E') \frac{dE'}{E'} \quad (71)$$

It is easily confirmed that the solution to (71) is given by

$$\phi(E) = \frac{C}{N_k \sigma_{t,k}(E) E} \quad (72)$$

where

C: a constant that is defined by the source intensity.

Equation (72) suggests that the asymptotic neutron spectrum in a pure scatterer is inversely proportional to the macroscopic total cross section and the neutron energy. In fact, in an LWR lattice, the overall behavior of the neutron spectrum in the resonance region is approximately given by $1/E$ even with absorption, since the moderator (H_2O) is almost a pure scatterer in the resonance energy region.

Unfortunately, the analytic solution to the equation for the slowing down of neutrons can be derived only under a very limited condition. Additional approximations will thus be necessary as a basis for further derivation. In the following sections, we discuss the major approximations that are behind the resonance calculations of many lattice physics codes.

3.4.2 Narrow Resonance Approximation

First, let us assume that the homogeneous material is composed of a resonance nuclide and other (nonresonant) nuclides. Even though the material may contain multiple resonance nuclides, the narrow resonance (NR) approximation to be discussed below will be valid when there is no coincident resonance overlap among nuclides (which will be discussed in more detail in a later section). Now, assume that the energy dependence of cross sections for nonresonant nuclides is assumed to be constant, with no absorption, that is, their total cross sections are equal to the potential scattering cross sections ($\sigma_{t,k} = \sigma_{s,k} = \sigma_{p,k}$). This assumption can be justified by the fact that this potential scattering, which is independent of the incident neutron energy, is dominant for nonresonant nuclides in the resonance energy range. With this assumption, (70) becomes as follows:

$$\left(N_r \sigma_{t,r}(E) + \sum_{k \neq r} N_k \sigma_{p,k} \right) \phi(E) = \frac{1}{1 - \alpha_r} \int_E^{E/\alpha_r} N_r \sigma_{s,r}(E') \phi(E') \frac{dE'}{E'} + \sum_{k \neq r} \frac{1}{1 - \alpha_k} \int_E^{E/\alpha_k} N_k \sigma_{p,k} \phi(E') \frac{dE'}{E'} \quad (73)$$

where the subscript r denotes a resonance nuclide.

It should be noted again that (73) assumes that only a resonance nuclide has energy dependence on cross sections, that is, other nuclides have a constant total and scattering cross sections. As discussed later, this simplification (which neglects the resonance overlap effect) is one of the weaknesses of this resonance calculation method. In actual fuel, a fuel material could have a

very diverse composition due to burnup (through the generation of minor actinides and fission products, which have many distinct resonances) and/or its initial mixed loading (e.g., MOX fuel, which includes both uranium and plutonium isotopes).

Unfortunately, the right-hand side of (73) contains an unknown function of energy E' , that is, neutron flux. Therefore, some assumptions are necessary in order to analytically solve (73).

For the purpose of further simplification, the resonance width of nuclide r is assumed to be narrow compared to the slowing down width. This means that most neutrons that appear near the resonance peak energy come from outside of the resonance peak (i.e., the nonresonant energy range) due to much higher energies. Furthermore, from (72), we see that the neutron spectrum in the nonresonant part is assumed to be proportional to $1/E$, since the energy dependence of the total cross section in the nonresonant part is fairly flat. Though the neutron spectrum around the resonance peak does not have a $1/E$ shape, its contribution to the integration of the energy is small because of the narrow resonance width. With these assumptions, the second term in the right-hand side of (73) can be reduced into the following:

$$\begin{aligned} \sum_{k \neq r} \frac{1}{1 - \alpha_k} \int_E^{E/\alpha_k} N_k \sigma_{p,k} \phi(E') \frac{dE'}{E'} &= \sum_{k \neq r} \frac{N_k \sigma_{p,k}}{1 - \alpha_k} \int_E^{E/\alpha_k} \phi(E') \frac{dE'}{E'} \\ &\approx \sum_{k \neq r} \frac{N_k \sigma_{p,k}}{1 - \alpha_k} \int_E^{E/\alpha_k} \frac{1}{E'} \frac{dE'}{E'} \\ &= \sum_{k \neq r} N_k \sigma_{p,k} \frac{1}{E} \end{aligned} \quad (74)$$

Note that the proportional constant C in (72) has been taken arbitrarily as 1 for normalization of the flux such that $E\phi(E) = 1$ above the resonance.

Next, we will estimate the first term in the right-hand side of (73). For this estimation, two additional approximations are introduced. The scattering cross section of a resonant nuclide in the nonresonant part is considered as a constant, since it is dominated by the potential scattering in this energy range. Furthermore, the shape of the neutron spectrum is approximated by $1/E$, as are the treatments for other nuclides. Using these assumptions, we have

$$\begin{aligned} \frac{1}{1 - \alpha_r} \int_E^{E/\alpha_r} N_r \sigma_{s,r}(E') \phi(E') \frac{dE'}{E'} &\approx \frac{N_r \sigma_{p,r}}{1 - \alpha_r} \int_E^{E/\alpha_r} \phi(E') \frac{dE'}{E'} \\ &\approx \frac{N_r \sigma_{p,r}}{1 - \alpha_r} \int_E^{E/\alpha_r} \frac{1}{E'} \frac{dE'}{E'} = N_r \sigma_{p,r} \frac{1}{E} \end{aligned} \quad (75)$$

By substituting (74) and (75) into (73), we obtain the following equation:

$$\left(N_r \sigma_{t,r}(E) + \sum_{k \neq r} N_k \sigma_{p,k} \right) \phi(E) = \frac{N_r \sigma_{p,r} + \sum_{k \neq r} N_k \sigma_{p,k}}{E} \quad (76)$$

Finally, the energy dependence of the neutron flux is given by

$$\begin{aligned} \phi(E) &= \frac{N_r \sigma_{p,r} + \sum_{k \neq r} N_k \sigma_{p,k}}{N_r \sigma_{t,r}(E) + \sum_{k \neq r} N_k \sigma_{p,k}} \frac{1}{E} \\ &= \frac{\sigma_{p,r} + \sigma_0}{\sigma_{t,r}(E) + \sigma_0} \frac{1}{E} \end{aligned} \quad (77)$$

In (77), the background cross section (σ_0), is defined as

$$\sigma_0 = \left(\sum_{k \neq r} N_k \sigma_{p,k} \right) / N_r \quad (78)$$

Equation (77) is the analytic form for the energy dependence of the neutron flux obtained by the narrow resonance (NR) approximation. Note that the absolute value of the neutron flux is not necessary in the resonance calculation, since the neutron flux is used as the weighting function. Though (72) is limited to a pure scatter, (77) is an extension that accounts for absorption, and can thus be used in the case of general homogeneity.

The background cross section defined by (78) is a fictitious microscopic cross section that determines the depression of the neutron flux at resonance peak energy. When the background cross section is very small, the energetic neutron flux behavior given by (77) approaches that in (72), in which the contribution of scattering from other nuclides is not considered. In this case, the neutron flux is inversely proportional to the microscopic total cross section of the resonance nuclide. Note that the variation due to the $1/E$ part is much smoother than that in the microscopic cross section. On the contrary, when the background cross section is very large, the neutron flux given by (77) approaches $1/E$, which is an asymptotic neutron spectrum in which no absorption is considered, that is, the scattering of other nonresonant nuclides dictates the spectrum. The actual neutron flux variation will be between the two extreme cases above, and would be interpolated by the background cross section.

The background cross section plays a very important role in resonance calculation theory, as will be described later.

During the derivation of (77), many assumptions were used. It is worthwhile to summarize the assumptions used in the NR approximation:

- No resonance overlap is considered.
- Nonresonant nuclides have constant scattering cross sections, which are dominated by the potential scattering.
- The resonant nuclide has a constant scattering cross section above the resonance, which is dominated by the potential scattering.
- The slowing down of neutrons is dominated by elastic scattering.
- The energy dependence of the neutron flux in the nonresonant part is asymptotic ($1/E$ shape).
- The neutron source within the resonance energy range is dominated by scattered neutrons coming from outside of the resonance peak. In other words, the resonance peak is so narrow compared to the average energy loss of neutrons due to elastic scattering.
- The source of neutron scattering is calculated by the asymptotic $1/E$ spectrum.

Though the above assumptions help to greatly simplify the expression of the energy dependence of the neutron flux, some of them may be a source of significant error. Since a resonance peak is assumed to be narrow, the NR approximation is more appropriate for a higher energy region in which the resonance is narrower than the slowing down width, in a relative sense. On the other hand, the accuracy of the NR approximation diminishes for broad resonances in the epithermal energy region (e.g., the resonance of ^{238}U at 6.7 eV). The accuracy of the NR approximation will be discussed later in more detail.

3.4.3 Wide Resonance Approximation

The first term in the right-hand side of (73) can be simplified by another assumption, namely the assumption that a resonant nuclide has infinite mass. This means that the width of the resonance peak is “wide” compared to the average energy loss due to scattering. In this regard, this approximation is called the wide resonance (WR) approximation, or the wide resonance infinite (mass) absorber (WRIA) approximation. When the mass of a nuclide is infinite, no energy loss is expected in the elastic scattering reaction. This physical observation suggests that the first term in (73), which is the energy integral of an in-scatter neutron by the resonant nuclide, is equal to the out-scatter reaction at energy E , that is,

$$\begin{aligned}
 \lim_{\alpha_r \rightarrow 1} \frac{1}{1 - \alpha_r} \int_E^{E/\alpha_r} N_r \sigma_{s,r}(E') \phi(E') \frac{dE'}{E'} &\approx \lim_{\alpha_r \rightarrow 1} \frac{1}{1 - \alpha_r} N_r \sigma_{s,r}(E) \phi(E) \int_E^{E/\alpha_r} \frac{dE'}{E'} \\
 &= N_r \sigma_{s,r}(E) \phi(E) \lim_{\alpha_r \rightarrow 1} \frac{1}{1 - \alpha_r} \ln \left(\frac{1}{\alpha_r} \right) \\
 &= N_r \sigma_{s,r}(E) \phi(E) \lim_{\alpha_r \rightarrow 1} \frac{-\ln \alpha_r}{1 - \alpha_r} \\
 &= N_r \sigma_{s,r}(E) \phi(E)
 \end{aligned} \tag{79}$$

Here, the energy dependence of the scattering cross section and the neutron flux is assumed to be constant within the narrow integration range, $E/\alpha_r \sim E$. By substituting (79) into (73) and applying the NR approximation for nonresonant nuclides, we obtain

$$\left(N_r \sigma_{t,r}(E) + \sum_{k \neq r} N_k \sigma_{p,k} \right) \phi(E) = N_r \sigma_{s,r}(E) \phi(E) + \frac{\sum_{k \neq r} N_k \sigma_{p,k}}{E} \tag{80}$$

Since $\sigma_{a,r}(E) = \sigma_{t,r}(E) - \sigma_{s,r}(E)$, (80) is rewritten as

$$\left(N_r \sigma_{a,r}(E) + \sum_{k \neq r} N_k \sigma_{p,k} \right) \phi(E) = \frac{\sum_{k \neq r} N_k \sigma_{p,k}}{E} \tag{81}$$

The final form of flux, is then

$$\begin{aligned}
 \phi(E) &= \frac{\sum_{k \neq r} N_k \sigma_{p,k}}{N_r \sigma_{a,r}(E) + \sum_{k \neq r} N_k \sigma_{p,k}} \frac{1}{E} \\
 &= \frac{\sigma_0}{\sigma_{a,r}(E) + \sigma_0} \frac{1}{E}
 \end{aligned} \tag{82}$$

where $\sigma_0 = \left(\sum_{k \neq r} N_k \sigma_{p,k} \right) / N_r$.

Note that the narrow resonance approximation is still applied to the nonresonant nuclides to derive (82). Therefore, the above derivation is sometimes called the WR–NR approximation, which means that the WR approximation is applied to the resonant nuclide, while the NR approximation is applied to the nonresonant nuclides. In this context, the above approximation

Figure 15

Neutron fluxes $\phi(E)$ obtained by the NR, WR approximations, and the numerical solution of the slowing down equation (SD) (homogeneous mixture of ^{238}U and hydrogen, 293 K, $\sigma_0 = 50$ barn)

is also referred to as the narrow resonance infinite mass (NRIM) approximation. The above assumption is justified by the fact that the energy loss from the slowing down by nonresonant nuclides (e.g., hydrogen) is generally much larger than the width of a resonance peak.

A comparison of (77) and (82) provides useful insight into the energy dependence of the neutron flux at the resonance peak. In fact, when the scattering reaction of the resonant nuclide is neglected (i.e., $\sigma_{p,r}$ and $\sigma_{s,r}(E)$ are zero), (77) and (82) become identical. This observation is adequate, since the scattering reaction of a resonant nuclide is essentially “neglected” in the WR approximation. Due to the assumptions in the WR approximation, it is more appropriate to treat broad resonances appearing in the epithermal-low energy range.

Figure 15 shows neutron spectra in a homogeneous mixture of ^{238}U and hydrogen around 7 eV, as obtained by different methods. The background cross section (σ_0) is 50 barn and the temperature is 293 K. The neutron flux is normalized at 8 eV. The ratios of the two approximated results to the reference are also shown. The reference result is obtained by the numerical solution of the slowing down equation, and the two approximate solutions (the NR and WR approximations) are also depicted in Fig. 15. Since the resonance of ^{238}U at 6.7 eV is located in a lower energy region and is relatively wide, the WR approximation is in better agreement with the reference solution.

Differences in the neutron spectrum affect the effective cross section during energy condensation. Tables 8 and 9 show a comparison of the effective microscopic capture cross sections of ^{238}U and ^{235}U obtained by the NR and WR approximations, and offer an accurate slowing down equation. Table 8 indicates that the NR approximation gives higher accuracy than the WR approximation in the higher energy range, while the WR approximation works better in the lower energy range. In comparison with ^{238}U shown in Table 8, the capture cross section of ^{235}U shown in Table 9 is accurately calculated by both the NR and WR

■ Table 8

Background cross section = 50 barn, 293 K, homogeneous mixture of ^{238}U and hydrogen; values are in barn.

approximations, since the background cross section (1,000 barn, which is typical for ^{235}U in an LWR lattice) is much larger than that of ^{238}U in this calculation, and the peak of the resonance cross section is smaller and narrower than ^{238}U . Note that the typical peak values of the resonance cross sections are 10,000 barns and 1,000 barns for the microscopic total cross sections of ^{238}U and ^{235}U , respectively. In the case of a more shielded condition, the difference between the NR and WR approximations will be larger for ^{235}U .

3.4.4 Intermediate Resonance Approximation

Concept

The NR and WR approximations give the two limiting conditions in neutron slowing down for a resonant nuclide. Actual resonance peaks, however, appear to have an “intermediate” resonance width, which would be a blend of the “narrow” and “wide” ones. The intermediate resonance (IR) approximation offers a compromise approach for resonances of intermediate width (Sehgal and Goldstein 1966; Goldstein 1967; Ishiguro 1968; Ishiguro and Takano 1969).

Background cross section = 1,000 barn, 293 K, homogeneous mixture of ^{235}U and hydrogen; values are in barn.

The discussion in [3.4.3](#) clarifies that the difference between the NR and WR approximations can be found in their differing treatment of the scattering cross section of a resonant nuclide. In other words, the scattering cross section of a resonant nuclide is fully incorporated in the NR approximation, but is completely neglected in the WR approximation. This observation naturally provides for an intermediate approach, that is, only a part of the scattering cross section of a resonant nuclide is taken into account:

$$\begin{aligned}
 \phi(E) &= \frac{\lambda N_r \sigma_{p,r} + \sum_{k \neq r} N_k \sigma_{p,k}}{N_r \sigma_{a,r}(E) + \lambda N_r \sigma_{p,r} + \sum_{k \neq r} N_k \sigma_{p,k}} \frac{1}{E} \\
 &= \frac{\lambda \sigma_{p,r} + \sigma_0}{\sigma_{a,r}(E) + \lambda \sigma_{p,r} + \sigma_0} \frac{1}{E} \tag{83}
 \end{aligned}$$

where λ is the IR parameter. The NR and WR approximations correspond to $\lambda = 1$ and $\lambda = 0$, respectively. By choosing an appropriate IR parameter, (83) gives better accuracy for resonances of intermediate width.

Historically, the IR parameter was introduced to provide an analytical expression for the energy dependence of the neutron flux at resonances of intermediate width. However, in the practical world of lattice physics computing, slowing down calculations are carried out by the numerical solution of (70) during the stage of cross section libraries; we can thus accurately evaluate the energy dependence of the neutron flux even for resonances of intermediate width. In this sense, an analytical expression for the energetic behavior of neutron flux is no longer necessary in order to evaluate the effective cross section.

In spite of the above description, the IR parameter still plays a very important role in today's lattice physics computation. In the slowing down calculations, the "effective" width of a resonance depends not only on the actual width of the resonance peak, but also on the average increment of lethargy (average energy loss) in the collision between a neutron and a target nuclide.

Let us assume a resonance peak. This resonance peak is "narrow" when hydrogen is used as a moderator nuclide. The same resonance peak, however, would be "wide" when a neutron loses its energy due to collisions with a heavier nuclide (e.g., oxygen, uranium). This discussion suggests that the width of resonance effectively depends also on the mass of the moderator nuclide. The IR parameter can be used to correct the mass effect of a moderator nuclide. \blacktriangleright Table 10 shows the effective capture cross sections of ^{238}U in the 172 XMAS groups when various nuclides are assumed as moderator. This result was obtained through a numerical solution of the slowing down equation. The background cross section in \blacktriangleright Table 10, which influences the magnitude of the self-shielding effect, is assumed to be 50 barns.

\blacktriangleright Table 10 clearly indicates that the mass of the moderator nuclide has a significant impact on the effective cross sections even if the background cross section is the same. The actual dependence of the effective cross section on the mass of the moderator nuclide is somewhat complicated, as can be seen in this table. However, heavy nuclides generally contribute less to the background cross section than do light nuclides such as hydrogen, since the energy loss of a neutron through a collision is much smaller and also the IR factor is small for resonant nuclides. Since the variation in the effective cross section in \blacktriangleright Table 10 comes from the superficial "relative width" of a resonance peak, it would be adequately captured by the IR parameter. In order to apply the IR parameter to all nuclides, (83) is extended as follows:

$$\phi(E) = \frac{\lambda_r \sigma_{p,r} + \sigma_0}{\sigma_{a,r}(E) + \lambda_r \sigma_{p,r} + \sigma_0} \frac{1}{E} \quad (84)$$

$$\sigma_0 = \left(\sum_{k \neq r} \lambda_k N_k \sigma_{s,k} \right) / N_r \quad (85)$$

where λ_r and λ_k are the IR parameters for resonance nuclide r and the non-resonance nuclide k , respectively. Equation (84) indicates that the scattering of all nuclides is taken into account with use of the IR parameter, that is, the "effective" scattering cross section is used through $\lambda_k \sigma_{s,k}$. When nuclide k is hydrogen, $\lambda_k = 1$, while $\lambda_k < 1$ for other nuclides. In general, the value of the IR parameter becomes smaller when the mass of a nuclide becomes heavier.

Background cross section = 50 barn, ²⁹³K, edited in 172 XMAS groups.

Numerical Procedure

A detailed procedure to evaluate the IR parameter is presented below (MacFarlane and Muir 1994a):

1. Case 1: Perform the slowing down calculation with a homogeneous mixture of hydrogen and a resonance nuclide (e.g., ²³⁸U). The composition of the homogeneous mixture is adjusted to give a typical background cross section for a resonance nuclide. For example, in the case of ²³⁸U in a light water reactor lattice, 50 barn may be used. The evaluated effective cross section is σ_{Case1} .
2. Case 2: Perform another slowing down calculation with a homogeneous mixture of hydrogen and the resonance nuclide used in Case 1. The composition of the homogeneous mixture is slightly changed from that in Case 1 so that the background cross section for the resonance nuclide is increased slightly. If the background cross section cannot be directly specified in the slowing down calculation, the number density of the moderator nuclide is adjusted. In Case 2, for example, 55 barn is used, a number density that is 10% more than that in Case 1. The evaluated effective cross section is σ_{Case2} .
3. Case 3: Perform the third slowing down calculation with a homogeneous mixture of another moderator nuclide (e.g., oxygen) and the resonance nuclide used in Case 1. The composition of the homogeneous mixture is adjusted to give the same background cross section as in Case 2. Since the (potential) scattering cross section is different among nuclides, the

80	2.26E+01	0.986	0.993	0.994	0.949	0.983	0.984	0.148	0.415	0.591
88	7.52E+00	0.872	0.977	0.988	0.654	0.938	0.969	0.043	0.198	0.348

293 K; a represents the mass number; Lower energy for group 88 is 6.16 eV.

composition of the homogeneous mixture is changed accordingly from that in Case 2. In the case of oxygen, the potential scattering cross section is approximately 3.9 barn, while that of hydrogen is 20.5 barn. Thus, the number density of oxygen in Case 3 will be $20.5/3.9 \approx 5.25$ times larger than that of hydrogen in Case 2. The evaluated effective cross section is σ_{Case3} . When the NJOY code is used, one can arbitrarily set the mass of the admixed moderator. Therefore, we can easily perform Case 3 in the NJOY code, as will be described later (MacFarlane and Muir 1994a).

4. Compute the IR parameter by

$$\lambda = \frac{\sigma_{\text{Case3}} - \sigma_{\text{Case1}}}{\sigma_{\text{Case2}} - \sigma_{\text{Case1}}} \quad (86)$$

In (86), the variation in the effective cross section and that of the background cross section is assumed to have a linear relationship. This treatment is justified since the background cross section and the effective cross section has smooth correlation as shown in Fig. 22 and variation of the background cross section is very small in the above calculation.

Examples of evaluation results of the IR parameter for the ^{238}U and ^{235}U absorption cross section are shown in Tables 11 and 12, respectively. In both tables, the 172-group XMAS-type energy group structure is assumed. In the 88th group (7.52 eV–6.16 eV), which includes the large resonance of ^{238}U , the IR parameters for oxygen ($a = 16$), light nuclides ($a = 40$), and uranium ($a = 238$) are approximately 0.87, 0.65, and 0.04, respectively, when the background cross section is 50 barn. This result clearly shows the significance of the IR parameter in the resonance calculation.

Table 12 provides other interesting observations. The IR parameters for ^{235}U are clearly different from those for ^{238}U . For example, the IR parameters of the ^{235}U absorption cross section for oxygen, light nuclide, and uranium are 1.0, 0.77, and 0.15, respectively, in the 88th group. Since the width of the resonance peak for ^{235}U is generally narrower than that for ^{238}U , the IR

293 K; a represents mass number; Lower energy for group 88 is 6.16 eV.

parameter becomes larger than that of ^{238}U . The systematic estimation of the IR parameter clarifies that the IR parameter depends not only on the resonance nuclide, but also on the magnitude of the background cross section, the temperature, and the energy range (energy group).

The above observation highlights a conflict with (84), which is commonly used in many lattice physics codes. In that equation, the IR parameter is assumed to be a constant that is inherent to each moderator nuclide, that is, the dependency of the IR parameter on various other parameters (temperature, background cross section, and energy range) cannot be directly incorporated. This is a limitation of the conventional IR method, in which only one IR parameter is considered for each nuclide.

We should therefore choose an appropriate IR parameter for each nuclide. First, since ^{238}U is a dominant resonance absorber in light water reactor calculations, ^{238}U can be assumed as a typical resonance absorber. For the background cross section, a typical value for ^{238}U (e.g., 50 barn) can be assumed. For the energy range, the major resonance of ^{238}U in 6.7 eV is considered a typical resonance. Fortunately, temperature has less impact on the IR parameter, since hot operating conditions will be used in the evaluation of the IR parameter.

Some additional discussion related to the IR parameter will be useful. In today's lattice physics codes, the tabulation of an effective cross section (more generally, a cross section library) is performed through a nuclear data processing code such as NJOY (MacFarlane and Muir 1994a). In NJOY, the mass of a moderator nuclide and its background cross section are given

independently through user input. The former is given as the $\alpha = \left(\frac{A-1}{A+1}\right)^2$ parameter for the admixed moderator, and the latter is given by a combination of the fraction of the admixed moderator cross section γ and the background cross section σ_0 . Note that the cross section of the admixed moderator is given by $\gamma\sigma_0$. The remaining part, that is, $(1 - \gamma)\sigma_0$, is generally assumed to be hydrogen.

In conventional lattice physics codes, the mass effect of the moderator is treated through the above approach, that is, correction by the IR parameter. However, when we can freely draw a blueprint of a cross section library for a lattice physics code, the mass effect of the moderator can be incorporated by a correction table that is similar to a self-shielding factor table. In this case, the library has a correction table for each nuclide, which gives the correction factor of the effective cross section for various masses of the moderator. Although the size of such a library will be larger than that of the current one, one can expect it to yield a more accurate treatment. Such a consideration becomes especially useful when lattice physics codes are applied to non-LWRs, for example, heavy water reactors, graphite reactors, and fast reactors.

3.5 Resonance Self-Shielding in a Heterogeneous Systems

3.5.1 Neutron Slowing Down in a Heterogeneous Isolated System

Formulation of Neutron Slowing Down Equation

In this subsection, we will discuss resonance self-shielding in a heterogeneous system (Dirac 1943; Weinberg and Wigner 1958; Dresner 1960; Rosenstein 1960; Goldstein and Cohen 1962; Stamm'ler and Abbate 1983; Rothenstein and Segev 1986). Since various difficulties arise in the treatment of a heterogeneous system, we will start with an isolated system, in which there is an isolated lump of resonance material in a large moderator. A fuel rod in a large moderator region, for example, is an isolated system.

Since it is necessary to know the energy dependence of the neutron spectrum in detail in order to evaluate the effect of resonance shielding, we will consider the neutron slowing down equation in an isolated heterogeneous system:

$$\begin{aligned} \Sigma_{t,f}(E)\phi_f(E)V_f = P_{f \rightarrow f}(E)V_f \int_0^\infty dE' \Sigma_{s,f}(E' \rightarrow E)\phi_f(E') \\ + P_{m \rightarrow f}(E)V_m \int_0^\infty dE' \Sigma_{s,m}(E' \rightarrow E)\phi_m(E') \end{aligned} \quad (87)$$

where

$\Sigma_{t,f}(E)$: macroscopic total cross section in fuel,

$\Sigma_{s,f}(E' \rightarrow E)$: macroscopic scattering cross section in fuel,

$\Sigma_{s,m}(E' \rightarrow E)$: macroscopic scattering cross section in moderator,

$\phi_f(E), \phi_m(E')$: neutron fluxes in fuel and moderator, respectively,

V_f, V_m : volumes of fuel and moderator, respectively, and

$P_{f \rightarrow f}(E), P_{m \rightarrow f}(E)$: fuel-to-fuel, and moderator-to-fuel collision probabilities, respectively.

Space dependent neutron transport can be described in various ways, for example, the discrete-ordinates method, or the method of characteristics. However, the collision probability method is well suited to describe the neutron balance in fuel and moderator regions, since in a simple system, analytical approaches with some approximations can be applied to collision probabilities.

The approximations involved for the collision probability calculation have a crucial meaning in the equivalence theory, as will be discussed later.

If we assume that the neutron slowing down is dominated by elastic scattering, the right-hand side of (87) can be written as

$$\begin{aligned} \Sigma_{t,f}(E)\phi_f(E)V_f &= P_{f\rightarrow f}(E)V_f \sum_{k\in f} \int_E^{E/\alpha_k} \frac{dE' N_k \sigma_{es,k}(E') \phi_f(E')}{(1-\alpha_k)E'} \\ &+ P_{m\rightarrow f}(E)V_m \sum_{k\in m} \int_E^{E/\alpha_k} \frac{dE' N_k \sigma_{es,k}(E') \phi_m(E')}{(1-\alpha_k)E'} \end{aligned} \quad (88)$$

where k is a nuclide index.

When the NR approximation discussed in 3.4.2 is applied to the right-hand side of (88), it becomes

$$\Sigma_{t,f}(E)\phi_f(E)V_f = \frac{1}{E} (P_{f\rightarrow f}(E)V_f \Sigma_{p,f} + P_{m\rightarrow f}(E)V_m \Sigma_{p,m}) \quad (89)$$

where

$\Sigma_{p,f}$: macroscopic potential scattering cross section of fuel, and
 $\Sigma_{p,m}$: macroscopic potential scattering cross section of moderator.

In an isolated system, the fuel-to-fuel collision probability can be written as the fuel-to-moderator collision probability

$$P_{f\rightarrow f}(E) = 1 - P_{f\rightarrow m}(E) \quad (90)$$

where

$P_{f\rightarrow m}(E)$: fuel-to-moderator collision probability.

Equation (90) can be derived from the normalization condition of collision probability, that is, the sum of the collision probabilities for fuel-to-fuel, and fuel-to-moderator, is unity. By substituting (90) into (89), we obtain

$$\Sigma_{t,f}(E)\phi_f(E)V_f = \frac{1}{E} ((1 - P_{f\rightarrow m}(E)) V_f \Sigma_{p,f} + P_{m\rightarrow f}(E) V_m \Sigma_{p,m}) \quad (91)$$

Reciprocity Theorem

Two different collision probabilities now appear in (91). A further simplification can be made to derive the analytic form for the energy dependence of the neutron spectrum in the fuel region. Next, we will consider the reciprocity theorem

$$P_{m\rightarrow f}(E) V_m \Sigma_{p,m} = P_{f\rightarrow m}(E) V_f \Sigma_{t,f}(E) \quad (92)$$

In (92), the total cross section of the moderator is assumed to be equal to the potential scattering cross section, which is energy independent.

An intuitive understanding of (92) is as follows. Equation (92) is rewritten as

$$\frac{P_{m\rightarrow f}(E)}{V_f \Sigma_{t,f}(E)} = \frac{P_{f\rightarrow m}(E)}{V_m \Sigma_{p,m}} \quad (93)$$

Since $P_{m \rightarrow f}(E)$ is the collision probability from moderator to fuel, it is proportional to the attenuation between moderator and fuel, the fuel volume, and the total cross section of the fuel. Therefore, $P_{m \rightarrow f}(E)/(V_f \Sigma_{t,f}(E))$ represents the attenuation between moderator and fuel. A similar consideration of $P_{f \rightarrow m}(E)$ yields $P_{f \rightarrow m}(E)(V_m \Sigma_{p,m})$ that is the attenuation between fuel and moderator. Since the neutron attenuation between two points does not have directional dependence (i.e., attenuation from A to B is equivalent to attenuation from B to A), we achieve the equality of (93). Note that $\Sigma_{p,m}$ and $\Sigma_{t,m}$ are assumed to be equal in the above discussion.

By substituting (92) into (91), we obtain

$$\phi_f(E) = \frac{1}{E} \left((1 - P_{f \rightarrow m}(E)) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + P_{f \rightarrow m}(E) \right) \quad (94)$$

If an accurate value for the fuel-to-moderator collision probability $P_{f \rightarrow m}(E)$ is known, the accurate energy dependence of the neutron flux can be evaluated using (94). A detailed numerical calculation for $P_{f \rightarrow m}(E)$ would give, of course, an accurate result, but such numerical calculation would require considerable computation time. An approximate analytic expression for $P_{f \rightarrow m}(E)$ is therefore needed for an efficient evaluation of the energy dependence of the neutron flux. This approach yields an important by-product: the concept of equivalence between heterogeneous and homogeneous systems, which will be discussed later.

Estimation of Escape Probability and Average Chord Length

In an isolated system, the collision probability from the fuel-to-moderator region is equivalent to the neutron escape probability from the fuel, $P_e(E)$, which is defined by the probability that a neutron born in the fuel region will escape from the fuel without a collision in the fuel, and will suffer its first collision in the moderator.

The escape probability of a neutron, which is flying in direction $\vec{\Omega}$, and whose distance to the fuel lump surface is s , is given by $\exp(-\Sigma_{t,f}(E)s)$. Since the small volume around the neutron is expressed as $(\vec{n} \cdot \vec{\Omega}) dS ds$, the volume average of the escape probability for direction $\vec{\Omega}$ is given by

$$\begin{aligned} P_e(E, \vec{\Omega}) &= \frac{1}{V_f} \int_S (\vec{n} \cdot \vec{\Omega}) dS \int_0^l \exp(-\Sigma_{t,f}(E)s) ds \\ &= \frac{1}{\Sigma_{t,f}(E)V_f} \int_S (\vec{n} \cdot \vec{\Omega}) dS \{1 - \exp(-\Sigma_{t,f}(E)l)\} \end{aligned} \quad (95)$$

where

- $\vec{\Omega}$: neutron flight direction,
- \vec{n} : normal vector to surface,
- S : surface area of a fuel lump,
- l : track length of neutron in a fuel lump (chord length), and
- s : coordinate along neutron flight direction.

Note that the integration of (95) is carried out for $\vec{n} \cdot \vec{\Omega} > 0$.

The physical meaning of (95) can be explained by  Fig. 16.

Since $P_e(E, \vec{\Omega})$ depends on $\vec{\Omega}$, the average on $\vec{\Omega}$ is considered in order to obtain the final form of $P_e(E)$, that is,

$$P_e(E) = \frac{1}{4\pi} \int_{\vec{n} \cdot \vec{\Omega} > 0} P_e(E, \vec{\Omega}) d\vec{\Omega} \quad (96)$$

■ **Figure 16**
Calculation of escape probability

Using (95) and (96), the escape probability from an isolated fuel lump is given as follows:

$$\begin{aligned} P_e(E) &= \frac{1}{4\pi V_f} \int_{\vec{n} \cdot \vec{\Omega} > 0} d\vec{\Omega} \int_S (\vec{n} \cdot \vec{\Omega}) dS \int_0^l \exp(-\Sigma_{t,f}(E)s) ds \\ &= \frac{1}{4\pi \Sigma_{t,f}(E) V_f} \int_{\vec{n} \cdot \vec{\Omega} > 0} d\vec{\Omega} \int_S dS (\vec{n} \cdot \vec{\Omega}) \{1 - \exp(-\Sigma_{t,f}(E)l)\} \end{aligned} \quad (97)$$

In order to obtain a detailed form of (97), the distribution function of chord length l , which also depends on $\vec{\Omega}$, is necessary. The distribution function of the chord length is given as follows (Dirac 1943):

$$f(l)dl = \frac{\int_l^{l+dl} d\vec{\Omega} \int_S dS (\vec{n} \cdot \vec{\Omega})}{\int_{\vec{n} \cdot \vec{\Omega} > 0} d\vec{\Omega} \int_S dS (\vec{n} \cdot \vec{\Omega})} \quad (98)$$

The value of $f(l)dl$ represents the probability of the chord length's appearance between l and $l + dl$. ► **Figure 16** presents $(\vec{n} \cdot \vec{\Omega})dS$ as the weight of a chord, whose direction is $\vec{\Omega}$, and which cuts the surface area of dS . As a result, the numerator of (98) shows the summation of the weights of chords whose lengths are between l and $l + dl$, and the denominator shows the summation of the weight of all chords.

The denominator of (98) can be rewritten as follows:

$$\begin{aligned} \int_{\vec{n} \cdot \vec{\Omega} > 0} d\vec{\Omega} \int_S dS (\vec{n} \cdot \vec{\Omega}) &= \int_{\cos \theta > 0} d\vec{\Omega} \int_S dS \cos \theta = \int_0^1 \mu d\vec{\Omega} \int_S dS \\ &= \int_0^1 2\pi \mu d\mu \int_S dS = \pi S \end{aligned} \quad (99)$$

where

$$\begin{aligned} \mu &= \cos \theta, \\ d\vec{\Omega} &= \cos \theta d\theta \int_0^{2\pi} d\varphi = 2\pi d\mu. \end{aligned}$$

The average chord length \bar{l} is given by

$$\bar{l} = \int_0^\infty l f(l) dl \quad (100)$$

■ Table 13

Parameters for resonance calculation in simple heterogeneous geometry

Geometry	Surface area	Volume	Average chord length
Slab (H : width of slab)	$2S$	SH	$2H$
Cylinder (R : radius)	$2\pi R$	πR^2	$2R$
Hollow cylinder*	$2\pi(R+r)$	$\pi(R^2-r^2)$	$2(R-r)$
Sphere (R : radius)	$4\pi R^2$	$4\pi R^3/3$	$4R/3$

*Void is assumed for hollow part. Inner radius is r .

By substituting (98) and (99) into (100), we obtain

$$\bar{l} = \frac{1}{\pi S} \int_{4\pi} d\vec{\Omega} \int_S dS l(\vec{n} \cdot \vec{\Omega}) = \frac{1}{\pi S} \int_{4\pi} d\vec{\Omega} V = \frac{V \cdot 4\pi}{\pi S} = \frac{4V}{S} \quad (101)$$

Note that the following relationship is used in the above derivation:

$$\int_S dS l(\vec{n} \cdot \vec{\Omega}) = V \quad (102)$$

A chord in a lump and its nearby volume constitutes a small “cylinder,” whose bottom area and height are dS and $l(\vec{n} \cdot \vec{\Omega})$, respectively. Thus, $dS l(\vec{n} \cdot \vec{\Omega})$ indicates the volume of the small cylinder in which a chord is contained. Therefore, the integration of the volume of each small cylinder gives the total volume of a lump.

Equation (101) suggests that the average chord length is given by the volume and the surface area of a lump. Typical average chord lengths using simple geometry, which frequently appear in lattice physics computations, are summarized in ► Table 13.

Using (98), (99), and (101), (98) can be rewritten as

$$\int_l^{l+dl} d\vec{\Omega} \int_S dS(\vec{n} \cdot \vec{\Omega}) = \pi S \cdot f(l) dl = \frac{4\pi V}{\bar{l}} f(l) dl \quad (103)$$

By substituting (103) into (97), we obtain

$$\begin{aligned} P_e(E) &= \frac{1}{4\pi \Sigma_{t,f}(E) V_f} \int_{\vec{n} \cdot \vec{\Omega} > 0} d\vec{\Omega} \int_S dS(\vec{n} \cdot \vec{\Omega}) \{1 - \exp(-\Sigma_{t,f}(E)l)\} \\ &= \frac{1}{4\pi \Sigma_{t,f}(E) V_f} \int_0^\infty \int_l^{l+dl} d\vec{\Omega} \int_S dS(\vec{n} \cdot \vec{\Omega}) \{1 - \exp(-\Sigma_{t,f}(E)l)\} \\ &= \frac{1}{4\pi \Sigma_{t,f}(E) V_f} \int_0^\infty \frac{4\pi V_f}{\bar{l}} f(l) dl \{1 - \exp(-\Sigma_{t,f}(E)l)\} \\ &= \frac{1}{\Sigma_{t,f}(E) \bar{l}} \int_0^\infty dl f(l) \{1 - \exp(-\Sigma_{t,f}(E)l)\} \end{aligned} \quad (104)$$

When the actual form of the chord distribution function is known, an analytic form of the escape probability can be derived. Though the actual chord distribution function depends on the shape of the fuel lump, we assume it is given by the following:

$$f(l) dl = \frac{1}{\bar{l}} \exp(-l/\bar{l}) dl \quad (105)$$

Equation (105) indicates the probability of a longer chord existing exponentially decreases as the length of the chord increases (Sauer 1963). Such a distribution is, clearly, a poor approximation for many shapes. The form of (105) remains important, however, if we are to derive the equivalence between heterogeneous and homogeneous systems.

By substituting (105) into (104), we obtain

$$\begin{aligned}
 P_e(E) &= \frac{1}{\Sigma_{t,f}(E)\bar{l}} \int_0^\infty dl f(l) \{1 - \exp(-\Sigma_{t,f}(E)l)\} \\
 &= \frac{1}{\Sigma_{t,f}(E)\bar{l}} \int_0^\infty dl \frac{1}{l} \exp(-l/\bar{l}) \{1 - \exp(-\Sigma_{t,f}(E)l)\} \\
 &= \frac{1}{\Sigma_{t,f}(E)\bar{l} + 1}
 \end{aligned} \tag{106}$$

Equation (106) is Wigner's rational approximation for the escape probability (Weinberg and Wigner 1958). Equation (106) suggests that the escape probability from a lump, which has a great optical thickness $\Sigma_{t,f}(E)\bar{l}$, becomes smaller. This is the case for a large total cross section and/or large average chord length. On the contrary, when the optical thickness of a lump is small, the escape probability approaches unity. Such a situation can be observed in a small lump with a small total cross section. We see then, that Wigner's rational approximation satisfies our intuitive sense of the physical properties of the escape probability. In fact, Wigner's rational approximation gives an accurate value for the black limit (infinite $\Sigma_{t,f}(E)\bar{l}$, $P_e(E) = 0$) and the white limit (zero $\Sigma_{t,f}(E)\bar{l}$, $P_e(E) = 1$).

Approximations of Neutron Spectrum in a Heterogeneous System

By approximating the escape probability using the rational approximation in (106), we can derive the "equivalence" between heterogeneous and homogeneous systems, as follows.

Equation (94) is rewritten as follows:

$$\begin{aligned}
 \phi_f(E) &= \frac{1}{E} \left((1 - P_{f \rightarrow m}(E)) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + P_{f \rightarrow m}(E) \right) \\
 &= \frac{1}{E} \left((1 - P_e(E)) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + P_e(E) \right)
 \end{aligned} \tag{107}$$

By substituting (106) into (107), we can derive the following equation:

$$\begin{aligned}
 \phi_f(E) &= \frac{1}{E} \left(\left(1 - \frac{1}{\Sigma_{t,f}(E)\bar{l} + 1} \right) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + \frac{1}{\Sigma_{t,f}(E)\bar{l} + 1} \right) \\
 &= \frac{1}{E} \frac{\Sigma_{p,f}\bar{l} + 1}{\Sigma_{t,f}(E)\bar{l} + 1} \\
 &= \frac{1}{E} \frac{\Sigma_{p,f} + 1/\bar{l}}{\Sigma_{t,f}(E) + 1/\bar{l}}
 \end{aligned}$$

$$\begin{aligned}
&= \frac{1}{E} \frac{\Sigma_{p,f} + \Sigma_e}{\Sigma_{t,f}(E) + \Sigma_e} \\
&= \frac{1}{E} \frac{N_r(\sigma_{p,r} + \sigma_{0,f}) + \Sigma_e}{N_r(\sigma_{t,r}(E) + \sigma_{0,f}) + \Sigma_e} \\
&= \frac{1}{E} \frac{\sigma_{p,r} + (\sigma_{0,f} + \Sigma_e/N_r)}{\sigma_{t,r}(E) + (\sigma_{0,f} + \Sigma_e/N_r)} \tag{108}
\end{aligned}$$

where

Σ_e : macroscopic escape cross section,

N_r : number density of the resonance nuclide,

$\sigma_{p,r}$: potential scattering cross section of the resonance nuclide, and

$\sigma_{0,f} = \sum_{k \neq r} N_k \sigma_{s,k} / N_r$: background cross section for the resonance nuclide.

The escape cross section is defined by the inverse of the average chord length ($\Sigma_e = 1/\bar{l}$). When the average chord length is small, the escape cross section becomes large, and vice versa. This suggests that the escape cross section is related to the escape probability from a fuel lump.

Various assumptions are used to derive the above equivalence between heterogeneous and homogeneous systems. They are summarized as follows:

- No resonance overlap is considered.
- Nonresonant nuclide has a constant scattering cross section.
- Resonant nuclide has a constant scattering cross section.
- Neutron slowing down is dominated by elastic scattering.
- Energy dependence of neutron flux at nonresonant part is asymptotic ($1/E$).
- Use of narrow resonance (NR) approximation for neutron slowing down source.
- The escape probability from a lump is approximated by Wigner's rational approximation, that is, (106).

The accuracy of (108) thus depends on the validity of the above assumptions. The approximation for the escape probability, particularly, has a significant impact on the equivalence theory.

3.5.2 Equivalence Theory

When we compare (77) and (108), an apparent similarity can be found. Indeed, by adding the escape cross section to both the numerator and the denominator of (77), we can derive (108). The physical interpretation of this relationship is given as follows.

When a fuel lump has a large escape probability (i.e., an optically thin lump), neutrons entering from the moderator can easily reach everywhere in the fuel lump. This means that the energy dependence (depression) of the neutron flux at the resonance peak is mitigated by the incoming neutrons from the moderator. In other words, neutrons in a fuel lump with a large escape probability will likely experience a collision in the moderator, so that the depression of the neutron flux in the fuel becomes smaller. This effect is captured through the escape cross section. This is analogous to our discussion of the background cross section given by (78). In the previous discussion of a homogeneous system, we noted that the depression of the neutron flux at the resonance peak is mitigated by the background cross section.

The above discussion is the essence of the equivalence theory between heterogeneous and homogeneous systems, that is, the energy dependence of neutron flux can be approximated in the same analytic form by a different argument, σ_0 or $\sigma_{0,f} + \Sigma_e/N_r$.

To sum up, the background cross section with the NR approximation is given by
In a homogeneous system:

$$\sigma_{0,r} = \sum_{k \neq r} N_k \sigma_{p,k} / N_r = \sum_{k \neq r} N_k \sigma_{s,k} / N_r \quad (109)$$

In heterogeneous system:

$$\sigma_{0,r} = \sigma_{0,f} + \Sigma_e / N_r = \sum_{k \neq r} N_k \sigma_{s,k} / N_r + \Sigma_e / N_r \quad (110)$$

In other words, the effect of heterogeneity on the energy dependence of the neutron flux is represented by the fictitious escape cross section, which is equivalent to, and has the same effect as, the background cross section. Therefore, when the effective cross sections are tabulated for various background cross sections, the result can be used not only for a homogeneous system, but also for a heterogeneous system. From the viewpoint of cross section preparation, this equivalence significantly reduces the size of the tabulation table for effective cross sections. If the equivalence is not used, the effective cross sections for various heterogeneous systems will be tabulated independently. The tabulation of effective cross sections will be discussed in more detail in [3.6](#).

The distribution function of the chord length given by (105) is chosen in order to derive an analytic form of neutron flux that is consistent with that of a homogeneous system. This is a key point of the equivalence theory. In this context, other expressions for the escape probability can be used in the framework of the equivalence theory, as is discussed in [3.5.3](#).

3.5.3 Various Approximations for Escape Probability

Incorporation of the Bell Factor

In [3.5.1](#), the escape probability from a fuel lump was approximated by Wigner's rational approximation of (106) in order to achieve equivalence between heterogeneous and homogeneous systems. Though Wigner's rational approximation reflects our intuition regarding the behavior of the escape probability, better approximations can be used (Levine 1963; Carlvik 1967; Chiarella and Keane 1969; Mizuta 1970; Stamm'ler and Abbate 1983; Hébert and Marleau 1991). One of the improved rational approximations involves a correction by the Bell factor, as follows:

$$P_e(E) = \frac{a_B}{\Sigma_{t,f}(E)\bar{l} + a_B} = \frac{a_B \Sigma_e}{\Sigma_{t,f}(E) + a_B \Sigma_e} \quad (111)$$

where

a_B : the Bell factor.

The escape probability, $P_e(E)$, is a function of the total cross section and the shape of the fuel lump (i.e., the average chord length). Therefore, when the escape probability is evaluated by

an accurate method (e.g., numerical calculation by the collision probability method), the Bell factor can be evaluated by

$$a_B = \frac{P_e}{1 - P_e} \Sigma_{t,f} \bar{l} \quad (112)$$

In a typical situation that appears in LWR lattice physics computations, $a_B = 1.1$ – 1.4 gives adequate results (Levine 1963). By substituting (111) into (107), we obtain

$$\phi_f(E) = \frac{1}{E} \frac{\sigma_{p,r} + (\sigma_{0,f} + a_B \Sigma_e / N_r)}{\sigma_{t,r}(E) + (\sigma_{0,f} + a_B \Sigma_e / N_r)} \quad (113)$$

A comparison of (113) and (108) clarifies the merit of (111). In fact, the escape cross section is modified from Σ_e to $a_B \Sigma_e$ in (113). In other words, the escape probability (which is equivalent to the neutron inflow effect) is underestimated in Wigner's rational approximation as it is conventionally used, as given by (106).

Though the Bell factor is considered as an adjustment parameter, its range of validity can be mathematically derived as follows. When the value of $\Sigma_{t,f}(E) \bar{l}$ is small, (104) is approximated by the Taylor series expansion

$$\begin{aligned} P_e(E) &= \frac{1}{\Sigma_{t,f}(E) \bar{l}} \int_0^\infty dl f(l) \{1 - \exp(-\Sigma_{t,f}(E)l)\} \\ &\cong \frac{1}{\Sigma_{t,f}(E) \bar{l}} \int_0^\infty dl f(l) \left[1 - \left\{1 - \Sigma_{t,f}(E)l + (\Sigma_{t,f}(E)l)^2/2\right\}\right] \\ &= \frac{1}{\bar{l}} \int_0^\infty dl f(l)l - \frac{1}{2} \frac{\Sigma_{t,f}(E)}{\bar{l}} \int_0^\infty dl f(l)l^2 \\ &= 1 - \frac{1}{2} \Sigma_{t,f}(E) \frac{\bar{l}^2}{\bar{l}} \\ &\cong \frac{1}{1 + \frac{1}{2} \Sigma_{t,f}(E) \frac{\bar{l}^2}{\bar{l}}} \\ &= \frac{a_B}{\Sigma_{t,f}(E) \bar{l} + a_B} \end{aligned} \quad (114)$$

where

$$a_B = 2 \frac{(\bar{l})^2}{\bar{l}^2}.$$

The Schwarz inequality is established for arbitrary function $f(l)$.

$$\int l^2 f(l) dl > \left\{ \int l f(l) dl \right\}^2 \quad (115)$$

From (115), we have the following relationship:

$$\bar{l}^2 > (\bar{l})^2 \quad (116)$$

Therefore,

$$a_B = 2 \frac{(\bar{l})^2}{\bar{l}^2} < 2 \quad (117)$$

Utilization of the Bell factor increases the accuracy of the escape probability, which can be rigorously reproduced for a particular energy point (i.e., particular fuel cross section) by choosing an appropriate value for the Bell factor. However, such rigorous reproduction of the escape probability for all energy ranges (i.e., for various fuel cross sections) is impossible, so it still includes an error factor that has the potential to impact resonance calculations.

N-Terms Rational Approximations

Further improvement of the escape probability can be achieved by using the summation form of the rational approximations. In order to derive this approximation, the distribution function of the chord length is approximated by a summation of the exponential functions

$$f(l)dl = \sum_{n=1}^N c_n \exp(-d_n l) dl \quad (118)$$

By substituting (118) into (104), we obtain

$$\begin{aligned} P_e(E) &= \frac{1}{\Sigma_{t,f}(E)\bar{l}} \int_0^\infty dl \sum_{n=1}^N c_n \exp(-d_n l) \{1 - \exp(-\Sigma_{t,f}(E)l)\} \\ &= \frac{1}{\Sigma_{t,f}(E)\bar{l}} \sum_{n=1}^N c_n \int_0^\infty dl \exp(-d_n l) \{1 - \exp(-\Sigma_{t,f}(E)l)\} \\ &= \sum_{n=1}^N \frac{c_n/d_n}{\Sigma_{t,f}(E)\bar{l} + d_n\bar{l}} \\ &= \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E)\bar{l} + a_n} \end{aligned} \quad (119)$$

where

$$\begin{aligned} a_n &= d_n \bar{l}, \\ b_n a_n &= c_n / d_n. \end{aligned}$$

For a very small optical length, (119) can be reduced into

$$P_e(E) = \lim_{\Sigma_{t,f}(E)\bar{l} \rightarrow 0} \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E)\bar{l} + a_n} = \sum_{n=1}^N b_n \quad (120)$$

Since $P_e(E)$ should be approaching unity for a very small optical length, we obtain the normalization condition as follows:

$$\sum_{n=1}^N b_n = 1 \quad (121)$$

Wigner's rational approximation of (106) gives an accurate result for an escape probability with a large $\Sigma_{t,f}(E)\bar{l}$. In order to be consistent with the derivatives of (106) when there is large $\Sigma_{t,f}(E)\bar{l}$, the following constraint on the coefficients of (119) should be satisfied:

$$\sum_{n=1}^N b_n a_n = 1 \quad (122)$$

Note that (122) is an additional constraint, and may not necessarily be satisfied. For example, (111) and (124) do not satisfy (122).

Equation (119) is considered as a superposition of the rational approximations with the Bell factor, that is, a_n and b_n are the Bell factor for each rational approximation and the corresponding weight of each term.

Carlvik's Two-Term Rational Approximation

A well-known approximation for the escape probability for the cylindrical geometry in (119) is given by Carlvik et al. (Carlvik 1967; Stamm'ler and Abbate 1983):

$$P_e(E) = 2 \frac{2}{\Sigma_{t,f}(E)\bar{l} + 2} - \frac{3}{\Sigma_{t,f}(E)\bar{l} + 3} \quad (123)$$

For slab geometry, Roman gives the following (Stamm'ler and Abbate 1983):

$$P_e(E) = 1.1 \frac{1.4}{\Sigma_{t,f}(E)\bar{l} + 1.4} - 0.1 \frac{5.4}{\Sigma_{t,f}(E)\bar{l} + 5.4} \quad (124)$$

The three term rational approximation is also considered to increase the accuracy of the escape probability from a fuel lump (Hébert and Marleau 1991).

By substituting (119) into (107), we obtain

$$\begin{aligned} \phi_f(E) &= \frac{1}{E} \left((1 - P_e(E)) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + P_e(E) \right) \\ &= \frac{1}{E} \left(\left(1 - \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E)\bar{l} + a_n} \right) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E)\bar{l} + a_n} \right) \\ &= \frac{1}{E} \left(\left(\sum_{n=1}^N b_n - \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E)\bar{l} + a_n} \right) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E)\bar{l} + a_n} \right) \\ &= \frac{1}{E} \left(\sum_{n=1}^N b_n \frac{\Sigma_{t,f}(E)\bar{l}}{\Sigma_{t,f}(E)\bar{l} + a_n} \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E)\bar{l} + a_n} \right) \\ &= \frac{1}{E} \sum_{n=1}^N b_n \frac{\Sigma_{p,f}\bar{l} + a_n}{\Sigma_{t,f}(E)\bar{l} + a_n} \\ &= \frac{1}{E} \sum_{n=1}^N b_n \frac{\sigma_{p,r} + \sigma_{0,f} + a_n/\bar{l}/N_r}{\sigma_{t,r}(E) + \sigma_{0,f} + a_n/\bar{l}/N_r} \\ &= \frac{1}{E} \sum_{n=1}^N b_n \frac{\sigma_{p,r} + \sigma_{0,f} + a_n \Sigma_e / N_r}{\sigma_{t,r}(E) + \sigma_{0,f} + a_n \Sigma_e / N_r} \\ &= \frac{1}{E} \sum_{n=1}^N b_n \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}} \end{aligned} \quad (125)$$

where

$$\sigma_{0,n} = \sigma_{0,f} + a_n \Sigma_e / N_r.$$

Evaluation of the Effective Cross Section from N-Term Rational Approximation

Equation (125) is given by the superposition of (113). Though the background cross section for each term in (125) is given by $\sigma_{0,n} = \sigma_{0,f} + a_n \Sigma_e / N_r$, it cannot be directly applied to the interpolation of effective cross sections, due to the superposition of several terms. In this case, the equivalent background cross section for (125) is given as follows:

$$\begin{aligned}
 \sigma_{g,x} &= \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \phi_f(E)}{\int_{E_g}^{E_{g-1}} dE \phi_f(E)} \\
 &= \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \frac{1}{E} \sum_{n=1}^N b_n \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}}{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sum_{m=1}^N b_m \frac{\sigma_{p,r} + \sigma_{0,m}}{\sigma_{t,r}(E) + \sigma_{0,m}}} \\
 &= \sum_{n=1}^N b_n \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}}{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}} \frac{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}}{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sum_{m=1}^N b_m \frac{\sigma_{p,r} + \sigma_{0,m}}{\sigma_{t,r}(E) + \sigma_{0,m}}} \quad (126)
 \end{aligned}$$

In order to simplify (126), we can use the following relationship:

$$\sigma_{g,x,n} = \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \phi_n(E)}{\int_{E_g}^{E_{g-1}} dE \phi_n(E)} = \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}}{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}} \quad (127)$$

In (127), $\sigma_{g,x,n}$ is a effective cross section whose background cross section is given by $\sigma_{0,n}$.

Next, we use the following relationship:

$$\begin{aligned}
 \sigma_{g,a,n} &= \frac{\int_{E_g}^{E_{g-1}} dE \sigma_{a,r}(E) \phi_n(E)}{\int_{E_g}^{E_{g-1}} dE \phi_n(E)} = \frac{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sigma_{a,r}(E) \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}}{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}} \\
 &= \frac{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sigma_{a,r}(E) \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}}{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{a,r}(E) - \sigma_{a,r}(E) + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}} \\
 &= \frac{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sigma_{a,r}(E) \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}}{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} - \int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sigma_{a,r}(E) \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}} \frac{1}{\sigma_{p,r} + \sigma_{0,n}}} \\
 &= \frac{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sigma_{a,r}(E) \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}}{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} - \frac{1}{\sigma_{p,r} + \sigma_{0,n}} \int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sigma_{a,r}(E) \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}} \quad (128)
 \end{aligned}$$

From (128), we have

$$\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sigma_{a,r}(E) \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}} \bigg/ \int_{E_g}^{E_{g-1}} dE \frac{1}{E} = \frac{\sigma_{g,a,n}}{1 + \frac{\sigma_{g,a,n}}{\sigma_{p,r} + \sigma_{0,n}}} \quad (129)$$

By using (129), we can derive the following equation:

$$\begin{aligned} & \frac{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}}{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sum_{m=1}^N b_m \frac{\sigma_{p,r} + \sigma_{0,m}}{\sigma_{t,r}(E) + \sigma_{0,m}}} \\ &= \frac{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}}{\sum_{m=1}^N b_m \int_{E_g}^{E_{g-1}} dE \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{0,m}}{\sigma_{t,r}(E) + \sigma_{0,m}}} \\ &= \frac{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{a,r}(E) - \sigma_{a,r}(E) + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}}{\sum_{m=1}^N b_m \int_{E_g}^{E_{g-1}} dE \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{a,r}(E) - \sigma_{a,r}(E) + \sigma_{0,m}}{\sigma_{t,r}(E) + \sigma_{0,m}}} \\ &= \frac{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} - \int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sigma_{a,r}(E) \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}} \frac{1}{\sigma_{p,r} + \sigma_{0,n}}}{\sum_{m=1}^N b_m \left(\int_{E_g}^{E_{g-1}} dE \frac{1}{E} - \int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sigma_{a,r}(E) \frac{\sigma_{p,r} + \sigma_{0,m}}{\sigma_{t,r}(E) + \sigma_{0,m}} \frac{1}{\sigma_{p,r} + \sigma_{0,m}} \right)} \\ &= \frac{1 - \frac{1}{\sigma_{p,r} + \sigma_{0,n}} \int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sigma_{a,r}(E) \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}} \bigg/ \int_{E_g}^{E_{g-1}} dE \frac{1}{E}}{\sum_{m=1}^N b_m \left(1 - \frac{1}{\sigma_{p,r} + \sigma_{0,m}} \int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sigma_{a,r}(E) \frac{\sigma_{p,r} + \sigma_{0,m}}{\sigma_{t,r}(E) + \sigma_{0,m}} \bigg/ \int_{E_g}^{E_{g-1}} dE \frac{1}{E} \right)} \\ &= \frac{1 - \frac{1}{\sigma_{p,r} + \sigma_{0,n}} \frac{\sigma_{g,a,n}}{1 + \sigma_{g,a,n}/(\sigma_{p,r} + \sigma_{0,n})}}{\sum_{m=1}^N b_m \left(1 - \frac{1}{\sigma_{p,r} + \sigma_{0,m}} \frac{\sigma_{g,a,m}}{1 + \sigma_{g,a,m}/(\sigma_{p,r} + \sigma_{0,m})} \right)} \\ &= \frac{f_n}{\sum_{m=1}^N b_m f_m} \quad (130) \end{aligned}$$

where

$$f_n = \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{p,r} + \sigma_{0,n} + \sigma_{g,a,n}}.$$

Finally, by using (127) and (130), (126) is rewritten as follows:

$$\sigma_{g,x} = \frac{\sum_{n=1}^N w_n \sigma_{g,x,n}}{\sum_{n=1}^N w_n} \quad (131)$$

where

$$w_n = b_n f_n.$$

Resonance Integral and Effective Cross Section

When the resonance integral is tabulated in a cross section library, the following relationship can be used (Stamm'ler et al. 1973):

$$\begin{aligned}
 \sigma_{g,x} &= \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \phi_f(E)}{\int_{E_g}^{E_{g-1}} dE \phi_f(E)} \\
 &= \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \frac{1}{E} \sum_{n=1}^N b_n \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}}{\int_{E_g}^{E_{g-1}} dE \frac{1}{E} \sum_{n=1}^N b_n \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}} \\
 &= \frac{\sum_{n=1}^N b_n \int_{E_g}^{E_{g-1}} dE \sigma_x(E) \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}}{\sum_{n=1}^N b_n \int_{E_g}^{E_{g-1}} dE \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}}} \\
 &= \frac{\sum_{n=1}^N b_n \left(\int_{E_g}^{E_{g-1}} (dE/E) \right) \cdot I_{g,x}(\sigma_{0,n})}{\sum_{n=1}^N b_n \int_{E_g}^{E_{g-1}} dE \frac{1}{E} \left(1 - \frac{\sigma_{a,r}(E)}{\sigma_{t,r}(E) + \sigma_{0,n}} \right)} \\
 &= \frac{\sum_{n=1}^N b_n \left(\int_{E_g}^{E_{g-1}} (dE/E) \right) \cdot I_{g,x}(\sigma_{0,n})}{\sum_{n=1}^N b_n \left(\int_{E_g}^{E_{g-1}} (dE/E) \right) - \sum_{n=1}^N b_n \int_{E_g}^{E_{g-1}} dE \sigma_{a,r}(E) \frac{1}{E} \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}} \frac{1}{\sigma_{p,r} + \sigma_{0,n}}} \\
 &= \frac{\sum_{n=1}^N b_n \left(\int_{E_g}^{E_{g-1}} (dE/E) \right) \cdot I_{g,x}(\sigma_{0,n})}{\left(\int_{E_g}^{E_{g-1}} (dE/E) \right) - \sum_{n=1}^N b_n \left(\int_{E_g}^{E_{g-1}} (dE/E) \right) \cdot I_{g,a}(\sigma_{0,n}) / (\sigma_{p,r} + \sigma_{0,n})} \\
 &= \frac{\sum_{n=1}^N b_n I_{g,x}(\sigma_{0,n})}{1 - \sum_{n=1}^N b_n I_{g,a}(\sigma_{0,n}) / (\sigma_{p,r} + \sigma_{0,n})} \tag{132}
 \end{aligned}$$

where $I_{g,x}$ is the resonance integral per unit lethargy width as defined by

$$I_{g,x}(\sigma_{0,n}) = \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \phi_n(E)}{\int_{E_g}^{E_{g-1}} dE \frac{1}{E}} \approx \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \left(\frac{1}{E} \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}} \right)}{\int_{E_g}^{E_{g-1}} dE \frac{1}{E}}$$

The resonance integral, which is the energy integration of the reaction rate that is defined by $\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \phi(E)$, is used instead of the effective cross section in the resonance calculation of

Figure 17

Comparison of various approximations for the escape probability from an infinite cylinder. The horizontal axis shows the average optical length of an infinite cylinder, that is, diameter multiplied by the macroscopic total cross section

some lattice physics codes, for example, the WIMS code. The resonance integral and the effective cross section can be converted into each other using (181), and can thus be considered as almost “equivalent” quantities. As a shortcut for (132), the following can be used as an “equivalent” background cross section:

$$\bar{\sigma}_0 = \left(\sum_{n=1}^N b_n \sqrt{\sigma_{0,n}} \right)^2 \quad (133)$$

The above relationship is justified, since the resonance integral has a strong correlation with the square root of the background cross section for the practical value of background cross sections, as will be discussed in Sect. 3.6.3 with reference to Fig. 22.

We have thus far described three different approximations for the escape probability. Figures 17 and 18 show the accuracy of these approximations for an infinite cylindrical fuel lump. Carlvik’s two-term rational approximation of (123) clearly gives better results than the others, and Wigner’s approximation with the Bell factor is the next best. Wigner’s rational approximation as conventionally used gives accurate results for the white and the black limits, but shows a considerable discrepancy at a medium optical thickness, which is mainly the case in common LWR lattice calculations.

3.5.4 Neutron Slowing Down in a Heterogeneous Lattice System

Formulation of Slowing Down Equation in Lattice System

In Sect. 3.5.1, we discussed the energy dependence of the neutron flux in an isolated fuel lump, in which a neutron escaping from one fuel lump never enters other fuel lumps. In an actual fuel assembly, however, many fuel rods are packed in one assembly, so that neutrons that escape from one fuel rod do in fact enter other fuel rods. In this case, the “effective” escape

■ Figure 18

Accuracy of various approximations for the escape probability from an infinite cylinder. The horizontal axis shows the average optical length of the infinite cylinder, that is, the diameter multiplied by the macroscopic total cross section

from a fuel is reduced, so the energy dependence of the neutron flux is affected (Dresner 1960; Rosenstein 1960).

Let us consider an ideal fuel assembly in which the fuel rods are very tightly packed. If there is no gap between fuel pellets (i.e., no moderator and cladding in a fuel assembly), the energy dependence of the neutron flux will be identical to that in a homogeneous system composed of only fuel material. This suggests that the energy dependence of the neutron flux can be roughly expressed as an intermediate dynamic between that found in isolated heterogeneous and homogeneous systems.

The equivalence theory gives a unified description of the energy dependence of the neutron flux in isolated and homogeneous systems. From (108), the neutron flux in an isolated fuel lump is expressed as

$$\phi_f(E) = \frac{1}{E} \frac{\sigma_{p,r} + (\sigma_{0,f} + \Sigma_e/N_r)}{\sigma_{t,r}(E) + (\sigma_{0,f} + \Sigma_e/N_r)} \quad (134)$$

When the escape cross section Σ_e becomes zero, (134) is reduced into that in the homogeneous system given by (77). That is, (134), which is based on the equivalence theory, can express the neutron flux in both heterogeneous and homogeneous systems. We can therefore expect that the neutron flux in a heterogeneous lattice system can also be described in the framework of the equivalence theory, if we adjust the escape cross section. The final goal of this subsection, then, is to derive a definition of the escape cross section in lattice systems.

In the following part, we first discuss a regular lattice system, which consists of an infinite regular array of fuel rods. A regular lattice system, however, does not apply to actual fuel assemblies because they contain many irregularities, for example, guide and instrumentation thimbles in PWR, water channels, gap water, and part length rods in BWR. Such irregularities

have, of course, an impact on neutron flux. Treatment to account for these irregularities will be also discussed later in this subsection.

We begin with the neutron balance equation for a heterogeneous system:

$$\Sigma_{t,f}(E)\phi_f(E)V_f = \sum_j P_{j \rightarrow f}(E)V_j \int_0^\infty dE' \Sigma_{s,j}(E' \rightarrow E)\phi_j(E') \quad (135)$$

where

j : region number in a heterogeneous system, which includes the fuel in question, the moderator, and other fuels.

Recalling the derivation of (89), (135) can be transformed with the NR approximation into the following:

$$\phi_f(E) = \frac{1}{E} \sum_j \frac{P_{j \rightarrow f}(E)V_j \Sigma_{p,j}}{\Sigma_{t,f}(E)V_f} \quad (136)$$

We then consider (137) and (138), which are the normalization conditions of the collision probabilities, and the reciprocity theorem discussed in (92), respectively

$$\sum_{j \neq m} P_{f \rightarrow j}(E) = 1 - P_{f \rightarrow m}(E) \quad (137)$$

$$P_{j \rightarrow f}(E)V_j \Sigma_{t,j}(E) = P_{f \rightarrow j}(E)V_f \Sigma_{t,f}(E) \quad (138)$$

In an actual system composed of multiple regions, m in (137) includes not only the moderator, but also other regions, with the exception of fuel (e.g., cladding). By substituting (137) and (138) into (136), (136) can be rewritten as follows:

$$\begin{aligned} \phi_f(E) &= \frac{1}{E} \sum_j \frac{P_{j \rightarrow f}(E)V_j \Sigma_{p,j}}{\Sigma_{t,f}(E)V_f} \\ &= \frac{1}{E} \sum_j \frac{P_{f \rightarrow j}(E)V_f \Sigma_{t,f}(E)}{\Sigma_{t,j}(E)} \frac{\Sigma_{p,j}}{\Sigma_{t,f}(E)V_f} \\ &= \frac{1}{E} \sum_j \frac{P_{f \rightarrow j}(E)\Sigma_{p,j}}{\Sigma_{t,j}(E)} \\ &= \frac{1}{E} \left(\sum_{j \neq m} \frac{P_{f \rightarrow j}(E)\Sigma_{p,j}}{\Sigma_{t,j}(E)} + \frac{P_{f \rightarrow m}(E)\Sigma_{p,m}}{\Sigma_{t,m}(E)} \right) \\ &\cong \frac{1}{E} \left(\frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} \sum_{j \neq m} P_{f \rightarrow j}(E) + P_{f \rightarrow m}(E) \right) \\ &= \frac{1}{E} \left((1 - P_{f \rightarrow m}(E)) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + P_{f \rightarrow m}(E) \right) \end{aligned} \quad (139)$$

In the above derivation, we applied an important assumption, namely, that the macroscopic total cross sections in the fuel regions are spatially constant. This assumption is justified because identical or similar compositions are used in an LWR fuel assembly. However, the above assumption could introduce a crucial error for fuel assemblies of various compositions. Furthermore, no absorption is assumed for the moderator region; that is, the total cross section and the (potential) scattering cross section are identical in the moderator region. Also, the scattering reaction is dominated by the potential scattering, which has an energetically constant cross section.

Dancoff Correction or Dancoff Factor

When (139) and (94) are compared, we can find that they have an identical form, that is, the neutron fluxes in both isolated and lattice systems can be described by a unified analytical form. Note that the above discussion assumes the same composition of fuel, but the regularity of the lattice is not assumed. In this context, (139) can be applied to irregular and general arrangements of heterogeneous fuel.

In the case of an isolated system, the collision probability from the fuel to the moderator is evaluated as the escape probability from the fuel, and is approximated by the rational approximation in order to derive the equivalence between heterogeneous and homogeneous systems. Thus, a similar approach will be useful for (139).

In a lattice system, the number of neutrons entering a fuel region decreases, since part of the neutrons in the moderator region is absorbed into “other” fuels. In other words, other fuels make “shadows” for the fuel we consider. In order to consider the shadowing effect in a lattice system, the Dancoff correction C is used (Stamm’ler and Abbate 1983; Sugimura and Yamamoto 2006):

$$C = \frac{I_0 - I}{I_0} \quad (140)$$

where

I_0 : number of neutrons entering the fuel region in an isolated system,

I : number of neutrons entering the fuel region in question in a lattice system.

When the number of entering neutrons is the same in both isolated and lattice systems, the Dancoff correction is zero ($I = I_0$). On the contrary, when the number of neutrons from the moderator region is fully shadowed, that is, $I = 0$, the Dancoff correction is 1. Thus, the Dancoff correction represents the degree of the shadowing effect by other fuel rods.

The Dancoff correction can also be defined in terms of the reduction of the escape probability. That is, some of the neutrons escaping from a fuel may have their next collision in other fuels. On the contrary, in the case of an isolated fuel (with a convex shape), all neutrons escaping from a fuel have their next collision in the moderator. Thus, the “effective” neutron escape probability from a fuel is reduced in lattice geometry.

Dancoff Correction and Collision Probability in the Moderator

When the thickness of the moderator is l , the un-collided probability between fuels is given by $\exp(-\Sigma_{t,m}l)$. Here l is defined by the distance between one fuel from which a neutron escapes, and another fuel in which the neutron has a collision. Thus, the Dancoff correction is given by the following equation:

$$C = \frac{\int_{\vec{n} \cdot \vec{\Omega} > 0} d\vec{\Omega} \int_S dS (\vec{n} \cdot \vec{\Omega}) \exp(-\Sigma_{t,m}l)}{\int_{\vec{n} \cdot \vec{\Omega} > 0} d\vec{\Omega} \int_S dS (\vec{n} \cdot \vec{\Omega})} \quad (141)$$

In the case of isolated geometry, the Dancoff correction is zero, since $\exp(-\Sigma_{t,m}l)$ is zero for infinite l . When the isotropic neutron source is uniformly distributed, (140) and (141) give identical results, which can be proved through selected formulations (Kobayashi 1995). Since approximations for (141) can be derived more easily than those for (140), in the following discussion we will consider (141). Note that (140) is used for the neutron current method and the

enhanced neutron current method, which are suitable for the evaluation of the Dancoff correction in complicated and large geometries (Sugimura and Yamamoto 2006; Yamamoto 2009). Explanations of these methods will be given later.

In order to discuss the characteristics of the Dancoff correction, an approximate expression for the Dancoff correction will be derived, though it is not used in actual lattice physics calculations. We now consider the chord length distribution in the moderator region, $f(l)dl$, which is a concept similar to the escape probability from a fuel discussed in [3.5.1](#). With the chord distribution function, the Dancoff correction is given by

$$C = \int_0^{\infty} dl f(l) \exp(-\Sigma_{t,m} l) \quad (142)$$

[Equation \(142\)](#) indicates that the Dancoff correction is given by the average of probability that there will not be a collision with the moderator. In some lattice physics computations, the Dancoff factor D is also used:

$$\begin{aligned} D &= 1 - C = 1 - \int_0^{\infty} dl f(l) \exp(-\Sigma_{t,m} l) \\ &= \int_0^{\infty} dl f(l) - \int_0^{\infty} dl f(l) \exp(-\Sigma_{t,m} l) \\ &= \int_0^{\infty} dl f(l) \{1 - \exp(-\Sigma_{t,m} l)\} \end{aligned} \quad (143)$$

In order to incorporate the Dancoff correction into the equivalence theory, approximations similar to those used for the escape probability from fuel are applied to the Dancoff correction. First, the chord length distribution is approximated by the exponential function, which is used for the escape probability from fuel, that is, [\(105\)](#):

$$f(l)dl = \begin{cases} 0 & (l < l_m) \\ \frac{1}{\bar{l} - l_m} \exp\{-(l - l_m)/(\bar{l} - l_m)\} d(l - l_m) & (l \geq l_m) \end{cases} \quad (144)$$

where l_m is the minimum thickness of the moderator between two fuels. From the definition, the chord length function is zero for $l < l_m$. Therefore, the chord length distribution for the moderator is defined by the parallel translation of the chord length distribution for a fuel region, which is given by [\(105\)](#). By substituting [\(144\)](#) into [\(142\)](#), we obtain

$$\begin{aligned} C &= \int_0^{\infty} dl f(l) \exp(-\Sigma_{t,m} l) \\ &= \int_{l_m}^{\infty} \frac{1}{\bar{l} - l_m} \exp\{-(l - l_m)/(\bar{l} - l_m)\} \exp(-\Sigma_{t,m} l) d(l - l_m) \\ &= \frac{\exp(-\Sigma_{t,m} l_m)}{\Sigma_{t,m} \cdot (\bar{l} - l_m) + 1} \end{aligned} \quad (145)$$

[\(145\)](#), particularly, becomes Wigner's rational approximation for the escape probability from the moderator when $l_m = 0$:

$$C = \frac{1}{\Sigma_{t,m} \bar{l} + 1}. \quad (146)$$

■ Figure 19

Example of the macroscopic cross section of light water (under typical LWR operating conditions)

Note that the moderator region among the fuel is “isolated” when $l_m = 0$. In this case, (146) gives the escape probability for an isolated “moderator” lump. A corresponding equation for a fuel is given by (106). From the perspective of its physical meaning, the Dancoff correction is similar to that of the escape probability from fuel, that is, the escape probability from the moderator. However, since the total cross section of the moderator is fairly constant in the resonance energy range, as shown in ► Fig. 19, the Dancoff correction is incorporated in the equivalence theory as an independent energy constant. It depends only on the chord length distribution of the moderator region and the total cross section of the moderator, and does not depend on the fuel cross section.

Dancoff Correction and Escape Probability for an Isolated Fuel Lump

When the angular distribution of neutrons entering from the moderator region into the fuel is isotropic, the collision probability from the fuel to the moderator in a lattice system is expressed as follows (Kobayashi 1995):

$$P_{f \rightarrow m}(E) = \frac{(1 - C)P_e(E)}{1 - (1 - \Sigma_{t,f}(E)\bar{l}P_e(E))C} \quad (147)$$

where

$P_{f \rightarrow m}(E)$: collision probability from the fuel to the moderator in a lattice system, and
 $P_e(E)$: escape probability from the fuel (i.e., collision probability from the fuel to the moderator in an isolated system).

When Wigner's rational approximation with the Bell factor is applied to (147), we obtain

$$\begin{aligned}
 P_{f \rightarrow m}(E) &= \frac{(1-C)P_e(E)}{1 - (1 - \Sigma_{t,f}(E)\bar{l})P_e(E)} C \\
 &= \frac{(1-C) \cdot \frac{a_B}{\Sigma_{t,f}(E)\bar{l} + a_B}}{1 - \left(1 - \Sigma_{t,f}(E)\bar{l} \cdot \frac{a_B}{\Sigma_{t,f}(E)\bar{l} + a_B}\right) C} \\
 &= \frac{g(C, a_B)}{\Sigma_{t,f}(E)\bar{l} + g(C, a_B)} \tag{148}
 \end{aligned}$$

where

$$g(C, a_B) = \frac{(1-C)a_B}{1 + C(a_B - 1)} \tag{149}$$

By comparing (111) and (148), we have the following relationship:

$$\frac{\bar{l}^{iso}}{\bar{l}^{lat}} = \frac{4V}{S^{iso}} \frac{S^{lat}}{4V} = \frac{S^{lat}}{S^{iso}} = \frac{\Sigma_e^{lat}}{\Sigma_e^{iso}} = \frac{g(C, a_B)/\bar{l}}{a_B/\bar{l}} = \frac{(1-C)}{1 + C(a_B - 1)} \tag{150}$$

Therefore, the "effective" surface area of the fuel from which the inflow of neutrons is reduced in the lattice system due to the shadowing effect of other fuels. In the case of Wigner's rational approximation ($a_B = 1$):

$$\frac{S^{lat}}{S^{iso}} = (1-C) \tag{151}$$

Thus, the Dancoff correction directly shows the reduction in the effective surface area of the fuel in the lattice system.

Equivalence Theory in Lattice System

By substituting (148) into (139), we obtain

$$\begin{aligned}
 \phi_f(E) &= \frac{1}{E} \left((1 - P_{f \rightarrow m}(E)) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + P_{f \rightarrow m}(E) \right) \\
 &= \frac{1}{E} \left(\left(1 - \frac{g(C, a_B)}{\Sigma_{t,f}(E)\bar{l} + g(C, a_B)} \right) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + \frac{g(C, a_B)}{\Sigma_{t,f}(E)\bar{l} + g(C, a_B)} \right) \\
 &= \frac{1}{E} \frac{\Sigma_{p,f}\bar{l} + g(C, a_B)}{\Sigma_{t,f}(E)\bar{l} + g(C, a_B)} \\
 &= \frac{1}{E} \frac{\Sigma_{p,f} + g(C, a_B)/\bar{l}}{\Sigma_{t,f}(E) + g(C, a_B)/\bar{l}} \\
 &= \frac{1}{E} \frac{\Sigma_{p,f} + g(C, a_B)\Sigma_e}{\Sigma_{t,f}(E) + g(C, a_B)\Sigma_e}
 \end{aligned}$$

$$\begin{aligned}
&= \frac{1}{E} \frac{N_r(\sigma_{p,r} + \sigma_{0,f}) + g(C, a_B)\Sigma_e}{N_r(\sigma_{t,r}(E) + \sigma_{0,f}) + g(C, a_B)\Sigma_e} \\
&= \frac{1}{E} \frac{\sigma_{p,r} + (\sigma_{0,f} + g(C, a_B)\Sigma_e/N_r)}{\sigma_{t,r}(E) + (\sigma_{0,f} + g(C, a_B)\Sigma_e/N_r)} \quad (152)
\end{aligned}$$

If we invoke the relevant discussion of the equivalence theory, the background cross section for nuclide r is given by

$$\sigma_{0,r} = \sigma_{0,f} + g(C, a_B)\Sigma_e/N_r \quad (153)$$

When (113) and (153) are compared, the background cross section in a lattice system becomes smaller than that in an isolated system, since $g(C, a_B) \leq a_B$. In a lattice system, the self-shielding effect is larger than it is in an isolated system, as was discussed previously. Equation (153) represents this physical phenomenon. When $a_B = 1$, the background cross section is given by

$$\sigma_{0,r} = \sigma_{0,f} + D\Sigma_e/N_r \quad (154)$$

In the case of an isolated system ($D = 1$), the background cross section for nuclide r given by (154) is equivalent to (110), which was originally derived for an isolated system.

3.5.5 Calculation of the Dancoff Factor and Background Cross Sections

Calculation of Dancoff Factor Using the Collision Probability Method

Once the Dancoff correction has been calculated, we can estimate the background cross section in a lattice geometry, as shown in (154). Though various analytical methods have been developed for the estimation of the Dancoff correction in simple geometries (i.e., slab, cylinder), the following numerical procedure with the collision probability method is actually used in today's lattice physics codes. We will now consider the value of $\Sigma_{t,f}(E)\bar{I}P_{f \rightarrow m}(E)$, whose detailed analytic form is derived from (147)

$$\Sigma_{t,f}(E)\bar{I}P_{f \rightarrow m}(E) = \Sigma_{t,f}(E) \frac{(1-C)\bar{I}P_e(E)}{1 - (1 - \Sigma_{t,f}(E)\bar{I}P_e(E))C} \quad (155)$$

In conventional equivalence theory, we treat a fuel as black, that is, the total cross section of a fuel is very large. By applying this assumption, we obtain

$$\begin{aligned}
\lim_{\Sigma_{t,f}(E) \rightarrow \infty} \Sigma_{t,f}(E)\bar{I}P_{f \rightarrow m}(E) &= \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \frac{\Sigma_{t,f}(E)\bar{I}(1-C)P_e(E)}{1 - C + \Sigma_{t,f}(E)\bar{I}P_e(E)C} \\
&= \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \frac{(1-C)P_e(E)}{(1-C)/(\Sigma_{t,f}(E)\bar{I}) + P_e(E)C} \\
&= \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \frac{(1-C)P_e(E)}{P_e(E)C} = \frac{(1-C)}{C} \quad (156)
\end{aligned}$$

where

$$\bar{I} = 4V/S.$$

In actual numerical computations, the total cross section of a fuel region is set at a sufficiently large value (e.g., 10^5 cm^{-1}), and then the collision probability from a fuel to the moderator is calculated (Tsuchihashi et al. 1982; Stamm'ler and Abbate 1983; Ishiguro 1985). Once the collision probability from a fuel to the moderator is obtained, the Dancoff correction is evaluated by (156). Note that the chord length is calculated by the volume and surface area of the fuel region, that is, $\bar{l} = 4V/S$, as given in (101). Once the Dancoff correction is obtained, we can easily evaluate the background cross section, which is used for the calculation of effective cross sections.

The above derivation also represents a potential source of error in the Dancoff correction method. For example, let us consider a fuel pellet that is annularly subdivided into multiple regions. Such a subdivision is usually used for a Gadolinia-bearing fuel pellet. The Dancoff correction for the inner region of a subdivided fuel pellet is clearly unity, since the collision probability from the inner region of the fuel to the moderator approaches zero, due to the large total cross section in a pellet. In other words, neutrons cannot “escape” from the inner region of the fuel to the moderator at resonance peak energy, because they always experience collisions in the outer regions of the fuel pellet, which have a very large total cross section. When the Dancoff correction is unity ($C = 1$ or $D = 0$), the background cross section becomes identical to that of a homogeneous system. The above discussion suggests that spatial dependent self-shielding cannot be directly handled by the Dancoff correction given by (156), which represents a major drawback of the conventional equivalence theory.

That said, the above discussion of the Dancoff correction also shows the advantage it offers. The Dancoff correction does not depend on the composition (cross section) of a fuel; it is calculated by the geometry and the cross section of the moderator. Variations in the cross section in the moderator region are very smooth, especially in the resonance energy range, as shown in  Fig. 19. The calculation of the Dancoff correction is thus greatly simplified, and once the Dancoff correction is obtained (with a representative moderator cross section), it can be used for all resonance energy groups.

In the equivalence theory, the heterogeneity effect for a fuel region is incorporated through the escape cross section, and the property of a moderator is taken into account through the Dancoff correction. The escape cross section and the Dancoff correction are both constants. In reality, interaction takes place between the fuel and moderator regions through the “communication” of neutrons, that is, the neutron spectrum in each region is affected by the spectrum in the other region. In the equivalence theory, this situation is simplified, and the effects of the moderator, and of other fuels on the neutron spectrum, are treated independently through the escape cross section, and the Dancoff correction, respectively. Such simplicity contributes greatly to the success of the equivalence theory in conventional resonance calculations. Again, however, it should be noted that such simplification could restrict the application of the Dancoff correction.

Neutron Current Method for Dancoff Correction Calculation

In the following part of this subsection, two numerical methods to evaluate the Dancoff correction and the background cross section are introduced, that is, the neutron current method and the enhanced neutron current method (Sugimura and Yamamoto 2006; Yamamoto 2008, 2009). In conventional equivalence theory, the heterogeneous effect (the Dancoff correction) is evaluated by the collision probability method, as was previously discussed. Though the collision probability method is very efficient for a simple geometry, its applicability to large and

complicated geometries is quite limited due to its computational inefficiency. For example, a collision probability calculation of an LWR fuel assembly still requires considerable computation time, even with the latest computers. For this reason, direct calculation of the Dancoff correction for a large geometry using the collision probability method would be limited by the computation time it requires.

Recently, the method of characteristics has been widely used for neutron transport calculations in lattice physics computations. The neutron current and the enhanced neutron current methods utilize the method of characteristics, rather than the collision probability method, to evaluate the Dancoff correction and the background cross section in a heterogeneous geometry (Sugimura and Yamamoto 2006; Yamamoto 2008, 2009). Using these methods, the Dancoff correction and the background cross section in a large and complicated geometry, such as that of an LWR fuel assembly, can be easily calculated.

The neutron current method and the enhanced neutron current method are based on the approximations used in the equivalence theory, that is, the NR approximation, the rational approximation for the escape probability, and the black-limit approximation of a fuel lump. Thus, they are mathematically equivalent to the equivalence theory used in current lattice physics codes. In other words, the accuracy of these methods is the same as that of the conventional equivalence theory. Though many lattice physics codes utilize collision probability methods for the evaluation of the Dancoff correction in a simple geometry, in a large geometry (even in an entire LWR core) the Dancoff correction is easily calculated by the neutron current and the enhanced neutron current methods.

The original definition of the Dancoff correction is given by the reduction of the incoming neutron current into fuel regions, as shown in (140). In the neutron current method, the Dancoff correction is calculated by the neutron flux in the fuel region as follows:

$$C = \frac{\phi_0 - \phi}{\phi_0} \quad (157)$$

where

ϕ_0 : neutron flux of fuel region at isolated system, and

ϕ : neutron flux of fuel region at lattice system.

When we assume that there is no neutron (slowing down) source in a fuel region, and that the fuel is purely an absorber material with a very large absorption cross section, the average neutron flux in a fuel region will be proportional to the incoming neutron current into the fuel. In such a case, (157) can be rewritten as follows:

$$C = \frac{I_0 - I}{I_0} = \frac{\phi_0 - \phi}{\phi_0} \quad (158)$$

Since the transport codes used in lattice physics computations have the capability to estimate the neutron flux in each region, the definition of the Dancoff correction given by (157) is useful, and is easily adopted in current lattice physics codes. That is, when a lattice physics code utilizes the method of characteristics for transport calculations, the transport module can be directly used for estimation of the Dancoff correction.

A detailed discussion of the validity of (158) is given as follows. For the sake of simplicity, we will consider a fuel-moderator two-region system.

Recalling (94), the energy dependence of the neutron flux in an isolated fuel lump is given by

$$\phi_f(E) = \frac{1}{E} \left((1 - P_{f \rightarrow m}(E)) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + P_{f \rightarrow m}(E) \right) \quad (159)$$

With (139), that in a lattice system is

$$\phi_f(E) = \frac{1}{E} \left((1 - P_{F \rightarrow M}(E)) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + P_{F \rightarrow M}(E) \right) \quad (160)$$

Note that the fuel and moderator regions in a lattice system are indicated by F and M , respectively, to distinguish them from those in an isolated system (f and m). When the black-limit approximation is applied to the fuel region, (159) can be simplified as follows:

$$\begin{aligned} \phi_0 &= \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \phi_f(E) \\ &= \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \frac{1}{E} \left((1 - P_{f \rightarrow m}(E)) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + P_{f \rightarrow m}(E) \right) \\ &= \frac{1}{E} \lim_{\Sigma_{t,f}(E) \rightarrow \infty} P_{f \rightarrow m}(E) \\ &= \frac{1}{E} \left(1 - \lim_{\Sigma_{t,f}(E) \rightarrow \infty} P_{f \rightarrow f}(E) \right) \end{aligned} \quad (161)$$

Note that the normalization condition for collision probability, that is, $P_{f \rightarrow m}(E) = 1 - P_{f \rightarrow f}(E)$, is used. Similarly, for the lattice system

$$\begin{aligned} \phi &= \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \phi_F(E) \\ &= \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \frac{1}{E} \left((1 - P_{F \rightarrow M}(E)) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + P_{F \rightarrow M}(E) \right) \\ &= \frac{1}{E} \lim_{\Sigma_{t,f}(E) \rightarrow \infty} P_{F \rightarrow M}(E) \\ &= \frac{1}{E} \left(1 - \lim_{\Sigma_{t,f}(E) \rightarrow \infty} P_{F \rightarrow F}(E) - \lim_{\Sigma_{t,f}(E) \rightarrow \infty} P_{F \rightarrow F'}(E) \right) \end{aligned} \quad (162)$$

where

$P_{F \rightarrow M}(E) = \sum_{j \neq F, F'} P_{F \rightarrow j}(E)$: collision probability from fuel F to other regions, except for fuel (F and F'), and

$P_{F \rightarrow F'}(E) = \sum_{j=F'} P_{F \rightarrow j}(E)$: collision probability from fuel F to other fuels F' (fuel F is not included in fuel F').

Here, the relationship $P_{F \rightarrow M}(E) = 1 - P_{F \rightarrow F}(E) - P_{F \rightarrow F'}(E)$ is used.

By substituting (161) and (162) into (157), we obtain

$$\begin{aligned}
 C &= \frac{\phi_0 - \phi}{\phi_0} \\
 &= \frac{\frac{1}{E} \left(1 - \lim_{\Sigma_{i,f}(E) \rightarrow \infty} P_{f \rightarrow f}(E) \right) - \frac{1}{E} \left(1 - \lim_{\Sigma_{i,f}(E) \rightarrow \infty} P_{F \rightarrow F}(E) - \lim_{\Sigma_{i,f}(E) \rightarrow \infty} P_{F \rightarrow F'}(E) \right)}{\frac{1}{E} \left(1 - \lim_{\Sigma_{i,f}(E) \rightarrow \infty} P_{f \rightarrow f}(E) \right)} \\
 &= \frac{\lim_{\Sigma_{i,f}(E) \rightarrow \infty} P_{F \rightarrow F}(E) - \lim_{\Sigma_{i,f}(E) \rightarrow \infty} P_{f \rightarrow f}(E) + \lim_{\Sigma_{i,f}(E) \rightarrow \infty} P_{F \rightarrow F'}(E)}{1 - \lim_{\Sigma_{i,f}(E) \rightarrow \infty} P_{f \rightarrow f}(E)} \\
 &= \frac{\lim_{\Sigma_{i,f}(E) \rightarrow \infty} P_{F \rightarrow F'}(E)}{1 - \lim_{\Sigma_{i,f}(E) \rightarrow \infty} P_{F \rightarrow F}(E)} \tag{163}
 \end{aligned}$$

Note that the fuel-to-fuel self-collision probabilities are identical in both isolated and lattice systems (i.e., $P_{f \rightarrow f}(E) = P_{F \rightarrow F}(E)$), since the fuel-to-fuel self-collision probabilities depend only upon the property of the fuel lump we are considering.

The original definition of the Dancoff correction states that a fraction of the neutrons escaping from a fuel lump suffer their first collision in other fuel lumps. The numerator and denominator of (163) represent the collision probability in other fuel lumps, and the escape probability from the fuel we are considering. Thus (163), which is derived from an analytic expression of the neutron flux, is mathematically identical to that of the original definition of the Dancoff correction. The above discussion can easily be extended to more complicated systems with more than two materials.

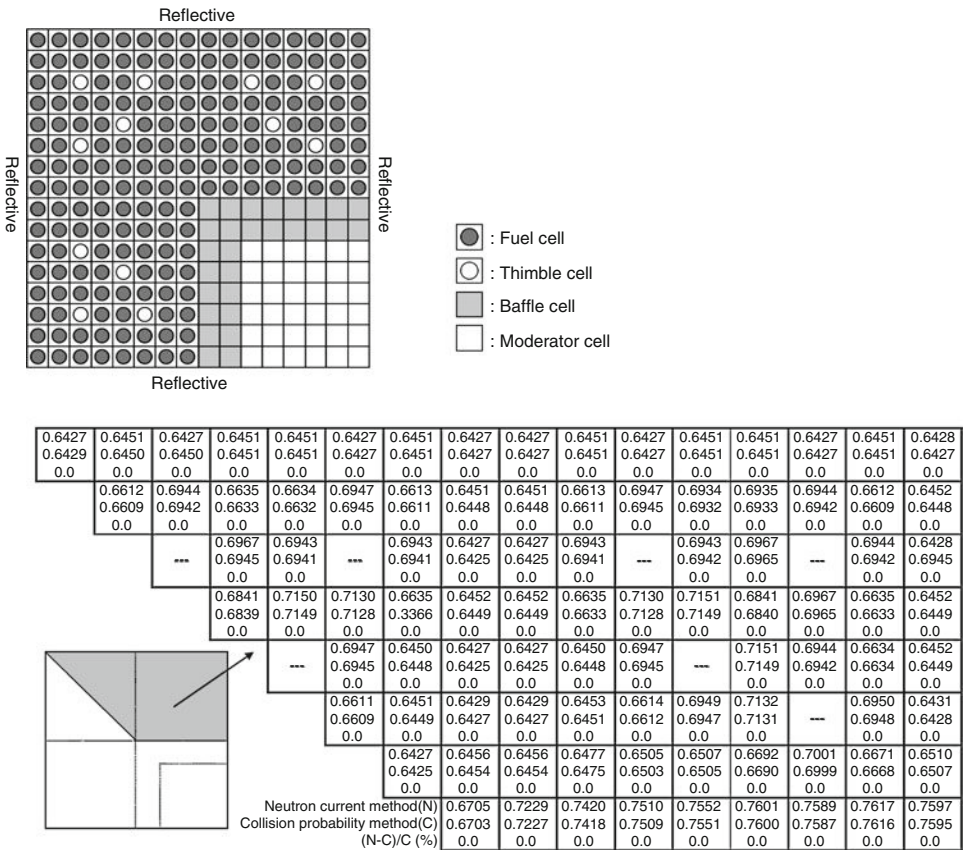

In the actual numerical computation of the Dancoff factor, the following procedure is followed:

- a. The total cross section of each material in the system, except for the fuel, is set to be equivalent to the value of the potential scattering cross section of each material. No scattering is assumed (scattering cross section is set at zero), so the total and absorption cross sections are identical for each material.
- b. The neutron source intensity of each material in the system, except for the fuel, is set to be equivalent to the value of the potential scattering cross section (the NR approximation).
- c. The total cross section of the fuel is set to be sufficiently large, for example, 10^5 cm^{-1} . No scattering is assumed (scattering cross section is set at zero), so the total and the absorption cross sections are identical, in terms of fuel.
- d. The neutron source intensity in the fuel is set at zero.
- e. Perform a one-group fixed-source neutron transport calculation in an isolated system, in which the fuel lump in question is put in a sufficiently large moderator.
- f. Evaluate the neutron flux in the fuel region obtained in step (e).
- g. Perform a one-group fixed-source neutron transport calculation in a lattice system.
- h. Evaluate the neutron flux in the fuel region obtained in step (g).
- i. Evaluate the Dancoff correction by (157).

Using the neutron current method, the Dancoff correction can be evaluated not only for a fuel, but for other resonance materials as well. For example, zirconium isotopes, which are used

in cladding, channel boxes and water rods, have resonances, so that appropriate self-shielding should be taken into account. Since cladding, channel boxes and water rods form a complicated geometry in a BWR fuel assembly, it becomes quite difficult to calculate the Dancoff correction accurately. However, the neutron current method offers an easy way to evaluate the Dancoff correction for zirconium isotopes in a complicated geometry.

An example of the calculation results of the Dancoff factors D ($D = 1 - C$) for fuel pins is shown in  Fig. 20, which represents a typical setting of a fuel assembly adjacent to a baffle plate in a PWR (Sugimura and Yamamoto 2006). The Dancoff factor depends on the position of the fuel rod, and it becomes large for fuel rods that are adjacent to a baffle plate. Since the same resonance material (uranium) does not exist in the baffle and reflector regions, neutrons from the baffle–reflector region are not “shadowed.” Thus, the Dancoff factor becomes large; that is, the Dancoff correction becomes small in the region near the baffle–reflector. Furthermore, the Dancoff factors obtained by the neutron current method are consistent with those obtained by the conventional collision probability method.

 **Figure 20**
Example of Dancoff factors in a large and complicated geometry

Enhanced Neutron Current Method for Background Cross Section Evaluation

In the neutron current method, two transport calculations are needed to evaluate the Dancoff correction in isolated and lattice systems. The enhanced neutron current method offers a simpler way to calculate the background cross section; one fixed-source transport calculation in one group is sufficient to evaluate the background cross section, including the heterogeneous effect (Yamamoto 2008, 2009). In the enhanced neutron current method, the total reaction rate of fuel region $\Sigma_{t,f}(E)\phi_f(E)$ is considered. By using (152), we obtain

$$\Sigma_{t,f}(E)\phi_f(E) = \Sigma_{t,f}(E) \frac{\Sigma_{p,f} + g(C, a_B)\Sigma_e}{\Sigma_{t,f}(E) + g(C, a_B)\Sigma_e} \quad (164)$$

Note that the term $1/E$ is omitted since its variation is much smoother than that due to the resonance peak, and the source intensity can be adjusted. That is, the source intensity due to slowing down by the potential scattering is considered to be $\Sigma_{p,f}$, instead of $\Sigma_{p,f}/E$.

When the black-limit approximation is applied to the fuel, (164) can be reduced as follows:

$$\begin{aligned} \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \Sigma_{t,f}(E)\phi_f(E) &= \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \Sigma_{t,f}(E) \frac{\Sigma_{p,f} + g(C, a_B)\Sigma_e}{\Sigma_{t,f}(E) + g(C, a_B)\Sigma_e} \\ &= \Sigma_{p,f} + g(C, a_B)\Sigma_e \\ &= N_r(\sigma_{p,r} + \sigma_{0,f}) + g(C, a_B)\Sigma_e \\ &= N_r\sigma_{p,r} + N_r(\sigma_{0,f} + g(C, a_B)\Sigma_e/N_r) \end{aligned} \quad (165)$$

By using (165), we can derive the background cross section, including the heterogeneous effect, as follows:

$$\begin{aligned} \sigma_0 &= \sigma_{0,f} + g(C, a_B)\Sigma_e/N_r \\ &= \frac{\lim_{\Sigma_{t,f}(E) \rightarrow \infty} \Sigma_{t,f}(E)\phi_f(E) - N_r\sigma_{p,r}}{N_r} \\ &= \frac{\lim_{\Sigma_{t,f}(E) \rightarrow \infty} \Sigma_{t,f}(E)\phi_f(E)}{N_r} - \sigma_{p,r} \end{aligned} \quad (166)$$

In lattice geometry, the Dancoff correction can also be derived using (166), that is,

$$g(C, a_B) = \frac{\lim_{\Sigma_{t,f}(E) \rightarrow \infty} \Sigma_{t,f}(E)\phi_f(E) - N_r\sigma_{p,r} - N_r\sigma_{0,f}}{\Sigma_e} \quad (167)$$

The value of $\lim_{\Sigma_{t,f}(E) \rightarrow \infty} \Sigma_{t,f}(E)\phi_f(E)$, which is the total reaction rate, can be evaluated by means of a transport calculation by using the method of characteristics. The escape cross section is given by $S/(4V)$. The number density and the potential scattering cross sections are known values. Therefore, the right-hand side of (167) can be evaluated. When the Bell factor is unity, $g(C, a_B)$ becomes the Dancoff factor D ($D = 1 - C$), from the definition of $g(C, a_B)$ given by (149).

The actual calculation procedure of the enhanced neutron current method is as follows:

- a. The total cross sections of a material in the system, except for the fuel, are set to be equivalent to the potential scattering cross section. No scattering is assumed, so the total and absorption cross sections are identical in these materials.
- b. The neutron source intensities of the materials in the system (including the fuel region) are set to be equivalent to the potential scattering cross section (the NR approximation).
- c. The total cross section of the fuel is set to be sufficiently large, for example, 10^5 cm^{-1} . No scattering is assumed, so the total and the absorption cross sections in the fuel are identical.
- d. Perform a one-group fixed-source neutron transport calculation in the lattice system.
- e. Evaluate the total reaction rate $\Sigma_{t,f}(E)\phi_f(E)$ in each fuel region.
- f. Evaluate the background cross section by (166). The Dancoff factor can be evaluated by (167) with the Bell factor $a_B = 1$, if necessary.

The enhanced neutron current method gives a different background cross section for each fuel rod, which reflects the spatial source distribution in the moderator region, and the spatial variation of the neutron inflow to the fuels. In this method, the shadowing effect from the other fuel rods is naturally taken into account.

Since the fuel region is considered as a completely black material, that is, all fuels are treated as being made of the same material with a very large absorption cross section, the difference in fuel cross sections among fuel rods cannot be taken into account in this method. In this context, the enhanced neutron current method is consistent with the conventional equivalence theory, with Wigner's rational approximation and the Dancoff correction. Therefore, the enhanced neutron current method cannot be applied to self-shielding calculations in which the grayness of a fuel must be taken into account, for example, calculation of the space-dependent effective cross section in a pellet.

One may consider the possibility of applying the N -term rational approximation in the derivation of the enhanced neutron current method. However, since the accuracy of Wigner's rational approximation is the same as that of the N -term rational approximation, the accuracy of the enhanced neutron current method cannot be improved by incorporation of the N -term rational approximation. The following formulation will clarify this discussion.

First, by recalling the discussion for (119) and (148), we assume that the fuel-to-moderator collision probability can be expressed by the following rational approximation:

$$P_{f \rightarrow m}(E) = \sum_{n=1}^N \frac{g(C, a_B) b_n a_n}{\Sigma_{t,f}(E) \bar{l} + g(C, a_B) a_n} \quad (168)$$

By substituting (168) into (139) and using (121), we obtain

$$\phi_f(E) = \frac{1}{E} \sum_{n=1}^N b_n \frac{\Sigma_{p,f} + g(C, a_B) a_n \Sigma_e}{\Sigma_{t,f}(E) + g(C, a_B) a_n \Sigma_e} \quad (169)$$

Therefore, the total reaction rate is given by

$$\begin{aligned}
 \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \Sigma_{t,f}(E) \phi_f(E) &= \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \Sigma_{t,f}(E) \sum_{n=1}^N b_n \frac{\Sigma_{p,f} + g(C, a_B) a_n \Sigma_e}{\Sigma_{t,f}(E) + g(C, a_B) a_n \Sigma_e} \\
 &= \sum_{n=1}^N b_n \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \Sigma_{t,f}(E) \frac{\Sigma_{p,f} + g(C, a_B) a_n \Sigma_e}{\Sigma_{t,f}(E) + g(C, a_B) a_n \Sigma_e} \\
 &= \sum_{n=1}^N b_n \{ \Sigma_{p,f} + g(C, a_B) a_n \Sigma_e \} \\
 &= \sum_{n=1}^N b_n \Sigma_{p,f} + \sum_{n=1}^N b_n g(C, a_B) a_n \Sigma_e \\
 &= \Sigma_{p,f} \sum_{n=1}^N b_n + g(C, a_B) \Sigma_e \sum_{n=1}^N b_n a_n \\
 &= \Sigma_{p,f} + g(C, a_B) \Sigma_e \tag{170}
 \end{aligned}$$

Equation (170) indicates that the total reaction rate is the same as that in (165), which is derived with the one-term rational approximation. In other words, the obtained background cross section is independent of the number of terms in the rational approximation. This is to be expected, since the behavior of the N -term rational approximation converges with that of the one-term rational approximation at the black limit.

In the enhanced neutron current method, the black limit is assumed for evaluation of the background cross section. However, it can be extended to include the “grayness” of the fuel by including the total reaction rate obtained by the moderate magnitude of the total cross sections, that is, a_n and b_n is determined by the least square fitting of $\Sigma_{t,f}(E) \phi_f(E) = \Sigma_{t,f}(E) \sum_{n=1}^N b_n \frac{\Sigma_{p,f} + g(C, a_B) a_n \Sigma_e}{\Sigma_{t,f}(E) + g(C, a_B) a_n \Sigma_e}$. This approach is a generalization of Hébert and Marleau (1991), in which the collision probability method is used (Koike et al. 2010).

3.5.6 Stamm’ler’s Method for a Heterogeneous Lattice System

In [3.5.5](#), the lattice effect was considered in terms of the Dancoff correction, and the escape probability from a fuel lump in a lattice system was corrected (reduced) by applying the Dancoff correction.

There is another approach to treating the lattice effect in the equivalence theory, which is discussed in detail by Stamm’ler et al. and is currently being adopted in major lattice physics codes, such as CASMO, WIMS, and PHOENIX (Stamm’ler and Abbate 1983). In this subsection, Stamm’ler’s treatment of the lattice effect will be briefly reviewed.

In an infinite lattice system, the collision probability from region I to J is assumed to be expressed by

$$p_{IJ} = p_{ij} + p_{ib} R p_{bj} + p_{ib} R p_{bb} R p_{bj} + p_{ib} R p_{bb} R p_{bb} R p_{bj} + \dots \tag{171}$$

where

- p_{IJ} : collision probability from region I to J in a lattice system,
- p_{ij} : collision probability from i to j in an isolated system,
- p_{bb} : transmission probability of a neutron from cell boundary b to another cell boundary b ,
- p_{ib} : transmission probability of a neutron born in region i to reach cell boundary b ,
- p_{bj} : collision probability that a neutron entering cell boundary b will suffer its first collision in region j , and
- R : reflection probability at cell boundary b .

In (171), several paths from region I to J in the lattice system are taken into account, so that the collision probability becomes larger than it is in an isolated system. The first term of the right-hand side of (171) is the direct collision from region i to j inside a cell. The second term represents a collision from region i to the cell boundary, then from the cell boundary to region j in another cell. The third term represents a collision from region i to the cell boundary, then from the cell boundary to another cell boundary (transmission of the cell), and finally from the cell boundary to region j . When a neutron is passing through a cell boundary, the reflection probability is taken into account by considering the neutron reflection at the fuel assembly boundary. When a fuel assembly becomes large, the reflection probability approaches unity, since most of the fuel cells are not adjacent to the assembly boundary.

Equation (171) can be transformed as follows:

$$p_{IJ} = p_{ij} + \frac{Rp_{ib}p_{bj}}{1 - Rp_{bb}} \quad (172)$$

By incorporating several physical considerations, whose details are given by Stamm'ler and Abbate (1983), we obtain the following formula:

$$p_{FF} = p_{ff} + \frac{x(1 - p_{ff})^2}{x(1 - p_{ff}) + A + B} \quad (173)$$

where

$$x = \frac{4V_f}{S_f} \Sigma_{t,f}$$

$$A = \frac{S_b}{S_f t_{fb}^2} \gamma_b^0$$

$$B = \frac{S_b}{S_f t_{fb}^2} \frac{f(1 - g)}{1 - f(1 - g)}$$

S_b : surface area of cell boundary,

S_f : surface area of fuel lump (pellet),

V_f : volume of fuel lump,

t_{fb} : transmission probability that neutrons leaving a fuel surface with cosine angular distribution will reach the cell boundary,

γ_b^0 : blackness of a cell when the total cross section of the fuel is zero,

f : ratio of assembly surface area to that of the sum of all cell surface areas,

g : first-flight reflection probability across the gap between fuel assemblies.

Note that $B = 0$ in the case of an infinite regular lattice, that is, pin cell geometry.

In contrast to the Dancoff correction, this method naturally incorporates the energy dependence of the shadowing effect among fuel rods. The relationship between the Dancoff factor and Stamm'ler's method is shown as follows:

$$D = \lim_{\Sigma_{t,f} \rightarrow \infty} \frac{1 - p_{FF}}{1 - p_{ff}} = 1 - \frac{1}{1 + A + B} \quad (174)$$

Therefore, the Dancoff correction method is considered to be an asymptotic case with a black-limit approximation.

Next, we will try to express (173) with a rational approximation in order to derive an equivalence relationship. For an isolated fuel lump with a cylindrical shape, we can apply Carlvik's two-term rational approximation, as defined by (123):

$$P_e(E) = 1 - P_{ff}(E) = 2 \frac{2}{\Sigma_{t,f}(E)\bar{l} + 2} - \frac{3}{\Sigma_{t,f}(E)\bar{l} + 3} \quad (175)$$

Substituting (175) into (173), and after some algebra, we obtain

$$p_e^{lat} = 1 - p_{FF} = \beta_1 \frac{\alpha_1}{x + \alpha_1} + \beta_2 \frac{\alpha_2}{x + \alpha_2} \quad (176)$$

where

$$\begin{aligned} \alpha_{1,2} &= \frac{(5C + 6) \mp \sqrt{C^2 + 36C + 36}}{2(C + 1)} \\ C &= A + B \\ \beta_1 &= \frac{C' - \alpha_1}{\alpha_2 - \alpha_1} \\ \beta_2 &= 1 - \beta_1 \\ C' &= \frac{4C + 6}{C + 1} \end{aligned}$$

By substituting (176) into (139) we obtain

$$\phi_f(E) = \frac{1}{E} \sum_{n=1}^2 \beta_n \frac{\sigma_{p,r} + \sigma_{0,n}}{\sigma_{t,r}(E) + \sigma_{0,n}} \quad (177)$$

where

$$\sigma_{0,n} = \sigma_{0,f} + \alpha_n \Sigma_e / N_r$$

Now we have a form identical to that in (125). Therefore, with (131), (132), or (133), we can derive the effective cross section using Stamm'ler's method.

The advantages and disadvantages of Stamm'ler's method are summarized as follows:

- Energy dependence of the shadowing effect for a regular lattice is taken into account approximately.
- Boundary effect of a fuel assembly is taken into account approximately using an average.
- Approximate treatment of the assembly boundary effect.

- Rational approximation for the escape probability.
- This method only yields the effective cross section for an “average pin cell” in a fuel assembly. Effective cross sections that are position-dependent due to lattice irregularity (e.g., gap water, water holes, or water rods) cannot be evaluated. The Dancoff correction is still needed to evaluate such effects.

3.5.7 Potential Limitations of the Equivalence Theory

In [3.5](#), the equivalence theory for resonance calculations, which is widely used for current lattice physics computations, is discussed. In the explanation of each method, several crucial approximations used in the equivalence theory were pointed out (Mizuta 1970). Since these approximations largely determine the accuracy and applicability of the equivalence theory, a review of the approximations used in the equivalence theory is most useful. They are summarized as follows:

1. No resonance overlap is considered.

In the neutron slowing down calculation, the cross section variation is considered only for a resonance isotope, and the scattering cross section is assumed to be constant and dominated by the potential scattering, which is independent of energy. Since various nuclides exist in fuel, especially in a burnt fuel, coincident overlaps among resonance peaks of different nuclides are inevitable. The effect of such resonance overlap has an impact on the energy dependence of the neutron flux. In the preparation of a cross section library, the slowing down calculation for an ultrafine energy group structure is usually carried out with point-wise cross sections. The slowing down calculation is numerically carried out with a resonance nuclide and an energetically constant background cross section. In a common multigroup cross section library, therefore, the resonance overlap effect is not taken into account. The resonance overlap effect will be discussed in more detail in [3.10](#), since it has a considerable impact on effective cross section evaluation.

2. Nonresonant nuclide has a constant scattering cross section.

In an LWR lattice, the major contributors to the slowing down of neutrons are hydrogen and oxygen. In the resonance energy range, these nuclides have fairly constant cross sections, so this assumption is appropriate. Note that in the preparation of a cross section, a constant background cross section is assumed in the slowing down calculation.

3. Resonant nuclide has a constant scattering cross section.

In reality, the scattering cross section of a resonance nuclide in the resonance energy range is not constant, and sometimes has peaks of the scattering cross section (resonance scattering), as shown in [Fig. 21](#). Though the constant scattering cross section is assumed in the NR, WR, and IR approximations, the explicit energy dependence of the scattering cross section of a resonance nuclide is taken into account in the slowing down calculation in cross section library preparation. This inconsistency would be a source of error in the equivalence theory.

■ Figure 21

Microscopic capture and elastic scattering cross sections of ^{238}U (ENDF/B-VII, 300 K)

4. Neutron slowing down is dominated by elastic scattering.

In the resonance energy range, this assumption is appropriate. However, we should take care that neutron slowing down due to elastic scattering does not incorporate the thermal vibration of the target nuclides. If the thermal vibration is taken into account, the energy dependence of the neutron flux will be changed. This simplification (no thermal vibration in the slowing down calculation in the resonance energy range) could be a source of error not only for the equivalence theory, but also for other resonance calculation methods, including the continuous-energy Monte Carlo method (Lee et al. 2009).

5. Energy dependence of the neutron flux in the nonresonant part is asymptotic.

In the equivalence theory, the energy dependence of the neutron flux in the nonresonant part is assumed to be asymptotic ($1/E$). However, in cross section library preparation, the neutron slowing down calculation is usually explicitly carried out for a resonance nuclide with a constant background cross section. In reality, therefore, the energy dependence of the neutron flux in the nonresonant part is not assumed to be asymptotic. This inconsistency would be a cause of error in the equivalence theory.

6. The NR, WR, and IR approximations.

In cross section library preparation, hydrogen is usually used as a background nuclide. Therefore, when the moderator in a system consists of only hydrogen, the homogeneous term in the background cross section (except for the escape cross section) will not be a source of error. However, since various nuclides exist in a system, the slowing down of neutrons by these nuclides should be accurately taken into account in an actual situation. In this context, both the NR and WR approximations will be a source of error, since these methods incorporate approximations to evaluate the source of the slowing down. The IR approximation offers an adjustment

factor for various nuclides with a heavier mass. As discussed in [▶ 3.4.4](#), the conventional IR approximation, which utilizes one IR parameter for a nuclide, is still a source of error since one IR parameter cannot be applied to all self-shielding situations.

7. Escape probability from a fuel lump.

In the equivalence theory, the escape probability from a fuel lump is approximated by the rational approximation to derive the equivalence between homogeneous and heterogeneous systems. However, since the rational approximation cannot rigorously reproduce the escape probability from a fuel lump for all fuel cross section values, it is a source of error in the equivalence theory.

8. Dependence of the Dancoff correction on the moderator cross section.

The Dancoff correction depends on the cross section of the moderator, which is theoretically energy dependent. However, in actual lattice physics computations, the Dancoff correction is usually assumed to be constant throughout the resonance energy range. Though the cross section of the moderator is fairly flat in this energy range, this assumption could be a source of error.

9. The same fuel material (cross section) for all fuel.

The lattice effect, that is, the shadowing effect by other fuels, is incorporated through the Dancoff correction or Stamm'ler's method. These methods are based on the assumption that all fuels in the system consist of the same material (cross section). However, various fuel materials are used in a single fuel assembly, and different types of fuel assemblies may be loaded into adjacent positions in a core. The shadowing effect that is evaluated using the above assumption may not be accurate.

10. Spatially constant cross section in fuel and moderator.

In the evaluation of the escape probability from a fuel lump, the cross section in a fuel lump is assumed to be spatially constant. This situation captures a fuel pellet well, before burnup. However, once a fuel pellet experiences burnup, the fuel composition has a spatial variation due to the gradient of flux in the fuel pellet and the space-dependent resonance shielding effect. For example, ^{239}Pu is generally produced on the pellet surface due to the spatially self-shielding effect of ^{238}U . Therefore, this assumption might be a source of error in the equivalence theory. Fortunately, as several studies have confirmed, the spatial average treatment does not have a significant impact on the accuracy of resonance calculations (Rothenstein et al. 1988; Stoker and Weiss 1996).

11. Black approximation in the Dancoff correction evaluation.

In the evaluation of the Dancoff correction, a fuel lump is assumed to be black, that is, is assumed to behave as a completely absorbent material. This is a source of error in the capture of the lattice effect. For example, let us consider the resonance shielding of ^{239}Pu in a UO_2 pellet. In the beginning of life, the number density of ^{239}Pu is small. In this situation, the self-shielding of ^{239}Pu is not black, that is, it is in an intermediate, diluted (or "gray") condition. However, in the estimation of the Dancoff correction, the entire nuclide is assumed to be black, and could thus be a source of error. The Dancoff correction for a resonance nuclide with a low concentration would therefore be overestimated, since the resonance nuclide is assumed to be completely black, that is, is assumed to have a very large macroscopic cross section.

3.6 Tabulation of Self-Shielding Factors

3.6.1 Cross Section Processing and Effective Cross Sections

In the framework of the equivalence theory, multigroup cross sections are prepared by solving the slowing down equation in a homogeneous medium, as was discussed in [Sect. 2](#). A number of cross section processing codes, such as NJOY, are used for cross section preparation. Cross section processing codes perform slowing down calculations for various background cross sections and temperature conditions, since the self-shielding effect significantly depends on these parameters. Finally, cross section processing codes output the relationship among the background cross section, the temperature, and the effective cross section. These parameters are tabulated in the cross section library of lattice physics codes.

In a typical cross section library, the effective cross sections are not directly tabulated as a function of the background cross section and temperature. Instead, the base cross section for the reference temperature (e.g., 293 K) and infinite background cross section (e.g., 10^{10} barn), and their ratios to the base cross sections for other temperatures and background cross sections, are tabulated in a cross section library (Abagyan et al. 1980). The ratio is the self-shielding factor, which is defined as

$$f(\sigma_0, T) = \frac{\sigma(\sigma_0, T)}{\sigma(\sigma_0^{\text{inf}}, T_{\text{ref}})} \quad (178)$$

where

$f(\sigma_0, T)$: self-shielding factor for the background cross section (σ_0) and temperature (T);
 $\sigma(\sigma_0^{\text{inf}}, T_{\text{ref}})$: base cross section and σ_0^{inf} is a sufficiently large background cross section, for example, 10^{10} barn, and T_{ref} is a reference temperature, for example, room temperature; and
 $\sigma(\sigma_0, T)$: effective cross section at the background cross section (σ_0) and temperature (T).

The shielded cross section is reconstructed as

$$\sigma(\sigma_0, T) = \sigma(\sigma_0^{\text{inf}}, T_{\text{ref}})f(\sigma_0, T) \quad (179)$$

A cross section library that tabulates the reference cross sections and the shielding factors is referred to as a Bondarenko-type cross section library.

Another choice is the tabulation of the base cross section at a reference condition and the deviation of a cross section from the base cross section. The design of the MATXS format, for example, was based on this concept (Macfarlane and Muir 1994a). In this case, the shielded cross section is reconstructed by

$$\sigma(\sigma_0, T) = \sigma(\sigma_0^{\text{inf}}, T_{\text{ref}}) + \Delta\sigma(\sigma_0, T) \quad (180)$$

where $\Delta\sigma(\sigma_0, T)$: difference of effective cross section at the background cross section (σ_0) and temperature (T).

When a cross section does not have resonance, the difference of the cross section in (180) will be zero at the same temperature. Therefore, we can naturally compress the size of a cross section library by truncating (or compressing) the zero values in the self-shielding factor table. This explains the superiority of the MATXS format.

The resonance integral given in (132) can be also used instead of the effective cross section. The resonance integral is converted into the effective cross section as follows:

$$\sigma_{g,x} = \frac{I_{g,x}(\sigma_0, T)}{1 - I_{g,a}(\sigma_0, T)/(\sigma_{p,r} + \sigma_0)} \quad (181)$$

where

$\sigma_{g,x}$: effective cross section of reaction type x ,

$I_{g,x}(\sigma_0, T)$: resonance integral of reaction type x for background cross section (σ_0) and temperature T ,

$I_{g,a}(\sigma_0, T)$: resonance integral of absorption reaction for background cross section (σ_0), and temperature T ,

σ_0 : background cross section, and

$\sigma_{p,r}$: potential scattering cross section of the resonance nuclide.

In the case of the N -term rational approximation, (132) is used to obtain the effective cross section.

3.6.2 Interpolation of Self-Shielding Factor Table

Since the self-shielding factor table is tabulated for discrete values of background cross sections and temperatures, interpolation is necessary in order to obtain an effective cross section for a desired background cross section and temperature.

Since the range of the background cross section is very wide (typically 10–10¹⁰ barn), linear interpolation is not a suitable approach. The grid point for the background cross section is often chosen as the equal interval on a logarithmic axis. In fact, the dependence of an effective cross section on the background cross section is expressed as a reasonably smooth function when the background cross section is expressed on a logarithmic axis, as shown in  Fig. 22.

Therefore, interpolation by the background cross section should be performed on a logarithmic basis. A higher-order polynomial function could be used to increase the accuracy of the interpolation. However, an unphysical polynomial dip would degrade the accuracy of the interpolation when the grid points of the background cross section are not appropriate and/or the variation in the effective cross sections is steep.

Though the accuracy of linear interpolation on a log–log scale is generally lower than that of a higher-order polynomial, the method of linear interpolation is more robust. Therefore, one should carefully check the validity of the cross section interpolation method when it is implemented in a lattice physics code. In general, the reproducibility of the effective cross section should be checked against various background cross sections and temperatures, including the intervals between tabulation points.

When the property of the neutron spectrum is taken into account, the following formula will be also suitable for interpolation:

$$\sigma_{g,x}(\sigma_0) = \sigma_{g,x}(\sigma_0 = \infty) \cdot \frac{\sigma_0^{-1} + a - \sigma_0 b}{\sigma_0^{-1} + c - \sigma_0 d} \quad (182)$$

where

a, b, c, d : parameters for interpolation.

■ Figure 22

Variations in the resonance integral and effective cross section (absorption) of ^{238}U at 900 K, for 80 g (22.6–19.45 eV) and 88 g (7.52–6.16 eV) of 172 XMAS group structure

Equation (182) was originally derived for subgroup cross sections (to be described later) based on the NR approximation for neutron flux in a resonance peak (Yamamoto 2003, 2004).

In the original derivation, the four coefficients in (182) were analytically derived. In the actual interpolation procedure, however, the coefficients in (182) (a , b , c , and d) can be evaluated by the tabulated data set for the background cross section and the effective cross section. Since (182) well reproduces the behavior of the effective cross section for a wide range of background cross sections, (182) offers an accurate approach to interpolation.

Examples of a number of interpolation schemes are shown below:

$$RI(\sigma_0) = a + b\sqrt{\sigma_0} \quad (183)$$

$$\sigma_{eff}(\sigma_0)/\sigma_{eff}(\sigma_0 = \infty) = \sqrt{\sigma_0} \exp[-f\sigma_0] \quad (184)$$

$$\sigma_{eff}(\sigma_0)/\sigma_{eff}(\sigma_0 = \infty) = 1 + a(\tan h(b \ln[\sigma_0] + c) - 1) \quad (185)$$

$$\sigma_{eff}(\sigma_0)/\sigma_{eff}(\sigma_0 = \infty) = \sqrt{(a + \sigma_0)/(a + b + \sigma_0)} \quad (186)$$

$$RI(\sigma_0)/RI(\sigma_0 = \infty) = (\sigma_0/(a + \sigma_0))^b. \quad (187)$$

Equations (183)–(185) are used in the WIMS (Askew et al. 1966), EPRICELL, and IDX (Kidmon 1975) codes, respectively, and (186) and (187) have been proposed by Segev (1975, 1981).

When the resonance integral is used, the root of the background cross section can be used as an interpolation variable, since the resonance integral has a strong linear relationship with the root of the background cross section, as discussed in (133).

The effective cross section is generally a very smooth function of temperature. It can be therefore be interpolated by a quadratic polynomial, or by a combination of constant, root, and linear terms of temperature in Kelvin. Since the resonance integral has a strong correlation with the root of temperature in Kelvin, it could be interpolated with the root of temperature in Kelvin. However, for more accurate interpolation, the root and linear terms of temperature in Kelvin are both necessary.

Interpolation of the self-shielding factor table may dominate the accuracy of the effective cross section. One should therefore be careful in the choice and application of an interpolation scheme, and the accuracy of the interpolation should be confirmed though comparison with other interpolation schemes and/or integration tests of a lattice physics code. For example, variations in the assembly k -infinity should show a smooth dependence on the variations in fuel temperature. Similarly, the assembly k -infinity should be a smooth function of the number density of a resonance absorber. Some anomalies in the calculated k -infinity could signify inappropriate interpolation of the effective cross section.

Finally, it should be noted that, taking into account the advances in affordable PCs, the fine grid points of the background cross section and temperature in a cross section library are recommended, rather than utilization of a sophisticated interpolation scheme.

3.7 Ultrafine Group Method

3.7.1 Homogeneous System

In a homogeneous system, the Boltzmann transport equation shown in (64) can be simplified as follows:

$$\Sigma_t(E)\phi(E) = \int_0^\infty dE' \Sigma_s(E' \rightarrow E)\phi(E') + \chi(E) \int_0^\infty dE' \nu \Sigma_f(E')\phi(E') \quad (188)$$

The scattering term, that is, the first term of the right-hand side of (188), can be reduced as follows when the elastic scattering is dominant:

$$\begin{aligned} \int_0^\infty dE' \Sigma_s(E' \rightarrow E)\phi(E') &= \int_0^\infty dE' \Sigma_{es}(E')P(E' \rightarrow E)\phi(E') \\ &= \sum_k \int_E^{E/\alpha_k} \frac{dE' N_k \sigma_{es,k}(E')\phi(E')}{(1 - \alpha_k)E'} \end{aligned} \quad (189)$$

In the ultrafine group method, the fission source in (188) can be approximated as a fixed source, which is assumed to be independent of neutron flux. In this case, since the absolute value of the fixed source can be arbitrarily set, the sum of the fission source is set at unity, that is, $\int_0^\infty dE' \nu \Sigma_f(E')\phi(E') = 1$. Finally, (188) is rewritten as follows:

$$\Sigma_t(E)\phi(E) = \sum_k \int_E^{E/\alpha_k} \frac{dE' N_k \sigma_{es,k}(E')\phi(E')}{(1 - \alpha_k)E'} + \chi(E) \quad (190)$$

Unfortunately, (190) cannot be analytically solved, except for the particular case ($\alpha_k = 0$, $\sigma_{es,k} = \text{const.}$). A numerical solution, however, can be easily obtained by means of sufficient energy discretization (Ishiguro 1974; Tsuchihashi et al. 1982; Rothenstein et al. 1988; Macfarlane and Muir 1994a; Kobayashi 1995; MC** 2-2 1999; Hazama et al. 2006; Sugimura and Yamamoto 2007).

When the variations in the cross sections and neutron flux in an energy range (energy group) is assumed to be constant, (190) can be converted into a multigroup form as follows:

$$\Sigma_{t,fg}\phi_{fg} = \sum_k \sum_{fg'} \frac{\Sigma_{es,k,fg'}\phi_{fg'}\Delta E_{fg'}}{(1-\alpha_k)\overline{E}_{fg'}} + \chi_{fg} \quad (191)$$

where

$$\begin{aligned} fg &= \{E|E_{fg} \leq E \leq E_{fg-1}\} \\ \Delta E_{fg} &= E_{fg-1} - E_{fg} \\ \overline{E}_{fg} &= \sqrt{E_{fg}E_{fg-1}} \\ fg' &= \{\overline{E}_{fg'} | \overline{E}_{fg} \leq \overline{E}_{fg'} \leq \overline{E}_{fg}/\alpha_k\} \end{aligned}$$

In (191), neutron flux is defined as the average value in a group, and is different from that in a common multigroup equation (integrated value in a group). It should be again noted that the width of an energy group should be narrow enough to neglect variations in the cross section and the neutron flux inside a group. The typical width of this ultrafine energy group is $\Delta U_{fg} = \ln(E_{fg}/E_{fg-1}) = 0.0002 \sim 0.001$, which is sufficiently narrower than that of the energy loss of elastic scattering by a heavy nuclide (e.g., 0.0168 for ^{238}U) and the widths of the major resonance peaks (Ishiguro 1974).

Equation (191) can be solved by the following procedure. The neutron flux for the first group is given by

$$\phi_1 = \frac{\chi_1}{\Sigma_{t,1}} \quad (192)$$

For the second group

$$\phi_2 = \frac{1}{\Sigma_{t,2}} \left(\sum_k \frac{\Sigma_{es,k,1}\phi_1\Delta E_1}{(1-\alpha_k)\overline{E}_1} + \chi_2 \right) \quad (193)$$

For the third group

$$\phi_3 = \frac{1}{\Sigma_{t,3}} \left(\sum_k \left(\frac{\Sigma_{es,k,1}\phi_1\Delta E_1}{(1-\alpha_k)\overline{E}_1} + \frac{\Sigma_{es,k,2}\phi_2\Delta E_2}{(1-\alpha_k)\overline{E}_2} \right) + \chi_3 \right) \quad (194)$$

By repeating the above procedure, the neutron fluxes for successive energy groups can be recursively solved unless up-scattering is taken into account.

Note that the removal cross section, which is defined by

$$\Sigma_{r,fg} = \Sigma_{t,fg} - \frac{\Sigma_{es,k,fg}\Delta E_{fg}}{(1-\alpha_k)\overline{E}_{fg}} \quad (195)$$

could be used in (192)–(194) in order to be consistent with (191). However, the second term in the right-hand side of (195), which represents self-scattering, is sufficiently small in the ultrafine energy group structure. Thus, direct utilization of the total cross section is justified.

Direct implementation of the above procedure entails considerable computation cost, since the summation of the slowing down source that appears in the right-hand side of (192)–(194) will be large, especially when a material contains hydrogen, whose α_k is nearly zero. For this reason, several numerical techniques can be applied.

The slowing down source terms for group fg and $fg - 1$ are given as follows:

$$S_{fg} = \sum_k \sum_{fg'=fg'_{k,fg}}^{fg-1} \frac{\Sigma_{es,k,fg'} \phi_{fg'} \Delta E_{fg'}}{(1 - \alpha_k) \bar{E}_{fg'}} \quad (196)$$

$$S_{fg-1} = \sum_k \sum_{fg'=fg'_{k,fg-1}}^{fg-2} \frac{\Sigma_{es,k,fg'} \phi_{fg'} \Delta E_{fg'}}{(1 - \alpha_k) \bar{E}_{fg'}} \quad (197)$$

where

$fg'_{k,fg}$: upper energy group from which neutrons are down-scattered into fg , for nuclide k ,
 $fg'_{k,fg-1}$: upper energy group from which neutrons are down-scattered into $fg - 1$, for nuclide k .

By subtracting (196) and (197), we obtain

$$\begin{aligned} S_{fg} - S_{fg-1} &= \sum_k \sum_{fg'=fg'_{k,fg}}^{fg-1} \frac{\Sigma_{es,k,fg'} \phi_{fg'} \Delta E_{fg'}}{(1 - \alpha_k) \bar{E}_{fg'}} - \sum_k \sum_{fg'=fg'_{k,fg-1}}^{fg-2} \frac{\Sigma_{es,k,fg'} \phi_{fg'} \Delta E_{fg'}}{(1 - \alpha_k) \bar{E}_{fg'}} \\ &= \sum_k \sum_{fg'=fg'_{k,fg}}^{fg-2} \frac{\Sigma_{es,k,fg'} \phi_{fg'} \Delta E_{fg'}}{(1 - \alpha_k) \bar{E}_{fg'}} + \sum_k \frac{\Sigma_{es,k,fg-1} \phi_{fg-1} \Delta E_{fg-1}}{(1 - \alpha_k) \bar{E}_{fg-1}} \\ &\quad - \sum_k \sum_{fg'=fg'_{k,fg}}^{fg-2} \frac{\Sigma_{es,k,fg'} \phi_{fg'} \Delta E_{fg'}}{(1 - \alpha_k) \bar{E}_{fg'}} - \sum_k \sum_{fg'=fg'_{k,fg-1}}^{fg'_{k,fg}-1} \frac{\Sigma_{es,k,fg'} \phi_{fg'} \Delta E_{fg'}}{(1 - \alpha_k) \bar{E}_{fg'}} \\ &= \sum_k \frac{\Sigma_{es,k,fg-1} \phi_{fg-1} \Delta E_{fg-1}}{(1 - \alpha_k) \bar{E}_{fg-1}} - \sum_k \sum_{fg'=fg'_{k,fg-1}}^{fg'_{k,fg}-1} \frac{\Sigma_{es,k,fg'} \phi_{fg'} \Delta E_{fg'}}{(1 - \alpha_k) \bar{E}_{fg'}} \end{aligned} \quad (198)$$

Equation (198) indicates that the slowing down source of group fg can be calculated by adding the contribution from group $fg-1$ (the first term in the right-hand side of (198)), and subtracting the contributions of $fg'_{k,fg-1} \leq fg' \leq fg'_{k,fg} - 1$ (the second term in the right-hand side of (198)) from the slowing down source of group $fg - 1$. Since the number of energy groups that satisfies $fg'_{k,fg-1} \leq fg' \leq fg'_{k,fg} - 1$ is small, the computational load for estimating the slowing down source is significantly reduced.

Finally, (191) can be rewritten as follows:

$$\Sigma_{t,fg} \phi_{fg} = S_{fg-1} + \sum_k \frac{\Sigma_{es,k,fg-1} \phi_{fg-1} \Delta E_{fg-1}}{(1 - \alpha_k) \bar{E}_{fg-1}} - \sum_k \sum_{fg'=fg'_{k,fg-1}}^{fg'_{k,fg}-1} \frac{\Sigma_{es,k,fg'} \phi_{fg'} \Delta E_{fg'}}{(1 - \alpha_k) \bar{E}_{fg'}} + \chi_{fg} \quad (199)$$

The number of nuclides can reach several hundred for a burnt pellet, in which there are many heavy and fission product nuclides. In such a case, the computational load for the right-hand side of (199) would be heavy. In order to reduce this load, the nuclides can be categorized by their atomic mass, since slowing down due to elastic scattering depends on atomic mass. For example, in a typical LWR analysis, zirconium and uranium can be considered as representative nuclides for cladding, fission products, and heavy nuclides, in addition to hydrogen and oxygen (Sugimura and Yamamoto 2007).

The above numerical solution is used to solve the neutron slowing down equation in a homogeneous system, and is used in major codes such as NJOY. Furthermore, (199) is also used to evaluate the neutron slowing down source in the heterogeneous calculation that will be discussed in the next subsection.

Once the neutron flux in each energy group is obtained, the effective cross section is given by (200), which is the common definition

$$\sigma_g = \frac{\sum_{fg \in g} \Delta E_{fg} \sigma_{fg} \phi_{fg}}{\sum_{fg \in g} \Delta E_{fg} \phi_{fg}} \quad (200)$$

3.7.2 Heterogeneous System

In a heterogeneous system, the neutron slowing down equation is given by (201), when the collision probability is used for the transport kernel.

$$\Sigma_{t,i}(E) \phi_i(E) V_i = \sum_j P_{j \rightarrow i}(E) V_j \left(\int_0^\infty dE' \Sigma_{s,j}(E' \rightarrow E) \phi_j(E') + \chi_j(E) \int_0^\infty dE' \nu \Sigma_{f,j}(E') \phi_j(E') \right) \quad (201)$$

By applying the same approximations (multigroup and fixed source) used in [Sect. 3.7.1](#), we obtain

$$\Sigma_{t,f,fg} \phi_{f,fg} V_f = \sum_j P_{j \rightarrow f,fg} V_j (S_{j,fg} + \chi_{j,fg}) \quad (202)$$

When the collision probability in each group is evaluated, (202) can be easily solved. Since (202) contains neutron transport in space, its application is practically limited to a small system, such as a pin cell. Since (202) is a common multigroup form of the transport equation, other transport theories, for example, the discrete-ordinate method or the method of characteristics, can be used. However, the collision probability method is a practical choice due to its superiority for a small system, as discussed in [Sect. 4](#).

Even if a small system is considered, estimation of the collision probability for each group may require considerable computational effort, since in ultrafine energy group calculations, the typical number of energy groups ranges from some tens of thousand to a hundred thousand. Since the collision probability calculation in a one-dimensional system (e.g., cylinder) is quite rapid, a cylindrical approximation with a white boundary condition is a practical choice for an ultrafine energy group calculation in a heterogeneous system.

However, since typical LWR lattices adopt a square shape, a cylindrical approximation would introduce considerable error to the evaluation of neutron flux. Since estimation of the collision probability in a general two-dimensional geometry requires the numerical integration of angle and space with a ray-tracing method, its direct implementation becomes impractical due to the longer computation time required. Collision probabilities are therefore pre-tabulated for various cross sections in each region, and the collision probabilities in each group are obtained by an interpolation of the table (Ishiguro 1974). Though such table interpolation offers a simple, practical approach to the estimation of collision probability, its application is practically limited to a small system, in which there are just a few regions.

The number of regions in a heterogeneous system is, of course, larger than that in a homogeneous system. Thus, evaluations of the slowing down sources for all regions require a longer

■ Figure 23

Typical neutron slowing down source in an LWR cell. Note that the fission source is assigned above 10 eV

computation time. Some typical slowing down sources and neutron fluxes in an LWR cell are shown in [Figs. 23](#) and [24](#). These figures suggest that the neutron source in the moderator region is fairly close to $1/E$, in which the NR approximation is well established for the neutron slowing down source. Therefore, the neutron source in the moderator region can be given $1/E$ as a fixed source, and no slowing down calculation would be carried out for the moderator region. Such an approximation not only gives good results, but also considerably reduces the computation time required (Sugimura and Yamamoto 2007).

3.7.3 Limitations of the Ultrafine Energy Groups Method

The approximations used in the ultrafine energy groups method are summarized as follows:

- Neutron slowing down is dominated by elastic scattering.
- Fission source is treated as a fixed source.
- Cross section and neutron flux are assumed to be constant in a group.
- Thermal up-scattering is not taken into account.

■ Figure 24
Typical neutron fluxes in an LWR cell

For a heterogeneous system, the following additional approximations would be taken into account, which are common in typical transport calculations:

- Angular/spatial discretization, and
- Treatment of anisotropic scattering.

The above assumptions usually have small impact on common lattice physics computations for an LWR, if sufficient considerations are taken into account. The ultrafine group method thus offers much greater accuracy than the equivalence theory, and can also overcome a number of deficiencies of that theory (NR/WR/IR approximations, escape probability approximations, resonance overlap, and so on). In fact, the result of the ultrafine group method is usually comparable to that of the continuous-energy Monte Carlo method. The largest and most crucial drawback of this method is its applicability to a large geometry, for example, its direct application to an entire fuel assembly will require hours of calculation with a modern PC, which would be prohibitive in production lattice physics computations. Therefore, the ultrafine group method would be coupled with other resonance calculation methods in order to reinforce its weak points. For example, the ultrafine group calculation can be carried out in a homogeneous system to correct the resonance overlap effect, or it can be carried out in pin cell geometry, with

the position dependency corrected by the conventional equivalence theory with the Dancoff factor (Sugimura and Yamamoto 2007).

3.8 Subgroup Method

3.8.1 General Concept

In the subgroup method, an energy group is subdivided into several subgroups in order to accurately consider variations in the cross section within a group. Since the subgroup method can accurately calculate the effective cross section even if the number of the subgroups in an energy group is a few to several, some lattice physics codes (e.g., APOLLO, WIMS, and HELIOS) incorporate the subgroup method for evaluation of the effective cross section (Nikoleav et al. 1971, 1973; Levitt 1972; Sinitsa and Nikoleav 1973; Cullen 1974, 1986; Ribon 1986; Halsall 1995; Hébert 1998; Loubiere et al. 1999; Yamamoto and Takeda 2000; Sublet and Ribon 2002; Hébert and Coste 2002; Yamamoto 2003, 2004; Hébert 2004, 2005a; Chiba and Unesaki 2006; Yamamoto and Takeda 2006).

The basic concept of the subgroup method is as follows. Variations in neutron flux mainly depend on the magnitude of the cross section, as described in the resonance theory for a homogeneous system, for example, (77). Therefore, when a group is divided into several subgroups according to the magnitude of the cross section, the variations in the neutron flux in a subgroup would be smaller than that in the original group structure. The concept of the subgroup method based on the above explanation is shown in  Fig. 14.

A subgroup structure defined by the above approach has one distinguishing feature: the energy range for a subgroup is no longer contiguous as in the conventional multigroup method. Direct utilization of this physical concept in a resonance calculation is referred to as the direct approach. Though the direct approach yields a clear and intuitive insight into the subgroup method, it also has drawbacks. The most significant drawback is that the subgroup averaged cross section still has dependency on the background cross section, though its dependency on the background cross section is much smaller than that of the effective cross section as defined in a conventional multigroup structure.

On account of this deficiency, the direct approach is not widely used in present day lattice physics codes. Instead of the direct approach, the concept of the probability table method is widely used in practical applications. In this approach, the cross sections of subgroups and their weights (corresponding to the energy group width of each subgroup in the direct method) are chosen so that they are independent of the background cross section. In the probability table approach, the parameters for subgroups (their cross sections and weights) become nonphysical, and no longer have corresponding distinguishing energy ranges as in the direct method.

Though the concept of the probability table is widely used in lattice physics computations, we will discuss the direct approach first, since an intuitive physical understanding of the direct approach is much easier than the probability table approach. An explanation of the probability table approach will be provided after we discuss the direct approach. Two separate methods to generate the probability table are also discussed in this subsection.

3.8.2 Direct Approach

The neutron transport equation for the “direct” subgroup approach is obtained by the energy integration of the following transport equation for a subgroup sg :

$$\vec{\Omega} \cdot \nabla \psi(\vec{r}, E, \vec{\Omega}) + \Sigma_t(\vec{r}, E, \vec{\Omega}) \psi(\vec{r}, E, \vec{\Omega}) = Q(\vec{r}, E, \vec{\Omega}) \quad (203)$$

We obtain

$$\vec{\Omega} \cdot \nabla \psi_{sg}(\vec{r}, \vec{\Omega}) + \Sigma_{t,sg}(\vec{r}) \psi_{sg}(\vec{r}, \vec{\Omega}) = Q_{sg}(\vec{r}) \quad (204)$$

Cross section for subgroup sg is given as follows:

$$\sigma_{sg}(\vec{r}) = \frac{\int_{sg} dE \sigma(E) \phi(\vec{r}, E)}{\int_{sg} dE \phi(\vec{r}, E)} \quad (205)$$

Note that the angular dependence of the neutron source and of the effective cross section in sg is neglected for the sake of simplicity. Such simplification is also used for conventional effective cross sections in a multigroup energy structure. The effective cross section for a conventional multigroup structure is obtained with the neutron scalar flux of subgroup sg , which is obtained as a solution of (204)

$$\sigma_g(\vec{r}) = \frac{\sum_{sg \in g} \sigma_{sg}(\vec{r}) \phi_{sg}(\vec{r})}{\sum_{sg \in g} \phi_{sg}(\vec{r})} \quad (206)$$

In the equivalence theory, the spatial distribution of the neutron flux is evaluated approximately by the escape probability from a fuel lump. In contrast to the equivalence theory, the spatial distribution of the neutron flux is evaluated by the explicit transport calculation in each subgroup. Therefore, the subgroup method can give more accurate results than the equivalence theory. Furthermore, application of the conventional equivalence theory is limited to the average value of a fuel lump, and the spatial distribution of the self-shielding effect cannot be evaluated, since it relies on the escape probability from a fuel lump. The subgroup method can, however, be applied to more general conditions, which include the spatial distribution of the self-shielding effect.

When a subgroup structure is sufficiently fine, variations in the cross section and neutron spectrum in a subgroup can be neglected. Under such conditions, the subgroup method will be consistent with the ultrafine group method. That said, the essential usefulness of the subgroup method is due to the high accuracy that can be obtained even with a small number of subgroups. In this context, the subgroup method is considered as a resonance calculation method that is different from the ultrafine group method.

The effectiveness of the subgroup method depends on the accuracy or appropriateness of the subgroup parameters when a small (i.e., practical) number of subgroups is used in calculations. Since a cross section in a subgroup depends on the neutron spectrum in a subgroup, its evaluation is important. In the direct approach, we have the freedom to choose the energy group structure for subgroups, so we should find a better energy group structure for a subgroup. The neutron flux is approximately inversely proportional to the magnitude of the cross section. Therefore, a subgroup structure, which is defined by the magnitude of the cross section and has discrete ranges, as shown in  Fig. 14, is clearly better than the conventional approach

(sequential division of energy range), since variations in the cross section in a group (and thus variations in the neutron flux in a group) are smaller than those in a conventional group structure with a contiguous energy range.

The subgroup cross section becomes independent of the background cross section (or the shielding condition) when the resonance cross section has a “step shape,” that is, the cross section in each subgroup is constant. In reality, however, we cannot neglect variations in the cross section in a subgroup, so the subgroup cross section inevitably has dependency on the neutron spectrum. Therefore, in the direct approach of the subgroup method, the subgroup cross section is evaluated by

$$\sigma_{sg}(\sigma_0) = \frac{\int_{sg} dE \sigma(E) \phi(E, \sigma_0)}{\int_{sg} dE \phi(E, \sigma_0)}$$

$$sg = \{ E | \sigma_{sg,\min} \leq \sigma(E) \leq \sigma_{sg,\max} \} \quad (207)$$

where

σ_{sg} : subgroup cross section in subgroup sg .

$\phi(E, \sigma_0)$ is obtained by solving a slowing down equation in a homogeneous system composed of hydrogen and the resonance nuclide in question. By performing slowing down calculations for different background cross sections, we can tabulate the dependency of subgroup cross sections on the background cross sections. Once the background cross section in a heterogeneous geometry is evaluated, the subgroup cross section can be obtained through interpolation of the pre-tabulated data. This approach is the same as in the conventional equivalence method, but provides better accuracy, since the sensitivity (variation) of the subgroup cross section on the background cross section is smaller. However, since the above approach still relies on the equivalence between homogeneous and heterogeneous systems, it presents a potential source of error.

When the direct approach of the subgroup method is applied to a general geometry, the evaluation of the background cross section becomes difficult, especially in the evaluation of the space-dependent effective cross section. Since the equivalence theory relies on the rational approximation for the neutron escape probability from a fuel lump, it cannot directly treat the inner regions of a resonance lump. In fact, the heterogeneous term in the background cross section for the inner region of a fuel lump will be zero, since the Dancoff correction becomes unity in such a case. The inner region of a fuel lump is surrounded by fuels, which in a Dancoff factor evaluation are black; thus, the Dancoff correction is unity for such inner regions. In other words, the appropriate derivation of the background cross section for general geometry is difficult, which is why application of the direct approach of the subgroup method has been limited (Yamamoto 2003).

A recent study, however, presents the possible resolution of this issue by using the effective cross section as an index of the self-shielding condition. In this approach, the following procedures are used to evaluate the effective cross section in a general heterogeneous system (Yamamoto et al. 2009a, b):

1. Tabulate the subgroup and the effective cross sections, which are defined by (205) and (206), respectively, versus the background cross section. The subgroup and effective cross sections are evaluated through slowing down calculations in a homogeneous system with various background cross sections.

2. Perform a transport calculation using the tabulated subgroup cross sections. For the first iteration, the subgroup cross sections with an infinite-dilution condition can be used as a starting point.
3. Evaluate the effective cross section by (206) with the subgroup neutron flux obtained in (2).
4. A corresponding background cross section that reproduces the effective cross section obtained in (3) is then estimated from the tabulated data.
5. Update the subgroup cross sections with the background cross section obtained in (4).
6. Repeat (2)–(5) until convergence; a few iterations are sufficient to obtain converged results.

By using the above approach, the evaluation of the background cross section, which is a difficult step in the application of the direct approach of the subgroup method, can be avoided. The above procedure can thus be a practical way to apply the direct approach of the subgroup method in general geometry.

3.8.3 Probability Table Approach

In the direct approach of the subgroup method, the energy group structure for each subgroup is explicitly specified. Contrary to this, in the probability table approach, the energy group structure is not explicitly defined (Levitt 1972; Cullen 1974, 1986; Ribon 1986; Halsall 1995; Hébert 1998; Sublet and Ribon 2002; Hébert and Coste 2002; Hébert 2005a; Chiba and Unesaki 2006). In the mathematical context, it is considered as a utilization of the Lebesgue integration, that is, the integration of neutron spectrum $f(E)$ into energy is converted to that on a cross section

$$\int_{E_g}^{E_{g-1}} dE f(E) = \int_{\sigma_{\min,g}}^{\sigma_{\max,g}} d\sigma f(\sigma) p(\sigma) \quad (208)$$

where

σ : cross section,

$f(E)$: neutron spectrum (dependence of neutron flux on energy),

$f(\sigma)$: neutron spectrum (dependence of neutron flux on cross section),

$p(\sigma)$: probability that cross section in group g is σ ,

$\sigma_{\min,g}$: minimum value of cross section in group g ,

$\sigma_{\max,g}$: maximum value of cross section in group g .

Note that $f(\sigma)$ and $f(E)$ represent the same physical quantity but have different formulas. Variations in $f(\sigma)$ are much smoother than those of $f(E)$ since the neutron spectrum is a smooth function of the magnitude of the cross section. Recalling the NR approximation, the neutron flux is expressed as

$$f(\sigma) = \frac{\sigma_0}{\sigma(E) + \sigma_0} \quad (209)$$

which is a smooth function of the cross section (σ) of a resonant nuclide.

In (209), the $1/E$ dependence is omitted since variations in neutron flux due to $1/E$ are not very large. The probability density function for the cross section, $p(\sigma)$, is also a smooth function of the cross section. An example of $p(\sigma)$ is shown in  Fig. 25.

The above discussion suggests that the integration in the right-hand side of (208) is easier than that in the left-hand side, since the behavior of the integrand is much smoother. Coarse discretization can therefore be used in the integration of the right-hand side of (208).

■ Figure 25

Cumulative probability density function of cross section for ^{238}U (88 group in the 172-group XMAS structure (7.52–6.16 eV), in which there is a large resonance of ^{238}U)

By adopting the concept of the probability density of the cross section, we can define a set of subgroup cross sections and their associated weights that are independent of the background cross section, that is, generalized subgroup cross sections and weights can be derived. Since these parameters are independent of the magnitude of self-shielding, they can be used in any configuration, including the space-dependent self-shielding in a fuel lump, which is difficult to handle using the conventional direct approach of the subgroup method.

The above approach, however, also has a significant drawback. By adopting the integration procedure on the cross section, energy-dependent information is lost. That is, each subgroup defined by the probability table method has no physical energy group structure. This creates difficulty in the treatment of the temperature distribution in a configuration. The shape of a resonance cross section depends on temperature, due to the Doppler broadening effect, as shown in [Fig. 26](#).

When there is temperature distribution in a system, we have different sets of subgroup cross sections and their associated probabilities (weights), even for a nuclide. However, since the implicit energy group structure for each subgroup is different, direct utilization of subgroup parameters with different temperatures cannot be justified in transport calculations. Let us assume two different multigroup cross section sets with totally different energy group structures, but with the same number of energy groups. We can perform a transport calculation that simultaneously uses these two multigroup cross section sets, since the number of energy groups is the same. However, such calculation is, clearly, meaningless. Because direct application of the probability table method for a temperature-dependent problem causes the above inconsistency, care must be taken.

We now consider a set of subgroup cross sections and their associated probabilities, σ_{sg} and p_{sg} . Note that σ_{sg} is constant in a subgroup. Intuitive interpretation of the probability is the fraction of the energy range of the corresponding subgroup within an energy group. When the probability is larger, the corresponding subgroup occupies a larger fraction in an energy group. The subgroup cross section physically represents the average cross section in a subgroup.

■ **Figure 26**
Variations in a ^{238}U capture cross section due to Doppler broadening

However, it must again be remembered that each subgroup has no explicit energy range, and thus these remain abstract and rather mathematical properties.

With the subgroup parameters (subgroup cross sections and probabilities), we have the following equations:

$$\int_{E_g}^{E_{g-1}} dE f(E) = \int_{\sigma_{\min,g}}^{\sigma_{\max,g}} d\sigma f(\sigma) p(\sigma) = \sum_{sg \in g} f_{sg} p_{sg} \quad (210)$$

$$\sum_{sg \in g} p_{sg} = 1 \quad (211)$$

where

$$f_{sg} = f(\sigma_{sg})$$

Equation (210) means that the neutron flux can be integrated through a quadrature set, whose quadrature points and associated weights are σ_{sg} and p_{sg} , respectively. Under this assumption, the effective cross section can be obtained by

$$\sigma_g = \frac{\int_{E_g}^{E_{g-1}} dE \sigma(E) \phi(E)}{\int_{E_g}^{E_{g-1}} dE \phi(E)} = \frac{\int_{\sigma_{\min,g}}^{\sigma_{\max,g}} d\sigma \sigma \phi(\sigma) p(\sigma)}{\int_{\sigma_{\min,g}}^{\sigma_{\max,g}} d\sigma \phi(\sigma) p(\sigma)} = \frac{\sum_{sg \in g} \sigma_{sg} \phi_{sg} p_{sg}}{\sum_{sg \in g} \phi_{sg} p_{sg}} \quad (212)$$

Once the subgroup parameters, that is, σ_{sg} and p_{sg} are known, we can evaluate the effective cross section through the neutron flux for subgroup ϕ_{sg} , which is obtained by a transport calculation for each subgroup. A set of subgroup parameters is called a probability table, which is obtained by a number of numerical calculations that will be discussed later.

Since subgroup parameters are chosen to be independent of the background cross section, they can in principle be used in any configuration. Such flexibility is the advantage of the probability method. However, as discussed previously, an explicit energy group structure cannot be

defined (or is lost) in the derivation of the subgroup cross section. Therefore, application of this method to a problem with temperature distribution is limited.

The fitting and the moment methods are major approaches to the derivation of subgroup parameters. From a historical point of view, they represent the origin of the subgroup method. A more intuitive approach, that is, the direct approach discussed [▶ 3.8.2](#), was devised as a physical interpretation of the subgroup method based on the probability table approach.

3.8.4 Fitting Method

The fitting method is a numerical calculation procedure to derive a set of probability tables used in the subgroup method (Nikoleav et al. 1971; Levitt 1972). In the following, we will discuss the derivation based on the NR approximation.

When the NR approximation for the neutron flux is applied to the formulation of the subgroup cross section, we obtain the following equation:

$$\sigma_{t,sg}(\sigma_0) = \frac{\int_{sg} dE \sigma_t(E) \phi(E, \sigma_0)}{\int_{sg} dE \phi(E, \sigma_0)} = \frac{\int_{sg} dE \sigma_t(E) \frac{1}{\sigma_t(E) + \sigma_0}}{\int_{sg} dE \frac{1}{\sigma_t(E) + \sigma_0}} \quad (213)$$

The band probability is defined by the width of the energy range for each subgroup, as follows:

$$p_{sg} = \frac{\int_{sg} dE}{\int_g dE} \quad (214)$$

The numerator in (213) can be written as follows:

$$\begin{aligned} \int_{sg} dE \sigma_t(E) \frac{1}{\sigma_t(E) + \sigma_0} &= \int_{sg} dE \frac{\sigma_t(E) + \sigma_0 - \sigma_0}{\sigma_t(E) + \sigma_0} \\ &= \int_{sg} dE - \sigma_0 \int_{sg} dE \frac{1}{\sigma_t(E) + \sigma_0} \end{aligned} \quad (215)$$

By substituting (214) and (215) into (213), we obtain the following:

$$\begin{aligned} \sigma_{t,sg}(\sigma_0) &= \frac{\int_{sg} dE - \sigma_0 \int_{sg} dE \frac{1}{\sigma_t(E) + \sigma_0}}{\int_{sg} dE \frac{1}{\sigma_t(E) + \sigma_0}} \\ &= \frac{p_{sg} \int_g dE}{\int_{sg} dE \frac{1}{\sigma_t(E) + \sigma_0}} - \sigma_0 \end{aligned} \quad (216)$$

From (216), we have the following relationship:

$$\int_{sg} dE \frac{1}{\sigma_t(E) + \sigma_0} = \frac{p_{sg} \int_g dE}{\sigma_{t,sg}(\sigma_0) + \sigma_0} \quad (217)$$

By substituting (214) and (217) into (215), we obtain

$$\begin{aligned} \int_{s_g} dE \sigma_t(E) \frac{1}{\sigma_t(E) + \sigma_0} &= p_{sg} \int_g dE - \sigma_0 \frac{p_{sg} \int_g dE}{\sigma_{t,sg}(\sigma_0) + \sigma_0} \\ &= \frac{\sigma_{t,sg}(\sigma_0) p_{sg} \int_g dE}{\sigma_{t,sg}(\sigma_0) + \sigma_0} \end{aligned} \quad (218)$$

With (213), (217) and (218), the total cross section is given as follows:

$$\begin{aligned} \sigma_{t,g}(\sigma_0) &= \frac{\int_{E_g}^{E_{g-1}} dE \sigma_t(E) \frac{1}{\sigma_t(E) + \sigma_0}}{\int_{E_g}^{E_{g-1}} dE \frac{1}{\sigma_t(E) + \sigma_0}} \\ &= \frac{\sum_{sg \in g} \int_{s_g} dE \sigma_t(E) \frac{1}{\sigma_t(E) + \sigma_0}}{\sum_{sg \in g} \int_{s_g} dE \frac{1}{\sigma_t(E) + \sigma_0}} \\ &= \frac{\sum_{sg \in g} \frac{\sigma_{t,sg}(\sigma_0) p_{sg} \int_g dE}{\sigma_{t,sg}(\sigma_0) + \sigma_0}}{\sum_{sg \in g} \frac{p_{sg} \int_g dE}{\sigma_{t,sg}(\sigma_0) + \sigma_0}} \\ &= \frac{\sum_{sg \in g} \frac{\sigma_{t,sg}(\sigma_0) p_{sg}}{\sigma_{t,sg}(\sigma_0) + \sigma_0}}{\sum_{sg \in g} \frac{p_{sg}}{\sigma_{t,sg}(\sigma_0) + \sigma_0}} \end{aligned} \quad (219)$$

In (219), the subgroup cross section has dependency on the background cross section. However, we assume that the subgroup cross sections are independent of the background cross section, so the effective cross section is defined as

$$\sigma_{t,g}(\sigma_0) = \frac{\sum_{sg \in g} \frac{\sigma_{t,sg} p_{sg}}{\sigma_{t,sg} + \sigma_0}}{\sum_{sg \in g} \frac{p_{sg}}{\sigma_{t,sg} + \sigma_0}} \quad (220)$$

In the fitting method, the subgroup parameters (a set of subgroup cross sections and associated probabilities) are chosen to satisfy (220) through a fitting procedure. When the number of subgroup is N , we have $2N$ unknowns for the subgroup cross sections and the probabilities. The normalization condition for the probabilities can be used as a constraint.

$$\sum_{sg \in g} p_{sg} = 1 \quad (221)$$

In addition, we should consider at least $2N - 1$ relations between the background cross section and the effective cross section in order to complete a set of equations with which to estimate

unknowns:

$$\sigma_{t,g}(\sigma_{0,l}) = \frac{\sum_{sg \in g} \frac{\sigma_{t,sg} p_{sg}}{\sigma_{t,sg} + \sigma_{0,l}}}{\sum_{sg \in g} \frac{p_{sg}}{\sigma_{t,sg} + \sigma_{0,l}}} \quad (l = 1, 2, \dots, 2N - 1) \quad (222)$$

We can use more than $2N - 1$ relations for the background cross section and the effective cross section. In this case, the subgroup parameters are evaluated through the least square fitting. Therefore, this approach is usually called the fitting method.

In principle, there is not a general set of subgroup parameters that is independent of the background cross section. Therefore, even if we use the fitted subgroup parameters, the effective cross section cannot be exactly reproduced for every background cross section. This is a shortcoming of the fitting method. Furthermore, when the number of subgroups increases, the fitting procedure used for (222) sometimes runs into numerical difficulties and may provide a nonphysical solution for the subgroup parameters, for example, negative and/or imaginary probabilities and subgroup cross sections.

Despite this deficiency, the fitting method remains a major approach to the derivation of subgroup cross sections since it gives the “general” subgroup parameters that can be used for any geometry, and estimation of the effective cross section in general geometry becomes easy once the subgroup is obtained. Furthermore, in the fitting method, the band probabilities and subgroup cross sections are chosen to reproduce the effective multigroup cross section, which in a homogeneous system, is usually generated through an accurate numerical solution of the slowing down equation (ultrafine group calculation). In this context, the fitting method can implicitly incorporate the “slowing down” effect, which is obtained by the ultrafine group calculation.

3.8.5 Moment Method

The moment method is another approach to estimating subgroup parameters (Ribon 1986; Hébert and Coste 2002; Hébert 2005a). In this method, we use the following “moment” of a cross section:

$$M_{t,n} = \frac{\int_{E_g}^{E_{g-1}} dE \sigma_t(E)^n}{\int_{E_g}^{E_{g-1}} dE} \quad (223)$$

where n is the order of a moment. Using the probability density function of the cross section and applying the integration with a cross section, (223) can be rewritten as follows:

$$\begin{aligned} M_{t,n} &= \frac{\int_{E_g}^{E_{g-1}} dE \sigma_t(E)^n}{\int_{E_g}^{E_{g-1}} dE} = \frac{\int_{\sigma_{t,\min,g}}^{\sigma_{t,\max,g}} d\sigma_t \sigma_t^n p(\sigma_t)}{\int_{\sigma_{t,\min,g}}^{\sigma_{t,\max,g}} d\sigma_t p(\sigma_t)} \\ &\approx \frac{\sum_{sg \in g} \int_{\sigma_{t,\min,g}}^{\sigma_{t,\max,g}} d\sigma_t \sigma_t^n \delta(\sigma_t - \sigma_{t,sg}) p_{sg}}{\sum_{sg \in g} \int_{\sigma_{t,\min,g}}^{\sigma_{t,\max,g}} d\sigma_t \delta(\sigma_t - \sigma_{t,sg}) p_{sg}} \\ &= \frac{\sum_{sg \in g} \sigma_{t,sg}^n p_{sg}}{\sum_{sg \in g} p_{sg}} = \sum_{sg \in g} \sigma_{t,sg}^n p_{sg} \end{aligned} \quad (224)$$

The moment of a cross section using the subgroup parameters is given by

$$m_{t,n} = \sum_{sg \in g} \sigma_{t,sg}^n p_{sg} \quad (225)$$

In the moment method, we also have $2N$ unknowns for the subgroup cross sections and probabilities, just as in the fitting method. Since the normalization condition for probability is also used in the moment method, we should consider the $2N - 1$ constraints for different moments:

$$\sum_{sg \in g} p_{sg} = 1 \quad (226)$$

$$\frac{\int_{E_g}^{E_{g-1}} dE \sigma_t(E)^n}{\int_{E_g}^{E_{g-1}} dE} = \sum_{sg \in g} \sigma_{t,sg}^n p_{sg} \quad (n = I + 1, I + 2, \dots, I + 2N - 1, I : \text{integer}) \quad (227)$$

When $n = 0$, (227) is reduced to (226). By solving (226) and (227), (i.e., $\sum_{sg \in g} p_{sg} = 1$ and $M_{t,n} = m_{t,n}$), we can obtain the subgroup parameters. However, (226) and (227) require the solution of the n th degree equation, which would be difficult to obtain. In the following part, a numerical procedure for the evaluation of subgroup parameters using the Pade approximation, as proposed by Ribon et al. is described (Ribon 1986).

First, in the case of $I = 0$, we define a polynomial of order $2N - 1$, which contains the moments of a cross section in its coefficients:

$$F(z) = \sum_{n=0}^{\infty} m_{t,n} z^n = \sum_{n=0}^{2N-1} m_{t,n} z^n + r(z^{2N}) \quad (228)$$

where $r(z^{2N})$ indicates a residual term.

When the value of z is chosen to satisfy $\sigma_{t,sg} z < 1$, (228) can be rewritten as follows:

$$\begin{aligned} F(z) &= \sum_{n=0}^{2N-1} m_{t,n} z^n + r(z^{2N}) \\ &= \sum_{n=0}^{2N-1} \sum_{sg \in g} \sigma_{t,sg}^n p_{sg} z^n + r(z^{2N}) \\ &= \sum_{sg \in g} p_{sg} \sum_{n=0}^{2N-1} (\sigma_{t,sg} z)^n + r(z^{2N}) \\ &= \sum_{sg \in g} p_{sg} \frac{1}{1 - \sigma_{t,sg} z} + r'(z^{2N}) \end{aligned} \quad (229)$$

$F(z)$ can be also expressed by $M_{t,n}$ since $m_{t,n}$ should reproduce $M_{t,n}$, that is, $M_{t,n} = m_{t,n}$. Using the Pade approximation, $F(z)$ can be written as follows:

$$F(z) = \sum_{n=0}^{2N-1} M_{t,n} z^n + R(z^{2N}) = \frac{\sum_{n=0}^{N-1} a_n z^n}{\sum_{n=0}^N b_n z^n} + R'(z^{2N}) \quad (230)$$

where $R(z^{2N})$ is a residual term, which is slightly different from $r(z^{2N})$.

Note that the summation of the polynomial order in the numerator and denominator of the Pade approximation should be $2N - 1$, in order to approximate a polynomial of order $2N - 1$. Thus, the order of polynomials for the numerator and denominator in (230) is chosen to be $N - 1$ and N , respectively ($N - 1 + N = 2N - 1$). In the Pade approximation, the coefficients in (230) can be determined by the following set of $2N$ linear equations:

$$\begin{aligned} a_n &= \sum_{m=0}^n M_{t,n-m} b_m & (n = 0, 1, \dots, N-1) \\ 0 &= \sum_{m=0}^N M_{t,N+n-m} b_m & (n = 0, 1, \dots, N-1) \end{aligned} \quad (231)$$

where

$$b_0 = 1$$

Once we know the coefficients of a_n and b_n , (230) can be transformed into the following:

$$\begin{aligned} F(z) &= \frac{\sum_{n=0}^{N-1} a_n z^n}{\sum_{n=0}^N b_n z^n} + R'(z^{2N}) = \frac{\sum_{n=0}^{N-1} a_n z^n}{1 + \sum_{n=1}^N b_n z^n} + R'(z^{2N}) \\ &= \frac{\sum_{n=0}^{N-1} a_n z^n}{\prod_{n=1}^N \left(1 - \frac{z}{z_n}\right)} + R'(z^{2N}) = \sum_{n=1}^N \frac{\omega_n}{1 - \frac{z}{z_n}} + R'(z^{2N}) \end{aligned} \quad (232)$$

where

ω_n : a coefficient defined by a_n and b_n .

In (232), the denominator is factorized with the roots of $1 + \sum_{n=0}^N b_n z^n = 0$, expressed by z_n . By comparing (229) and (232), we find that the subgroup cross section is given by

$$\sigma_{t,sg=n} = \frac{1}{z_n} \quad (234)$$

Therefore, the subgroup cross section can be evaluated using the roots of $1 + \sum_{n=0}^N b_n z^n = 0$. Once we have the subgroup cross sections, the associated probabilities are calculated by

$$M_{t,n} = m_{t,n} = \sum_{sg \in g} \sigma_{t,sg}^n p_{sg} \quad (n = 1, 2, \dots, N) \quad (235)$$

The moments for other cross sections (except for the total cross section) are defined by

$$M_{x,n} = \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \sigma_t(E)^n}{\int_{E_g}^{E_{g-1}} dE} \quad (236)$$

$$m_{x,n} = \sum_{sg \in g} \sigma_{x,sg} \sigma_{t,sg}^n p_{sg} \quad (237)$$

When the values of $\sigma_{t,sg}$ and p_{sg} are known, the moments for other cross sections can be derived by equating (236) and (237), that is,

$$M_{x,n} = m_{x,n} \quad (238)$$

In the above derivation, the moments of the cross sections with an integer order are preserved. The above procedure is generally used in the moment method. However, it could also be extended to non-integer moments (Chiba and Unesaki 2006). Let us consider an effective cross section based on the NR approximation:

$$\sigma_{x,g}(\sigma_0) = \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \frac{1}{\sigma_t(E) + \sigma_0}}{\int_{E_g}^{E_{g-1}} dE \frac{1}{\sigma_t(E) + \sigma_0}} \quad (239)$$

By considering very small and large values for the background cross section, we have the following expressions for the infinite-dilute and fully shielded conditions:

$$\begin{aligned} \sigma_{x,g}(\sigma_0 = \infty) &= \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E)}{\int_{E_g}^{E_{g-1}} dE} = \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \sigma_t(E)^0}{\int_{E_g}^{E_{g-1}} dE \sigma_t(E)^0} \\ &= \frac{M_{x,0}}{M_{t,0}} \end{aligned} \quad (240)$$

$$\begin{aligned} \sigma_{x,g}(\sigma_0 = 0) &= \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \frac{1}{\sigma_t(E)}}{\int_{E_g}^{E_{g-1}} dE \frac{1}{\sigma_t(E)}} = \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \sigma_t(E)^{-1}}{\int_{E_g}^{E_{g-1}} dE \sigma_t(E)^{-1}} \\ &= \frac{M_{x,-1}}{M_{t,-1}} \end{aligned} \quad (241)$$

In the above equations, the asymptotic neutron flux ($1/E$) is assumed to be unity. Equations (240) and (241) suggest that an effective cross section for a particular background cross section may be given by an interpolation of n :

$$\sigma_{x,g}(\sigma_0) = \frac{M_{x,n}}{M_{t,n}} \quad (242)$$

in which $-1 \leq n \leq 0$, since all shielded conditions appear between two extreme conditions, that is, the infinite-dilute ($n = 0$) and the fully shielded ($n = -1$) conditions.

The above discussion justifies the preservation of the cross section moments of a non-integer order. A previous study also indicates that the accuracy of the effective cross sections in a homogeneous geometry is improved by preservation of the non-integer moments of the cross sections (Chiba and Unesaki 2006).

In the conventional moment method, which preserves the integer moments of cross sections, no distinct physical properties are directly taken into account during the derivation process. On the contrary, in the non-integer approach, neutron flux behavior is partly (at least in the infinite-dilute and the fully shielded conditions) taken into account in the generation process of the subgroup cross sections. Thus, the accuracy of the subgroup parameters derived by the preservation of non-integer moments becomes higher.

3.8.6 Improvements in the Probability Table Approach

Various efforts are still being made to improve the probability table approach. Some of the issues addressed by these improvements are introduced below.

In general, subgroup parameters are generated with the slowing down calculation in a homogeneous system. However, the subgroup parameters generated in a homogeneous system may not exactly reproduce the effective cross section in a heterogeneous system. Therefore, the generation of subgroup parameters using the slowing down calculation in a heterogeneous geometry is proposed, in order to increase the accuracy of the actual calculation results in a heterogeneous fuel assembly (Joo et al. 2009).

Direct application of the probability table approach for nonuniform temperature problems poses difficulties, as was discussed earlier. However, because nonuniform temperature distribution appears in actual reactor core analyses, a countermeasure to this is important. Several methods have thus far been proposed to address this issue (Joo et al. 2005; Wemple et al. 2007).

Resonance overlap (or interference), which will be discussed in ▶ 3.10, may also have an impact on the calculation accuracy of the subgroup method. This topic has also been investigated by several researchers (Hébert 2004).

3.9 Other Methods

3.9.1 Tone's Method

In fast reactor calculations, a resonance calculation based on Tone's method is sometimes used (Tone 1975). In this method, a resonance absorber is not approximated as black, the escape probability from a fuel lump is directly evaluated by the collision probability method, and the rational approximation in the equivalence theory is not explicitly used. Therefore, the background cross section for a general heterogeneous geometry can be evaluated with approximated treatment of the space-dependent self-shielding effect.

Recalling (136), the neutron flux in region i can be calculated by considering the contribution of neutron sources in other regions:

$$\phi_i(E) = \frac{1}{E} \sum_j \frac{P_{j \rightarrow i}(E) V_j \Sigma_{p,j}}{\Sigma_{t,i}(E) V_i} \quad (243)$$

Note that the NR approximation is used for the neutron slowing down source in each region. In Tone's method, we introduce the following key approximation:

$$\frac{P_{j \rightarrow i}(E)}{\Sigma_{t,i}(E)} = \alpha_i(E) \frac{P_{j \rightarrow i,g}}{\Sigma_{t,i,g}} \quad (244)$$

where g denotes a group averaged property. For example, the collision probability $P_{j \rightarrow i,g}$ is the group average collision probability, which is obtained by a set of multigroup cross sections. Equation (244) indicates that the fine energy dependency of the collision probability inside an energy group relies only on target region i . In reality, the energy dependence of the collision probability relies not only on region i , but on other regions as well, including the source region. In other words, with the exception of region i , cross sections are assumed to be energetically

constant in an energy group. In a more physical interpretation, a resonance nuclide in question is not included (or can be neglected) in other regions, in the evaluation of the background cross section. This is a major assumption in Tone's method that represents a potential cause of error.

By substituting (244) into (243), we obtain

$$\phi_i(E) = \frac{1}{E} \alpha_i(E) \sum_j \frac{P_{j \rightarrow i, g} V_j \Sigma_{p, j}}{\Sigma_{t, i, g} V_i} \quad (245)$$

In addition to the above equation, the reciprocity theorem and the normalization condition for collision probabilities are also taken into account:

$$P_{j \rightarrow i}(E) V_j \Sigma_{t, j}(E) = P_{i \rightarrow j}(E) V_i \Sigma_{t, i}(E) \quad (246)$$

$$\sum_j P_{i \rightarrow j}(E) = 1 \quad (247)$$

Equation (247) can be transformed as follows, by substituting (244) and (246) into (247):

$$\begin{aligned} 1 &= \sum_j P_{i \rightarrow j}(E) \\ &= \sum_j \frac{P_{j \rightarrow i}(E) V_j \Sigma_{t, j}(E)}{V_i \Sigma_{t, i}(E)} \\ &= \sum_j \alpha_i(E) \frac{P_{j \rightarrow i, g} V_j \Sigma_{t, j}(E)}{\Sigma_{t, i, g} V_i} \\ &= \alpha_i(E) \frac{1}{\Sigma_{t, i, g} V_i} \sum_j P_{j \rightarrow i, g} V_j \Sigma_{t, j}(E) \end{aligned} \quad (248)$$

Finally, using (248), α is expressed as follows:

$$\alpha_i(E) = \frac{\Sigma_{t, i, g} V_i}{\sum_j P_{j \rightarrow i, g} V_j \Sigma_{t, j}(E)} \quad (249)$$

By substituting (249) into (245), we obtain:

$$\begin{aligned} \phi_i(E) &= \frac{1}{E} \alpha_i(E) \sum_j \frac{P_{j \rightarrow i, g} V_j \Sigma_{p, j}}{\Sigma_{t, i, g} V_i} \\ &= \frac{1}{E} \frac{\Sigma_{t, i, g} V_i}{\sum_j P_{j \rightarrow i, g} V_j \Sigma_{t, j}(E)} \sum_j \frac{P_{j \rightarrow i, g} V_j \Sigma_{p, j}}{\Sigma_{t, i, g} V_i} \\ &= \frac{1}{E} \frac{\sum_j P_{j \rightarrow i, g} V_j \Sigma_{p, j}}{\sum_j P_{j \rightarrow i, g} V_j \Sigma_{t, j}(E)} \end{aligned}$$

$$\begin{aligned}
& \cong \frac{1}{E} \frac{\sum_j P_{j \rightarrow i, g} V_j \cdot \left(N_{r, j} \sigma_{p, r} + \sum_{k \neq r} N_{k, j} \sigma_{p, k} \right)}{\sum_j P_{j \rightarrow i, g} V_j \cdot \left(N_{r, j} \sigma_{t, r}(E) + \sum_{k \neq r} N_{k, j} \sigma_{p, k} \right)} \\
& = \frac{1}{E} \frac{\sigma_{p, r} \sum_j P_{j \rightarrow i, g} V_j N_{r, j} + \sum_j P_{j \rightarrow i, g} V_j \sum_{k \neq r} N_{k, j} \sigma_{p, k}}{\sigma_{t, r}(E) \sum_j P_{j \rightarrow i, g} V_j N_{r, j} + \sum_j P_{j \rightarrow i, g} V_j \sum_{k \neq r} N_{k, j} \sigma_{p, k}} \\
& = \frac{1}{E} \frac{\sigma_{p, r} + \left(\sum_j P_{j \rightarrow i, g} V_j \sum_{k \neq r} N_{k, j} \sigma_{p, k} \right) / \left(\sum_j P_{j \rightarrow i, g} V_j N_{r, j} \right)}{\sigma_{t, r}(E) + \left(\sum_j P_{j \rightarrow i, g} V_j \sum_{k \neq r} N_{k, j} \sigma_{p, k} \right) / \left(\sum_j P_{j \rightarrow i, g} V_j N_{r, j} \right)} \\
& = \frac{1}{E} \frac{\sigma_{p, r} + \sigma_0}{\sigma_{t, r}(E) + \sigma_0} \tag{250}
\end{aligned}$$

where

$$\sigma_0 = \frac{\sum_j \sum_{k \neq r} P_{j \rightarrow i, g} V_j N_{k, j} \sigma_{p, k}}{\sum_j P_{j \rightarrow i, g} V_j N_{r, j}} \tag{251}$$

We assume that with the exception of a resonance nuclide, cross sections are approximated by a constant potential scattering cross section.

Equation (251) indicates that the background cross section is obtained by the collision probabilities among regions, volume, number densities, and potential cross sections. Since collision probabilities depend on the effective cross sections, which in turn depend on the background cross sections, an iteration calculation procedure is necessary, which is as follows:

1. Assume initial background cross sections for resonance nuclides. They can be evaluated using the conventional equivalence method with the Dancoff correction.
2. Evaluate the effective cross sections of resonance nuclides using the conventional equivalence theory.
3. Evaluate group-wise collision probability using the effective cross section evaluated in (2).
4. Update the background cross section using (251).
5. Repeat (2)–(4) until convergence. A few iterations are usually sufficient to obtain the converged result.

Tone's method seeks to incorporate actual collision probabilities among regions through the approximation of (244). Therefore, it is more applicable to general geometry than the conventional equivalence method. Furthermore, since only the definition of the background cross section is changed, it has a closer affinity to the conventional equivalence method than to the subgroup method.

An example of a performance comparison between the subgroup and Tone's methods in a fast reactor fuel assembly is shown in  Fig. 27 (Chiba 2003). The fuel assembly used for the comparison is shown on the left side of  Fig. 27, in which there are 169 fuel pins. The effective microscopic capture cross section of ^{238}U in each fuel rod is evaluated at 300 K. JENDL3.2 is used throughout the comparison. The number of energy groups (70 groups) and the energy group structure used in this comparison, is the same as in JSF-3-3.2R. The moment method is

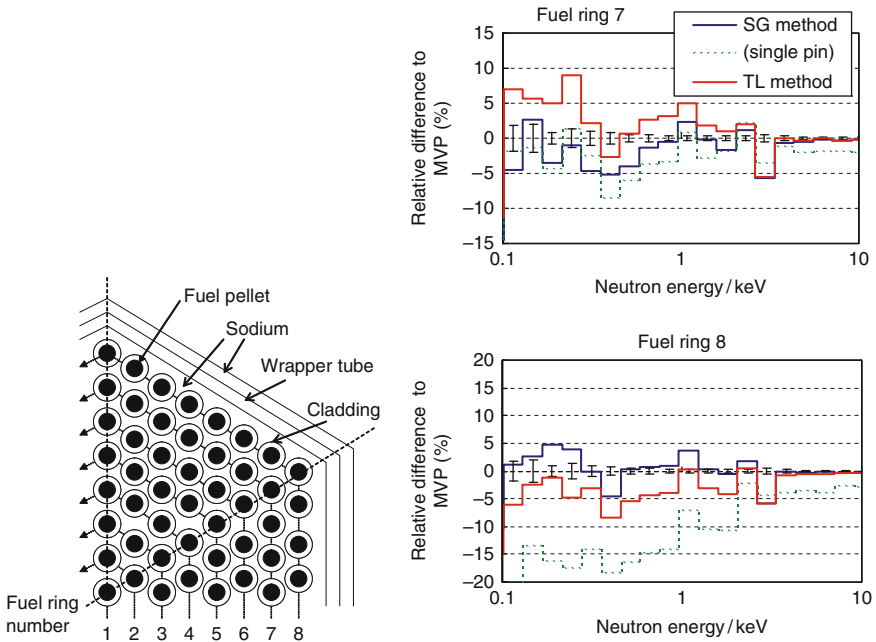

Figure 27

Schematic view of fast reactor fuel assembly, and the difference between effective cross sections obtained by the subgroup method and Tone's method (SG; subgroup, TL; table lookup by Tone's method) (Chiba 2003)

used to generate the subgroup parameters in the subgroup method. The number of subgroups is set at less than or equal to five.

The wrapper tube and sodium in the peripheral region of the assembly create position dependency on the effective cross sections in a fuel assembly. That is, the effective cross sections in the outer ring of the fuel assembly become larger, since ^{238}U is not included in the wrapper tube and sodium, and they act as a neutron source of heavy nuclides in the resonance energy region. In fast reactor calculations, this effect is called the double heterogeneity effect: pellet, cladding, and coolant for the primary and fuel rods, and wrapper and sodium for the secondary heterogeneity.

In order to verify the significance of the position dependency, the subgroup method is also applied to a single pin-cell geometry, which does not consider the wrapper tube and sodium in the peripheral region.

A comparison of the effective cross section for ^{238}U is shown on the right side of Fig. 27. The reference result is obtained by the continuous-energy Monte Carlo code, MVP. In this comparison, the subgroup method gives better accuracy than Tone's method. In the outermost fuel ring (ring 8), the double heterogeneity effect exerts a considerable effect on the effective cross sections, so such an effect must be accurately taken into account. Since BWR fuel assembly also has a similar structure (channel box with gap water around the fuel assembly), the position dependency of the effective cross section is also important.

The above results suggest that the subgroup method gives better accuracy than Tone's method. In this context, Tone's method can be considered as a simple and reasonably accurate resonance calculation method that can be applied to general geometry. Due to this feature, some lattice physics codes adopt this method as the resonance calculation method.

The advantages and disadvantages of Tone's method are summarized as follows:

- Contributions to a background cross section from other regions are taken into account approximately through region-wise and group-wise collision probabilities.
- Its affinity to the conventional equivalence theory is high. Cross section libraries and self-shielding factors prepared for the conventional method with equivalence theory can be directly used in Tone's method.
- The "gray regions" from the viewpoint of the resonance calculation can be approximately treated. Thus the space-dependent self-shielding effect in a fuel lump could be evaluated approximately.
- The NR approximation is used. Note that this method is primarily intended for fast reactor calculations, in which the NR approximation displays a high degree of accuracy. In this context, this method can be accurately applied to resonances in a higher energy range in LWR calculations, in which the NR approximation is valid.
- The energy dependence of collision probabilities among regions are approximated using (244).
- Iteration calculations are required for effective cross sections, in which calculation of the collision probabilities is included, though only a few iterations are needed to obtain converged results. If one's initial rough predictions for effective cross sections is reasonably good, no iteration may be necessary.

3.9.2 The Stoker–Weiss Method and the Space-Dependent Dancoff Method (SDDM)

The Stoker–Weiss Method

The Stoker–Weiss method is another approach to estimating the space-dependent self-shielding effect for the annular regions of a cylindrical fuel rod (Stoker and Weiss 1996; Matsumoto et al. 2005; Matsumoto et al. 2006). This method derives an approximate expression of the escape probability from the annular regions in a fuel pellet not only for an outer ring, but for the inner rings as well.

From a practical point of view, the space-dependent self-shielding effect is important because

- Larger resonance capture of ^{238}U on the pellet surface area causes a higher plutonium buildup in the outer region of a fuel pellet.
- The power distribution inside a pellet is significantly affected by the plutonium buildup and power distribution as the outer region becomes higher at middle to end of life. Consequently, burnup on the pellet surface becomes higher than that of the pellet average, which has an impact on the fission gas release from a pellet, which could be a one of the mechanical limitations of a fuel rod.
- The temperature distribution in a pellet is influenced by the power distribution inside it, for example, the pellet centerline and the average temperature.

Figure 28

Annular subdivisions of a fuel pellet

Therefore, a simple method to estimate the self-shielding effect inside a pellet is important, mainly for the mechanical evaluation of a fuel rod and a fuel assembly.

From the viewpoint of the resonance calculation, many studies have clarified that the subdivision of a fuel pellet into multiple annular regions does not have a major impact on the accuracy of the resonance calculation, even if the spatial distribution of the number density due to burnup is taken into account. This means that the average treatment of resonance nuclides can be justified for a fuel pellet, at least from the viewpoint of the resonance calculation. A more detailed discussion of this will be offered in [3.11.3](#).

Though the major objective of a lattice physics computation is to provide cross section sets for a core calculation code, the calculation results are also used in mechanical design and safety analyses (e.g., decay heat is dominated by the number densities of heavy and fission product nuclides, which are calculated by a lattice physics code).

Let us now assume that an isolated fuel pellet is annularly subdivided into multiple annular rings, as shown in [Fig. 28](#). The final objective of the Stoker–Weiss method is to derive an expression of the energy dependence of a neutron spectrum for an annular region i with the N -term rational approximation.

When the macroscopic cross section is assumed to be spatially constant inside a pellet region, and the NR approximation is applied to calculate the slowing down source, the neutron flux in region i is expressed as

$$\phi_i(E) = \frac{1}{E} \left((1 - P_{i \rightarrow m}(E)) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + P_{i \rightarrow m}(E) \right) \quad (252)$$

where i is a region in a pellet ($i \in f$); a detailed derivation of the above equation is given in [\(139\)](#).

In the Stoker–Weiss method, the escape probability from region i to the moderator region m , $P_{i \rightarrow m}(E)$ is assumed to be expressed as

$$P_{i \rightarrow m}(E) = DP_{e,i}(E) \quad (253)$$

where $P_{e,i}(E)$ is the escape probability of a neutron from a fuel, which includes region i , and D is the Dancoff factor (which is unity for isolated fuel). When the number of annular regions in a pellet is one, (253) is reduced into the conventional equivalence theory with the Dancoff factor.

Theoretically, the Dancoff factor should be an energy-dependent parameter in (253). However, the energy dependence of the Dancoff factor is neglected in the derivation of this method.

In order to evaluate $P_{e,i}(E)$, we start from the escape probability for an isolated lump, that is, (106):

$$P_e(E) = \frac{1}{\Sigma_{t,f}(E)\bar{l}} \int_0^\infty dl f(l) \{1 - \exp(-\Sigma_{t,f}(E)l)\} \tag{254}$$

In (254), $\exp(-\Sigma_{t,f}(E)l)$ denotes the transmission probability of a fuel lump, and thus $1 - \exp(-\Sigma_{t,f}(E)l)$ is the probability that a neutron entering from the surface of a fuel lump will suffer a collision in the fuel lump. Consequently, $\int_0^\infty dl f(l) \{1 - \exp(-\Sigma_{t,f}(E)l)\}$ gives the expected value of the collision probability in a fuel lump.

When a neutron entering a fuel pellet has its first collision in region i (in the fuel pellet) with the probability of $\gamma_i(E)$, the escape probability from region i can be expressed as

$$P_{e,i}(E) = \frac{1}{\Sigma_{t,f}(E)\bar{l}_i} \int_0^\infty dl f(l) \{1 - \exp(-\Sigma_{t,f}(E)l)\} = \frac{\gamma_i(E)}{\Sigma_{t,f}(E)\bar{l}_i} \tag{255}$$

where

$\bar{l}_i = 4V_i/S_f$, which is the ‘‘average chord length’’ of region i , expressed by the volume of region i (V_i) and the surface of a fuel pellet (S_f). Note that the definition of the average chord length in this derivation (\bar{l}_i) is different from the conventional one, which is defined by $\bar{l}_i = 4V_i/S_i$. In (255), a neutron that enters from the pellet surface (S_f) collides at region i (V_i). However, in the conventional definition, a neutron that enters from region i (S_i) collides at region i (V_i).

In (255), $\gamma_i(E)$ is also considered as the blackness of region i . The blackness of a solid cylinder that includes region i (ABC in \blacktriangleright Fig. 29) is approximated by

$$\gamma_{i,ABC}(E) = (\gamma_{i,OBC}(E) - \gamma_{i,OAB}(E)) \tag{256}$$

Figure 29
Calculation geometry of blackness for a cylinder

A similar expression for the solid cylinder that includes region $i - 1$ is given by

$$\gamma_{i-1,ABC}(E) = (\gamma_{i-1,OBC}(E) - \gamma_{i-1,OAB}(E)) \quad (257)$$

Equations (256) and (257) assume that the blackness of each region can be synthesized by the subtraction that is shown in  Fig. 29.

Finally, in the Stoker–Weiss method, the blackness of region i is evaluated by (258), since the blackness of ring i can be approximated by subtraction of the blackness for the solid cylinders, including regions i and $i - 1$:

$$\gamma_i(E) = (\gamma_{i,OBC}(E) - \gamma_{i,OAB}(E)) - (\gamma_{i-1,OBC}(E) - \gamma_{i-1,OAB}(E)) \quad (258)$$

Next, we will try to estimate each component on the right-hand side of (258). Recalling (254), the collision probability in a region can be expressed by the product of the optical length of a region $(\Sigma_{t,f}(E)\bar{l})$ and the escape probability $P_e(E)$:

$$\int_0^\infty dl f(l) \{1 - \exp(-\Sigma_{t,f}(E)l)\} = \Sigma_{t,f}(E)\bar{l} \times P_e(E) \quad (259)$$

Using the above observation, the blackness for solid region OBC can be evaluated by the following:

$$\begin{aligned} \gamma_{i,OBC}(E) &= (\text{Entering probability to the region } OBC \text{ for a neutron entering the fuel}) \\ &\quad \times (\text{Collision probability in the solid region } OBC) \\ &= (\text{Entering probability to the region } OBC \text{ for a neutron entering the fuel}) \\ &\quad \times (\text{Optical length of the solid region } OBC) \\ &\quad \times (\text{Escape probability from the solid region } OBC) \\ &= \rho_i \times \Sigma_{t,f}(E)\bar{l}_{i,BC} \times \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E)\bar{l}_{i,BC} + a_n} \end{aligned} \quad (260)$$

The entering probability into region OBC is given by

$$\rho_i = r_i/R \quad (261)$$

where r_i and R are the radii of region i , and the fuel pellet, respectively, and the escape probability from the solid region OBC is approximated by the N -term rational approximation.

The average chord length from O (origin of a neutron entering a fuel pellet) to arc BC , is analytically derived through some algebra, and given by

$$\bar{l}_{i,BC} = \frac{2R}{\pi} \left(\sqrt{1 - \rho_i^2} + \frac{1}{\rho_i} \sin^{-1} \rho_i + \frac{\pi}{2} \rho_i \right) \quad (262)$$

Similarly, the average chord length from O to arc AB is

$$\bar{l}_{i,AB} = \frac{2R}{\pi} \left(\sqrt{1 - \rho_i^2} + \frac{1}{\rho_i} \sin^{-1} \rho_i - \frac{\pi}{2} \rho_i \right) \quad (263)$$

By applying the above derivation to the other terms in (258), we have the following relationship for the blackness of ring i :

$$\begin{aligned}
 \gamma_i(E) &= (\gamma_{i,OBC}(E) - \gamma_{i,OAB}(E)) - (\gamma_{i-1,OBC}(E) - \gamma_{i-1,OAB}(E)) \\
 &= \rho_i \Sigma_{t,f}(E) \overline{l_{i,BC}} \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \overline{l_{i,BC}} + a_n} - \rho_i \Sigma_{t,f}(E) \overline{l_{i,AB}} \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \overline{l_{i,AB}} + a_n} \\
 &\quad - \rho_{i-1} \Sigma_{t,f}(E) \overline{l_{i-1,BC}} \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \overline{l_{i-1,BC}} + a_n} \\
 &\quad + \rho_{i-1} \Sigma_{t,f}(E) \overline{l_{i-1,AB}} \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \overline{l_{i-1,AB}} + a_n}
 \end{aligned} \tag{264}$$

By substituting (264) into (255), we obtain

$$\begin{aligned}
 P_{e,i}(E) &= \frac{\gamma_i(E)}{\Sigma_{t,f}(E) \overline{l_i}} \\
 &= \frac{1}{\Sigma_{t,f}(E) \overline{l_i}} \left[\begin{aligned} &\rho_i \Sigma_{t,f}(E) \overline{l_{i,BC}} \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \overline{l_{i,BC}} + a_n} \\ &- \rho_i \Sigma_{t,f}(E) \overline{l_{i,AB}} \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \overline{l_{i,AB}} + a_n} \\ &- \rho_{i-1} \Sigma_{t,f}(E) \overline{l_{i-1,BC}} \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \overline{l_{i-1,BC}} + a_n} \\ &+ \rho_{i-1} \Sigma_{t,f}(E) \overline{l_{i-1,AB}} \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \overline{l_{i-1,AB}} + a_n} \end{aligned} \right] \\
 &= \frac{\rho_i \overline{l_{i,BC}}}{\overline{l_i}} \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \overline{l_{i,BC}} + a_n} - \frac{\rho_i \overline{l_{i,AB}}}{\overline{l_i}} \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \overline{l_{i,AB}} + a_n} \\
 &\quad - \frac{\rho_{i-1} \overline{l_{i-1,BC}}}{\overline{l_i}} \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \overline{l_{i-1,BC}} + a_n} + \frac{\rho_{i-1} \overline{l_{i-1,AB}}}{\overline{l_i}} \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \overline{l_{i-1,AB}} + a_n} \\
 &= \sum_{m=1}^4 c_m \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \overline{l_m} + a_n}
 \end{aligned} \tag{265}$$

The coefficients c_m and average chord length $\overline{l_m}$ that appear in (265) are summarized in **Table 14**.

The coefficient c_m satisfies the following relationship:

$$\sum_{m=1}^4 c_m = 1 \tag{266}$$

■ **Table 14**
Coefficients and average chord length used in (265) of the Stoker–Weiss method

M	c_m	\bar{l}_m
1	$\rho_i \bar{l}_m / l_i$	$\bar{l}_{i,BC}$
2	$-\rho_i \bar{l}_m / l_i$	$\bar{l}_{i,AB}$
3	$\rho_{i-1} \bar{l}_m / l_i$	$\bar{l}_{i-1,BC}$
4	$-\rho_{i-1} \bar{l}_m / l_i$	$\bar{l}_{i-1,AB}$

With (253) and (265), $1 - P_{i \rightarrow m}(E)$ can be expressed as

$$\begin{aligned}
 1 - P_{i \rightarrow m}(E) &= \sum_{m=1}^4 c_m \sum_{n=1}^N b_n - D \sum_{m=1}^4 c_m \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \bar{l}_m + a_n} \\
 &= \sum_{m=1}^4 c_m \sum_{n=1}^N b_n \left(1 - D \frac{a_n}{\Sigma_{t,f}(E) \bar{l}_m + a_n} \right) \\
 &= \sum_{m=1}^4 c_m \sum_{n=1}^N b_n \frac{\Sigma_{t,f}(E) \bar{l}_m + (1-D)a_n}{\Sigma_{t,f}(E) \bar{l}_m + a_n} \tag{267}
 \end{aligned}$$

where $\sum_{n=1}^N b_n = 1$ is used by recalling (121).

Finally, by substituting (267) into (252), the energy dependence of the neutron flux in region i is given by

$$\begin{aligned}
 \phi_i(E) &= \frac{1}{E} \left((1 - P_{i \rightarrow m}(E)) \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} + P_{i \rightarrow m}(E) \right) \\
 &= \frac{1}{E} \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} \sum_{m=1}^4 c_m \sum_{n=1}^N b_n \frac{\Sigma_{t,f}(E) \bar{l}_m + (1-D)a_n}{\Sigma_{t,f}(E) \bar{l}_m + a_n} \\
 &\quad + D \frac{1}{E} \sum_{m=1}^4 c_m \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \bar{l}_m + a_n} \tag{268}
 \end{aligned}$$

When the macroscopic total cross section is very large, the energy dependence of the neutron flux can be approximated as follows:

$$\begin{aligned}
 \phi_i(E) &= \frac{1}{E} \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} \sum_{m=1}^4 c_m \sum_{n=1}^N b_n \frac{\Sigma_{t,f}(E) \bar{l}_m + (1-D)a_n}{\Sigma_{t,f}(E) \bar{l}_m + a_n} + \frac{1}{E} D \sum_{m=1}^4 c_m \sum_{n=1}^N \frac{b_n a_n}{\Sigma_{t,f}(E) \bar{l}_m + a_n} \\
 &\approx (1-D) \frac{1}{E} \sum_{m=1}^4 c_m \sum_{n=1}^N b_n \frac{\Sigma_{p,f} \bar{l}_m}{\Sigma_{t,f}(E) \bar{l}_m} + D \frac{1}{E} \sum_{m=1}^4 c_m \sum_{n=1}^N b_n \frac{\Sigma_{p,f} \bar{l}_m + a_n}{\Sigma_{t,f}(E) \bar{l}_m + a_n} \\
 &= (1-D) \frac{1}{E} \sum_{m=1}^4 c_m \sum_{n=1}^N b_n \frac{\sigma_0}{\sigma_{a,r}(E) + \sigma_0} + D \frac{1}{E} \sum_{m=1}^4 c_m \sum_{n=1}^N b_n \frac{\sigma_{0,mn}}{\sigma_{a,r}(E) + \sigma_{0,mn}} \tag{269}
 \end{aligned}$$

where

$$\begin{aligned}\sigma_0 &= \Sigma_{p,f} / N_r \\ \sigma_{0,mn} &= (\Sigma_{p,f} + a_n / \bar{l}_m) / N_r\end{aligned}$$

In the above derivation, the following approximations are used:

$$\begin{aligned}\frac{1}{E} \frac{\Sigma_{p,f}}{\Sigma_{t,f}(E)} \sum_{m=1}^4 c_m \sum_{n=1}^N b_n \frac{(1-D)a_n}{\Sigma_{t,f}(E)\bar{l}_m + a_n} &\approx 0 \\ \frac{1}{E} \sum_{m=1}^4 c_m \sum_{n=1}^N b_n \frac{\Sigma_{p,f}\bar{l}_m}{\Sigma_{t,f}(E)\bar{l}_m + a_n} &\approx \frac{1}{E} \sum_{m=1}^4 c_m \sum_{n=1}^N b_n \frac{\Sigma_{p,f}\bar{l}_m}{\Sigma_{t,f}(E)\bar{l}_m}\end{aligned}$$

In (125) and (132) we derived a formula for the effective cross section when the energy dependence of the neutron flux is given by the N -term rational approximation. Considering the similarity between (125) and (269), and by applying (132), we can derive the following formula for the effective cross section:

$$\begin{aligned}\sigma_{g,x,i} &= \frac{\int_{E_g}^{E_{g-1}} dE \sigma_x(E) \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \phi_i(E)}{\int_{E_g}^{E_{g-1}} dE \lim_{\Sigma_{t,f}(E) \rightarrow \infty} \phi_i(E)} \\ &= \frac{(1-D)I_{g,x}(\sigma_0) + D \sum_{m=1}^4 c_m \sum_{n=1}^N b_n I_{g,x}(\sigma_{0,mn})}{1 - (1-D)I_{g,a}/\sigma_0 - D \sum_{m=1}^4 c_m \sum_{n=1}^N b_n I_{g,a}(\sigma_{0,mn})/\sigma_{0,mn}}\end{aligned}\quad (270)$$

Once the Dancoff factor D is evaluated, the effective cross section in each annular ring can be evaluated by (270). Since the background cross section for each annular ring is evaluated by the potential scattering cross section and the geometry information of an annularly divided fuel pellet, the application and implementation of the Stoker–Weiss method for common lattice physics codes are easy.

Space-Dependent Dancoff Method (SDDM)

The above method can be modified by incorporating Stamm'ler's method for the evaluation of blackness, as described in [3.5.6](#) (Matsumoto et al. 2005; Matsumoto et al. 2006). The improved approach is called the spatially dependent Dancoff method, or SDDM. Recalling (173), we have the following relationship between the fuel-to-fuel collision probability in isolated and lattice systems in Stamm'ler's method:

$$p_{FF} = p_{ff} + \frac{x(1-p_{ff})^2}{x(1-p_{ff}) + A + B}\quad (271)$$

Recalling (255), the blackness for the fuel regions in the isolated and the lattice systems are given by

$$\gamma_F = \frac{4V_f}{S_f} \Sigma_{t,f}(1-p_{FF}) = x(1-p_{FF})\quad (272)$$

and

$$\gamma_f = \frac{4V_f}{S_f} \Sigma_{t,f}(1 - p_{ff}) = x(1 - p_{ff}) \quad (273)$$

respectively. By substituting (272) and (273) into (271), we obtain

$$\gamma_F = \frac{\gamma_f C}{\gamma_f + C} \quad (274)$$

where

$$C = A + B \text{ (} A \text{ and } B \text{ is given in (173)).}$$

Care should be taken that C in (274) is different from the Dancoff correction. The term expressed by C represents the effect of a finite fuel assembly. In SDDM, this term is assumed to be proportional to the fractional radius of region i , that is, $\rho_i = r_i/R$.

By utilizing (274) and considering the above discussion, (258) can be written as

$$\gamma_i^{lat} = \left(\frac{\rho_i C \gamma_{i,OBC}}{\gamma_{i,OBC} + \rho_i C} - \frac{\rho_i C \gamma_{i,OAB}}{\gamma_{i,OAB} + \rho_i C} \right) - \left(\frac{\rho_{i-1} C \gamma_{i-1,OBC}}{\gamma_{i-1,OBC} + \rho_{i-1} C} - \frac{\rho_{i-1} C \gamma_{i-1,OAB}}{\gamma_{i-1,OAB} + \rho_{i-1} C} \right) \quad (275)$$

By applying Carlvik's two-term rational approximation for $\gamma_{i,OBC}$, $\gamma_{i,OAB}$, $\gamma_{i-1,OBC}$, $\gamma_{i-1,OAB}$, we have the following formula for escape probability based on SDDM:

$$P_{e,i}(E) = \sum_{m=1}^4 c_m \sum_{n=1}^2 \frac{\beta_n \alpha_n}{\Sigma_{t,f}(E) \overline{l}_m + \alpha_n} \quad (276)$$

where

$$\begin{aligned} \alpha_{1,2} &= \frac{(5C + 6) \mp \sqrt{C^2 + 36C + 36}}{2(C + 1)} \\ \beta_1 &= \frac{C' - \alpha_1}{\alpha_2 - \alpha_1} \\ \beta_2 &= 1 - \beta_1 \\ C' &= \frac{4C + 6}{C + 1} \\ C &= A + B \text{ (} A \text{ and } B \text{ is given in (173)).} \end{aligned}$$

Therefore, the energy dependence of the neutron flux is

$$\phi_i(E) = \frac{1}{E} \sum_{m=1}^4 c_m \sum_{n=1}^2 \beta_n \frac{\sigma_{0,mn}}{\sigma_{t,r}(E) + \sigma_{0,mn}} \quad (277)$$

where

$$\sigma_{0,mn} = \sigma_{0,f} + \alpha_n \Sigma_e / N_r = \sigma_{0,f} + \alpha_n / N_r / \bar{l}_m \text{ and}$$

$$\sigma_{0,f} = \sum_{k \neq r} N_k \sigma_{s,k} / N_r$$

Finally, the effective cross section can be obtained by

$$\sigma_{g,x,i} = \frac{\sum_{m=1}^4 c_m \sum_{n=1}^2 \beta_n I_{g,x}(\sigma_{0,mn})}{1 - \sum_{m=1}^4 c_m \sum_{n=1}^2 \beta_n I_{g,a}(\sigma_{0,mn}) / \sigma_{0,mn}} \quad (278)$$

When (270) and (278) are compared, (278), that is, SDDM, gives a more consistent formula than the original Stoker–Weiss method.

The advantages and disadvantages of the Stoker–Weiss method (or SDDM method) are summarized as follows:

- It is an extension of the equivalence method and can be easily implemented in conventional lattice physics codes.
- The calculation procedure for the background cross section in each region is simple.
- Since the derivation of the background cross section is based on the analytic approach for a cylinder with annular divisions, its extension to a general geometry is impossible.
- The NR approximation is used.
- The Dancoff factor is used to incorporate the shadowing effect of other fuel rods. In the case of SDDM, Stamm'ler's method is used.
- The macroscopic total cross section is assumed to be spatially constant in a fuel pellet, which means no variations in the temperature and/or number density distribution in a pellet.

Previous studies have revealed that the spatial variation of the number density of a resonance nuclide does not have a significant impact on the calculation accuracy of the effective cross section. Thus, the Stoker–Weiss method can be applied to a resonance calculation in which the distribution of the number density in a pellet exists. On the contrary, when the temperature profile in a pellet is taken into account, the Stoker–Weiss method will not be very accurate. In such a case, particular considerations need to be incorporated (Matsumoto et al. 2006).

◆ *Figure 30* shows the space-dependent effective cross section in a UO_2 fuel pellet that was obtained by the Stoker–Weiss method. In the outer region, the effective cross section is larger than that in the inner regions, due to neutron inflow from the moderator region. Thus, this method reproduces the trend intuited for the space-dependent effective cross sections.

◆ *Figure 31* shows a comparison of the number density distributions obtained by SDDM and by the continuous-energy Monte Carlo method. SDDM well produces the plutonium buildup on the pellet surface, which is referred to as the rim effect. This comparison clarifies that SDDM can be applied to evaluate not only the space-dependent effective cross sections, but also the number density distribution in a pellet. Therefore, the power depression inside a pellet, which is an important factor in the mechanical design of a fuel rod, can also be evaluated by this method. Burnup calculation by the continuous-energy Monte Carlo method can also provide such results, but the Stoker–Weiss and SDDM methods are more suitable for production calculations, due to the short computation time they require.

Figure 30

Example of space dependency of the effective cross section of ^{238}U in a fuel pellet calculated by the Stoker–Weiss method (293 K, typical PWR cell, pellet radius is 0.4 cm) (Matsumoto et al. 2005)

Comparison of absorption reaction rates obtained by SDDM and continuous-energy Monte Carlo code MVP, at the end of life of UO_2 fuel (Matsumoto et al. 2005)

3.10 Resonance Overlap Effect

3.10.1 Overview

Various resonance calculation methods have been discussed in this section thus far. These resonance calculation methods (except for the ultrafine group method) assume just one resonance nuclide in a system – no interference of the resonance peaks of different nuclides is considered. In reality, however, a fuel pellet contains many resonance nuclides, especially in burnt fuels. Consequently, a discrepancy arises between the calculation model (i.e., resonance theory) and the actual situation regarding prediction error of the effective cross section. This discrepancy is referred to as the resonance overlap (or interference) effect (Hébert 2004).

From the viewpoint of the “gross” neutronics characteristics of a fuel assembly, the impact of the resonance overlap effect is, fortunately, not very large. However, if more detailed information is necessary, such as the nuclide number densities of burnt fuel or the reaction rate of a particular nuclide, then the resonance overlap effect might play a very important role. Consideration of the resonance overlap effect, therefore, should not be neglected in the resonance calculation of a lattice physics code.

For example, let us consider the effective cross section of ^{151}Sm at 6.16–7.524 eV (88th group of the 172 XMAS groups). In this energy range, ^{238}U has a large resonance peak at 6.7 eV, as shown in  Fig. 32. Therefore, the typical neutron spectrum in the fuel shows a significant depression in this energy range due to the resonance absorption of ^{238}U . The neutron slowing down source in this energy range is also far from the asymptotic one (which is typically constant in the NR approximation).

^{151}Sm also has large resonance in this energy range. When the resonance overlap between ^{151}Sm and ^{238}U is not taken into account, the effective cross section for ^{151}Sm at 6.16–7.524 eV

 **Figure 32**
Resonance overlap between ^{238}U and ^{151}Sm (microscopic absorption cross section at 300 K)

with a low number density (nearly the infinite-dilution condition) is 1,185 barn, while it becomes 898 barn when distortion of the neutron spectrum due to the presence of ^{238}U is taken into account. The resulting difference in the effective cross sections is approximately 25%, which has a significant impact on the absorption reaction rate of ^{151}Sm . Though the impact on the k -infinity of a fuel assembly is limited due to the low contribution of ^{151}Sm , the number density of ^{151}Sm during burnup is significantly mispredicted if the resonance interference effect is not taken into account.

We can see similar observations for more important nuclides, for example, ^{235}U . Since there are coincident resonance overlaps between ^{238}U and ^{235}U , the accuracy of the effective cross section of ^{235}U in some energy groups becomes lower if the overlap effect is neglected. A previous study suggests that the resonance overlap effect between ^{235}U and ^{238}U is approximately 0.2% dk/k on k -infinity for a typical UO_2 LWR fuel assembly. In MOX fuel, similar resonance interference is observed between ^{239}Pu and ^{238}U . The effect is reported to be approximately 0.2% dk/k , which is close to that between ^{235}U and ^{238}U .

In the following subsection, a countermeasure for the resonance overlap effect will be discussed.

3.10.2 Resonance Interference Factor (RIF) Table

In principle, the resonance overlap effect can occur between any two resonance nuclides. However, in the typical situation of LWR lattices, the resonance overlap effect between ^{238}U and other resonance nuclides is dominant, and the interferences among other resonance nuclides can be considered as a second-order effect. This can be justified by the fact that the number density of ^{238}U is usually much larger than that of other resonance nuclides, so that the neutron spectrum in a fuel pellet is dominated by the resonance absorption of ^{238}U . Thus, from an engineering perspective, the treatment of the resonance overlap effect can be simplified to those between ^{238}U and other resonance nuclides.

Since the effective cross section is affected by the resonance overlap effect, it can be corrected by the resonance interference (overlap) factor, which is prepared in advance of lattice physics computations. In more detail, the resonance interference factors defined by the following equation are evaluated and tabulated in a cross section library:

$$\text{RIF}_{k,g,N_{^{238}\text{U}}} = \frac{\sigma_{\text{eff},k,g}(N_{^{238}\text{U}})}{\sigma_{\text{eff},k,g}(0)} \quad (279)$$

where

$\text{RIF}_{k,g,N_{^{238}\text{U}}}$: resonance interference factor for nuclide k and energy group g , when the number density of ^{238}U is $N_{^{238}\text{U}}$;

$\sigma_{\text{eff},k,g}(N_{^{238}\text{U}})$: effective cross section for nuclide k and energy group g , when the number density of ^{238}U is $N_{^{238}\text{U}}$; and

$\sigma_{\text{eff},k,g}(0)$: effective cross section for nuclide k and energy group g , when the number density of ^{238}U is zero, that is, no resonance overlap effect is considered.

In the resonance calculation, the effective cross section without consideration of the resonance overlap is evaluated first, then the RIF is multiplied by the obtained effective cross section in order to capture the resonance overlap effect.

The RIF table can be prepared by the NJOY code or by utilization of the ultrafine group spectrum calculations. In the usual spectrum calculation based on the NR approximation, a typical asymptotic neutron spectrum with $1/E$ (or similar shape) is used as a starting point, then the actual neutron spectrum with the depression due to a resonance peak is evaluated by

$$\phi(E) = \phi_{\text{asymptotic}}(E) \frac{\sigma_0}{\sigma_t(E) + \sigma_0} \quad (280)$$

The neutron spectrum obtained by (280) is then used to collapse the cross section to obtain a group averaged effective cross section. The NJOY code also has the following option:

$$\phi(E) = \phi_{\text{input}}(E) \frac{\sigma_0}{\sigma_t(E) + \sigma_0} \quad (281)$$

where

$\phi_{\text{input}}(E)$: user-specified neutron spectrum.

In order to consider the resonance overlap effect, the following procedure can be followed:

1. Perform the spectrum calculation for ^{238}U using (280).
2. Use the spectrum obtained in (1) as the user-specified spectrum in (281).
3. Collapse the cross section to obtain the effective cross section using the neutron spectrum obtained in (2).

The effective cross section obtained in (3) includes the resonance overlap effect with ^{238}U . It can therefore be used as the numerator in (279). Since the neutron spectrum obtained in (1) depends on the background cross section (number density) of ^{238}U , several calculations with different shielding conditions (different background cross sections and/or number densities of ^{238}U) should be carried out. The evaluated RIFs are edited as a table for the utilization of resonance calculations in lattice physics codes.

3.10.3 Utilization of an Ultrafine Energy Group Cross Section

We can also use an ultrafine energy group cross section to correct the resonance overlap effect. The ultrafine energy group spectrum calculation discussed in 3.7 can precisely capture any resonance overlap effect, so it can be used to incorporate the effect. However, as previously discussed in 3.7, direct application of the ultrafine energy group calculation for a whole fuel assembly still requires an impractical amount of computation time, so the appropriate combination with other methods would be required. For example, an ultrafine energy group calculation is carried out in simple pin cell geometry, and the position-dependence of the effective cross section due to the shadowing effect of other fuel rods is evaluated through the Dancoff correction (Sugimura and Yamamoto 2007).

Since a neutron spectrum calculation for an ultrafine energy group requires some computation time, a more simplified approach can be used to capture the resonance interference effect. Since an approximate neutron spectrum can be obtained by the NR (or IR)

approximation, the following procedures can be used to evaluate the resonance overlap factor “on the fly”:

1. By recalling (108), evaluate the neutron spectrum using the NR approximation with one resonance nuclide,

$$\begin{aligned}\phi_{f,\text{no-RI}}(E) &= \frac{1}{E} \frac{\Sigma_{p,f} + \Sigma_e}{\Sigma_{t,f}(E) + \Sigma_e} \\ &= \frac{1}{E} \frac{N_r(\sigma_{p,r} + \sigma_{0,f}) + \Sigma_e}{N_r(\sigma_{t,r}(E) + \sigma_{0,f}) + \Sigma_e}\end{aligned}\quad (282)$$

where

Σ_e : macroscopic escape cross section,

$$\sigma_{0,f} = \sum_{k \neq r} N_k \sigma_{p,k} / N_r.$$

2. Evaluate the neutron spectrum using the NR approximation with multiple resonance nuclides,

$$\begin{aligned}\phi_{f,\text{with-RI}}(E) &= \frac{1}{E} \frac{\Sigma_{p,f} + \Sigma_e}{\Sigma_{t,f}(E) + \Sigma_e} \\ &= \frac{1}{E} \frac{\sum_k N_k \sigma_{p,k} + \Sigma_e}{\sum_k N_k \sigma_{t,k}(E) + \Sigma_e}\end{aligned}\quad (283)$$

3. The resonance interference factor is evaluated by

$$\begin{aligned}\text{RIF}_g &= \frac{\sigma_{k,g,\text{with-RI}}(\vec{r})}{\sigma_{k,g,\text{no-RI}}(\vec{r})} = \frac{\int_{E_g}^{E_{g-1}} dE \sigma_k(E) \phi_{f,\text{with-RI}}(\vec{r}, E)}{\int_{E_g}^{E_{g-1}} dE \phi_{\text{with-RI}}(\vec{r}, E)} \\ &\quad \times \frac{\int_{E_g}^{E_{g-1}} dE \phi_{f,\text{no-RI}}(\vec{r}, E)}{\int_{E_g}^{E_{g-1}} dE \sigma_k(E) \phi_{\text{no-RI}}(\vec{r}, E)}\end{aligned}\quad (284)$$

Note that the IR approximation can be also used in the above procedure.

The advantages and disadvantages of this method are summarized as follows:

- The resonance interference factor can be evaluated with the actual composition of the resonance material. Therefore, the resonance interference not only for ^{238}U , but also for other nuclides can be taken into account.
- Since the resonance interference factor is evaluated “on the fly,” additional computation time is necessary. The ultrafine energy group calculation, particularly, requires some computation time, though it is accurate. The second approach with the NR (or IR) approximation could yield a solution that offers a compromise between calculation accuracy and computation time.
- The ultrafine energy group calculation is applied to the resolved resonance energy range, which is ~ 10 keV for heavy resonance isotopes. In order to accurately cover this energy range,

a few to several tens of thousand energy group is necessary. If the number of nuclides considered in the evaluation of the resonance interference factor increases, these cross sections with fine energy resolution require considerable memory storage.

Some of the most recent lattice physics codes adopt this approach to capture the resonance interference effect (Wehlage et al. 2005; Sugimura and Yamamoto 2007).

3.11 Other Topics in Resonance Calculations

3.11.1 Effective Temperature Used in Resonance Calculation

The effective cross section depends not only on the background cross section, but also on the temperature, due to the Doppler broadening of the cross section. The temperature of a fuel pellet varies across its volume during power generation. The shape of the temperature distribution is approximately parabolic in a pellet during steady-state operation. In lattice physics computations, a fuel pellet is commonly treated as a single region, since equivalence theory is widely used. In this case, the choice of “average temperature” is very important in resonance calculations.

Resonance absorption generally takes place on the surface of a resonance lump, due to neutron injection from the moderator. Thus, the surface region should assume more importance than the center region.

Several estimation methods have been developed to date:

- Simple volume average model

$$T_{f,eff} = \frac{1}{V_f} \int_{V_f} T_f(\vec{r}) d\vec{r} \quad (285)$$

- Rowland’s model (for parabolic temperature distribution) (Rowlands 1962)

$$T_{f,eff} = T_s + \frac{4}{9}(T_c - T_s) \quad (286)$$

where

T_s : surface temperature, and

T_c : centerline temperature

- Arnold and Dannels’s model (for parabolic temperature distribution) (Arnold and Dannels 1960)

$$T_{f,eff} = T_s + 0.35(T_c - T_s) \quad (287)$$

- Chord average model (Kruijff 1994; Kruijff and Jansen 1996)

$$T_{f,eff} = \int_S \int_{\vec{n} \cdot \vec{\Omega} > 0} d\vec{\Omega} g(\vec{r}_s, \vec{\Omega}) \frac{\int_0^{L(\vec{r}_s, \vec{\Omega})} T(l) dl}{L(\vec{r}_s, \vec{\Omega})} \quad (288)$$

■ **Table 15**
Weight factors of temperature for the chord average model (10 equi-volumes in an annularly divided cylindrical pellet). Regions 1 and 10 indicate the center and surface, respectively

Region	Weight
1	0.079560
2	0.081776

Source: Matsumoto et al. (2006).

where

$L(\vec{r}_s, \vec{\Omega})$: chord length at position \vec{r}_s on surface S and in direction $\vec{\Omega}$,

$g(\vec{r}_s, \vec{\Omega})$: probability distribution of a chord, which is given by $g(\vec{r}_s, \vec{\Omega}) = n \cdot \vec{\Omega} / (\pi S)$ in the case of isotropic and uniform incident incoming neutrons.

From the viewpoint of integrated parameters such as k-infinity, the above definitions do not yield a considerable discrepancy. However, with respect to the temperature coefficients of a fuel pellet (i.e., the Doppler coefficient), the chord average model more accurately reproduces reference results obtained using a continuous-energy Monte Carlo method. Under transient conditions, the temperature distribution inside a pellet may not have a parabolic shape. For example, during very fast transitions such as a reactivity initiated accident (RIA), which occurs as a rapid increase in reactivity on control rod ejection for LWRs, the temperature distribution may be proportional to the power distribution inside a pellet because of the adiabatic variation of the temperature. The power density is greater on the pellet surface than in the center, so the maximum temperature may appear near the surface in a rapid transition. Both the Rowland and the Arnold and Dannels models assume a parabolic temperature distribution, which is appropriate for the steady state, but which might not be applicable in transient cases. Therefore, the chord average model becomes useful in such a case.

When a fuel pellet is divided into ten annularly equi-volume regions, the weight factors used in the chord average model are those given in ➤ [Table 15](#).

3.11.2 Temperature Distribution in a Resonance Region

Several resonance calculation methods that can handle the spatial resonance self-shielding effect were discussed in ➤ [3.7–3.9](#). When a fuel pellet is subdivided into annular regions, it

is straightforward to consider the temperature distribution in each annular region. However, direct utilization of space-dependent resonance shielding methods with a temperature profile may go beyond the assumptions used in the resonance calculation model.

Since the ultrafine energy group calculation is based on the “first principle,” it can handle the temperature distribution in a fuel lump, and gives a reliable result even with the temperature profile.

The subgroup parameters are generated by the fitting or the moment methods, which assume a certain temperature. Since the probability (weight) of each subgroup and of the subgroup cross section are temperature-dependent, they cannot be directly applied to a space-dependent self-shielding calculation with a temperature profile. Let us consider a subgroup. This subgroup has a certain probability, which “physically” corresponds to the ratio of the energy range in an energy group. This probability depends on the temperature, and takes on another value for a different temperature. This means that the ratio of the energy range for a particular subgroup in an energy group changes due to temperature. Subgroup parameters with different temperatures have different and inconsistent “energy group structures,” so they cannot be used in the same calculation. On the contrary, when a subgroup parameter is generated through the direct method with a fixed energy group structure, it can be applied to a temperature distribution problem because there is no inconsistency in the subgroup parameters for different temperatures. Several studies have been carried out to address this inconsistency in the probability table approach to a temperature-dependent problem (Joo et al. 2005).

The Tone method and the Stoker–Weiss method (or SDDM) also assume a constant macroscopic cross section throughout a fuel lump. Thus, the direct application of these methods to a temperature distribution problem would result in misprediction, and particular considerations would be necessary (Matsumoto et al. 2006).

3.11.3 Treatment of Number Density Distribution in a Pellet

Resonance capture by ^{238}U mainly occurs on the pellet surface due to the spatial self-shielding effect. As a result, plutonium buildup in the surface region becomes dominant, as shown in  [Fig. 31](#).

Resonance calculation methods based on the equivalence theory (including Tone, Stoker–Weiss, SDDM) assumes a constant macroscopic cross section in a fuel lump. Strictly speaking, then, the spatial distributions of resonance nuclides cannot be taken into account and are neglected. Fortunately, previous studies have clarified that the distribution of number density in a pellet has a small impact on the calculation results, so it can be treated as a constant throughout the fuel region in common lattice physics computations (Stoker and Weiss 1996). Therefore, the simple average of number density can be applied to a fuel region in the resonance calculation. Such treatment greatly simplifies the resonance treatment in actual calculations. Note that the subgroup method and the ultrafine energy group calculation method accurately handle these effects, since no assumption regarding the constant cross section is taken into account.

As will be discussed in  [Sect. 6](#), a gadolinia-bearing fuel pellet is subdivided into several annular regions in order to capture the depletion characteristics of gadolinia (the onion skin effect). In this case, we can apply the space-dependent self-shielding method to evaluate the space-dependent effective cross section in each ring. However, in common lattice physics computation such detailed treatment is not necessary, that is, a pellet’s average number density can be used in the resonance calculation, and the same effective cross section can be used in all regions inside a pellet. Note that the number densities in each region are independently

tracked through the burnup calculation, since the reaction rates in each region are different due to spatial variations in the neutron spectrum (even if an identical effective cross section is used in all regions).

3.11.4 Resonance Calculation for Non-Heavy Nuclides

➤ Section 3 mainly considers the resonance calculation for heavy nuclides, for example, ^{238}U . However, a resonance treatment for other nuclides also has important role.

In LWR fuel, gadolinia is commonly used as a burnable absorber. Since the major isotopes of Gd have large resonances and are used with high-content, the self-shielding effect should be taken into account. As described in ➤ Sect. 3.11.3, the spatial dependence of the number densities of Gd isotopes can be handled through the simple average over a pellet in the resonance treatment.

The absorbers used in LWRs also have large resonances, that is, Ag, In, and Cd for PWR, and Hf for BWR. Since the number densities of these resonance nuclides in the absorber are high, the resonance treatment is important in order to accurately predict the reactivity value of the control rod. When an infinite-dilute cross section is used for absorber nuclides, the reactivity value of a control rod will be significantly over-predicted.

Zircaloy is used not only as a cladding material, but also as a structural material such as a water rod, channel box, and grid spacer. Because zirconium isotopes have resonances in the medium energy range, the self-shielding effect of these isotopes would be taken into account, even though absorption by zirconium isotopes is low. In a typical LWR cell, the self-shielding effect of the zirconium isotopes reaches $0.1\% \Delta k/k$, which is considerable. The number densities of the zirconium isotopes in Zircaloy are almost constant, and the shapes of Zircaloy are limited (e.g., cladding and channel box). Pre-tabulation of these isotopes for a particular background cross section might therefore be efficient in practical applications.

Structural material such as Fe, Ni, and Cr have many sharp resonances in the medium energy range. These materials are used for the reflector material in APWR/EPR, and the resonance shielding effect should be taken into account in the reflector calculations. Since the angular dependency of the neutron flux is very large in the reflector, particular care becomes necessary in the resonance calculation for the reflector material. A similar situation can be found in the blanket calculation for a fast breeder reactor. In this case, application of the subgroup method is effective (Yamamoto and Takeda 2000).

3.11.5 Verification and Validation of Resonance Calculation Model

Since many assumptions and approximations are used in resonance calculation models, the verification and validation of these models is very important. Since the verification and validation of a resonance calculation model can be carried out in a small geometry, utilization of a continuous-energy Monte Carlo code is very useful.

In comparison with the results achieved using Monte Carlo code, the effective cross section is usually considered as a benchmark quantity. We must remember, however, that the effective cross sections in lattice physics computations are just intermediate products. Our final objective is the evaluation of neutronics characteristics such as k -infinity and fission rate distribution. In

this sense, the microscopic reaction rates are rather more important than the effective cross sections. Indeed, even if the effective cross sections show excellent agreement in their Monte Carlo and the resonance calculation results, this does not necessarily mean that the resonance calculation model has given accurate reaction rates (Sugimura and Yamamoto 2007). When the effective cross section obtained by a resonance calculation model exactly reproduces the Monte Carlo result, they would still produce inconsistent reaction rates, due to the energy collapsing process that is inevitably included in a resonance calculation model (Rothenstein et al. 1988; Sugimura and Yamamoto 2007). This consideration should not be neglected in the validation and verification process.

3.12 Summary

In [▶ Sect. 3](#), resonance calculation methods to estimate the effective cross section for successive pin cell and/or assembly calculations are described. Since a direct numerical solution to the neutron slowing down equation in a general heterogeneous geometry is still time consuming for practical applications, various calculation models, for example, the equivalence theory, the subgroup method, ultrafine group calculation in small geometry, the Tone method, the Stoker-Weiss (or SDDM) method, have been developed, and are applied in current lattice physics codes.

These models adopt various approximations that could be valid under certain conditions. One should therefore carefully consider the limitations of resonance calculation models and the potential prediction errors associated with the approximations. In this context, the current major resonance methods are still an approximate science, as opposed to the science of approximation, in which prediction errors associated with approximations are well controlled. Therefore, validation and verification of a resonance calculation model in a lattice physics code is quite important.

4 Energy Condensation Scheme

4.1 Introduction

Energy condensation refers to the generation of a unique flux spectrum in each material region of the problem that can be used to condense cross sections from the energy group structure of the cross section library (e.g., hundreds of energy groups) to a smaller energy group structure in preparation for the fine-mesh assembly transport solution (e.g., at most, a couple dozen energy groups). The scheme that will be discussed in this section was used in CASMO-4 and LANCER02 and consists of a series of one-dimensional pin-cell calculations followed by a two-dimensional coupling calculation. This section develops the theory behind the scheme and describes the numerics used to solve the system of equations.

Note that not all lattice physics codes use a condensation scheme. Those that do not use a condensation scheme perform the fine-mesh assembly transport calculation in the energy group structure of the cross section library. For the major fuel vendors who design dozens of reload cores each year requiring the need to design and analyze hundreds of different bundles on their way to finding the best fit for their cores, the need to perform millions of lattice calculations annually almost necessitates the need for a condensation scheme. For small fuel vendors or

utilities that may analyze a very limited number of reload core designs annually, the need for a condensation scheme in the lattice physics code is not so great.

It is important to keep in mind that, at this point in our lattice physics computational scheme, we are only concerned with generating a good condensation flux with which to collapse cross sections. We are allowed to sacrifice accuracy – especially spatial accuracy – for execution speed. However, the number of energy groups required for the fine-mesh assembly transport solution is directly proportional to the accuracy of the condensation spectra, so it is in our best interest to produce a reasonably accurate condensation flux.

4.2 Pin-Cell Spectral Calculations

Our condensation scheme begins with a series of one-dimensional pin-cell spectral calculations. The pin-cell spectral calculations are used to generate a flux spectrum in each region of each pin cell in the lattice, where the term *pin cell* implies a system consisting of a fuel rod plus the coolant in the immediate vicinity. It is also meant to include each of the inert rods present in the assembly, such as water rods and any absorber pins. The flux spectra in each region of the cell are generated in the energy group structure of the cross section library. During the pin-cell spectral calculations, each pin cell in the lattice is isolated from the influence of all other cells. Once all the pin-cell spectral calculations have been completed, we will perform a two-dimensional coupling calculation to modify the flux spectrum in each region of each cell to account for the influence of the surroundings.

For each pin cell, the square coolant region is approximated by a cylinder, preserving the volume of the outer coolant region and allowing for a purely one-dimensional analysis to be performed. White boundary conditions are applied to the outer edge of the cell to simulate perfect reflection in the true square geometry.

To help drive the flux across each pin cell, a buffer zone of average fuel material may be placed on the outside of the coolant zone. The pin-cell analysis is a fixed source calculation, where the neutron fission spectrum is used as the neutron source and may be placed in the buffer zone, exclusively, or in both the buffer zone and the fuel pellet. Either approach works equally well. The use of a fixed source helps to speed up convergence of the solution to the transport equation without adversely affecting the accuracy of the solution.

Because the pin-cell calculation is a purely one-dimensional problem, any solution technique to the transport equation is a viable choice. We can choose to solve the integrodifferential form of the transport equation using discrete ordinates, or we can choose to solve the integral form of the transport equation using the method of collision probabilities. Our choice is to use the method of collision probabilities because of its superior performance on physically small problems containing only a few mesh. ➤ Sections 4.2.1 and ➤ 4.2.2 will be devoted to the method of collision probabilities as applied to the pin-cell spectral calculations in a lattice physics code. The contents of this section have been taken from lectures given to postgraduate students in a course on computational reactor analysis at The Pennsylvania State University in 1990 (Knott 1990). Citations are absent from the bulk of the text because the material has been derived from first principles. The interested reader is directed to Lewis and Miller (1984) and Stamm'ler and Abbate (1983), from which much of the material have been culled. For an excellent discussion on the method of collision probabilities, the interested reader is directed to the seven publications that comprise Ingvar Carlvik's Ph.D. thesis (Carlvik 1967a, b, c, d, 1965,

1966a, b; Carlvik and Pershagen 1959) along with one additional publication that did not appear in his thesis (Carlvik 1966c).

4.2.1 General Theory

The spectral calculation determines the neutron flux distribution across the pin cell by solving the integral form of the transport equation using the method of collision probabilities. The integral equation is derived from the integrodifferential form of the Boltzmann transport equation

$$\frac{1}{|v|} \frac{\partial \Phi(\vec{r}, E, \hat{\Omega}, t)}{\partial t} = Q(\vec{r}, E, \hat{\Omega}, t) - \Omega \cdot \nabla \Phi(\vec{r}, E, \hat{\Omega}, t) - \Sigma_t(\vec{r}, E) \Phi(\vec{r}, E, \hat{\Omega}, t) \quad (289)$$

where the source term, $Q(\vec{r}, E, \hat{\Omega}, t)$, is the total source of neutrons at location \vec{r} , with energy E , traveling in direction $\hat{\Omega}$, at time t , and is given by

$$Q(\vec{r}, E, \hat{\Omega}, t) = \iint \Sigma_s(\vec{r}, E' \rightarrow E, \hat{\Omega}' \rightarrow \hat{\Omega}) \Phi(\vec{r}, E', \hat{\Omega}', t) dE' d\hat{\Omega}' + S(\vec{r}, E, \hat{\Omega}, t) \quad (290)$$

In the above expressions, $\Phi(\vec{r}, E, \hat{\Omega}, t)$ is the angular flux, $\Sigma_t(\vec{r}, E)$ is the total macroscopic cross section, and $\Sigma_s(\vec{r}, E' \rightarrow E, \hat{\Omega}' \rightarrow \hat{\Omega})$ is the macroscopic scattering cross section. $S(\vec{r}, E, \hat{\Omega}, t)$ is the source of neutrons at location \vec{r} , either internal (i.e., due to fission) or external.

In lattice physics calculations, only time-independent problems are considered and the steady state Boltzmann equation to be solved is expressed as

$$\Omega \cdot \nabla \Phi(\vec{r}, E, \hat{\Omega}) + \Sigma_t(\vec{r}, E) \Phi(\vec{r}, E, \hat{\Omega}) = Q(\vec{r}, E, \hat{\Omega}) \quad (291)$$

Equation (291) describes neutron motion as viewed from a fixed reference point, giving rise to the partial derivative in the streaming term. If neutron motion were viewed from the neutron's frame of reference, the partial derivative in the streaming term reduces to a total derivative along the path of motion of the neutron

$$\frac{d\Phi(\vec{r}, E, \hat{\Omega})}{ds} + \Sigma_t(\vec{r}, E) \Phi(\vec{r}, E, \hat{\Omega}) = Q(\vec{r}, E, \hat{\Omega}) \quad (292)$$

where s is the track along which the neutron is traveling across the region at location \vec{r} .

Equation (292) may be solved to obtain an expression for the angular flux. We first solve the homogeneous portion of the equation, where the source term, $Q(\vec{r}, E, \hat{\Omega})$, is set to zero. The homogeneous solution is

$$\Phi^h(\vec{r}, E, \hat{\Omega}) = C e^{-\int_0^s \Sigma_t(s', E) ds'} \quad (293)$$

where s is measured along the streaming path from the differential volume element dV' to the differential volume element of interest, dV , as illustrated in  Fig. 33.

Next Lagrange's method of varying the constant is used, where the integration constant in (293), C , is assumed to be a function of the streaming length, $C(s)$. This solution is back-substituted into (292) and the entire differential equation is integrated along s from $-\infty$

Figure 33
Coordinate system for the integral transport equation

to the differential volume of interest, dV . The final expression for the integrating constant is given by

$$\int_{-\infty}^s dC(s') ds' = \int_{-\infty}^s Q(s', E, \hat{\Omega}) \cdot e^{\int_0^{s'} \Sigma_t(s'', E) ds''} ds' \quad (294)$$

$$C(s) = C(-\infty) + \int_{-\infty}^s Q(s', E, \hat{\Omega}) \cdot e^{\int_0^{s'} \Sigma_t(s'', E) ds''} ds' \quad (295)$$

Back-substituting (295) into (293) gives the general form of the integral equation for the angular flux at location \vec{r} ,

$$\Phi(\vec{r}, E, \hat{\Omega}) = \int_{-\infty}^s Q(s', E, \hat{\Omega}) \cdot e^{-\int_{s'}^s \Sigma_t(s'', E) ds''} ds' \quad (296)$$

where the $C(-\infty)$ term in (295) has been taken to be zero since it would take a neutron, infinitely far away, an infinite length of time to travel along the streaming path in order to reach the volume element located at \vec{r} and, infinitely long ago, there were no neutrons.

To visualize the integral equation, imagine standing at a point in space. If you wished to calculate the neutron flux at that point, you would look around yourself in all directions and count up all the neutrons that are streaming toward you along lines that originate from the location of each neutron's most recent collision (i.e., birth). The angular fluxes would be the number of neutrons streaming toward you along each specific line. Each time you moved your head to look in a different direction, you would be viewing a different angular flux. To calculate a scalar flux, you would simply count up all neutrons moving toward you from all directions.

The energy dependence in (296) is represented by neutrons that are moving at different speeds along each of those lines. As we move to [Sect. 5](#), we will refer to these lines as *characteristics* and we will view our system from the neutron's point of view as it moves along the line, instead of viewing our system while standing still and watching the neutron move toward us.

If we assume that all self-scattering and total cross sections in the library have been transport corrected, then scattering can be modeled, mathematically, in the same way as an isotropic source is modeled. In addition, the only source of neutrons are those due to fission, which is inherently isotropic, and the angular source term, $Q(\vec{r}, E, \hat{\Omega})$, may be expressed in terms of the total source term, $q(\vec{r}, E)$, as

$$Q(\vec{r}, E, \hat{\Omega}) = \frac{q(\vec{r}, E)}{4\pi} = \int \frac{\Sigma_s(\vec{r}, E' \rightarrow E)}{4\pi} \int_{4\pi} \Phi(\vec{r}, E', \hat{\Omega}') d\hat{\Omega}' dE' + \frac{s(\vec{r}, E)}{4\pi} \quad (297)$$

where the fixed scalar source term, $s(\vec{r}, E)$, can be due to fission or may be a constant external source. The angular source due to fission has the following appearance:

$$S(\vec{r}, E, \hat{\Omega}) = \frac{s(\vec{r}, E)}{4\pi} = \frac{\chi(E)}{k^\infty} \int \frac{\nu \Sigma_f(\vec{r}, E')}{4\pi} \int_{4\pi} \Phi(\vec{r}, E', \hat{\Omega}') d\hat{\Omega}' dE' \quad (298)$$

Here, k^∞ is the infinite multiplication factor, which assumes no leakage of neutrons from the system, and is calculated as

$$k^\infty = \frac{\iint \nu \Sigma_f(\vec{r}, E) \phi(\vec{r}, E) \cdot d^3\vec{r} \cdot dE}{\iint \Sigma_a(\vec{r}, E) \phi(\vec{r}, E) \cdot d^3\vec{r} \cdot dE} \quad (299)$$

and the scalar flux at location \vec{r} in (299) is the integration of the angular flux over all directions,

$$\phi(\vec{r}, E) = \int_{4\pi} \Phi(\vec{r}, E, \hat{\Omega}) d\hat{\Omega} \quad (300)$$

Using (300), the source term in (297) may be expressed in terms of the scalar flux alone, as

$$Q(\vec{r}, E, \hat{\Omega}) = \frac{q(\vec{r}, E)}{4\pi} = \frac{1}{4\pi} \left[\int \Sigma_s(\vec{r}, E' \rightarrow E) \phi(\vec{r}, E') dE' + \frac{\chi(E)}{k^\infty} \int \nu \Sigma_f(\vec{r}, E') \phi(\vec{r}, E') dE' \right] \quad (301)$$

Substituting (301) into (296) yields

$$\Phi(\vec{r}, E, \hat{\Omega}) = \int_{-\infty}^s \frac{q(s', E)}{4\pi} \cdot e^{-\int_{s'}^s \Sigma_t(s'', E) ds''} ds' \quad (302)$$

Equation (302) is the integral equation for the angular flux, where all sources are considered to be isotropic (using transport-corrected cross sections to account for anisotropic effects). The

integral equation may be formulated directly for the scalar flux by using (300) and integrating (302) over all angles. Hence,

$$\phi(\vec{r}, E) = \int_{4\pi} \Phi(\vec{r}, E, \hat{\Omega}) \cdot d\hat{\Omega} = \int_{4\pi} \int_{-\infty}^{\infty} \frac{q(s', E)}{4\pi} \cdot e^{-\int_{s'}^{\infty} \Sigma_t(s'', E) ds''} ds' \cdot d\hat{\Omega} \quad (303)$$

Since the path of integration over s' stretches to infinity in all directions, all space is included in the integral $ds' d\hat{\Omega}$. As such, the line integral in (303) may be converted to a volume integral by the following change of variables:

$$\vec{r}' = \vec{r} - s' \cdot \hat{\Omega} \quad (304)$$

Rearranging (304)

$$s' = |\vec{r} - \vec{r}'| \quad (305)$$

Multiplying and dividing the integrand in (303) by s'^2 we get

$$\phi(\vec{r}, E) = \int_{4\pi} d\hat{\Omega} \int_0^{\infty} s'^2 \frac{q(\vec{r}', E) e^{-\tau(\vec{r}' \rightarrow \vec{r}, E)}}{|\vec{r} - \vec{r}'|^2} ds' \quad (306)$$

where $\tau(\vec{r}' \rightarrow \vec{r}, E)$ is the distance between points \vec{r}' and \vec{r} in mean free paths (i.e., the optical distance), represented by

$$\tau(\vec{r}' \rightarrow \vec{r}, E) = \int_{r'}^r \Sigma_{tr}(s', E) ds' \quad (307)$$

If we now take a spherical coordinate system with \vec{r} at the origin, as illustrated in  Fig. 34, the incremental volume centered about \vec{r}' is

$$dV' = 4\pi \cdot d\hat{\Omega} \cdot ds' \cdot s'^2 \quad (308)$$

where we have made use of the definition for the incremental solid angle $d\hat{\Omega} = d\varphi \cdot \sin \theta \cdot d\theta / 4\pi$. Combining (308) with (306), we obtain our new expression of the integral equation for the scalar flux with isotropic sources,

$$\phi(\vec{r}, E) = \int q(\vec{r}', E) \cdot \frac{e^{-\tau(\vec{r}' \rightarrow \vec{r}, E)}}{4\pi |\vec{r} - \vec{r}'|^2} \cdot dV' \quad (309)$$

The exponential term in (309) represents the non-collision probability along a streaming path, which may intersect regions of different material properties (i.e., cross sections). We may write (309) in a more compact form as

$$\phi(\vec{r}, E) = \int_{-\infty}^0 dV' \cdot T(\vec{r}' \rightarrow \vec{r}, E) \cdot q(\vec{r}', E) \quad (310)$$

Figure 34
Spherical coordinate system centered at r

where $T(\vec{r}' \rightarrow \vec{r}, E)$ is referred to as the transport matrix between \vec{r}' and \vec{r} for neutrons at energy E ,

$$T(\vec{r}' \rightarrow \vec{r}, E) = \frac{1}{4\pi |\vec{r} - \vec{r}'|^2} \cdot \exp \left\{ - \int_{\vec{r}'}^{\vec{r}} \Sigma_{tr}(s, E) ds \right\} \quad (311)$$

To convert (310) into a form that is amenable for computations, we split the problem geometry into regions where the flux is considered to be flat and, therefore, the source distribution will be constant across the region. The discretized form of the integral equation becomes

$$\phi_i^g = \sum_{i'} T_{i' \rightarrow i}^g \cdot q_{i'}^g \cdot V_{i'} \quad (312)$$

where i is the mesh in which the flux is being calculated and the summation is over all mesh in the problem, including the mesh i itself; g is the energy group. The solution to the integral equation reduces to determining the transport matrix for the geometry of the system.

4.2.2 The Method of Collision Probabilities in Slab Geometry

In all solutions to the transport equation, we must solve for the motion of neutrons in all three dimensions. This is true regardless of the dimensionality of the problem. The dimensionality of the problem merely reflects the number of axes along which material boundaries exist. For example, a one-dimensional problem contains material boundaries along one axis and is infinite along the other two axes. Similarly, a two-dimensional problem contains material boundaries along two axes and is infinite along the third axis. Regardless of the dimensionality of the problem, we must always model neutron motion in all three dimensions. In most transport solution techniques, such as the method of characteristics or discrete ordinates, we must model neutron motion explicitly in all directions through the use of a quadrature set. In the method of collision

Figure 35
Cylindrical coordinate system for slab geometry

probabilities with isotropic sources, though, it is possible to integrate over all polar directions of motion analytically. This removes a great deal of the computational burden. Once we do this, we need only compute neutron motion numerically in the plane of the problem.

We begin our derivation for the method of collision probabilities in slab geometry. We will then move into cylindrical geometry, which is our desired geometry for the pin-cell calculation. In slab geometry, to perform the polar integration, we begin by expressing the volume element in cylindrical coordinates,

$$dV' = \rho \cdot d\rho \cdot d\omega' \cdot dx' \quad (313)$$

The coordinates to (313) are illustrated in Fig. 35. Using the cylindrical coordinate system, the integral equation can be expressed as

$$\phi(x, E) = \int_{-\infty}^{\infty} dx' \cdot q(x', E) \int_0^{\infty} \rho \cdot d\rho \int_0^{2\pi} \frac{e^{-\tau(\vec{r}' \rightarrow \vec{r}, E)}}{4\pi |\vec{r}' - \vec{r}|^2} \cdot d\omega' \quad (314)$$

where $\tau(\vec{r}' \rightarrow \vec{r}, E)$ now represents the distance, in mean free paths, between \vec{r}' and \vec{r} at some energy, E .

Integrating over $d\omega'$, we get 2π , and (314) becomes

$$\phi(x, E) = 2\pi \int_{-\infty}^{\infty} dx' \cdot q(x', E) \int_0^{\infty} \rho \cdot d\rho \cdot \frac{e^{-\tau(\vec{r}' \rightarrow \vec{r}, E)}}{4\pi |\vec{r}' - \vec{r}|^2} \quad (315)$$

Since the cross sections change only in the x -direction of motion, the optical path between \vec{r}' and \vec{r} , $\tau(\vec{r}' \rightarrow \vec{r}, E)$, may be expressed in terms of the projected length onto the x -axis. Here, we let γ be the projected ratio,

$$\gamma = \frac{|\vec{r}' - \vec{r}|}{|x' - x|} = \frac{\text{true}}{\text{projected}} \quad (316)$$

Then, $\tau(\vec{r}' \rightarrow \vec{r}) = \gamma \cdot \tau(x' - x)$. Using the right triangle illustrated in Fig. 35

$$|\vec{r}' - \vec{r}|^2 = \rho^2 + |x' - x|^2 \quad (317)$$

and, therefore, we can rearrange (317) to get an expression for $\rho \cdot d\rho$,

$$\begin{aligned}
 \rho^2 &= |\vec{r}' - \vec{r}|^2 - |x' - x|^2 \\
 &= y^2 \cdot |x' - x|^2 - |x' - x|^2 \\
 &= (y^2 - 1) \cdot |x' - x|^2 \\
 \rho &= \sqrt{(y^2 - 1)} \cdot |x' - x| \\
 d\rho &= \frac{1}{2\sqrt{(y^2 - 1)}} \cdot 2y \cdot dy \cdot |x' - x| \\
 &= \frac{1}{\sqrt{(y^2 - 1)}} \cdot y \cdot dy \cdot |x' - x|
 \end{aligned} \tag{318}$$

Now, we may express the integral in ρ in terms of the projected ratio, γ ,

$$\rho \cdot d\rho = y \cdot dy \cdot |x' - x|^2 \tag{319}$$

Substituting (319) into (315) we get the equation for the flux expressed in terms of the projected ratio

$$\begin{aligned}
 \phi(x, E) &= 2\pi \int_{-\infty}^{\infty} dx' \cdot q(x', E) \int_0^{\infty} \rho \cdot d\rho \cdot \frac{e^{-\tau(\vec{r}' \rightarrow \vec{r}, E)}}{4\pi |\vec{r}' - \vec{r}|^2} \\
 &= \int_{-\infty}^{\infty} dx' \cdot q(x', E) \int_1^{\infty} \gamma \cdot dy \cdot |x' - x|^2 \cdot \frac{e^{-\gamma\tau(x' \rightarrow x, E)}}{2y^2 \cdot |x' - x|^2} \\
 &= \int_{-\infty}^{\infty} dx' \cdot q(x', E) \int_1^{\infty} \frac{dy}{2y} \cdot e^{-\gamma\tau(x' \rightarrow x, E)}
 \end{aligned} \tag{320}$$

Although the above transformation may seem pointless, it actually simplifies things because the integral over γ may be expressed in terms of the exponential integral, $E_n(\tau)$,

$$E_n(\tau) = \int_1^{\infty} \frac{dy}{y^n} e^{-\gamma\tau} \tag{321}$$

Our integral equation for the scalar flux with isotropic sources now becomes much more compact,

$$\phi(x, E) = \int_{-\infty}^{\infty} dx' \cdot q(x', E) \cdot \frac{1}{2} E_1 \tau [(x' \rightarrow x, E)] \tag{322}$$

Numerical recipes for exponential integrals are widely available in the literature. The interested reader is directed to the Appendix contained in citation (Stamm'ler and Abbate 1983).

For our slab, we divide the interval between the left boundary and the right boundary of the slab into I number of mesh, where the scalar flux is constant (flat) across each mesh. The width of mesh i is $\Delta_i = x_i - x_{i-1}$.

The scalar flux in mesh i is calculated as

$$\phi_i^g = \frac{1}{\Delta_i} \int_{x_{i-1}}^{x_i} dx \cdot \phi(x, E) = \frac{1}{\Delta_i} \int_{x_{i-1}}^{x_i} dx \int_1^\infty dx' \cdot \frac{1}{2} E_1 [\tau(x' \rightarrow x, E)] \cdot q(x', E) \quad (323)$$

where the flat flux approximation leads to the following expression for the source:

$$q(x, E) = q_i^g = \sum_{g'} \Sigma_{s,i}^{g' \rightarrow g} \phi_i^{g'} + \frac{\chi^g}{k^\infty} \sum_{g'} \nu \Sigma_{f,i}^{g'} \phi_i^{g'} \quad (324)$$

Multiplying (323) through by $\Sigma_{tr,i}^g \cdot \Delta_i$, we get

$$\Sigma_{tr,i}^g \cdot \Delta_i \cdot \phi_i^g = \sum_{i'=1}^I P_{i' \rightarrow i}^g \cdot \Delta_{i'} \cdot q_{i'}^g \quad (325)$$

The left-hand side of (325) represents the total number of interactions in mesh i . On the right-hand side of the equation, $\Delta_{i'} \cdot q_{i'}^g$ represents the total number of neutrons born in mesh i' , and $P_{i' \rightarrow i}^g$ represents the probability that a neutron travels undisturbed from mesh i' to mesh i , where it suffers its first collision. In this context, $P_{i' \rightarrow i}^g$ is a true probability in the sense that $\sum_i P_{i' \rightarrow i}^g = 1$. That is, the neutron must eventually interact with something, somewhere.

Comparing (323) against (325), the collision probability can be expressed as

$$P_{i' \rightarrow i}^g = \frac{\Sigma_{tr,i'}^g}{\Delta_{i'}} \int_{x_{i-1}}^{x_i} dx \int_{x_{i'-1}}^{x_{i'}} dx' \cdot \frac{1}{2} E_1 [\tau(x' \rightarrow x, E)] \quad (326)$$

Integrating, we get the following expression for the collision probability between mesh i' and i :

$$P_{i' \rightarrow i}^g = \frac{1}{2 \Sigma_{tr,i'}^g \cdot \Delta_{i'}} \left[\begin{array}{l} E_3(\tau_{i' \rightarrow i}^g) \\ -E_3(\tau_{i' \rightarrow i}^g + \Sigma_{tr,i}^g \cdot \Delta_i) \\ -E_3(\tau_{i' \rightarrow i}^g + \Sigma_{tr,i'}^g \cdot \Delta_{i'}) \\ +E_3(\tau_{i' \rightarrow i}^g + \Sigma_{tr,i}^g \cdot \Delta_i + \Sigma_{tr,i'}^g \cdot \Delta_{i'}) \end{array} \right] \quad (327)$$

and the collision probability within mesh i ,

$$P_{i \rightarrow i}^g = 1 - \frac{1}{2 \Sigma_{tr,i}^g \cdot \Delta_i} [1 - 2E_3(\Sigma_{tr,i}^g \cdot \Delta_i)] \quad (328)$$

where $\tau_{i' \rightarrow i}^g$ is the optical path between mesh i' and i along the x -axis, in energy group g . Note that the optical path does not rely on the direction of motion of the neutron. In other words, $\tau_{i' \rightarrow i}^g = \tau_{i \rightarrow i'}^g$, which is the *optical reciprocity relationship*. In arriving at our final expression in (327) and (328), we have made use of the relationship $E_n(\tau) = \int_\tau^\infty E_{n-1}(x) dx$.

For a slab with vacuum boundary conditions, a neutron can only make it from mesh i' to mesh i if it starts off streaming in the direction of mesh i . If it streams in the opposite direction, it will have a collision or leak through the vacuum boundary without ever reaching mesh i . The

collision probabilities represented by (327) are referred to as *black body* CP's since, should a neutron reach the system boundary, it is lost forever. In this way, the boundary acts as a perfect absorber (i.e., black).

For reflective boundary conditions, all neutrons have some chance of reaching mesh i from mesh i' . To account for this, we can take one of two approaches to correct our black body CP's. We may extend the calculation of $P_{i' \rightarrow i}^g$ to include the reflection off each surface to the slab. Usually, the calculation of collision probabilities will proceed until $\tau_{i' \rightarrow i}^g$ is beyond a preset value, typically between 6 and 10 mean free paths. A neutron that is born 6 mean free paths from mesh i has an e^{-6} chance of reaching the mesh without suffering a collision. This probability is only 1 in 400, which can usually be ignored without impacting the results. The trouble with this approach is the sheer amount of bookkeeping required, especially in the fast energy groups where the mean free paths can be very large. Neutrons may bounce from boundary to boundary many times before reaching the preset limit on mean free path.

An alternative approach would be to calculate the total current on both boundaries caused by the flux in each mesh. Once the surface currents are known, the contribution to the flux in each mesh caused by the current on each surface can be calculated. To do this, we need to calculate the collision probability from mesh i to surface j , which ends up appearing as

$$P_{i \rightarrow j}^g = \int_{S_j} dS \int_{A_i} dA \cdot \hat{n} \cdot |\vec{r} - \vec{r}'| \frac{E_2[\tau(\vec{r} \rightarrow \vec{r}')] }{|\vec{r} - \vec{r}'|^2} \\ = [E_3(\tau_{i \rightarrow j}^g) - E_3(\tau_{i \rightarrow j}^g) + \Sigma_{tr,i}^g \Delta i] \quad (329)$$

Then the current on surface j is the sum of all neutrons arriving on the surface from all mesh in the problem and also from the other surface to the slab. The contribution from each mesh can be expressed as

$$J_j^g = \sum_{i=1}^I P_{i \rightarrow j}^g \cdot q_i^g \cdot \Delta i \quad (330)$$

The contribution from the other surface of the slab will be addressed shortly.

The τ values in (327) and (329) are measured as the shortest distance between two mesh, or between a mesh and a surface. For mesh that share a common surface (i.e., mesh that neighbor each other), $\tau_{i' \rightarrow i}^g = 0$ and $E_3(0) = 1/2$. Similarly, for mesh that neighbor a slab boundary, $\tau_{i \rightarrow j}^g = 0$.

To represent the boundary condition ideally, we would need to know the angular distribution of the flux as it reaches the surface. Since we are solving directly for the scalar flux, we do not know the angular flux distribution. Therefore, we must make some sort of assumption. For illustrative purposes, we will say that the angular flux is distributed isotropically as it reaches the surface. Then, for example, the current along the west surface of the slab is given by

$$J_{\text{west}}^g = \int_{\hat{\Omega} \cdot \hat{n} < 0} d\hat{\Omega} |\hat{\Omega} \cdot \hat{n}| \Phi_{\text{west}}^g(\hat{\Omega}) = \int_{\hat{\Omega} \cdot \hat{n} < 0} d\hat{\Omega} |\hat{\Omega} \cdot \hat{n}| \frac{\phi_i^g}{4\pi} = \frac{1}{4} \phi_{\text{west}}^g \quad (331)$$

where we are only concerned with neutrons traveling to the west. Rearranging (331) we get an expression for the flux along the west surface of the slab,

$$\phi_{\text{west}}^g = 4J_{\text{west}}^g \quad (332)$$

The expression for the scalar flux can now include the contribution from the surface currents (assuming an isotropic angular flux distribution)

$$\phi_i^g = \sum_{i'=1}^I T_{i' \rightarrow i}^g \cdot \Delta_{i'} \cdot q_{i'}^g + 4 \sum_{j=1}^J T_{j \rightarrow i}^g \cdot J_j^g \quad (333)$$

where the transport matrices are given by

$$T_{i' \rightarrow i}^g = \frac{1}{\Sigma_{tr,i}^g \cdot \Delta_i} P_{i' \rightarrow i}^g$$

$$T_{j \rightarrow i}^g = \frac{1}{2\Sigma_{tr,i}^g \cdot \Delta_i} P_{j \rightarrow i}^g$$

and the currents are calculated from

$$J_j^g = \sum_{i=1}^I T_{i \rightarrow j}^g \cdot q_i^g \cdot \Delta_i \quad (334)$$

Note that the transport matrices are insensitive to the direction of motion of the neutron,

$$T_{i' \rightarrow i}^g = T_{i \rightarrow i'}^g \quad (335)$$

(335) is the optical reciprocity relationship, where the transport matrices are diagonally symmetric and only the diagonal elements and upper triangle elements need to be calculated; the lower triangle elements of the matrix can be filled in with the values from the upper triangle.

4.2.3 The Method of Collision Probabilities in Cylindrical Geometry

In slab geometry, we are able to represent neutron streaming in all directions through the slab by using the exponential integral in the streaming term during the calculation of collision probabilities. This is extremely efficient because we now need only know the width of each mesh in order to determine all the first flight collision probabilities. We are able to express the collision probability this way because the neutron's angle of motion with respect to the slab normal is constant. As a result, the track length of the neutron through the slab is the same regardless of the point at which the neutron enters the slab. This is illustrated schematically in  Fig. 36, where the angle of motion with respect to the x -axis is referred to as ω .

We cannot do the same thing in cylindrical geometry because the face of the cylinder is not flat, as the face of the slab is. In cylindrical geometry, we can only perform the integration analytically over all polar directions. To perform the integration over azimuthal directions of motion, we must use streaming tracks.

For cylindrical geometry, infinite in the z -direction, the integration over the polar angle, θ , is equivalent to determining the flux at a point caused by a line source. If the line source is isotropic, and the point at which the flux is to be determined is a distance t from the line source, then the flux may be calculated by integrating along the line source

$$\phi(P) = \int_{-\infty}^{\infty} \frac{e^{-\Sigma R}}{4\pi R^2} dz = \int_{-\infty}^{\infty} \frac{e^{-\rho}}{4\pi R^2} dz \quad (336)$$

Figure 36
A neutron streaming through a slab

where we have defined $\rho = \Sigma_{tr}R$ to be the optical distance from a point on the line source to the point at which the flux is to be calculated. And the length of R can be expressed as $R = t / \cos \theta$, where t is the closest distance of point P to the line source. The coordinates for this system are illustrated in Figs. 37 and 38.

If we define $\tau = \Sigma_{tr}t$, then $\rho = \tau / \cos \theta$, where τ is in mean free paths. Then (336) becomes

$$\phi(P) = \int_{-\infty}^{\infty} \frac{e^{-(\tau/\cos \theta)}}{4\pi(t^2/\cos^2 \theta)} dz = \int_0^{\infty} \frac{e^{-(\tau/\cos \theta)}}{2\pi(t^2/\cos^2 \theta)} dz \tag{337}$$

where we have made use of the symmetry of the system about the plane of the problem.

Using Fig. 38, we make the following change of variables:

$$\begin{aligned} dz &= \frac{R \cdot d\theta}{\cos \theta} \\ &= \frac{t \cdot d\theta}{\cos^2 \theta} \end{aligned} \tag{338}$$

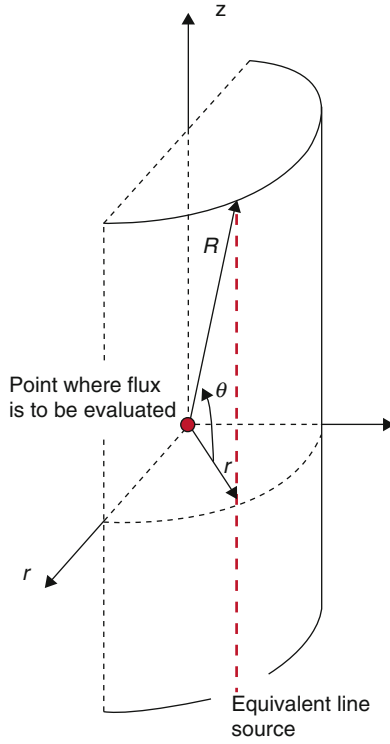

Figure 37
Coordinate system for calculating the flux at a point

Figure 38
Variables in cylindrical geometry

Substituting (338) into (337) we get

$$\begin{aligned}\phi(P) &= \int_0^{\pi/2} \frac{e^{-(\tau/\cos\theta)}}{2\pi t} d\theta \\ &= \frac{Ki_1(\tau)}{2\pi t}\end{aligned}\quad (339)$$

where $Ki_1(\tau)$ is the first order Bickley–Naylor function, defined as

$$Ki_n(\tau) = \int_0^{\pi/2} \exp\left\{-\frac{\tau}{\cos\theta}\right\} \cos^{n-1}\theta \cdot d\theta \quad (340)$$

The probability of a neutron actually traveling the projected distance, $\tau = \Sigma_{tr}t$, is given by

$$p(\tau) = \int_{\tau}^{\infty} Ki_1(\tau') \cdot d\tau' = Ki_2(\tau) \quad (341)$$

In cylindrical geometry, the Bickley–Naylor functions serve the same purpose as the exponential integral serves in slab geometry. The main difference is that the exponential integral accounts for motion in all directions, whereas the Bickley–Naylor function accounts for motion only out of the plane of the problem. However, by using the Bickley–Naylor functions, we need now only account for neutron streaming in the plane of the problem. This is much more efficient than having to numerically account for streaming in three dimensions and helps to simplify our analysis. This is the great benefit of using the method of collision probabilities over other transport solution techniques. As with the exponential functions, numerical recipes for Bickley–Naylor functions are contained in the Appendix in citation (Stamm'ler and Abbate 1983).

The coordinate system for the azimuthal and spatial integration is shown in  Fig. 39, where φ represents the azimuthal angle, and h represents the spatial dimension. For this particular geometry, the azimuthal integration can be rolled into the spatial integration. Also, due to symmetry in the azimuthal plane, we need only model 1/4 of the cylinder – applying perfect reflection along the x - and y -axes and a vacuum boundary condition along the outer edge of the cylinder. The resulting coordinate system is shown in  Fig. 40, where each track drawn at a different h value represents a different φ angle. Collision probabilities will be integrated along these tracks in order to calculate the corresponding transport matrix.

Going through the same exercise for the scalar flux as was followed for slab geometry, we come out with the following expressions for the collision probabilities in cylindrical geometry:

$$\begin{aligned}P_{i' \rightarrow i}^g &= Ki_3(\tau_{i' \rightarrow i}^g) - Ki_3(\tau_{i' \rightarrow i}^g + \tau_{i' \rightarrow i'}^g) - Ki_3(\tau_{i' \rightarrow i}^g + \tau_{i \rightarrow i}^g) \\ &\quad + Ki_3(\tau_{i' \rightarrow i}^g + \tau_{i \rightarrow i}^g + \tau_{i' \rightarrow i'}^g) \\ P_{i \rightarrow i}^g &= \Sigma_{tr,i}^g V_i - \left[\frac{\pi}{4} - Ki_3(\tau_{i \rightarrow i}^g) \right] \\ P_{s \rightarrow i}^g &= Ki_3(\tau_{s \rightarrow i}^g) - Ki_3(\tau_{s \rightarrow i}^g + \tau_{i \rightarrow i}^g) \\ P_{s' \rightarrow s}^g &= Ki_3(\tau_{s' \rightarrow s}^g)\end{aligned}\quad (342)$$

Figure 39

Spatial and angular variables for cylindrical geometry

Figure 40

Angular variable combined with spatial variable

where i and i' represent mesh in the problem; and s and s' represent surfaces in the problem. The elements of the transport matrix are given by

$$\begin{aligned}
 T_{i' \rightarrow i}^g &= \frac{1}{\sum_{tr,i}^g V_i \sum_{tr,i'}^g V_{i'}} \int P_{i' \rightarrow i}^g(h) \cdot dh = \frac{1}{\sum_{tr,i}^g V_i \sum_{tr,i'}^g V_{i'}} \sum_m P_{i' \rightarrow i}^g(h_m) \cdot \Delta h \\
 T_{i \rightarrow i}^g &= \frac{1}{(\sum_{tr,i}^g V_i)^2} \int P_{i \rightarrow i}^g(h) \cdot dh = \frac{1}{(\sum_{tr,i}^g V_i)^2} \sum_m P_{i \rightarrow i}^g(h_m) \cdot \Delta h \\
 T_{s' \rightarrow i}^g &= \frac{1}{\sum_{tr,i}^g V_i A_{s'}} \int P_{s' \rightarrow i}^g(h) \cdot dh = \frac{1}{\sum_{tr,i}^g V_i A_{s'}} \sum_m P_{s' \rightarrow i}^g(h_m) \cdot \Delta h \\
 T_{s' \rightarrow s}^g &= \frac{1}{A_s A_{s'}} \int P_{s' \rightarrow s}^g(h) \cdot dh = \frac{1}{A_s A_{s'}} \sum_m P_{s' \rightarrow s}^g(h_m) \cdot \Delta h
 \end{aligned} \tag{343}$$

Figure 41 Integration variables associated with annular geometry

where V_i represents the volume of a mesh, which in our one-dimensional cylinder is actually the area of the mesh; and A_s represents the surface area of each outer surface of the cylinder, which in our one-dimensional cylinder is actually the outer perimeter of the cylinder. This is shown in Fig. 41. The figure also contains an example of the track distances across the different mesh of the cylinder. These are the track lengths used to calculate the τ values in (342).

To apply the method of collision probabilities, the cylindrical problem is subdivided into a number of small annular mesh. The scalar flux and, hence, the source across each mesh is assumed to be constant. To obtain an accurate solution to the integral equation, the size of each mesh must be small enough such that the flat source approximation is valid. If the source exhibits large variations across a given mesh, the mesh in question would need to be subdivided into smaller mesh where the source variations were not so extreme.

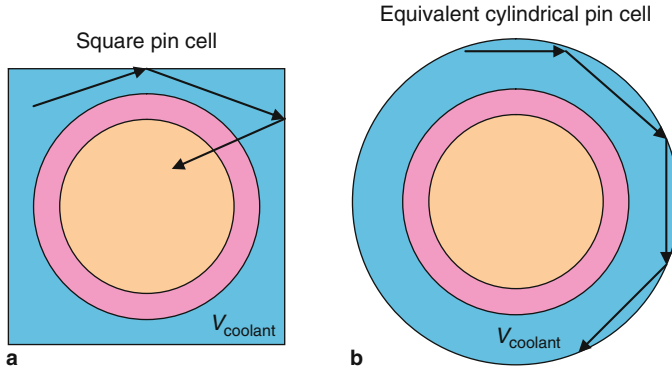

For cylindrical geometry, the equation for the scalar flux is given by

$$\phi_i^g = T_{i \rightarrow i}^g \cdot q_i^g \cdot V_i + \sum_{i' \neq i} q_{i'}^g \cdot V_{i'} \cdot T_{i' \rightarrow i}^g \tag{344}$$

In this formulation, the surface of the cylinder is considered to be non reentrant. That is, if a neutron reaches the surface of the cylinder, it leaks out of the system and does not return. In this respect, the collision probabilities represented in (342) are for a black boundary. We will correct these accordingly in Sect. 4.2.4 to account for reflection along the edge of the cylinder.

4.2.4 White Boundary Conditions

As mentioned earlier, the spectral calculation takes the true geometry of each pin cell – cylindrical fuel and clad regions imbedded in a square coolant zone – and cylindricalizes the coolant

■ **Figure 42**
Neutron streaming effects in a cylindrical cell

region of the cell, preserving the coolant volume, in order to allow for a one-dimensional calculation to be performed on the cell. To isolate the cell from its assembly surroundings, the surfaces along the square coolant region are assumed to be perfectly reflecting. In this way, the spectral calculation generates an infinite spectrum for each pin cell.

Once the pin cell has been cylindricalized, the boundary conditions applied to the equivalent cylindrical coolant region must be consistent with those that would be applied to the square coolant region. Applying perfect reflection along the outer surface of the cylindrical cell will not, however, produce results equivalent to the results generated from a two-dimensional pin-cell calculation. The reason for this is best illustrated in [▶ Fig. 42](#). Here, [▶ Fig. 42a](#) illustrates a neutron streaming across a square coolant region of the true pin-cell geometry at a rather shallow angle relative to the top surface of the cell. Following a few reflections off the boundary of the cell, the neutron streams into the fuel region and is potentially absorbed. [▶ Figure 42b](#) illustrates the same neutron streaming across the coolant region of the cylindrical cell geometry at the same shallow angle relative to the boundary of the cell. Regardless of the number of times the neutron reaches the boundary of the cell, it will never be reflected through the fuel region unless it suffers a scattering collision. As a result, the flux in the coolant region of the cylindrical cell will be overestimated and the cylindrical cell geometry will produce results that are not entirely representative of the results generated in the true geometry of the cell. In even simpler terms, perfect reflection imposes the constraint that a neutron will forever stream back and forth along the same ray trace shown in [▶ Fig. 41](#) unless it suffers a scattering collision. It is easy to see from [▶ Fig. 42a](#) that this is not the case for a square boundary.

To provide a more accurate estimate of the flux in the coolant region of the equivalent cylindrical cell, a “white” boundary condition is applied at the outer surface of the one-dimensional pin-cell geometry, rather than perfect reflection. Here, a neutron reaching the boundary of the system is reflected back into the system with a cosine distribution. In this way, neutrons moving at steep angles relative to the surface of the cylinder are weighed more heavily than neutrons that move at shallow angles relative to the surface of the cylinder, thereby minimizing the streaming effect illustrated in [▶ Fig. 42](#). By using the white boundary condition, most results from the equivalent cell geometry agree nicely with results from the true cell geometry that uses perfect reflection.

Carlvik's method is used to update all collision probabilities from a black boundary to a white boundary (Carlvik 1967a). Here, the vector R_i^g is determined following the calculation of the black boundary $P_{i' \rightarrow i}^g$,

$$R_i^g = \sum_{tr,i}^g V_i - \sum_{i'} \sum_{tr,i'}^g V_{i'} P_{i' \rightarrow i}^g \quad (345)$$

The black boundary collision probabilities are all updated using the relationship

$$\sum_{tr,i}^g V_i \hat{P}_{i' \rightarrow i}^g = \sum_{tr,i}^g V_i P_{i' \rightarrow i}^g - \frac{R_{i'} R_i}{\sum_j R_j} \quad (346)$$

where $P_{i' \rightarrow i}^g$ is a black boundary collision probability, and $\hat{P}_{i' \rightarrow i}^g$ is a white boundary collision probability. Once the collision probabilities have been updated, (344) may be solved directly for the scalar flux. (344) should be rewritten to reflect the fact that we have modified the collision probabilities in (342). Our new expression for the scalar flux is

$$\phi_i^g = \hat{T}_{i \rightarrow i}^g \cdot q_i^g \cdot V_i + \sum_{i' \neq i} q_{i'}^g \cdot V_{i'} \cdot \hat{T}_{i' \rightarrow i}^g \quad (347)$$

where the modified transport matrix elements are given by

$$\begin{aligned} \hat{T}_{i' \rightarrow i}^g &= \frac{1}{\sum_{tr,i}^g V_i \sum_{tr,i'}^g V_{i'}} \sum_m \hat{P}_{i' \rightarrow i}^g(h_m) \cdot \Delta h \\ \hat{T}_{i \rightarrow i}^g &= \frac{1}{\left(\sum_{tr,i}^g V_i\right)^2} \sum_m \hat{P}_{i \rightarrow i}^g(h_m) \cdot \Delta h \\ \hat{T}_{s' \rightarrow i}^g &= \frac{1}{\sum_{tr,i}^g V_i A_{s'}} \sum_m \hat{P}_{s' \rightarrow i}^g(h_m) \cdot \Delta h \\ \hat{T}_{s' \rightarrow s}^g &= \frac{1}{A_s A_{s'}} \sum_m \hat{P}_{s' \rightarrow s}^g(h_m) \cdot \Delta h \end{aligned} \quad (348)$$

4.2.5 Buffer Zone

For normal fuel pin cells, the fuel pellet itself produces neutrons via the fission process and the cell can sustain its own chain reaction for the pin-cell spectral calculation. For inert cells, such as water rods, control rods, or vanish portions of part length rods, there is no neutron source within the pin cell and, hence, there is no way of generating a solution to the integral transport equation. Similarly for fuel pins containing Gadolinium, the Gd cross sections are so large at energies below 1 eV that it becomes difficult to produce a realistic thermal flux spectrum within the pin cell without an external source of neutrons.

In an effort to impose consistency between different pin-cell spectral calculations, all pin cells can be modeled with an outer buffer zone comprised of a representative amount of fuel, cladding, and water. For normal fuel pins, the buffer zone is slightly detrimental because it places fuel material too close to the coolant region. But for inert rods and rods containing Gadolinium, the buffer zone helps to drive the neutron flux across the problem. The size of the buffer zone is somewhat irrelevant to the solution of the problem. For application in most lattice physics codes, the buffer zone can be chosen to be equivalent in size to eight pin cells.

■ **Figure 43**
Geometry of a pin cell with a buffer zone attached

The buffer zone is placed on the outside of each pin cell, as illustrated in ► [Fig. 43](#), and the white boundary condition described in ► [4.2.4](#) is applied at the outer surface of the buffer zone.

The cross sections for the buffer zone can be created in many different ways. The results to the analysis are highly insensitive to the method used. The easiest way to create cross sections for the buffer zone is to simply volume-average all materials in the problem into a single, homogenized material. When applying this simple averaging technique, one should ensure that none of the strong absorbers in the assembly are included in the buffer material. That is, materials for the control blade, control rods, absorber pins, and any fuel pins containing Erbium or Gadolinium should be left out of the average. Inclusion of the strong absorbers into the material will produce a spectrum that is too hard. Another alternative for creating the cross sections for the buffer zone material is to perform a single pin-cell calculation on a representative pin cell (that does not contain a buffer zone) and use the flux from that calculation to flux- and volume-weight the cross sections into a homogenized material. Either approach is perfectly acceptable.

4.2.6 Numerics of the Pin-Cell Spectral Calculation

The pin-cell spectral calculations can be treated as fixed source problems. The fission cross sections of all fuel regions are set to zero and a fixed source of neutrons is defined to exist in the buffer zone only, using the fission spectrum as the neutron source. This is done to help speed up convergence of the solution without adversely affecting the final neutron distribution.

The routine begins by calculating the collision probabilities between all mesh in the problem, using [\(342\)](#). The surface terms are dropped from consideration because they are now rolled into the white boundary correction,

$$\begin{aligned}
 P_{i' \rightarrow i}^g(h) &= Ki_3(\tau_{i' \rightarrow i}^g) - Ki_3(\tau_{i' \rightarrow i}^g + \tau_{i' \rightarrow i'}^g) - Ki_3(\tau_{i' \rightarrow i}^g + \tau_{i \rightarrow i}^g) \\
 &\quad + Ki_3(\tau_{i' \rightarrow i}^g + \tau_{i \rightarrow i}^g + \tau_{i' \rightarrow i'}^g) \\
 P_{i \rightarrow i}^g(h) &= \sum_{i'r,i}^g V_i - \left[\frac{\pi}{4} - Ki_3(\tau_{i \rightarrow i}^g) \right]
 \end{aligned}
 \tag{349}$$

The black boundary collision probabilities are then modified for a white boundary condition using (346). Next, the transport kernel is calculated using (343), where a Gaussian quadrature is used to perform the integration over angle. Once again, the surface terms are dropped from the explicit calculation because they are implicit in the modified collision probability terms,

$$\begin{aligned}\hat{T}_{i' \rightarrow i}^g &= \frac{1}{\Sigma_{tr,i}^g V_i \Sigma_{tr,i'}^g V_{i'}} \sum_m \hat{P}_{i' \rightarrow i}^g(h_m) \cdot \Delta h \\ \hat{T}_{i \rightarrow i}^g &= \frac{1}{(\Sigma_{tr,i}^g V_i)^2} \sum_m \hat{P}_{i \rightarrow i}^g(h_m) \cdot \Delta h\end{aligned}\quad (350)$$

Once the transport kernel has been calculated for the system, the iteration scheme begins. The one-group expression for the flux can be written from (312) as

$$\phi_i = \sum_{i'} q'_{i'} V_{i'} \hat{T}_{i' \rightarrow i} + \sum_{i' \neq i} \Sigma_{s,i'} \phi_{i'} V_{i'} \hat{T}_{i' \rightarrow i} + \Sigma_{s,i} \phi_i V_i \hat{T}_{i \rightarrow i} \quad (351)$$

where the superscript representing the energy group has been dropped and the self-scattering portion of the source has been isolated from the in-scattering and the fixed source, $q'_{i'}$. Rearranging (351) to isolate the in-scattering source term, we get

$$\phi_i - \Sigma_{s,i} \phi_i V_i \hat{T}_{i \rightarrow i} - \sum_{i' \neq i} \Sigma_{s,i'} \phi_{i'} V_{i'} \hat{T}_{i' \rightarrow i} = \sum_{i'} q'_{i'} V_{i'} \hat{T}_{i' \rightarrow i} \quad (352)$$

$$\sum_{i'} \phi_{i'} (\delta_{i,i'} - \Sigma_{s,i'} V_{i'} \hat{T}_{i' \rightarrow i}) = \sum_{i'} q'_{i'} V_{i'} \hat{T}_{i' \rightarrow i} \quad (353)$$

where the in-scattering and fixed source term is given by

$$q'_{i'}{}^g = \sum_{g' \neq g} \Sigma_{s,i'}^{g' \rightarrow g} \phi_{i'}^{g'} + \chi_{i'}^g \quad (354)$$

recalling that the fixed source is zero everywhere other than in the buffer zone.

(352) may be expressed in one-group matrix notation as

$$\underline{\underline{A}}_{ii'} \phi_i = \underline{\underline{B}}_i \quad (355)$$

where

$$\begin{aligned}\underline{\underline{A}}_{ii'} &= \delta_{i,i'} - \Sigma_{s,i'} V_{i'} \hat{T}_{i' \rightarrow i} \\ \underline{\underline{B}}_i &= \sum_{i'} q'_{i'} V_{i'} \hat{T}_{i' \rightarrow i}\end{aligned}\quad (356)$$

The solution to (355) is of the form

$$\phi_i = \underline{\underline{A}}_{ii'}^{-1} \underline{\underline{B}}_i \quad (357)$$

where the $\underline{\underline{A}}$ matrix is inverted only once, prior to beginning the iteration process, using Gaussian elimination.

The iteration scheme consists of a series of inner iterations that are used to converge the scalar flux in each energy group. The inner iterations are contained within outer iterations that

are used to converge the source distribution. Since the pin-cell spectral calculations are treated as a fixed source problem, the flux in the fast energy groups can be solved directly without the need for an outer iteration. The outer iterations are used only to treat up-scattering in the thermal energy groups below ~ 2 eV.

The calculation begins by initializing all scalar flux values in all groups, all mesh, to unity. This represents the flux distribution from the 0 outer iteration. Using this flux initialization, the total (scalar) source in each region of the problem is calculated as

$$q_{i,iter}^g = \sum_{g' < g} \Sigma_{s,i}^{g' \rightarrow g} \phi_{i,iter}^{g'} + \sum_{g' > g} \Sigma_{s,i}^{g' \rightarrow g} \phi_{i,iter-1}^{g'} + \chi_{i,iter-1}^g \quad (358)$$

where *iter* refers to the current outer iteration. The first summation in (358) is over all energy groups above the current group, *g*. The second summation in (358) is over all energy groups below the current group, *g*. The value χ_i^g is the fixed source and is present only in the buffer zone. For energy groups above the thermal up-scattering threshold, the second summation in (358) is always zero and (357) can be solved directly to obtain the fast flux distribution across the pin cell. For thermal energy groups, the flux distribution in lower energies influences the flux distribution in higher energies via thermal up-scattering and the outer iterations are used to drive the flux distribution to a converged solution.

Following the completion of an outer iteration, a fundamental mode rebalancing of the group flux distribution is performed in order to properly normalize the flux and ensure neutron conservation in the thermal groups. The fundamental mode calculation is performed on an equivalent homogeneous system using flux and volume weighted cross sections from the pin-cell calculation

$$\bar{\Sigma}_x^g = \frac{\sum_i \Sigma_{x,i}^g \phi_i^g V_i}{\sum_i \phi_i^g V_i} \quad (359)$$

The fundamental mode equation to be solved is a simple balance equation

$$\begin{aligned} \bar{\Sigma}_{tr}^g \psi^g &= \sum_{g' \neq g} \bar{\Sigma}_s^{g' \rightarrow g} \psi^{g'} + \bar{\Sigma}_s^{g \rightarrow g} \psi^g + \bar{\chi}^g \\ (\bar{\Sigma}_{tr}^g - \bar{\Sigma}_s^{g \rightarrow g}) \psi^g &= \sum_{g' \neq g} \bar{\Sigma}_s^{g' \rightarrow g} \psi^{g'} + \bar{\chi}^g \\ \psi^g &= \frac{\bar{q}^g}{\bar{\Sigma}_r^g} \end{aligned} \quad (360)$$

where the source term does not contain self-scattering and $\bar{\Sigma}_r^g$ is the removal cross section, given by $\bar{\Sigma}_r^g = \bar{\Sigma}_{tr}^g - \bar{\Sigma}_s^{g \rightarrow g}$.

Following the solution to (360), the scalar flux distribution is scaled using

$$\hat{\phi}_i^g = \phi_i^g \cdot \frac{\psi^g}{\sum_i \phi_i^g V_i} \quad (361)$$

Once the flux has converged, the infinite multiplication factor for the pin cell can be calculated from

$$k^\infty = \frac{\sum_g v \bar{\Sigma}_f^g \psi^g}{\sum_g \bar{\Sigma}_a^g \psi^g} \quad (362)$$

4.3 Coupling Calculation

The flux from the pin-cell calculations can be used, directly, as a condensation spectrum to generate broad-group cross sections for the fine-mesh transport solution. Since each pin-cell calculation was performed by isolating the pin from the rest of the assembly, the spectra are only a fair approximation of the actual distribution of neutrons in energy in the various regions of the pin cell (fuel pellet, cladding, and coolant region). If we choose to use these spectra to condense cross sections, we will end up having to carry a lot of broad energy groups in order to preserve accuracy at the fine-mesh assembly level. We will also run into a dilemma with respect to condensing cross sections in the outer regions of the assembly. For example, we have no specific flux spectrum from the series of pin-cell calculations with which to condense the outer water gaps of a BWR fuel assembly, the channel shroud, or regions of the control blade. We will need to use either the spectrum from one of the pin-cell regions, or possibly from the buffer zone – neither of which is an adequate choice. By performing a two-dimensional coupling calculation, we can avoid this dilemma.

The coupling calculation is used to adjust the energy distribution of neutrons from the pin-cell spectral calculations to account for the effects of the true surroundings. Once the energy distribution from the series of pin-cell calculations is adjusted, the resulting flux spectra are used to condense macroscopic cross sections in each material region of the problem from the energy group structure of the cross section library to a smaller, broad-group energy structure in preparation for the fine-mesh transport calculation. The coupling calculation is performed on the entire lattice using homogenized pin-cell cross sections. As such, the solution may be obtained in a straightforward Cartesian geometry and any solution technique to the transport equation is a viable candidate for the coupling calculation.

The solution techniques considered for the coupling calculation include the explicit transport techniques of discrete ordinates, collision probabilities, and the method of characteristics. Approximate techniques considered for the coupling calculation include transmission probabilities (TP) and diffusion theory. Obviously, the explicit transport techniques offer the greatest accuracy. Their main deficiency is execution speed, especially for the large number of energy groups we are considering. In addition, one might wonder why we would bother performing a coupling calculation at all if we are going to use an explicit transport technique to do it. That is, we should simply perform the fine-mesh assembly transport calculation in the energy group structure of the cross section library and be done with it. So, our only real choices for the coupling calculation are the two approximate techniques – TP and diffusion theory. The major assumption used in the derivation of the diffusion approximation is that scattering is the dominant process taking place in the problem. For normal fuel regions and water regions, this assumption is true. For strongly absorbing regions, however, such as control blades, control rods, absorber pins, and fuel pins containing Erbium or Gadolinium, this assumption is very

poor and the use of diffusion theory becomes questionable. Around highly absorbing regions, diffusion theory underestimates the gradient of the flux dip across the absorber and calculates a much flatter flux profile than other solution techniques. The result is too many neutrons being placed directly in, and around, the absorber region and a resulting flux spectrum that is too hard. This is highly undesirable from the point of view of producing a condensation spectrum. As a result, in this section we will focus on a coupling scheme based on a response matrix formulation that uses a simplified transmission probabilities method. The method is accurate in terms of distributing neutrons in energy, and is extremely fast.

4.3.1 The Method of Transmission Probabilities

As in the pin-cell spectral calculations, the transmission probabilities method solves the integral form of the transport equation. In collision probabilities, (347) represent contributions to the scalar flux in mesh i from all other mesh in the system, as well as from the system boundary. The number of solutions to (347) required to calculate a new flux distribution for each energy group is equal to the square of the number of mesh in the problem. If the system being analyzed has many mesh and many energy groups, the number of times (347) must be solved may become very large indeed. In addition, the amount of memory needed to store the transport matrix, (348), for large problems with hundreds of energy groups is excessive, and it may become necessary to store only portions of the matrix in memory at any given time.

This burden on the computer system renders the collision probabilities technique, in its present form, a rather poor choice for large problems such as a whole fuel assembly. The burden on the computer system can be relaxed significantly by coupling mesh together via their surface currents, rather than via their scalar fluxes.

In the transmission probabilities technique, an outgoing current is calculated along each surface of each mesh. The outgoing current will become the incoming current to the neighboring mesh. This eliminates the first summation in (347) for the scalar flux and leaves only the contribution to the scalar flux from neutrons born within a particular mesh, and from the incoming currents along all surfaces to the mesh. The equations to be solved are then reduced to

$$\phi_i^g = T_{i \rightarrow i}^g \cdot q_i^g \cdot V_i + 4 \sum_{s'_i} T_{s'_i \rightarrow i}^g \cdot J_{s'_i, in}^g \cdot A_{s'_i} \quad (363)$$

$$J_{s_i, out}^g = q_{i'}^g \cdot V_{i'} \cdot T_{i' \rightarrow s_i}^g + 4 \sum_{s'_i \neq s_i} T_{s'_i \rightarrow s_i}^g \cdot J_{s'_i, in}^g \cdot A_{s'_i} \quad (364)$$

where $J_{s_i, out}^g$ becomes $J_{s'_i, in}^g$ to the subsequent mesh. All summations in (363) and (364) are over surfaces to mesh i only. It should be remembered that, in the derivation of these equations, the source – and hence the scalar flux – was assumed to be constant across a mesh.

The average neutron current crossing a mesh surface is calculated from the outward directed angular flux distribution along the surface as

$$J_{s_i}^g = \int |\hat{n} \cdot \hat{\Omega}_m| \cdot \Phi_{m, i}^g \cdot d\hat{\Omega}_m = \sum_m \sin \varphi_m \cdot \cos \theta_m \cdot \Phi_{m, i}^g \cdot \omega_m \quad (365)$$

Figure 44
Variables for calculating the surface current leaving a mesh

where the current is normal to the mesh surface. The meanings of the variables used in (365) are illustrated in Fig. 44.

In methods that solve the integrodifferential form of the Boltzmann transport equation, such as the discrete ordinates method, the equations are formulated in terms of the angular flux and the current can be easily calculated, if desired. In integral transport theory, though, the angular dependency of the flux is integrated out of the equation prior to formulating the numerical solution. By doing so, the integral equation is solved directly in terms of the scalar flux, which is usually the desired quantity. The one drawback to this process, in relation to transmission probabilities, is that the angular flux is needed in order to determine the current.

To calculate a current passing through each surface of each mesh, the angular flux must now be approximated in some manner. In the response matrix technique that uses a simplified transmission probabilities method, the angular flux crossing each surface of each mesh is assumed to be distributed isotropically in angle and uniformly in space along the surface

$$\Phi_{m,i}^g = \frac{\phi_i^g}{4\pi} \tag{366}$$

where m represents a specific direction of motion, of which there are a total of 4π radian. (366) leads to the following expression for the current crossing a surface:

$$J_{s_i}^g = \int_{\hat{\Omega} \cdot \hat{n} > 0} d\hat{\Omega} |\hat{\Omega} \cdot \hat{n}| \Phi(\vec{r}, \hat{\Omega}) = \frac{\phi_i^g}{4} \tag{367}$$

From (367), the relationship between the scalar flux and the current is given by

$$4J_{s_i}^g = \phi_i^g \tag{368}$$

where s is a surface to mesh i .

In the coupling calculation routine, the current crossing any boundary is assumed to be isotropically distributed in angle. For a very detailed calculation in space, this would be a very poor approximation. For homogenized pin cells, however, this is actually a better approximation than one might think and allows the simplified transmission probabilities method to be used successfully to generate a reasonably accurate condensation flux. Remember that, at this stage of the calculational scheme, we are focusing on obtaining an accurate energy distribution of neutrons and not so much an accurate spatial distribution.

4.3.2 Numerics of the Coupling Calculation

As in the method of collision probabilities, the transmission probabilities technique reduces to calculating reasonably accurate transport probabilities between all surfaces of a mesh. The equations to be solved here are similar to those introduced for the collision probabilities method

$$\begin{aligned} T_{i \rightarrow i}^g &= \frac{1}{(\sum_{tr,i}^g V_i)^2} \int \frac{d\varphi}{2\pi} \int P_{i \rightarrow i}^g(\varphi, h) dh \\ T_{s \rightarrow i}^g &= \frac{1}{\sum_{tr,i}^g V_i A_s} \int \frac{d\varphi}{2\pi} \int P_{s \rightarrow i}^g(\varphi, h) dh \\ T_{s' \rightarrow s}^g &= \frac{1}{A_s A_{s'}} \int \frac{d\varphi}{2\pi} \int P_{s' \rightarrow s}^g(\varphi, h) dh \end{aligned} \quad (369)$$

where the $P_{i \rightarrow i}^g(\varphi, h)$'s represent the collision probabilities, given by

$$\begin{aligned} P_{i \rightarrow i}^g(\varphi, h) &= \sum_{tr,i}^g V_i - \left[\frac{\pi}{4} - Ki_3(\tau_{i \rightarrow i}^g) \right] \\ P_{s \rightarrow i}^g(\varphi, h) &= \frac{1}{2} \left[\frac{\pi}{4} - Ki_3(\tau_{s \rightarrow i}^g) \right] \\ P_{s' \rightarrow s}^g(\varphi, h) &= Ki_3(\tau_{s' \rightarrow s}^g) \end{aligned} \quad (370)$$

In the above equation, the A_s 's represent the surface areas of a mesh, and the $\tau_{i \rightarrow i}^g$'s represent the optical distances between surfaces of a mesh, in mean free paths, in the xy -plane of the problem. The $Ki_3(\tau_{i \rightarrow i}^g)$ values are the Bickley–Naylor functions arising from the integration over polar angle performed analytically, as discussed previously. Note that collision probabilities for the coupling calculation are calculated on a mesh by mesh basis and are, therefore, much simpler than the collision probabilities calculated for the pin-cell spectral calculations.

The integrations in (369) are performed numerically using sets of parallel, equidistant tracks (separated by a distance dh), which are traced over each mesh individually at several evenly spaced angles (distributed every $\Delta\varphi$ radians). The collision probabilities between the various surfaces are then calculated along these tracks.

The numerics of the coupling calculation are very similar to those of the pin-cell spectral calculations. Here, though, streaming tracks are traced over each mesh in the system individually in order to obtain the optical distances, τ , needed to solve (370) and to perform the integrations over angle and space contained in (369).

Figure 45
Area between different angles of motion

For a specified number of azimuthal angles, L , the azimuthal boundaries are evenly spaced and the direction of the streaming tracks are distributed according to

$$\varphi_l = \left(l - \frac{1}{2} \right) \cdot \Delta\varphi \quad (371)$$

The weight associated with each direction, $d\varphi = \Delta\varphi$, is then given by

$$\Delta\varphi = \frac{2\pi}{L} \quad (372)$$

The weight represents the area between different directions, as illustrated in Fig. 45. Since the integration over polar angles was performed analytically, giving rise to the Bickley–Naylor functions, polar angles of motion out of the plane of the problem need not be specified.

Tracks are traced across each mesh individually and the distance of each track is calculated by determining the intersection of each track with each surface of the mesh, as illustrated in Fig. 46. The optical distance along each track is then calculated as

$$\tau_{k,l,i}^g = \sum_{tr,i}^g s_{k,l,i} \quad (373)$$

where k is a specific track number; l is a specific angle of motion; and i is a specific mesh in the system.

The total length of the line segment across the mesh is calculated as

$$s_{k,l,i} = \frac{\Delta x - x_0}{\cos \varphi_l}, \quad \text{for } \varphi_l < \frac{\pi}{2}$$

$$s_{k,l,i} = \frac{x_0}{\cos \varphi_l}, \quad \text{for } \varphi_l > \frac{\pi}{2} \quad (374)$$

■ **Figure 46**
Streaming rays traced across a mesh at a specific angle

The exiting point of the line segment along the y -axis is calculated as

$$y_{\text{out}} = y_0 + s_{k,l,i} \cdot \sin \varphi_l \quad (375)$$

If $y_{\text{out}} > \Delta y$, then the track exits along the top of the mesh and the track length is re-calculated as

$$s_{k,l,i} = \frac{\Delta y - y_0}{\sin \varphi_l} \quad (376)$$

During the ray tracing, the code keeps track of the surface along which the segment enters and leaves the mesh. These surfaces will be used in the calculation of volume-to-surface and surface-to-surface transmission probabilities.

Rays are traced over each individual mesh at azimuthal angles from 0 to π and neutrons are assumed to flow in both directions along a single segment, thus integration for all azimuthal angles (2π) is not necessary.

The transport matrices, (369), are then calculated as

$$\begin{aligned} T_{i \rightarrow i}^g &= \frac{1}{(\sum_{tr,i}^g V_i)^2} \sum_l \frac{\Delta \varphi}{2\pi} \sum_k dh \cdot \left\{ \sum_{tr,i}^g V_i - \left[\frac{\pi}{4} - Ki_3(\tau_{k,l,i}^g) \right] \right\} \\ T_{i,s \rightarrow i}^g &= \frac{1}{2\sum_{tr,i}^g V_i A_{i,s}} \sum_l \frac{\Delta \varphi_l}{2\pi} \sum_k dh \cdot \left[\frac{\pi}{4} - Ki_3(\tau_{k,l,i}^g) \right] \\ T_{i,s' \rightarrow i,s}^g &= \frac{1}{A_{i,s} A_{i,s'}} \sum_l \frac{\Delta \varphi_l}{2\pi} \sum_k Ki_3(\tau_{k,l,i}^g) \end{aligned} \quad (377)$$

where the surface areas and volumes in (377) are those that are approximated by the ray tracing,

$$\begin{aligned} V_i &= \sum_l \sum_k dh \cdot \frac{\Delta\varphi_l}{2\pi} \cdot s_{k,l,i} \\ A_{i,s} &= \sum_l \sum_k dh \cdot \frac{\Delta\varphi_l}{2\pi} \end{aligned} \quad (378)$$

Note that the surface summations in (377) and (378) include only those tracks, k , that actually intersect the specific surface, whereas the volume summations include all tracks, k , traced at each azimuthal angle, l .

4.3.3 Solution to the Response Matrix Equations

For the coupling calculation, the scalar flux in all groups, all mesh, is initialized to unity prior to the start of the first iteration. All inward directed currents along the boundaries of the problem, in all energy groups, are initialized to $1/4$, from (367). This initialization supplies an initial guess to the solution technique and the iterative algorithm may begin.

Inner Iterations

The inner iterations are used to converge the scalar flux distribution throughout the entire problem domain in a single energy group. The inner iterations will also drive the current along the system boundaries to converge. These are the solutions to (363) and (364).

The scalar flux distribution is considered converged when the following criterion is met within each mesh of the problem:

$$\frac{|\phi_{i,iter}^g - \phi_{i,iter-1}^g|}{\phi_{i,iter}^g} < \varepsilon \quad (379)$$

where ε is the convergence criterion on the scalar flux, which can be loosely set to 10^{-4} .

The outward directed current coming in contact with the boundary of the system is considered converged when the following criterion is met within each mesh along the problem boundary:

$$\frac{|J_{s,i,out,iter}^g - J_{s,i,out,iter-1}^g|}{J_{s,i,out,iter}^g} < \varepsilon \quad (380)$$

where ε is the convergence criterion on the current, which can be loosely set to 10^{-4} . The subscripts in (380) represent only the mesh, and surfaces of those mesh, which lie along the system boundary.

During an inner iteration, the source term of neutrons born into the energy group of interest, g , is constantly being updated using the scalar flux from inner iterations in higher energy groups. In this way the source takes on the appearance

$$q_i^g = \sum_{g' < g} \Sigma_{s,i}^{g' \rightarrow g} \phi_{i,iter}^{g'} + \sum_{g' \geq g} \Sigma_{s,i}^{g' \rightarrow g} \phi_{i,iter-1}^{g'} + \frac{\chi_i^g}{k_\infty} \left[\sum_{g'} \nu \Sigma_{f,i}^{g'} \phi_{i,iter-1}^{g'} \right] \quad (381)$$

where group 1 is the highest energy group of the cross section library. This defines a Gauss–Seidel scheme for the inner iterations.

In lattice physics computations, the fission source can be represented as a production kernel, similar to the way in which the scattering source is represented as a kernel, and the fission source term may be rolled up into the scattering source term as

$$q_i^g = \sum_{g' < g} \Sigma_{s,i}^{g' \rightarrow g} \phi_{i,iter}^{g'} + \sum_{g' \geq g} \Sigma_{s,i}^{g' \rightarrow g} \phi_{i,iter-1}^{g'} + \frac{1}{k^\infty} \sum_{g'} \Sigma_{p,i}^{g' \rightarrow g} \phi_{i,iter-1}^{g'} \quad (382)$$

where the production kernel is defined as

$$\Sigma_{p,i}^{g' \rightarrow g} = \chi_i^g \nu \Sigma_{f,i}^{g'} \quad (383)$$

Outer Iterations

Just as mesh are coupled together via their surface currents, energy groups are coupled together via the scattering and fission sources. The outer iterations are used to converge the source distribution and, hence, the eigenvalue to the problem. The outer iterations redistribute the source neutrons resulting from the updated scalar flux distribution generated during the sweep through the inner iterations. A complete sweep of inner iterations through all energy groups of the problem defines one outer iteration.

The source is considered to be converged when the following criterion is met during two successive iterations,

$$\frac{|k_{iter}^\infty - k_{iter-1}^\infty|}{k_{iter}^\infty} < \varepsilon \quad (384)$$

where ε is the convergence criterion on the eigenvalue, which can be loosely set to 10^{-4} .

During an outer iteration, the fission source distribution is held constant and the scattering distribution is updated continuously using results from the most recent inner iteration.

Fundamental Mode Rebalance

Following completion of an outer iteration, a fundamental mode rebalancing of the group flux distribution is performed in order to properly normalize the flux and ensure neutron conservation. The fundamental mode calculation is performed on an equivalent homogeneous system using flux and volume weighted cross sections from the heterogeneous calculation. The resulting group flux values from the homogeneous calculation are then used to rebalance the magnitude of the heterogeneous group flux values.

The equation to be solved here is equivalent to (360)

$$\phi_{FM}^g = \frac{\bar{q}^g}{\bar{\Sigma}_r^g} \quad (385)$$

where the source term does not include self scattering and the fission source is normalized to unity by the multiplication factor. Hence,

$$\bar{q}^g = \sum_{g' \neq g} \bar{\Sigma}_s^{g' \rightarrow g} \phi_{FM}^{g'} + \frac{\bar{\chi}^g}{k^\infty} \sum_{g'} \nu \bar{\Sigma}_f^{g'} \phi_{FM}^{g'} \quad (386)$$

where the flux and volume weighted cross sections for the fundamental mode calculation are calculated from

$$\bar{\Sigma}_x^g = \frac{\sum_i \Sigma_{x,i}^g \phi_i^g V_i}{\sum_i \phi_i^g V_i} \quad (387)$$

In (387), x represents the desired reaction (e.g., fission, absorption, etc.).

Since there are no neutron leakage effects across the boundaries of the problem (i.e., perfect reflection is assumed along all boundaries), the multiplication factor in (387) can be calculated directly as the ratio of neutron production in the system to neutron destruction

$$k^\infty = \frac{\sum_{g'} \nu \bar{\Sigma}_f^{g'} \phi_{\text{FM}}^{g'}}{\sum_{g'} \bar{\Sigma}_a^{g'} \phi_{\text{FM}}^{g'}} \quad (388)$$

If we normalize the flux in such a way that there is only one neutron being absorbed in the entire problem, then the denominator to (388) becomes unity and the multiplication factor is simply the sum of all neutrons born through fission

$$k^\infty = \sum_{g'} \nu \bar{\Sigma}_f^{g'} \phi_{\text{FM}}^{g'} \quad (389)$$

Plugging (389) into (386) yields the final expression for the fundamental mode homogeneous source

$$\bar{q}^g = \sum_{g'} \bar{\Sigma}_s^{g' \rightarrow g} \phi_{\text{FM}}^{g'} + \bar{\chi}^g \quad (390)$$

Due to up-scattering in the thermal energy groups, the solution to (385) defines an iterative process and the fundamental mode equation is solved directly with no acceleration. Following the solution to (385), the scalar flux distribution from the solution to (363) is scaled using the solution from the fundamental mode calculation

$$\hat{\phi}_{i,iter}^g = \phi_{i,iter}^g \cdot \frac{\phi_{\text{FM}}^g}{\sum_i \phi_{i,iter}^g V_i} \quad (391)$$

4.3.4 Geometry of the Coupling Calculation

The coupling calculation takes the true geometry of the lattice and homogenizes all non-rectangular regions into an equivalent rectangular geometry and an equivalent set of material cross sections. Homogenization of the material sets is done using a straightforward flux and volume weighting of the heterogeneous material sets. The flux used in the homogenization process is obtained from the pin-cell spectral calculations. If there exists no flux from the pin-cell spectral calculations for regions that are to be homogenized, then the homogenization is done in a straightforward volume weighting process.

For a typical LWR lattice, all pin cells are homogenized into a single equivalent material set

$$\bar{\Sigma}_{x,I}^g = \frac{\sum_{i \in I} \Sigma_{x,i}^g \phi_i^g V_i}{\sum_{i \in I} \phi_i^g V_i} \quad (392)$$

where i represents a region of the pin cell (fuel, clad, and coolant), and I represents the homogenized square.

For the inner regions of the fuel bundle, most cells take part in the pin-cell spectral calculations and, therefore, there exist flux spectrums for each of the various regions of the cell. In rare circumstances, there may not exist a flux spectrum for the various regions of a cell. In such cases, the materials are volume weighted into a single homogeneous set

$$\bar{\Sigma}_{x,I}^g = \frac{\sum_{i \in I} \Sigma_{x,i}^g V_i}{\sum_{i \in I} V_i} \quad (393)$$

For BWR lattices, (393) is also used to homogenize the inner water gap, along the inside wall of the channel, with the channel wall itself. For absorber pins of a cruciform control blade, fluxes can be obtained from a special series of pin-cell spectral calculations performed on each absorber tube and (392) can be used to homogenize all absorber tubes into a single homogeneous material set. The final geometry of the coupling calculation appears as in  Fig. 47, where the red mesh lines represent the geometry of the coupling calculation.

For regions containing strong absorbers, such as control blades, control rods, burnable absorber pins, or fuel pins containing Gadolinium or Erbium, the homogenized cross sections will grossly overestimate the actual absorption rate in the heterogeneous cell. One way of accounting for this is to calculate correction factors for the homogenized material. The correction factors are determined by performing one additional pin-cell calculation on the absorber cell that uses the homogenized cross sections in all regions of the cell – fuel, clad, and coolant.

 Figure 47

Typical geometry of coupling calculation

The cross sections for the buffer zone are the same as those used in the heterogeneous pin-cell calculation.

The reaction rate in the homogenized cell is then compared against the averaged reaction rate in the combined regions of the heterogeneous cell. Correction factors are determined that, when applied to the homogenized cross sections, produce equivalent reaction rates in the homogenized cell. This involves an iterative process, where the correction factors are estimated using the results from the first homogenized pin-cell analysis,

$$R^g = \frac{\sum_i \Sigma_{tr,i}^g \phi_i^g V_i}{\overline{\Sigma_{tr}^g} \bar{V}} \quad (394)$$

The new homogenized cross sections are estimated to be $\overline{\Sigma_{x,\text{new}}^g} = R^g \cdot \overline{\Sigma_{x,\text{old}}^g}$. Using these new homogenized cross sections, the homogenized pin-cell calculation is re-performed. This process continues until the reaction rates using the homogenized cross sections match those from the heterogeneous pin cell. Note that there is a unique correction factor for each energy group.

For normal fuel pins, the correction factors will be unity or close enough to unity that no correction needs to be applied to the homogenized cross section set. For strong absorber pins, such as fuel pins containing Gadolinium, the correction factors will be far from unity in the thermal energy groups. They will be close to unity above the thermal energy cut-off of 0.625 eV.

Use of the correction factors will produce a slightly better condensation spectrum, depending on the number of strong absorber pins present in the fuel assembly. For problems containing a cruciform control blade, the use of correction factors is almost a necessity in order to obtain meaningful results.

Once the homogenized materials have been constructed, the material layout has been assigned, and the transmission matrices have been calculated, the code can proceed to solve for the flux and current in each mesh by the use of a red–black iteration scheme. The layout for this scheme is illustrated in  Fig. 48, where each mesh is assigned either a “red” or “black” declaration. Here, the flux and outward directed currents for all red mesh are solved first. The inward currents to all black mesh are set equal to the newly calculated outward currents from the corresponding red mesh. The flux and outward directed currents for all black mesh are then solved. The inward currents to all red mesh are then set equal to the outward currents from the corresponding black mesh. And so on and so forth. An inner iteration is complete when the outward currents and mesh fluxes have converged for a given source distribution in a given energy group.

4.4 Cross Section Condensation

The energy distribution of neutrons from the series of one-dimensional pin-cell calculations are updated with the flux spectra from the two-dimensional response matrix calculation

$$\tilde{\phi}_i^g = \phi_i^g \cdot \frac{\phi_I^g V_I}{\sum_{i \in I} \phi_i^g V_i} \quad (395)$$

■ **Figure 48**
Red–black iteration scheme

where i represents a region of the pin cell (fuel, clad, and coolant), and I represents the homogenized rectangle from the coupling calculation.

Fluxes for the surrounding regions of the lattice – channel box wall, water gaps, etc. – are obtained directly from the response matrix solution. Fluxes for the absorber tubes of a control blade are obtained from the special series of pin-cell calculations performed on each absorber tube and updated with the flux from the response matrix solution. Equation (395) represents the flux for each material region of the problem that will be used to condense the macroscopic cross sections. The final energy group structure for the fine-mesh transport calculation depends on the accuracy of the condensation scheme, the energy group boundaries in the original cross section library, and the types of problems to be analyzed by the lattice physics code. The broad-group cross sections are created using the following expression:

$$\Sigma_{x,i}^G = \frac{\sum_{g \in G} \Sigma_{x,i}^g \tilde{\phi}_i^g}{\sum_{g \in G} \tilde{\phi}_i^g} \quad (396)$$

where g represents the fine-group energy structure of the cross section library, and G represents the broad-group energy structure of the condensed cross sections. The summations in (396) are performed for all fine-groups within a broad-group.

The primary assumptions used in the derivation of the response matrix method are as follows: the scalar flux is flat across each mesh; the angular flux is distributed isotropically across the surface of each mesh; and the angular flux is spatially constant along the surface of each mesh. For normal fuel cells and water regions, these assumptions are not entirely bad. In fact,

when grouped together for such situations, the errors associated with each assumption tend to balance and one is left with a surprisingly better-than-expected solution to the transport equation. For strongly absorbing, relatively thin regions, though, the angular flux emerging from a mesh is highly anisotropic. This is most noticeable in mesh used to model the presence of the cruciform control blade. Under such conditions, neutrons that strike the blade surface head-on, have a much greater chance of streaming across the blade without interacting than do neutrons that strike the blade surface at a steep angle. The assumption of an isotropic current, however, tends to suppress the transmission probability of the neutrons that strike the blade head-on. This results in an excess of absorptions taking place in the black regions of the model, including Gadolinium pins. The increased strength of the control blade will tend to cause the flux to be pushed away from the control blade corner of the problem, across the lattice to the corner where the detector resides. The increased strength of Gadolinium pins will tend to push neutrons away from Gd pins, to pins along the edge of the bundle.

4.5 Sundries

Due to the limitations mentioned above, there is a lower limit to the number of energy groups that must be maintained for the broad-group, fine-mesh transport calculation in order to preserve the accuracy of the fine-group library structure. It is up to the developer to determine the appropriate energy boundaries for the broad-group cross section set.

The most direct way of determining the broad-group energy structure is via trial and error. To do this, the lattice physics code must be developed in such a way as to ensure that the fine-mesh transport calculation is capable of providing a solution in the energy group structure of the cross section library. This provides the code with the ability to generate a reference solution for any condensed group structure. Once a fine-group reference solution exists, groups can be combined to determine which boundaries are necessary for the broad-group solution and which groups can be combined. In general, the more energy groups that exist in the fine-group cross section library, the more groups are needed in the broad-group structure to maintain a desired accuracy.

The energy boundaries required for a desired accuracy will depend on the problem being analyzed and the materials present in the bundle design. Fuel designs containing Gadolinium as an absorber require more thermal energy groups for a desired accuracy than do fuel designs containing, say, Erbium or Boron as an absorber. Fuel designs containing a cruciform control blade require more fast energy groups for a desired accuracy than do fuel designs, which contain pin-sized control fingers inserted directly into the assembly. Fuel designs containing mixed-oxide fuel require more thermal and epithermal energy groups for a desired accuracy than do fuel designs containing, say, uranium-oxide fuel.

In general, it is perfectly acceptable to determine unique broad-group energy structures for different types of problems, so long as the lattice physics code is capable of accurately determining the type of problem being analyzed. Alternatively, the lattice physics code may contain a single broad-group energy structure that is applicable to all problems. This single group structure will likely contain more detail than needed for most problems being analyzed, but will remove the chance that the code will accidentally use the wrong group structure on a certain type of problem.

5 Fine-Mesh Assembly Calculation

5.1 Introduction

Once the cross sections have been condensed to the broad-group structure (if, indeed, there exists a cross section condensation scheme to the specific lattice physics code), we are ready to perform the fine-mesh, two-dimensional heterogeneous transport calculation on the entire lattice. Since we are interested in modeling the lattice in its exact geometry, we are limited to techniques that solve the integral form of the transport equation. Due to the overwhelming benefits associated with the method of characteristics (MoC), as discussed in [Sect. 1](#), we will dedicate this section to developing that method and not discuss other alternatives any further.

Unless otherwise indicated, the content of this section is based on unpublished lectures given to postgraduate students in a course on computational reactor analysis at The Pennsylvania State University in 1990 (Knott 1990). The interested reader is directed to the original paper by Askew (Askew 1972), or the follow-up paper by Halsall (Halsall 1980), for a brief introduction to the MoC. Similar information can be found in Knott (1991), Knott and Edenius (1993), Goldgerg et al. (1995), Cho and Hong (1996), Roy (1998), Postma and Vujic (1999), Kosaka and Saji (2000), Kim et al. (2002), Jevremovic et al. (2002). This section presents a much broader description of the method of characteristics than is found in any of the references.

5.2 General Theory of the Method of Characteristics

5.2.1 Introduction

The characteristics form of the steady state Boltzmann transport equation is derived from the integrodifferential form of the equation

$$\frac{1}{|v|} \frac{\partial \Phi(\vec{r}, E, \hat{\Omega}, t)}{\partial t} = Q(\vec{r}, E, \hat{\Omega}, t) - \Omega \cdot \nabla \Phi(\vec{r}, E, \hat{\Omega}, t) - \Sigma_t(\vec{r}, E) \Phi(\vec{r}, E, \hat{\Omega}, t) \quad (397)$$

Which, after rearranging for steady state applications, becomes

$$\Omega \cdot \nabla \Phi(\vec{r}, E, \hat{\Omega}) - \Sigma_t(\vec{r}, E) \Phi(\vec{r}, E, \hat{\Omega}) = Q(\vec{r}, E, \hat{\Omega}) \quad (398)$$

where the source term, $Q(\vec{r}, E, \hat{\Omega})$, is the total angular source of neutrons at location \vec{r} , with energy E , traveling in direction $\hat{\Omega}$, and is expressed as

$$Q(\vec{r}, E, \hat{\Omega}) = \iiint \Sigma_s(\vec{r}, E' \rightarrow E, \hat{\Omega}' \rightarrow \hat{\Omega}) \Phi(\vec{r}, E', \hat{\Omega}') dE' d\hat{\Omega}' + S(\vec{r}, E, \hat{\Omega}) \quad (399)$$

In the above expressions, $\Phi(\vec{r}, E, \hat{\Omega})$ is the angular flux, $\Sigma_t(\vec{r}, E)$ is the total macroscopic cross section, and $\Sigma_s(\vec{r}, E' \rightarrow E, \hat{\Omega}' \rightarrow \hat{\Omega})$ is the macroscopic scattering cross section. $S(\vec{r}, E, \hat{\Omega})$ is the angular source of neutrons at location \vec{r} , either internal (i.e., due to fission) or external.

[Equation \(398\)](#) describes neutron motion as viewed from a fixed reference point, giving rise to the partial derivative in the streaming term. If neutron motion is viewed from the neutron's

frame of reference, the partial derivative in the streaming term reduces to a total derivative along the path of motion of the neutron and (398) becomes

$$\frac{d\Phi(\vec{r}, E, \hat{\Omega})}{ds} + \Sigma_t(\vec{r}, E)\Phi(\vec{r}, E, \hat{\Omega}) = Q(\vec{r}, E, \hat{\Omega}) \quad (400)$$

where s is the track along which the neutron is traveling across the region at location \vec{r} (i.e., the location relative to the fixed reference point).

Equation (400) is the characteristics form of the transport equation and describes neutron motion as viewed through the eyes of the neutron – if, indeed, neutrons do have eyes.

5.2.2 Solution to the Characteristics Form of the Transport Equation

At this point in our derivation of the MoC, we will focus exclusively on one-dimensional slab problems. A little later in this section, we will move into one-dimensional cylindrical geometry, which is a prelude to moving into two-dimensional geometries for orthogonal systems. We choose to start with one-dimensional slab geometry because many of the most important features of the method of characteristics can be described easily for such a system. We will use slab geometry to introduce all features of the MoC, including simple quadrature sets, flat source regions, a simple iteration scheme, and a simple acceleration technique. Once we get into two-dimensional geometry, we will describe the more complicated features used in modern lattice physics codes.

To make things as simple as possible, we will assume that all scattering and all sources (fission and fixed) are isotropic. That is, there are no preferred angles of emission. Anisotropic effects can easily be represented using transport-corrected cross sections, which were briefly alluded to in [Sect. 1](#).

For an isotropic scalar source of total strength q , the isotropic angular source in each direction of travel will be $Q = q/4\pi$ and the transport equation becomes

$$\frac{d\Phi}{ds} + \Sigma_{tr}\Phi = \frac{q}{4\pi} \quad (401)$$

where Σ_{tr} is the transport cross section and the arguments associated with each variable have been dropped to simplify the equation. Equation (401) has the solution

$$\Phi(s) = \Phi(0)e^{-\Sigma_{tr}s} + \frac{q}{4\pi\Sigma_{tr}}(1 - e^{-\Sigma_{tr}s}) \quad (402)$$

where s is the characteristic along which the neutron is traveling and $s=0$ is the location of the neutron at time $t=0$, as illustrated in [Fig. 49](#).

Equation (402) is only applicable if we can assume that the source of neutrons inside the region of interest is constant. In such cases, the scalar flux will also be constant and we can solve directly for the value of the angular flux exiting the mesh, based on the value of the angular flux entering the mesh,

$$\Phi_{\text{out}} = \Phi_{\text{in}}e^{-\Sigma_{tr}t/\cos\varphi} + \frac{q}{4\pi\Sigma_{tr}}(1 - e^{-\Sigma_{tr}t/\cos\varphi}) \quad (403)$$

Figure 49

Coordinate system for the characteristics equation

Figure 50

Angular flux across a region of constant material properties

The variables in (403) are illustrated in [Fig. 50](#).

The average value of the angular flux, $\bar{\Phi}$, along any track segment is calculated by integrating the value of the angular flux along the entire length of the track segment and dividing by the length of the segment,

$$\bar{\Phi} = \frac{\int_0^{t/\cos\varphi} \Phi(s) ds}{\int_0^{t/\cos\varphi} ds} = \frac{\int_0^{t/\cos\varphi} \left\{ \Phi(0)e^{-\Sigma s} + \frac{q}{4\pi\Sigma}(1 - e^{-\Sigma s}) \right\} ds}{t/\cos\varphi} \quad (404)$$

After carrying out the integration in the numerator of (404), we are left with the following expression for the average value of the angular flux along a track segment

$$\bar{\Phi} = \frac{\frac{1}{\Sigma} \left\{ \Phi(0) - \Phi(0)e^{-\Sigma t/\cos\varphi} + \frac{qt}{4\pi\cos\varphi} - \frac{q}{4\pi\Sigma}(1 - e^{-\Sigma t/\cos\varphi}) \right\}}{t/\cos\varphi} \quad (405)$$

Combining the second and fourth terms in the numerator, we can express the average value of the angular flux along a track segment in a more compact form

$$\bar{\Phi} = \frac{q}{4\pi\Sigma} + \frac{\Phi(0) - \Phi(t)}{\Sigma t/\cos\varphi} = \frac{q}{4\pi\Sigma} + \frac{\Delta}{\Sigma t'} \quad (406)$$

Figure 51
Angular flux across multiple regions

where $\Delta = \Phi(0) - \Phi(t)$ is the change in the angular flux along the track segment; and $t' = t / \cos \varphi$ is the true length of the segment in the xy -plane of the problem across the mesh. Note that the average angular flux in (406) is the value along a specific track segment, across a specific mesh, at a specific angle, in a specific energy group. There will be many such values crossing each slab at different angles, in different energy groups.

If we have multiple slabs, the angular flux exiting each successive slab can be calculated as

$$\begin{aligned} \Phi(t_1) &= \Phi(0)e^{-\Sigma_1 t'_1} + \frac{q_1}{4\pi\Sigma_1}(1 - e^{-\Sigma_1 t'_1}) \\ \Phi(t_2) &= \Phi(t_1)e^{-\Sigma_2 t'_2} + \frac{q_2}{4\pi\Sigma_2}(1 - e^{-\Sigma_2 t'_2}) \\ \Phi(t_3) &= \Phi(t_2)e^{-\Sigma_3 t'_3} + \frac{q_3}{4\pi\Sigma_3}(1 - e^{-\Sigma_3 t'_3}) \\ \Phi(t_n) &= \Phi(t_{n-1})e^{-\Sigma_n t'_n} + \frac{q_n}{4\pi\Sigma_n}(1 - e^{-\Sigma_n t'_n}) \end{aligned} \quad (407)$$

where the calculation of the angular flux exiting one slab is a cascading effect into the next slab, as illustrated in Fig. 51. Note that the energy dependence has been omitted from (407) and that the parameter Σ is understood to represent the transport-corrected total cross section of each material region.

If we apply this principle to a number of different directions, L , then the scalar flux in each slab can be calculated from the average angular flux across each slab at each of the different angles,

$$\phi_n^g = \int_{\hat{\Omega}} \overline{\Phi}_n^g(\hat{\Omega}) d\hat{\Omega} = \sum_i \overline{\Phi}_n^g(\varphi_i) \cdot \Delta\varphi_i \quad (408)$$

where $\Delta\varphi_i$ is the solid angle subtended by the direction φ_i (i.e., the weight associated with direction φ_i), and is illustrated in Fig. 52.

Figure 52

Weight associated with angular direction

Equation (408) can be rewritten as

$$\phi_n^g = \sum_m \bar{\Phi}_{m,n}^g \omega_m = \sum_m \left(\frac{q_n^g}{4\pi \Sigma_{tr,n}^g} + \frac{\Delta_{m,n}^g}{\Sigma_{tr,n}^g t'_{m,n}} \right) \omega_m \quad (409)$$

where $\sum_m \omega_m = 4\pi$, noting that the directions cover polar angles out of the xy -plane of the problem as well as azimuthal angles in the xy -plane of the problem.

For our isotropic source and transport-corrected cross sections

$$\sum_m \frac{q_n^g}{4\pi \Sigma_{tr,n}^g} \omega_m = \frac{q_n^g}{\Sigma_{tr,n}^g} \quad (410)$$

and we arrive at our final expression for the scalar flux in each slab

$$\phi_n^g = \frac{q_n^g}{\Sigma_{tr,n}^g} + \frac{1}{\Sigma_{tr,n}^g} \sum_m \frac{\Delta_{m,n}^g}{t'_{m,n}} \cdot \omega_m \quad (411)$$

The flux in (411) is assumed to be a constant value within a given mesh (i.e., the flat flux approximation).

5.3 Quadrature Sets

5.3.1 Introduction

The $d\hat{\Omega}$ in (408) represents the weight associated with each particular direction, $\hat{\Omega}$, which together make up the quadrature set. Here it should be pointed out that neutrons always travel in three dimensions. The problem being studied may be a one- or two-dimensional problem, but

■ **Figure 53**
Coordinates describing the direction of motion of a neutron

neutrons are always moving in all directions. The only detail that separates a one-dimensional problem from a two-dimensional or three-dimensional problem is the fact that there are material boundaries along only one axis of the coordinate system – the material regions all stretching to infinity along the remaining axes. Neutrons, however, are traveling at every imaginable angle to the one finite dimension. Therefore, we must model neutron motion in all three dimensions regardless of the dimensionality of the problem.

The direction of a neutron may be described using an azimuthal angle, φ , and a polar angle, θ . For all of our discussions, the azimuthal angle is measured from the positive x direction in the xy -plane of the problem. The polar angle is measured down from the positive z -direction, as illustrated in [► Fig. 53](#).

To model neutron transport, we need to trace streaming paths (i.e., characteristics) across the system in a number of directions. We then solve for $\bar{\Phi}_n^g(\hat{\Omega}_m)$ along each characteristic, across each slab, n , in each direction, $\hat{\Omega}_m$, using (406), and calculate ϕ_n^g using (411). This is done best by choosing a set of azimuthal angles and a set of polar angles, which together will determine each unique direction of motion, as illustrated by the quadrature ball contained in [► Fig. 54](#).

5.3.2 Azimuthal Angles

For lattice physics calculations, the azimuthal angles in the characteristics method are evenly spaced in the xy -plane of the problem. If we wish to model four azimuthal directions of motion, say, we would split the directions up evenly in the xy -plane such that the *boundaries* of motion occur at intervals calculated from the following expression:

$$\Delta\varphi = \frac{2\pi}{I} = \frac{2\pi}{4} = \frac{\pi}{2} \quad (412)$$

In this way, the azimuthal *boundaries* are located at angles: $\varphi_0 = 0$, $\varphi_1 = \pi/2$, $\varphi_2 = \pi$, $\varphi_3 = 3\pi/2$, and $\varphi_4 = 2\pi (= 0)$. The azimuthal *direction of motion* takes place through the center of two neighboring *boundaries*,

$$\bar{\varphi}_i = \frac{1}{2}(\varphi_{i-1} + \varphi_i) \quad (413)$$

■ Figure 54
Typical quadrature ball

■ Figure 55
Azimuthal boundaries and angles of motion for $l = 4$

Each azimuthal direction of motion represents neutrons that travel at all angles in between the two surrounding azimuthal boundaries, as illustrated in [Fig. 55](#). The neutrons that are modeled as traveling along the $\bar{\varphi}_1 = \pi/4$ characteristic, for instance, actually represent all neutrons traveling at angles between $\varphi_0 = 0$ and $\varphi_1 = \pi/2$. The neutrons that are modeled as traveling along the $\bar{\varphi}_2 = 3\pi/4$ characteristic represent all neutrons traveling at angles between $\varphi_1 = \pi/2$ and $\varphi_2 = \pi$. And so on, and so forth.

The weight associated with each azimuthal direction of motion is then given by

$$\omega_i = \frac{2\pi}{I} \quad (414)$$

where I is the total number of azimuthal directions of motion in the quadrature set.

5.3.3 Polar Angles

Choosing polar directions of motion is somewhat more complicated than choosing azimuthal directions of motion and is open to one of several different methods. We will discuss a couple of very simple methods and then make mention of the more complicated, more accurate methods, that are used in most lattice physics codes. The two methods to be discussed in this section are those associated with *equal weights* and *equal angles*.

Equal Weights Quadrature Set

To generate an *equal weights* quadrature set, we choose polar directions of motion that will result in all directions having equal polar weights (and, hence, equal weights in all directions of motion). The weights associated with each direction are calculated from the differential area on a unit sphere subtended by all boundaries for a given direction of motion, such as that illustrated in [► Fig. 54](#). To calculate *equal weights* for all directions of motion, we proceed in the following manner: The differential area on a unit sphere associated with each direction, $\hat{\Omega}_m$, is given by

$$dA = \hat{\Omega}_m^2 \sin \bar{\theta}_m d\theta d\varphi \quad (415)$$

where the variables are defined in [► Fig. 56](#). For a unit sphere, $|\hat{\Omega}| = 1$, and (415) can be expressed as

$$dA = \sin \bar{\theta}_m \cdot d\theta \cdot d\varphi \quad (416)$$

■ Figure 56
Differential surface area on a unit sphere

The total area associated with each direction, $\hat{\Omega}_m$, subtended on the unit sphere is then calculated as

$$A = \int_{\theta_{j-1}}^{\theta_j} \int_{\phi_{i-1}}^{\phi_i} dA = \int_{\theta_{j-1}}^{\theta_j} \int_{\phi_{i-1}}^{\phi_i} \sin \bar{\theta} \cdot d\theta \cdot d\phi = (\phi_i - \phi_{i-1})(\cos \theta_{j-1} - \cos \theta_j) \quad (417)$$

Since the spacing between azimuthal angles is $\Delta\varphi = \varphi_i - \varphi_{i-1}$, equal areas on the unit sphere require

$$A = \frac{4\pi}{I \cdot J} \quad (418)$$

where I is the total number of azimuthal angles, and J is the total number of polar angles. Rearranging (417) and setting it equal to (418) yields

$$(\cos \theta_{j-1} - \cos \theta_j) = \frac{4\pi}{I \cdot J \cdot \Delta\varphi} \quad (419)$$

From (412), $\Delta\varphi = 2\pi/I$ so the boundaries to the polar directions can be expressed as

$$\theta_j = \cos^{-1} \left\{ \cos \theta_{j-1} - \frac{2}{J} \right\} \quad (420)$$

where $\theta_0 = 0$.

We would like the polar direction of motion to pass through the centroid of the surface area subtended by the polar boundaries. Therefore, the polar directions of motion are calculated as

$$\bar{\theta}_j = \cos^{-1} \left\{ \frac{1}{2} (\cos \theta_j + \cos \theta_{j-1}) \right\} \quad (421)$$

The corresponding polar weights associated with the polar directions are the differential areas on the surface of the unit sphere created by the polar boundaries

$$\omega_j = \cos \theta_j - \cos \theta_{j-1} \quad (422)$$

Equal Angles Quadrature Set

For the *equal angles* quadrature set, we run through exactly the same scenario as we went through to generate the *equal weights* quadrature set. For the *equal angles* quadrature set, we are interested in distributing the angles uniformly in the polar direction, just as we have done with the azimuthal angles in the xy -plane of the problem. Without actually showing the mathematics associated with the derivation, the *equal angles* requirement leads us to make the following choices for the polar boundaries, polar directions of motion, and associated weights, respectively,

$$\Delta\theta = \frac{\pi}{J} \quad (423)$$

$$\bar{\theta}_j = \cos^{-1} \left\{ \frac{1}{2} (\cos \theta_j + \cos \theta_{j-1}) \right\} \quad (424)$$

$$\omega_j = \cos \theta_j - \cos \theta_{j-1} \quad (425)$$

where the polar boundaries are distributed from $\theta_0 = 0$ to $\theta_j = \pi$. Note that, in the *equal weights* quadrature set, only the distribution of polar *boundaries* is different from that in the *equal areas* distribution. The equations used to calculate the angles of motion and associated weights are the same for the *equal angles* quadrature as they are for the *equal weights* quadrature.

This section has described the generation of two slightly different quadrature sets – *equal weights* and *equal angles*. Both of these quadrature sets are perfectly acceptable for use with the method of characteristics. Different quadrature sets will require a different number of polar angles to obtain the same accuracy. That is, the *equal weights* quadrature set places more emphasis on neutrons that stream at angles close to the plane of the problem. In contrast, the *equal angles* quadrature set places the same emphasis on neutrons streaming in any direction out of the plane of the problem. The *equal angles* quadrature set is preferable for three-dimensional transport problems because it distributes the angles symmetrically in all directions, similar to the way in which our azimuthal directions are distributed symmetrically in the *xy*-plane of the problem. The *equal weights* quadrature set is preferable for one- and two-dimensional problems because angles are weighted toward the plane of motion.

For one- and two-dimensional problems, better distributions of angles are generated using Legendre and Gaussian quadratures. These quadrature sets will be discussed later in this section, once we reach the subject of two-dimensional applications. For now, we can say that the MoC problem reduces to tracing characteristics across the system at several angles, along each of which we will solve the transport equation. For the cases being described presently, we will focus solely on systems where all sources are isotropic and all cross sections have been transport-corrected such that scattering can be treated mathematically as being isotropic.

5.4 Geometry Routine

5.4.1 Introduction

The first step we take in writing a computer code to solve the characteristics form of the transport equation is to lay down the streaming paths along which our neutrons will travel. In order to do this, we must first assign material IDs to each region of the problem and then subdivide each material region into a suitable number of mesh that represent the flat source regions. This is illustrated in [▶ Fig. 57](#).

In an arrangement such as this, we might hold data in arrays structured by both mesh and region. That is, the array that holds the scalar flux in each mesh of the problem, say, might be structured as flux (mesh, region). Alternatively, mesh could be numbered sequentially beginning from the left side of the problem and moving to the right. This approach is depicted in

Figure 57
Example of flat source mesh and material numbers

■ Figure 58

Alternative example of flat source mesh and material numbers

► Fig. 58. The scalar flux in each mesh would be held in an array such as `flux (mesh)`. Then we would need another array, `material (mesh)`, which defined the material for each mesh. Either approach is acceptable. At one time, when memory was scarce, we would choose the most economical approach, that is, the one that used the least amount of memory. Nowadays, though, memory is plentiful and it is more important to choose the most intuitive approach, that is, the one that provides the most clarity to the programmer and especially to subsequent programmers who need to decipher the original programmer's work.

To begin our application of the MoC, we first lay down the paths in the azimuthal direction only (i.e., in the xy -plane of the problem). Once we calculate all the t 's in (411) – through all mesh of the system, at all azimuthal angles of motion – we can ratio each of the path lengths with the sine of the various polar angles to obtain the true track length at each of the directions of motion, $\hat{\Omega}_m$.

So, we have some system of slabs (i.e., mesh) with boundaries at $\{x_0, x_1, x_2, \dots, x_N\}$, where N is the total number of slabs in the problem. In each of these regions we have a set of constant cross sections and, possibly, an external source that is also spatially constant across the slab region.

Now we choose the number of azimuthal angles and polar angles at which we would like to solve the transport equation. Let I be the total number of azimuthal angles we choose and let J be the total number of polar angles we choose. We calculate the azimuthal boundaries, $\bar{\varphi}_i$'s, to the quadrature set using (412), and we calculate the azimuthal directions of motion, $\bar{\varphi}_i$'s, using (413). The weights associated with each azimuthal direction of motion, ω_i 's, are calculated using (414).

5.4.2 Neutron Streaming and Symmetry in Slab Geometry

There are a couple of points that can be made here regarding neutron motion in the xy -plane of the problem and out of the xy -plane of the problem.

To begin with, when we lay down tracks for the neutrons to stream along, we lay them down such that each track has a counter-track in the opposite direction. This is a requirement in order to model perfectly reflecting (i.e., mirror symmetric) boundary conditions. For instance, if we choose to lay four tracks down in the azimuthal direction, we have tracks at $\bar{\varphi}_1 = \pi/4$, $\bar{\varphi}_2 = 3\pi/4$, $\bar{\varphi}_3 = 5\pi/4$, and $\bar{\varphi}_4 = 7\pi/4$. The $\bar{\varphi}_3 = 5\pi/4$ track is in the opposite direction to the $\bar{\varphi}_1 = \pi/4$ track, and the $\bar{\varphi}_4 = 7\pi/4$ track is in the opposite direction to the $\bar{\varphi}_2 = 3\pi/4$ track. Since neutrons are indifferent to the direction at which they stream along a given track, we may – if we so desire – lay down tracks only between $0 \leq \bar{\varphi} \leq \pi$ in the problem and allow neutrons to travel in both directions along each track. This will help simplify our ray-tracing routine.

Figure 59
Neutrons moving at equivalent azimuthal angles

Secondly, in a one-dimensional problem such as a slab problem, neutrons travel at azimuthal angles between $0 \leq \bar{\varphi} \leq \pi$ in an identical fashion to the way in which they travel at azimuthal angles between $\pi \leq \bar{\varphi} \leq 2\pi$, as illustrated in [Fig. 59](#).

We may take advantage of these observations within our geometry routine, if we care to, by only having to trace tracks over our slab system at azimuthal angles between $0 \leq \bar{\varphi} \leq \pi$. If we choose to do this, we must compensate for the neglected directions by modifying our azimuthal weights, to wit,

$$\omega_i = 2 \times \frac{2\pi}{I} = \frac{4\pi}{I} \tag{426}$$

where I still represents the number of azimuthal directions of motion distributed between $0 \leq \bar{\varphi} \leq 2\pi$.

Lastly, in one- and two-dimensional geometries, neutrons travel at polar angles between $0 \leq \bar{\theta} \leq \pi/2$ in an identical fashion to the way in which they travel at polar angles between $\pi/2 \leq \bar{\theta} \leq \pi$. We may take advantage of this point in a manner similar to the azimuthal symmetry condition described for slab geometry. That is, we can trace tracks in the upper hemisphere of the problem, only, and modify the polar weights to account for symmetry in the lower hemisphere of the problem

$$\omega_j = 2(\cos \theta_j + \cos \theta_{j-1}) \tag{427}$$

where J now represents the total number of polar directions between $0 \leq \bar{\theta} \leq \pi/2$.

5.4.3 Ray Tracing in Slab Geometry

We now have a set of azimuthal angles, $\{\bar{\varphi}_1, \bar{\varphi}_2, \bar{\varphi}_3, \dots, \bar{\varphi}_I\}$, which are distributed between $0 \leq \bar{\varphi} \leq 2\pi$ (although we will only trace rays between $0 \leq \bar{\varphi} \leq \pi$), and associated weights, $\{\omega_1, \omega_2, \omega_3, \dots, \omega_I\}$, which are all equal and sum to 2π . We know, from the problem definition, the widths of all N slabs in the system, $\{\Delta x_1, \Delta x_2, \Delta x_3, \dots, \Delta x_N\}$. We may determine the track lengths through each slab, at each azimuthal angle, in the xy -plane of the problem,

$$t_{i,n} = \frac{\Delta x_n}{\cos \bar{\varphi}_i} \tag{428}$$

where each direction carries with it a weight of ω_i .

Once we have all the track lengths traced through all the slabs at all the desired azimuthal angles, and we have a weight associated with each of the azimuthal directions of motion, we can generate the polar angles of neutron motion, which will complete our quadrature set. Once again, as with the generation of the azimuthal angles, we take advantage of the symmetry of the problem and generate angles only between $0 \leq \bar{\theta} \leq \pi/2$. Each direction represents neutrons moving in both the upper and lower hemispheres of the problem. We generate our set of polar angles, $\{\bar{\theta}_1, \bar{\theta}_2, \bar{\theta}_3, \dots, \bar{\theta}_J\}$, and associated weights, $\{\omega_1, \omega_2, \omega_3, \dots, \omega_J\}$, based on either the *equal weights or equal angles* equations – or perhaps from a Legendre or Gaussian quadrature. The polar weights sum to 2.

With our polar angles of motion, we can ratio the track lengths from the plane of the problem into the upper hemisphere

$$t_{i,j,n} = \frac{t_{i,n}}{\sin \bar{\theta}_j} \quad (429)$$

We now have our quadrature set and our track lengths, which have been measured in the xy -plane of the problem and ratioed to their proper lengths in the polar direction. Now we can begin to solve the transport equation for the flux distribution.

5.5 Solution to the Characteristics Equation

5.5.1 Introduction

We have, really, only one equation to solve, namely,

$$\Phi_{\text{out}} = \Phi_{\text{in}} e^{-\Sigma_{tr} t} + \frac{q}{4\pi\Sigma_{tr}} (1 - e^{-\Sigma_{tr} t}) \quad (430)$$

which is to be solved using the assumptions mentioned before and restated below:

1. All scattering is transport corrected and can be modeled as isotropic
2. All sources are inherently isotropic
3. The source and, hence, scalar flux is constant within a mesh (i.e., flat flux approximation).

Equation (430) represents two physical processes: $\Phi_{\text{in}} e^{-\Sigma_{tr} t}$ are the number of neutrons that stream across the mesh without suffering a collision; and $q \cdot (1 - e^{-\Sigma_{tr} t}) / 4\pi\Sigma_{tr}$ are the number of neutrons that are picked up along the track from scatterings and sources as the track crosses the mesh. Together, these two processes determine the number of neutrons that reach the end of the track on the other side of the mesh.

Equation (430) is very simple to solve. For any problem we analyze, we will always know the cross sections beforehand. These will be the cross sections that are created from the energy condensation scheme (i.e., if one exists for the lattice physics code). In our geometry routine, we have already calculated the ratioed track lengths crossing every mesh, $t_{i,j,n}$. All we need to know in order to solve (430) is the angular flux entering the mesh at the beginning of the track, and the total source term within the mesh – Φ_{in} and q , respectively.

5.5.2 Initialization of the Flux

The need to know Φ_{in} and q brings us to the flux initialization. For lack of a better choice, we may simply guess at what Φ_{in} and q are everywhere. This constitutes our initial flux guess that will be used to start solving (430). We set $\phi = 1.0$ in every energy group, every mesh of the problem. For the Φ_{in} 's, we only need to guess these values along one boundary of the slab problem since Φ_{out} will become Φ_{in} as we move along each track. So, a good guess for Φ_{in} is to set it equal to $\Phi_{in} = 1/4\pi$ in all groups, in all directions, along one edge of the slab problem.

Now we may calculate the $\Phi_{in} e^{-\Sigma_{tr} t}$ part of the Φ_{out} equation, leaving us to determine the q part.

5.5.3 Calculating the Source Term

The total angular source term is a combination of three separate sources:

1. Scattering: $Q_s(\vec{r}, E, \hat{\Omega}) = \int \int \Sigma_s(\vec{r}, E' \rightarrow E, \hat{\Omega}' \rightarrow \hat{\Omega}) \Phi(\vec{r}, E', \hat{\Omega}') dE' d\hat{\Omega}'$
2. Fission: $Q_f(\vec{r}, E, \hat{\Omega}) = \chi(\vec{r}, E) \int \nu \Sigma_f(\vec{r}, E', \hat{\Omega}) \phi(\vec{r}, E') dE'$
3. Fixed external: $Q_{ext}(\vec{r}, E, \hat{\Omega}) = S(\vec{r}, E, \hat{\Omega})$

Scattering Source

As mentioned earlier, all scattering is assumed isotropic for our purposes. Anisotropic scattering effects are accounted for by transport-correcting the self scattering and total cross sections. By doing so, we can express the scattering cross section as

$$\Sigma_s(\vec{r}, E' \rightarrow E, \hat{\Omega}' \rightarrow \hat{\Omega}) = \frac{1}{4\pi} \Sigma_s(\vec{r}, E' \rightarrow E) \quad (431)$$

Then the integral over angle in the scattering source term becomes

$$\begin{aligned} Q_s(\vec{r}, E, \hat{\Omega}) &= \int \int \Sigma_s(\vec{r}, E' \rightarrow E, \hat{\Omega}' \rightarrow \hat{\Omega}) \Phi(\vec{r}, E', \hat{\Omega}') dE' d\hat{\Omega}' \\ &= \frac{1}{4\pi} \int \Sigma_s(\vec{r}, E' \rightarrow E) \phi(\vec{r}, E') dE' \end{aligned} \quad (432)$$

In multigroup theory, where the entire range of energies is discretized into a number of energy groups, the scattering kernel is defined as elements which make up a matrix

$$Q_{s,n}^g = \frac{1}{4\pi} \int \Sigma_s(\vec{r}, E' \rightarrow E) \phi(\vec{r}, E') dE' = \frac{1}{4\pi} \sum_{g'} \Sigma_{s,n}^{g' \rightarrow g} \phi_n^{g'} \quad (433)$$

Here, the quantity $\Sigma_{s,n}^{g' \rightarrow g} \phi_n^{g'}$ defines the total number of neutrons within the mesh n , within energy group g' , which have scattering collisions and are scattered into an energy within group g – our energy of interest. Out of all the neutrons that are scattered into energy group g , only $1/4\pi$ of them are traveling in direction Ω – our direction of interest.

Fission Source

For criticality problems, the only source of fresh neutrons are those born into the fast energy groups of the problem via fission. Neutrons born via fission are assumed to be distributed

isotropically (a good assumption) and integration of the angular fission source over all angles reduces to

$$\begin{aligned} Q_f(\vec{r}, E, \hat{\Omega}) &= \chi(\vec{r}, E) \int v\Sigma_f(\vec{r}, E', \hat{\Omega})\phi(\vec{r}, E') dE' \\ &= \chi(\vec{r}, E) \int \frac{v\Sigma_f(\vec{r}, E')}{4\pi} \phi(\vec{r}, E') dE' \end{aligned} \quad (434)$$

In multigroup form,

$$Q_{f,n}^g = \chi(\vec{r}, E) \int \frac{v\Sigma_f(\vec{r}, E')}{4\pi} \phi(\vec{r}, E') dE' = \chi_n^g \sum_{g'} \frac{v\Sigma_{f,n}^{g'}}{4\pi} \phi_n^{g'} \quad (435)$$

Here, we sum up all the fissions that occur in mesh n per unit volume,

$$\sum_{g'} v\Sigma_{f,n}^{g'} \phi_n^{g'} \quad (436)$$

and distribute those neutrons within the various fast energy groups using the fission spectrum, χ_n^g , which can be unique for each fuel material in the problem. The fission spectrum is normalized to unity,

$$\sum_{g'} \chi_n^g = 1.0 \quad (437)$$

The fission neutrons are then distributed isotropically by dividing the total scalar fission source by 4π . Equation (435) can be expressed as a production kernel, $\Sigma_{p,n}^{g' \rightarrow g}$, in a manner similar to the scattering kernel,

$$Q_{f,n}^g = \chi_n^g \sum_{g'} \frac{v\Sigma_{f,n}^{g'}}{4\pi} \phi_n^{g'} = \sum_{g'} \frac{\Sigma_{p,n}^{g' \rightarrow g}}{4\pi} \phi_n^{g'} \quad (438)$$

where

$$\Sigma_{p,n}^{g' \rightarrow g} = \chi_n^g \sum_{g'} v\Sigma_{f,n}^{g'} \quad (439)$$

External Source

For an external source of neutrons with energy E , located at position \vec{r} , with total (scalar) strength $s(\vec{r}, E)$, we distribute the neutrons isotropically such that

$$Q_{ext}(\vec{r}, E, \hat{\Omega}) = \frac{s(\vec{r}, E)}{4\pi} \quad (440)$$

or in multigroup form

$$Q_{ext,n}^g = \frac{s_n^g}{4\pi} \quad (441)$$

Total Source for a Non-Multiplying System

For a non-multiplying system, there is no source due to fission. For such a system, we are interested only in the flux distribution and not the multiplication factor. This is the type of problem solved when determining a gamma distribution. The external source in such instances is the gamma source resulting from the neutron flux distribution and contains contributions from neutron slowing down (scattering), from the fission process, and from the decay of fission products from an excited state to a more stable state. The final total (scalar) source distribution for a non-multiplying system would be expressed as

$$q_n^g = q_{s,n}^g + q_{ext,n}^g = \sum_{g'} \Sigma_{s,n}^{g' \rightarrow g} \phi_n^{g'} + s_n^g \quad (442)$$

Total Source for a Multiplying System

For a multiplying system, we may or may not have an external source. If we have an external source, then we are concerned with a subcritical system where the total source term is expressed as

$$q_n^g = q_{s,n}^g + q_{f,n}^g + q_{ext,n}^g = \sum_{g'} \left(\Sigma_{s,n}^{g' \rightarrow g} + \Sigma_{p,n}^{g' \rightarrow g} \right) \phi_n^{g'} + s_n^g \quad (443)$$

Lattice physics applications consist of multiplying systems with no external sources. For these types of problems the total scalar source is expressed as

$$q_n^g = q_{s,n}^g + q_{f,n}^g = \sum_{g'} \left(\Sigma_{s,n}^{g' \rightarrow g} + \frac{\Sigma_{p,n}^{g' \rightarrow g}}{k^\infty} \right) \phi_n^{g'} \quad (444)$$

which is similar to the expression of the source in (443) with the external source having been removed from the equation. The parameter k^∞ in (444) is the infinite multiplication factor and, for a system with no neutron leakage, is equal to the volume integrated number of neutrons born through fission divided by the volume integrated number of neutrons absorbed in the system,

$$k^\infty = \frac{\sum_n \sum_g \nu \Sigma_{f,n}^g \phi_n^g V_n}{\sum_n \sum_g \Sigma_{a,n}^g \phi_n^g V_n} \quad (445)$$

where V_n is the volume of each mesh in the system.

Physically, (445) describes a mesh, n , where there are $\sum_g \nu \Sigma_{f,n}^g \phi_n^g$ fission neutrons being born *per unit volume*. To calculate the total number of fission neutrons born in mesh n , we simply multiply by the volume of the mesh. This is only possible because we have assumed that the scalar flux is constant across mesh n , as are the cross sections. In a similar manner, there are $\sum_g \Sigma_{a,n}^g \phi_n^g$ neutrons absorbed in mesh n *per unit volume*. To calculate the total number of neutrons absorbed in mesh n , we once again multiply by the volume of the mesh. As before, this is possible because we have assumed that the scalar flux and the cross sections are constant across the volume. Mathematically, k^∞ is used to stabilize the source of neutrons from one flux iteration to the next.

So, now we can calculate q for each slab in the problem and we have all the information we need to solve the transport equation

$$\Phi_{\text{out}} = \Phi_{\text{in}} e^{-\Sigma_{tr}t} + \frac{q}{4\pi\Sigma_{tr}} (1 - e^{-\Sigma_{tr}t}) \quad (446)$$

5.5.4 Boundary Conditions

Boundary conditions in the characteristics method are applied to the angular flux only. There are two types of boundary conditions we will examine for slab geometry – periodic and reflective. Each of these will be discussed below. We will not examine vacuum boundary conditions because they are not applied in single assembly lattice physics analysis, although they can be applied when generating nodal discontinuity factors for water reflector regions. Such applications, however, are beyond the scope of this chapter.

Periodic Boundary Conditions

Periodic boundary conditions require the value of the angular flux in group g , in direction $(\bar{\varphi}_i, \bar{\theta}_j)$, entering the western-most surface of the system of slabs ($n = 1$) to be equal to the value of the angular flux in group g , moving in direction $(\bar{\varphi}_i, \bar{\theta}_j)$, leaving the eastern-most surface of the system of slabs ($n = N$). This is illustrated in  Fig. 60 and expressed mathematically as

$$\begin{aligned} \Phi_{\text{in},n=1}^g(\bar{\varphi}_i, \bar{\theta}_j) &= \Phi_{\text{out},n=N}^g(\bar{\varphi}_i, \bar{\theta}_j) \quad \text{for } 0 \leq \bar{\varphi}_i \leq \pi/2 \\ \Phi_{\text{in},n=N}^g(\bar{\varphi}_i, \bar{\theta}_j) &= \Phi_{\text{out},n=1}^g(\bar{\varphi}_i, \bar{\theta}_j) \quad \text{for } \pi/2 \leq \bar{\varphi}_i \leq \pi \end{aligned} \quad (447)$$

Reflective Boundary Conditions

Reflective boundary conditions require a fraction, α , of the value of the angular flux hitting the boundary of the system along the characteristic traveling in direction $\bar{\varphi}_i$ to be reflected back along the companion characteristic traveling in direction $\pi - \bar{\varphi}_i$. This is illustrated in  Fig. 61 and expressed mathematically as

$$\Phi_{\text{in},n=N}^g(\bar{\varphi}'_i, \bar{\theta}'_j) = \alpha \cdot \Phi_{\text{out},n=N}^g(\bar{\varphi}_i, \bar{\theta}_j) \quad (448)$$

 Figure 60

Periodic boundary condition in slab geometry

Figure 61
Reflective boundary condition in slab geometry

where the primes on the azimuthal and polar angles represent the reflective counterparts to the incident angles. For $\alpha = 1.0$, we have perfect reflexion. For $\alpha = 0.0$, we have a perfect vacuum condition.

For the reflective boundary condition, we must make sure we have distributed the azimuthal angles in such a way that there exists a reflective counterpart for each incident direction. For the equally distributed set of azimuthal angles we use in our implementation of the method of characteristics, this criterion is satisfied automatically. For I azimuthal directions distributed evenly between $0 \leq \bar{\varphi}_i \leq \pi$, the reflected counterpart to angle i is angle $i' = I - i + 1$.

5.5.5 Convergence

Convergence of the Angular Flux

For each energy group, g , we have an initial value for the inward flux along the surface of the problem, in azimuthal direction i , polar direction j , which is represented by $\Phi_{in,n=1}^g(\bar{\varphi}_i, \bar{\theta}_j)$. We march along the track until we reach the opposite boundary of the slab system, at which point we have an outwardly directed angular flux, $\Phi_{out,n=N}^g(\bar{\varphi}_i, \bar{\theta}_j)$. This then becomes the inward value for the angular flux in the reflected (or periodic) direction, using (448). This replaces the

previous value for the inward directed angular flux in direction $(\bar{\varphi}'_i, \bar{\theta}'_j)$. The difference in the two values – the value of the angular flux at the end of the previous iteration, and the value of the angular flux at the end of the present iteration – is a measure of how close we are to the true solution to the problem. When the difference between the two angular flux values is within a certain criterion, ε , for all inward directions, along both surfaces of the slab system, the angular flux for that particular energy group is assumed to be converged,

$$\left| \frac{\Phi_{\text{new,in},n}^g(\bar{\varphi}_i, \bar{\theta}_j) - \Phi_{\text{old,in},n}^g(\bar{\varphi}_i, \bar{\theta}_j)}{\Phi_{\text{new,in},n}^g(\bar{\varphi}_i, \bar{\theta}_j)} \right| < \varepsilon \quad (449)$$

where $n = 1$ represents the western-most surface to the slab system and $n = N$ represents the eastern-most surface to the slab system. (449) must hold true for all i 's and j 's in order to satisfy a fully converged solution to the problem in a given energy group.

Convergence of the Scalar Flux

At the end of each inner iteration, in addition to testing for convergence of the angular flux, the scalar flux is also tested for convergence. The same principle applies here as for the angular flux.

We begin the iteration with some value for the scalar flux in group g , $\phi_n^g(\text{old})$. This value for the scalar flux is used to calculate the source term prior to solving for the new flux distribution. With the source distribution frozen, we solve for a new scalar flux distribution, $\phi_n^g(\text{new})$. The new scalar flux is calculated by solving the equation

$$\phi_n^g(\text{new}) = \frac{q_n^g}{\Sigma_{tr,n}^g} + F_n^g \quad (450)$$

where

$$q_n^g = \sum_{g' < g} \left(\Sigma_{s,n}^{g' \rightarrow g} + \frac{\Sigma_{p,n}^{g' \rightarrow g}}{k^\infty} \right) \phi_n^{g'}(\text{new}) + \sum_{g' \geq g} \left(\Sigma_{s,n}^{g' \rightarrow g} + \frac{\Sigma_{p,n}^{g' \rightarrow g}}{k^\infty} \right) \phi_n^{g'}(\text{old}) \quad (451)$$

$$F_n^g = \sum_j \sum_i \frac{\Delta_{i,j,n}^g \cdot \omega_i \cdot \omega_j}{\Sigma_{tr,n}^g t_{i,j,n}} \quad (452)$$

In (452), $\Delta_{i,j,n}^g = \Phi_{\text{in},n}^g(\bar{\varphi}_i, \bar{\theta}_j) - \Phi_{\text{out},n}^g(\bar{\varphi}_i, \bar{\theta}_j)$ is the change in the angular flux value along the characteristic as it passes through a mesh.

The difference between the old and new value of the scalar flux will approach zero as the solution converges. Typically, as in the case of the angular flux, convergence is declared when the following statement is satisfied in every mesh:

$$\left| \frac{\phi_n^g(\text{new}) - \phi_n^g(\text{old})}{\phi_n^g(\text{new})} \right| < \varepsilon \quad (453)$$

Convergence of the Multiplication Factor

Prior to starting an outer iteration, the multiplication factor for the old flux distribution is calculated, k^∞ . As the fission source distribution converges, so too will the multiplication factor.

From one iteration to the next, we check for convergence of the multiplication factor

$$\left| \frac{k^\infty(\text{new}) - k^\infty(\text{old})}{k^\infty(\text{new})} \right| < \varepsilon \quad (454)$$

Equation (454) will always be satisfied if both (449) and (453) are satisfied. That is, the multiplication factor will always be converged if the flux distribution is converged. For this reason, satisfying (454) is relatively irrelevant.

5.5.6 Accelerating the Flux Convergence

For large problems, the number of iterations needed for convergence may become extreme if the initial flux guess is far from the converged solution. In order to reduce the number of iterations needed to satisfy convergence requirements, we would like to accelerate the convergence rate. We wish to accelerate the energy convergence as well as the spatial convergence. This section presents two methods that can be applied to accelerate the convergence of the scalar flux.

Energy Acceleration

Following completion of an outer iteration, a fundamental mode rebalancing of the group flux distribution is performed in order to properly normalize the flux and ensure neutron conservation. The fundamental mode calculation is performed on an equivalent homogeneous system using flux and volume weighted cross sections from the heterogeneous calculation. The resulting group flux values from the homogeneous calculation are then used to rebalance the magnitude of the heterogeneous group flux values. The description of the fundamental mode rebalancing calculation for the MoC is identical to that found in [Sect. 4](#) for the rebalance applied to the coupling calculation.

The equation to be solved here is equivalent to (310),

$$\phi_{\text{FM}}^g = \frac{\bar{q}^g}{\bar{\Sigma}_r^g} \quad (455)$$

where the source term does not include self scattering and the fission source is normalized to unity by the eigenvalue. Hence,

$$\bar{q}^g = \sum_{g' \neq g} \bar{\Sigma}_s^{g' \rightarrow g} \phi_{\text{FM}}^{g'} + \frac{\bar{\chi}^g}{k^\infty} \sum_{g'} \nu \bar{\Sigma}_f^{g'} \phi_{\text{FM}}^{g'} \quad (456)$$

The flux and volume weighted cross sections for the fundamental mode calculation are calculated from

$$\bar{\Sigma}_x^g = \frac{\sum_i \Sigma_{x,i}^g \phi_i^g V_i}{\sum_i \phi_i^g V_i} \quad (457)$$

where x represents the desired reaction.

For problems exhibiting no neutron leakage across the boundaries (i.e., perfect reflection along all boundaries), the multiplication factor in (457) can be calculated directly as the ratio of neutron production in the system to neutron destruction, as in (445),

$$k^\infty = \frac{\sum_{g'} \nu \bar{\Sigma}_f^{g'} \phi_{\text{FM}}^{g'}}{\sum_{g'} \bar{\Sigma}_a^{g'} \phi_{\text{FM}}^{g'}} \quad (458)$$

If we normalize the flux in such a way that there is only one neutron being absorbed in the entire problem, then the denominator to (458) becomes unity and the multiplication factor is simply the sum of all neutrons born through fission,

$$k^\infty = \sum_{g'} \nu \bar{\Sigma}_f^{g'} \phi_{\text{FM}}^{g'} \quad (459)$$

Plugging (459) into (456) yields the final expression for the fundamental mode homogeneous source

$$\bar{q}^g = \sum_{g'} \bar{\Sigma}_s^{g' \rightarrow g} \phi_{\text{FM}}^{g'} + \bar{\chi}^g \quad (460)$$

Due to up-scattering in the thermal energy groups, the solution to (455) defines an iterative process and the fundamental mode equation is solved directly, with no acceleration. Following the solution to (455), the scalar flux distribution from the solution to (411) is scaled using the rebalance factors,

$$\hat{\phi}_n^g = \phi_n^g \cdot \frac{\phi_{\text{FM}}^g}{\sum_n \phi_n^g V_n} \quad (461)$$

where the summation in (461) is over all mesh in the problem.

Spatial Acceleration

The scalar flux can be accelerated spatially using a simple coarse mesh rebalance (CMR) throughout the system. This is especially important since the characteristics equations are not based on a neutron balance and solution to the equations does not necessarily conserve neutrons from one iteration to the next. Coarse mesh are determined by material region. Each material region may be subdivided into smaller mesh to improve the accuracy of the flat flux approximation. The CMR is performed to ensure neutron conservation within each material region – or coarse mesh – of the problem.

The balance equation to be solved in each coarse mesh is defined as

$$\left[\sum_{m \in n} \Sigma_{r,m}^g \phi_m^g V_m + \sum_{s \in n} J_{\text{out},s,n}^g \right] \cdot f_n^g = \sum_{m \in n} q_m^g V_m + \sum_{s' \in n'} J_{\text{in},s',n'}^g \cdot f_{n'}^g \quad (462)$$

where m represents the mesh subdivisions within a coarse mesh material region, n ; s represents the surfaces to the coarse mesh, n ; s' represents the surfaces to the neighboring coarse mesh, n' . The variables in (462) are illustrated in  Fig. 62.

The currents must be accumulated as the inner iterations are performed. The contribution to the outgoing current along a coarse mesh surface is calculated as

$$J_{\text{out},s,n}^g = \sum_j \sum_i \sum_{k_m} \Phi_{k_m,i,j}^g \cdot \omega_i \cdot \omega_j \cdot |\cos \varphi_i \cdot \sin \theta_j| \quad (463)$$

Figure 62
Variables for the coarse mesh rebalance calculation

where k_m represents a track segment crossing mesh m , and the accumulation is only performed if mesh m is along the edge of coarse mesh n .

Equation (462) is solved iteratively for the balance factors, f_n^g . Once the balance factors are determined, the scalar flux is updated,

$$\phi_m^g = \phi_m^g \cdot f_n^g \tag{464}$$

for all mesh subdivisions, m , within coarse mesh region n . The CMR calculation is performed at the end of each inner iteration. Note that the CMR method is not inherently stable and the acceleration scheme can diverge or oscillate when mesh become optically very thin or very thick. The interested reader is directed to refer to, for instance, Reed (1971), Yamamoto et al. (2004), Cefus and Larsen (1990), Adams and Larsen (2002), Cho and Park (2003), and Lee and Downar (2003) for more information on convergence issues associated with acceleration techniques.

5.6 Cylindrical Geometry

5.6.1 Introduction

So far, only slab geometry has been discussed. The remaining one-dimensional geometries are cylindrical and spherical. For the characteristics method, spherical geometry is a special case of cylindrical geometry. Cylindrical geometry also forms the basis for moving on to complex geometries in two dimensions. Therefore, cylindrical geometry will be discussed in this section as a prelude to the discussion of two-dimensional analysis.

For our one-dimensional geometry, we consider a cylinder that is infinite in the z -direction and may contain many annular regions. If we use the coordinate system shown in **Fig. 63**, then the azimuthal angles of motion are constructed from the radius vector, \vec{R} , and a track parallel with the x -axis and perpendicular to the y -axis. The two lines are located such that the radius vector intersects the track at the outer radius of the cylinder.

■ **Figure 63**
Coordinates used for MoC cylindrical geometry

The intersection of the track occurs at some height along the y -axis. This height, or y -intersection, may be calculated by equating the equations of the two lines

$$\vec{R}^2 = x_i^2 + y_i^2 \text{ radius of outer annulus} \quad (465)$$

$$t_i = 2\vec{R} \cos \bar{\varphi}_i \quad (466)$$

where t_i is the track length spanned across the cylinder by the characteristic associated with azimuthal angle $\bar{\varphi}_i$.

We know \vec{R} from the problem definition, and we have chosen $\bar{\varphi}_i$ from our quadrature set. The value of x_i is the point along the x -axis at which the track intersects the outer radius of the cylinder and is easily calculated as

$$x_i = \vec{R} \cos \bar{\varphi}_i = \frac{1}{2} t_i \quad (467)$$

and the y -intercept is calculated as

$$y_i = \vec{R} \sin \bar{\varphi}_i \quad (468)$$

From (468), if $r_n > y_i$, then track t_i passes through annulus n , where r_n is the radius of annulus n .

$$r_n^2 = x_n^2 + y_i^2 \quad \text{or} \quad x_n = \sqrt{r_n^2 - y_i^2} \quad (469)$$

Figure 64
Track segments along a single characteristic

and track segment $\tau_{n,i}$ at azimuthal angle i , passing through region n , may be calculated as

$$\tau_{n,i} = x_n - x_{n-1} \tag{470}$$

This is illustrated in Fig. 64.

5.6.2 Choosing the Azimuthal Angles of Motion

Even Angle Distribution

As in the case of slab geometry, we wish to model neutron motion in the azimuthal plane of the problem in several unique directions. We could stick with our original choice of an evenly spaced set of azimuthal directions and boundaries, φ_i and $\bar{\varphi}_i$, respectively. To this end, we would have tracks crossing the system as shown in Fig. 65.

The above choice of four unique directions evenly distributed between $0 \leq \bar{\varphi}_i \leq \pi/2$ generates the boundaries, directions, and associated weights on a unit cylinder listed in Table 16. Note that the weight associated with each direction of motion is equivalent to the distance between parallel lines.

It can be seen from the table that, for our equal angle quadrature set, we will have more characteristics concentrated toward the top of the cylinder than we have near the center of the cylinder. This distribution is highly undesirable.

■ Figure 65
Evenly distributed angles in the azimuthal plane of a cylinder

■ Table 16
Evenly distributed angles in azimuthal plane of unit cylinder

i	φ_i	$\bar{\varphi}_i$	y_i	\bar{y}_i	ω_i
0	0°	–	0.00000	–	–
1	22.5°	11.25°	0.38268	0.19509	0.38268
2	45°	33.75°	0.70711	0.55557	0.32443
3	67.5°	56.25°	0.92388	0.83147	0.21677
4	90°	78.75°	1.00000	0.98079	0.07612

To correct for this skewed distribution, we wish to distribute the characteristics evenly, or more precisely we wish to produce azimuthal angles with the same weights, which requires the characteristic boundaries to be distributed evenly.

Even Boundary Distribution

From our previous example, if we wish to distribute the four characteristic boundaries evenly, we choose to enforce the following constraint:

$$\Delta y = \frac{R}{I} \quad (471)$$

where R is the outer radius of the cylinder and I is the total number of azimuthal angles. Then the y -intercepts of the boundaries are calculated as

$$y_i = R \sin \varphi_i \quad (472)$$

and the angles of motion are defined by rearranging (472)

$$\varphi_i = \sin^{-1} \left(\frac{y_i}{R} \right) \quad (473)$$

The location of the characteristic passing between the boundaries should be chosen to preserve the mean chord length of the prism being intersected. In the xy -plane, the mean chord length of a circle is simply the ratio of the area to the diameter,

$$\frac{A}{D} = \frac{\pi R^2}{2R} = \frac{\pi R}{2} \quad (474)$$

To convert this to the mean chord of a cylinder, we multiply by the mean secant of the azimuthal angle, where the mean secant is calculated as

$$\sec \varphi = \frac{\int_0^{\pi/2} \sec \varphi \cdot \cos^2 \varphi \cdot d\varphi}{\int_0^{\pi/2} \cos^2 \varphi \cdot d\varphi} = \frac{4}{\pi} \quad (475)$$

and the mean chord length for a complete cylinder then becomes $2R$.

The mean chord length for a horizontal slice through a cylinder can be calculated in a similar manner. This calculation results in an expression for the angle of travel for the characteristic passing through the slice

$$\begin{aligned} \sec \bar{\varphi}_i &= \frac{\omega_i}{\frac{1}{2}(\varphi_i - \varphi_{i-1}) + \frac{1}{4}(\sin 2\varphi_i - \sin 2\varphi_{i-1})} \\ &= \frac{\sin \varphi_i - \sin \varphi_{i-1}}{\frac{1}{2}(\varphi_i - \varphi_{i-1}) + \frac{1}{4}(\sin 2\varphi_i - \sin 2\varphi_{i-1})} \end{aligned} \quad (476)$$

Inverting (476) gives

$$\cos \bar{\varphi}_i = \frac{\frac{1}{2}(\varphi_i - \varphi_{i-1}) + \frac{1}{4}(\sin 2\varphi_i - \sin 2\varphi_{i-1})}{\sin \varphi_i - \sin \varphi_{i-1}} \quad (477)$$

From (477), the expression for the angle of travel for the characteristic passing through the centroid of the horizontal slice in the xy -plane of the problem is

$$\begin{aligned} \bar{\varphi}_i &= \cos^{-1} \left\{ \frac{\frac{1}{2}(\varphi_i - \varphi_{i-1}) + \frac{1}{4}(\sin 2\varphi_i - \sin 2\varphi_{i-1})}{\sin \varphi_i - \sin \varphi_{i-1}} \right\} \\ &= \cos^{-1} \left\{ \frac{\frac{1}{2}(\varphi_i - \varphi_{i-1}) + \frac{1}{4}(\sin 2\varphi_i - \sin 2\varphi_{i-1})}{\omega_i} \right\} \end{aligned} \quad (478)$$

For our previous example of four azimuthal directions of motion between $0 \leq \bar{\varphi}_i \leq \pi/2$, the new angles and weights using the *equal weights* quadrature will be those listed in [Table 17](#).

Table 17

Evenly distributed boundaries in azimuthal plane of unit cylinder

i	φ_i	$\bar{\varphi}_i$	y_i	\bar{y}_i	ω_i
0	0°	–	0.00	–	–
1	14.4775°	8.3168°	0.25	0.19509	0.25

Evenly distributed characteristics in the azimuthal plane of a cylinder

5.6.3 An Alternative Tracking Approach

General Theory

Rather than concerning ourselves with the azimuthal boundaries and positioning of the azimuthal angle of motion, there is a somewhat simpler, more direct way to track across our cylindrical system. We may lay tracks across the system, evenly spaced at increments of dy , as shown in [Fig. 66](#). Each characteristic has associated with it a “width,” which extends from the characteristic, half the way to the next characteristic on either side, as illustrated in [Fig. 67](#). The weight that is associated with each characteristic is then equal to the width of the characteristic, dy . The width of each characteristic is easily calculated by dividing the radius of the cylinder by the number of azimuthal directions of motion (i.e., the number of characteristics),

$$dy = \frac{R}{I} \quad (479)$$

Figure 67
Characteristic “widths”

Here, I is the number of characteristics in the NE quadrant of the cylinder and dy is the spacing between tracks and also between boundaries.

For one-dimensional cylinders, which exhibit azimuthal symmetry, we need only trace in the NE quadrant of the problem, since all other quadrants would be reflections of the NE quadrant. Since each characteristic has associated with it a width, we have two cylinder areas – (1) the *true* area of the NE quadrant $A_{\text{true}} = \pi R^2/4$, and (2) the area *approximated* by the characteristic widths,

$$A_{\text{approx}} = \sum_i t_i \cdot dy \tag{480}$$

where t_i is the length of the i th characteristic across the NE quadrant of the cylinder in the xy -plane of the problem.

Example

If we have many annular rings, but only a few characteristics, then we may end up with A_{approx} being much different from the A_{true} value. To illustrate this, let us suppose we have the system contained in **Fig. 68**.

If we look at the innermost ring – region 1 – then the true area of that region is

$$A_{\text{true}} = \frac{\pi r_1^2}{4} = \frac{\pi(0.74'')^2}{4} = 0.43 \text{ in}^2$$

and the x -intercept of the first characteristic with the radius of region 1 occurs at

$$\tau_{1,1} = \sqrt{r_1^2 - y_1^2} = \sqrt{(0.74'')^2 - (0.45'')^2} = 0.58745''$$

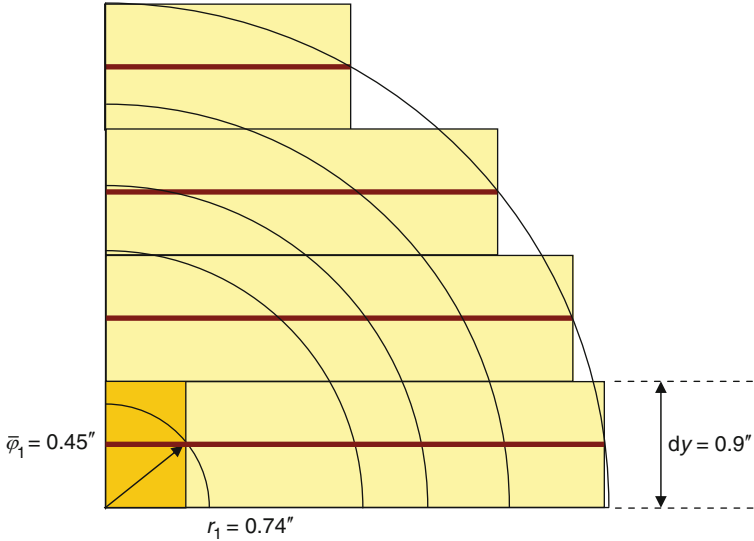

Figure 68
System with many annular rings and few characteristics

The approximated area of region 1 is calculated using (480)

$$A_{\text{approx}} = \tau_{1,1} \cdot dy = 0.58745'' \times 0.9'' = 0.52871 \text{ in}^2$$

In this example, the approximated area through region 1 is overestimated by

$$\% \text{diff} = \frac{|A_{\text{approx}} - A_{\text{true}}|}{A_{\text{true}}} \times 100\% = \frac{|0.52871 \text{ in}^2 - 0.43 \text{ in}^2|}{0.43 \text{ in}^2} \times 100\% = 23\%$$

Therefore, $\tau_{1,1}$ is really 23% longer than it should be and we will get too few neutrons being passed from region 1 to region 2 along this track segment if we leave it to remain as it is.

Track Adjustments

To correct for the poor estimation of the region area, we can adjust the track length until $A_{\text{approx}} = A_{\text{true}}$. We do this using the ratio below,

$$\tau'_{1,1} = \tau_{1,1} \cdot \frac{A_{\text{true}}}{A_{\text{approx}}} \quad (481)$$

For our example above, we would perform the following ratio:

$$\tau'_{1,1} = 0.58745'' \times \frac{0.43 \text{ in}^2}{0.52871 \text{ in}^2} = 0.47777''$$

In this way, we have reduced the true track length by 23% to ensure that the approximated area is correct. This will help to ensure that a proper number of neutrons are passed through region 1 to region 2, and vice versa.

Figure 69 Definition of track segments in MoC cylindrical coordinates

In general, then, we keep a running tally of the approximated area in each region using (480) and ratio all track segments following the completion of the tracking routine

$$\tau'_{n,i} = \tau_{n,i} \cdot \frac{A_{\text{true}}}{A_{\text{approx}}} = \tau_{n,i} \cdot \frac{\pi(r_n^2 - r_{n-1}^2)}{4 \sum \tau_{n,i} dy} \tag{482}$$

where the parameters in (482) are illustrated in Fig. 69. The transport equation may then be solved using the ratioed track lengths

$$\Phi_{\text{out},n}^g(\bar{\varphi}_i, \bar{\theta}_j) = \Phi_{\text{in},n}^g(\bar{\varphi}_i, \bar{\theta}_j) e^{-\sum_n^g \tau'_n(\bar{\varphi}_i, \bar{\theta}_j)} + \frac{q_n^g}{4\pi \sum_n^g} \left(1 - e^{-\sum_n^g \tau'_n(\bar{\varphi}_i, \bar{\theta}_j)} \right) \tag{483}$$

5.6.4 Modification to the Characteristics Equation

The solution to the transport equation must now be modified in order to apply our new tracking approach. In slab geometry, our ray tracing was precise and we kept track of the following summation in (411):

$$\sum_j \sum_i \frac{\Delta_n^g(\bar{\varphi}_i, \bar{\theta}_j) \cdot \omega_i \cdot \omega_j}{\tau_n(\bar{\varphi}_i, \bar{\theta}_j)} \tag{484}$$

where $\Delta_n^g(\bar{\varphi}_i, \bar{\theta}_j)$ is the change in the value of the angular flux across a mesh, moving in azimuthal direction $\bar{\varphi}_i$ and polar direction $\bar{\theta}_j$; and $\tau_n(\bar{\varphi}_i, \bar{\theta}_j)$ is the length of the track segment crossing the mesh. These lengths are always precise in slab geometry and all characteristics cross all slab regions in the problem.

In cylindrical geometry, the situation is different because not all characteristics cross each of the annular cylindrical regions and the characteristics do not preserve the true volume of each annular region. We can modify the summation in (484) to compensate for this. First, we rewrite (484) in a form that includes the length of the track segment projected onto the xy -plane of the problem

$$\sum_j \sum_i \frac{\Delta_n^g(\bar{\varphi}_i, \bar{\theta}_j) \cdot \omega_i \cdot \omega_j}{\tau'_{n,i} / \sin \bar{\theta}_j} = \sum_j \sum_i \frac{\Delta_n^g(\bar{\varphi}_i, \bar{\theta}_j) \cdot \omega_i \cdot \omega_j \cdot \sin \bar{\theta}_j}{\tau'_{n,i}} \quad (485)$$

Now we can substitute our expression for the approximated volume into (485) to replace the length of the projected track segment

$$\sum_j \sum_i \frac{\Delta_n^g(\bar{\varphi}_i, \bar{\theta}_j) \cdot \omega_i \cdot \omega_j \cdot \sin \bar{\theta}_j}{\tau_{n,i} \cdot \frac{A_{\text{true}}}{A_{\text{approx}}}} = \frac{1}{A_{\text{true}}} \sum_j \sum_i \Delta_n^g(\bar{\varphi}_i, \bar{\theta}_j) \cdot \omega_i \cdot \omega_j \cdot \sin \bar{\theta}_j \cdot dy \quad (486)$$

Substituting (486) into (411) gives us our modified expression for the scalar flux in cylindrical geometry,

$$\phi_n^g = \frac{q_n^g}{4\pi \Sigma_{tr,n}^g} + \frac{dy}{\Sigma_{tr,n}^g A_{\text{true}}} \sum_j \left(\omega_j \cdot \sin \bar{\theta}_j \sum_i \Delta_n^g(\bar{\varphi}_i, \bar{\theta}_j) \cdot \omega_i \right) \quad (487)$$

5.7 Two-Dimensional Geometry

For two-dimensional characteristics calculations, we take an approach similar to the approach we took for the one-dimensional cylindrical geometry. We assign a width to each characteristic and trace characteristics across the entire system at several azimuthal angles between $0 \leq \bar{\varphi} \leq 2\pi$. In one dimension, neutrons traveled at angles between $0 \leq \bar{\varphi} \leq \pi$ in an identical fashion to the way in which they traveled at angles between $\pi \leq \bar{\varphi} \leq 2\pi$. Therefore, we needed only to model neutron motion between $0 \leq \bar{\varphi} \leq \pi$ and account for the remaining azimuthal angles by doubling the associated weight, ω_i . Similarly, neutrons traveled at polar angles between $0 \leq \bar{\theta} \leq \pi/2$ in an identical fashion to the way in which they traveled at angles between $\pi/2 \leq \bar{\theta} \leq \pi$ and we accounted for this symmetry by modeling neutron motion only between $0 \leq \bar{\theta} \leq \pi/2$ and doubling the associated polar weight, ω_j .

In two dimensions, neutron motion in the polar direction is still symmetric about the xy -plane of the problem. That is, neutron motion above the plane is symmetric to neutron motion below the plane. Neutron motion within the xy -plane, though, is not symmetric about either the x -axis or y -axis and we must model neutron motion explicitly at all azimuthal angles between $0 \leq \bar{\varphi} \leq 2\pi$. The tracking routine may be eased somewhat by tracing across the system at angles between $0 \leq \bar{\varphi} \leq \pi$ only, and allowing neutrons to travel in both directions along each track during the characteristics solution.

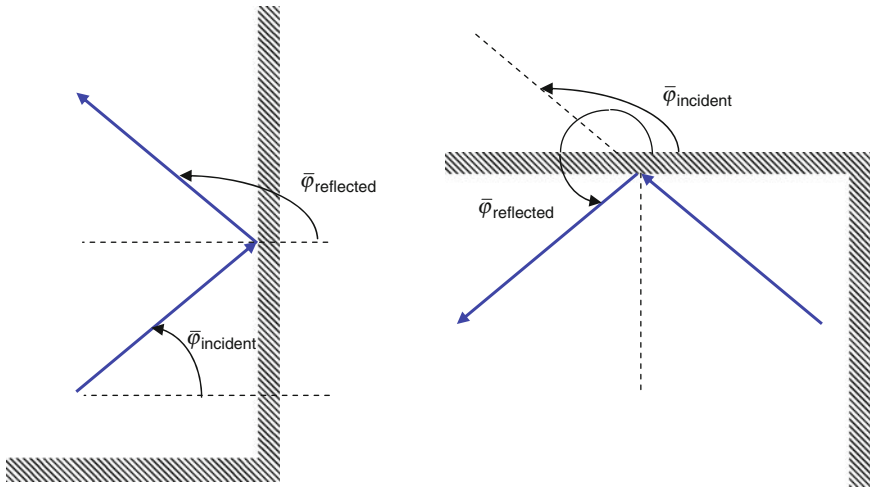

Figure 70
Reflected tracks off different boundaries to the two-dimensional problem

As in the one-dimensional case for reflective boundary conditions, we have a set of unique characteristics, which are distributed between $0 \leq \bar{\varphi} \leq \pi/2$. In one-dimension, we had the associated reflected tracks distributed between $\pi/2 \leq \bar{\varphi} \leq \pi$. In two-dimensional problems, we have tracks reflecting off the top and bottom boundaries of the problem, as well as off the side boundaries to the problem, as illustrated in **Fig. 70**. This leads to three reflected angles between $\pi/2 \leq \bar{\varphi} \leq 2\pi$ – one reflected angle in each directional quadrant of the problem. To this end, then, we must make sure that the end of each incident characteristic aligns precisely with the beginning of its reflected counterpart.

To ensure perfect reflection in two dimensions, track separations and streaming angles in the xy -plane of the problem must be altered based on the overall dimensions of the problem. We specify the number of azimuthal angles of motion that are to be used to model neutron streaming, I , and the separation of the set of parallel, equidistantly spaced tracks, d , at each azimuthal angle. The unadjusted set of azimuthal angles will be evenly spaced at angles defined by the following expressions:

$$\bar{\varphi}_i = \frac{1}{2}(\varphi_i + \varphi_{i-1}), \quad \text{where } \varphi_0 = 0^\circ \tag{488}$$

$$\varphi_i - \varphi_{i-1} = \frac{2\pi}{I} \tag{489}$$

where I is the number of azimuthal angles distributed between $0 \leq \varphi_i \leq 2\pi$.

If the system is of total width X and total height Y , then the total number of system widths spanned by a characteristic moving in the azimuthal direction of motion i , with a characteristic separation of distance d , is

$$nx = \frac{X \sin \bar{\varphi}_i}{d} \tag{490}$$

■ **Figure 71**
System heights and widths spanned by characteristic

and the total number of system heights spanned is

$$ny = \frac{X \cos \bar{\varphi}_i}{d} \quad (491)$$

This is illustrated in ► [Fig. 71](#).

In order to ensure that all tracks in direction $\bar{\varphi}_i$ align themselves with their reflective counterparts at the boundaries of the system, nx and ny are rounded up to the nearest integer values and the updated angle of streaming is then calculated as

$$\bar{\varphi}'_i = \tan^{-1} \left(\frac{ny_i}{nx_i} \right) \quad (492)$$

along with the updated separation distance

$$d'_i = \frac{X}{\sqrt{ny_i^2 + nx_i^2}} \quad (493)$$

Using these angles and separations, the azimuthal set of parallel, equidistantly spaced tracks are traced across the system at angles between $0 \leq \bar{\varphi}'_i \leq \pi$. For the angles between $\pi \leq \bar{\varphi}'_i \leq 2\pi$, the previous tracks are used, allowing neutrons to travel in the opposite direction.

For reflection cases, we have a separate reflected angle for each boundary of the system – north, south, east, and west.

For two-dimensional cases, the solution to the characteristics form of the transport equation is slightly different from the slab geometry case, since now each characteristic has associated

with it a width, d'_i . The average angular flux through mesh n at angle $(\bar{\varphi}'_i, \bar{\theta}_j)$ is equivalent to the cylindrical geometry case and is calculated by averaging the contribution from all tracks that pass through mesh n at angle i ,

$$\bar{\Phi}_n^g(\bar{\varphi}'_i, \bar{\theta}_j) = \frac{\sum_k \bar{\Phi}_{k,n}^g(\bar{\varphi}'_i, \bar{\theta}_j) \cdot t_{k,n}(\bar{\varphi}'_i, \bar{\theta}_j) \cdot d'_i}{\sum_k t_{k,n}(\bar{\varphi}'_i, \bar{\theta}_j) \cdot d'_i} \quad (494)$$

where the sum over k are the tracks at azimuthal angle $\bar{\varphi}'_i$, polar angle $\bar{\theta}_j$, which pass through mesh n .

As before, the scalar flux is considered flat across mesh n and is given by

$$\begin{aligned} \phi_n^g &= \sum_j \sum_i \bar{\Phi}_n^g(\bar{\varphi}'_i, \bar{\theta}_j) \cdot \omega_i \cdot \omega_j \\ \phi_n^g &= \frac{q_n^g}{4\pi \sum_{tr,n}^g} + \sum_j \sum_i \frac{\sum_k \frac{\Delta_{k,n}^g(\bar{\varphi}'_i, \bar{\theta}_j)}{\sum_{tr,n}^g \cdot t_{k,n}(\bar{\varphi}'_i, \bar{\theta}_j)} \cdot t_{k,n}(\bar{\varphi}'_i, \bar{\theta}_j) \cdot d'_i}{\sum_k t_{k,n}(\bar{\varphi}'_i, \bar{\theta}_j) \cdot d'_i} \cdot \omega_i \cdot \omega_j \\ \phi_n^g &= \frac{q_n^g}{4\pi \sum_{tr,n}^g} + \frac{1}{\sum_{tr,n}^g} \sum_j \sum_i \sum_k \frac{\Delta_{k,n}^g(\bar{\varphi}'_i, \bar{\theta}_j)}{t_{k,n}(\bar{\varphi}'_i, \bar{\theta}_j)} \cdot \omega_i \cdot \omega_j \end{aligned} \quad (495)$$

where the expression for the average angular flux along track segment k , crossing mesh n , in azimuthal direction $\bar{\varphi}'_i$, polar direction $\bar{\theta}_j$, represented by the variable $\bar{\Phi}_{k,n}^g(\bar{\varphi}'_i, \bar{\theta}_j)$, has been expanded using (406).

As with the cylindrical geometry calculation, each track length should be ratioed with the quotient of the approximated-to-true area of the mesh being subtended by the characteristic. This leads to an expression equivalent to (482),

$$t'_{k,n}(\bar{\varphi}'_i, \bar{\theta}_j) = t_{k,n}(\bar{\varphi}'_i, \bar{\theta}_j) \cdot \frac{A_{\text{approx}}}{A_{\text{true}}} \quad (496)$$

This, in turn, leads to an expression for the scalar flux equivalent to (487),

$$\phi_n^g = \frac{q_n^g}{4\pi \sum_{tr,n}^g} + \frac{1}{\sum_{tr,n}^g \cdot A_{\text{true},n}} \sum_j \sum_i \omega_i \cdot \omega_j \cdot d_i \cdot \sin \bar{\theta}_j \cdot \sum_k \Delta_{k,n}^g(\bar{\varphi}'_i, \bar{\theta}_j) \quad (497)$$

where

$$\Delta_{k,n}^g = \Phi_{k,n}^g(s=0) - \Phi_{k,n}^g(s=t'_{k,n}), \text{ in direction } \bar{\varphi}'_i, \bar{\theta}_j \quad (498)$$

The angular fluxes are calculated along each characteristic in the same manner as before,

$$\begin{aligned} \Phi_{\text{out},k,n}^g(\bar{\varphi}'_i, \bar{\theta}_j) &= \Phi_{\text{in},k,n}^g(\bar{\varphi}'_i, \bar{\theta}_j) \cdot \exp\{-\sum_{tr,n}^g \cdot t'_{k,n}(\bar{\varphi}'_i, \bar{\theta}_j)\} \\ &+ \frac{q_n^g}{4\pi \sum_{tr,n}^g} \left[1 - \exp\{-\sum_{tr,n}^g \cdot t'_{k,n}(\bar{\varphi}'_i, \bar{\theta}_j)\} \right] \end{aligned} \quad (499)$$

The main difference between the slab geometry calculation and the two-dimensional calculation is that, in slab geometry, there was one characteristic per azimuthal angle and each characteristic passed through all regions of the problem. In two-dimensions, there are many characteristics per azimuthal angle (the k subscript in the summations) and no single characteristic passes through all regions of the problem. We must, therefore, keep track of the region through which each characteristic, k , in azimuthal direction i , passes.

5.8 Mesh Subdivisions for Two-Dimensional Problems

The ray-tracing routine is the most complex module associated with the MoC. Ray tracing, itself, is not all that complicated. However, the calculation of true areas for all the complicated mesh shapes requires a great effort and is fairly cumbersome to implement. The true area of each mesh is required to accurately solve (496) and (497). Alternatively, one could make the assumption that enough ray-tracing detail will be used that the approximated area will be close enough to the true area to remove the need to ratio the track lengths. Such an assumption would simplify the ray-tracing module significantly, hopefully without overly penalizing the accuracy of the solution.

There are different approaches to ray tracing. The details that will be described in this section are based on the approach used in CASMO-4 and LANCER02. This approach has been shown to be extremely advantageous, in terms of execution speed. It uses predefined cell types that are commonly found in all LWR lattice designs and is preferred because it simplifies the calculation of true mesh areas. Alternative approaches include generalized geometry routines, such as those routinely used in Monte Carlo codes, and factorial geometry, such as that used in AEGIS. For such routines, the calculation of true mesh areas can become complicated and the correction in (496) might need to be abandoned. The other benefit of using predefined cell types is that meshing can be predetermined by the programmer and, therefore, is guaranteed to be adequate. For generalized ray-tracing routines, the meshing is typically left to the user, who may or may not have an adequate feel for the meshing needs of the problem being solved. The accuracy of the MoC depends on the size of the flat source mesh – especially those used in the thermal energy range – so inadequate meshing can produce misleading results. The interested reader is directed to refer Jevremovic et al. (2001), Yamamoto et al. (2005), Sugimura et al. (2007), West and Emmet (1980), and Weiss and Ball (1991).

5.8.1 Assigning Material Regions

Before we begin to ray trace, we first define the various material regions of the problem and then split each material region into an adequate number of flat source/flat flux mesh. The materials are the broad-group macroscopic cross section sets from the condensation scheme (if one exists).

To do this, we must first assign *cell* numbers to the problem. We define a *cell* to be a large region of the lattice that may contain multiple material regions, such as a whole pin cell or a portion of a control blade that contains one or more absorber pins and sheathing. All *cells* are rectangular, as illustrated in  Fig. 72, and are part of a Cartesian grid. The *cells* are numbered sequentially starting, for example, in the upper left-hand corner of the problem and working across the row and then down the columns. Note that the oversized water rod in the center

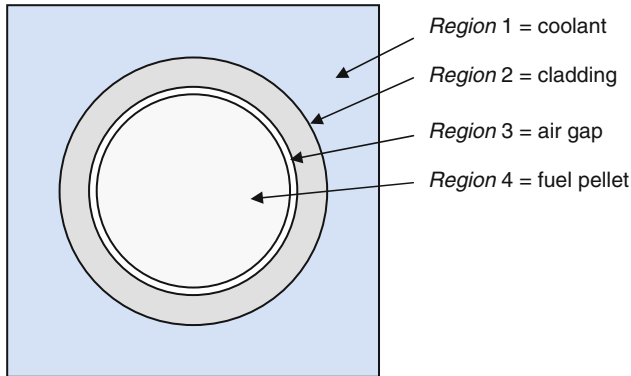

Figure 72
Definition of cells

of the lattice in Fig. 72 has been divided into four *cells* by our Cartesian grid. This will be addressed by four separate ray-tracing routines.

The cell numbers are held by a two-dimensional array, such as “CellNumber(maxx,maxy),” where “maxx” is the number of *cells* along the *x*-axis of our lattice, and “maxy” is the number of *cells* along the *y*-axis of our lattice, which in Fig. 72 would be 10 × 10.

Within each *cell*, there may be multiple material *regions*, each one representing a different material type. For instance, within a pin *cell*, there is a coolant *region*, a cladding *region*, possibly an air gap *region* between the fuel pellet and the cladding, and a fuel pellet *region*. If the fuel pellet contains Gadolinium, there may be multiple pellet *regions* defined in order to accurately model the spatial self-shielding nature of the Gadolinium. Each of the pellet *regions* is its own unique material type. The *regions* within a *cell* can be thought of as levels in our lattice physics code, where the base level is the outermost material in the *cell* and you add levels as you move further into the *cell*. This is illustrated for a simple pin *cell* in Fig. 73, where the coolant material forms the base *region* and the *region* numbers (i.e., levels) increase as the cylinders become smaller.

From a programming point of view, we would represent this using a two-dimensional array. For instance, we may define material sets for each *region* of each *cell* using an array

■ **Figure 73**
Definition of regions within a cell

such as “MaterialPerRegion(regions,cells).” Then we would need a one-dimensional array that described the number of *regions* per *cell*, such as “RegionsPerCell(cells).” The value of “cells” in the two arrays would come from our “CellNumber(maxx,maxy)” variable.

5.8.2 Meshing

Each *cell* in the problem needs to be broken into a number of *mesh* that are small enough to accurately represent the source and the flux as being perfectly flat within the *mesh*. In an LWR lattice, the *regions* within each *cell* are usually small enough to accurately be used as flat source *mesh* without further subdivision for neutron energies in the epithermal and fast range. That is, for neutron energies above roughly 2 eV, the cross sections are small enough and consistent enough from one material region to the next to use a *mesh* such as that illustrated in ► Fig. 72 to represent the flux and the source as being perfectly flat. In the thermal energy range below 2 eV, though, some cross sections can be very large indeed and the size of the cross sections may vary wildly from one material region to the next. This is especially true for regions containing strong thermal absorbers, such as the B4C or hafnium absorber pins in a control blade, or fuel pellets containing Gadolinium. In such cases, the flux will change rapidly across a material *region* and the material *region* will need to be subdivided into much smaller *mesh* in order to produce an accurate solution to the characteristics equation.

During the initial development of CASMO-4 (early 1990s), computer memory was at a premium and it was necessary to devise clever schemes to save memory wherever possible. One way of minimizing the memory required by the MoC solution was by using two separate mesh – a coarse mesh for all energy groups above 2 eV, and a fine mesh for all energy groups below 2 eV. This was acceptable for all lattice calculations except BWRs containing a cruciform control blade in one corner of the problem. For those cases, it was necessary to apply the fine mesh to all energy groups in order to properly model the steep flux gradient across the bundle that was created by the presence of the control blade. The use of the dual mesh system allowed the MoC to be applied on machines with small memory, but at a price. Accuracy – primarily at cold

■ **Figure 74**
Example of *mesh* ordering

conditions – was somewhat compromised. Also, since the mesh changed for different energy groups, there had to be a way of superimposing the fine mesh onto the coarse mesh and vice versa. This complicated bookkeeping within the code. Today, memory is plentiful and there is no need to micro-manage memory on a scale like that, so the fine mesh is always used for all energy groups. This makes bookkeeping within the code much simpler.

➤ *Figure 74* contains an example of a pin cell that has been subdivided into octants of equal areas. The cell has been subdivided in this way because it lends itself to an easy calculation of true areas for each *mesh*. The figure contains an example of a numbering scheme used for the *mesh* layout. Any numbering scheme is valid – the important point being that a consistent scheme exists that allows the ray-tracing routine to determine the *mesh* through which the characteristic passes. In this scheme, we might have a three-dimensional array to hold the flux or area of each mesh, such as “MeshArea(mesh,regions,cells).”

5.8.3 Defining Various Cell Types

The different types of *cells* are distinguished by their contents. ➤ *Figure 75* contains examples of some of the *cells* that might be defined internally by the MoC ray-tracing module. The most common *cell* found in a typical problem is a square or rectangular cell that may or may not contain imbedded cylinders. The origin of the imbedded annular cylinders is typically centered in the cell, although this is not necessarily a requirement and is sometimes modified by the code internally, as will be explained later in this section. Other *cells* may contain imbedded slabs at different angles. A collection of *cells* can be created to handle pins along the edge of the bundle that abut the channel shroud of a BWR. Unique *cells* exist along each different face of the channel and in each corner of the channel. The corner *cells* are created to handle the specific intricacies of the rounded channel corners and the thick–thin nature of channel walls on modern BWR assembly designs. Additional *cells* can be created to handle the oversized water rods and water boxes found in designs from the various fuel vendors.

■ Figure 75
Examples of different type of cells

For such a scheme, we should define a two-dimensional array to carry the type of each *cell* in the lattice, such as “CellType(maxx,maxy).” For each *cell* type, we create a unique ray-tracing routine that is specific for the contents of that *cell*, that is, imbedded cylinders, or orthogonal slabs, or whatever. Then, for any characteristic we trace across the geometry of the problem, we will know what type of *cell* we are traversing at any point in the lattice and we will enter the appropriate ray-tracing routine, which has been written specifically for the type of geometry contained within the *cell*. If the lattice physics code is being developed for a specific application, such as analyzing BWR or PWR fuel designs, this is the preferred approach, in terms of execution speed and ease of use. The major drawback is that the code requires modifications if a new geometry is introduced into a fuel design. But that rarely happens. The different geometries that exist in fuel designs today have remained unchanged for decades.

■ **Figure 76**
Modifying cell boundaries to accommodate oversized rods

For most LWR applications, the MoC ray-tracing routine can be limited to dealing with imbedded cylinders that have a common origin within the cell of interest. A special exception to this rule-of-thumb is made for some legacy BWR fuel designs that contained water rods whose center of origin was located in a neighboring cell. This situation is illustrated in [▶ Fig. 75](#) as cell types 31 through 37, where the two water rods were centered in cells 33 and 36, respectively, and cell 31 contained contributions from each. But for most cells, the physical dimensions of the rod can safely be prohibited from crossing the cell boundaries. For bundles containing water rods that occupy multiple cell locations, for example, cells 51 through 54 in [▶ Fig. 75](#), the MoC ray-tracing routine can be written to modify the Cartesian grid boundaries in such a way that the water rods fit entirely within four cells. When this happens, the pins in rows of cells neighboring the water rod will be shifted from their cell centers and the cells themselves will be modified from a square to a rectangular shape, as illustrated in [▶ Fig. 76](#). In the figure, all pins shaded in blue are those whose origins have been shifted from the center of the cell by the new grid boundaries.

[▶ Figure 77](#) contains details of two cells taken from [▶ Fig. 76](#). These are the two cells labeled “1” and “2” in [▶ Fig. 76](#). Both cells have had a grid boundary adjusted by the presence of the oversized water rod in the center of the lattice. Cell “1” has had its east boundary moved further to the east, increasing the area of the cell. Cell “2” has had its west boundary moved to the east, reducing the area of the cell. Mesh subdivisions are always centered in the

■ **Figure 77**
Mesh subdivisions centered in annular regions

middle of the annular cylinders. This is done to simplify the ray-tracing logic. Unfortunately, this action results in somewhat uncommon mesh shapes and complicates the calculation of the true area of some mesh subdivisions. In contrast, if no imbedded annular cylinders exist in the mesh, the azimuthal subdivisions can be drawn between diagonal corners of the mesh. Note that annular *mesh* subdivisions are allowed to intersect with the *cell* boundaries, whereas annular *material boundaries* are not allowed to intersect with the *cell* boundaries. The coding must be capable of distinguishing between *mesh boundaries* and *material boundaries* when imposing this limitation.

5.8.4 Meshing of Control Blade Cells

The presence of the control blade presents its own challenge, in terms of the *cells* that are created by the Cartesian grid, not only for the ray tracing, but especially for the calculation of the true area for each mesh subdivision in the control blade. In essence, the same Cartesian grid as that illustrated in ► [Fig. 76](#) is placed over the geometry of the bundle with or without the control blade being present. In instances when the control blade is present, the interior of some of the *cells* take on more complicated geometries, as illustrated in ► [Fig. 78](#). Each *cell* of the control blade will contain multiple absorber tubes and it is possible that each absorber tube can be made up of a unique material (B₄C, Hafnium, etc.). The Cartesian grid boundaries can intersect the control blade at any point, which complicates the calculation of the true areas of the mesh subdivisions in each *cell*.

5.8.5 Final Mesh Layout

The final geometry layout consists of a mesh that resembles that illustrated in ► [Figs. 77](#) and [78](#). That is, the fine mesh are very small and are used to model the steep flux gradients present primarily in the thermal energy groups. The mesh layout for a typical BWR assembly is illustrated in ► [Fig. 79](#). The lavender colored pins in the figure represent pellets containing Gd₂O₃.

■ **Figure 78**
An example of control blade cells

For such locations, the pellets will be subdivided annularly into multiple concentric rings. Each ring in the pellet is represented by a set of unique material cross sections. This allows for an accurate modeling of the Gadolinium radial depletion rate.

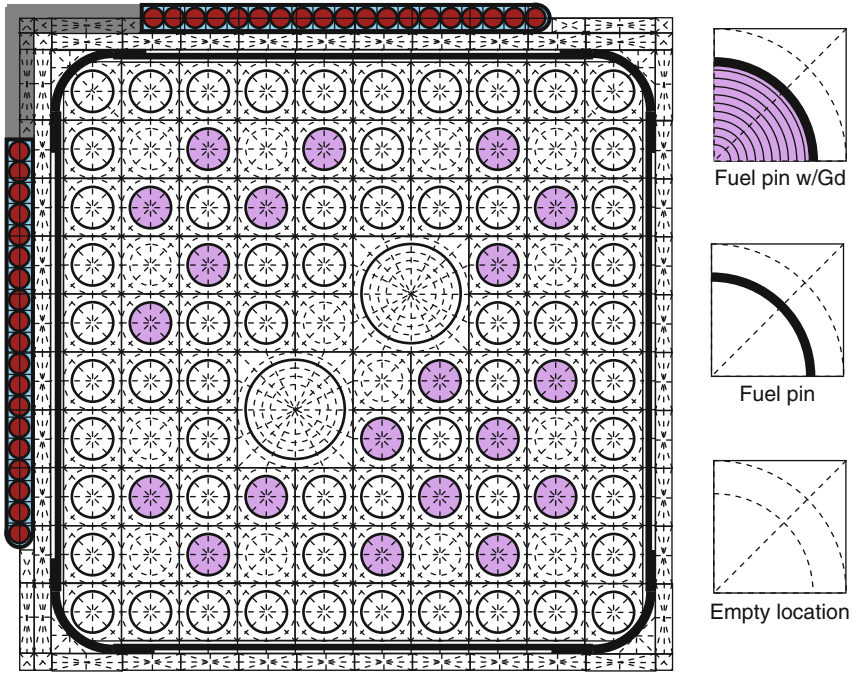

For a typical modern fuel design, the fine-mesh layout will contain approximately 5,000 flat source/flat flux mesh. The water gaps should be subdivided vertically and horizontally such that no gap mesh is wider than 0.5 cm. After the outer gaps have been subdivided, additional azimuthal mesh should be applied to further subdivide each gap mesh into octants, as illustrated in ► [Fig. 79](#). Large water rods should be subdivided annularly into smaller fine-mesh sizes to better model thermal flux gradients across the rod.

5.9 Two-Dimensional Ray Tracing

5.9.1 The Cyclic Tracking Approach

Once the problem has been segmented into various *cell* types, the MoC routine is ready to begin ray tracing across the problem. Ray tracing takes place only for the azimuthal directions of motion. The resulting track lengths are raised out of the plane of the problem to each of the various polar angles and the track lengths are adjusted accordingly. For any given azimuthal angle of motion, $\overline{\varphi}'_i$, the ray-tracing routine will first determine the number of characteristics that begin along the x -axis and the y -axis and will then determine the coordinates of the origin of each characteristics. The separation of the characteristics along the x and y axes is calculated as

$$\delta x_i = \frac{d_i}{|\sin \overline{\varphi}'_i|} \quad (500)$$

■ **Figure 79**
 Typical *mesh* layout for a BWR assembly calculation

and

$$\delta y_i = \frac{d_i}{|\cos \bar{\varphi}_i|} \quad (501)$$

as illustrated in ► [Fig. 80](#).

As described in ► [5.7](#), the azimuthal angle has been slightly modified to ensure that each characteristic aligns with its reflective counterpart along each boundary of the problem, and the separation between parallel characteristics has been slightly adjusted to ensure that there are a perfect integral number of characteristics covering the problem geometry. To avoid a characteristic originating in a corner of the problem, the entire set of characteristics is centered along the axes. This results in the first characteristic along each axis being shifted by an amount equal to half the separation distance along that particular axis,

$$\delta x_{i,0} = \frac{\delta x_i}{2} \quad (502)$$

and

$$\delta y_{i,0} = \frac{\delta y_i}{2} \quad (503)$$

■ Figure 80
Origin of each characteristic at a given angle

Once the origin of each track is determined, the code may begin to trace the characteristics across the geometry of the problem. The module first determines the *cell* being crossed by the characteristic. Based on the specific *cell* type, the module will enter the appropriate ray-tracing routine and proceed to determine all intersections of *mesh* lines with the crossing characteristic. The basic principles of each ray-tracing routine are illustrated in ► Fig. 81.

Within any *cell* containing imbedded cylinders, the origin of the *cell* is placed at the center of the annular rings. The fine-*mesh* subdivisions are also centered in the middle of the annular cylinders. This simplifies the ray-tracing routine for *cells* that contain imbedded cylinders whose origin is not located in the center of the *cell*. The entrance point to the *cell*, (x_{in}, y_{in}) , is known either from the exit point from the neighboring *cell*, or from the origin of the characteristic along one of the outer problem boundaries. The width of the *cell* in the x and y directions is also known, x_{dim} and y_{dim} , respectively. The total length of the characteristic across the *cell* can then be calculated as

$$l = \frac{x_e - x_{in}}{\cos \bar{\varphi}'_i}, \quad \text{if } \bar{\varphi}'_i < \pi/2 \quad (504)$$

or

$$l = \frac{x_w - x_{in}}{\cos \bar{\varphi}'_i}, \quad \text{if } \bar{\varphi}'_i > \pi/2 \quad (505)$$

The exiting point of the characteristic along the y -axis is calculated as

$$y_{out} = y_{in} + l \cdot \sin \bar{\varphi}'_i \quad (506)$$

■ **Figure 81**
Intersections of *mesh* with a passing characteristic

If y_{out} is determined to lie outside the boundaries of the *cell*, then the track length is recalculated as

$$l = \frac{y_n - y_{\text{in}}}{\sin \bar{\varphi}'_i} \quad (507)$$

y_{out} is then equal to y_n and x_{out} is calculated as

$$x_{\text{out}} = x_{\text{in}} + l \cdot \cos \bar{\varphi}'_i \quad (508)$$

The ray-tracing routine keeps track of the surface of the *cell* that is crossed when the characteristic enters and exits the *cell*. This information is later used during the coarse mesh rebalance acceleration scheme, described later in this section.

Once the entrance and exit points are known, all intersections within the *cell* may be determined. This is done by equating the equation of the line for the characteristic with the equation of the line/arc for each *mesh* or material *region* in the *cell*. The equation of the line for the characteristic is expressed as

$$y = m_c x + b_c \quad (509)$$

where m_c is the slope of the line of the characteristic, calculated as $\tan \bar{\varphi}'_i$; and b_c is the point at which the characteristic intersects the y -axis, as illustrated in ► [Fig. 82](#).

Figure 82
Variables associated with the equation of the characteristic

The y -axis intercept is calculated as

$$b_c = y_{in} - (x_{in} \cdot \tan \bar{\varphi}'_i) \quad (510)$$

And the closest the characteristic approaches to the origin of the *cell* is

$$\delta_c = |b_c \cdot \cos \bar{\varphi}'_i| \quad (511)$$

The equation for any annular cylinder in the *cell* is given by

$$r_{cyl}^2 = x^2 + y^2 \quad (512)$$

or

$$y = \sqrt{r_{cyl}^2 - x^2} \quad (513)$$

Equating (513) with (509) produces the two values for the x -intercept of the characteristic with the cylinder,

$$x = \frac{-m_c b_c \pm \sqrt{m_c^2 r_{cyl}^2 + r_{cyl}^2 - b_c^2}}{m_c^2 + 1} \quad (514)$$

The corresponding y -intercept values can be obtained by plugging the x -intercept values into (513) or (509). These intercepts are only calculated if $\delta_c < r_{\text{cyl}}$, otherwise, the characteristic cannot cross the boundary of the cylinder. After determining the coordinate intercepts of the characteristic with the cylinder, the routine checks to make sure that the intercepts lie within the *cell* boundaries. This is necessary because the cylindrical *fine-mesh* subdivision in the coolant is allowed to cross the *cell* boundaries.

Similar logic is used to determine the intercept of the characteristic with a slab imbedded in a *cell*. Slabs are typically vertical or horizontal and the equation of the line representing the slab is then of the form

$$x = \text{const} \quad (515)$$

or

$$y = \text{const} \quad (516)$$

The constants that represent the equation of the line for the various vertical slabs may be plugged directly into (509) to determine the corresponding y -intercepts. For horizontal slabs, (509) is rearranged prior to plugging in the constants and is subsequently solved for the corresponding x -intercept. After determining the intercepts, the routine checks to make sure the intercepts lie within the *cell* boundaries. If not, the characteristic cannot cross the slab within the *cell* and the intercepts are discarded. Intersections of the characteristic with the *fine-mesh* subdivisions are determined in a similar manner.

The number of intersections resulting from ray tracing over a typical LWR lattice is usually on the order of one million. That is, we will end up having to solve the transport equation approximately one million times for each inner iteration we perform. Even on today's computers, this is a rather daunting task. The solution to our problem will go much faster if we hold the ray-tracing results in tightly packed one-dimensional arrays. In the early days, this was also necessary in order to manage memory properly. However, that is no longer a consideration for single assembly calculations.

In any event, we wish to hold the ray-tracing data in tightly packed, one-dimensional arrays. One way to do this is to simply allocate enough space that we could not possibly surpass it. That is, we could allocate an array, such as "TrackLengths(2000000)." A more economical approach is the one taken in CASMO-4 and LANCER02. In this approach, the ray-tracing routine is entered twice in a row. The first time the routine is entered, none of the information is retained except for the total number of track lengths traced. Using this one value, all ray-tracing arrays are dimensioned to the minimum size needed and the ray-tracing routine is entered for the second time. The second time through, all information is retained.

From the ray-tracing routine, we need only save: the track lengths; the *mesh*, *region*, and *cell* through which each track passes; and the *cell* surface across which each track crosses (if, indeed, it does cross a *cell* surface). The last bit of information is used for the acceleration scheme.

Once we have the tracking information, our best approach is to calculate all mean free paths in all energy groups and hold them in memory in preparation for the iteration scheme. That is, we calculate the following portion of (499):

$$\exp \left\{ -\Sigma_{tr,n}^g \cdot t'_{k,n} (\bar{\varphi}'_i) / \sin \bar{\theta}_j \right\} \quad (517)$$

If there are one million track segments, three polar angles of motion in the quadrature set, and 20 energy groups, the entire size of the array needed to hold (517) will be 60 million words, or

240 Mb. A sizeable amount of memory, but worth every bit of it (pun intended) based on the amount of execution time it saves during the iteration process. The alternative is to evaluate the exponential for every track segment in the problem, for every iteration we perform. This is a very expensive proposition, in terms of computation time.

To employ (517), (499) should be rearranged in a simplified form

$$\Phi_{k,n,\text{out}}^g(\bar{\varphi}'_i, \bar{\theta}_j) = \hat{Q}_n^g + \exp[-\Sigma_{tr,n}^g \tau_{k,n}(\bar{\varphi}'_i, \bar{\theta}_j)] \cdot (\Phi_{k,n,\text{in}}^g(\bar{\varphi}'_i, \bar{\theta}_j) - \hat{Q}_n^g) \quad (518)$$

where $\tau_{k,n}(\bar{\varphi}'_i, \bar{\theta}_j) = t'_{k,n}(\bar{\varphi}'_i) / \sin \bar{\theta}_j$ is the modified track length after being lifted out of the xy -plane of the problem to the appropriate polar angle; and $\hat{Q}_n^g = q_n^g / 4\pi \Sigma_{tr,n}^g$ is the term containing the angular source. The scalar source term concealed in (518) is expressed as

$$q_n^g = \sum_{g'} \left(\Sigma_{s,n}^{g' \rightarrow g} + \frac{\Sigma_{p,n}^{g' \rightarrow g}}{k^\infty} \right) \phi_n^{g'} \quad (519)$$

where the production cross section is defined as $\Sigma_{p,n}^{g' \rightarrow g} = \chi_n^g \sum_{g'} \nu \Sigma_{f,n}^{g'}$.

The scalar flux in (519) – for any given *mesh*, n – is obtained using (497).

5.9.2 The Macro-Band Approach

In the cyclic tracking approach, all characteristics were traced across the entire width of the problem and the end of each characteristic aligned precisely with the beginning of its reflective counterpart along the problem boundaries. An alternative approach to the cyclic tracking method is to employ a macro-band method. In this method, ray tracing takes place on an individual *cell* basis only and characteristics are not forced to align along the boundaries of each *cell*. Instead, angular fluxes at the beginning of a track segment are inferred from the interpolation of the two closest track segments exiting the neighboring *cell*. This is illustrated in  Fig. 83 where the ends of the red characteristics do not align precisely with the beginning of the blue

 **Figure 83**
Macro-bands and characteristics

characteristics. To get the value of the angular flux entering a *cell*, the angular flux exiting the neighboring *cell* is linearly interpolated.

The macro-bands are the dotted lines in the pin cells in [▶ Fig. 83](#). They bound the singularities that arise from the intercept of the mesh in the *cell* with the characteristic at angle $\bar{\varphi}_i$. The macro-bands ensure that no characteristic ever passes through a singularity. In our cyclic tracking routine, this was ensured by continuously nudging the track away from a local singularity. We want to avoid singularities because, in such cases, it is unclear which mesh is being intersected. By nudging the characteristic in one direction or another, we force the track to pass through one of the multiple mesh that are part of the singularity.

In the macro-band method, which was first implemented commercially in the HELIOS CCCP method, characteristics are distributed evenly between macro-bands. If desired, characteristics can take on different spacing between different macro-bands, as illustrated in the figure. In subsequent implementations of the concept, such as in the AEGIS lattice physics code, the bands are distributed according to a Gauss–Legendre quadrature set, which improves the accuracy of integration (Yamamoto et al. 2005).

The macro-band method is superior to the cyclic tracking method at treating singularities, but at the price of having to estimate the angular flux at the cell boundaries. Either ray-tracing approach is perfectly adequate for an LWR lattice physics code. The choice is up to the programmer’s own preference.

5.10 Quadrature Sets for Two-Dimensional LWR Lattice Calculations

5.10.1 Quadratures for Modeling Polar Motion

The quadrature sets described previously in this section were based on simple formulas that either forced all weights to be equal, or forced all angle increments to be equal. These types of quadratures serve as very good examples for developing the theory of the MoC, but are rather inefficient when used to represent neutron streaming out of the plane of the problem, resulting in the need to model many angles of motion in order to arrive at an accurate solution to the transport equation. The integration can be performed much more efficiently with the use of other quadrature sets that will be discussed in this section.

The use of a Legendre quadrature set is far more efficient for two-dimensional transport problems than either the equal weights or equal angles quadrature sets described in [▶ 5.3.3](#). An adequate set of Legendre quadratures are given in [▶ Table 18](#) (Lewis and Miller 1984). There are six separate Legendre quadratures contained in the table from which to choose. For the majority of production analyses, the $N = 6$ quadrature set should be sufficient. This set of angles and weights models neutron motion out of the plane of the problem in three unique polar directions. Solutions using the $N = 6$ quadrature set are virtually saturated and there is little measurable improvement in results by going to a quadrature set that contains more polar directions of motion. The μ values in [▶ Table 18](#) represent the cosine of the polar angle of motion, that is, $\mu_j = \cos \theta_j$. For problems containing mixed-oxide pellets, more polar angles are usually needed in order to account for changes in the flux out of the plane of the problem due to the much larger thermal absorption cross sections.

An even more efficient set of angles and weights can be obtained by minimizing the error involved in numerically integrating the Bickley functions of the collision probability method.

Table 18

Legendre quadratures for modeling polar motion

$P_N(\mu_j)$	j	$\pm\mu_j$	ω_j
$N = 2$	1	0.57735 02691	1.00000 00000

This approach leads to the set of angles and weights contained in [Table 19](#) (Yamamoto et al. 2007). Using this quadrature set, an accurate solution to the transport equation can usually be obtained from $N = 2$ for typical uranium-oxide problems. As with all other quadrature sets, more detail may be necessary for problems containing mixed-oxide pellets. Note that the values in the table are the $\mu_j = \sin \theta_j$, not the $\mu_j = \cos \theta_j$.

Alternative polar angle quadrature sets are available in Leonard and McDaniel (1995) and Sanchez et al. (2002).

5.10.2 Quadratures for Modeling Azimuthal Motion

Azimuthal angles of motion are distributed evenly throughout the plane of the problem. There is really no other reasonable choice for distributing the angles in the azimuthal direction for LWR lattice physics calculations. The same set of angles can be used for all energy groups or different quadratures can be used for different energy ranges. In general, the energy ranges that are of interest in lattice physics problems can be split into three separate distributions. This is

■ **Table 19**
Tabuchi–Yamamoto quadratures for modeling
polar motion

$P_N(\mu_j)$	j	$\pm\mu_j$	ω_j
$N = 2$	1	0.798184	1.000000
$N = 4$	1	0.363900	0.212854
	2	0.899900	0.787146
$N = 6$	1	0.166648	0.046233

	3	0.932954	0.670148

done in an effort to accurately capture the distinct features of neutron motion as the neutrons lose energy via scattering collisions.

A very large number of angles are required to accurately model neutron motion above 500 keV in order to capture the streaming effect exhibited between isolated fuel pellets. The streaming effect occurs as a result of the neutrons being born in the isolated fuel pellets at very high energies. As the neutrons stream away from the pellets, they suffer very few collisions, and those collisions that do take place tend to result in the neutron losing a substantial amount of energy and slowing down below the 500 keV threshold. Because of this, the angular flux is highly anisotropic and many azimuthal angles are needed in order to properly model the phenomenon. Below the 500 keV threshold, many collisions are taking place in the coolant and, to a lesser extent, in the oxide pellet itself and the angular flux becomes more isotropic such that fewer azimuthal angles are needed to capture the physics of the problem. To produce accurate results, as many as 128 evenly spaced azimuthal angles of motion should be used in all energy groups above 500 keV and 64 evenly spaced azimuthal angles of motion should be used in all energy groups below 500 keV.

In addition to using a different number of directions to model neutron streaming over different energy ranges, a different track spacing between parallel characteristics can be used over different energy ranges. The track spacing is dictated by the variation in cross sections from one material region of the problem to another. Above the up-scatter cut-off point of ~ 2 eV most material cross sections are of a similar size and flux gradients are considered to be relatively mild across the problem. This is true even across the resonance energy range. For energy ranges exhibiting a relatively flat flux profile, the characteristics can be widely spread apart without affecting the accuracy of the solution. As the flux begins to exhibit larger gradients, though, the characteristics must be much closer together in order to accurately capture the physics of the problem. Typical values for track separation are 1 to 2 mm in all groups above the up-scatter cut-off energy of 2 eV and 0.5 to 1 mm in all groups below the up-scatter cut-off energy.

The combination of variations in the number of azimuthal angles and the spacing of parallel characteristics typically produces three separate quadratures for the MoC solution. The three quadrature sets are listed in ▶ [Table 20](#). Note that a single quadrature set can be used, but should include the maximum detail from each of the three sets listed in ▶ [Table 20](#). That is, 128 azimuthal angles, two polar angles, and a characteristic separation of between 0.05 and 0.1 cm.

■ **Table 20**

Typical quadrature sets for different energy ranges

Range	Upper energy	Lower energy	I^\dagger	$J^{\dagger\dagger}$	d_j [cm]
Fast	20 MeV	500 keV	128	2	0.1–0.2
Epithermal	500 keV	2 eV	64	2	0.1–0.2
Thermal	2 eV	10^{-5} eV	64	2	0.05–0.1

[†] Number of azimuthal angles distributed over 2π rad.

^{††} Number of polar angles distributed over $\pi/2$ rad.

This will increase execution time with no improvement in accuracy, but will ease some of the bookkeeping within the code.

5.11 Acceleration Schemes for Two-Dimensional Calculations

The method of characteristics is notoriously slow to converge. Thankfully, this is not much of a problem for lattice physics calculations, for a couple of reasons. First, there exist a couple of sufficient acceleration schemes to speed up convergence. Second, there almost always exists a very good flux guess from which to begin the iteration process for a new calculation. Because of this second reason, the flux is rarely far from a converged solution and the acceleration scheme becomes less important. This is a consequence of the sheer number of state points that must be analyzed by the lattice physics code in order to provide the needed data to the three-dimensional nodal code. Each state point differs little from the previous point analyzed and the flux from one point is an excellent starting guess for the following point.

In this section, we will discuss two very reasonable and easily implemented acceleration schemes for the MoC. Both schemes are equally acceptable for single assembly lattice physics calculation. The CMFD scheme is superior for very large problems that contain multiple assemblies. Such calculations, though, are outside the scope of providing cross section data to three-dimensional nodal codes.

5.11.1 Coarse Mesh Rebalance

Coarse mesh rebalance, discussed in “Spatial acceleration” for one-dimensional slabs, is an adequate scheme for accelerating the spatial convergence rate of the two-dimensional characteristics solution. Once again, we want to solve the balance equation given in (462) and reproduced below,

$$\left[\sum_{m \in n} \Sigma_{r,m}^g \phi_m^g V_m + \sum_{s \in n} J_{\text{out},s,n}^g \right] \cdot f_n^g = \sum_{m \in n} q_m^g V_m + \sum_{s' \in n'} J_{\text{in},s',n'}^g \cdot f_{n'}^g \quad (520)$$

where m represents the *fine mesh* within a *cell*, n ; s represents the surfaces to the *cell*; and s' represents the surfaces to neighboring *cell*, n' . The coarse mesh are the *cells* of the problem, such as those illustrated in  Fig. 72. The solutions to the coupled balance equations are the

f_n^g values – one for each coarse mesh in the problem. Once the f_n^g values are known, the scalar flux can be modified as

$$\phi_m^g = \phi_m^g \cdot f_n^g \quad (521)$$

for all *fine mesh*, m , within *cell* n . The angular flux along the cell boundaries can also be modified,

$$\Phi_{k,i,j,m}^g = \Phi_{k,i,j,m}^g \cdot f_n^g \quad (522)$$

Equation (520) is solved using a red–black iteration scheme, just as was done for the two-dimensional coupling calculation in [Sect. 4](#). All values of f_n^g are initialized to unity to begin the iterations. With these initial values, a sweep is performed across the entire problem, solving the balance equation for the f_n^g values in all red *cells*. Following this, a second sweep is performed across the entire problem, solving the balance equation for the f_n^g values in all black *cells* – using the newly calculated f_n^g values in all red *cells* from the previous sweep. This process continues, un-accelerated, until the f_n^g value in all *cells* converge. The currents in (520) are calculated as

$$J_{\text{out},s,n}^g = \sum_j \sum_i \sum_k \Phi_{k,i,j,m}^g \cdot \omega_i \cdot \omega_j \cdot |\cos \varphi_i \cdot \sin \theta_j| \quad (523)$$

where i is an azimuthal angle; j is a polar angle; and k is a specific characteristic crossing the *cell*. The inward-directed current across a surface is calculated in the same way, but for the opposite azimuthal angles. For instance, along the east face of a *cell*, the outward-directed angles of motion extend from $-\pi/2$ to $\pi/2$, whereas the inward-directed angles of motion extend from $\pi/2$ to $3\pi/2$. Along the west surface to the cell, the situation is exactly the opposite.

The acceleration is performed following each inner iteration. For this acceleration scheme, there should only be one inner iteration performed per energy group. This scheme is not guaranteed to converge, so it is prudent to include a check for oscillations or divergence between applications. It is very rare that the scheme not converge for typical LWR lattice physics calculations. However, for somewhat extreme cases, such as 100% voided coolant cases at hot conditions, it is possible for the scheme to fail. If it appears that the scheme is diverging or oscillating, the scheme can simply be disengaged for the problem and the MoC iterations can continue un-accelerated. A more rigorous formulation can be found in Yamamoto (2005) as applied to generalized geometries, not just LWRs. In Yamamoto (2005), the CMR is applied to accelerate the solution both spectrally and spatially.

5.11.2 Coarse Mesh Finite Difference

A slightly different approach that can be used to accelerate both the spatial and spectral convergence rate simultaneously is the coarse mesh finite difference scheme (CMFD) that has been applied very successfully to nodal iterations (Smith 1983). Here, we are solving the diffusion equation using a diffusion coefficient that preserves the details from the MoC solution. The information needed to apply the CMFD scheme is similar to that needed to apply the CMR.

For lattice physics calculations, the CMFD acceleration technique is applied on a cell basis, just like the CMR technique (Smith and Rhodes 2000; Cho 2002; Joo et al. 2002; Smith and

Rhodes 2002; Clarno 2007). For a given energy group, the contents of a cell are homogenized using the typical formula (we have dropped the broad energy group symbol from the following variables for conciseness)

$$\bar{\Sigma}_{x,I} = \frac{\sum_{i \in I} \Sigma_{x,i} \phi_i V_i}{\bar{\phi}_I V_I} \quad (524)$$

where the average scalar flux in the cell is given by

$$\bar{\phi}_I = \frac{\sum_{i \in I} \phi_i V_i}{V_I} \quad (525)$$

and V_I is just the total volume of the cell.

To solve the diffusion equation, we make reference to the variables depicted in [Fig. 84](#). We want to solve for the flux in a given coarse mesh (i.e., cell), namely $\bar{\psi}_I$. Within each coarse mesh, the diffusion equation is given by

$$\frac{\partial J_I}{\partial u} + \bar{\Sigma}_{r,I} \bar{\psi}_I = S_I \quad (526)$$

where, along the surface of each coarse mesh, the current is defined as

$$J_I = -D_I \frac{\partial \psi(u)}{\partial u} \quad (527)$$

Here, u is the direction either along the x -axis or the y -axis; and $\bar{\Sigma}_{r,I}$ is the removal cross section, $\bar{\Sigma}_{r,I} = \bar{\Sigma}_{tr,I} - \bar{\Sigma}_{s,I}^{g \rightarrow g}$. The total source, S_I , is defined in the usual way (i.e., scatterings plus fissions).

Using the current from our MoC solution, that is, (523), we can define a diffusion coefficient along each surface of each cell that preserves the details from the fine-mesh calculation. For the u_i^+ surface we would have

$$\hat{D}(u_i^+) = -\frac{\hat{J}(u_i^+) + \bar{D}(u_i^+) \{\bar{\phi}_{I+1} - \bar{\phi}_I\}}{\bar{\phi}_{I+1} + \bar{\phi}_I} \quad (528)$$

Figure 84
Parameters for the CMFD scheme

where

$$\tilde{D}(u_I^+) = \frac{2\bar{D}_{I+1}\bar{D}_I}{\bar{D}_{I+1}\Delta u_I + \bar{D}_I\Delta u_{I+1}} \quad (529)$$

The current in (528) is the net current from the MoC solution. It is defined as $\hat{J}(u_I^+) = J_{\text{out}}(u_I^+) - J_{\text{in}}(u_I^+)$ along the east surface to the cell, and as $\hat{J}(u_I^-) = J_{\text{in}}(u_I^-) - J_{\text{out}}(u_I^-)$ along the west surface to the cell. That is, it is the net current moving in the positive u direction. The cell-averaged diffusion coefficient is calculated in the usual way, $\bar{D}_I = (3\bar{\Sigma}_{tr,I})^{-1}$. The surface current can be expressed by rearranging (529), to wit,

$$\hat{J}(u_I^+) = -\tilde{D}(u_I^+) \{\bar{\phi}_{I+1} - \bar{\phi}_I\} - \hat{D}(u_I^+) \{\bar{\phi}_{I+1} + \bar{\phi}_I\}.$$

Using these parameters, we solve the diffusion equation for the average flux in each cell,

$$\left\{ \hat{J}(x_I^-) - \hat{J}(x_I^+) \right\} - \left\{ \hat{J}(y_I^-) - \hat{J}(y_I^+) \right\} + \bar{\Sigma}_{r,I} \bar{\psi}_I V_I = S_I V_I \quad (530)$$

$$S_I = S_I^g = \sum_{g' \neq g} \bar{\Sigma}_{s,I}^{g' \rightarrow g} \psi_I^{g'} + \frac{\chi_I^g}{k^\infty} \sum_{g'} \nu \Sigma_{f,I}^{g'} \psi_I^{g'} \quad (531)$$

More information on acceleration techniques for the MoC can be found in Yamamoto (2005), Smith and Rhodes (2000), Cho (2002), Joo et al. (2002), Smith and Rhodes (2002), and Clarno (2007).

5.12 Treating Very Thin Cylindrical Regions

One of the few drawbacks with the method of characteristics is in its treatment of very thin, highly absorbing cylindrical regions. Unfortunately, these regions are very common in certain PWR fuel designs, where they arise in the form of a very thin layer of ZrB₂ sprayed onto the outside of fuel pellets as a burnable absorber, referred to as IFBA pellets. The layer is, on average, no thicker than 0.002 cm.

The issue is depicted in  Fig. 85, where three rays are illustrated to bisect the fuel pellet and the absorber coating. The rectangles depicted in the figure represent the area associated with the track lengths that bisect the absorber coating. In the case on the left, the characteristics are arranged in such a way that one of the tracks just happens to skim along the edge of the thin absorber region. In the case on the right, the characteristics are shifted ever so slightly and no track skims the edge of the thin absorber region. Because the region is so strongly absorbent, the solution is very sensitive to the length of track that bisects it and we will get two very different solutions to the situation depicted in the figure. This is highly undesirable. With our cyclic tracking method, the only way to truly avoid this sensitivity is to distribute characteristics with a spacing equal to the width of the region – 0.002 cm – which is out of the question.

An alternative solution to our dilemma is to homogenize the thin coating with the fuel pellet. If we have performed a pin-cell spectral calculation on this pin to generate a spectrum with which to condense cross sections, then we have a good flux distribution to use for the homogenization. Assuming that our flux from the pin-cell spectral calculation is represented

■ **Figure 85**
Characteristics skimming a thin, strongly absorbent region

as ϕ_{fuel}^g in the fuel pellet and ϕ_{absorber}^g in the absorber coating, where g is our fine-group energy structure, we first collapse the individual cross sections using the typical formula

$$\begin{aligned}\Sigma_{x,\text{fuel}}^G &= \frac{\sum_{g \in G} \Sigma_{x,\text{fuel}}^g \phi_{\text{fuel}}^g}{\sum_{g \in G} \phi_{\text{fuel}}^g} \\ \Sigma_{x,\text{absorber}}^G &= \frac{\sum_{g \in G} \Sigma_{x,\text{absorber}}^g \phi_{\text{absorber}}^g}{\sum_{g \in G} \phi_{\text{absorber}}^g}\end{aligned}\quad (532)$$

where G represents the broad-group energy structure. While we are collapsing cross sections, we must also collapse the flux in the two regions since we will need the flux to homogenize the broad-group cross sections of the two regions, to wit,

$$\begin{aligned}\psi_{x,\text{fuel}}^G &= \sum_{g \in G} \phi_{\text{fuel}}^g \\ \psi_{x,\text{absorber}}^G &= \sum_{g \in G} \phi_{\text{absorber}}^g\end{aligned}\quad (533)$$

Now we homogenize the two regions using flux and volume weighting to preserve the reaction rates

$$\bar{\Sigma}_x^G = \frac{\Sigma_{x,\text{fuel}}^G \psi_{\text{fuel}}^G V_{\text{fuel}} + \Sigma_{x,\text{absorber}}^G \psi_{\text{absorber}}^G V_{\text{absorber}}}{\psi_{\text{fuel}}^G V_{\text{fuel}} + \psi_{\text{absorber}}^G V_{\text{absorber}}}\quad (534)$$

After homogenizing the regions, we still want to maintain the true geometry of the pellet and the coating during the MoC solution in order to simplify the bookkeeping in the code. To account for this, the cross sections represented by (534) are applied to both the fuel pellet and the absorber coating.

Following the MoC solution, we must back out the true flux in the absorber coating and the fuel pellet. To do this, we first average the MoC flux in the fuel pellet and the absorber coating using a straightforward volume weighting

$$\bar{\phi}_{\text{fuel}}^G = \frac{\phi_{\text{fuel}}^G V_{\text{fuel}} + \phi_{\text{absorber}}^G V_{\text{absorber}}}{V_{\text{fuel}} + V_{\text{absorber}}} \quad (535)$$

With this average flux, we can superimpose the condensed flux from the pin-cell spectral calculation and obtain the true flux for each region,

$$\begin{aligned} \phi_{\text{fuel}}^G &= \frac{\psi_{\text{fuel}}^G}{\bar{\phi}_{\text{fuel}}^G} \cdot \left\{ \frac{\psi_{\text{fuel}}^G V_{\text{fuel}} + \psi_{\text{absorber}}^G V_{\text{absorber}}}{V_{\text{fuel}} + V_{\text{absorber}}} \right\} \\ \phi_{\text{absorber}}^G &= \frac{\psi_{\text{absorber}}^G}{\bar{\phi}_{\text{fuel}}^G} \cdot \left\{ \frac{\psi_{\text{fuel}}^G V_{\text{fuel}} + \psi_{\text{absorber}}^G V_{\text{absorber}}}{V_{\text{fuel}} + V_{\text{absorber}}} \right\} \end{aligned} \quad (536)$$

This approach works remarkably well to provide consistently accurate results when extremely thin cylindrical regions are present in the fuel design. Alternatively, this entire issue can be avoided by moving to a ray-tracing method based on macro-bands.

5.13 Final Comments

This section has presented a very detailed derivation of the method of characteristics, in its most fundamental, simplistic form. Within this derivation, it was assumed that scattering effects could be treated as being isotropic, with transport-corrected cross sections accounting for the majority of effects caused by anisotropic scattering. When analyzing a single lattice employing perfectly reflective or periodic boundaries, such an assumption is quite adequate – especially for neutron calculations, but even for gamma calculations. If particles are allowed to leak out of the system through the boundaries, though, this assumption may be invalidated.

It was also assumed that the use of a flat flux/flat source approximation was valid and would produce accurate results, so long as the fine-mesh were small enough to capture all flux gradient effects in the thermal groups. Once again, when analyzing a single lattice employing perfectly reflective or periodic boundaries, such an assumption is quite adequate. If multiple bundles are to be analyzed, or if large areas of water are to be included in the problem, such an assumption may be invalidated.

In any case, the fundamental concepts described in this section are contained in many of today's lattice physics codes and an understanding of this section should provide the reader with a reasonably good grasp of current lattice physics transport methods.

It is interesting to note that, in the not too distant past, the fine-mesh transport solution in a lattice physics code accounted for the overwhelming majority of computer resources (memory use and execution time). Back in the day, when it was common – almost necessary – for cross section libraries to be limited to 100 energy groups and 100 different isotopes, and when burnup chains were linearized, the fine-mesh transport solution could easily account for two-thirds of the total execution time, or more. In some current lattice physics codes employing a cross section condensation scheme, the fine-mesh transport solution accounts for less than one-third of the total execution time and is, by no means, limiting on memory requirements. The biggest

burden on computer resources in these lattice physics codes is in constructing the macroscopic scattering matrices from the microscopic data contained in the cross section library. Here, we are referring to the construction of a matrix containing possibly 600×600 elements from as many as 200 isotopes (if the contribution from fission products is included). This has to be done in every fuel region in the lattice. An equal amount of execution time can be spent solving the burnup chains in their matrix form. Like the calculation of the macroscopic scattering matrix, this has to be done in every fuel region of the lattice, which can easily exceed 200 unique regions in a BWR lattice containing 20 or so Gadolinium pins, each split into 10 or 12 multiple depletion rings. These two pieces of the lattice physics code – constructing macroscopic scattering matrices and solving the burnup matrix – can easily account for two-thirds of the total execution time of a modern lattice physics code.

6 Burnup Calculation

6.1 Objective

Nuclear fission is one of the principal mechanisms in the generation of energy from nuclear fuels. The composition of fuels varies during irradiation in a nuclear reactor core. In the vocabulary of reactor physics, the change in fuel composition due to nuclear fission, neutron capture, radioactive decay, and other factors, is referred to as “burnup.” The burnup of a nuclear fuel is different from the conventional concept of burnup, which is based on chemical reactions. Therefore, when uranium “burns” in a nuclear reactor core, there is no emission of CO_2 since the burnup of a nuclear fuel is based on nuclear reactions. While energy is released by changes in the chemical bonding states of materials in conventional burnup, in nuclear burnup, energy is generated by the changes in nuclear binding. If burnup is viewed as a “process of energy generation through changes in a material,” then nuclear fission can quite naturally be considered a burnup phenomenon. In this sense, the technical term burnup seems quite aptly and carefully chosen.

The properties of nuclear fuels depend on the composition of the fuel. The characteristics of the reactor core therefore undergo changes during burnup. In practice, precise prediction of core lifetime and reactor behavior during burnup is an essential part of reactor core analysis. In fact, the prediction accuracy of burnup calculations is a critical factor in the reactor analysis sequence.

In this section, the physics of the burnup of nuclear fuel is discussed. The fundamental theoretical basis for burnup phenomena will first be discussed, and then the major numerical solution schemes for solving the burnup equation will be presented. The burnup behavior of gadolinium, a burnable poison in nuclear fuel, is quite important in actual core analysis, but its behavior is somewhat complicated, requiring special treatment in numerical modeling and calculations. ➤ 6.4 will therefore be devoted to the treatment of gadolinium-bearing fuels. Finally, some discussion will be presented on power normalization, which plays an inevitable role in burnup calculations.

In reactor core analysis, there are two levels of burnup calculation, that is, burnup in lattice physics analysis, and burnup in core analysis. This section focuses on the former, that is, burnup calculation in lattice physics computations.

6.2 The Physics of Burnup and its Modeling

6.2.1 Phenomena during Burnup

During burnup in a nuclear reactor, the following phenomena occur in nuclear fuels:

Depletion of Fissile Nuclides (a)

The fissile nuclides (e.g., $^{235}_{92}\text{U}$, $^{239}_{94}\text{Pu}$) deplete during burnup due to fission reactions. This effect has a negative impact on fuel reactivity since the number of fissile nuclides decreases during burnup.

Conversion from Fertile Nuclide to Fissile Nuclide (b)

Fertile nuclides become fissile nuclides through neutron capture and beta decay, for example,

The conversion effect increases the number of fissile nuclides, and thus has a positive impact on fuel reactivity during burnup.

Production of Fission Products (c)

The fissions of fissionable nuclides yield various fission products. Since these fission products are neutron absorbers, they have a negative impact on fuel reactivity.

The above three phenomena, that is, (a)–(c), take place simultaneously in nuclear fuel during burnup. In thermal reactors (e.g., light water reactors), the conversion effect is rather small, and the absorption by fission products is large, due to the thermal neutron spectrum. Note that this conversion takes place by means of the resonance capture of fertile material in the epithermal energy region; thus, the conversion is generally small in thermal reactors.

Absorption cross sections of some fission products are large in the thermal energy region. Therefore, since the negative effects on reactivity ((a) and (c)) are large, and the positive effect (b) is small in thermal reactors, the multiplication factor of nuclear fuel decreases as burnup proceeds.

The above dynamic is different in typical fast reactors. Since fast neutrons dominate nuclear reactions in a fast reactor core, the conversion effect is much larger than it is in thermal reactors. Furthermore, the absorption by fission products is small due to the absence of thermal neutrons. Consequently, due to greater conversion (the positive reactivity effect) and smaller absorption by fission products (negative reactivity effect), the reduction of the multiplication factor of nuclear fuel during burnup becomes smaller than that in thermal reactors.

In addition to the above effects, which have a major impact on fuel reactivity, the following phenomena must also be considered as contributors to fuel reactivity:

Decay

Various nuclides are produced during burnup but many of them are unstable, so they are transformed into other nuclides through α -, β -decay, spontaneous fission, and other processes. This decay has a considerable impact on fuel reactivity, as will be described later.

Transmutation of Nuclides due to Neutron Absorption

Conversion is included in this category. During burnup, various reactions due to neutron absorption take place as follows:

- (n, 2n): neutron absorption followed by emission of two neutrons
- (n, 3n): neutron absorption followed by emission of three neutrons
- (n, 4n): neutron absorption followed by emission of four neutrons
- (n, γ): neutron absorption followed by emission of gamma radiation
- (n, p): neutron absorption followed by emission of a proton
- (n, d): neutron absorption followed by emission of a deuteron
- (n, t): neutron absorption followed by emission of a triton
- (n, α): neutron absorption followed by emission of an alpha particle
- Other

The transmutation of nuclides due to neutron absorption is very important, especially for burnup calculations of burnable poison in a light water reactor analysis. Burnable poison is used to flatten out the variations in reactivity during burnup and to improve the characteristics of the core neutronics. The burnable absorber nuclides loaded in a reactor core at the beginning of cycle (BOC) are depleted and converted to other nuclides during burnup through neutron capture. Thus, the negative reactivity of the burnable poison diminishes or disappears at the end of cycle (EOC); that is, the burnable poison is “burnt-out” at EOC.

The flattening of variations in reactivity provides several merits in actual core design. In the case of PWR, a higher reactivity of fresh fuel assemblies at BOC requires a higher boron concentration to suppress excess reactivity in the core. However, a high boron concentration may create problems related to water chemistry, for example, excess deposition of crud on the cladding. A high boron concentration may also have a negative impact on core safety, since the moderator temperature coefficient tends to be positive, and reactivity insertion during a boron dilution accident tend to be large. In the case of BWR, higher core reactivity may reduce the shutdown margin, making core design difficult. The above discussion clearly indicates the important role of burnable poison in light water reactor core design. In fact, a burnable poison is almost always used in light water reactor core designs, with a few exceptions (e.g., no burnable poison is used in the short operating cycle).

Boron, gadolinium, and erbium are the major burnable absorber materials in light water reactor designs. The actual implementation and design of these burnable poisons in a fuel assembly is a key topic in fuel design for which lattice physics computation is used.

6.2.2 Burnup Chain

Design and Setup of Burnup Chain

As described in the previous section, various transmutations of nuclides occur during burnup in a reactor core. In a burnup analysis, a series of nuclide changes is treated by the concept of a “chain,” since the transmutations of nuclides occur successively. In reactor physics calculations, this chain is known as the burnup chain. For example, the conversion from a fertile to a fissile nuclide, $^{238}\text{U} \rightarrow ^{239}\text{U} \rightarrow ^{239}\text{Np} \rightarrow ^{239}\text{Pu}$, is a typical burnup chain that appears in reactor analysis.

In general, burnup chains are classified in terms of the following nuclides:

- a. Heavy nuclides (Th, U, Pu, Am, Cm, etc.)
- b. Fission products (Xe, Sm, Pm, etc.)
- c. Burnable absorber or burnable poison nuclides (B, Gd, Er, etc.)

The actual nuclide transmutations in nuclear fuels are highly complicated, with several thousands of nuclides being produced and disappearing through various nuclear reactions. Since the direct modeling of such complex nuclide behavior is not feasible, lattice physics computation treats the specific nuclides that have significant or considerable impact on the characteristics of neutronics.

From the viewpoint of calculation accuracy, of course, detailed modeling is desirable; that is, the treatment of as many nuclides as possible. However, many cross section libraries for these nuclides must be prepared, and their effective cross sections must be evaluated in resonance calculations in order to treat the many nuclides. Since such detailed treatment is quite burdensome in terms of memory storage and computation time, the number of nuclides used in a burnup calculation must be selectively limited. In the case of a burnup calculation in a small configuration, for example, single pin-cell geometry or a fuel assembly, a very detailed burnup chain can be used. In actual reactor core calculations, however, the scale of the calculation configuration must be carefully assessed, as discussed below.

Let us assume that a set of burnup chains, which includes 300 nuclides, is used for a reactor core analysis. Note that a set of burnup chains with 300 nuclides is a detailed one in current burnup analysis. When the variations in nuclide number densities are tracked in each fuel pin, the required memory storage for a three-dimensional PWR whole-core analysis is evaluated as follows:

$$1[\text{byte/nuclide}] \times 300[\text{nuclides/burnup region}] \times 300[\text{burnup regions/fuel assembly(radial)}] \\ \times 193[\text{fuel assemblies/core}] \times 60[\text{meshes/fuel assembly(axial)}] = 10^9[\text{byte}].$$

The above rough estimate suggests that 1 GB of memory storage is necessary to hold the nuclide number densities when 300 nuclides are tracked in pin-by-pin whole-core analysis.

In order to reduce the computational burden, the number of nuclides explicitly (independently) treated in burnup calculations may be limited to the major nuclides that have a considerable impact on the neutronics characteristics. Those that have a lesser impact would be gathered and treated in an approximate manner as one or several groups. Fission products, in particular, are often modeled as several groups of pseudo fission product nuclides that comprise multiple fission products. The modeling of pseudo fission products depends on the burnup chain, and there are variations on this, ranging from a very simple one-group model (combine all fission products that are not explicitly treated), to a complicated model (which considers dependency on fissile nuclide, saturation, and the non-saturation behaviors of number density during burnup). For example, the MVP-BURN code, which is a continuous energy Monte Carlo code with burnup capability, has several burnup chains, as shown in [Table 21](#).

The burnup chain used in the MVP-BURN code is depicted in [Figs. 86–88](#).

In the case of a Monte Carlo burnup calculation, since continuous energy (point-wise) cross section data for each nuclide are stored in memory, utilization of a detailed burnup chain requires a larger amount of memory. Furthermore, the reaction rate estimate (tally) of each nuclide, which is inevitable in a burnup calculation, requires a longer computation time when

Table 21
Burnup chains implemented in the MVP-BURN code

Name	Number of heavy nuclides	Number of FPs	Number of pseudo FPs	Note

the number of nuclides in a calculation configuration is large. In general, therefore, the utilization of a simple burnup chain model that satisfies the purpose and accuracy requirements of the analysis is desirable. Note that “pseudo” treatment, which is sometimes used for fission products, is not usually applied to heavy nuclides; the less important heavy nuclides are simply omitted from the burnup chain.

Our discussion thus far has focused particularly on the neutronics characteristics, which is major objective of lattice physics computing. In high burnup and MOX fuels, however, evaluation of the source term, that is, the neutron/gamma source intensities and heat generation rate, becomes important for fuel storage and reprocessing. These source terms depend on the isotopic composition of the fuel. For example, the neutron source intensity and heat generation rate are generally dominated by ^{242}Cm , ^{244}Cm , and ^{238}Pu , respectively.

A dedicated code that has an extensive burnup chain, for example, ORIGEN2, is commonly used to estimate the source term, since the important nuclides may not be included in the burnup chain of a common lattice physics code, in which nuclides are selected from the point of view of neutronics. A detailed burnup analysis code such as ORIGEN2, however, applies an approximate treatment to the cross section of each nuclide. For example, ORIGEN2 has one-group cross section libraries that are generated and collapsed under the neutron spectra of several typical reactor types. Users can select a cross section library that is suitable for their analysis. Though various cross section libraries are provided, the neutron spectrum assumed for library generation may not well reproduce that of the analysis configuration. As a consequence, dedicated burnup analysis codes are not superior to lattice physics codes in terms prediction accuracy for nuclide number density.

The above discussion suggests that any new burnup chain developed for lattice physics computations might have capability of source term estimation. In fact, instead of pseudo fission products, most recent lattice physics codes adopt detailed burnup chains in which 20–30 heavy and 200–300 fission-product nuclides that are explicitly considered.

Evaluation of Fission-Product Yield

One of the most troublesome tasks in the design of a burnup chain is the evaluation of fission-product yields. The fission-product yield is given in a nuclear data file (e.g., the ENDF

Figure 86
Burnup chain of MVP-BURN code for heavy nuclides (Standard burnup chain) (Okumura et al. 2000, 2007)

■ Figure 89

Simplified chain for ^{105}Pd in the MVP-BURN code

fission-product data or the JNDC nuclear data library of fission products), in which the yield values for more than 1,000 fission products are given (McLane 2001; Ihara 1989). In contrast, just a few dozen to a few hundred fission products are independently treated in lattice physics codes. This difference (more than a thousand versus a few hundred) should be carefully taken into account when the fission-product yield is being set. A simple treatment that neglects the yields of nuclides not included in the burnup chain is not appropriate.

For example, let us consider the part of the burnup chain in [Fig. 87](#), namely $^{105}\text{Rh} \rightarrow ^{105}\text{Pd}$. This part of the burnup chain is expressed somewhat differently in the Simplified and the Developer chains of the MVP-BURN code, as shown in [Figs. 89](#) and [90](#).

In the Simplified chain, ^{105}Pd is produced directly from a fission reaction. But in the Standard chain shown in [Fig. 87](#), ^{105}Pd is partly produced from the beta decay of ^{105}Rh , and the rest is produced from a fission reaction. Finally, in the Developer chain, the production of ^{105}Pd has three paths: a neutron capture of ^{104}Pd , a beta decay of ^{105}Rh , and a fission reaction. The fission-product yields for these chains are compared in [Table 22](#).

[Table 22](#) clearly indicates that the yields of ^{105}Rh and ^{105}Pd are very different in the different burnup chains. In the Developer chain, the yields for ^{105}Rh and ^{105}Pd are very small (effectively zero). These are the independent yields, that is, the number of fission products directly produced from a fission reaction. In the Standard chain, though the yield for ^{105}Pd is the same as that from the Developer chain, ^{105}Rh has a larger yield of 9.63844×10^{-3} . This is the cumulative yield, which is obtained by summing the yields of the “upstream” fission products of ^{105}Rh , for example, ^{104}Ru and ^{105}Ru . In other words, the “upstream” fission products of ^{105}Rh are assumed to be immediately transformed into ^{105}Rh along the burnup chain. The cumulative yield is estimated based upon this consideration. A similar assumption is used for the Simplified chain, in which the upstream fission products of ^{105}Pd are immediately transformed into ^{105}Pd after a fission reaction.

The above discussion suggests that the estimation of fission yields (whether independent or cumulative) depends on the design of a burnup chain, and is a very complicated task. A common practice today is to adopt an ad hoc approach, that is, the utilization of small ad hoc codes that calculate the independent and cumulative yield.

Table 22
Yields of ^{105}Rh and ^{105}Pd in the burnup chains of the MVP-BURN code

Name	^{105}Rh	^{105}Pd
Developer	1.70062E-08	9.99776E-13
Standard	9.63844E-03	9.99776E-13
Simplified	–	9.63844E-03

Estimation of Cross Sections and Yields for Pseudo Fission Products

When the number of fission products in a burnup chain is small, the pseudo fission products should be used in order to maintain the prediction accuracy of the burnup dependency of fuel reactivity (Garrison and Roos 1962; Iijima and Yoshida 1982; Ikehara et al. 1998). The cross sections and yields of the pseudo fission products are evaluated and adjusted with the calculation results of a detailed burnup chain, for example, the Developer chain in the MVP-BURN code. Therefore, in a strict sense, the cross section and yield of pseudo fission products depend on the reactor types being analyzed. Different pseudo fission-product nuclides may therefore need to be prepared for different reactor types.

The utilization of a detailed burnup chain with many independent fission products reduces the importance of the pseudo fission products. For example, when 112 fission products are independently considered in a BWR burnup analysis, we can capture more than 98% of the neutron absorption by the fission products. In this case, the reactivity discrepancy caused by the utilization of pseudo fission products is less than $0.1\% \Delta k/k$ up to 100 GW d/t (Ikehara et al. 1998). Utilization of a more detailed burnup chain, such as the Developer chain of the MVP-BURN code, allows for the elimination of the pseudo fission product. If we take into account the ongoing improvements in computer platforms, the incorporation of a detailed burnup chain is recommended.

Branching Ratio

Some nuclides can produce different daughter nuclides after the decay of the neutron capture reaction. For example, ^{241}Am can be transformed into $^{242\text{m}}\text{Am}$ or ^{242}Am after the capture of a neutron. The ratio of branch (branching ratio) is inherent to the reaction and the nuclide. Though the branching ratio depends on the neutron energy, there are not many experimental results on this relationship. The branching ratio can therefore be a source of error in burnup calculations. Though the major sources of error in burnup calculations are sometimes considered to be the accuracy of the effective cross section and neutron spectrum, etc., the branching ratio can also be an important factor.

6.2.3 Burnup Equation

Burnup of a Fissile Nuclide

As a first step, a very simple burnup model is discussed here. The variation of the number density of ^{235}U number is treated as an example.

The variation of ^{235}U during burnup can be described by (537).

$$\frac{dN^{235}\text{U}(t)}{dt} = -N^{235}\text{U}(t) \times \sigma_a(t) \times \phi(t) \quad (537)$$

where

$N^{235}\text{U}(t)$: number density of ^{235}U [cm^{-3}],
 $\sigma_a(t)$: microscopic absorption cross section of ^{235}U (= capture + fission) [cm^2],
 $\phi(t)$: neutron flux [$\text{cm}^{-2} \text{s}^{-1}$].

Equation (537) indicates that the reduction rate of the fissile (i.e. ^{235}U) number density is given by the absorption reaction rate. Note that the absorption includes not only the fission reaction but also the capture reaction. In an actual situation, the production of ^{235}U (e.g., by the neutron capture of ^{234}U) and its decay may be considered, but they are omitted here for the sake of simplicity. Note that the reaction rate is given by (538).

$$R = N \times \sigma \times \phi \quad (538)$$

where

R : reaction rate (e.g., [$\text{cm}^{-3} \text{s}^{-1}$]),
 N : number density (e.g., [cm^{-3}]),
 σ : microscopic cross section (e.g., [cm^2]),
 ϕ : neutron flux (e.g., [$\text{cm}^{-2} \text{s}^{-1}$]).

When the neutron flux and microscopic absorption cross section are assumed to be constant, (537) can be written as follows:

$$\frac{dN^{235}\text{U}(t)}{dt} = -N^{235}\text{U}(t) \times \sigma_a \times \phi \quad (539)$$

Equation (539) is a basic differential equation and its solution is analytically expressed by

$$N^{235}\text{U}(t) = N^{235}\text{U}(0) \exp(-\sigma_a \phi t) \quad (540)$$

In common burnup analyses, the initial number density, the microscopic cross section, and neutron flux are given as input data. Therefore, the number density of ^{235}U is expressed as a function of burnup time. For example, when the microscopic absorption cross section of ^{235}U and the neutron flux are approximately given by 1,000 [barn] (=1,000 $\times 10^{-24}$ [cm^2]) and 10^{13} [$\text{cm}^{-2} \text{s}^{-1}$], respectively, the variation of the number density of ^{235}U is expressed by

$$N^{235}\text{U}(t) = N^{235}\text{U}(0) \exp(-10^{-8}t) \quad (541)$$

where unit of t is [s].

In the above derivation, the microscopic cross section and neutron flux are assumed to be constant. However, these parameters generally depend on the burnup time, so (540) cannot be directly applied to a reactor core analysis. In actual burnup analyses, the microscopic cross section and neutron flux are assumed to be constant during a short period Δt , and number density is evaluated by

$$N^{235}\text{U}(t + \Delta t) = N^{235}\text{U}(t) \exp(-\sigma_a \phi \Delta t) \quad (542)$$

This is the fundamental temporal discretization in burnup calculation. Further discussion will be provided in [6.3](#).

Burnup Equation with Multiple Nuclides

In the previous section, we focused on a simple burnup equation with a nuclide. In our next step, more complicated burnup equations with multiple nuclides ($^{238}\text{U} \sim ^{241}\text{Pu}$) will be discussed. These burnup equations are important in common reactor analyses as conversion reactions. The burnup equations for these nuclides are as follows:

$$^{238}\text{U} : \frac{dN^{238}\text{U}(t)}{dt} = -N^{238}\text{U}(t) \times \sigma_a^{238}\text{U} \times \phi \quad (543)$$

$$^{239}\text{Pu} : \frac{dN^{239}\text{Pu}(t)}{dt} = -N^{239}\text{Pu}(t) \times \sigma_a^{239}\text{Pu} \times \phi + N^{238}\text{U}(t) \times \sigma_c^{238}\text{U} \times \phi \quad (544)$$

$$^{240}\text{Pu} : \frac{dN^{240}\text{Pu}(t)}{dt} = -N^{240}\text{Pu}(t) \times \sigma_a^{240}\text{Pu} \times \phi + N^{239}\text{Pu}(t) \times \sigma_c^{239}\text{Pu} \times \phi \quad (545)$$

$$^{241}\text{Pu} : \frac{dN^{241}\text{Pu}(t)}{dt} = -N^{241}\text{Pu}(t) \times \sigma_a^{241}\text{Pu} \times \phi + N^{240}\text{Pu}(t) \times \sigma_c^{240}\text{Pu} \times \phi \quad (546)$$

Note that decays are omitted for the sake of simplicity. Though ^{239}Pu is generated from ^{238}U through ^{239}U and ^{239}Np , it is assumed to be produced directly from ^{238}U .

Care should be taken that both the absorption and capture cross sections are used in (543)–(546). The vanishing rate of a nuclide is given by its absorption rate, but the conversion rate of a nuclide, for example, transmutation from ^{238}U to ^{239}Pu , is given by the capture rate. Therefore, the absorption cross section is used for the vanishing term and the capture cross section is used for the production term, which corresponds to a conversion from an ancestor nuclide.

As described previously, since microscopic cross sections, neutron flux, and initial number densities are given as input parameters, variations in the number densities of $^{238}\text{U} - ^{241}\text{Pu}$ can be evaluated by the analytical solutions in (543)–(546). Though this example treats only four nuclides, the analytical solutions are highly complicated. In an actual burnup analysis, the number of nuclides is much larger than in the above example.

Burnup Equation in General Form

Based on the discussion in this section so far, we will now derive a general burnup equation in which the production and disintegration of nuclides are considered. In general, the production or disintegration of a nuclide is described by (547)

$$\frac{dN_i}{dt} = \text{production rate} - \text{absorption rate} - \text{decay rate} \quad (547)$$

Equation (547) is written in the form of a burnup equation as follows:

$$\frac{dN_i}{dt} = \sum_j \gamma_{ji} \sigma_{f,j} N_j \phi + \sigma_{c,i-1} N_{i-1} \phi + \sum_k \lambda_{ki} N_k - \sigma_{a,i} N_i \phi - \lambda_i N_i \quad (548)$$

where

N_i : number density of nuclide i [cm^{-3}],

γ_{ji} : yield of nuclide i from a fission of nuclide j [-],

- $\sigma_{f,j}$: microscopic fission cross section of nuclide j [cm^2],
 ϕ : neutron flux [$\text{cm}^{-2} \text{s}^{-1}$],
 $\sigma_{c,i-1}$: capture cross section of nuclide $i - 1$ [cm^2],
 λ_{ki} : decay constant of nuclide k to nuclide i [s^{-1}],
 λ_i : decay constant of nuclide i [s^{-1}],
 $\sigma_{a,i}$: absorption cross section of nuclide i [cm^2].

The first term on the right side of (548) shows the direct production from a fission. When the nuclide i is not a fission product, this term is zero. The second term is the production due to neutron capture, that is, (n, γ) reaction. The third term is the production due to decay of other nuclides, which considers α - and β -decays. The fourth and last terms are the disintegration by the neutron absorption, and the decay, respectively. Note that (548) is not truly rigorous since some nuclear reactions have been omitted. For example, $(n, 2n)$, $(n, 3n)$, and (n, p) reactions are not taken into account. If these reactions are important, they would be also considered as additional terms in (548).

Equation (548) is an extension of the burnup equation, as discussed in this section so far, and is a differential equation of the first order (Bateman 1910). When the number densities of nuclides are considered as a vector, (548) can be written in a more general form:

$$\frac{d\vec{N}}{dt} = \mathbf{A}\vec{N} \quad (549)$$

where

- \vec{N} : vector of nuclide number density,
 \mathbf{A} : the burnup matrix.

When the nuclides in a vector \vec{N} are arranged in order of atomic mass (light fission products appear first, then heavy fission products, and finally heavy nuclides), the typical structure of the burnup matrix \mathbf{A} is that shown in  Fig. 91.

The analytical solution of (549) is formally given by the following formula, when the element of the burnup matrix is constant.

$$\vec{N}(t) = \exp(\mathbf{A}t)\vec{N}(0) \quad (550)$$

Equation (550) is a natural extension of (540), which is derived for a single nuclide. The term $\exp(\mathbf{A}t)$ is called the matrix exponential, but its analytical expression for a general case cannot, unfortunately, be obtained. For example, when the rank of matrix \mathbf{A} is two, $\exp(\mathbf{A})$ is given as follows:

$$\text{MatrixExp} \left[\begin{pmatrix} a & b \\ c & d \end{pmatrix} \right] = \begin{pmatrix} \frac{e^{\frac{a+d}{2}} \left(\alpha \cosh\left(\frac{\alpha}{2}\right) + (a-d) \sinh\left(\frac{\alpha}{2}\right) \right)}{\alpha} & \frac{2be^{\frac{a+d}{2}} \sinh\left(\frac{\alpha}{2}\right)}{\alpha} \\ \frac{2ce^{\frac{a+d}{2}} \sinh\left(\frac{\alpha}{2}\right)}{\alpha} & \frac{e^{\frac{a+d}{2}} \left(\alpha \cosh\left(\frac{\alpha}{2}\right) + (d-a) \sinh\left(\frac{\alpha}{2}\right) \right)}{\alpha} \end{pmatrix}$$

where $\alpha = \sqrt{(a-d)^2 + 4bc}$.

The above result suggests that when the number of nuclides is from several dozen to a few hundred, it is impractical to seek a direct solution through the analytical approach; some approximations should be used in order to practically obtain the analytical solution, as will be discussed later. Therefore, in an actual burnup calculation, the numerical solution of (550) is necessary.

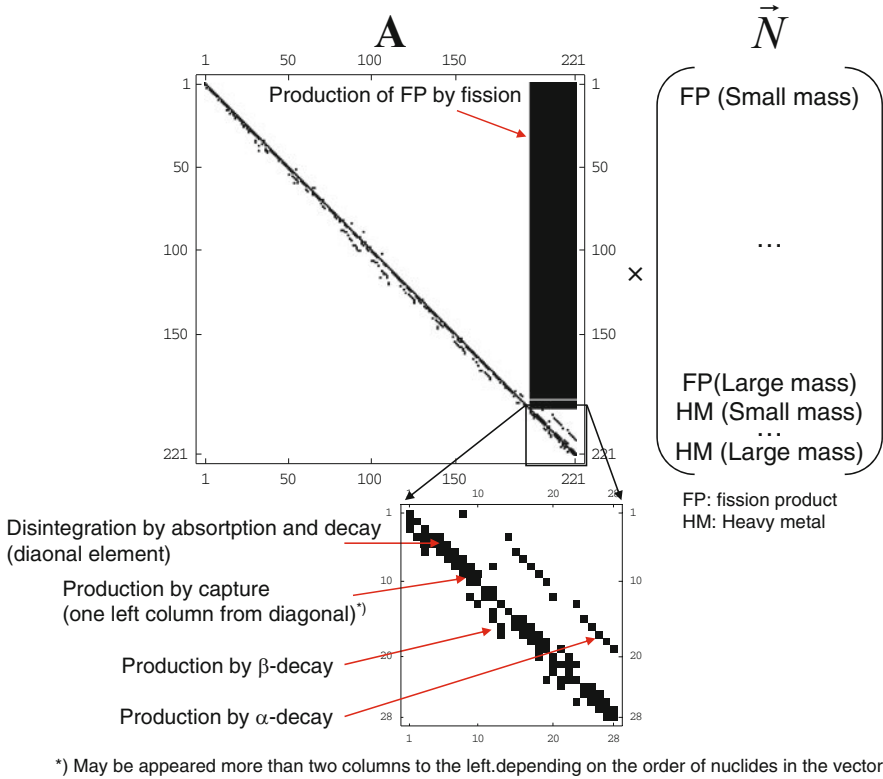

Figure 91
Typical structure of a burnup matrix

6.2.4 Burnup, Burnup Time, and Normalization of Neutron Flux

Burnup and Burnup Time

Burnup is expressed as the cumulative energy output per unit weight of the initial heavy metal loading. Since the cumulative energy release from a nuclear fuel is very large, MWd/t or GWd/t is commonly used as the unit of burnup. ISO states that “M” (mega, 10^6), “G” (giga, 10^9), and “W” (Watt) must be written in upper case letters, while “d” (day) and “t” (ton) must be written in the lower case. The value of 1 MWd/t indicates that 1 t of heavy metal sustains 1 MW energy production for 1 d, and that a value of 1 GWd/t shows that 1 t of heavy metal sustains 1 GW energy production for 1 d.

One must be careful when defining the weight of the heavy metal used in burnup. Since the weight of heavy metal diminishes during burnup due to fission reactions, the weight of the heavy metal at initial loading (i.e., beginning of life) is used for the definition of a burnup unit.

In burnup calculations, not only burnup (e.g., MWd/t) but also burnup time (e.g., in second) is important. In actual in-core fuel management calculations, the planned cycle length is given

as burnup time (days or months). The conversion of these two parameters (burnup and burnup time) is therefore quite important. The conversion of units can be carried out as follows:

- a. Conversion from Burnup Time (e.g., Day) to Burnup (e.g., MWd/t)

$$\text{Burnup (MWd/t)} = \text{Thermal output (MW)} \times \text{duration (day)} \div \text{heavy metal weight (t)}$$

Note that the initial (beginning of life) value of the heavy metal weight should be used in the above relationship. The thermal output and the initial heavy metal weight of a fuel assembly for unit axial length are usually used in lattice physics computations, while those for the entire core are used in core calculations.

- b. Conversion from Burnup to Burnup Time

$$\text{Duration (day)} = \text{Burnup (MWd/t)} \div \text{Thermal output (MW)} \times \text{Heavy metal weight (t)}$$

Normalization of Neutron Flux

The neutron transport calculation in a lattice physics computation is carried out as an eigenvalue calculation; thus, the neutron flux is obtained as a relative value. However, the absolute value of the neutron flux is necessary in order to perform the burnup calculation. Normalization of the neutron flux to an absolute value is performed as follows:

1. Integrate the thermal output by fission reaction over the entire configuration.
2. Evaluate the normalization factor by (input thermal output)/(integrated thermal output).
3. Normalize the neutron flux by the normalization factor obtained in (2).

Normalization of the neutron flux and the conversion between burnup time and burnup can be sources of error. Furthermore, since errors related to these calculations are often not apparent, care must be taken in actual lattice physics/in-core fuel management calculations. The following points in the analyses should be checked:

- a. Unit of thermal output (W/kW/MW)

The input unit of thermal output depends on the codes used in the calculation. Some lattice physics/core calculation codes may use non-SI units.

- b. Specification of power normalization (whole core, an assembly, an assembly per unit axial height, power density, etc.)

Care must be taken with the power normalization input of a lattice physics code. The power normalization input greatly depends on the lattice physics codes, and various specifications are possible, that is, thermal output for a whole assembly, power linear density for fuel assembly or fuel pin, power density per unit heavy metal weight (W/gHM), and power density per unit volume (W/cm³). One should be careful regarding the specification used in the lattice physics code for the analysis.

- c. Specification of Heavy Metal Weight

In the USA, a non-SI unit, for example, short ton (st) may be used instead of ton (t). Since the difference between the two is not very large (1 st = 0.907 t), it is quite difficult to find out their discrepancy in a burnup calculation. However, when the conversion from MWd/t to d, or d to MWd/t is carried out with an incorrect weight unit, a difference of approximately 10% takes place, which is completely unacceptable in actual in-core fuel management calculations.

Furthermore, in lattice physics and core calculations, the precise value of the total heavy metal weight is necessary in order to estimate burnup. We would again emphasize

here that the initial heavy metal weight is used for burnup calculations. In the evaluation of heavy metal weight, detailed specifications of the fuel assembly should be taken into account. For example, a gadolinia-bearing fuel rod contains less heavy metal than an ordinary fuel rod without burnable poison. Fuel assemblies from different fuel vendors may have different heavy metal weights. Since heavy metal weight has a direct impact on the value of a burnup, it should be accurately calculated with this in mind.

d. Lattice/Core Volume

Since the total thermal output is calculated through the integration of power density over configuration, the volume of the calculation configuration is important. If an inaccurate volume is given, the normalized power will reflect that discrepancy.

As discussed above, there can be various reasons for wrong power normalization, that is, an inaccurate estimate of the absolute value of the neutron flux. Since common lattice physics codes internally use both burnup and burnup time, they are both printed in the output list. Therefore, when the specification for burnup is given in MWd/t or GWd/t, the burnup time (day) should be confirmed. The inverse, of course, is also true: when the burnup time is used in the input data, the burnup in units of MWd/t or GWd/t should be checked. This double checking is very useful for preventing errors related to burnup specifications.

6.3 Numerical Scheme

6.3.1 Potential Causes of Error in a Numerical Solution

As discussed in the previous subsections, a general solution for the burnup equation is given by (550). However, it is difficult to obtain a general analytic solution of (550) that can be used for numerical calculations. A numerical solution is therefore inevitable in practical burnup calculations. Before we present a detailed discussion of a numerical solution, potential causes of error in a numerical solution for the burnup equation are discussed below.

Error in Reaction Rate (Production, Absorption, and Decay Rates)

The microscopic reaction rate (e.g., $\sigma_a(t)\phi(t)$) is given as the product of a microscopic cross section and the neutron flux. In order to accurately evaluate microscopic reaction rates, effective microscopic cross sections and the neutron fluxes in burnup regions must be precisely evaluated. However, since precise evaluation of these parameters is still a major research topic in reactor physics, some errors are still inevitable when present calculation methods are used. This is especially true for nuclides with resonances, in which the resonance interference effect and other factors can become a source of error. Furthermore, the number densities of resonant nuclides (especially fission products and higher heavy nuclides) vary during burnup, so the magnitude of the self-shielding effect also changes. In the beginning of life, their self-shielding effect is very small, and infinite-dilute treatment is appropriate. But the self-shielding effect gradually becomes larger as the burnup proceeds, so it must be accurately taken into account.

Temporal Discretization Error of the Differential Equation of Burnup Equation

In order to numerically solve the differential equation, temporal discretization may be necessary, which introduces some error. This issue will be discussed later in more detail.

Temporal Discretization Error in Reaction Rates of Burnup Equation

The reaction rates that appear in the burnup equation depend on the burnup time, since both the microscopic cross section and neutron flux vary during burnup. They are usually assumed to be constant, however, within a particular time-step in the numerical solution of the burnup equation. This assumption introduces some error in the reaction rates used in the burnup equation. The discrepancy could be large when the temporal variation of the reaction rate is large. A detailed discussion of this point will be offered in the latter part of this section.

Normalization Error of Thermal Output

As described previously, the neutron flux used in a burnup calculation should be an absolute value rather than the relative one obtained in the eigenvalue calculation. The absolute value of the neutron flux is normalized with the thermal output of a reactor. The thermal output of an actual reactor is estimated by the heat balance of the primary cooling system. Since it requires measurement values for the inlet/outlet temperatures, the flow rate of the primary coolant and so on, these measured values contain errors. Therefore, the thermal output of a reactor core based on the measured value may also include some uncertainty. Consequently, the absolute neutron flux evaluated from the measured core thermal output may also be in error. Generally speaking, though the error in the core thermal output is not very large, it is nonetheless a potential cause of error in the burnup analysis.

Error in Initial Composition of Fuel

The initial composition of the fuel can be a source of error in burnup calculation and is often overlooked. Actual fuels inevitably have fluctuations in their properties, for example, ^{235}U enrichment and heavy metal loading. The tolerances of these fluctuations in the manufacturing process are set based on their impact upon the neutronics properties. Therefore, they have a limited impact on core behavior, for example, core k -effective. That said, fluctuations in the initial fuel composition may not be negligible in regard to the calculation of nuclide number densities, which are often required in the post-irradiation examination (PIE) of fuel assemblies. An error in initial number density has an especially large impact on nuclides whose number density is small. In any case, the nominal value of the fuel's isotopic composition should not be used without cross-checking the mill-sheet.

6.3.2 General Remarks on Numerical Solutions for the Burnup Equation

The general form of the burnup equation is (549) and its solution is formally given by (550). Solution methods for the burnup equation have long been the subject of investigation (England 1962; Ball and Adams 1967; Lapidus and Luus 1967; Vondy 1962; Bell 1973; Tasaka 1977), and the major results of this inquiry are implemented in the ORIGEN2 code, which is a dedicated burnup analysis code for general purposes (Croff 1980). The reference manual of the ORIGEN2 code well summarizes the numerical solution methods for the burnup equation, and also provides useful information. Since the numerical methods used in the ORIGEN2 code are sophisticated, many burnup calculation codes adopt the one used in the ORIGEN2 code.

In fact, this type of burnup equation, that is, the first-order differential equation, has frequently appeared not only in the field of reactor physics, but also in the fields of physics, chemistry, economics, and systems analysis. Studies of this type of equation have also been independently carried out in the field of applied mathematics. Moler and Loan (2003) summarizes the results of the investigations in this field, and reviews various methods used to solve the matrix exponential, that is, (550). Though more than 20 methods are described by Moler and Loan (2003), only 3~4 of them have been applied in the field of reactor physics.

In the following sections, a fundamental method to solve the differential equation (the Euler method), and typical numerical solutions used in burnup analysis (the Runge-Kutta method, the matrix exponential method, the matrix decomposition method, the Bateman method) are described. Furthermore, the Padé approximation, which is a general numerical method used to solve the matrix exponential, and the Krylov subspace method, which is suitable for estimating the matrix exponential of a sparse matrix, are also explained.

Note that the microscopic reaction rate ($\sigma\phi$) is assumed to be constant throughout a particular burnup step. In other words, the elements of burnup matrix \mathbf{A} remain constant during a burnup step. A consideration of variations in the microscopic reaction rate will be presented in [6.3.11](#).

6.3.3 The Euler Method

The Euler method is a quite simple numerical method based on the finite-difference scheme. When (549) is differentiated with respect to the temporal variable, we obtain (551):

$$\frac{d\vec{N}}{dt} \approx \frac{\vec{N}^{l+1} - \vec{N}^l}{\Delta t} = \mathbf{A}\vec{N}^l \quad (551)$$

where l shows the number of burnup steps. Equation (551) can be transformed into the following:

$$\vec{N}^{l+1} = (\mathbf{I} + \mathbf{A}\Delta t)\vec{N}^l \quad (552)$$

where \mathbf{I} shows the unit matrix. Since the value of \vec{N}^l is known (input values), the nuclide number densities at $l + 1$ step can be obtained by (552).

Equation (549) can be also differentiated as (553):

$$\frac{d\vec{N}}{dt} \approx \frac{\vec{N}^{l+1} - \vec{N}^l}{\Delta t} = \mathbf{A}\vec{N}^{l+1} \quad (553)$$

Equation (553) can be transformed into (554)

$$\vec{N}^{l+1} = (\mathbf{I} - \mathbf{A}\Delta t)^{-1}\vec{N}^l \quad (554)$$

The nuclide number densities at step $l + 1$ can be obtained by (554).

The numerical method shown in (551) and (552) is an explicit method, and that of (553) and (554) is an implicit method. Though the computation time for a burnup step is short in the explicit method, the time-step size must be fine in order for a reliable result to be obtained. When a coarser burnup step is used in the explicit method, we often encounter numerical instability. In the case of the implicit method, the inverse of the matrix, that is, $(\mathbf{I} - \mathbf{A}\Delta t)^{-1}$, is

necessary, so that a longer computation time is required for a complicated burnup chain. However, the numerical stability of the implicit method for a coarse burnup step is much higher than that of the explicit method.

Temporal discretization errors from both methods diminish as finer burnup step sizes are used in calculations. However, since the number of burnup steps to achieve a particular burnup is increased with a finer burnup step, there can be a considerable accumulation of round-off errors in the numerical solution. Furthermore, the computation time naturally increases with an increasing number of burnup steps. The appropriate burnup step should be chosen with consideration for these observations. Note that though the Euler method is a simple numerical method, it does not offer a high degree of accuracy under practical calculation conditions. For this reason it is not usually used for actual lattice physics computations.

6.3.4 The Runge–Kutta Method

The Runge–Kutta method is one of the most widely used numerical methods applied to differential equations, and is frequently offered as illustrative material for lectures on numerical methods. Though there are several formulations for the Runge–Kutta method, the second- or fourth-order Runge–Kutta methods are commonly used for numerical calculations.

In the second-order Runge–Kutta method, (555)–(557) are used:

$$\vec{d}_1 = \frac{d\vec{N}}{dt}(t^l, \vec{N}^l) \Delta t = \mathbf{A} \vec{N}^l \Delta t \quad (555)$$

$$\vec{d}_2 = \frac{d\vec{N}}{dt} \left(t^l + \frac{\Delta t}{2}, \vec{N}^l + \frac{\vec{d}_1}{2} \right) \Delta t = \mathbf{A} \left(\vec{N}^l + \frac{\vec{d}_1}{2} \right) \Delta t \quad (556)$$

$$\vec{N}^{l+1} = \vec{N}^l + \vec{d}_2 \quad (557)$$

where $\frac{d\vec{N}}{dt}(t^l, \vec{N}^l)$ shows $\frac{d\vec{N}}{dt}$ at time t^l and number density \vec{N}^l .

The governing concept of the Runge–Kutta method is shown in  Fig. 92: the gradient at the midpoint of burnup steps is estimated by (556), and is used to obtain the number density

 **Figure 92**
Concept of the second-order Runge–Kutta method

at the next step. Since the gradient at the midpoint of a burnup step gives better accuracy than that at the beginning, the calculation accuracy exceeds that of the Euler method, which uses the gradient at the beginning of the burnup step.

The fourth-order Runge–Kutta method utilizes the following equations:

$$\vec{d}_1 = \frac{d\vec{N}}{dt}(t^l, \vec{N}^l)\Delta t = \mathbf{A}\vec{N}^l\Delta t \quad (558)$$

$$\vec{d}_2 = \frac{d\vec{N}}{dt}\left(t^l + \frac{\Delta t}{2}, \vec{N}^l + \frac{\vec{d}_1}{2}\right)\Delta t = \mathbf{A}\left(\vec{N}^l + \frac{\vec{d}_1}{2}\right)\Delta t \quad (559)$$

$$\vec{d}_3 = \frac{d\vec{N}}{dt}\left(t^l + \frac{\Delta t}{2}, \vec{N}^l + \frac{\vec{d}_2}{2}\right)\Delta t = \mathbf{A}\left(\vec{N}^l + \frac{\vec{d}_2}{2}\right)\Delta t \quad (560)$$

$$\vec{d}_4 = \frac{d\vec{N}}{dt}(t^l + \Delta t, \vec{N}^l + \vec{d}_3)\Delta t = \mathbf{A}(\vec{N}^l + \vec{d}_3)\Delta t \quad (561)$$

$$\vec{N}^{l+1} = \vec{N}^l + \frac{\vec{d}_1 + 2\vec{d}_2 + 2\vec{d}_3 + \vec{d}_4}{6} \quad (562)$$

Though the governing concept of the fourth-order Runge–Kutta method is similar to that of the second-order method, the “average gradient” between burnup steps is estimated in a more sophisticated manner, as shown in  Fig. 93.

The accuracy of the fourth-order Runge–Kutta method is high and its computation time is short. Furthermore, since it can handle any form of burnup matrix, it can be applied to very complicated burnup chains. The above features make the fourth-order Runge–Kutta method a practical numerical method for the burnup equation, which is adopted by some lattice physics codes (Morimoto et al. 1989).

 Figure 93

Concept of the fourth-order Runge–Kutta method

6.3.5 The Matrix Exponential Method

The matrix exponential method directly performs the numerical calculation of (550), which is a general solution of the burnup equation. The matrix exponential can be evaluated by the Taylor series expansion as follows:

$$\exp(\mathbf{A}\Delta t) = \mathbf{I} + (\mathbf{A}\Delta t) + \frac{(\mathbf{A}\Delta t)^2}{2!} + \frac{(\mathbf{A}\Delta t)^3}{3!} + \dots \quad (563)$$

Since the evaluation of (563) directly gives a general numerical solution to the burnup equation, the matrix exponential method seems to be an ideal numerical method. In actual computation, however, the convergence of the expansion series given in (563) can pose a numerical problem. For example, let us numerically estimate the value of $\exp(-100)$ by applying the Taylor series expansion:

$$\exp(-100) = 1 + (-100) + \frac{(-100)^2}{2!} + \frac{(-100)^3}{3!} + \dots \quad (564)$$

Note that the value of $\exp(-100)$ is approximately 4×10^{-44} . The salient point is whether or not the present value can be obtained through the numerical computation of (564). The actual numerical computation shows that the maximum value of a term on the right side of (564) appears to be approximately $n = 100$, that is, $(-100)^{100}/100! \sim 1 \times 10^{42}$. Therefore, in order to estimate $\exp(-100)$ with five significant digits, at least $42 + 44 + 5 = 92$ significant digits will be necessary during computation, due to the severe round-off error. The number of digits in double-precision calculations in common computer languages (e.g., Fortran, C, C++) is 16, and so 92 significant digits is for all purposes impractical.

A similar consideration becomes relevant in the evaluation of (563). Roughly speaking, the diagonal elements, that is, absolute value of the disintegration term due to absorption and decay, are largest in matrix \mathbf{A} . When a burnup matrix is a diagonal matrix, its matrix exponential can be obtained through exponentials of the diagonal elements. Therefore, the convergence of (563) is dominated by the largest diagonal elements. In other words, when short-lived nuclides exist in the burnup chain, the absolute values of these disintegration terms ($-\lambda - \sigma_a \phi$) in the diagonal position of the burnup matrix become large, so that the convergence of the Taylor series expansion becomes slower. Note that a higher absorption reaction could have a similar impact on a numerical calculation, but a large decay constant is far more important in actual burnup calculations.

To address this more precisely, the maximum norm of burnup matrix \mathbf{A} must be considered. When the norm of a matrix is defined by (565), the maximum (absolute) term that appears in the Taylor series expansion of (563) does not exceed $(|\mathbf{A}|\Delta t)^n/n!$, where n is the largest integer that does not exceed $|\mathbf{A}|\Delta t$ (Lapidus and Luus 1967).

$$|\mathbf{A}| = \min \left\{ \max_i \sum_j |a_{ij}|, \max_j \sum_i |a_{ij}| \right\} \quad (565)$$

In the ORIGEN2 code, (566) is used to limit the value of $|\mathbf{A}|\Delta t$ (Croff 1980):

$$|\mathbf{A}|\Delta t \leq -2 \ln(0.001) \leq 13.855 \quad (566)$$

In this case, the maximum value of $(|\mathbf{A}|\Delta t)^n/n!$ is obtained at $n = 13$, which is approximately 1.1×10^5 . When double-precision calculations (16 significant digits) are used for the numerical

computation of (563), the elements of the matrix exponential for the burnup matrix have significant digits up to 10^{-11} . Therefore, when five significant digits are required in calculation results, a value as small as 10^{-6} can be treated by applying the above limitation.

The limitation of (566) can be satisfied by forcing $\exp(-d\Delta t) < 0.001$, where d is the maximum (absolute) value of the diagonal elements. Since d is the disintegration rate (= absorption rate + decay rate), the value of $|\mathbf{A}|$ does not exceed $2d$. For example, in the case of ^{135}Xe , it transforms into ^{136}Xe due to neutron capture or into ^{135}Cs due to decay. Let us assume that the diagonal element of a burnup matrix for ^{135}Xe is -1.0 , and the transformation ratio to ^{136}Xe , and the decay ratio to ^{135}Cs , are 0.4 and 0.6 , respectively. In this case, the summation of absolute values of the row elements for ^{135}Xe is $|-1.0| + |0.4| + |0.6| = 2.0$, which corresponds to twice the absolute value of the diagonal element (-1.0). Consequently, we have the following relationship:

$$|\mathbf{A}|\Delta t \leq 2d\Delta t \leq -2\ln(\exp(-d\Delta t)) \leq -2\ln(0.001) \quad (567)$$

In the case of actual burnup calculations, the above relationship can be satisfied by limiting d or Δt . The most direct approach is to limit Δt as follows:

$$\Delta t \leq \frac{-2\ln(0.001)}{2d} \quad (568)$$

The apparent drawback of this method is that an impractically small Δt may be obtained for a large d . For example, in the case of the ‘‘Developer’’ burnup chain of the MVP-BURN code, the maximum value of d is given by ^{106}Rh , whose half-life is 29.8 s:

$$d = \ln(2)/29.8 \approx 0.0233[\text{s}^{-1}] \quad (569)$$

By substituting (569) into (568), we obtain Δt in order to satisfy (567) as follows:

$$\Delta t \leq \frac{-2\ln(0.001)}{2 \times 0.0233} \approx 297[\text{s}] \quad (570)$$

A typical burnup step in lattice physics computations is 100–1,000 MWd/t. When a typical power density for a PWR is used, these burnup steps correspond to 3–30 d. Since this burnup step (3–30 d) is much larger than that in (570), some compensatory measures become necessary.

There are two possible ways to resolve this issue. The first is to utilize the scaling and squaring method, which utilizes the following nature of a matrix:

$$\exp(\mathbf{A}\Delta t) = \exp\left(m \frac{\mathbf{A}\Delta t}{m}\right) = \left[\exp\left(\frac{\mathbf{A}\Delta t}{m}\right)\right]^m = \left[\exp\left(\mathbf{A} \frac{\Delta t}{m}\right)\right]^m \quad (571)$$

By using (571), an integer m is defined to satisfy $\Delta t/m \leq \frac{-2\ln(0.001)}{2d}$. The scaling and squaring method is a very effective way to compute a matrix exponential. This is especially true when $m = 2^n$. In the above case, however, m would be approximately 1,000, so the round-off error and computational cost would be considerable.

The second approach is the modification of the burnup chain, which eliminates nuclides with a high disintegration rate (d) and treats them independently. Nuclides with a high disintegration rate attain a radiation equilibrium state with precursors in a short time. Therefore, an

equilibrium solution that is obtained by ignoring the temporal differentiation on the left side of (548) can be used:

$$0 = \sum_j \gamma_{ji} \sigma_{f,j} N_j \phi + \sigma_{c,i-1} N_{i-1} \phi + \sum_k \lambda_{ki} N_k - \sigma_{a,i} N_i \phi - \lambda_i N_i \quad (572)$$

Equation (572) yields the following solution:

$$N_i = \frac{\sum_j \gamma_{ji} \sigma_{f,j} N_j \phi + \sigma_{c,i-1} N_{i-1} \phi + \sum_k \lambda_{ki} N_k}{\sigma_{a,i} \phi + \lambda_i} \quad (573)$$

A nuclide with a very high disintegration rate may be treated by the Bateman method, as described in Sect. 8.3.7, since neither the matrix exponential method nor application of the equilibrium solution yields appropriate results. The equilibrium solution, the Bateman method, and the matrix exponential method are used in the ORIGEN2 code in order to compensate for the weakness of each method.

Finally, we will discuss an important relationship among the matrix exponential method, the Euler method and the Runge–Kutta method. In many textbooks on numerical computation, these methods are explained independently. The Euler method, however, is an approximation that considers up to the second terms (i.e., up to the first order) in the Taylor series expansion shown in (563). This becomes obvious when (552) and (563) are compared.

When the elements of the burnup matrix are constant in a burnup step, the Runge–Kutta method of the second order considers up to the third terms (i.e., up to the second order) in the Taylor series expansion. This can be confirmed by substituting (555) and (556) into (557), then comparing the result with (563). Similarly, the Runge–Kutta method of the fourth order considers up to the fifth terms (i.e., up to the fourth order) in the Taylor series expansion, which can be confirmed by substituting (558)–(561) into (562), then comparing the result with (563).

To sum up, in the Taylor series expansion of the burnup matrix:

Consideration up to the second terms (the first order): the Euler method.

Consideration up to the third terms (the second order): the Runge–Kutta method of the second order.

Consideration up to the fifth terms (the fourth order): the Runge–Kutta method of the fourth order.

From the above viewpoint, both the Euler and Runge–Kutta methods can be considered as variations of the matrix exponential method. Furthermore, the above discussion also suggests the limitation of the Euler and Runge–Kutta methods for nuclides with a high disintegration rate. Since both methods truncate the Taylor series expansion, the limitations of the burnup step in these methods are expected to be smaller than that shown in (568).

6.3.6 The Matrix Decomposition Method

Let us assume that a burnup matrix \mathbf{A} can be decomposed by two matrixes \mathbf{L} and \mathbf{D} :

$$\mathbf{A} = \mathbf{L}\mathbf{D}\mathbf{L}^{-1} \quad (574)$$

The substitution of (574) into (563) yields

$$\begin{aligned}
 \exp(\mathbf{A}\Delta t) &= \mathbf{I} + (\mathbf{LDL}^{-1}\Delta t) + \frac{(\mathbf{LDL}^{-1}\Delta t)^2}{2!} + \dots \\
 &= \mathbf{LL}^{-1} + \mathbf{L}(\mathbf{D}\Delta t)\mathbf{L}^{-1} + \frac{(\mathbf{LDL}^{-1}\mathbf{LDL}^{-1}\Delta t^2)}{2!} + \dots \\
 &= \mathbf{LL}^{-1} + \mathbf{L}(\mathbf{D}\Delta t)\mathbf{L}^{-1} + \frac{(\mathbf{LD}^2\mathbf{L}^{-1}\Delta t^2)}{2!} + \dots \\
 &= \mathbf{LL}^{-1} + \mathbf{L}(\mathbf{D}\Delta t)\mathbf{L}^{-1} + \mathbf{L}\frac{(\mathbf{D}\Delta t)^2}{2!}\mathbf{L}^{-1} + \dots \\
 &= \mathbf{L}\left(\mathbf{I} + (\mathbf{D}\Delta t) + \frac{(\mathbf{D}\Delta t)^2}{2!}\dots\right)\mathbf{L}^{-1} \\
 &= \mathbf{L}\exp(\mathbf{D}\Delta t)\mathbf{L}^{-1}
 \end{aligned} \tag{575}$$

Equation (575) indicates that the matrix exponential of \mathbf{A} can be replaced by that of \mathbf{D} . When \mathbf{D} is a matrix with a general form, the transformation shown in (575) is not of value, though it requires a computational cost similar to that of $\exp(\mathbf{D}\Delta t)$. However, if \mathbf{D} is a diagonal matrix, which has nonzero elements only at diagonal positions, then the above formulation has practical merit

$$\mathbf{D} = \begin{bmatrix} \alpha_1 & & & 0 \\ & \alpha_2 & & \\ & & \dots & \\ 0 & & & \alpha_n \end{bmatrix}. \tag{576}$$

In this case, the matrix exponential of \mathbf{D} is expressed by

$$\exp(\mathbf{D}\Delta t) = \begin{bmatrix} \exp(\alpha_1\Delta t) & & & 0 \\ & \exp(\alpha_2\Delta t) & & \\ & & \dots & \\ 0 & & & \exp(\alpha_n\Delta t) \end{bmatrix}, \tag{577}$$

thus $\exp(\mathbf{A}\Delta t)$ can be easily obtained by (575). In this method, once a matrix is decomposed, then the matrix exponential is evaluated by the decomposed matrixes; this is called the matrix decomposition method.

Next, we should consider a numerical procedure that evaluates the matrixes of \mathbf{D} and \mathbf{L} . Such a procedure is common in the field of linear algebra, that is, the diagonalization of a matrix, which is equivalent to evaluate all eigenvalues and eigenvectors of matrix \mathbf{A} . Note that the diagonal elements of matrix \mathbf{D} correspond to the eigenvalues, and the matrix \mathbf{L} is composed of eigenvectors. In general, the calculation of eigenvalues and eigenvectors requires computation time, so that matrix decomposition is inevitably time consuming. However, the diagonal matrix \mathbf{D} can be obtained easily when the burnup equation is approximated as follows:

$$\begin{aligned}
 \frac{dN_i}{dt} &= \sum_j \gamma_{ji}\sigma_{f,j}N_j\phi + \sigma_{c,i-1}N_{i-1}\phi + \lambda_{i-1}N_{i-1} - \sigma_{a,i}N_i\phi - \lambda_iN_i \\
 &= F_i + (\sigma_{c,i-1}\phi + \lambda_{i-1})N_{i-1} - (\sigma_{a,i}\phi + \lambda_i)N_i
 \end{aligned} \tag{578}$$

Equation (578) is different from (548) in the following points:

- a. The production rate from a fission is assumed to be constant.
- b. The production from a “previous” nuclide, only, is taken into account.

By incorporating the above assumptions, the burnup equation and the burnup matrix become as follows:

$$\frac{d\vec{N}}{dt} = \mathbf{A}\vec{N} + \vec{F} \tag{579}$$

$$\mathbf{A} = \begin{bmatrix} -\sigma_{a,1} - \lambda_1 & 0 & 0 & \dots & 0 \\ \sigma_{c,1} + \lambda_1 & -\sigma_{a,2} - \lambda_2 & \dots & \dots & \dots \\ 0 & \dots & \dots & \dots & \dots \\ \dots & 0 & \dots & -\sigma_{a,n-1} - \lambda_{n-1} & 0 \\ 0 & \dots & 0 & \sigma_{c,n-1} + \lambda_{n-1} & -\sigma_{a,n} - \lambda_n \end{bmatrix} \tag{580}$$

The diagonalization of matrix **A** given by (580) is easy. The matrixes of **L** and **D** are assumed as follows:

$$\mathbf{L} = \begin{bmatrix} l_{1,1} & l_{2,1} & \dots & \dots & l_{n,1} \\ l_{1,2} & l_{2,2} & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & l_{n-1,n-1} & \dots \\ l_{1,n} & \dots & \dots & \dots & l_{n,n} \end{bmatrix}, \quad \mathbf{D} = \begin{bmatrix} \alpha_1 & 0 & \dots & \dots & 0 \\ 0 & \alpha_2 & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \alpha_{n-1} & 0 \\ 0 & \dots & \dots & 0 & \alpha_n \end{bmatrix} \tag{581}$$

Equation (574) can be transformed into

$$\mathbf{AL} = \mathbf{LD} \tag{582}$$

Therefore, by comparing each element of the matrixes in (582), the following relationship can be obtained:

$$(-\sigma_{a,1} - \lambda_1)l_{1,1} = l_{1,1}\alpha_1 \tag{583}$$

$$(\sigma_{c,1} + \lambda_1)l_{1,1} + (-\sigma_{a,2} - \lambda_2)l_{1,2} = l_{1,2}\alpha_1 \tag{584}$$

Since (583) and (584) are the recurrence relationships, the elements in matrixes **L** and **D** can be easily obtained. Here, column vector of matrix **L** is eigenvector thus they can be normalized arbitrary. The analytical solution of (579) is

$$\begin{aligned} \vec{N}^{l+1} &= \exp(-\mathbf{A}\Delta t) \left[\vec{N}^l - \mathbf{A}^{-1}\vec{F} \right] + \mathbf{A}^{-1}\vec{F} \\ &= \mathbf{L} \exp(\mathbf{D}\Delta t) \mathbf{L}^{-1} \left[\vec{N}^l - \mathbf{A}^{-1}\vec{F}^l \right] + \mathbf{A}^{-1}\vec{F}^l \end{aligned} \tag{585}$$

The inverse of matrix **A** is given as follows:

$$\mathbf{A}^{-1} = \mathbf{LD}^{-1}\mathbf{L}^{-1} \tag{586}$$

since

$$\mathbf{AA}^{-1} = \mathbf{I} \tag{587}$$

The matrix decomposition method can estimate an accurate solution but has the following drawbacks:

- a. A complicated burnup chain that includes the neutron capture, α -, β -decay, and (n, 2n) reactions cannot be directly treated

As shown in (578), the production of a nuclide is limited by a fission and the “previous” nuclide, that is, there are only two paths. Therefore, even if there are multiple production paths, for example, ^{239}Pu is produced from α -, β -decay and (n, 2n) reactions, direct treatment of these production paths is not possible; the “linearization” of the burnup chain is necessary.

- b. All burnup chains must be linearized

For example, let us consider the production of ^{244}Cm from ^{241}Pu in the burnup chains shown in  Fig. 86. In order to linearize a burnup chain, all production paths should be treated independently. Therefore, the following five linearized burnup chains need to be solved.

Once the solutions for these five burnup equations are obtained, the final solution can be reconstructed through the summation of these solutions. This is a somewhat complicated treatment in the actual implementation of a numerical solution.

The above discussion suggests that number of burnup equations significantly increases when linearization is carried out for a complicated burnup chain.

- c. A numerical difficulty (divide by zero) appears when two nuclides have identical disintegration rates (= absorption + decay rate)
- d. A burnup chain with a “circuit shape” cannot be treated

For example, the burnup chain of $^{241}\text{Pu} \rightarrow ^{242}\text{Pu} \rightarrow ^{243}\text{Am} \rightarrow ^{244}\text{Cm} \rightarrow ^{240}\text{Pu} \rightarrow ^{241}\text{Pu}$ is an example of a circuit-shaped chain.

The matrix decomposition method is a numerically efficient method (Knott and Edenius 1993). However, it is not very suitable for treating very complicated burnup chains.

6.3.7 Bateman Method

The Bateman method utilizes an analytic solution for first-order linear differential equations (Okumura et al. 2007; Bateman 1910; Tasaka 1977; Villarino et al. 1992). The general solution for the linearized burnup equation shown in (578) is given as follows:

$$\begin{aligned}
 N_i(t + \Delta t) &= N_i(t) \exp(-d_i \Delta t) \\
 &+ \sum_{k=1}^{i-1} N_k(t) \left[\sum_{j=k}^{i-1} \frac{\exp(-d_j \Delta t) - \exp(-d_i \Delta t)}{d_i - d_j} a_{j+1,j} \prod_{\substack{n=k \\ n \neq j}}^{i-1} \frac{a_{n+1,n}}{d_n - d_j} \right] \quad (588)
 \end{aligned}$$

where $a_{i,j}$ is the element of matrix \mathbf{A} and $d_i = -a_{i,i}$. Note that F_i is assumed to be zero in the above derivation. Equation (588) has a very complicated form that includes several summation and multiplication operations.

The matrix decomposition method and the Bateman method solve the identical equation since both methods treat the same linearized burnup chain. The difference between these methods is the actual solution method: numerical calculation for a matrix is used in the matrix decomposition method, and the analytic solution is used in the Bateman method.

Though the accuracy of the Bateman method is superior due to its utilization of the analytic solution, it presents several problems that are identical to those of the matrix decomposition method:

- Since linearization of the burnup chain is necessary, some approximations may be necessary for a complicated burnup chain.
- Numerical difficulty arises when two nuclides have identical disintegration rates. In this case, the denominator in (588) becomes zero.
- A circulating burnup chain cannot be directly treated.

The issue of (b) can be avoided by deriving the analytical solution with the assumption of an identical disintegration rate (i.e., $d_i = d_j$ or $d_n = d_j$). Issue (c) can be approximately treated by terminating and cutting the circuit burnup chain at a certain point. Note that the degree of error due to the approximation of terminating the burnup chain is negligible when the number of burnup steps is sufficiently large.

The Bateman method is used in the ORIGEN2 code for short-lived nuclides, as described ▶ 6.3.5. The MVP-BURN code (Okumura et al. 2000) also utilizes the Bateman method, whose burnup module is based on the DCHAIN code developed by JAERI (former JAEA) (Tasaka 1977).

6.3.8 The Padé Approximation

The Padé approximation of (p, q) -order for the exponential function is given as follows:

$$\exp(x) \cong \frac{N_{pq}(x)}{D_{pq}(x)} \quad (589)$$

where

$$N_{pq}(x) = \sum_{k=0}^p \frac{(p+q-k)!p!}{(p+q)!k!(p-k)!} x^k$$

$$D_{pq}(x) = \sum_{k=0}^q \frac{(p+q-k)!q!}{(p+q)!k!(q-k)!} (-x)^k$$

Equation (589) can be reduced into the Taylor series expansion when $q = 0$:

$$\frac{N_{p0}(x)}{D_{p0}(x)} = 1 + x + \frac{x^2}{2!} + \cdots + \frac{x^p}{p!} \quad (590)$$

The Padé approximation for the matrix exponential utilizes (589) rather than the conventional Taylor series expansion, that is,

$$\exp(A\Delta t) \cong \frac{N_{pq}(A\Delta t)}{D_{pq}(A\Delta t)} \quad (591)$$

In general, convergence of the Padé approximation is faster than that of the Taylor series expansion. The Padé approximation with $p = q$ (the diagonal Padé approximation) is frequently used due to the special advantages it offers in computation time and numerical stability.

The Padé approximation is, of course, a series of expansion, so the problems of slower convergence and round-off error manifest when the norm of $\mathbf{A}\Delta t$ is large. For this reason, the scaling and squaring method is also used to efficiently estimate for a matrix exponential with a large norm.

The Padé approximation is widely used as the numerical solution of the matrix exponential method (Moler and Loan 2003). For example, Mathematica and Matlab adopt the Padé approximation and the scaling and squaring method to evaluate a matrix exponential.

The Padé approximation has also been successfully applied to the burnup calculation for a complicated burnup chain (Yamamoto et al. 2007). However, since the Padé approximation is best suited to calculation for a dense-matrix, the Krylov subspace method is more suitable for a burnup calculation when the burnup matrix is very sparse, as shown in  Fig. 91.

6.3.9 The Krylov Subspace Method

The matrix exponential method and the Padé approximation offer a general numerical scheme to evaluate the matrix exponential. Burnup calculations in lattice physics computing, however, have the following features:

- a. Only the number densities are necessary as calculation results, that is, the matrix exponential itself is not necessary.
- b. The burnup matrix is a sparse matrix with many zero elements.

The Krylov subspace method is a new numerical method that utilizes the above features and is being applied in the fields of molecular dynamics and computational finance (Moler and Loan 2003). By using the Krylov subspace method, stiff burnup calculations with short-lived nuclides, which are difficult to treat by conventional methods, for example, the matrix exponential and the Runge–Kutta methods, have been successfully carried out in short computation time (Yamamoto et al. 2007). A detailed theoretical description of this method is shown by Yamamoto et al. (2007). A theoretical outline of the Krylov subspace method is offered as follows.

When (563) is truncated by m -1th order, we have the following polynomial:

$$\vec{N}(t + \Delta t) \cong c_0 \vec{N}(t) + c_1 (\mathbf{A}\Delta t)^1 \vec{N}(t) + c_2 (\mathbf{A}\Delta t)^2 \times \vec{N}(t) + \cdots + c_{m-1} (\mathbf{A}\Delta t)^{m-1} \times \vec{N}(t) \quad (592)$$

where

$$c_k = \frac{1}{k!}$$

The group of the vectors appearing in (592) is known as the Krylov subspace, which is defined as follows:

$$\mathbf{K}_m(\mathbf{A}\Delta t, \vec{N}(t)) = \text{Span} \{ \vec{N}(t), (\mathbf{A}\Delta t)\vec{N}(t), (\mathbf{A}\Delta t)^2\vec{N}(t), \dots, (\mathbf{A}\Delta t)^{m-1}\vec{N}(t) \}$$

Equation (592) is an example of a polynomial that approximately estimates $\vec{N}(t + \Delta t)$ with the m th order Krylov subspace. Therefore, when the appropriate coefficients, that is, c_k , can be chosen, a better estimate of $\vec{N}(t + \Delta t)$ may become possible. In the Krylov subspace method, c_k are chosen to minimize the square residual of the prediction error for $\vec{N}(t + \Delta t)$. Roughly speaking, appropriate c_k , which depend on matrix \mathbf{A} , are chosen by the least square fitting in the Krylov subspace method, while the conventional method (e.g., the matrix exponential method) utilizes $c_k = \frac{1}{k!}$ regardless of the burnup matrix.

The above explanation suggests that the Krylov subspace method offers an advantage in the choice of expansion coefficients, and is thus different from conventional methods. Since the matrix exponential method and the Runge–Kutta method also utilize a part of the Krylov subspace, they might be classified as a variation of the Krylov subspace method with fixed expansion coefficients.

6.3.10 Numerical Example

Test calculations to confirm the validity of the Krylov subspace method are offered and explained below. The calculation configuration is the pin-cell geometry of UO₂ fuel in PWR whose enrichment is 4.1 wt%. The initial number densities and geometry of this configuration are shown in [Table 23](#).

The linear power density is set at 179 W/cm. The burnup calculation up to 1 MWd/t (~2,300 s) is carried out by the matrix exponential method (the Taylor series expansion) and the

■ Figure 94

Maximum absolute error of number densities versus order of Taylor series expansions or dimensions of Krylov subspace

Krylov subspace method. The burnup chain used in this calculation is the “Developer” burnup chain of the MVP-BURN code, which consists of 28 heavy nuclides and 193 fission products (a total of 221 nuclides). The nuclide with the shortest half-life in this burnup chain is ^{106}Rh (29.8 s), and the norm of the burnup matrix ($\mathbf{A}\Delta t$) is $\ln(2)/29.8 \times 2,300 = 0.0233 \times 2,300 = 53.6$, which is quite large. The reference solution is obtained by Mathematica, in which evaluation of the matrix exponential is performed by the Padé approximation.

The maximum (absolute) error of number densities at 1 MW d/t is shown in [Fig. 94](#). In the case of Taylor series expansion, the maximum absolute error increases as the order of Taylor series expansion increases, which suggests that a very large expansion order will be necessary to obtain the converged result. Even if such Taylor series expansion is numerically evaluated, the reliability of the result is doubtful because of the severe numerical round-off error, as discussed in [6.3.5](#). In the Krylov subspace method, on the other hand, the maximum absolute error of nuclide number densities rapidly decreases with an increasing order of expansion (i.e., the order of Krylov subspace dimensions), and sufficient accuracy is obtained when the order of dimension is 14. The number densities of the nuclides and their associated errors are presented in [Figs. 95–99](#).

Next, burnup calculations up to 100, 1,000, 10,000 and 100,000 MW d/t are carried out by the fourth-order Runge–Kutta, Padé (order $p = 2, 4, 6, 8$) and Krylov subspace (order of dimension = 5, 10, 20, 30, 40, 50, 60) methods, and the accuracy of their calculations are compared. Note that three different time-steps, that is, 0.0001, 0.001, and 0.002 d are used in the fourth-order Runge–Kutta method. In the Padé and Krylov subspace methods, burnup steps are automatically adjusted in order to keep the error of nuclide number densities sufficiently small. Once again, the burnup chain used in the calculation is the “Developer” chain of the MVP-BURN code. The reference solution is obtained by the Mathematica.

■ **Figure 99**

Example of microscopic absorption rate during burnup

The maximum errors of nuclide number densities after burnup, and calculation times, are summarized in [▶ Tables 24](#) and [▶ 25](#). From these tables we can make the following observations:

- In the Runge–Kutta method, a very fine burnup step is necessary in order to obtain the appropriate result. The burnup step should be set at less than 0.001 d (~ 90 s) in the present burnup calculation, due to the presence of a short-lived nuclide (^{106}Rh). Consequently, the computation time becomes impractically long.
- Both the Padé and Krylov subspace methods give accurate results from a practical point of view.
- The Krylov subspace method is between several and several hundred times faster than the Padé method.
- When the dimension of subspace is increased, the accuracy of the expansion by the subspace increases; thus, the width of the burnup step can be reduced in order to achieve sufficient accuracy. The computation time for matrix manipulations, however, then becomes longer. On the contrary, when the dimension of subspace is decreased, the accuracy of the expansion decreases; thus, the burnup step must be increased. The computation time for matrix manipulations, however, then becomes shorter. Consequently, in terms of computation time, there is an adequate dimension of the Krylov subspace.

The above observations suggest that the Krylov subspace method can provide an accurate solution in a short computation time for a complicated burnup chain with short-lived nuclides.

In the actual implementation of the Krylov subspace method, a well-established package such as EXPOKIT can be used (Sidje 1998). The utilization of such sophisticated software reduces the work of implementation.

6.3.11 Predictor–Corrector Method

There are two sources of error in the numerical simulation of a burnup calculation, that is, temporal discretization errors in the sections so far, and the reaction rate. The former topic has been addressed in the previous subsections. The latter topic, the temporal discretization error in the reaction rate, is treated in this section.

First, we consider a very simple burnup equation for an absorber nuclide:

$$\frac{dN}{dt} = -\sigma_a(t)\phi(t)N \quad (593)$$

■ **Table 24**

* Diverged.

** Not evaluated.

The analytic solution of (593) is given as follows:

$$N(T + \Delta t) = N(T) \exp\left(-\int_T^{T+\Delta t} \sigma_a(t)\phi(t)dt\right) \quad (594)$$

In a common burnup calculation, the absorption cross section and the neutron flux are given as constants at the discrete burnup step (T). Thus (594) can be written as

$$N(T + \Delta t) = N(T) \exp\left(-\int_T^{T+\Delta t} \sigma_a(t)\phi(t)dt\right) \cong N(T) \exp(-\sigma_a(T)\phi(T)\Delta t) \quad (595)$$

When the absorption cross section and neutron flux is fairly constant throughout a burnup step, the accuracy of (595) is high. However, when the behavior of the absorption rate is not constant, as shown in  Fig. 99, the integrated absorption rate during $T \sim T + \Delta t$ is underestimated. The number density of a nuclide is therefore overestimated; that is, a nuclide appears to have burned more slowly than it actually did.

*** Not evaluated.

Variations in the reaction rate, such as those shown in  Fig. 99, frequently occur in actual burnup calculations. Such a trend is especially apparent when a burnable absorber, for example, gadolinium, is used in a fuel. The number density of a burnable absorber decreases as burnup proceeds. Consequently, the neutron flux in the burnable absorber becomes higher since the macroscopic absorption cross section of the absorber becomes smaller. Furthermore, the neutron spectrum shifts to a lower energy region (becomes “softer”) since the macroscopic thermal absorption cross section of the burnable absorber becomes smaller. A multigroup (energy-averaged) microscopic cross section becomes larger during burnup due to its softer neutron spectrum. Consequently, the microscopic reaction rate ($\sigma\phi$) becomes larger during burnup.

The temporal discretization error due to (595) can be suppressed by reducing the time-step in a burnup calculation. In other words, utilization of a finer burnup step can limit the temporal

discretization error. However, evaluation of the reaction rate, that is, evaluations of an effective microscopic cross section and neutron flux, is the most time-consuming part of actual burnup calculations. Therefore, the number of reaction rate calculations (i.e., those of an effective microscopic cross section and neutron flux) should be minimized in terms of computation time.

One way to resolve the above conflict is the predictor–corrector (PC) method. Roughly speaking, the PC method performs burnup calculation using a time-averaged absorption reaction rate during a time-step, through pre-evaluation of the absorption rate at $T + \Delta t$.

The actual calculation procedure of the PC method is as follows (Method 1):

- a. Evaluate the microscopic reaction rate with the number density of burnup step n .
- b. Perform the burnup calculation to burnup step $n + 1$ using the reaction rate obtained in (a). This calculation step is called the predictor step.
- c. The number density of burnup step $n + 1$ is estimated using the calculation result of (b). The microscopic reaction rates at this point (burnup step $n + 1$) are then evaluated.
- d. Again perform the burnup calculation using the average microscopic reaction rates of (a) and (c). This step is called the corrector step.

The following alternative method (Method 2) can also be used:

- a. Evaluate the microscopic reaction rate with the number density of burnup step n .
- b. Perform burnup calculation to burnup step $n + 1$ using the reaction rate obtained in (a). This calculation step is called the predictor step.
- c. The number density of burnup step $n + 1$ is estimated using the calculation result of (b). The microscopic reaction rates at this point (burnup step $n + 1$) are then evaluated.
- d. Again perform burnup calculation using the microscopic reaction rates of (c). This step is called the corrector step.
- e. Average the number densities obtained in (b) and (d) to obtain the final results.

Because two reaction rate calculations (predictor and corrector) are necessary for a burnup step in the PC method, it would seem to require longer computation time. However, since the PC method enables the width of the burnup step to be increased by a factor of 10, the computational efficiency of the PC method is actually much greater than that of the conventional method. Therefore, the PC method is the inevitable choice for production lattice physics and core simulation codes.

6.3.12 Sub-Step Method

As described in [▶ 6.3.11](#), reaction rate calculations dominate the computation time of a lattice physics computation. Therefore, the time-step size for reaction rate calculations can be longer than that for temporal discretization of the burnup equation, as shown in [▶ Fig. 100](#). Such “double” time-step setting is called the sub-stepping method.

In common lattice physics codes, the burnup steps for reaction rate evaluations are given as input data. Since the sub-step is automatically (and internally) set by the lattice physics codes, users are usually not aware of this. For example, the MVP-BURN code subdivides an input burnup step into 20 sub-steps to which the numerical solution of the burnup calculation is applied, using the Bateman method.

■ Figure 100
Concept of sub-stepping method for burnup calculation

■ Figure 101
Variation of power density during a time-step

There are two objectives to incorporating the sub-stepping method:

Reduction of Temporal Discretization Error

Temporal discretization error inevitably occurs in a numerical solution by the Euler, Runge–Kutta, matrix exponential, Padé, and Krylov subspace methods, all of which contain a degree of error due to truncation of the expansion series of a matrix exponential. The temporal discretization error can be reduced by the sub-stepping method (though the discretization error from the reaction rate cannot be reduced). Since the matrix decomposition and Bateman methods utilize the “analytic solution” for the burnup equation, temporal discretization error might not be produced by these methods. However, they still suffer from temporal discretization error since in actual calculations, the burnup chain is approximated (e.g., cut the “circuit chain”). Therefore, the sub-stepping method is also useful for these methods.

Power Normalization during Burnup Step

In light water reactor calculations, fissile nuclides are depleted during burnup. Since the neutron flux is normalized at the beginning of the time-step, power density gradually decreases during burnup, as shown in  Fig. 101.

■ Figure 102

Variation of power with power normalization at sub-step during burnup step

Since burnup is evaluated by the time integration of power, the calculated burnup will be underestimated in [Fig. 101](#). Therefore, the following power normalization is carried out at sub-step m , that is, the normalized factor Norm_m is multiplied by the reaction rate.

$$P = \text{Norm}_m \sum_i \left(\sum_k \kappa_k \sigma_{f,k,i} N_{k,i} \right) \phi_i V_i \quad (596)$$

where

P : power (input data) [J s^{-1}],

κ_k : released energy per fission of nuclide k [J],

$\sigma_{f,k,i}$: microscopic fission cross section of nuclide k in region i [cm^2],

$N_{k,i}$: number density of nuclide k in region i [cm^{-3}],

ϕ_i : neutron flux [$\text{cm}^{-2} \text{s}^{-1}$],

V_i : region volume [cm^3].

By using the above power normalization, the underestimation of burnup can be avoided, as shown in [Fig. 102](#).

6.3.13 Cooling Calculation

The composition of fuels varies during shutdown due to the decay of nuclides. This variation of fuel composition during shutdown has a considerable impact on core characteristics, so this effect must be taken into account in actual in-core fuel management calculations.

In light water reactor analyses, the following decays are important:

This decay has an impact on criticality during the immediate return to power after a scram. It is also a cause of Xe oscillation. Since the half-life of ^{135}Xe is also short (9 h), in a startup analysis after refueling, all Xe is assumed to have decayed (no Xe).

$^{149}\text{Pm} \rightarrow (\text{Half-Life } 54 \text{ h}) \rightarrow ^{149}\text{Sm}$

This has an impact on the core characteristics during the startup operation. Since ^{149}Sm is a stable isotope, all ^{149}Pm is assumed to have decayed into ^{149}Sm (peak condition of Sm) in the startup analysis.

 $^{239}\text{Np} \rightarrow (\text{Half-Life } 2.4 \text{ days}) \rightarrow ^{239}\text{Pu}$

This has an impact on the criticality during return to power after a scram. The positive reactivity effect of this decay is partly canceled out by the negative reactivity effect of $^{149}\text{Pm} \rightarrow ^{149}\text{Sm}$, whose half-life is similar to that of ^{239}Np . Therefore, in an analysis of return to power during a few days after a shutdown, the decay of both $^{149}\text{Pm} \rightarrow ^{149}\text{Sm}$ and $^{239}\text{Np} \rightarrow ^{239}\text{Pu}$ should either be taken into account, or not considered at all.

 $^{148\text{m}}\text{Pm} \rightarrow (\text{Half-Life } 41 \text{ days}) \rightarrow ^{148}\text{Sm}$

This has an impact on the core characteristics of a startup physics test after a normal periodic inspection and refueling that requires a few months.

 $^{148}\text{Pm} \rightarrow (\text{Half-Life } 2.6 \text{ years}) \rightarrow ^{148}\text{Sm}$

Since the half-life of this decay is quite long, it has an impact on the reactivity of reinserted fuels, which were irradiated during a cycle then temporarily stored in the spent fuel pool for future use. When reinserted fuels with long-term cooling are used, the present decay will affect the core characteristics.

 $^{155}\text{Eu} \rightarrow (\text{Half-Life } 4.7 \text{ years}) \rightarrow ^{155}\text{Gd}$

This also has an impact on the reactivity of reinserted fuels. It is a major cause of reactivity variations in reinserted fuels that have been stored for a long time.

 $^{241}\text{Pu} \rightarrow (\text{Half-Life } 14.4 \text{ years}) \rightarrow ^{241}\text{Am}$

This has a major impact on the reactivity of reinserted fuels. This decay reaction is especially important for MOX fuels, since a considerable amount of ^{241}Pu is initially loaded in them. In a core design loaded with MOX fuels, this cooling effect should be taken into account not only for spent MOX fuels, but also for fresh MOX fuels. In order to estimate the decay amount, an accurate cooling time (the span of time from fuel composition characterization to fuel loading) is necessary.

A cooling calculation can be carried out as a burnup calculation with a very low power density. Note that zero power density might cause numerical problems, so the utilization of a very low power density might be appropriate in actual cooling calculations.

6.4 Burnup in Gadolinia-Bearing Fuel

Gadolinia (Gd_2O_3) is a common burnable absorber used in light water reactors. A comparison of the microscopic absorption cross sections of major nuclides used as burnable absorber is shown in  Fig. 103. This figure indicates that the absorption cross section of gadolinium (^{155}Gd , ^{157}Gd) is considerably larger than those of other nuclides. This blackness, that is, the

■ Figure 103

Comparison of microscopic absorption cross sections of major burnable absorber nuclides

strong neutron absorption property of gadolinia, requires some particular consideration in a burnup analysis.

First, since the absorption cross section of gadolinium is very large, gadolinia-bearing fuel rods are generally sparsely located (scattered) in fuel assemblies. Therefore, a gadolinia-bearing fuel assembly has a higher neutronics heterogeneity due to the presence of the “black” regions. Such “black” regions should be handled through sophisticated calculation methods, for example, a neutron transport calculation with explicit geometry treatment. Otherwise, the prediction error will be greater than that of conventional fuel assemblies without gadolinia-bearing fuel rods.

The second point is the unique burnup properties of a gadolinia-bearing fuel rod. This point will be discussed in detail in the next section.

In the following sections, modeling considerations in the accurate handling of a gadolinia-bearing fuel assembly are discussed.

6.4.1 Onion-Skin Effect

The mean free path of thermal neutrons in a gadolinia-bearing fuel pellet is very short, due to the large absorption cross section of gadolinia isotopes. At the beginning of life, thermal neutrons entering from a moderator into a pellet are immediately absorbed by gadolinium nuclides at the surface. Therefore, gadolinium nuclides are depleted from the pellet surface like the layered skins of an onion. This particular burnup behavior of gadolinium isotopes is called the “onion-skin” effect.

In the numerical modeling of a gadolinia-bearing fuel pellet, the onion-skin effect should be carefully treated since it has a significant impact on the neutronics characteristics of a gadolinia-bearing fuel assembly. To accurately capture the onion-skin effect, a gadolinia-bearing fuel pellet

■ Figure 104

Effect of annular division of gadolinia-bearing fuel pellet (17×17 PWR fuel assembly with 24 Gd-bearing fuel rods of 10 wt% Gd_2O_3)

is annularly divided into regions ranging in number from several to more than a dozen, and the depletion of gadolinium isotopes is explicitly tracked in each annular region. Note that ordinary UO_2 fuel usually has one spatial region in a pellet.

The effect of the annular divisions of a gadolinia-bearing fuel pellet on fuel assembly k -infinity is shown in [Fig. 104](#). This figure shows that the annular division of a gadolinia-bearing fuel pellet has a significant impact on the k -infinity of a fuel assembly, and more than several annular regions are necessary to obtain an accurate result.

The onion-skin effect requires detailed spatial modeling of the gadolinia-bearing fuel pellet. Such modeling, however, requires a very burdensome calculation, which is why various numerical techniques have been used in practical lattice physics computations. Previously, the “off-line” depletion calculation for a gadolinia-bearing fuel pellet was used in conventional lattice physics codes. In this approach, a gadolinia-bearing fuel pellet is depleted in one-dimensional cylindrical geometry, which consists of an annularly divided pellet, clad, moderator, and buffer regions. The buffer region simulates the spectrum environment of adjacent fuel cells in order to reproduce the neutron spectrum in a gadolinia-bearing fuel pellet. The depletion calculation in one-dimensional geometry is carried out prior to the assembly calculation, and spatially homogenized and energetically collapsed cross sections for a gadolinia-bearing fuel pellet or fuel cell are provided in the subsequent assembly calculation. Since the “off-line” depletion calculation is carried out in one-dimensional geometry, detailed spatial discretization (annular divisions) of a gadolinia-bearing fuel pellet can be used within a short computation time.

Though the off-line approach has merit in terms of computation time, its accuracy depends on the calculation conditions used in the one-dimensional transport calculation. Since the actual assembly configuration in two-dimensional geometry is approximated by one-dimensional geometry, there is some ambiguity in the setting of the buffer region. In fact, the difference between the neutron spectrum obtained by one-dimensional geometry and that

obtained by explicit two-dimensional geometry sometimes becomes considerable, and can be a major cause of error in the burnup calculation of a gadolinia-bearing fuel assembly.

Ongoing progress in the computational environment and the requirement of increased accuracy strongly promote the utilization of more advanced and sophisticated treatment of a gadolinia-bearing fuel assembly. As described in [▶ Sect. 5](#), the latest lattice physics codes explicitly treat the heterogeneous geometry of the entire fuel assembly in the spectrum calculation, in which annular divisions of the gadolinia-bearing fuel pellet are also explicitly and directly taken into account. Such detailed modeling of fuel assembly improves the prediction accuracy of burnup behavior of a gadolinia-bearing fuel assembly, since the neutron spectrum in a gadolinia-bearing fuel pellet (and thus the absorption reaction rate of gadolinium isotopes) is more accurately evaluated than it is by the conventional model that utilizes the buffer region.

6.4.2 Asymmetry Effect in Gadolinium Depletion

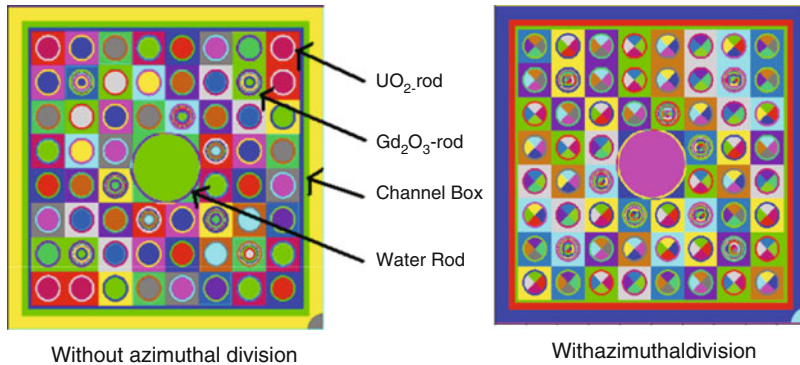

The previous section describes the necessity of the annular division of a gadolinia-bearing fuel pellet due to the onion-skin effect. Such modeling is appropriate when the adjacent fuel cells are similar from the viewpoint of the neutron spectrum. In other words, when the neutron spectra entering into a gadolinia-bearing fuel pellet are fairly uniform in azimuthal direction, the annular division (without azimuthal division) of a pellet is adequate, since the depletion rate of gadolinium isotopes is azimuthally uniform.

However, in actual situations, especially in a BWR fuel assembly, the neutron spectrum is highly space-dependent due to the presence of gap water and large water holes. Therefore, the azimuthal dependence of the gadolinium depletion rate (asymmetry effect in gadolinium depletion) should be taken into account for an accurate prediction of the burnup behavior of a gadolinia-bearing fuel assembly.

In order to capture the asymmetry effect, a gadolinia-bearing fuel pellet should be azimuthally divided, in addition to the annular division. The magnitude of the asymmetry effect is evaluated in an 8×8 BWR fuel assembly with gadolinia-bearing fuel rods (Tohjo et al. 2006). A continuous energy Monte Carlo calculation code is used to evaluate the asymmetry effect in this calculation, since detailed spatial discretization in the azimuthal direction cannot be directly modeled by many lattice physics codes.

Calculation geometries are shown in [▶ Fig. 105](#). The left model is an ordinary spatial (material) discretization used in lattice physics computations. Unlike this, the right model has an azimuthal division in addition to the discretization used in the left one. These two calculation models are used for burnup calculation by the continuous energy Monte Carlo burnup code. The difference of the k -infinity at 40% voided condition is shown in [▶ Fig. 106](#). This figure indicates that the asymmetry effect reaches $0.15\% \Delta k/k$ at 10,000 MW d/t, where gadolinium is almost burned out. When the gadolinia-bearing fuel pellet is azimuthally divided, the depletion of gadolinium isotopes is independently tracked in each azimuthal region. Consequently, the k -infinity of the Gd-bearing fuel assembly changes, due to variations in the burnup behavior of gadolinium isotopes.

Though the asymmetry depletion effect is not very large in this case, it could be larger when the azimuthal variation of the neutron spectrum becomes more significant. For example, in a conventionally designed fuel assembly, the gadolinia-bearing fuel rods are sparsely located,

■ **Figure 105**
Calculation geometries used for asymmetry effect of gadolinium depletion

■ **Figure 106**
Difference of assembly k -infinity with and without azimuthal division in 8×8 BWR assembly. Difference is defined by (without – with)/with

but they may be placed side-by-side in order to improve their performance. In such a case, the asymmetry depletion effect should be carefully investigated and its impact should be estimated.

6.4.3 Various Numerical Techniques for Gadolinium Depletion

The predictor–corrector method to reduce the effect of the constant reaction rate approximation in a burnup step is discussed in 6.3.11. However, even if the PC method is used, the typical time-step size used for a Gd-bearing fuel assembly is 0.2 GW d/t (Knott and Wehlage 2007), since the absorption reaction rate of gadolinium isotopes changes rapidly during burnup. Since gadolinium typically burns out at 10–20 GW d/t, from several dozen to a hundred burnup steps are still necessary to accurately deplete a Gd-bearing fuel assembly with the PC method.

In order to reduce this computational burden, some numerical techniques have been developed. One of these is the dual-time depletion method (Rhodes et al. 2006; Knott and Wehlage 2007). In this approach, only the pin-cell calculation for the Gd-bearing fuel rods is performed at a fine time-step size, and the time-consuming assembly calculation is executed at a coarser time-step. By synthesizing these two different calculations (i.e., pin cell and assembly), we can obtain the assembly calculation results that are equivalent to a fine time-step analysis. The reference suggests that the time-step size for assembly calculations can be increased to five times larger than that of the conventional burnup method, without dual-time stepping.

Another approach is the consideration of reaction rate variation during a time-step. In the conventional approach, the coefficients of the burnup equation (i.e., the reaction rates) are assumed to be constant during a time-step. This assumption is used for both the predictor and corrector burnup calculations. The final results are obtained by averaging the predictor and corrector burnup calculation results in order to cancel out the discretization error caused by the assumption of a constant reaction rate. In order to more accurately capture the depletion of each nuclide, the variation of reaction rates within a burnup step can be taken into account. These variations are incorporated by using the linear (Knott and Wehlage 2007) or the quadratic (Rhodes et al. 2006) function of the burnup time.

One of the problems with the conventional PC method is the error in the estimate of reaction rates in a corrector step. The reaction rates of a corrector step are estimated based on the number density obtained by a predictor step. Therefore, when the calculation accuracy of the predictor step is not sufficient, the number densities used in the corrector step may contain some error. Thus, the estimated corrector reaction rates might not be predicted accurately. This is especially true for a Gd-bearing fuel assembly, since the neutron flux in a Gd-bearing fuel rod rapidly increases before the burnout of gadolinia. In this case, the reaction rates in Gd-bearing fuel rods at a predictor step are smaller than the “true” (or the average during the time-step) values, so that the depletion of gadolinium isotopes will be smaller. Since the gadolinia content will be higher than the appropriate (or “true”) value in the corrector calculation, the reaction rates in the Gd-bearing fuel rod are also underestimated. Consequently, the reaction rates in the Gd-bearing fuel rod will be underestimated, since both the predictor and the corrector reaction rates are underestimated. This, in fact, is one of the dominant errors in the conventional PC method.

The traditional countermeasure for this problem is the iteration of the corrector calculations. That is, corrector calculations are carried out until the corrector reaction rates are converged with the best-estimated number densities (obtained by the average of the predictor and updated corrector results). The apparent drawback of this approach is the computation time it requires. Since the corrector calculations need to be repeated, the computation time per time-step will increase.

Another approach is to utilize the relationship between gadolinium number density and the microscopic reaction rate of gadolinium isotopes. In fact, the microscopic reaction rates (i.e., reaction rate per atom) of gadolinium isotopes are approximately proportional to their number densities, at least within a moderate burnup step-size. By using this relationship, improved corrector reaction rates are estimated by the projection (or extrapolation) of the conventional PC results. This approach does not require additional corrector calculation; it is computationally efficient (Yamamoto et al. 2009).

A comparison of the accuracy achieved with the conventional PC and the “projected” PC (PPC) methods is presented in  Fig. 107. Apparently, the PPC method gives better accuracy than the conventional PC method. By using the PPC method, the width of the burnup step-size

■ Figure 107

Comparison of k -infinity for Gd-bearing fuel assembly (17×17 PWR fuel, 4.1 wt% enrichment, 10 wt% Gd_2O_3)

can be increased (less than doubled), that is, the number of the burnup step can be reduced (by less than half). Note that we can apply higher-order polynomials to represent the relationship between the number densities of gadolinium and their microscopic reaction rates. The drawback of the higher-order method is the amount of memory it requires. For example, in order to use the second-order polynomial, additional memory storage to maintain the microscopic reaction rates at three burnup points is necessary.

6.5 Summary

In this section, various aspects of the burnup calculations used in lattice physics computation, that is, physics, modeling, numerical methods, and other topics are summarized. Since the burnup calculation is one of the dominant factors contributing to the overall accuracy of calculations, its treatment is important. Though the burnup calculation is a major part of a lattice physics code, a detailed description of this issue can be hardly be found in common textbooks. This subsection would be helpful for both the users and developers of lattice physics codes.

7 Case Matrix

7.1 Introduction

All the individual state points that need to be analyzed by the lattice physics code to fully characterize the fuel design for use in a specific three-dimensional nodal code are referred to as

the *case matrix*. The case matrix will vary between different nodal codes and between different reactor types (i.e., between BWRs and PWRs). The necessity for a case matrix arises from our need to condense and homogenize cross sections over the entire lattice in order to generate two-group nodal data. To perform the condensation and homogenization, we need a very detailed flux distribution. The flux distribution changes as the conditions in the core change, and as the isotopics of the fuel change. This requires us to analyze the lattice every time the isotopics change substantially (i.e., burnup calculation) or every time a core parameter changes substantially (i.e., branch calculation), giving rise to a large collection of different cases. In this section, we will describe the approach used to build cross sections for use in a nodal code such as SIMULATE-3 (Dean et al. 2005). This is by no means an exhaustive discussion on case matrices and the reader should be aware that there are other ways of designing a case matrix to support a nodal code.

7.2 Cross Section Dependencies in BWRs

In general, macroscopic nodal cross sections for a specific reactor condition (e.g., exposure, fuel temperature, and moderator density) can be pieced together as the sum of a base cross section and a collection of partial cross sections, where each partial cross section is used to account for changes in the base cross section due to perturbations in various reactor conditions. To a good approximation, this can be expressed for BWRs as

$$\begin{aligned} \Sigma_x^g = & \Sigma_{x,V}^g(E, U) + \delta\Sigma_{x,TF}^g(E, V) + \delta\Sigma_{x,TM}^g(E, V) + \delta\Sigma_{x,CR}^g(E, V) \\ & + \delta\Sigma_{x,HCR}^g(E) + \delta\Sigma_{x,HTF}^g(E) + \delta\Sigma_{x,SDC}^g(E) \end{aligned} \quad (597)$$

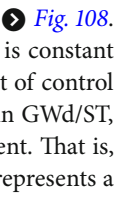

where x is a reaction type (e.g., absorption and fission); g is one of the two energy groups (either fast or thermal). The various cross sections have the following definitions:

- $\Sigma_{x,V}^g(E, U)$ is the base cross section as a function of instantaneous void content in the coolant, V ; exposure, E ; and historical void content, U (to be explained soon).
- $\delta\Sigma_{x,TF}^g(E, V)$ is the change in the base cross section at different exposures and different void conditions due to a change in fuel temperature, TF .
- $\delta\Sigma_{x,TM}^g(E, V)$ is the change in the base cross section at different exposures and different void conditions due to a change in the moderator temperature, TM .
- $\delta\Sigma_{x,CR}^g(E, V)$ is the change in the base cross section at different exposures and different void conditions due to the insertion of a control blade, CR .
- $\delta\Sigma_{x,HCR}^g(E)$ is the change in the base cross section at different exposures due to the removal of a control blade following a period of time during which the blade was inserted, HCR . This is referred to as the *control blade history* effect.
- $\delta\Sigma_{x,HTF}^g(E)$ is the change in the base cross section at different exposures due to extended operation at a fuel temperature other than the average fuel temperature, HTF . This is referred to as the *fuel temperature history* effect.
- $\delta\Sigma_{x,SDC}^g(E)$ is the change in the base cross section at different exposures following an extended period of inactivity, SDC . This is referred to as the *shutdown cooling* effect.

Historical Void

In (597), the *historical* void content in the coolant, U , is the void level at which the fuel has been depleted. In contrast, the *instantaneous* void content, V , is the amount of void currently in the coolant. To illustrate, a node may deplete for the first 6 months of operation with a void content of 50% (i.e., half vapor, half liquid). This 50% represents the *historical* void content, which is a function of time. It is also the instantaneous void content because it is the void level at which the node is currently operating. If, after 6 months of operation, the conditions in the core change and the void redistributes itself such that the node is filled with 35% void (i.e., 35% vapor, 65% liquid), we would say that our *instantaneous* void content is now 35%, but our *historical* void content remains 50% until we begin to deplete the node at this new void level. Then, assuming the void content remains at 35% for the foreseeable future, the new historical void content will slowly change from 50 to 35% over time.

The *historical* void content determines the isotopics of the fuel with time: higher void content produces a harder spectrum, which produces more Plutonium through U^{238} capture and depletes less U^{235} due to less thermal fission. When the node changes void instantaneously, the effect of the change is determined by the isotopes present in the fuel, which are determined by the historical void content. So, a node at an exposure of 20 GWd/ST that instantaneously changes from $U = 50\%$, $V = 50\%$ to $U = 50\%$, $V = 35\%$ will differ in reactivity from a node at an exposure of 20 GWd/ST that instantaneously changes from $U = 60\%$, $V = 60\%$ to $U = 60\%$, $V = 35\%$, simply because the isotopes will have built up differently over time in the two nodes. Although the two nodes currently contain the same void at the same exposure, their reactivities are different because their operating histories have been different.

The relationship between *instantaneous* void and *historical* void is illustrated in  [Fig. 108](#). In the figure, the saw tooth green line represents the void level over time, which is constant for long periods, but changes abruptly as core conditions change (e.g., adjustment of control blades, changes in core flow rate). In the graph, the abscissa is burnup, expressed in GWd/ST, and the ordinate is water density, expressed in g/cc, which is inverse to void content. That is, as void content increases, the water density decreases. The blue line in the graph represents a straightforward averaging of the void over time using the relationship

$$U = \frac{\sum V_i \cdot \Delta E_i}{\sum \Delta E_i} \quad (598)$$

This would be considered a crude estimate of void history. The orange line in the graph represents the true historical void content, defined by the reactivity worth of the node at any point in time. It can be closely approximated by the expression

$$U = \frac{\sum \exp\{0.08 \cdot \Delta E_i\} \cdot V_i \cdot \Delta E_i}{\sum \exp\{0.08 \cdot \Delta E_i\} \cdot \Delta E_i} \quad (599)$$

In (599), the exponential term is a weighting function that describes the decay of spectral effects from past void levels. In (598), the weighting function was set to unity for the straightforward averaging with time. The graph in  [Fig. 108](#) should be interpreted as follows: At any point in time, the reactivity of a node that has operated with the void levels represented by the V curve, is equivalent to having depleted the node at a constant void level defined by the U (*exact*) curve and then branching to the instantaneous void level represented by V . So, for example, the reactivity of the node at an exposure of 30 GWd/ST and an instantaneous water density of 0.742 g/cc in the figure (i.e., 0% void at hot operating conditions), can be determined by depleting the node

Figure 108

Relationship between instantaneous and historical void

at a constant water density of 0.377 g/cc (i.e., approximately 50% void at hot operating conditions) for 30 GWd/ST and then instantaneously branching to a water density of 0.742 g/cc. In this way, the lattice physics code does not have to follow the exact operating history of a node in order to supply cross sections to the nodal code. We simply need to deplete each lattice at several different historical void levels and perform back branch calculations periodically to different instantaneous void levels in order to generate sufficient cross section information for the nodal code. The nodal code can then interpolate between the explicit points analyzed by the lattice physics code in order to obtain cross sections for a specific core condition.

We now need to determine the number of different historical void levels that need to be analyzed by the lattice physics code in order to supply the nodal code with sufficient information to achieve the accuracy we desire. This number can be ascertained by inspecting [Fig. 109](#), which contains a graph of the fast group macroscopic cross section as a function of void fraction in the coolant (void fraction is defined as void percentage divided by 100, so a void fraction of 0.1 is 10% void, and so on). In the figure, there are two separate curves represented. The first curve is the magenta line, which is the fast group absorption cross section for the node. It has been generated by performing a detailed analysis of the lattice at void fraction increments of 0.1 (i.e., 10% void increments). This is the reference solution. The second curve is the black line that has been generated by fitting a quadratic through the explicit points at void fractions of 0, 0.4, and 0.8 (highlighted by the blue squares on the graph). Here, it can be seen that the cross section can be accurately represented as a quadratic between void fractions of 0 and 0.8. However, beyond a void fraction of 0.8, the cross section no longer behaves as a quadratic and the extrapolated points beyond a void fraction of 0.8 deviate significantly from the reference solution.

The implications of [Fig. 109](#) are rather significant. Years ago, when power densities at most BWRs were consistently at or below 50 kW/L, exit void fractions from fuel bundles were within the 0.8 range. From the quadratic fit in [Fig. 109](#), it can be seen that very little error

Figure 109
Behaviour of cross section as a function of void fraction

would be incurred by producing explicit data at void fractions of 0, 0.4, and 0.8 and then fitting a quadratic through the three points. Today, after years of power up-rates at many BWRs, the exit void fraction is close to 1.0. If the nodal code uses data from the lattice code that has been generated at explicit void fractions of 0, 0.4, and 0.8, the reactivity at the top of the core will be underestimated and the nodal code will model the axial power shape as being too bottom-peaked early in the cycle. This will result in the nodal code depleting the fuel in the bottom of the core too rapidly, causing the power shape to become too top-peaked during the second half of the cycle.

In order for the nodal code to provide us with the accuracy we desire, the lattice physics code will have to provide cross section data at four different void levels and then the nodal code can use a polynomial to interpolate between explicit data points. This is illustrated in [Fig. 110](#), where a polynomial has been fit through explicit data points at void fractions of 0, 0.4, 0.8, and 1. Note that there will be an inherent error in our cross sections from our polynomial interpolation scheme. That is, the black polynomial trend does not lie precisely on the magenta line. This is the error we will have to live with if we choose to implement this particular case matrix scheme.

The lattice physics code must supply the nodal code with tables of all the cross sections needed to solve the nodal diffusion equation. This includes fast and thermal group data for absorption and production cross sections, as well as the diffusion coefficient. In addition, the nodal code requires data for the fast group removal cross section, energy release values (κ), and a few parameters needed for modeling Xenon transients. If there are 15,000 nodes in the reactor model, then the nodal code has to perform approximately $12 \times 15,000$ interpolations for every analysis, or nearly 200,000 interpolations. This number does not include all the other tables of data that need to be interpolated, such as pin power form functions. If we want the nodal code to use a third-order polynomial fit to interpolate between points in our tables of cross sections, this could become very time consuming.

■ Figure 110

Polynomial fit to cross section data

A more economical approach is to allow the nodal code to interpolate linearly between explicit points in the cross section tables. But interpolating linearly between the four explicit data points is not going to provide us with the accuracy we desire. So we break the process into two steps. Our first step is to gather the explicit data points from the lattice physics code with a processing code that fits the data with a polynomial and creates intermediate points in our tables. That is, we gather the data points at void fractions of 0, 0.4, 0.8, and 1 from the lattice physics code and then allow the processing code to create additional points at void fractions of, say, 0.2 and 0.6 using a polynomial interpolation. The processing code creates tables for the nodal code that include data at void fractions of 0, 0.2, 0.4, 0.6, 0.8, and 1. Then the nodal code can interpolate linearly between all points in the table. This saves us a great deal of time during the nodal analysis without appreciably affecting our accuracy. It also saves us from having to analyze six explicit void fractions with the lattice physics code, which also saves us a great deal of time.

We will return to the topic of void in a later section.

Exposure

► *Figure 111* contains several graphs of reactivity from the depletion of a BWR lattice at various void fractions. The graph can be broken into three distinct regions. The first region consists of exposures between 0 and 0.25 GWd/ST. To help put these numbers in perspective, a single day of full power operation at a typical BWR accounts for approximately 0.025 GWd/ST of exposure, so the first region on the graph accounts for roughly 10 days of full power operation. During this period, the fuel is building in fission products, which account for a drop in reactivity of roughly 2% (i.e., $-0.02 \Delta\rho$ of reactivity).

The second region on the graph encompasses the rise in reactivity from an exposure of 0.25 GWd/ST to approximately 20 GWd/ST. During this period of time, the Gadolinium in the fuel design, which is used to hold down reactivity during the bundle's first cycle of operation, is

■ **Figure 111**
Reactivity as a function of exposure and void fraction

being depleted. The rise in reactivity, and the length of time that the rise lasts, is proportional to the Gadolinium loading. Different designs will have different rises and also different slopes to that rise. However, the point that is being made here is that there will be such a rise whenever Gadolinium is present. The reactivity peak is reached when the Gadolinium has been completely depleted from the bundle.

The third region of the curve consists of all data beyond the reactivity peak – in this case from an exposure of approximately 20 to 65 GWd/ST. This represents the typical reactivity let-down as the U^{235} depletes. It is not linear because there is Pu^{239} being bred due to U^{238} capture, and the Pu^{239} is producing energy during the depletion. Note that the reactivity letdown curve has a steeper slope for the smaller void fractions. As the void fraction increases, the flux spectrum hardens and more U^{238} capture takes place. As a result, there is more Pu available at the higher void fractions and the bundle's energy is consumed more slowly.

It is very important for the lattice physics code – and the nodal code – to accurately capture the detail of the bundle depletion around the reactivity peak. Since we never know exactly where this peak will occur until after the fuel design has been analyzed, the lattice physics code must be able to track the Gadolinium isotopes in the fuel and automatically take time-steps small enough to capture the details of this depletion. As a rule of thumb, time-step sizes for BWR fuel designs should probably not exceed 0.5 GWd/ST until the bundle has surpassed the reactivity peak. This ensures that the onion-skin style of depletion of the Gadolinium pins will be modeled with sufficient accuracy. Once the Gadolinium has been exhausted, it is customary to take time-steps that can range in size from 2.5 to 5 GWd/ST. When the lattice physics results are tabularized for use in the nodal code, it is crucial to ensure that enough exposure detail is maintained such that the reactivity peak is explicitly captured.

Void Coefficient

$\Sigma_{x,V}^g(E, U)$ in (597) represents the base cross section, which accounts for changes in reactivity due to changes in void content. These are the tables of cross sections alluded to in “Historical void” of this section, when we discussed depleting the lattice at several different void levels (i.e., void histories) and then performing a series of back branches at various exposures to various instantaneous void levels. In practice, we would choose our four base void fractions – 0, 0.4, 0.8, and 1 – and, for each void fraction, perform lattice depletions to a final exposure that is guaranteed to encompass the entire operating lifetime of the bundle (e.g., 65 GWd/ST). During the depletion analysis, we save the pin-by-pin isotopic concentrations at each depletion step in a binary file that we will refer to as a *restart file*. The restart file allows us to go back to any point during the depletion of the lattice and perturb one of the system parameters, such as void, and re-perform the step to determine the change in cross sections due to the perturbed parameter.

For the base cross sections, we would like to generate a full three-dimensional table as a function of exposure, historical void, and instantaneous void. To do this, we deplete the lattice at our first void fraction – 0 – and then go back and perform branch calculations to the other three void fractions – 0.4, 0.8, and 1 – at various exposures. Next, we deplete the lattice at our second void fraction – 0.4 – and then go back and perform back branches to the other three void fractions – 0, 0.8, and 1 – at various exposures. And so on with the remaining two void fractions. This will create our three-dimensional table of base cross sections.

For BWRs, the instantaneous void coefficient is more than an order of magnitude larger (i.e., more negative) than any of the other reactivity coefficients.

Fuel Temperature Coefficient

$\delta\Sigma_{x,TF}^g(E, V)$ in (597) represents changes in the cross sections due to changes in fuel temperature. This is referred to as the Doppler coefficient, which varies linearly with the square root of the fuel temperature, $\sqrt{T_f}$, and changes as the composition of the fuel changes. That is, the Doppler coefficient is dependent upon the amount of Uranium, Plutonium, and Gadolinium in the fuel. The cases performed with the lattice physics code to generate the Doppler coefficient consist of back branches at various exposures to a different fuel temperature from each of the uncontrolled depletions. Since the Doppler coefficient is linear, it makes no difference what fuel temperature is chosen for the back branches, so long as the change in reactivity is large enough to be captured by the lattice physics code. Often times, users prefer to branch from the full power fuel temperature used for the base depletions at the four different void fractions, to the hot zero power fuel temperature of 561 K (550 °F).

Moderator Temperature Coefficient

$\delta\Sigma_{x,TM}^g(E, V)$ in (597) represents changes in the cross sections due to changes in the moderator temperature. In BWRs at hot operating conditions, the coolant enters the reactor at a slightly subcooled temperature, but reaches saturation conditions within the first foot or so of the bottom of the core. Once the temperature reaches saturation conditions, it does not change and all heat from the fuel goes into boiling the water. As a result, there really is no cross section dependence on moderator temperature at operating conditions. The moderator temperature dependence comes into play at shutdown conditions. Unlike PWRs, which warm the reactor vessel up to hot zero power conditions before going critical, BWRs can go critical at any zero power temperature. Consequently, the lattice physics code needs to generate enough cross section data so as to enable the nodal code to accurately model criticality conditions at any

temperature below hot zero power conditions. This can usually be accomplished by performing back branches at various exposures from each of the uncontrolled depletions to three separate temperatures between cold conditions (293 K, 68 °F) and hot zero power (approximately 561 K, 550 °F). The back branches have to be performed at both uncontrolled and controlled conditions. The nodal code can then use a straightforward quadratic fit through the cross sections to obtain data at any cold temperature.

Control Blade Coefficient

$\delta\Sigma_{x,CR}^g(E, V)$ in (597) represents changes in the cross sections due to the presence of the control blade. This is perhaps the most direct dependency in (597). The data for this coefficient is generated by performing back branches at various exposures from each of the uncontrolled depletions to an identical condition with the control blade inserted.

Control Blade History Coefficient

$\delta\Sigma_{x,HCR}^g(E)$ in (597) is usually referred to as the *control blade history* effect. When a control blade is present next to a fuel bundle, the blade hardens the spectrum by removing thermal neutrons from the surroundings. The hardened spectrum enhances neutron capture in U^{238} and promotes the build-up of Plutonium in the controlled bundle – primarily in the fuel pins along the edge of the bundle closest to the control blade. If the control blade is present for several weeks of full power operation, the Pu build-up can be substantial. When the blade is removed, the bundle will have a different isotopic composition from its composition prior to being controlled and its reactivity may have actually increased over the controlled period of time. If the bundle is now operated uncontrolled for a long period of time, the Pu will eventually be exhausted. This effect is usually modeled at the lattice physics level by depleting the fuel segment with the control blade present and then performing uncontrolled back branches at various exposures. The uncontrolled back branches are compared against uncontrolled depletions of the fuel segment and the appropriate adjustments are made to the cross sections to capture the effect. The control blade history effect is typically modeled at the nominal void level (e.g., 40% void).

Fuel Temperature History Coefficient

$\delta\Sigma_{x,HTF}^g(E)$ in (597) represents changes in the cross sections due to extended periods of operation at a fuel temperature other than the nominal fuel temperature. The fuel temperature is directly proportional to the power level. Higher fuel temperatures represent higher power levels and harden the flux spectrum. Lower fuel temperatures represent lower power levels and soften the flux spectrum. Operating a fuel segment at a higher or lower fuel temperature, relative to the nominal temperature, for an extended period of time will change the isotopic concentration of the fuel and, hence, its reactivity. The data for this effect is generated by depleting the fuel at either an elevated or diminished fuel temperature and then performing back branches to the nominal fuel temperature at various exposures. The depletion at the elevated fuel temperature can be performed at a single void fraction – say the nominal value of 0.4 – and applied to all void levels. The partial cross sections are determined by comparing the back branches against results from the base depletion for the nominal void fraction. In a BWR, fuel temperature history is a very minor effect compared to the other reactivity coefficients and can be ignored without significantly affecting the accuracy of the cross sections.

Shutdown Cooling Coefficient

$\delta\Sigma_{x,SDC}^g(E)$ in (597) represents the decay of certain important isotopes as the bundle cools during a period of inactivity – often referred to as *shutdown cooling*. For short periods of inactivity (i.e., days), the isotopes that are of most interest are the fission products Promethium and Iodine, which decay to Samarium and Xenon, respectively. These decays are important because the Sm^{149} and Xe^{135} absorption cross sections are very large in the thermal energy range and have a profound effect on the reactivity of the fuel. The Xe^{135} is also an unstable isotope and will eventually decay to Cs^{135} , which is neutronically inert. For long periods of inactivity (i.e., years), we are most interested in the decay of Pu^{241} to Am^{241} and, to a lesser extent, the decay of Eu^{155} to Gd^{155} .

To model shutdown cooling effects, the lattice physics code can perform back branches at various exposures from one of the voided depletions – say the nominal value of 40%. Several shutdown cooling times are analyzed at each exposure point. These cooling times are usually spaced to cover a wide range of periods of inactivity. For example, 1 day, 10 days, 30 days, 1 year, and 4 years. This is usually adequate to cover all bundles that would be discharged from the core at the end of a given cycle and possibly be reinserted into the core at the beginning of a future cycle. The partial cross sections are created by comparing the values from the branch cases against values for the base set at the nominal void.

Our final set of BWR cross section tables will consist of a three-dimensional table of base cross sections augmented by a combination of two-dimensional and three-dimensional tables of various partial cross sections. For the case matrix described in this section, we will have a total of five depletions: four uncontrolled depletions at void fractions of 0, 0.4, 0.8, and 1; and one controlled depletion at a void fraction of 0.4. We will then have a very large series of back branches needed to generate the partial cross sections to (597). A generic CASMO-4 case matrix for generating a BWR cross section model at hot operating conditions is shown in [Table 26](#). The case matrix for generating a corresponding BWR cross section model at cold shutdown conditions is shown in [Table 27](#). In the tables: U represents the historical void level; V represent the instantaneous void level; CR represents the presence of the control blade; TFU represents the fuel temperature; TMO represents the moderator temperature; SDC represents shutdown cooling time; and BOR represents the boron concentration in the coolant, which is included only to analyze the effectiveness of the standby liquid control system (SLCS). All cases in the hot case matrix are performed at hot saturation conditions (i.e., an average coolant temperature of approximately 550 °F at a vessel dome pressure of 1,040 psi). The hot, full power fuel temperature of 900 K contained in the two tables is meant for illustration purposes only. The true value for the fuel temperature is typically obtained from a fuel-mechanical analysis of the fuel rod.

The exposure vector for depletion cases consists of time-step sizes of 0.5 GWd/MTU up to an exposure of 20 GWd/MTU, which can be considered at or beyond the Gadolinium burnout point. Beyond the Gadolinium burnout point, time-step sizes of 2.5 GWd/MTU are taken. In general, branch cases are performed at exposure increments of 2.5 GWd/MTU up to an exposure of 20 GWd/MTU. Beyond that, branch cases are performed at exposure increments of 10 GWd/MTU. Note that it is important for the lattice physics code to be able to determine the Gadolinium burnout point because the point will change as a function of void content in the coolant. At very high void fractions, such as 0.8 and 1, the Gadolinium depletes extremely slowly due to the diminished number of thermal neutrons present and the burnout point can be several GWd/MTU beyond the equivalent point at lower void fractions. For the depletion case with the control blade present, the Gadolinium will take a very long time to deplete.

7.3 Cross Section Dependencies in PWRs

To a good approximation, the macroscopic cross section for a PWR can be expressed as

$$\begin{aligned} \Sigma_x^g = & \Sigma_{x,HTM}^g(E) + \delta\Sigma_{x,HBOR}^g(E) + \delta\Sigma_{x,TF}^g(E) + \delta\Sigma_{x,TM}^g(E) \\ & + \delta\Sigma_{x,BOR}^g(E) + \delta\Sigma_{x,CRD}^g(E) + \delta\Sigma_{x,HTF}^g(E) + \delta\Sigma_{x,SDC}^g(E) \end{aligned} \quad (600)$$

where x and g are as previously defined in (597). The various cross sections have the following definitions:

- $\Sigma_{x,HTM}^g(E)$ is the base cross section as a function of exposure and historical moderator temperature, *HTM*.
- $\delta\Sigma_{x,HBOR}^g(E)$ is the change in the base cross section at different exposures due to changes in the historical boron concentration, *HBOR*.
- $\delta\Sigma_{x,TF}^g(E)$ is the change in the base cross section at different exposures due to a change in fuel temperature, *TF*.

- $\delta\Sigma_{x, TM}^g(E)$ is the change in the base cross section at different exposures due to a change in the instantaneous moderator temperature, TM .
- $\delta\Sigma_{x, BOR}^g(E)$ is the change in the base cross section at different exposures due to a change in the instantaneous boron concentration, BOR .
- $\delta\Sigma_{x, CR}^g(E)$ is the change in the base cross section at different exposures due to the insertion of a control rod cluster, CR .
- $\delta\Sigma_{x, HTF}^g(E)$ and $\delta\Sigma_{x, SDG}^g(E)$ are as previously defined in (597).

Historical Moderator Temperature

In (600), the *instantaneous* and *historical* moderator temperatures fill a role similar to the role filled by the instantaneous and historical void concentrations in the BWR cross section model. In a PWR, the vessel is pressurized to approximately 2,250 psi and the coolant is not meant to boil. As the liquid coolant flows up the assembly, it picks up heat from the fuel rods and the temperature of the coolant steadily rises with elevation. As a result, the coolant is relatively cool at the bottom of the fuel and is relatively hot at the top of the fuel, with a difference in temperature of approximately 75 °F (i.e., approximately 40 K) between the inlet to and exit from the core. The fuel at the bottom of the core consistently experiences a softer spectrum (i.e., higher water density) compared to the fuel at the top of the core, which consistently experiences a harder spectrum (i.e., lower water density). As time goes by, this difference in the flux spectrum produces a difference in isotopic concentrations between the bottom of a fuel rod and the top of the rod.

In order to model the effect this axial variation in the flux spectrum has on the fuel, the nodal code applies an *historical moderator temperature* model that is similar to the historical void model applied for BWRs. However, since it is rare for the axial moderator temperature profile to change appreciably during PWR operation, there is no real need to perform back branches off the historical moderator temperature depletions the way we performed back branches off the historical void depletions for BWRs. Therefore, it is acceptable to use a two-dimensional table for the base set of cross sections as opposed to the three-dimensional table we used for our BWR model. To generate the cross sections, the lattice is depleted at multiple moderator temperatures, using a nominal fuel temperature and a nominal boron concentration in the coolant. The instantaneous moderator temperature is assumed to be equal to the historical moderator temperature.

Historical Boron Concentration

By now, the reader should be developing a fairly good understanding behind historical parameters. These parameters change the isotopic concentrations of the fuel during extended operation, caused by changes in the flux spectrum – either a hardening or softening effect. The instantaneous parameters are those that have an instantaneous effect on reactivity, but no effect on isotopic concentrations. In (600), the *historical* boron concentration is used to account for changes in the fuel isotopics caused by extended periods of operation at boron concentrations in the coolant, which are different from the nominal value used to generate the base set of cross sections.

The presence of soluble boron in the coolant has a hardening effect on the flux spectrum by removing thermal neutrons. To properly model the dependency of the cross sections on boron, we can simply re-deplete the lattice with multiple boron concentrations, at the nominal moderator temperature and the nominal fuel temperature. The partial cross sections, $\delta\Sigma_{x, HBOR}^g(E)$,

are then calculated simply as the difference between the depletion using the perturbed boron concentrations and the depletion using the nominal boron concentration. The instantaneous boron concentration is assumed to be equal to the historical boron concentration (i.e., no back branches).

Moderator Temperature Coefficient

$\delta\Sigma_{x, TM}^g(E)$ in (600) represents changes in the cross sections due to instantaneous changes in the moderator temperature. The data for this effect is generated by performing back branches at various exposures to a different moderator temperature from the nominal historical moderator temperature. This accounts for spectrum softening effects caused by a drop in moderator temperature (i.e., an increase in moderator density) or spectrum hardening effects caused by a rise in moderator temperature (i.e., a decrease in moderator density). The cross sections behave as a quadratic versus moderator temperature, so data should be generated at three separate moderator temperatures (e.g., 560, 580, and 600 K). The nominal level is typically the middle level (i.e., core mid-plane temperature at full power conditions).

Boron Coefficient

$\delta\Sigma_{x, BOR}^g(E)$ in (600) represents changes in the cross sections due to instantaneous changes in the soluble boron concentration in the coolant. The data for this effect are generated by performing back branches at various exposures to different boron concentrations from the nominal historical boron concentration. This accounts for spectrum softening effects caused by a reduction in boron concentration or spectrum hardening effects caused by an increase in boron concentration. The absorption cross sections behave as a quadratic versus boron concentration, so data should be generated at three separate boron levels (e.g., 0, 800, and 1,600 ppm). The nominal level is typically the middle level (i.e., middle of cycle level).

The remainder of the partial cross sections contained in (600) has been discussed in [7.2](#), so we will not revisit them here. All PWR reactivity coefficients are of a similar magnitude, so they are all equally important to the overall accuracy of the nodal cross section sets. This includes the historical fuel temperature coefficient, which was considered somewhat insignificant in the BWR cross section model because it was so much smaller than all the other effects.

For the case matrix described in this section, we will have a total of four depletions: the base depletion; a depletion at a perturbed moderator temperature; a depletion at a perturbed boron condition; and a depletion at a perturbed fuel temperature condition. A generic CASMO-4 case matrix for generating a PWR cross section model at hot operating conditions is contained in [Table 28](#). The case matrix for generating a corresponding PWR cross section model at cold shutdown conditions is contained in [Table 29](#). In the tables: *HTMO* represents the historical moderator temperature; *TMO* represent the instantaneous moderator temperature; *CR* represents the presence of the control blade; *HTFU* represents the historical fuel temperature; *TFU* represents the instantaneous fuel temperature; *HBOR* represents the historical boron concentration; *BOR* represents the instantaneous boron concentration; and *SDC* represents shutdown cooling times.

The exposure vector for PWR depletion cases consists of time-step sizes of 1 GWd/MTU up to an exposure of 15 GWd/MTU (assuming Gadolinium is not being used as a burnable absorber in the fuel design). Beyond that, time-step sizes of 2.5 GWd/MTU are taken. In general, branch cases are performed at exposure increments of 2 GWd/MTU up to an

exposure of 20 GWd/MTU. Beyond that, branch cases are performed at exposure increments of 10 GWd/MTU.

7.4 Summary

This section has provided a description of one possible way of constructing a case matrix for a nodal code. The models described in this section are by no means exhaustive and are meant only to provide the reader with a glimpse at the types of analyses performed using a lattice physics code to support a nodal code. There are other ways of designing a case matrix for a nodal code. The main premise, though, is to provide the reader with an appreciation for the number of cases needed to be performed by the lattice physics code in order to accurately capture the behavior of the fuel over its anticipated lifetime in the core. For BWRs, the case matrix we have described will require approximately 1,200 state points per lattice. If the fuel design contains 8 lattices, it will take approximately 10,000 lattice physics state point calculations to fully functionalize the behavior of the fuel. The PWR case matrix we described contains substantially less – approximately 800 state points, 300 of which are needed to model hot

operating conditions. With this knowledge, the reader can begin to appreciate the effort required to accurately model the fuel in the core of a nuclear power plant.

8 Edits

This section presents some of the more common data passed from a lattice physics code to a nodal code. It is by no means an exhaustive list and there are often times more than one way of calculating a parameter. A perfect example of this would be the diffusion coefficient, which has no precise definition at the lattice physics level. Nevertheless, this section should provide the reader with an understanding of some of the back-end calculations performed by the lattice physics code.

The contents of this section have been taken from various information edited from LANCER02 (Knott and Wehlage 2007) for use in the nodal codes PANACEA (Moore et al. 1999) and AETNA (Iwamoto et al. 2003), and from various information edited from CASMO-4 (Knott et al. 1995) for use in the nodal code SIMULATE-3 (Dean 2005).

8.1 Nomenclature

g = energy group structure of the nodal code (typically two groups)

r = material region (e.g., fuel, clad, and coolant)

s = surface length of a particular mesh (cm)

S = surface length of an entire side of the lattice (cm)

h = six-group delayed neutron structure

i = energy group structure of the lattice physics code's neutron cross section library

j = energy group structure of the lattice physics code's gamma library

dr = volume of material region r per unit height (cm^3/cm)

$V(r) = dr$

V_{ass} = volume of entire lattice per unit height (cm^3/cm)

V_{fuel} = total volume of all fuel pellets per unit height (cm^3/cm)

$N_m(r)$ = atomic number density for nuclide m ; at position r

A_m = atomic mass of nuclide m

ρ_m = density for nuclide m , in (g/cm^3)

$\sigma_{xm}(g, r)$ = microscopic cross section for reaction type x ; of nuclide m ; in energy group g ; at position r .

$\phi(g, r)$ = neutron flux in energy group g ; at position r

$\psi(g, s)$ = neutron surface flux in energy group g ; at surface position s

$\chi_m(i, h)$ = delayed neutron fission spectrum of nuclide m ; for neutrons born in energy group i ; to be deposited in delayed group h

$\Psi(i)$ = neutron flux in group i from fundamental mode calculation

$\Psi^\dagger(i)$ = adjoint flux in group i from fundamental mode calculation

8.2 Various Edits

Parameters that need to be edited by the lattice physics code for use in the accompanying nodal code may include some of the following:

Lattice-averaged atomic number densities of nuclide m

$$\bar{N}_m = \frac{\int V_{ass} N_m(r) dr}{\int V_{ass} dr} \quad (601)$$

Fuel-averaged atomic number density of heavy isotope m

$$\bar{N}_m = \frac{\int V_{fuel} N_m(r) dr}{\int V_{fuel} dr} \quad (602)$$

Decay constant of delayed neutrons in delayed group h

$$\bar{\lambda}(h) = \frac{\sum_m \lambda_m(h) \cdot \beta_m(h) \cdot \sum_g N_m \nu \sigma_{f,m}(g) \phi(g)}{\bar{\beta}(h) \cdot \sum_g \nu \bar{\Sigma}_f(g) \phi(g)} \quad (603)$$

where $\beta_m(h)$ is the delayed neutron fraction for nuclide m , in delayed group h ; and $\lambda_m(h)$ is its decay constant. The summation over m is performed over all fissile isotopes. The averaged delayed neutron fraction, $\bar{\beta}(h)$, is calculated as

$$\bar{\beta}(h) = \frac{\sum_m \beta_m(h) \cdot \sum_g N_m \nu \sigma_{f,m}(g) \phi(g)}{\sum_g \nu \bar{\Sigma}_f(g) \phi(g)} \quad (604)$$

Lattice-averaged flux per nodal group

$$\bar{\phi}(g) = \frac{\int_{V_{ass}} \phi(g, r) dr}{\int_{V_{ass}} dr} \quad (605)$$

where the fine-mesh flux in the nodal-group energy structure, $\phi(g, r)$, is calculated by a straightforward condensation

$$\phi(g, r) = \sum_{i \in g} \phi(i, r) \quad (606)$$

Boundary diffusion coefficient per nodal group for each assembly surface

$$\bar{D}_s(g) = \frac{\int_{S_{ass}} D(g, r) \psi(g, r) dS}{\int_{S_{ass}} dS} \quad (607)$$

where the integral is performed over one assembly surface only. There are four $\bar{D}_s(g)$ values edited: (1) north; (2) east; (3) south; and (4) west.

Effective delayed neutron fraction for delayed group h

The effective delayed neutron fraction accounts for the fact that delayed neutrons are born at energies lower than those of prompt neutrons and, hence, do not contribute to fast fission and have smaller leakage rates into (or out of) the system than prompt neutrons. The effective delayed neutron fraction is calculated as

$$\beta(h) = \frac{\sum_m \left[\sum_i \beta_m(h) \bar{\chi}_{d,m}(i, h) \Psi^\dagger(i) \cdot \sum_i \nu \bar{\sigma}_{f,m}(i) \bar{N}_m \Psi(i) \right]}{\sum_m \left\{ \left(1 - \sum_h \beta_m(h) \right) \left(\sum_i \bar{\chi}_{p,m}(i) \Psi^\dagger(i) \right) + \sum_h \beta_m(h) \left(\sum_i \bar{\chi}_{d,m}(i, h) \Psi^\dagger(i) \right) \right\} \cdot \sum_i \nu \bar{\Sigma}_f(i) \Psi(i)}$$

$$\begin{aligned} & \frac{\sum_m \left[\sum_i \beta_m(h) \bar{\chi}_{d,m}(i, h) \Psi^\dagger(i) \cdot \sum_i v \bar{\sigma}_{f,m}(i) \bar{N}_m \Psi(i) \right]}{\sum_i \bar{\chi}(i) \Psi^\dagger(i) \cdot \sum_i v \bar{\Sigma}_f(i) \Psi(i)} \\ & \frac{\sum_m \left[\sum_i \beta_m(h) \bar{\chi}_{d,m}(i, h) \Psi^\dagger(i) \cdot \sum_i v \bar{\sigma}_{f,m}(i) \bar{N}_m \Psi(i) \right]}{k^\dagger \sum_i v \bar{\Sigma}_f(i) \Psi(i)} \end{aligned} \quad (608)$$

where the summation over m includes the isotopes: Th²³², U²³³, U²³⁴, U²³⁵, U²³⁶, U²³⁸, Pu²³⁹, Pu²⁴⁰, Pu²⁴¹, and Pu²⁴²; $\bar{\chi}_{d,m}(i, h)$ is the delayed neutron fission spectrum from energy group i to delayed group h , for isotope m ; $\bar{\chi}_{p,m}(i)$ is the prompt neutron fission spectrum for isotope m ; and $\bar{\chi}(i)$ is the total fission spectrum for the homogeneous system. The adjoint flux, $\Psi^\dagger(i)$, can be obtained by solving the non-leakage adjoint form of the fundamental mode equation

$$\bar{\Sigma}_{tr}(i) \cdot \Psi^\dagger(i) = \sum_{i'} \left[\bar{\Sigma}_s(i \rightarrow i') + \frac{v \bar{\Sigma}_f(i)}{k^\dagger} \cdot \bar{\chi}(i') \right] \Psi^\dagger(i') \quad (609)$$

where the adjoint multiplication factor is given by

$$k^\dagger = \sum_{i'} \bar{\chi}(i') \Psi^\dagger(i') \quad (610)$$

All cross sections are flux-volume weighted over the entire assembly using the forward flux from the MoC solution after expanding it to the energy group structure of the cross section library (i.e., the fine-group structure). In this formulation, it is assumed that the flux-volume weighted assembly-averaged cross sections using the forward flux are not significantly different from the equivalent cross sections that would be created using a spatial adjoint flux distribution. This assumption is perfectly adequate when non-leakage boundary conditions are used (either perfect reflexion or periodic).

The effective delayed neutron fraction can be calculated a slightly different way by considering neutron leakage effects. The adjoint flux, $\Psi^\dagger(i)$, is obtained by solving the adjoint form of the fundamental mode equation that includes neutron leakage effects

$$\left[\bar{\Sigma}_{tr}(i) + \bar{D}(i) B^2 \right] \cdot \Psi^\dagger(i) = \sum_{i'} \left[\bar{\Sigma}_s(i \rightarrow i') + \frac{v \bar{\Sigma}_f(i)}{k^\dagger} \cdot \bar{\chi}(i') \right] \Psi^\dagger(i') \quad (611)$$

where B^2 is the value of the material buckling from the solution to the forward form of the fundamental mode calculation, (29). The value of $\beta(h)$ should be more accurate when including leakage effects into the adjoint flux spectrum, since neutron leakage out of the system occurs predominately in the fast energy groups.

Total effective delayed neutron fraction

$$\beta_{\text{total}} = \sum_{h=1}^6 \beta(h) \quad (612)$$

Lattice-averaged diffusion coefficient per nodal group

$$D(g) = \sum_{i \in g} \left\{ \frac{1/3}{\int_{V_{ass}} \Sigma_{tr}(i, r) \phi(i, r) dr} \right\} \quad (613)$$

where the lattice-averaged diffusion coefficient is calculated in the fine-group energy structure and collapsed directly to the nodal-group energy structure. Note that it is important that the spatial homogenization be performed on the transport cross section, not the diffusion coefficient. If the spatial homogenization is performed on the diffusion coefficient, any vacuum regions in the lattice (e.g., air gaps between fuel pellet and cladding) will skew the value of the coefficient.

In the context of (613), the lattice-averaged diffusion coefficient in each energy group is being condensed. That is, we calculate a diffusion coefficient in the fine-group energy structure of the cross section library and condense it to the nodal-group structure. An alternative approach would be to condense the transport cross section to the nodal-group structure and calculate a diffusion coefficient from that. The equation would then take the form

$$D(g) = \frac{1/3}{\sum_{i \in g} \left\{ \int_{V_{ass}} \Sigma_{tr}(i, r) \phi(i, r) dr \right\}} \quad (614)$$

Equations (613) and (614) will give different values for the diffusion coefficients, especially in the fast energy group. Neither approach is incorrect – nor correct. Most nodal methods modify the diffusion coefficient during the iteration process, so the choice is somewhat irrelevant. Nodal results should be somewhat insensitive to the method chosen in the lattice physics code.

Absorption reaction rates per isotope m

$$\Sigma_{a,m} = \sum_g \int_{V_{ass}} N_m(r) \sigma_{a,m}(g) \phi_g(r) dr \quad (615)$$

Effective energy release per fission, per fuel rod

$$\kappa(r) = \frac{E_{kinetic}(r) + E_\gamma(r) + E_\beta(r) + E_s(r)}{\sum_g \Sigma_f(g, r) \phi(g, r) V(r)} \quad (616)$$

where the energy terms are defined in (45)–(48).

Flux discontinuity factor per nodal group

$$DF_S(g) = \frac{\int_S \psi(g, s) ds}{\int_{V_{ass}} \phi(g, r) dr} \quad (617)$$

Lattice-averaged fast flux (above 1 MeV)

$$\bar{\Psi}_{fast} = \sum_{E_i \geq 1 \text{ MeV}} \Psi(i) \quad (618)$$

where the summation over energy group runs from 20 MeV (group 1) to the energy boundary closest to 1 MeV.

Relative fission rate per fuel rod

$$\text{FRR}(r) = \frac{\sum_g \int_{V_{x,y}} \Sigma_f(g, r) \phi(g, r) dr}{\left\{ \frac{\sum_g \int_{V_{\text{fuel}}} \Sigma_f(g, r) \phi(g, r) dr}{\int_{V_{\text{fuel}}} dr} \right\}} \quad (619)$$

Relative gamma energy deposition per fuel rod

$$\text{GRR}(r) = \frac{\sum_j \int_{V_{x,y}} \Sigma_e(j, r) \phi(j, r) dr}{\left\{ \frac{\sum_j \int_{V_{\text{fuel}}} \Sigma_e(j, r) \phi(j, r) dr}{\int_{V_{\text{fuel}}} dr} \right\}} \quad (620)$$

where $\Sigma_e(j, r)$ is the macroscopic energy deposition cross section for material region r in the energy group structure of the gamma library, j .

Gamma detector response

$$D^y = \left(\frac{1}{P} \right) \sum_j \sigma_{e,m}(j) \phi(j, r) \quad (621)$$

where $\phi(j, r)$ is the gamma flux in the narrow–narrow corner of the problem for BWRs, or in the location of the instrument thimble for PWRs; and $\sigma_{e,m}(j)$ is the microscopic energy deposition cross section for some nuclide of choice (e.g., Fe). P is the lattice power level, in MeV.

Fission detector response

$$D^n = \left(\frac{1}{P} \right) \sum_i \sigma_{f,U^{235}}(i) \phi(i, r) \quad (622)$$

where $\phi(i, r)$ is the fine-group flux in the narrow–narrow corner of the problem for BWRs, or in the location of the instrument thimble for PWRs; and $\sigma_{f,U^{235}}(i)$ is the fine-group microscopic fission cross section for U^{235} . P is the lattice power level, in MeV.

Nodal infinite multiplication factor

This is the multiplication factor obtained from the two-group cross sections. The two-group cross sections are created using the fine-group critical flux spectrum following the fundamental mode calculation. Since the cross sections are collapsed using the critical spectrum, the two-group multiplication factor will not be precisely equal to the multiplication factor from the fine-mesh assembly transport calculation unless the multiplication factor for the system just happens to be 1.0.

$$k = \frac{v\bar{\Sigma}_f(1) + v\bar{\Sigma}_f(2) \cdot \frac{\bar{\Sigma}_{\text{rem}}}{\bar{\Sigma}_a(2)}}{\bar{\Sigma}_a(1) + \bar{\Sigma}_{\text{rem}}} \quad (623)$$

Lattice-averaged microscopic cross section per isotope

$$\bar{\sigma}_x(g) = \frac{\int_{V_{ass}} N_m(r) \sigma_{x,m}(g, r) \phi(g, r) dr}{\int_{V_{ass}} N_m(r) \phi(g, r) dr} \quad (624)$$

where x is a reaction type, such as absorption, capture, fission, or production.

Average nodal-group neutron velocity

$$\bar{v}(g) = \frac{\sum_{i \in g} \Psi^\dagger(i)}{\sum_{i \in g} \frac{\Psi^\dagger(i)}{v(i)}} \quad (625)$$

where $v(i)$ is the neutron velocity in the fine-group energy structure (i.e., velocity at the mid-point of the energy group); and $\Psi^\dagger(i)$ is the adjoint flux from the fundamental mode solution, including leakage. The value can also be calculated using the forward flux if the adjoint flux is not available.

$$\bar{v}(g) = \frac{\sum_{i \in g} \Psi(i)}{\sum_{i \in g} \frac{\Psi(i)}{v(i)}} \quad (626)$$

where $\Psi(i)$ is the critical forward flux from the fundamental mode solution.

Lattice-averaged macroscopic cross section per nodal group

$$\bar{\Sigma}_a(g) = \frac{\sum_{i \in g} \int_{V_{ass}} \Sigma_a(i, r) \phi(i, r) dr}{\sum_{i \in g} \int_{V_{ass}} \phi(i, r) dr} \quad (627)$$

where x is a reaction type, such as absorption, fission, or production.

Lattice-averaged macroscopic scattering kernel per nodal group

$$\bar{\Sigma}_s(g' \rightarrow g) = \frac{\sum_{i \in g} \sum_{i' \in g'} \int_{V_{ass}} \Sigma_s(i' \rightarrow i, r) \phi(i', r) dr}{\sum_{i \in g} \sum_{i' \in g'} \int_{V_{ass}} \phi(i', r) dr} \quad (628)$$

Lattice-averaged macroscopic removal cross section per nodal group

$$\bar{\Sigma}_{rem}(1) = \bar{\Sigma}(1 \rightarrow 2) - \frac{\bar{\phi}(2)}{\bar{\phi}(1)} \bar{\Sigma}(2 \rightarrow 1) \quad (629)$$

Equation (629) represents the value for a two-group energy structure, where there is a nonzero removal cross section only for the fast group (i.e., group 1). For a three-group energy structure, the expressions for the various group-dependent removal cross sections become

$$\begin{aligned}\bar{\Sigma}_{\text{rem}}(1) &= \frac{v\bar{\Sigma}_f(1) + v\bar{\Sigma}_f(2) \cdot \frac{\bar{\phi}(2)}{\bar{\phi}(1)} + v\bar{\Sigma}_f(3) \cdot \frac{\bar{\phi}(3)}{\bar{\phi}(1)}}{k^\infty} - \bar{\Sigma}_a(1) \\ \bar{\Sigma}_{\text{rem}}(2) &= \bar{\Sigma}_{\text{rem}}(1) \cdot \frac{\bar{\phi}(1)}{\bar{\phi}(2)} - \bar{\Sigma}_a(2) \\ \bar{\Sigma}_{\text{rem}}(3) &= 0\end{aligned}\quad (630)$$

In the expression for the fast group removal cross section, $\bar{\Sigma}_{\text{rem}}(1)$, the infinite multiplication factor is calculated as

$$k^\infty = \frac{v\bar{\Sigma}_f(1) \cdot \bar{\phi}(1) + v\bar{\Sigma}_f(2) \cdot \bar{\phi}(2) + v\bar{\Sigma}_f(3) \cdot \bar{\phi}(3)}{\bar{\Sigma}_a(1) \cdot \bar{\phi}(1) + \bar{\Sigma}_a(2) \cdot \bar{\phi}(2) + \bar{\Sigma}_a(3) \cdot \bar{\phi}(3)}\quad (631)$$

The above formulations closely preserve the reactivity from the fine-mesh assembly calculation. The reactivity will not be preserved precisely because the flux used to condense cross sections from the fine-group structure to the nodal-group structure is the critical spectrum, not the infinite spectrum.

Microscopic fission cross section at TIP location

$$\sigma_f(g, r') = \frac{\sum_{i \in g} \sigma_{f, \text{U}^{235}}(i) \phi(i, r')}{\sum_{i \in g} \phi(i, r')}\quad (632)$$

where r' is the location of the TIP tube in the narrow–narrow water gap corner of a BWR problem. The microscopic fission cross section is the unshielded (i.e., infinitely dilute) value.

Lattice-averaged fission yield of various isotopes

$$Y_m = \frac{\sum_{m' \in V_{\text{fuel}}} Y_{m', m} N_{m'}(r) \sigma_{f, m'}(g, r) \phi(g, r) dr}{\int_{V_{\text{fuel}}} N_{m'}(r) \sigma_{f, m'}(g, r) \phi(g, r) dr}\quad (633)$$

where $Y_{m', m}$ is the yield from actinide m' to isotope m ; and the summation is performed over all actinides Th²²⁸ through Cm²⁴⁶. The isotopes, m , of interest are typically La¹⁴⁰, Ba¹⁴⁰, Ce¹⁴⁴, I¹³⁵, Xe¹³⁵, Pm¹⁴⁹, and Sm¹⁴⁹.

Thermal–hydraulic data

In addition to cross section data, the lattice physics code usually edits thermal–hydraulic related data to the nodal code, which may include some or all of the following:

- In-channel flow area (not including water rods) (cm²).
- Out-channel flow area (not including control blade) (cm²).
- Water rod flow area (cm²).
- Control blade flow area (cm²).
- Total flow area (cm²).

- Density of in-channel water (g/cm^3).
- Density of out-channel water (g/cm^3).
- Density of water in water rods (g/cm^3).
- Density of water in control blade (g/cm^3).
- Lattice-averaged water density (g/cm^3).
- Heated perimeter of all fuel rods (cm).
- Wetted perimeter of in-channel coolant (cm).
- Wetted perimeter of out-channel coolant (cm).
- Hydraulic diameter of in-channel coolant (cm).
- Number of heated pins.

8.3 Neutron Balance

Neutron balances typically include the following definitions:

Region integrated flux

$$\text{RIF}(g, r) = \sum_{r' \in r} \bar{\phi}(g, r') \cdot V(r') \quad (634)$$

In this nomenclature, the neutron balance is being performed over all the mesh included in the region of choice, r . They could be all the mesh in the lattice, or a subset defined by the user.

Region averaged flux

$$\text{RAF}(g, r) = \frac{\text{RIF}(g, r)}{\sum_{r' \in r} V(r')} \quad (635)$$

Integrated absorptions

$$\text{ABS}(g, r) = \text{RIF}(g, r) \cdot \bar{\Sigma}_a(g, r) \quad (636)$$

Integrated fissions

$$\text{FISS}(g, r) = \text{RIF}(g, r) \cdot \bar{\Sigma}_f(g, r) \quad (637)$$

Integrated neutron production

$$\text{NUFISS}(g, r) = \text{RIF}(g, r) \cdot \bar{\nu} \bar{\Sigma}_f(g, r) \quad (638)$$

Integrated neutron leakage

$$\text{LEAK}(g, r) = \text{RIF}(g, r) \cdot \bar{D}(g) \cdot B^2 \quad (639)$$

Integrated out-scattering

$$\text{OUTSC}(g, r) = \text{RIF}(g, r) \cdot \sum_{g' \neq g} \bar{\Sigma}_s(g \rightarrow g', r') \quad (640)$$

Integrated in-scattering

$$\text{INSC}(g, r) = \sum_{g' \neq g} \text{RIF}(g', r) \cdot \bar{\Sigma}_s(g' \rightarrow g, r') \quad (641)$$

Integrated neutron source

$$\text{SOURCE}(g, r) = \bar{\chi}(g) \sum_{g'} \frac{\text{RIF}(g', r) \cdot \overline{\nu \Sigma_f}(g, r)}{k_{eff}} \quad (642)$$

Net neutron in-current

$$\begin{aligned} \text{INCURR}(g, r) = & \text{ABS}(g, r) + \text{EAK}(g, r) + \text{OUTSC}(g, r) \\ & - \text{INSC}(g, r) - \text{SOURCE}(g, r) \end{aligned} \quad (643)$$

All cross sections in (636)–(642) are region-averaged, using the following expression:

$$\bar{\Sigma}_x(g, r) = \frac{\sum_{r' \in r} \Sigma_x(g, r') \cdot \phi(g, r') \cdot V(r')}{\sum_{r' \in r} \phi(g, r') \cdot V(r')} \quad (644)$$

The fluxes and cross sections have been condensed directly from the fine-group energy structure to the nodal-group energy structure

$$\Sigma_x(g, r') = \frac{\sum_{i \in g} \Sigma_x(i, r') \cdot \phi(i, r')}{\sum_{i \in g} \phi(i, r')} \quad (645)$$

$$\phi(g, r') = \sum_{i \in g} \phi(i, r') \quad (646)$$

9 Concluding Remarks

In this chapter, we have presented a rather verbose treatise on current lattice physics methodology. The salient features of a lattice physics code include the following:

- The generation of energy group-dependent neutron and gamma cross section libraries;
- A resonance calculation used to obtain cross sections from the neutron cross section library for resonance absorbers;
- A means of combining energy groups in order to accelerate the solution to the Boltzmann transport equation;
- A detailed solution to the Boltzmann transport equation to determine the spectral and spatial distribution of neutrons throughout the exact planar geometry of the fuel design;
- A fundamental mode calculation to account for neutron leakage effects in an ad hoc manner;
- The calculation of gamma sources and a detailed solution to the fixed-source Boltzmann transport equation to determine the spectral and spatial distribution of gamma particles throughout the exact planar geometry of the fuel design;
- Editing of nodal constants and various form functions;
- The saving of isotopic data to some sort of a restart file;
- And the solution to the burnup chains, assuming the analysis involves a time-step.

For some of these topics, there may exist multiple approaches that are equally well suited to solving the problem at hand. In such cases, we have tried to provide a broad description of the

various techniques. This is most notable in [▶ Sects. 3](#) and [▶ 6](#), which cover the resonance calculation and the solution to the burnup chains, respectively. In both sections, many different techniques have been presented. For other topics – most notably those concerned with solving the Boltzmann transport equation – there is one approach that is so vastly superior to all other approaches that we have simply concentrated on describing that one method in great detail such that the reader can fully appreciate its intricacies. This includes [▶ Sects. 4](#) and [▶ 5](#), which cover the group condensation scheme and the fine-mesh lattice transport calculation, respectively.

The accuracy of current state-of-the-art lattice physics codes for light water reactor analysis has now approached the level of accuracy of the Monte Carlo codes that are being used to generate reference solutions for benchmarking. As such, potential improvements stand to gain little in the way of accuracy and are little more than minor tweaks to the current methods. As computers become more powerful, the most significant improvements may be realized by adding more energy groups to the lower resonance region of the cross section library (i.e., below 100 eV), creating unshielded cross section groups and minimizing the importance of the resonance calculation described in [▶ Sect. 3](#). Beyond that, improvements in accuracy will most likely come from improvements to the raw cross section data and the processing of the data (e.g., the NJOY methodology), both of which are beyond the scope of the lattice physics code.

Recent developments in lattice physics are almost universally related to expanding the analysis to a collection of bundles, as opposed to analyzing a single bundle. Such two-dimensional multi-bundle analyses are not needed in order to generate cross sections for use in nodal codes, but rather are used as reference solutions for comparison to equivalent nodal calculations. These comparisons can sometimes serve to help uncover modeling deficiencies at the nodal level. This type of development really falls outside the traditional definition of a lattice physics code and could be thought of more appropriately as a convenient way of replacing the Monte Carlo analysis as a reference solution, since such analyses can be cumbersome to implement and time consuming to execute. In any event, this seems to be an area that is experiencing a great deal of attention at the moment with the promise that, at some point in the future, it will translate into a full three-dimensional modeling capability with thermal–hydraulic feedback and include an explicit thermal–mechanical treatment of the stresses experienced by the fuel cladding. Once again, such calculations would serve to provide reference solutions against which the nodal production code could be benchmarked.

Abstract: This chapter discusses how core isotopic depletion and fuel management are completed for reactor cores of nuclear power plants. First, core isotopic depletion is discussed, in particular, how the Bateman equation is numerically solved, and the behaviors of the fissile, fertile, burnable poison and transient fission products isotopes. The concepts of breeding, conversion, and transmutation are introduced. Nuclear fuel management is discussed next, with a strong emphasis on the fuel management for light water reactors (LWRs), given their predominance. The discussion utilizes the components of design optimization, those being objectives, decision variables, and constraints. The fuel management discussion first addresses out-of-core fuel management, which involves such decisions as cycle length; stretch out operations; and feed fuel number, fissile enrichment, and burnable poison loading and partially burnt fuel to reinsert, for each cycle in the planning horizon. In-core fuel management is introduced by focusing on LWRs, with the basis of making decisions associated with determining the loading pattern, control rod program, lattice design, and assembly design presented. This presentation is followed by a brief review of in-core fuel management decisions for heavy water reactors, very high temperature gas-cooled reactors, and advanced recycle reactors. Mathematical optimization techniques appropriate for making nuclear fuel management decisions are next discussed, followed by their applications in out-of-core and in-core nuclear fuel management problems. Next presented is a review of the computations that are required to support nuclear fuel management decision making and the tools that are available to accomplish this. The chapter concludes with a summary of the current state of depletion and nuclear fuel management capabilities, and where further enhancements are required to increase capabilities in these areas.

1 Burnup and Conversion

1.1 Introduction

To understand the behavior of a reactor's core over its operating lifetime, it is necessary to be able to predict the changes in the isotopic composition of the core as a function of both time and space. Given the isotopic composition of the core, macroscopic cross-section values as a function of time and space can be determined as follows.

$$\Sigma_x(\vec{r}, E, t) = \sum_j \sigma_{x_j}(\vec{r}, E, t) N_j(\vec{r}, t) \quad (1)$$

where

$\Sigma_x(\vec{r}, E, t)$ = macroscopic cross-section for reaction type x

$\sigma_{x_j}(\vec{r}, E, t)$ = microscopic cross-section for reaction type x of isotope j

$N_j(\vec{r}, t)$ = number density of isotope j

\vec{r}, E, t = spatial position, neutron energy, and time-independent variables

Equation (1) indicates that the microscopic cross-section is not only a function of neutron energy, but also of spatial position and time. These latter dependencies arise because of the temperature dependence originating from Doppler broadening and the thermal scattering kernel. Solving the neutron transport equation or an approximation to it, e.g., neutron diffusion equation, yields the flux distribution throughout the core, which in turn can be used to determine the power distribution and many other core attributes of interest.

The isotopic composition of the core is also of interest to access the performance of other stages of the nuclear fuel cycle than core performance. Concerns about criticality, radiation intensity, and heat load are relevant to back-end stages, e.g., storage, partitioning, and waste disposal, and even front-end stages when considering a closed fuel cycle, e.g., MOX fuel fabrication. Further, knowledge of isotopic compositions are used when a fuel pin failure has occurred in narrowing down the possible core location of the failed pin, and when completing gamma scans on a discharged fuel assembly to infer power production and discharge burnup. The composition of the fuel, now elemental rather than isotopic, is also utilized in materials' simulations to predict fuel performance attributes, e.g., swelling, fission product gas release, thermal conductivity, and melting temperature. It follows that what isotopes need to be tracked is dependent upon the intended usage.

1.2 The Bateman Equation

The Bateman balance equation mathematically describes the time dependency of the isotopic number densities. Assuming that the isotopes' spatial movement from their place of origination does not occur, the spatial dependence of the isotopic number densities can be suppressed if it is recognized that the Bateman equation is written for a specific spatial position \vec{r} as now indicated

$$\begin{aligned} \frac{dN_i(t)}{dt} = & \sum_j \left[\int_0^\infty \gamma_{ji}(E, t) \sigma_{f_j}(E, t) \phi(E, t) dE \right] N_j(t) \\ & + \sigma_{c_{i-1}}(E, t) \phi(E, t) N_{i-1}(t) + \lambda_{i'} N_{i'}(t) \\ & - \left\{ \left[\int_0^\infty (\sigma_{f_i}(E, t) + \sigma_{c_i}(E, t)) \phi(E, t) dE \right] + \lambda_i \right\} N_i(t) \end{aligned} \quad (2)$$

where

$\left[\int_0^\infty \gamma_{ji}(E, t) \sigma_{f_j}(E, t) \phi(E, t) dE \right] N_j(t)$ = creation rate of isotope i due to fission of isotope j

$\sigma_{c_{i-1}}(E, t) \phi(E, t) N_{i-1}(t)$ = creation rate of isotope i due to radiative neutron capture in isotope $i - 1$

$\lambda_{i'} N_{i'}(t)$ = creation rate of isotope i due to radioactive decay of isotope i'

$\left[\int_0^\infty (\sigma_{f_i}(E, t) + \sigma_{c_i}(E, t)) \phi(E, t) dE \right] N_i(t)$ = destruction rate of isotope i due to fission and radiative neutron capture

$\lambda_i N_i(t)$ = destruction rate of isotope i due to radioactive decay

Needless to say, for a specific isotope i not all destruction terms in (2) may appear. The implication is that not all isotopes are coupled to each other, which from a mathematical viewpoint means that the balance equation for a specific isotope i does not couple to all other isotopic balance equations.

It is noted that the neutron flux appears in the Bateman equation. But the neutron flux depends on the isotopic number density distributions in the core, which implies that a nonlinear problem must be solved. Assuming for now that the neutron flux is known, (2) can be written in compact matrix notation

$$\frac{d\bar{N}(t)}{dt} = \bar{A}(t)\bar{N}(t) \quad (3)$$

where the single bar denotes a column vector, the double bar denotes a matrix, and the elements of the coefficient matrix given by $(\overline{\overline{A}}(t))_{ij} = a_{ij}(t)$ denote the coefficient of one of the creation or destruction terms in (2).

1.3 Solution of the Bateman Equation

Assuming for now that the neutron flux is known so that the nonlinear coupling between the Bateman equation and neutron transport equation can be ignored, there are a number of approaches to solve (3) utilizing numerical methods. A challenge to numerically solve this equation is addressing the potential for a wide range of timescales associated with the different isotopes, implying that methods appropriate for solving a stiff system of equations may be necessary. Alternatively, those isotopes which are relatively short lived could be separated from (3), allowing the altered equation to be solved for isotopes with longer lives using nonstiff solvers and the isotopes with shorter lives treated separately using a different method. Mathematically, this implies that the coefficient matrix is partitioned into block submatrices and written as

$$\overline{\overline{A}} = \begin{bmatrix} \overline{\overline{A}}_{ll} & \overline{\overline{A}}_{ls} \\ \overline{\overline{A}}_{sl} & \overline{\overline{A}}_{ss} \end{bmatrix} \quad (4)$$

where l and s denote, respectively, the isotopes associated with the longer and shorter lives, and subscripts mn (where m and n equate to s or l) indicate the matrix elements associated with creation of isotopes m from isotopes n . If it is assumed now that the short-lived isotopes do not produce the long-lived isotopes, then $\overline{\overline{A}}_{ls} = 0$ and (4) reduces to a two-step solution given by

$$\frac{d\overline{N}_l(t)}{dt} = \overline{\overline{A}}_{ll}(t)\overline{N}_l(t) \quad (5)$$

and

$$\frac{d\overline{N}_s(t)}{dt} = \overline{\overline{A}}_{ss}(t)\overline{N}_s(t) + \overline{\overline{A}}_{sl}(t)\overline{N}_l(t) \quad (6)$$

enabling these two equations to be numerically solved utilizing different methods.

Methods that can be considered in solving the Bateman equations include all those methods associated with solving coupled first-order ordinary differential equations, e.g., finite difference, Runge-Kutta, matrix exponential, and under certain conditions analytic approaches, e.g., integrating factor technique or Laplace transforms. Nearly all these methods have been employed sometime in the past, but today two solution methods dominate.

The matrix exponential method (Moler and Van Loan 2003) is widely employed to solve problems where all sorts of coupling between isotopes can be accounted for. This is the method utilized in the ORNL-produced ORIGEN code (Bell 1973) and the CEA DARWIN code (Roque et al. 2002). Using the concepts of the integrating method to solve an ordinary differential equation and Taylor's series expansion, one can show that the solution to (3) can be written

$$\overline{N}(t_n) = \overline{N}(t_{n-1})e^{\int_{t_{n-1}}^{t_n} \overline{\overline{A}}(t)dt} \quad (7)$$

where

$$e^{\int_{t_{n-1}}^{t_n} \bar{\bar{A}}(t) dt} = \bar{I} + \sum_{m=1}^{\infty} \frac{\left(\int_{t_{n-1}}^{t_n} \bar{\bar{A}}(t) dt \right)^m}{m!} \quad (8)$$

where t_n and t_{n-1} denote the current and former discrete times associated with discretizing the time variable. If it is assumed that $\bar{\bar{A}}(t) = \bar{\bar{A}}(t_{n-1})$ for $t \in [t_{n-1}, t_n]$, then $\int_{t_{n-1}}^{t_n} \bar{\bar{A}}(t) dt = \bar{\bar{A}}(t_{n-1}) \Delta t_n$ defining $\Delta t_n = t_n - t_{n-1}$. To assure more rapid convergence of the infinite series, which in practice is approximated using a finite number of terms, note that

$$e^{\bar{\bar{A}}(t_{n-1}) \Delta t_n} = \left(e^{\bar{\bar{A}}(t_{n-1}) (\Delta t_n / q)} \right)^q \quad (9)$$

allowing scaling to be introduced. If the scale factor q is selected to be a power of 2, then (9) can be evaluated by successive squaring starting with the term $\left(e^{\bar{\bar{A}}(t_{n-1}) (\Delta t_n / q)} \right)$ evaluated using (8). It can be shown that the first few terms in the summation may have norms larger than one, but eventually they will become smaller than one and decrease in norm size as m increases. This is referred to as the “hump” effect. It is possible to determine the value of q such that at a specified value of m , the expansion will be over the “hump.” Also, one can obtain a series truncation error bound that indicates how many terms in the summation must be carried to assure a specified accuracy and a round-off error bound.

For the short-lived isotope chains, an analytic solution can be employed, again assuming that the coefficient matrix is constant over a time step. This avoids the necessity to introduce small time steps associated with numerical approximations. Vondy (1962) has analytically solved the Bateman equation for an arbitrary forward-branching chain

$$N_i(t_n) = N_i(t_{n-1}) e^{-|a_{ii}| \Delta t_n} + \sum_{k=1}^{i-1} N_k(t_{n-1}) \left[\sum_{j=k}^{i-1} \frac{e^{-|a_{jj}| \Delta t_n} - e^{-|a_{ii}| \Delta t_n}}{|a_{ii}| - |a_{jj}|} a_{j+1,j} \prod_{\substack{n=k \\ n \neq j}}^{i-1} \frac{a_{n+1,n}}{|a_{nn}| - |a_{jj}|} \right] \quad (10)$$

where N_i for $i = 1, 2, \dots$ denote the concentrations of the short-lived isotopes. This equation can be rearranged so that it can be programmed in a recursive manner, thereby minimizing the computational burden. As written, (10) assumes that only one long-lived isotope N_0 serves as the precursor for the short-lived isotopes, which can be corrected. Equation (10) can be extended to predict the concentration of the long-lived isotope that has associated with it short-lived precursors, i.e., those associated with the $\bar{\bar{A}}_s$ submatrix. Details on how this is accomplished in the case of the ORIGEN code can be found in Bell (1973).

When completing reactor physics calculations, one needs only to specifically treat isotopes where at least one of its macroscopic cross-section is large enough to affect the calculational solution. In this case the majority of the isotopes that exist in partially burnt fuel can be ignored. It is not uncommon to just specifically treat the fissile–fertile, transient fission products (if a thermal spectrum reactor), and reactivity control materials isotopes. Given the resulting limited number of linear chains, (10) can be used directly to predict the concentrations of the isotopes

in each linear chain. Use of (10) in this context denotes the second dominant solution method noted above. To account for fission products beyond the transient fission products, i.e., Pm^{149} , Sm^{149} , I^{135} , and Xe^{135} , one or more lumped fission products are introduced. Each lumped fission product is characterized by an effective fission product yield and capture cross-section so selected to approximately produce the correct capture rates as a function of exposure for a subset of fission products.

1.4 Results of Burnup Calculations

It is informative to look at the time behavior of several of the more important isotopes for reactor physics as the core is burned. What isotopes are present and their behaviors will be dependent upon the specific reactor type, e.g., boiling water reactor, heavy water reactor, and fast sodium reactor, and its associated fuel cycle, e.g., open fuel cycle and closed fuel cycle recycling only U and Pu.  [Figures 1](#) and  [2](#) present isotopic number densities for a representative Pressurized Water Reactor (PWR) lattice, which utilizes a lattice average fuel enrichment of 4.07 w/o and Erbium in the form of Erbium (Er_2O_3) as the burnable poison material.  [Figure 1](#) shows the fissile–fertile chain associated with uranium. As expected, this figure indicates that U235 is depleting in an approximately exponential fashion with time with a reduction to about 1 w/o at the time of discharge. For U238 the amount of depletion is very small.  [Figure 2](#) presents the plutonium isotopes, where, as expected, the lower mass isotopes build up and reach an equilibrium concentration sooner. The equilibrium concentration occurs when the creation rate equals the destruction rate.

1.5 The Breeding (Conversion) Ratio

The breeding (conversion) ratio is defined as the number of fissionable atoms produced to the number of fissionable atoms consumed in a reactor. If this ratio is greater or equal to 1, it is referred to as the breeding ratio. If less than 1, it is referred to as the conversion ratio. In terms of the coefficient matrix introduced in (3) it is mathematically defined by

Breeding (Conversion) Ratio at time t

$$= \frac{\sum_{i \in s_{\text{Capture}}} \left[\int_0^\infty \sigma_{c_i}(E, t) \phi(E, t) dE \right] N_i(t) + \sum_{i' \in s_{\text{Decay}}} \lambda_{i'} N_{i'}(t)}{\sum_{j \in s_{\text{Fissile}}} \left[\int_0^\infty (\sigma_{f_j}(E, t) + \sigma_{c_j}(E, t)) \phi(E, t) dE + \lambda_j \right] N_j(t)} \quad (11)$$

where s_{Fissile} refers to the set of fissile isotopes, e.g., U235, Pu239, and Pu241, s_{Capture} and s_{Decay} refer to the set of isotopes that either through neutron capture, e.g., Pu240, or decay, e.g., Np239, respectively, produces fissile isotopes. [Equation \(11\)](#) in reality is of little value since it refers to a specific time and spatial position (recall the spatial dependence has been suppressed). To obtain the value for a core over a reactor cycle, one reintroduces the spatial variable and integrates the numerator and denominator over the core volume and time from the beginning to the end of cycle rendering.

Figure 1
Uranium isotope concentrations versus burnup for a lattice

Figure 2
Plutonium isotopes concentrations versus burnup for a lattice

Breeding (Conversion) Ratio

$$= \frac{\int_{V_{Core}} d\vec{r} \int_{t_{BOC}}^{t_{EOC}} dt \left(\sum_{j \in S_{Capture}} \left[\int_0^\infty \sigma_{c_j}(\vec{r}, E, t) \phi(\vec{r}, E, t) dE \right] N_j(\vec{r}, t) + \sum_{i' \in S_{Decay}} \lambda_{i'} N_{i'}(\vec{r}, t) \right)}{\int_{V_{Core}} d\vec{r} \int_{t_{BOC}}^{t_{EOC}} dt \sum_{j \in S_{Fissile}} \left[\int_0^\infty (\sigma_{f_j}(\vec{r}, E, t) + \sigma_{c_j}(\vec{r}, E, t)) \phi(\vec{r}, E, t) dE + \lambda_j \right] N_j(\vec{r}, t)} \quad (12)$$

A high ratio can be obtained by selecting isotopes, which have a high number of fission neutrons produced per neutron capture.

1.6 Transmutation

Transmutation involves, via a nuclear reaction, the transmuting of a long half-life isotope into a stable or short half-life isotope. This is one possible manner of minimizing the heat and radio toxicity loads of high-level nuclear waste by transmitting Pu, minor actinides, and certain fission products. Minor actinides consist of the isotopes associated with elements of the actinide series of the periodic table minus U and Pu, which for spent fuel mainly implies Np237, Am241, Am243, Cu242-Cu248, and Ca249-Ca252. For isotopes that can fission, one desires to operate in a neutron energy range where the fission to capture cross-section is large, thereby avoiding the production of additional heavy isotopes via neutron capture. For Pu and minor actinides, a hard neutron spectrum accomplishes this. For fission products of interest, in particular Tc99, Cs135, and I129, which do not fission, they are best transmuted in a thermal spectrum via neutron capture.

Both critical and noncritical facilities are being considered as the source of neutrons. For critical facilities, a low conversion ratio design is desired, achieved by designing a fast reactor with a high fuel to coolant volume ratio. For a subcritical facility, an external neutron source is required, obtained using an accelerator-driven system (ADS), which creates neutrons by having high-energy protons collide with a high atomic number target, e.g., tungsten, mercury, and lead. By using a subcritical system, it is thought that some of the safety design requirements of a critical system that are more difficult to satisfy, such as having a proper reactivity power coefficient, can be avoided.

1.7 Burnable Poisons

As the fuel depletes, for a typical thermal reactor or any reactor where the conversion ratio is less than 1, the core reactivity decreases. The implication is to keep the reactor critical for the desired energy production; the core must start up with considerable excess reactivity. This excess reactivity must be offset with negative reactivity sources to make the core critical at the desired power level. If done by just utilizing control rods the cost would be high and the fuel duty increased due to the large number of control rods required, assuming this was even possible from a reactivity hold-down viewpoint. For a boiling water reactor (BWR) where the coolant flow rate through the core can be adjusted by the recirculation system, by operating at lower flow

rate core reactivity can be decreased. This occurs via the increased resonance capture from the reduced moderation due to the higher coolant void fraction. Since the majority of resonance capture is associated with U238, which produces Pu239 after neutron capture and beta decays, using coolant flow rate to control excess core reactivity is a desirable approach since excess neutrons are utilized to generate fissile material that is consumed later in the cycle. Flow stability and critical heat flux limit the flow reduction, hence reactivity reduction that can be achieved, implying the need for another source of excess reactivity control. For a PWR one can utilize soluble boron for excess reactivity control, which has neither an adverse cost nor fuel duty consequence. But as the soluble boron concentration is increased, the moderator density coefficient turns from positive to negative, which is adverse for overpower accidents that result in the decrease of moderator density. So even for PWRs as cycle length increases, requiring higher soluble boron concentrations to maintain criticality, at some point another reactivity control mechanism is required.

Burnable poisons consist of the introduction of a highly neutron-capturing material in the core, which depletes due to neutron capture. Since isotopes with large neutron capture cross-sections occur mainly in the thermal energy range, burnable poisons are only utilized in thermal reactors. Ideally, the rate of burnable poison material depletion is such that the associated reduction in negative reactivity introduced is equal to the reduction in positive reactivity associated with fuel depletion. Such a perfect balance is not possible in practice. Burnable poisons come in two varieties: discrete and integral burnable poisons. Discrete burnable poisons are only used in PWRs, where they are encased in a cladding material and displace fuel pin locations in the fuel assembly. A boron compound is normally selected as the burnable poison material. Integral burnable poisons do not displace fuel pins but are blended into the fuel matrix or coated on the fuel pellet surface. If blended with the UO_2 powder, gadolinia (Gd_2O_3) or erbia (Er_2O_3) powder is used, the powder subsequently pressed and baked to form the solid ceramic pellet. If coated on the pellet surface, this is done by a spraying application of a boron compound dissolved in a solvent, which subsequently evaporates. Both forms of burnable poisons suffer from not all the burnable poison material depleting, in particular, the isotopes with large thermal capture cross-sections. This introduces negative reactivity in the core requiring higher fuel enrichments to be used to satisfy the cycle energy requirement beyond what would have been required. Higher fuel enrichments are also required because burnable poison material is displacing fuel material. Discrete burnable poisons suffer from the additional penalties of neutron captures in the cladding material and for LWRs displacement of moderator, both of which introduce negative reactivity which is not desired near the end of cycle.

Natural erbium consists mainly of Er166, Er167, Er168, and Er170, with Er167 having a large thermal capture cross-section. The concentrations of the first three isotopes versus time are presented in [▶ Fig. 3](#) for the lattice design introduced in [▶ 1.4](#). Two behaviors are to be noted in this figure. Firstly, at representative discharge burnups the Erbium isotope with the large thermal capture cross-section (Er167) still exists with some abundance, implying a reactivity penalty that will increase the required fuel enrichment to achieve a desired discharge burnup. Secondly, the significant reason why Er167 exists with some abundance at higher burnups is due to the capture of neutrons in Er166, which produces Er167. [▶ Figure 4](#) shows the reactivity hold down associated with using an Erbia burnable poison using natural erbium and 100% enriched in Er167 material. The reactivity penalty of Er166 capturing a neutron and producing Er167 is evident in this figure.

2 Transient Fission Products

2.1 Transient Fission Product Equations

Transient fission products are defined as fission products, which can change concentrations over hours to weeks, and whose capture reaction rates are significant enough to affect the core's attributes. They are mainly of interest for thermal reactors, since the thermal capture cross-sections for certain fission products can be very large. The transient fission products of interest for thermal reactors are Pm^{149} , Sm^{149} , I^{135} , and Xe^{135} . These particular isotopes are of interest because Sm^{149} and Xe^{135} possess large thermal capture cross-sections so are poisons in thermal reactors. They are created by the following simplified paths:

and

2.2 Xenon Transient Phenomena and Control

The xenon concentration in a nuclear reactor core can vary over a time period of hours. This can occur during core escalation to power and shutdown, during load follow maneuvers, and during changes in the power distribution from control rod motion. The resulting xenon concentration transient will impact the core reactivity, a global phenomenon, and the core power distribution, a spatial phenomenon.

2.2.1 Global Phenomena

➤ *Figure 5* displays the behaviors of the transient fission products Sm^{149} and Xe^{135} for the lattice introduced in ➤ 1.4. For fresh fuel, there are no fission products present. Within several days of operation, Xe^{135} approaches its equilibrium concentration and hence appears in the figure at equilibrium all the time due to the scale used. After plant shutdown, a substantial increase in the concentration of Xe^{135} will occur over the first 10 hours or so, since the I^{135} decay rate is larger than the Xe^{135} decay rate, and destruction of Xe^{135} by neutron capture no longer exists. Subsequently, the Xe^{135} will decay away since the I^{135} decay source is substantially diminished. When load following using a nuclear reactor, a less severe Xe^{135} concentration transient is experienced. When reducing power, the Xe^{135} concentration will build up as in complete plant shutdown, but at a slower rate. If the reduced power is maintained the Xe^{135} concentration will eventually decrease to reach the equilibrium concentration associated with the reduced power. When performing an up power maneuver, the reverse behavior occurs. Initially, the Xe^{135} concentration will decrease rapidly due to destruction by neutron capture, but latter the Xe^{135} concentration will increase to reach the equilibrium concentration associated with the higher power. The effect of the changes in concentration on core reactivity along with that associated with the power

Figure 5
Xe135 and Sm149 isotopic concentrations versus burnup for a lattice

reactivity coefficient must be compensated for via the reactivity control system to maintain the reactor critical at the desired power level. If attempted by solely using control rods (blades), the resulting axially partial control rod insertions may result in unacceptable power distributions, so additional reactivity control devices will need to be employed, e.g., PWR soluble poison and BWR recirculation flow rate.

The buildup of Sm^{149} to its equilibrium concentration can be seen in Figure 4, which takes several weeks. The subsequent variation with burnup is due to the flux magnitude, flux energy-spatial spectra and fission product effective yield changing. Upon plant shutdown, the concentration of Sm^{149} reaches a maximum since the Pm^{149} decays to Sm^{149} , which is stable. The only source of Sm^{149} destruction is via neutron capture, which is now zero. The implication is that partially burnt fuel that is used in a reload cycle will start with zero concentrations of Pm^{149} , I^{135} , and Xe^{135} and maximum concentration of Sm^{149} . With regard to daily load follow, the more sluggish time behavior of Sm^{149} makes its effect on core reactivity much less important than that of Xe^{135} .

2.2.2 Spatial Phenomena

The behavior of Xe^{135} on a local basis can complicate power maneuvering for a thermal reactor, in particular in light water reactors (LWRs). Performing a down power maneuver, the moderator's density decreases as it flows up through the core, due to either the temperature rise in a PWR or void fraction increase in a BWR. Without compensatory action, the negative reactivity gradient due to the moderator density decrease with elevation is reduced with a power

reduction shifting the axial power distribution toward the upper core region. This results in an initial increase in the Xe^{135} concentration due to power reduction being less pronounced in the upper core region, which further shifts the axial power distribution toward the upper core region. Several hours later the top peaked axial power distribution will result in increased Xe^{135} production once the I^{135} has had time to decay. This introduces preferentially negative reactivity in the upper core region, which causes the axial power distribution to shift toward the lower core region. Now the same phenomena that occurred in the upper core region takes place in the lower core region. The resulting oscillation can either decay or grow with time, the determination dependent on the moderator reactivity density coefficient and its rate of change with moderator density. For a PWR the core becomes axially unstable later in life due to the more positive moderator reactivity density coefficient that occurs as the soluble boron concentration is decreased in order to keep the reactor critical as the fuel depletes. Regarding radial core oscillations due to Xe^{135} , they are not expected to occur over the entire cycle for both PWR and BWR.

3 Nuclear Fuel Management

3.1 Introduction

The focus of this section will be mainly on LWRs, both PWRs and BWRs, but much of the content is applicable to reactors of a different type. Nuclear fuel management is concerned with making the following decisions:

1. Cycle length between refueling outages, i.e., cycle energy requirement
2. Utilization of stretch out, i.e., operating reactor beyond when criticality can be maintained at full-rated power with nominal plant conditions
3. Fresh fuel assemblies number and compositions
4. Burnt fuel assemblies to reinsert
5. Burnable poison type and total loadings
6. Core loading pattern, i.e., fresh fuel, burnt fuel, and burnable poisons core locations
7. Control rod (blades) locations and core flow rate (only for BWRs) as function of burnup

These decisions are for each cycle in the planning horizon, which typically number between five and ten cycles for Decisions 1–5, and three to five cycles for Decisions 6 and 7.

Commercial nuclear power plants are reloaded on some frequency. This is necessary even if core criticality at full-rated power can be maintained, i.e., breeder reactor, because of material limitations of the nuclear fuel, which limit the time it can spend for producing power. Further, from an economic viewpoint periodic partial refueling of the reactor is desirable. Indeed, the maximum energy that can be extracted from nuclear fuel is obtained when continuous refueling is possible, e.g., approached by online refueling used in CANDU reactors.

Nuclear fuel management is typically subdivided into out-of-core nuclear fuel management and in-core nuclear fuel management. Out-of-core decisions address Decisions 1–5; whereas, in-core decisions address Decisions 6 and 7. This subdivision is convenient but should be recognized as artificial in that out-of-core and in-core nuclear fuel management decisions are truly coupled. The following presentation utilizes this subdivision.

3.2 Out-of-Core Nuclear Fuel Management

Out-of-core nuclear fuel management is concerned with making Decisions 1–5 noted in [3.1](#). Since any of those decisions will impact future reload cycles, out-of-core decision making involves a multicycle analysis. The overall fuel cycle is not mentioned as an out-of-core decision, but could be considered as one of the decisions. The overall fuel cycle refers to decisions associated with material flows throughout the various stages of the fuel cycle, i.e., mining and milling, conversion, enrichment, fuel fabrication, power generation, storage, separations, and waste disposal. Not all fuel cycle stages may be associated with a specific fuel cycle, e.g., the separation stage would be absent in an open fuel cycle and the enrichment stage could be absent for a heavy water thermal reactor. Possible fuel cycles include the U thermal reactor open fuel cycle, U-Pu thermal or fast reactor closed fuel cycle, U-Th thermal reactor closed fuel cycle, and various closed fuel cycles that recycle specific minor actinides and fission products either in homogenous or heterogeneous core designs. Several of these fuel cycles could work in tandem, which has been extensively studied considering merits such as resource utilization, proliferation resistance, high-level waste disposal, and economics (Dixon et al. 2008). To limit the following discussion, it has been assumed that the decision concerning the overall fuel cycle has been made.

Decision 1, the operating cycle length, is selected considering the seasonal energy demands of the electric utilities customers and electrical energy costs. The seasonal energy demand is highly dependent upon the geographic area that the electric utility services. Weather conditions will dictate the heating and air conditioning loads as a function of time of year. The mix of consumer and industry loads, and the types of industry, will also impact the electrical energy demands as a function of time of year. Peak loads may occur in the winter if heating using electrical energy, e.g., heat pumps or resistance heating, is dominant or in the summer if air conditioning load dominates. For a service territory where the industrial load dominates the consumer load, the load variation throughout the year may be slight. For many service territories, fall or spring will be the lowest demand sessions. Since nuclear electric plants have the lowest fuel costs, it is not desirable to take these plants off line for refueling outages during peak load sessions since loss of their generating capabilities would need to be offset by generation of electrical energy using higher fuel cost generating capability or intra-grid purchases.

The fuel cycle cost of a nuclear power plant also influences the selected cycle length. As the cycle energy requirement is increased, the fuel cycle cost of a nuclear power plant increases, as can be seen in [Fig. 6](#). The reason for this behavior will be explained later. So when selecting the cycle length, say 6, 12, 18, or 24 months minus the time for the refueling outage, one needs to consider the nuclear fuel cycle cost, replacement power fuel cycle cost, and outage operation and maintenance (O&M) cost. Mathematically this can be expressed as

$$\text{Grid Energy Cost} = \frac{\sum_p c_p E_p}{\sum_p E_p} \quad (13)$$

where c_p is the cost per unit energy and E_p is the energy produced over some time period for power plant p . Now customer demand requires that $\sum_p E_p = E_{\text{Grid}}$ where E_{Grid} denotes this demand. The cost per unit energy consists of capital, O&M, and fuel cost components. The capital cost component of the product $c_p E_p$ can be assumed nearly independent of whether power plant p is running or not, since it is related to retiring the debt and earning a return on

Figure 6

Fuel cycle cost versus cycle length for different assumed costs of uranium ore (\$/kg of yellowcake)

the capital investments, so it does not enter the decision about desired cycle length. Fixing this term in (13), and focusing on a specific nuclear power plant and its replacement power

$$\text{Effective Nuclear Energy Cost} = \text{Capital Energy Cost} + \frac{(c_{nuc}^{fuel} + c_{nuc}^{O\&M})E_{nuc} + \Delta C_{nuc}^{O\&M} + c_{rep}\Delta E_{rep}}{E_{nuc} + \Delta E_{rep}} \quad (14)$$

where the delta terms refer to the refueling outage either in terms of nuclear power plant O&M costs or replacement energy required. As the nuclear cycle length is increased, both the fuel cycle cost and the nuclear energy output increase. If it is assumed that the refueling outage length, replacement power cost, and replacement energy needed per outage are independent of cycle length, (14) implies that there is an optimum cycle length resulting from the trade-off of higher nuclear fuel cycle power cost versus lower nuclear outage O&M and replacement energy costs as cycle length is increased. This is shown in Fig. 7. If the ratio of replacement power cost to nuclear fuel cycle power cost increases, the optimum cycle length increases. Seasonal demand discussed above comes into play in (14) when it is recognized that the unit replacement power cost and/or amount of replacement power needed would increase if refueling outages occurred during periods of high electrical energy demand.

Once the operating cycle length is selected, the cycle energy requirement (E_{Cycle}), effective full power days ($EFPD$), and cycle burnup (BU_{Cycle}) can be determined. This is done as follows:

$$E_{Cycle} = Q \cdot CF \cdot T_{Cycle} \quad (15)$$

$$EFPD = CF \cdot T_{Cycle} \quad (16)$$

$$BU_{Cycle} = \frac{E_{Cycle}}{M_{HM}} \quad (17)$$

Figure 7

Effective fuel cycle cost versus cycle length for replacement power cost = 35 mills/kWh

where Q denotes the rated core thermal power (MWth), CF the capacity factor over the cycle, T_{Cycle} the cycle length (days), and M_{HM} the heavy metal (fissile + fertile) loading (MT or ST) for the total core when fresh fuel. The following example illustrates the utilization of these equations.

Example:

Rated Power = 3411MWth, Cycle Length = 548 days (18 months),

CF = 90%, Heavy Metal Loading 89.9 MTU

Cycle Energy Requirement = $3411 * 548 * 0.9 = 1,682,305 \text{ MWDth}$

Effective Full Power Days = $548 * 0.9 = 493.2$ days

Cycle Burnup = $1,682,305 / 89.9 = 18,713 \text{ MWD / MTU}$

Decision 2, utilization of stretch out, concerns operating the reactor beyond when criticality can be maintained at full-rated power with nominal plant conditions. Without consideration of stretch out, for a reactor with a conversion ratio less than 1, end-of-cycle (EOC) is assumed to occur when all excess reactivity control systems are such that minimum negative reactivity is inserted in the core, the core is at full-rated power at nominal conditions, and the core is just critical. The implication is that one additional fission event will cause the core to be marginally subcritical. Stretch out changes the definition of EOC by not demanding that the core be at full-rated power at nominal conditions when determining EOC. Since power reactors must possess a negative power reactivity coefficient for safety reasons, core reactivity increases as power decreases. This occurs due to less resonance capture from the lower fuel temperatures and more effective moderation in a light water reactor due to higher coolant density. Further, core reactivity will increase due to the reduced equilibrium xenon concentration that exists at a lower power. If no action is taken, when the core reaches nominal EOC, the power will thereafter

reduce with time since any additional fission will cause the core to go subcritical and therefore on a power reduction transient until criticality is restored. For this reason, such operation is referred to as coast down. For a limited time period during coast down in a PWR, full-rated power electrical energy production may be possible by further opening the turbine inlet valves, thereby maintaining high pressure turbine impulse pressure and decreasing the entropy loss across these valves. Eventually, the electric output will decrease, which may necessitate the generation or purchase of more expensive replacement power to meet customer needs.

Before commencing stretch out by coast down, alternatives do exist that minimize the loss of reduction in electric power output. For LWRs, which are substantially under-moderated near EOC, if the coolant density could be increased core reactivity would increase allowing full core power operation to be maintained beyond nominal EOC. For a BWR, this is accomplished by increasing the core flow rate above nominal 100% via the recirculation system, limited by the recirculation systems capability and moisture separators/dryers capabilities to produce dry steam. For a PWR that operates on a programmed reactor vessel average coolant temperature, by decreasing the programmed value the average coolant density in the reactor will increase, which in turn inserts positive reactivity. The average coolant temperature reduction is achieved by decreasing the reactor vessel inlet coolant temperature by reducing the preheating of the secondary side feed water. Again moisture separators/dryers ability to produce dry steam limits the extent that feed water temperature reduction can be utilized. Also note that decreasing feed water temperature will decrease steam generator pressure and eventually high pressure turbine impulse pressure once the turbine inlet valves go fully open, resulting in reduced electric power due to reduced thermodynamic efficiency.

The economically optimum extent of stretch out to utilize is determined by considering the reduced nuclear fuel cycle cost due to more energy being extracted from the core and the offsetting cost of replacement power. Early in stretch out, the logical thing to do is to utilize a coolant density increase because this minimizes the need for replacement power since rated or nearly rated electric power can be maintained. Thereafter, coast down can be commenced, necessitating the purchase of replacement power. At some point, the reduction in nuclear fuel cycle cost will be offset by the cost of replacement power, this point defining the economic optimum extent of stretch out to utilize. In practice, BWRs tend to routinely utilize stretch out, whereas PWRs seldom utilize stretch out.

Decisions 3, 4, and 5, which are fresh fuel assemblies number and compositions, burnt fuel assemblies to reinsert, and burnable poison type and total loadings, are highly coupled decisions. The objectives of making these decisions are

- Satisfying the cycle energy requirements
- Minimizing the fuel cycle cost

To discuss how these decisions are made, some definitions are useful.

Fuel Region: A group of fuel assemblies loaded into the reactor for the first time (fresh fuel) together. Note that these assemblies need not be identical, i.e., have the same average enrichment.

Fuel Batch: A subgroup of fuel assemblies from a fuel region, which has the same assembly average enrichment and also experiences the same irradiation (burnup) history.

The number of fuel assemblies in each fuel region and batch is one of the decisions that must be made. The result of making these decisions can be expressed in a cycling scheme table as illustrated in [▶ Table 1](#).

■ **Table 1**
Example of cycling scheme table

Cycle	1	2	3	4	5	...
Cycle length	500 days	325 days	325 days	325 days	325 days	...
Stretch out	No	No	No	No	No	...
BP loading	8% $\Delta\rho$	0% $\Delta\rho$	0% $\Delta\rho$	0% $\Delta\rho$	0% $\Delta\rho$...
Region/batch						
1/a	50 F/A	0	0	0	0	...
1/b	1	1	0	0	0	...
1/c	1	0	1	0	0	...
1/d	1	0	0	1	0	...
2	52	52	0	0	0	...
3	52	52	52	0	0	...
4/a	0	51	51	51	0	...
4/b	0	1	1	1	1	...
5/a	0	0	51	51	51	...
5/b	0	0	1	1	1	...
...

This table is for a PWR core with a total of 157 fuel assemblies in the core, as indicated by adding the number of assemblies in a column. Region 1 subdivides into Batches a, b, c, and d because of different irradiation histories. Actually, the Batches b, c, and d serve as the center fuel assembly in the core for Cycles 2, 3, and 4, respectively. Deviating from the normal definition of a fuel region for Cycle 1, Regions 1, 2, and 3 are designated even though these fuel assemblies are all loaded as fresh fuel at the same time, distinguished by differing enrichments and irradiation histories. Examining  [Table 1](#) along rows indicates the number of cycles a Region–Batch pairing is irradiated.

Assuming that the cycling scheme table is determined, which specifies the number of fuel assemblies in each region–batch pairing, the only free variable in a reload cycle to satisfy the cycle energy requirement is the fuel assembly enrichments for the region–batch pairings of the fresh fuel.

The following constraints are very important in making nuclear fuel management decisions.

- Maximum fuel enrichment must be less than or equal to the maximum enrichment allowed, e.g., enrichment specified in the Critical Materials License used to assure subcriticality throughout various stages of the nuclear fuel cycle, e.g., LWR: 5.0 w/o.
- Fuel discharge burnup must be less than or equal to the maximum burnup dictated by materials limitations.

The following types of burnup limits may be imposed:

- Region average burnup – Average of burnup of all assemblies in a region
- Batch average burnup – Average burnup of all assemblies in a batch
- Assembly burnup – Average burnup of an assembly, i.e., axially and radially averaged burnup of all rods in an assembly
- Rod burnup – Average burnup of a rod, i.e., axially averaged burnup of a rod
- Pellet burnup – Individual pellet burnup

Typical values for the region average discharge burnup limit, denoted $\langle BU \rangle_{\max}$, are (45–50) GWD/MTU for PWRs and (40–45) GWD/MTU for BWRs, where GWD denotes giga-watt days.

To understand how burnup limits impact out-of-core nuclear fuel management decisions, consider the impact of the region average discharge burnup limit, $\langle BU \rangle_{\max}$. To simplify the discussion, consider an equilibrium reload cycle, which is a cycle that has an infinite repetition of the same cycle energy requirement utilizing the same cycling scheme in each cycle. For an equilibrium cycle, the number of cycles a region is burned is equal to the number of fuel regions in the core. To see this, consider a PWR core with a total number of assemblies equal to 156 (removed center fuel assembly to simplify the example). Now assume that three regions are utilized in each equilibrium cycle, which produces the cycling scheme table shown in [Table 2](#).

It is clear that a three-region core produces three cycles of irradiation of each region. This implies that the region average discharge burnup is calculated by

$$\text{Region Average Discharge Burnup} = (\text{Number of Regions}) * (\text{Cycle BU})$$

Imposing the region average discharge burnup limit

$$\langle BU \rangle_{\text{Disc}} = (\text{Number of Regions}) * BU_{\text{Cycle}} \leq \langle BU \rangle_{\max}$$

and solving for the constraint on the number of regions

$$\text{Number of Regions} \leq \langle BU \rangle_{\max} / BU_{\text{Cycle}}$$

Table 2

Example of three-region core for equilibrium cycles

Cycle	n	$n+1$	$n+2$	$n+3$	$n+4$
Region ^a					
...
m	52	0	0	0	0
m + 1	52	52	0	0	0
m + 2	52	52	52	0	0
m + 3	0	52	52	52	0
m + 4	0	0	52	52	52
...	

^aBatch ID not shown since only one batch per region

The implication is that the maximum number of fuel regions that can be utilized is fixed. If the limit on number of regions allowed is exceeded, the region average discharge burnup limit will be violated. As region average discharge burnup limit is increased or cycle burnup is decreased, the number of fuel regions allowed increases. Consider the following PWR example.

$$\text{Given } \langle BU \rangle_{\max} = 48 \text{ GWD/MTU}, BU_{\text{Cycle}} = 16 \text{ GWD/MTU}$$

(determined from cycle length and capacity factor)

$$\text{Maximum Number of Regions} = 48/16 = 3$$

Now the number of feed (fresh) fuel assemblies for an equilibrium cycle is given by

$$\text{Number of Feed Fuel Assemblies} = \frac{\text{Total Number of Fuel Assemblies in Core}}{\text{Number of Regions}}$$

which for the PWR example noted above with a total number of fuel assemblies equal to 156 and using the maximum number of regions of 3 produces

$$\text{Number of Feed Fuel Assemblies} = 156/3 = 52$$

This example produces the cycling scheme table shown in [▶ Table 2](#).

What if the number of regions is not equal to an integer number as in our example? This of course is the more likely situation. Consider the following example.

$$\text{Cycle Length} = 589 \text{ days}, \text{CF} = 91\% \Rightarrow \text{Cycle BU} = 20.34 \text{ GWD/MTU}$$

$$\text{Maximum Number of Regions} = 48/20.34 = 2.36$$

This result implies that if the maximum number of regions is employed, that all fuel assemblies will be burnt two cycles and subset of assemblies (36%) will be burnt three cycles. The number of feed fuel assemblies is given for this example by

$$\text{Number of Feed Fuel Assemblies} = 156/2.36 = 66.1 \Rightarrow 67$$

which has been rounded up to obtain a whole assembly and avoid exceeding the region average discharge burnup limit. Since some assemblies are only burnt two cycles and others three cycles, the region splits into two batches due to different irradiation histories. To determine the number of fuel assemblies in each batch, one first calculates the number of assemblies in the batch burnt three cycles based upon filling the core, followed by a calculation of the number of assemblies in the batch burnt two cycles.

$$\text{Number of assemblies burnt 3 cycles} = 156 - 2 * 67 = 22$$

$$\text{Number of assemblies burnt just 2 cycles} = 67 - 22 = 45$$

■ **Table 3**

Example of 2.33 region core for equilibrium cycles

Cycle	n	$n+1$	$n+2$	$n+3$
Region/batch				
...
m/b	22	0	0	0
m + 1/a	45	0	0	0
m + 1/b	22	22	0	0
m + 2/a	45	45	0	0
m + 2/b	22	22	22	0
m + 3/a	0	45	45	0
m + 3/b	0	22	22	22
m + 4/a	0	0	45	45
m + 4/b	0	0	22	22
...

The associated cycling scheme table for this example is presented in [Table 3](#), where the figure caption has denoted that this cycling scheme corresponds to a 2.33 region core due to rounding up to a whole fuel assembly.

In practice, when loading the core with fuel assemblies, one wishes to retain quarter core symmetry. This implies that region and batch sizes must be a multiple of 4, which for our example has the following effect.

$$\text{Region Size} = 67 \Rightarrow 68$$

$$\text{Batch "b" Size} = 156 - 2^* 68 = 21 \Rightarrow 20$$

$$\text{Batch "a" Size} = 68 - 20 = 48$$

Note that the number of fuel assemblies in Batch b, which is the batch burnt three cycles, is rounded down to assure that the region average discharge burnup limit is not violated.

So far examples have been worked using the maximum number of regions allowed. Any number of regions less than the maximum allowed would be acceptable with regard to satisfying the region average discharge burnup limit. What determines the desired number of fuel regions is economics, in particular, minimization of the fuel cycle cost. In fact, the fuel cycle cost is minimized by using the maximum number of regions allowed. The inclination is to think that because using the maximum number of regions equates with using the least number of feed fuel assemblies, the economics is most favorable. But the favorable economics results for another reason. Two examples will show this.

Consider the case of an equilibrium cycle, uniform core power distribution, fixed $\langle BU \rangle_{Disc}$, variable feed enrichment selected to take the fuel to $\langle BU \rangle_{Disc}$, and variable cycle length. Now

for a one- and two-region core, the EOC core average burnup, i.e., average burnup of all fuel assemblies in the core at EOC, is

$$\begin{aligned} \text{Number of Regions} &= 1 \\ \langle BU \rangle_{\text{Core}} &= \langle BU \rangle_{\text{Disc}} \\ \text{Number of Regions} &= 2 \\ \langle BU \rangle_{\text{Core}} &= (BU_{\text{Disc}}/2)(1/2) + (BU_{\text{Disc}})(1/2) = 3/4 BU_{\text{Disc}} \end{aligned}$$

So a two-region core has 25% less core average burnup than a one-region core at EOC, implying that a lower feed fuel enrichment than anticipated could be utilized, resulting in fuel cycle cost reduction. For an N region core, one obtains

$$\begin{aligned} \text{Number of Regions} &= N \\ \langle BU \rangle_{\text{Core}} &= [(N + 1) / 2N] BU_{\text{Disc}} \end{aligned}$$

So the benefits of a reduced core average burnup at EOC become greater as more fuel regions are utilized, but the incremental benefits in increasing the number of regions by one decrease as the number of regions increases. In the limit of a very large number of regions, which would be associated with frequent online refueling, the core average burnup at EOC is reduced by 50% from that of a one-region core.

An alternative justification for why utilizing the maximum number of regions allowed is economically preferred can be obtained utilizing the linear reactivity model (LRM) (Driscoll et al. 1990). LRM assumes that the fuel's reactivity decreases linearly with burnup. Now assuming an equilibrium cycle, uniform core power distribution, variable $\langle BU \rangle_{\text{Disc}}$, fixed feed enrichment, and variable cycle length, one can determine the cycle energy production and $\langle BU \rangle_{\text{Disc}}$ as a function of the number of regions utilized.

$$\begin{aligned} \text{Number of Regions} &= 1 \\ \text{Core Reactivity} &= \rho = \rho_0 \left(1 - \frac{BU}{BU_1} \right) \end{aligned} \quad (18)$$

where ρ_0 denotes the beginning-of-life (BOL) core reactivity (set by feed enrichment) and BU the cycle burnup at any time during the cycle. At EOC core reactivity is zero and cycle burnup $BU = BU_{\text{Cycle}}$ so

$$0 = \rho_0 \left(1 - \frac{BU_{\text{Cycle}}}{BU_1} \right) \quad (19)$$

implying for a one-region core $BU_{\text{Cycle}} = BU_1$ and $\langle BU \rangle_{\text{Disc}} = 1^* BU_{\text{Cycle}} = BU_1$.

$$\begin{aligned} \text{Number of Regions} &= 2 \\ \text{Core Reactivity} &= \rho \approx \rho_0 \left(1 - \frac{BU}{BU_1} \right) \cdot \frac{1}{2} + \rho_0 \left(1 - \frac{BU_{\text{Cycle}}}{BU_1} - \frac{BU}{BU_1} \right) \cdot \frac{1}{2} \end{aligned} \quad (20)$$

where BU_{Cycle} denotes the EOC cycle burnup for this two-region core. Again at EOC core reactivity is zero and $BU = BU_{\text{Cycle}}$ so

$$0 = \rho_0 \left(1 - \frac{BU_{\text{Cycle}}}{BU_1} \right) \cdot \frac{1}{2} + \rho_0 \left(1 - \frac{BU_{\text{Cycle}}}{BU_1} - \frac{BU_{\text{Cycle}}}{BU_1} \right) \cdot \frac{1}{2} \quad (21)$$

■ **Table 4**
Increased energy output relative to a one-region core

Number of regions	Fuel energy output increase versus one-region core (%)
1	0
2	33
3	50
4	60
5	67
∞	100

which when solved indicates $BU_{Cycle} = (2/3)BU_1$ and $\langle BU \rangle_{Disc} = 2BU_{Cycle} = (4/3)BU_1$. The implication is that a two-region core produces 33% more energy than a one-region core when using the same fuel, i.e., for fuel of the same cost per unit mass. The results can be generalized to an N region core.

$$\begin{aligned}
 \text{Number of Regions} &= N \\
 \text{Core Reactivity} = \rho &\approx \sum_{i=1}^N \rho_0 \left(1 - (i-1) \frac{BU_{Cycle}}{BU_1} - \frac{BU}{BU_1} \right) \cdot \frac{1}{N} \quad (22)
 \end{aligned}$$

Completing similar operations as above finds $BU_{Cycle} = (2/[N+1])BU_1$ and $\langle BU \rangle_{Disc} = N \cdot BU_{Cycle} = (2N/[N+1])BU_1$. ➤ **Table 4** indicates the increased energy output per unit mass of fuel with reference to a one-region core.

It is clear that one wishes to utilize the maximum number of regions allowed, or equivalently the minimum number of feed fuel assemblies allowed. This will take the fuel close to but not exceed the region average discharge burnup limit. The logic for reaching this conclusion has been based on an equilibrium cycle and several other assumptions, but the same conclusion is drawn when considering nonequilibrium cycles and relaxing assumptions. The key is to load the core in successive cycles with a sufficient number of feed fuel assemblies such that they will be close to but not exceed the region average discharge burnup limit.

Having determined the cycling scheme table, i.e., the number of feed fuel assemblies in each cycle of the planning horizon, the only free design variables to assure that the cycle energy requirement is satisfied in each cycle in the planning horizon are the feed fuel enrichments. This follows since the reactivity of the partially burnt fuel that back fills the core has a fixed reactivity. If a required feed enrichment exceeds the maximum enrichment limit, which is not uncommon for high-energy BWR cores, this will necessitate loading more feed fuel assemblies than dictated by the region average discharge burnup limit.

When a region contains more than one batch due to irradiation history, e.g., 2.33 region core example, one has freedom what the batches' enrichments should be with the constraint that they be chosen to satisfy the cycle energy requirement. When one batch is going on for an extra cycle of irradiation, it is desirable to use a higher enrichment in this batch to carry reactivity forward into the extra cycle of irradiation. The enrichment difference between the two batches is limited by core power distribution and/or maximum enrichment limit considerations.

With regard to the partially burnt fuel to utilize to back fill the core, assemblies are selected such that discharge burnup limits are not violated with one more cycles of irradiation, the assemblies are mechanically sound ascertained by visual inspection during the refueling outage, and they carry maximum reactivity of the available assemblies.

Burnable poisons were previously introduced in [1.7](#). They are required to be utilized all the time in BWRs and sometimes in PWRs when larger cycle energy production, i.e., longer cycle lengths, occurs. Since they are affixed in the core either permanently, e.g., integral burnable poison, or for a cycle, e.g., discrete burnable poison, ideally they should burn out via neutron capture such that the resulting decrease in their negative reactivity just offsets the loss of reactivity due to the fuel burning. This cannot be accomplished, with the implication that the net core reactivity without other means of reactivity control could be increasing or decreasing as the core burns during the earlier portion of the cycle and eventually decreasing later in the cycle.

For PWRs the amount of burnable poison required is determined such that the soluble boron concentration required to produce criticality, with control rods mostly withdrawn and the core at full-rated power conditions, is reduced to a level that assures the moderator density coefficient is positive, i.e., moderator temperature coefficient is negative. The implication is that for shorter cycle lengths, such as 12 months, no burnable poison is required, but for cycle lengths of 18 months or longer, burnable poisons are normally required. Needless to say, the longer the cycle energy requirement, the higher the core reactivity at BOC, so the greater need for negative reactivity introduction via burnable poisons.

The need for burnable poisons in BWRs is based on the cold shutdown margin (CSM) requirement. A BWR must be capable of going from full-rated power (HFP) conditions to cold zero power (CZP) conditions based on the insertion of cruciform control blades. A PWR has the benefit of being able to increase the soluble boron concentration during the cool down either in a normal fashion or by utilizing the emergency boron injection system. Given the extensive bulk boiling in a BWR, utilization of a soluble poison is undesirable due to deposition on the fuel cladding surface. The reactivity swing due to moderator density, fuel temperature, and xenon concentration changes in going from HFP critical to CZP subcritical conditions clearly must be addressed via the cruciform control blades. However, to adjust the absolute core reactivity that exists at CZP, which must satisfy the CSM subcriticality limit assuming the most reactive control blade is stuck out, requires another source of negative reactivity. That source is burnable poisons, with the amount loaded such that the CSM limit is satisfied.

Discrete burnable poisons depending upon the PWR fuel assembly design either can be located in the guide tubes of a fuel assembly or displace fuel pins. The difference is that if placed in guide tubes, they can be removed after a cycle of irradiation; whereas, if displacing a fuel pin this is not possible. Discrete burnable poison designs have varied with time, with the burnable material being boron either contained in borosilicate glass tubing or B4C dispersed in an Al pellet matrix. Cladding material is typically the same as used for the fuel pin, so a zirconium alloy. By varying the number of burnable poison rods in a fuel assembly and the number of fuel assemblies containing burnable poison rods of a certain count, the amount of negative reactivity inserted can be matched against the need. Given the residual negative reactivity effect at EOC due to neutron capture in the burnable poison's cladding, and displacement of the moderator, and need to handle during refueling operations discrete burnable poison designs that are removable, there is a preference to utilize integral burnable poisons.

As noted in [1.7](#), integral burnable poisons introduce the burnable poison material by either coating the fuel pellet surface with the poison or mixing it with the fuel. A boron compound, which can be enriched in B10, is utilized for the integral fuel burnable absorber

(IFBA) design that coats the pellet surface. In addition to inserting negative reactivity via captures in the burnable poison, the coating is effective in maximizing the thermal self-shielding effect. For high cycle energy requirements, IFBA may burn out too quickly resulting in the critical boron concentration increasing to a level that the moderator temperature coefficient becomes positive at HFP. In this case, a combination of discrete burnable poisons and IFBA is necessary. For burnable poison material mixed with the fuel, Gadolinia (Gd_2O_3) and Erbium (Er_2O_3) are both utilized. Since the fuel is an oxide (UO_2), mixing the burnable poison oxide with the fuel power produces a ceramic pellet after baking. Typically Gadolinia concentrations are limited to about 8 w/o and Erbium concentrations to 2 w/o, which assures that the pellet's thermal and mechanical properties are still acceptable. Needless to say, the displacement of fuel material with burnable poison material will result in a higher fuel enrichment being required. An advantage of integral burnable poisons, in addition to overcoming some of the disadvantages of discrete burnable poisons, is that by a combination of concentration and number of fuel pins in the core containing burnable poison the rate of decrease of negative reactivity with burnup can be controlled. By using a higher concentration in fewer fuel pins, the rate of decrease of negative reactivity can be reduced while still maintaining the same initial total negative reactivity hold down. This occurs due to the increased thermal self-shielding associated with the higher concentration.

Independent of the type of burnable poison utilized, there is cost associated with utilizing them. The obvious cost is that of the burnable poison, but a more significant cost may be that associated with the increased fuel enrichment required to meet the cycle energy requirement so as to offset the residual burnable poison reactivity penalty at EOC.

Where to locate the burnable poison material in the core within the feed fuel assemblies is a decision that falls within the domain of in-core nuclear fuel management. Their location can have a significant impact on the power distribution, but also on the burnable poison worth as a function of the cycle depleting.

3.3 LWR In-Core Nuclear Fuel Management

In-core nuclear fuel management addresses Decision 6, core loading pattern, i.e., fresh fuel, burnt fuel, and burnable poisons core locations, and Decision 7, control rod (blades) locations and core flow rate (only for BWRs) as functions of burnup.

3.3.1 LWR Loading Pattern Selection

The major design objectives associated with selecting the core loading pattern are

- Minimization of the power peaking by making the core's power distribution as flat as possible (to increase margins to thermal limits, e.g., critical heat flux and fuel temperatures)
- Maximization of the cycle energy production for fuel to be loaded into the core

Maximization of the cycle energy production is achievable by minimization of neutron leakage, which implies a low flux on the core periphery. But if the flux is low on the core periphery so is the power, which implies that the power must be higher in the core interior to maintain the rated core power. This produces a conflict with the objective of minimizing power peaking, implying that a trade-off must be struck between these two objectives.

Focusing first on addressing the objective of minimizing power peaking, which one could view as a constraint versus an objective, this arises because of thermal limits on the fuel. The thermal limits that are most likely to be active include the

- Loss of coolant accident (LOCA) peak clad temperature (PCT) limit of 1, 205°C, which limits the maximum pellet linear power density to approximately 48 kW/m at HFP
- Critical heat flux (CHF), which denotes departure from nuclear boiling (DNB) for a PWR and Dryout for a BWR, not being exceeded during anticipated transients, which limits the maximum average fuel pin linear power density to approximately 29 kW/m at HFP
- Fuel cladding strain limit not be exceeded during anticipated transients

For PWRs the LOCA linear power density limit on the pellet is expressed in terms of the total peaking factor defined as

$$F_Q \equiv \frac{\text{Power}_{\text{Peak}}^{\text{Pellet}}}{\langle \text{Power}^{\text{Pellet}} \rangle} = \frac{\text{Max}_{x,y,z} P(x, y, z)}{\frac{1}{V_{\text{Core}}} \iiint_{V_{\text{Core}}} P(x, y, z) dx dy dz}$$

which in practice is likely to also have an axial dependence due to LOCA blow down and reflood characteristics, obtained by completing the numerator's maximization only over x, y . The DNB linear power density limit on the fuel pin is expressed in terms of the enthalpy rise (radial) peaking factor defined as

$$F_{\Delta H} \equiv \frac{\text{Power}_{\text{Peak}}^{\text{Rod}}}{\langle \text{Power}^{\text{Rod}} \rangle} = \frac{\text{Max}_{x,y} \frac{1}{L} \int_0^L P(x, y, z) dz}{\frac{1}{V_{\text{Core}}} \iiint_{V_{\text{Core}}} P(x, y, z) dx dy dz}$$

where the x, y dependence should be recognized as being on a unit rod discretization.

For BWRs the LOCA linear power density limit is expressed in terms of the Maximum fraction of Average Power RATio to the limiting value (MAPRAT) defined as

$$\text{MAPRAT} = \max_{x,y,z} \frac{\langle P(x, y, z) \rangle_{\text{Actual}}}{\langle P(x, y, z) \rangle_{\text{Limit}}}$$

where the powers have been radially averaged across a fuel assembly and the limit is fuel assembly type and burnup dependent. The Dryout limit is expressed as the Maximum Fraction of Limiting Critical Power Ratio (MFLCPR) defined as

$$\text{MFLCPR} = \max_{x,y,z} \frac{\text{CPR}(x, y, z)_{\text{Limit}}}{\text{CPR}(x, y, z)_{\text{Actual}}}$$

where CPR denotes the critical power. Finally, the cladding strain limit is expressed as the Maximum Fraction of Limiting Power Density (MFLPD) defined as

$$\text{MFLPD} = \max_{x,y,z} \frac{P(x, y, z)_{\text{Actual}}}{P(x, y, z)_{\text{Limit}}}$$

where powers are evaluated on a pellet-wise basis. Working with the PWR limits, since they are easier to interpret, the core average linear power density plays a key role and is defined by

$$\langle q' \rangle = \frac{Q \text{ (unit of kW)}}{(\text{Total Number of Fuel Assemblies in Core}) \left(\frac{\text{Fuel Rods}}{\text{Fuel Assembly}} \right) L \text{ (unit of m)}}$$

where Q denotes the full-rated core power and L the active fuel height, i.e., fuel pellet stack height. For a reload core with a fixed mechanical fuel design, the average linear power density is fixed. This implies in terms of peaking factors that the maximum pellet and rod linear powers are given by

$$\begin{aligned} \text{Maximum Pellet Power} &= F_Q * \langle q' \rangle * P_{Rel} \\ \text{Maximum Rod Power} &= F_{\Delta H} * \langle q' \rangle * P_{Rel} \end{aligned}$$

where P_{Rel} denotes the core relative power, so $P_{Rel} \in [0, 1]$. By imposing the thermal limits obtained is

$$F_Q \leq \frac{q'_{LOCA}}{\langle q' \rangle * P_{rel}} \quad (23)$$

and

$$F_{\Delta H} \leq \frac{q'_{CHF}}{\langle q' \rangle * P_{rel}} \quad (24)$$

Using (23) and (24) with the previously stated LOCA and DNB limits along with a typical average linear power density of 18.5 kW/m, one finds at full power that $F_Q \leq 2.5$ and $F_{\Delta H} \leq 1.5$.

Using these power peaking factors as representative limits, alternate core loading patterns will be assessed for their effectiveness. First consider a right cylindrical core employing one region, i.e., homogenous core, and no reflector. The one group diffusion equation solution for this core design is a Bessel function of the first type for the radial direction and a cosine function in the axial direction. This implies $F_Q = 3.63$ and $F_{\Delta H} = 2.31$, which to satisfy the thermal limits would necessitate approximately limiting core power to about 65% of rated power, i.e., $P_{Rel} = 0.65$. The unacceptable high power peaks originate because of high neutron leakage from the core periphery.

Addition of radial and axial core reflectors would reduce the power peaking but not to any acceptable level. In fact, all LWRs utilize reflectors in the form of the coolant surrounding the core, and make possible the addition of metallic radial core reflectors. Recognizing that cores utilize multiple fuel regions for improved economics, advantage can be taken of this by locating the most reactive region nearest to the core periphery, and regions of lesser and lesser reactivity further and further away from the core periphery. Such a loading will counteract the neutron leakage from the core radial periphery and is referred to as Out-In loading because of the fuel movement each successive cycle. Considering a three-region core, what one finds is indeed the flux and hence power is held up on the core periphery where the most reactive feed fuel is located, but the power is very low about the core center where the least reactive twice burnt fuel is located. This results in high power peaking in the mid-core where the mid-reactive once burnt fuel is located. The cause of this is the relative reactivity differences between the feed, once and twice burnt fuel, which cannot be adjusted since the initial enrichment of each fuel region is determined to satisfy the cycle energy requirement.

The correction to this problem is to mix in a checker-board pattern the mid and least reactive fuel in the core interior and retain the most reactive fuel on the core periphery, which is displayed in **Fig. 8** for a PWR. In this manner the least reactive fuel's flux and power are held up by neutron leakage from the mid-reactive fuel, which in turn holds down the power peaking in the mid-reactive fuel. **Figure 9** displays the assembly relative power distribution at BOC of an Out-In Check-board loading pattern for a three-region PWR core. The power peaking factors throughout the cycle are such that $F_Q \leq 1.8$ and $F_{\Delta H} \leq 1.35$ under HFP conditions with equilibrium xenon and samarium. The Xe^{135} spatial transients induced by load following will increase the F_Q value but it will still remain considerable below the LOCA imposed limit. The

Figure 8
Out-in checker-board loading pattern for a PWR

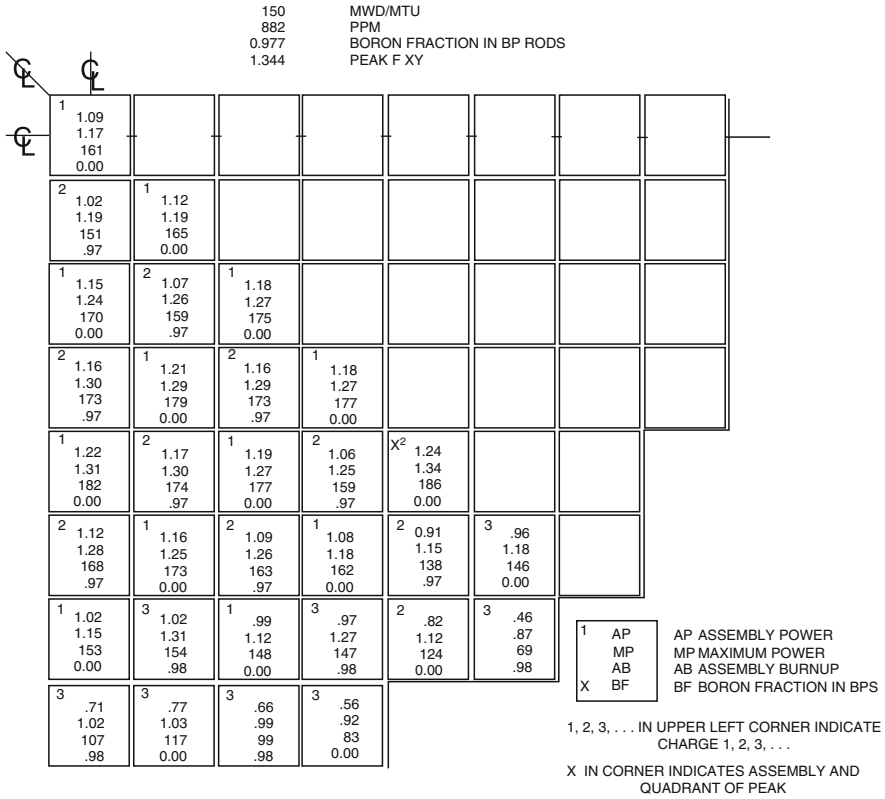

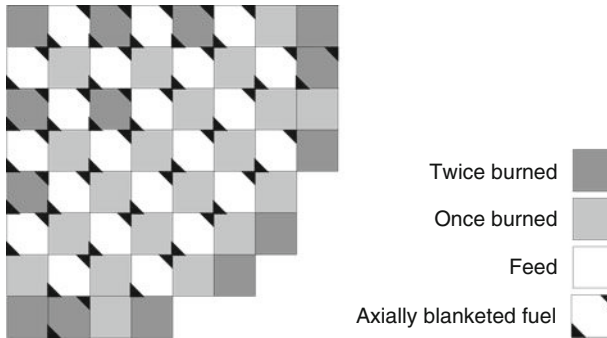

Figure 9
Relative radial power distribution at the beginning of cycle associated with Fig. 8 loading pattern

Out-in checker-board loading pattern served for many years as the preferred loading pattern given its effectiveness in satisfying the objective of minimizing power peaks. However, as noted earlier in satisfying this objective the radial neutron leakage is increased resulting in less energy being extracted from the core, so conflicts with this economically motivated objective.

Consider now how the objective of maximizing the cycle energy production for the fuel to be loaded into the core is to be achieved. This could be accomplished by minimizing neutron leakage and by maximizing the flux in the most reactive fuel in accordance with reactivity importance weighting. Clearly an In-Out loading strategy would accomplish this, where the most reactive fuel is placed in the core center spatial zone and lesser and lesser reactive fuel is placed further and further out from the core center. However, highly unacceptable power peaking would occur. If burnable poisons were required for reactivity hold down they could be preferentially placed in the high power, feed fuel assemblies to suppress power peaking. What is found is that more burnable poison is required to suppress the power peaking than required for reactivity hold down, and that the resulting additional burnable poison reactivity penalty more than offsets any savings due to the lower neutron leakage. An In-Out-In strategy which associates directly with a three-fuel region core would seem to be a compromise between an Out-In and In-Out loading strategy; however, it is again found that the residual burnable poison penalty associated with the excess burnable poisons required to suppress unacceptable power peaking

■ Figure 10

Ring of Fire low leakage loading pattern for a PWR for two different objective functions

now just about offsets the reduced neutron leakage reactivity effect, resulting in no net gain in cycle energy produced.

What has evolved is a more complicated loading pattern strategy referred to as a Low Leakage Loading Pattern (L^3P) with a Ring of Fire. In this approach some of the least reactive fuel assemblies are placed in the highest leakage locations, i.e., those with two sides of the assembly on the core periphery, and adjacent high leakage locations. Much of the feed fuel, which is the most reactive fuel, is placed one or two assembly pitches from the core periphery forming an approximate ring about the core center. These assemblies tend to operate at the highest powers, hence the reference to the Ring of Fire. The remaining least reactive and most reactive fuels are then check-boarded with the mid-reactive fuel, with a preference for locating the least reactive fuel assembly side-by-side with the most reactive fuel to both drive the least reactive fuel and decrease power peaking in the most reactive fuel. For a PWR, [▶ Fig. 10](#) displays an L^3P with a Ring of Fire. Very acceptable power peaking is obtained without the need to introduce additional burnable poison material beyond that required for reactivity hold down, hence no additional burnable poison reactivity penalty is experienced. This general approach to loading patterns is utilized for PWR cores. A difference for BWR cores is that the Ring of Fire is now composed of mid-reactive fuel assemblies versus the most reactive fuel. This is done to increase the CSM at BOC. Further there may be some clumping of fresh fuel in the interior about a control blade to increase the CSM at EOC.

3.3.2 LWR Control Rod Programming Selection

In addition to determining the core loading pattern, BWRs have the additional requirement of determining the control blade insertion patterns as a function of cycle exposure, referred to as Control Rod Programming (CRP). There is no such need for PWRs since at HFP most control rods are totally withdrawn from the core, with only a few control rods shallowly inserted. This is possible since the excess core reactivity is controlled by the soluble boron concentration. To position a group of control rods to the proper insertion depth, the soluble boron concentration is adjusted and the core is maintained critical by offsetting the reactivity change associated with the concentration change with the insertion depth of the control rods. The only reason why any control rods are shallowly inserted at HFP is because the automatic control system utilizes

control rod motion to maintain the programmed power level at the programmed vessel average coolant temperature. Since BWRs cannot utilize a soluble poison, the only mechanisms for controlling the core reactivity, e.g., maintaining the core critical, are via the control blades and core flow rate. At EOC clearly the control blades will be all withdrawn and the core flow rate will be maximized to keep the core critical at HFP as long as possible. But prior to EOC there are many control blade insertion patterns and core flow rate combinations that maintain the core critical. This freedom can be utilized to assure that the thermal limits are all satisfied. However, if not done properly a burnup distribution will develop that prevents the thermal limits from all being satisfied later in the cycle when control blades need to be more shallowly inserted, so less capable of power distribution control. In particular, if the control blades inserted stay longer covering a certain zone of the core, this zone will experience less burnup because the flux and hence power is suppressed in the vicinity of the control blade, referred to as burnup shadowing. At some point the control blade will need to be withdrawn to maintain the core critical, exposing a fuel zone with lower burnup and reduced equilibrium xenon concentration. This will result in a large local power increase that could cause a violation of a thermal margin and unacceptable fuel mechanical duty, e.g., Pellet–Clad Interaction. Two approaches to CRP have evolved, referred to as Conventional Core and Control Cell Core, to minimize burnup shadowing and fuel duty.

The Conventional Core approach focuses on not allowing a control blade to shadow a zone of the core too long. By switching on some frequency, which control blades are utilized to control core reactivity and perform power distribution control, the buildup of burnup shadowing is minimized to an acceptable level. When switching of control blades occur, referred to as a rod swap, the zones of the core that were previously shadowed will experience a local power increase which is within the acceptable range. This increase in local power increases the rate of local burnup, tending to heal the shadowed zone. To assure that the local power increase does not cause unacceptable fuel duty, the rod swap is completed at reduced power, normally about 85% of full-rated power. Since the resulting loss of energy production is economically undesirable, the time between rod swaps is desired to be maximized, which tends to occur at a time interval of several months.  [Figure 11](#) displays the layout of a conventional core for a BWR.  [Figure 12](#) shows the CRP for a BWR operating by using the Conventional Core approach. The numbers indicate the position of a control blade, which defines a control cell composed of the control blade and four face adjacent fuel assemblies. The unit utilized is a notch, which corresponds to a 0.0762 m (3 in.) movement. For a 3.66 m (144 in.) active fuel height, 48 notches implies complete withdrawal of the control blade and is not shown in the figure. The subset of control blades utilized over a specific time is specified. For the example presented in  [Fig. 12](#), there are four subsets utilized, referred to as A1, A2, B1, and B2 as illustrated in  [Fig. 13](#). A1 is utilized up to Burnup Step 5, at which time a rod swap occurs to A2. At Burnup Step 6 a rod swap occurs to B1, which is utilized up to Burnup Step 7 when a swap to B2 occurs. B2 is then maintained until Burnup Step 10 when a rod swap to A1 occurs and the sequence is repeated. At Burnup Step 18, which corresponds to EOC, as expected all control blades are withdrawn. The withdrawal positions as a function of burnup are so selected to keep the core critical and shape the power distribution such that the thermal limits are satisfied not only at the current time, but also at future times by avoiding unacceptable burnup shadowing. As noted earlier, the core's reactivity can be changed by changing the core flow rate, which is controlled by the recirculation flow rate. The implication is that the CRP is impacted by the selected core flow as a function of cycle exposure. To minimize fuel cycle cost i.e., minimize the feed enrichment required, core flow is selected to be as low as permitted early in the cycle, increasing coolant

■ Figure 11
Conventional core layout for a BWR

voiding, which hardens the neutron energy spectrum resulting in more Pu239 production via resonance capture in U238. Later in the cycle the core flow will need to be increased to maintain the core critical.

The Control Cell Core approach was developed to minimize or eliminate the need to do down powers during rod swaps by removing the need to do rod swaps. The basic idea is to select a single subgroup of control elements that will be utilized throughout the cycle to control core reactivity and the power distribution. By selecting the fuel assemblies in the control cells of this subgroup of control blades to be less reactive, burnup shadowing effects can be minimized since the rate of putting burnup on these fuel assemblies is reduced. Further, when control blade withdrawal does occur, neither thermal nor fuel duty limits will be violated since the local power increase starts from a lower power density and after the increase still is at an acceptable power density. To assure that the control cells involved utilize fuel assemblies that display an acceptable low reactivity, restrictions must be placed on the fuel assemblies that are located there. Further, to avoid multicycle buildup of burnup shadowing, including the concern of a significant burnup gradient across the fuel assembly, a fuel assembly is restricted over its lifetime to occupy a control cell only one cycle. So employing a Control Cell Core places further restrictions on the loading pattern. ➤ [Table 5](#) contrasts the key LP and CRP attributes of a Conventional Core and Control Cell Core. ➤ [Figure 14](#) indicates the positions of the control cells utilized and ➤ [Fig. 15](#) displays the CRP for a Control Cell Core. For high-energy cores, associated with extended cycle lengths and power uprates, it has proven difficult to utilize a Control Cell Core approach because the feed region size needs to be large to satisfy discharge burnup and enrichment limits, implying that it is not possible to load control cells to have lower reactivity.

What should be obvious at this point is that for BWRs, the determination of the loading pattern and the CRP is linked together, implying that their determinations must be completed together. As shall be seen shortly, things are even more complicated in that the determinations of the lattice and assembly designs are also linked to the determinations of the loading pattern and CRP.

CRP	Group control rods into patterns A-1, A-2, B-1, and B-2. Sequence through (swap) A and B patterns, e.g., A-1, A-2, B-1, B-2, with cycle burnup with regard to deep insertions. Slight down power must be done during swap to avoid pellet-clad interaction failures.	Use fixed group of control rods in control cells throughout the cycle with no or minimum need for rod swaps.

3.3.3 LWR Lattice and Assembly Selection

The loading pattern mainly effects the radial power distribution of the core. Is there any need to also do fuel management to effect the axial power distribution? Since axially the LWR fuel assembly is a single structural unit, the only manner of affecting the axial power distribution via the fuel assembly is by its design. Axial blankets are utilized in both PWRs and BWRs. They are introduced by replacing approximately 0.15 m (6 in.) at the top and bottom of the enriched typically 3.66 m (144 in.) fuel pellet stack with either natural solid or slightly enriched annular pellets. In doing this the cost of the uranium ore and enrichment service per unit energy produced is reduced, so the motivation is economic. As expected, axial neutron leakage is reduced

■ Figure 14
Control cell core layout for a BWR

due to the lower flux on the axial periphery, but in doing so axial power peaking is increased. So axial blankets work against a reduction in axial power peaking.

Returning to the need to address axial power peaking, PWRs via burnup naturally tend to suppress axial power peaking. For a Cycle 1 loaded with all fresh fuel, approximately a chopped cosine shape exists, which causes the higher power zone about the core mid-plane to receive burnup at a higher rate. If burnable poisons are not present or present such that reactivity decreases with fuel irradiation, this implies that about the core mid-plane the reactivity decreases faster than in the lower and upper axial zones of the core. This causes the characteristic double-hump axial power distribution associated with PWRs as displayed in [Fig. 16](#) to develop with burnup in Cycle 1. Since reload cores will have typically anywhere from one-half to two-thirds of the fuel being burnt from earlier cycles of irradiation, the double-hump shape appears throughout reload cycle cores. Given that PWRs only experience higher axial power peaking early in Cycle 1, and even then the power peaks are of acceptable magnitude, there is reduced need to address via assembly design axial power peaking control. What needs to be addressed is power peaking due to axial xenon transients as discussed in [2.2.2](#) and improper partial insertion of control rods, which is accomplished via control strategies, e.g., axial offset control, and power level-dependent control rod insertion limits.

The situation for BWRs in regard to the need to address axial power peaking is very different than for PWRs. Due to the increased voiding as the coolant flows up through the core, the moderating power decreases, hence reactivity decreases with elevation. If no counteractions were taken, the axial power distribution would be skewed toward the core bottom and high axial power peaking would occur. Burnup would partially mitigate this effect but not to an acceptable level. Given that BWRs utilize bottom entry control blades, since it is difficult to have top entry given the steam separators and dryers above the core, they can be partially inserted introducing negative reactivity in the core bottom somewhat offsetting the negative reactivity in the core top from coolant voiding. Near EOC the control blades will need to be nearly totally withdrawn making them not useful for axial power distribution control, and perhaps more important fuel duty would be increased by first inserting and later withdrawing the control

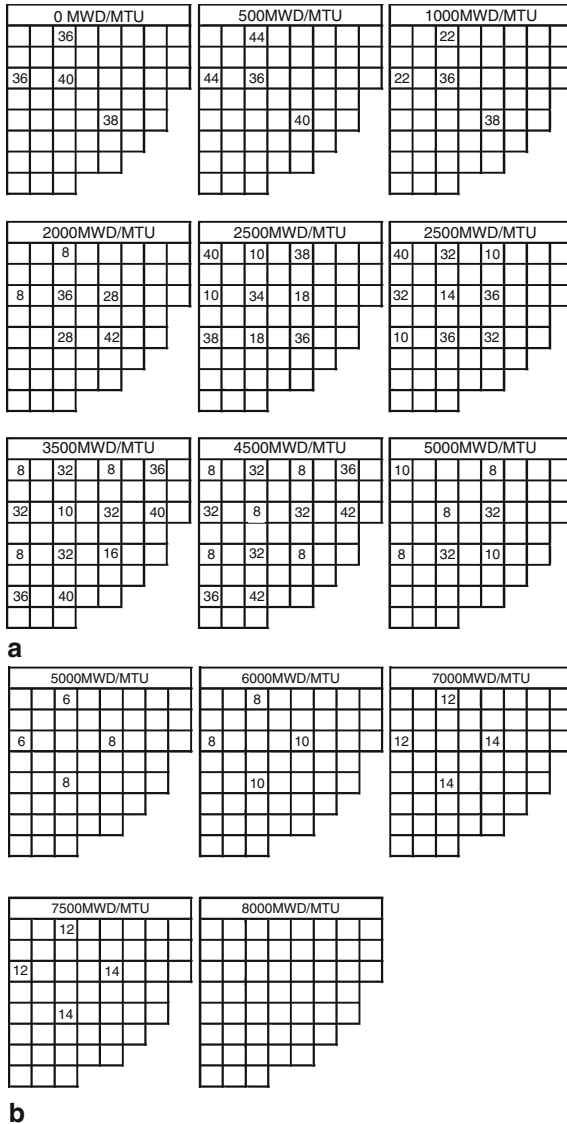

Figure 15
Control rod program associated with a control cell core for a BWR

blades. To minimize but not eliminate the need for partial control blades insertions, additional burnable poison material, which is Gadolinia in BWRs, is introduced in the lower portion of fuel assemblies. Note that about 15% of the fuel pins in an assembly may be part length, i.e., 2.74 m (108 in.) versus 3.66 m (144 in.) in stack height. This is mainly done to increase flow stability by minimizing the two-phase pressure drop and to increase the CSM by reducing the reactivity increase due to flux axial redistribution, but also impacts the axial power distribution during

■ Figure 16

Core average relative axial power distribution as a function of cycle burnup during Cycle 1 for a PWR

power operation. ➤ *Figure 17* displays how different lattice designs are used at different axial elevations. ➤ *Figure 18* shows the possible variability of axial power distributions for a fresh assembly as it burns in a BWR core due to a combination of partial control blade insertions and Gadolinia depletion. Such variability of the axial power distribution occurs from assembly to assembly at a fixed cycle burnup. The upper portion of this figure showing uncertainty will be discussed later.

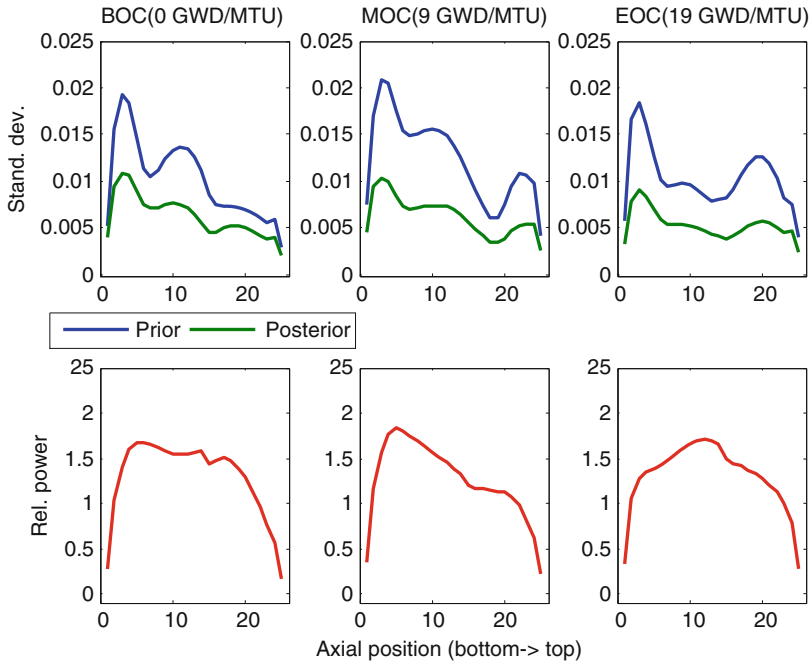

How axial heterogeneities are introduced into a fuel assembly is done by utilizing different lattice designs at different elevations as noted in ➤ *Fig. 17*. Recall that a lattice describes the geometry and composition of a fuel assembly in the x, y radial plane. With axial elevation, from a neutronics viewpoint one is concerned with axial power distribution shaping at operating conditions and minimizing the reactivity swing due to axial flux redistribution when going from operating to shutdown conditions, implying that the fuel assemblies' radially averaged axial reactivity profile is of interest. Radially, one is mainly concerned with the local power peaking that can occur within an assembly at elevations where the power may be higher. So fuel assembly design, which encompasses lattice design and at what elevations different lattice designs should be utilized, must address both axial and radial behavior requirements. The desirable features of the fuel assembly have been discussed above, but not in detail as to how this is accomplished and which is the subject of lattice design.

Local radial power peaking occurs in lattices mainly because of local concentrations of coolant. This follows since LWR cores are under-moderated for safety reasons, so any local zone of concentration of coolant will increase the reactivity in the fuel pins adjacent to this zone, resulting in local power peaking. This effect can be minimized by utilizing a geometry that

■ **Figure 17**
Fuel assembly and location of different lattice designs for a BWR

minimizes local zones of coolant concentration. Such an approach is utilized for some PWR fuel assembly designs. By displacing only a single fuel pin for either a guide tube or instrumentation sheath, which will be occupied by coolant if a control rod, discrete burnable poison rod or instrumentation thimble is not inserted within an assembly, the extent of power peaking in the adjacent fuel pins can be minimized. Likewise, by minimizing the inter-assembly gap, power peaking on fuel pins on the periphery of the fuel assembly can be minimized. As can be seen in ► [Fig. 19](#) for a fresh 17×17 PWR fuel assembly, this approach of minimizing local zones of coolant concentration is sufficiently effective that acceptable levels of local power peaking

■ Figure 18

Fresh assembly axial power distribution as a function of cycle burnup for a BWR

are achieved without the need for using different enrichments in the fuel pins. Other PWR fuel designs elect to displace a 2×2 array of unit cells for guide tubes and instrumentation sheath. Using this approach, lower enrichment fuel pins need to be utilized around their locations to obtain acceptable local power peaking. ➤ [Figure 20](#) presents an example of doing this by the so-called island design. With the introduction of burnable poison material, whether discrete or integral, local power peaking is increased while there is significant burnable poison material present. However, within the core if significant burnable poison material is present, the power density in this zone will be suppressed so that higher local power peaking can be accommodated. This is not to say that when using an integral burnable poison, which allows the freedom to decide where burnable poison material is placed, consideration of local power peaking is ignored.

Local power peaking is of much greater concern when designing BWR lattices. This occurs due to the large inter-assembly gap that is necessary to accommodate control blades and instrumentation, which in the case of a BWR are located outside the assembly channel box. Not only is the inter-assembly gap large, but it also contains higher density, subcooled coolant. Given that inside the channel box at all but the lower elevations will exist lower density, voided coolant, the fuel pins on the assembly periphery will experience much more effective neutron moderation, leading to a significant increase in flux and power density. This will be particularly true for the fuel pins on the corners since they are adjacent to where the inter-assembly gap forms a cross. Without the introduction of design features to counter the inter-assembly gap local

Figure 19

Pin-wise relative radial power distribution in a fuel assembly that utilizes small water holes for a PWR

moderation, unacceptable local power peaking would occur. For this reason fuel pins with different enrichments are utilized within the lattice. As expected and illustrated in [Figure 21](#) for the dominant lattice, the lowest enrichment pins will occupy some of the corner pin locations, and the enrichment of pins will increase for the fuel pins that are further away from the corners and periphery. The reason why the pin enrichments are generally lower in symmetric locations above versus below the diagonal axis running from the southwest corner to northeast corner can be due to a difference in the inter-assembly gap size, which is larger on the north and west surfaces to accommodate control blade insertion.

Without an additional design feature, a significant number of fuel pins of different enrichment would be required. Further, at the coolant void fractions BWRs operate at the core would be very under-moderated without an additional design feature. Now unit cell pitch could be increased, but that presents a structural challenge to designing spacers that would support fuel pins. So to both balance the local moderation effect caused by the inter-assembly gap and under moderation, fuel pins are displaced and replaced by water rods or slots. [Figure 21](#) indicates a lattice design that elects to displace 2×2 unit fuel cells. An alternative design forms an internal

■ Figure 20

Pin-wise fuel and Erbium enrichments in a fuel assembly that utilized large water holes for a PWR

cross within the fuel assembly formed by a 2×2 array of 5×5 unit fuel cells for a 10×10 fuel assembly design.

As mentioned earlier, BWR fuel assemblies have utilized part-length fuel pins in the upper core elevations as a mechanism to introduce more coolant and improve moderation. This actually introduces not one but two lattice designs, one associated with the axial span where the part-length fuel pin plenum volume exists and the other where the part-length rod is vanished. A typical number of fuel pins that are part length in a 10×10 array is 14 fuel pins or approximately 15% of all the fuel pins. Also mentioned previously was an assembly design that loaded more Gadolinia at lower elevations to improve the axial power distribution. ➤ *Figure 21* shows the addition of two additional 2 w/o Gadolinia-loaded fuel pins to the twelve 6 w/o Gadolinia-loaded fuel pins. As with the pin-wise enrichment distribution, the additional Gadolinia-loaded fuel pins are loaded closer to the wider inter-assembly gap.

➤ *Figure 17* indicates the lattice designs that can be found in a typical BWR fuel assembly. For this example, seven different lattice designs are utilized. Recognizing that each lattice design involved decisions concerning geometry and pin-wise isotopic compositions, and that lattice, assembly, loading pattern, and CRP design decisions are coupled, one begins to realize the complexity of BWR in-core nuclear fuel management. But on the positive side, where there is complexity due to the large number of design decisions that need to be made, there is opportunity for design creativity.

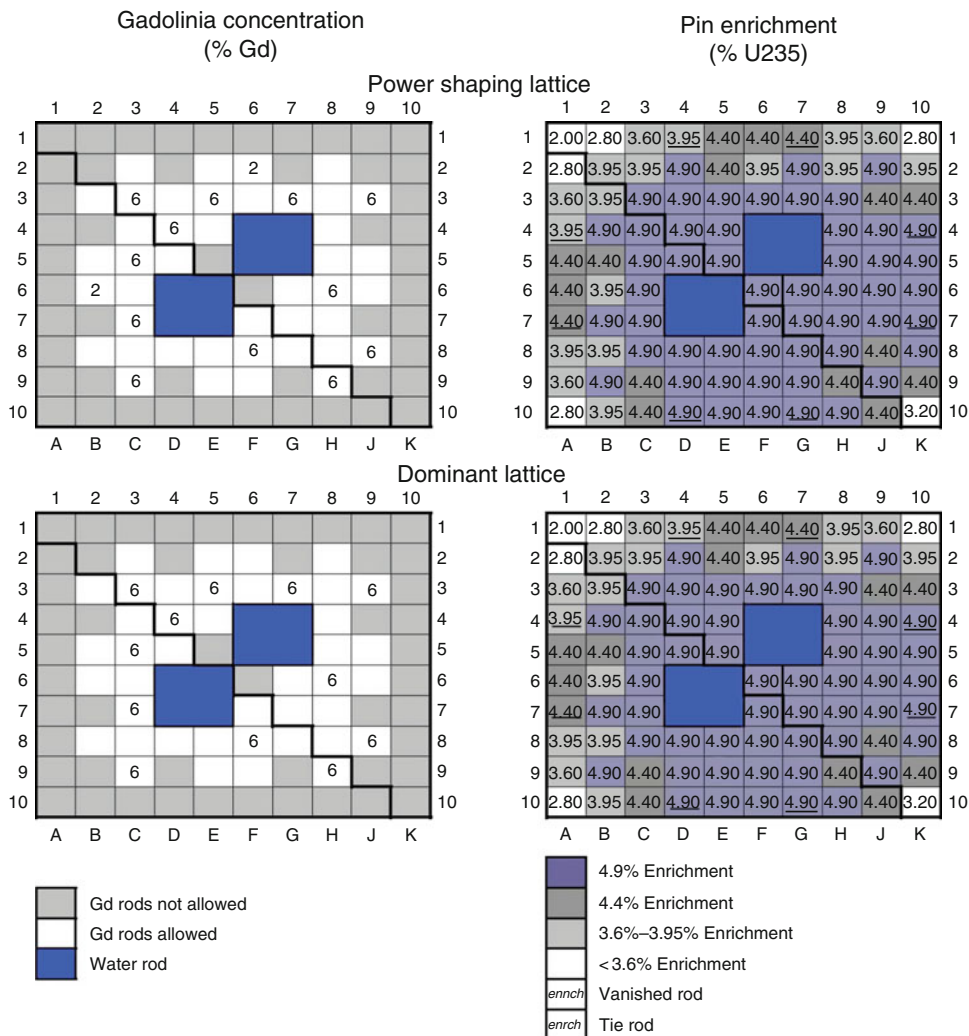

Figure 21
Pin-wise fuel and Gadolinia enrichments in the dominant and power shaping fuel lattices for a BWR

3.4 Non-LWR In-Core Nuclear Fuel Management

3.4.1 Introduction

In the following sections very brief descriptions of fuel management for reactor types other than LWRs, in particular heavy water reactors (HWR), very high temperature gas-cooled reactors (VHTR), and advanced recycle reactors (ARR) will be presented. Since VHTRs and ARRs have not been widely deployed on a commercial scale, the state of sophistication of nuclear fuel

management decision making in regard to meeting the various objectives within constraints in an optimum manner is less than that for LWRs.

3.4.2 Heavy Water Reactors

HWRs have many of the same limitations that are imposed on LWRs. A major difference with LWRs is online refueling, which is necessary since the reactors are designed to operate using natural uranium, hence the fuel's lifetime is short, e.g., 8 GWD/MTU versus that of LWR fuel, e.g., 45–50 GWD/MTU. The implication is that the fuel management decisions about cycle length between refueling outages, utilization of stretch out, fresh fuel assembly compositions, burnt fuel assemblies to reinsert, and burnable poison type and total loadings do not apply to an HWR. The core loading pattern decision now addresses, which fuel channel should be reloaded, how many bundles should be pushed (loaded), and at what frequency should this occur. The decisions regarding number of bundles to push and frequency of doing this is simple, determined by the requirement to keep the core critical for a certain period of time between pushes. Which fuel channels to push feed bundles into is done in such a way that the burnup of the fuel being discharged is approximately uniform factoring in power distribution constraint limits. Given a total of 380 fuel channels and 12 fuel bundles per channel, each with a length of about 0.5 m, over a typical week of operation at full power ten channels will be reloaded each with four or eight feed fuel bundles. Regarding control rod locations, the HWR has a diversity of reactivity control devices. They are utilized to both do power distribution shaping and control excess core reactivity. Zone controllers, which introduce light water (a poison in an HWR) in selected axial and radial core positions, provide excess core reactivity and power distribution controls. Adjusters, a weak absorber control device, are also used for controlling core reactivity and power distribution as required, and mechanical control absorbers, a strong absorber control device, are used mainly for controlling core reactivity. For a Cycle 1 core, a soluble poison may be added to the heavy water moderator, which for an HWR is distinct from the coolant. In no time the core takes on an equilibrium characteristic. Mathematical optimization software has been developed to assist in making the push decisions. In contrast to LWRs, HWRs do permit a positive coolant void coefficient. Fuel bundles, using a combination of slightly enriched uranium, central fuel rod blended burnable poison, and altered water to uranium ratio, have been designed to minimize the magnitude of the positive coolant void coefficient.

3.4.3 Very High Temperature Gas-Cooled Reactors

VHTR core designs being considered fall into two categories: prismatic and pebble bed. In the prismatic design, hexagonal blocks containing fuel, burnable poison, coolant channels, and control rod penetrations if appropriate, are placed side-by-side and stacked axially to create the core. For both designs TRISO particle fuel is employed, embedded within the graphite moderator. This adds an additional fuel management decision, which is the packing fraction of TRISO particle fuel within the graphite moderator. Like LWRs, VHTRs are batch refueled. So the nuclear fuel management decisions concerning cycle length between refueling outages, fresh fuel assemblies number and compositions, burnt fuel assemblies to reinsert, burnable poison type and total loadings, core loading pattern, and CRP all come into play. A multi-batch core design, like for LWRs, is planned to be employed, composed of fuel of different number of

cycles of irradiation. A major difference for a VHTR core is the ability to do three-dimensional loading patterns, since the fuel block can be located not only radially, but also axially within the core. Radial column shuffling, where all the blocks in a radial location move from one radial location to another with their axial positions retained (Kim and Venneri 2007), is one form of shuffling that has been examined. Given that the blocks in a radial column located in a control rod position may have additional holes in the block for control rod insertion, this will limit radial columns without these additional holes to noncontrol rod positions. Axial column shuffling has also been considered, where now radial position is retained but the axial position of blocks are shuffled (Kim et al. 2007). Commonly used is a ring loading pattern, where all the fuel blocks within a given radial ring will have the same number of cycles of irradiation. Given that a gas coolant is utilized, thermal limits for a VHTR are associated with fuel temperature limits.

Pebble bed reactor utilize online refueling, so a number of the nuclear fuel management decisions appropriate for LWRs are not applicable. Replacement of a burnt pebble by a feed pebble is done when the burnt pebble reaches a desired level of burnup. It follows that fuel enrichment is determined so as to take the pebble to the desired level of discharge burnup while retaining the reactor with sufficient excess core reactivity. Pebbles may differ in TRISO particle fuel packing fraction, burnable poison loading, and fuel enrichment. The rate of circulation of pebbles, which equates to the residence time of a pebble in the core for one of its multiple core passes, is determined factoring fuel composition, discharge burnup limit, desired number of passes, and power distribution. The lower the rate of circulation, the lower the number of passes of the pebble before discharge due to the longer residence time in the core. Like the prismatic design, the power distribution is limited by fuel temperature limits. The radial placement of pebbles on the top of the stack when feed, versus a random placement, accounting for their reactivity does influence the core's characteristics and can be considered an additional decision variable.

3.4.4 Advanced Recycle Reactor

Several different reactor types are being considered to fill the role of an ARR. The sodium fast reactor (SFR) is the prime candidate of these different types, so shall be discussed. SFRs can be designed to have a range of conversion ratios. If breeding is desired, use of axial and radial blankets composed of depleted uranium is the preferred configuration. In addition to the utilization of plutonium, one of the goals of ARRs is the destruction of minor actinides, which are the actinide elements above plutonium in the Periodic Table. Concepts being considered vary on whether minor actinides are mixed with the uranium and plutonium or contained in separate targets. Exactly what minor actinides will be recycled from spent fuel, which is dependent upon ease of separation, heat loading, fuel performance, and benefit of recycle, have yet to be decided. Regarding fuel management decisions, fissile material composition now becomes more complicated given that multiple elements each with multiple isotopes are involved. Given a closed fuel cycle, the isotopic composition of the recycled material available is variable. If a low conversion ratio is desired to maximize destruction of minor actinides, this implies a low fuel to sodium ratio, achieved by utilizing a smaller fuel pin radius. Some fuel management constraints include peak linear power density, maximum excess core reactivity, maximum cladding

fluence, maximum discharge burnup, and limits on various reactivity coefficients and reactivity device worths. A typical in-core fuel management scheme consists of two or three different fuel reactivities achieved by elemental mixtures, each loaded into a radial ring zone of the core, all done to flatten the power distribution. A no-fuel shuffling scheme may be employed, where in each refueling outage a fraction of the fuel in each radial ring zone may be replaced with fresh fuel assemblies without movement of any partially burnt assemblies. Given the long mean free path of neutrons in a fast reactor makes more possible the utilization of a no-fuel shuffling scheme.

3.5 Applications of Mathematical Optimization in Nuclear Fuel Management

3.5.1 Introduction

Earlier sections of this chapter have revealed the complexity of making nuclear fuel management decisions. This has motivated the development of capabilities to apply mathematical optimization to nuclear fuel management problem. Such capabilities should be viewed as an aid to the core design engineer since factors need to be considered, such as risk associated with a decision, which cannot be easily quantified and hence captured within a mathematical optimization capability. Since the majority of effort in applying mathematical optimization has been for LWR cores, the following discussion will reflect this. However, some of the capabilities developed for LWR cores could be adapted for utilization to non-LWR cores.

3.5.2 Mathematical Optimization Approaches Utilized for Nuclear Fuel Management

There are a wide range of mathematical optimization approaches available to consider for application to nuclear fuel management problems. Consistent with the language of mathematical optimization and what has been used throughout this chapter, the purpose of mathematical optimization is to minimize an objective function by the determination of the values of decision variables as limited by the imposed constraints. If the objective is to maximize an objective, this can be accomplished by minimization of the original negated objective function, so in the following minimization will always be assumed as the objective. Broadly speaking mathematical optimization approaches can be classified as deterministic or stochastic approaches. Linear programming and dynamic programming are two examples of widely used deterministic approach. Simulated annealing (SA) and genetic algorithms (GAs) are examples of widely used stochastic approach. When possible, a deterministic approach is to be preferred over a stochastic approach because of reduced computational effort and many times the capability to assure that the global optimum decisions have been determined. Unfortunately for many nuclear fuel management problems due to their characteristics deterministic approaches appear not to be applicable, implying that a stochastic approach needs to be utilized. Typical attributes of a nuclear fuel management problem are

- Nonlinear dependence of objective function and constraints on decision variables
- Multi-objective decision-making problem
- Lack of derivative information of objective function with respect to decision variables
- Mixed integer-continuous or integer-decision variables
- Highly constrained problem with feasible decision subdomains disjointed
- Multiple local minima of objective function for feasible solutions whose quality is nearly as good as the global minima solution
- A very large decision space

Clearly, for certain optimization problems that are nonlinear, one could attempt linearizing the problem about some assumed values of the decision variables, optimizing the linear problem using a deterministic approach, and relinearizing the problem about the updated decision variables, continuing this process until convergence of the decision variables. This approach has in the past been attempted to be utilized without success for the in-core optimization problem using the branch-and-bound linear programming approach to address the integer-decision variables. So the focus will be on stochastic optimization approaches, in particular SA and GAs. These two approaches have been selected for discussion because of their wide utilization in solving the nuclear fuel management optimization problem, but one should recognize that other stochastic optimization approaches have been utilized with success.

SA is based upon the physical analogy of cooling of a metal. It builds upon the statistical mechanics algorithm due to Metropolis (Metropolis et al., 1953) that was first introduced as a means of finding the equilibrium configuration of a collection of particles at a given temperature. The connection between the Metropolis algorithm and minimization was first noted by Pincus (1970), but it was Kirkpatrick (Kirkpatrick et al. 1983) who proposed that it forms the basis of an optimization technique for combinatorial problems, in which a set of candidate solutions to minimize an objective function is generated by random trial moves. The physical analogy is that if a metal is cooled too quickly, it will assume a structure that does not correspond to the lowest energy state. If a metal is cooled very slowly, it will assume a structure that does correspond to the lowest energy state but at the cost of increased cooling time. What one desires is the maximum cooling rate, which will assure that the metal will assume a structure that does correspond to the lowest energy state. Using this analogy, the SA stochastic optimization approach has been developed. Let f_C denote the current value of the objective function, which is associated with a set of values for the decision variables. Now randomly sample one or more of the decision variable values to form a perturbed state and determine f_P , the perturbed value of the objective function. Now determine whether the perturbed state replaces the current state by

$$f_C = \begin{cases} f_P & \text{if } f_P < f_C \text{ or } r \leq e^{(f_C - f_P)/T} \text{ if } f_P \geq f_C \\ f_C & \text{otherwise} \end{cases} \quad (25)$$

where r is a random number between 0 and 1 and T denotes the annealing temperature. What this acceptance criterion does is not only accept superior solutions, but also inferior solutions with some probability dependent upon the annealing temperature. This allows the optimization search to escape from local minima in its search for the global minima.

Key to SA is the rate of decreasing of the annealing temperature as the search progresses. The initial annealing temperature is selected to be high allowing the decision variables' search space to be spanned. Its specific value is set by randomly, successively sampling the set of decision

variables, evaluating the objective function values and standard deviation of the objective function values, σ_f , and specifying the initial annealing temperature by $T_o = A\sigma_f$. When substituting this expression into (25) it is recognized that by the selection of the value of A the initial annealing temperature is being selected so that a desired probability of accepting inferior solutions is attained. As the search progresses, the annealing temperature is decreased, with one possible way of doing this based upon

$$T_{k+1} = \alpha_k T_k \quad (26)$$

where k denotes the cooling step. A cooling step is completed after a certain number of histories, i.e., perturbation cases, are evaluated at annealing temperature T_k , which forms a Markov Chain. The length of Markov Chain has to be sufficient to establish an equilibrium Boltzmann distribution, which by an analogy to statistical mechanics indicates that the annealing temperature decrement should be determined by

$$\alpha_k = \max \left(\alpha_{\min}, e^{-[vT_k/(\sigma_f)_k]} \right) \quad (27)$$

where α_{\min} and v are selected, and $(\sigma_f)_k$ denotes the standard deviation of the objective function for the k th cooling step. Various attributes are evaluated to determine the length of the Markov Chain to assure that an equilibrium Boltzmann distribution has been approximately established.

Constraints need to be imposed during the optimization search. If a constraint is directly on the value a decision variable can take, this is simply enforced in the sampling of decision variable values. If the constraint relates to some limitation of the system being analyzed, e.g., maximum allowed fuel pin burnup, it can be imposed as a hard or soft constraint. If imposed as a hard constraint, if a history violates the constraint it is rejected from further consideration by SA. If imposed as a soft constraint, a penalty function is introduced where

$$P_k^m(\eta_{limit}^m, \eta_P^m) = \begin{cases} 0 & \text{if constraint not violated} \\ > 0 & \text{if constraint violated and increases with violation magnitude} \end{cases} \quad (28)$$

where m indicates the specific constraint, k denotes the fact that the penalty function magnitude increases with cooling steps for the same violation magnitude, and η_{limit}^m and η_P^m denote the attributes associated with constraint m and its limit and perturbed state value, respectively. Using the soft constraints the augmented objective function is formed

$$f_P^{Aug} = f_P + \sum_m P_k^m(\eta_{limit}^m, \eta_P^m) \quad (29)$$

and used in place of the true objective function in the SA selection of acceptance or rejection of a history. The rate of increase of the penalty function has to be such that the constraint violations are removed as the optimization search progresses, but not so fast that the search gets locked into a local minimum. This behavior is illustrated in  Fig. 22. Just as there are adaptive techniques for controlling the cooling rate of the annealing temperature, there are also adaptive techniques for controlling the rate of increase of each of the penalty functions. By using adaptive methods, the optimization search can proceed with greater assurance that the solutions within the vicinity of the global optimum solution can be located while minimizing the

■ **Figure 22**
Impact of penalty function multiplier on removing constraint violations

computational effort, which still can be substantial. To further reduce the computational burden, an early rejection approach can be utilized. In early rejection, one first determines the random number, r that appears in (25) and back calculates the value of f_p^{Aug} that would cause rejection of the perturbed history being evaluated. Many times constraints can be evaluated prior to the complete analysis of the perturbed history. Using a conservative low estimate of the true objective function value, f_p , and adding to (29) constraint violation penalty functions as the value of constraint violations become available, early rejection causing termination of further perturbed history evaluation will occur if the resulting value of (29) exceeds the predetermined rejection value. An example of where early rejection is most useful is in determining the loading pattern, where cycle depletion is required to assure that no constraints are violated throughout the cycle. If violations occur at some cycle depletion step, early rejection could then trigger termination of further cycle depletion steps.

Since a number of histories are generated, the best of the feasible solutions can be archived for later consideration by the designer when considering attributes that cannot be quantified. This is a nice feature associated with stochastic optimization and particularly attractive for nuclear fuel management optimization, where a number of local minima may exist nearly as good as the global minima but associated with quite different decision parameter values.

GAs are another class of popular stochastic optimization approaches (Goldberg 1989) used to complete the mathematical optimization of nuclear fuel management decisions. GAs' potential advantage over SA is the ability to efficiently locate the vicinity of the global optimum decisions by allowing large perturbations, but in doing so they have the potential disadvantage of not being able to efficiently determine the family of near optimum decisions because of the large perturbations. They are based on an analogy of the evolution of a biological system.

GAs employ a random search procedure in which the members of a population of solutions are either crossed over with one another, or mutated to form a new population of solutions which, on average, should be more fit than the previous generation of solutions. Unlike SA, which seeks to minimize a cost function, GAs seek to maximize the fitness of the population. To accomplish this, the GAs take the negation of the SA objective function as the fitness. A GA parameter known as the selection pressure takes the place of the SA temperature. The selection pressure is a measure of how greatly the more fit solutions are favored for reproduction into the next generation. A selection pressure of 1.0 implies no selection pressure, i.e., all solutions are equally likely to be allowed to reproduce. Increasing positive selection pressures makes it more likely that the more fit solutions will be the solutions allowed to reproduce offspring, which form the new solutions for the next generation. This results in an algorithm, which has all the advantages of SA, along with the drawback of SA of requiring the evaluation of a large number of histories. Because GAs operate on a population of solutions, rather than a single solution at a time, this permits GAs to explore numerous solution possibilities simultaneously. GA's ability to explore numerous solution possibilities simultaneously also provides a highly effective capability for multi-objective optimization. Like SA, hard and soft constraints can be utilized and archiving of the family of near optimum solutions is possible. Unlike adaptive SA, there are many more tuning features that need to be specified when using GAs, the specific features employed dependent upon the attributes of the optimization problem. Tuning features include population size, selection, archiving and elitism, mutation fraction, number of mutation changes per history (also a feature of SA), nature of crossover operator, and crowding and niching. These tuning features provide the opportunity to develop a robust and efficient mathematical optimization capability for a specific optimization problem, but also require more expertise and development time than SA to do this correctly.

Key measures of success in implementing any stochastic optimization approach are robustness and computational efficiency. Robustness denotes the ability to determine the family of near optimum decision variable values for a range of applications, e.g., determination of loading pattern for different LWR plants and reload cycles, independent of the initial guess of the decision variables values. This is demonstrated by analyzing a range of applications, and for each application completing the optimization several times for different initial guesses of the decision variables values. From these different applications and initial guesses the robustness of satisfying all the constraints can be judged, and from the different initial guesses for a specific application the standard deviation in the objective function value associated with the optimum decision variable values can be determined. What one seeks is a small standard deviation since one desires the minimum objective function value determined to be independent of the initial guess of decision variable values. To assure that the minimum objective function value found is close to the value associated with the true global optimum is a more difficult task to complete, since the true global optimum is not known for realistic problems. In this case, a brute force approach of sampling a very large number of histories using whatever optimization capability has been developed, e.g., a very slow annealing temperature cooling schedule may serve to provide some knowledge of the value of the objective function in the vicinity of the true optimum. Regarding computational efficiency, clearly the objective is to minimize the number of histories that must be analyzed to determine the family of near optimum solutions. Unfortunately, the minimum number of histories to accomplish this is not known, so comparison of one optimization approach versus another seems the only manner of getting some measure of computational efficiency.

3.5.3 Application of Mathematical Optimization to Out-of-Core Nuclear Fuel Management

In [3.1](#) the out-of-core nuclear fuel management decisions were presented as

- 1 Cycle length between refueling outages, i.e., cycle energy requirement
- 2 Utilization of stretch out, i.e., operating reactor beyond when criticality can be maintained at full-rated power with nominal plant conditions
- 3 Fresh fuel assemblies number and compositions
- 4 Burnt fuel assemblies to reinsert
- 5 Burnable poison type and total loadings

There are not many, perhaps no, examples of the capability to make all these out-of-core nuclear fuel management decisions simultaneously employing mathematical optimization. However, there are a few examples of making Decisions 3, 4, and 5 simultaneously employing mathematical optimization. The OCEON-P computer code (Comes and Turinsky 1988) is an example of having this capability, so will be discussed at length to provide some insight into what features need to be incorporated into such a code. OCEON-P, which completes Out-of-Core Nuclear Fuel Management Optimization for PWRs, has as its objectives minimization of the leveled fuel cycle cost over the planning horizon and minimization of engineering effort to accomplish this.

The decision variables determined for each cycle in the planning horizon include

- 1 Feed enrichment and number of assemblies for region/batch pairings
- 2 Partially burnt fuel assemblies to reinsert
- 3 Total burnable poison types and loadings
- 4 Batch power shares

Decision 4 is introduced to provide some degree of coupling between the out-of-core and in-core nuclear fuel management problems. By optimizing power shares, i.e., fraction of core energy produced by a region/batch pairing over the cycle, in the out-of-core optimization, the power shares can then be employed as input constraints for in-core fuel management optimization when determining loading patterns. The optimum power shares are determined by inputting multiple target EOC reactivities as a function of core location and feed region size, which are used to determine associated loading patterns during the out-of-core optimization search from which power shares are calculated.

The constants imposed on the optimization are the following:

- 1 Cycle energy requirements
- 2 Discharge burnup limits (region and batch averages)
- 3 Assembly lifetime
- 4 Moderator temperature coefficient
- 5 Minimum and maximum feed enrichments
- 6 Minimum and maximum feed batch sizes
- 7 Feed enrichment palette
- 8 Feed enrichment split options
- 9 Enrichment smoothing

Constraint 7 restricts feed enrichments to predefined values, so to satisfy cycle energy requirements split enrichments must generally be used. This constraint arises to minimize fuel manufacturing costs, in particular, the conversion of UF₆ to UO₂ powder. Constraint 9 is introduced to force the cycling scheme to approach equilibrium in the later cycles of the planning horizon. This is necessary since cycles beyond the last cycle in the planning horizon must be modeled to assure that no constraint violations occur due to decisions made within the planning horizon, and to evaluate the leveled fuel cycle cost since fresh fuel loaded in the planning horizon must be followed to final discharge, i.e., no further energy production.

The OCEON-P code major modules consist of an economic model, neutronics models, and optimization engine. The economic model uses a carrying charge model. The neutronics models consist of three models of different fidelity and computational burden, allowing the user to select which model or combination of models are to be utilized. The neutronics models available are the following:

- Linear Reactivity Model (LRM) (Driscoll et al. 1990) accounting for radial leakage effects
- FLAC model (Beard 1978) using coarse mesh, nodal FLARE technique
- Nuclear design core simulator via MPI linkage

Several optimization engines have been developed for OCEON-P that a user can select from:

- Single objective, biased Integer Monte Carlo Programming with hard constraints
- Single objective, biased, adaptive SA with soft constraints and early rejection (Anderson et al. 2007)
- Single objective GA (Du and Turinsky 2008) with soft constraints.

Of these optimization approaches, biased SA appears most robust and efficient for this particular application. By biased is inferred that the feed region sizes of each cycle and enrichment difference if using split enrichments are determined not by purely random sampling, but using probability distributions determined and updated during the optimization search based upon the economically attractive feasible solutions so far identified.

➤ *Figures 23* and ➤ *24* present the results of an OCEON-P optimization. ➤ *Figure 23* presents the feed/batch sizes and enrichments for the top 50 cases as ranked by leveled fuel cycle cost. All these cases are feasible. ➤ *Figure 24* shows the associated burnable poison loadings, where the burnable poison number refers to a specific burnable poison design, e.g., 12 Gadolinia rods of 6 w/o in an assembly, and the percentage of assemblies so loaded. ➤ *Figure 25* presents the cycling scheme table associated with one of the top 50 cases, identified by history number. This particular optimization did not optimize power shares, so their values are not presented.

A shortcoming of OCEON-P is its lack of tight coupling between out-of-core and in-core decision making. As mentioned, power shares derived from selecting among loading patterns characterized in terms of EOC assembly reactivity loading pattern candidates is employed to provide some degree of coupling. Given increased computational power, in particular, multiprocessors and multicores, capability has been developed to more tightly couple the out-of-core and in-core decisions. Capability to make out-of-core Decisions 3, 4, and 5 simultaneously with in-core Decision 6, which concerns determining the core loading pattern for a PWR over a limited number of reload cycles has been demonstrated utilizing SA as the optimization approach (Kropaczek 2009).

3.5.4 Application of Mathematical Optimization to In-Core Nuclear Fuel Management

A great deal of work has been successfully completed on using mathematical optimization to optimize in-core nuclear fuel management decisions. Recall that these decisions are:

- Core loading pattern, i.e., fresh fuel, burnt fuel, and burnable poisons core locations
- Control rod (blades) locations and core flow rate (only for BWRs) as function of burnup

These in turn involve additional design decisions about the lattice and assembly designs. Much of the mathematical optimization capability developed has been limited to only addressing one or two of the decisions that need to be made. In lattice design, there have been a number of successful efforts to incorporate mathematical optimization in the decision-making process (Francois et al. 2005; Hernandez-Noyola and Maldonado 2009). Examples of using various optimization approaches, such as linear programming and SA, exist. Many times the method of solution to the lattice physics problem, required to evaluate the objective function and constraints, is simplified to minimize the computational effort, e.g., using successive linear or quadratic functionalization of the objective function or constraint value dependences upon the decision variables. The problem with decoupling lattice optimization with the other in-core optimization aspects is how to define a meaningful objective function and constraints. Many

■ Figure 24

Feed fuel burnable poison types and fraction loadings in zones for PWR determined by mathematical optimization

times target lattice reactivity versus burnup is given as a constraint with the objective of minimizing the cost of enriched material in the lattice. Sometimes the local peaking factor is either imposed as an objective to be minimized or as a constraint. Clearly, the target lattice reactivity must be dependent upon where this lattice is located throughout the core. Likewise, the local peaking factor cannot be considered in isolation of what the lattice average powers are for all the locations of this lattice throughout the core. But the lattice locations throughout the core are determined by the loading pattern, and the associated lattice average powers are also dependent upon the CRP for a BWR. To address this coupling, one could consider iterating between the lattice optimization and loading pattern optimization, but when done in this loose fashion robustness of the optimization becomes questionable.

Some progress has been made on coupling the lattice and assembly optimization with the core's response to lattice designs (Jessee and Kropaczek 2005). In this work done for a BWR, it is assumed that the core loading pattern and CRP are fixed, and that there is a limited number of fuel pins characterized by fuel enrichment and Gadolinia w/o as a function of axial position. The decision variable is the radial positions of the candidate fuel pins within the feed fuel assemblies for a specified number of fuel assembly designs, which equates to the number of batches in a region assuming that irradiation history is not also used as a discriminator to define a batch. In BWR lingo, each feed fuel assembly design refers to a stream, so if N feed fuel assembly designs

Figure 25

Cycling scheme for lowest fuel cycle cost scheme for PWR determined by mathematical optimization

were specified to be utilized, an N-streaming core design would occur. In addition to imposing the number of streams as a constraint, the maximum number of different pin-type designs that can be utilized in a single stream and also for all streams from the candidate pin-type designs can be imposed as constraints. Since fuel manufacturing cost is increased by using more pin types, this constraint attempts to control fuel manufacturing cost. Using SA perturbations are made of the current fuel pin layout using the fuel-type pin designs provided for each stream of feed assemblies. The resulting lattices are analyzed using a linear superposition approach to reduce computational effort, with linearization recompleted at some frequency about the current optimized lattice designs. The results of the lattice analysis, i.e., homogenized few-group cross-sections, local pin power distribution, and F-factors used in CHF analysis, are then provided to the 3D core simulator to evaluate the objective function, i.e., minimization of feed fuel cost, and constraints on the core, e.g., cycle energy requirement, CSM, and thermal limits.

Figure 26

Core loading pattern for $N = 1$ and $N = 5$ streaming using mathematical optimization for a BWR

In addition, constraints on pin-type placement based on experience can be imposed, which are treated as hard constraints and limit the pin configurations that need to be considered.

► Figure 26 shows the loading patterns that are found when using $N = 1$ and $N = 5$ fresh fuel assembly types, where both loading patterns satisfying all constraints imposed but fuel cycle cost savings of about \$1 million for a cycle result for $N = 5$ over $N = 1$ due to a reduction of four fresh fuel assemblies.

Work has also been completed on BWR assembly optimization using mathematical optimization (Martin-del-Campo et al. 2002). Here again the lack of significantly tight coupling with the other design decisions that must be made likely compromises the quality of the overall optimum decision making.

The most work on using mathematical optimization in support of making fuel management decisions has been in making loading pattern decisions. SA, GAs, evolutionary algorithms, linear programming, steepest descent, and other methods have been historically utilized to complete the mathematical optimization. Here the SA and GAs approaches will be discussed. In particular, results for the FORMOSA-P (Kropaczek and Turinsky 1991; Maldonado and Turinsky 1995), a PWR loading pattern optimization code, and FORMOSA-B (Moore et al. 1998; Karve and Turinsky 1999; Karve and Turinsky 2001), a BWR loading pattern and CRP optimization code, will be presented.

FORMOSA-P can complete single- or multi-objective optimization selecting from the following objectives:

- 1 Minimize feed fuel enrichment (including split feed enrichments)
- 2 Maximize EOC core reactivity
- 3 Minimize radial peaking factor
- 4 Maximize region average discharge burnup
- 5 Minimize reactor vessel fluence

The decision variables optimized include:

- 1 Location of fuel assemblies
- 2 Rotation of fuel assemblies
- 3 Burnable poison loading in each fresh fuel assembly (type and quantity)
- 4 Partially burned fuel assemblies to reinsert
- 5 Feed fuel enrichment (if not fixed)

The decision variable for the core loading pattern is described mathematically by the binary values of $X_{l,m,n,o}$, where,

$$X_{l,m,n,o} = \begin{cases} 1 & \text{if fuel assembly of shade } m \text{ burnable poison type } n, \text{ and orientation } o \\ & \text{is located in core location } l \\ 0 & \text{otherwise} \end{cases}$$

where shade refers to a fuel assembly of the same feed enrichment and BOC burnup distribution. For example, if all the feed fuel assemblies were identical they would form a single shade, and if quarter core symmetry was applicable groups of four shuffled fuel assemblies would form shades.

The optimization is completed with the ability to impose the following constraints:

- 1 Discharge burnup limits: node, pin, assembly, and region averages
- 2 Radial power peaking factor (multi-rodged and unrodged configurations)
- 3 Target EOC critical soluble boron concentration for specified cycle energy production
- 4 Maximum soluble boron
- 5 Maximum moderator temperature coefficient at 0%, 50%, and 100% of rated power
- 6 Axial offset anomaly criteria

- 7 Maximum feed enrichment
- 8 Maximum number of burnable poison types to utilize
- 9 Maximum number of discrete burnable poison rods (if applicable)
- 10 Maximum reactor vessel fluence
- 11 Minimum excore detector response
- 12 Octant power tilt
- 13 Octant orientation mix
- 14 Region/batch maximum and minimum power sharing
- 15 Fuel assembly core placement and rotation restrictions
- 16 Fuel assembly position freeze constraint
- 17 Fresh fuel assembly burnable loading restrictions

The FORMOSA-P code major modules consist of an economic model, neutronics models, and optimization engine. The economic model evaluates the overnight feed fuel cost. The neutronics models consist of several different models of different fidelity and computational burden, allowing the user to select which model or combination of models are to be utilized. The neutronics models available are the following:

- Built-in modern nodal core simulator with the following capabilities: Cartesian or hexagonal geometries, microscopic or macroscopic cross-section models, thermal-hydraulic and transient fission product treatments, 3D to 2D consistent geometry collapse models (Keller and Turinsky 2001), generalized perturbation theory capability to reduce CPU time, and pin reconstruction with surface spectral history model.
- Nuclear design core simulator via MPI linkage, with capability to execute on multi-processor or networked computers.

Several optimization engines have been developed for FORMOSA-P that a user can select from:

- Single- or multi-objective, adaptive SA with soft constraints and early rejection (Engrand 1997)
- Single- or multi-objective GA with soft constraints (Keller 2001)

Note that multi-objective optimization capability has been included. The implementation utilizes true multi-objective optimization rather than an approach that forms a single objective from a sum of weighted objectives. This later approach causes the optimum family of solutions found to be dependent upon the weights selected, but how to select the values of the weights lacks a mathematical basis. By true multi-objective optimization is implied that the values of the decision variables that define the Pareto surface, which can be thought of as a trade-off surface of several objectives, are determined. It is easiest to describe this considering just two objectives. Given a value of Objectives A, one seeks to determine the minimum value of Objective B. By continuously changing the specific value of Objective A and determining the minimum value of Objective B, the Pareto surface is determined. This could be done by multiple single objective optimizations treating Objective A value as a constraint. Alternatively and with enhanced computational efficiency this can be done using the following multi-objective mathematical optimization approach, which requires the creation of a nondominated archive of solutions. Given N objectives, a solution X is said to be dominated by solution Y if

$$f^{(i)}(Y) < f^{(i)}(X) \quad \forall i = 1, N \quad (30)$$

■ **Figure 27**
Display of nondominated solutions when there are two objective functions

i.e., if solution Y is superior for all objectives. This is pictorially shown in [Fig. 27](#) for two objective functions. If a candidate solution dominates any solutions in the archives, then those solutions are removed from the archive, and the new solution is added. If the new solution is dominated by any solution in the archive, then the candidate solution is not archived. If the candidate solution neither dominates nor is dominated by any member of the archive, it is added to the archive.

In the Multi-Objective SA (MOSA) approach (Engrand 1997), a perturbed loading pattern is tested for possible inclusion into the nondominated archive before the simulated annealing acceptance test is performed. If a perturbed loading pattern solution is archived, then it is automatically accepted by SA as the new current loading pattern solution. For loading pattern solutions, which are not added to the nondominated archive, and thus accepted at the nondominated archiving stage, then, the loading pattern is accepted with a probability p given by

$$p = \prod_{i=1}^N e^{-(f_p^{(i)} - f_c^{(i)})/T_n} = e^{-\sum_{i=1}^N (f_p^{(i)} - f_c^{(i)})/T_n} \quad (31)$$

The implementation of Multi-Objective GA (MOGA) is much simpler because the concept of an archive already exists, that being the population of a generation (Parks 1996).

FORMOSA-P also has the capability to complete multicycle optimization, but this is done by optimizing each cycle's loading pattern without consideration of the other cycles, hence does not possess the capability to perform true multicycle optimization. It also lacks the capability to determine the optimum equilibrium cycle, which exists in other codes (Quist et al. 1999).

► [Figure 28](#) shows the behavior of the true objective function values and constraints as a single objective SA optimization progresses. This optimization was completed with the objective of maximizing the critical boron at the end of cycle. Note how the augmented objective function value can climb out of local minima due to the higher annealing temperatures early in the search. Constraint limits are removed at some point and the optimization search than

■ Figure 28

Objective function value versus history number for a single objective PWR loading pattern optimization

focuses on decreasing the true objective function value. This is because of how the constraint penalty functions increase in magnitude as the search progresses.

➤ [Figure 29](#) shows the results of a multi-objective optimization utilizing MOGA. Two objectives are being traded-off against each other, those being enrichment and radial peaking factor. As expected, as the radial peaking factor assumes large values, more freedom in selecting the loading pattern is taken advantage of in decreasing the feed enrichment.

Presented in ➤ [Table 6](#) are the standard deviations and other metrics of robustness of three optimization methods: MOSA, Single Objective SA (SOSA), and Single Objective GA (SOGA). The objectives are minimization of radial power peaking and minimization of feed enrichment. These metrics were obtained by rerunning FORMOSA-P a number of times, changing the random number seed, which results in a different optimization path to the vicinity of the global minima.

FORMOSA-B shares many of the features of FORMOSA-P, differing in the unique features of BWR versus PWR loading pattern determination and the need to determine the CRP coincident with the loading pattern. FORMOSA-B can complete single objective optimization by selecting from the following objectives:

1. Minimize total reload cost (i.e., overnight fresh fuel loading cost)
2. Maximize plant cycle length for fixed fresh fuel inventory (either maximization of EOC core reactivity or minimization of EOC critical flow)
3. Minimize the Maximum Linear Heat Generation Rate (MLHGR)
4. Maximize region average discharge burnup

■ Figure 29

Objective function values as search progresses for a dual-objective PWR loading pattern optimization

The decision variables optimized include:

1. Location of fuel assemblies
2. Fresh assembly types to load from palette of fresh assembly design types, including burnable poison configurations
3. Partially burned fuel assemblies to reinsert
4. Control rod program

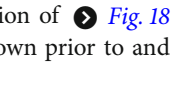

The optimization is completed with the ability to impose the following constraints:

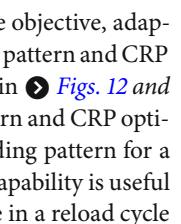

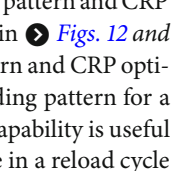

1. Fuel assembly placement restrictions associated with conventional or control cell cores
2. Maximum hot excess reactivity
3. Minimum and maximum core flows versus cycle burnup
4. Discharge burnup limits: node, pin, assembly, and region averages
5. Peak Linear Heat Generation Rate (MLHGR)
6. Maximum Average Planar Linear Heat Generation Rate (MAPLHGR)
7. Core Thermal Margin to Boiling Transition (MCPR)
8. Cold Shutdown Margin
9. Target core reactivity versus cycle burnup
10. Maximum number of fresh fuel assembly types to utilize
11. Octant power tilt
12. Fuel assembly core placement restrictions
13. Fuel assembly position freeze constraint

■ **Table 6**
Comparison of optimization performance of different methods

Attribute	MOGA	SOGA	SOSA
Mean Lowest Radial Peaking Factor	1.381	1.396	1.391

Mean Number of Loading Patterns Evaluated	45,300	24,717	25,592

14. Numerous heuristic rules associated with Control Rod Programming, e.g., exchange sequence, exchange frequency, deep and shallow allowed notch position ranges, and fixed full insertions (to shadow leakers), and associated restrictions on fuel assembly placement, e.g., Conventional and Control Cell Cores.

The FORMOSA-B code major modules consist of an economic model, neutronics models, and optimization engine. The economic model evaluates the overnight feed fuel cost. The neutronics model has the following features: 3D Cartesian geometry, microscopic or macroscopic cross-section models, two-phase thermal-hydraulic using drift flux model with by-pass flow and flow redistribution (with capability to insert proprietary constituents relationships, e.g., GEXL correlation), transient fission product treatment, 3D sub-core collapse model for CSDM evaluations, pin-wise reconstruction, and adaptive core simulator (Jessee et al. 2009) to enhance agreement with design basis core simulators as may be necessary. Note that the adaptive core simulator feature is important if using a core simulator during the optimization search that is not the design simulator. This follows since if these two simulators differ in their prediction of core attributes used to evaluate the objective function or constraints, it is likely that when the family of near optimum loading patterns and CRP pairings are reevaluated using the design simulator, some constraint violations could be predicted rendering the optimization not useful. Clearly, the best approach is to utilize the design simulator during the optimization if the computational burden can be tolerated. The other usage of adaptive simulation is to adapt the core simulator to reduce the uncertainties in the cross-section, which is displayed in the upper portion of  where the relative power uncertainty due to cross-section uncertainty is shown prior to and after adaptation.

The optimization engine developed for FORMOSA-B is based upon single objective, adaptive SA with soft constraints and early rejection. Results for a combined loading pattern and CRP optimization are presented in . Note that the CRPs presented earlier in  and  were generated using FORMOSA-B also in a combined loading pattern and CRP optimization. Needless to say, FORMOSA-B has the capability to optimize a loading pattern for a specified CRP or to optimize a CRP for a specified loading pattern. This later capability is useful for an operating BWR core, where the actual CRP used up to the current time in a reload cycle

■ Figure 30

Objective function value versus history number for a single objection BWR loading pattern and control rod pattern optimization

differs from the optimized CRP. In this case, one would want to reoptimize the CRP over the rest of the cycle.

3.6 Computational Design Sequences

This section discusses the design calculations needed to complete nuclear fuel management, and the methods employed to accomplish this. The discussion of the methods employed will be limited since other chapters in this handbook present in detail the methodologies.

3.6.1 Design Calculations Needed

From the presentation so far it is apparent that one must establish a core simulator model, deplete this model over the cycle, and perform branch calculations at various burnup steps to access whether the constraints placed on the core are being satisfied. ➤ Section 3.5 presents the out-of-core constraints for a PWR that are imposed in the OCEON-P code, the in-core constraints for a PWR that are imposed in the FORMOSA-P code, and the in-core constraints for a BWR that are imposed in the FORMOSA-B code. With the exception of the CSM constraint for a BWR, all these constraints are imposed within the normal power operating range. In addition to these constraints, there are numerous other constraints that originate due to safety limits. Many times these constraints can be expressed in terms of limits on point kinetic parameters,

power peaking factors, and control rod worths under normal or abnormal conditions. An example of such constraints is the Doppler temperature coefficient under normal, ejected control rod, and $N-1$ control rod, i.e., all control rods inserted except highest worth rod stuck out, conditions, for fuel temperatures and coolant densities that span the normal operating range and beyond. Other examples are the power peaking factor for an ejected control rod condition, and the control rod ejected rod worth. Such constraints originate because the associated constraint values are utilized in safety analysis where system transient codes are employed to assess nuclear safety. In the past it was common to utilize a point kinetics model to represent the neutronics behavior, i.e., core nuclear power, as a function of time. This capability has evolved to utilize 1D axial models of the core's neutronics behavior, and further to utilize 3D models of the core's neutronics behavior. In doing so, the simple approach of imposing constraints on core characteristics that could be represented by point kinetic parameters, power peaking factors, and control rod worths has become more challenging to utilize because how does one do bounding calculations where these characteristics are set to their limits within the context of using a 1D or 3D core simulator. Many times, technical specifications and startup acceptance test criteria relate to these core characteristics, so it is difficult to move beyond using them as constraints. Further, from a computational burden viewpoint, one does not wish to repeat all the safety analyses for every reload core, which would become more necessary if a core model is utilized that could not be characterized by bounding values.

The sequence of calculations required to complete a reload core analysis is presented in  **Fig. 31**. It starts with utilizing an evaluated nuclear data library such as ENDF/B, JEDL, or JEF. That library is processed to produce a many energy-group cross-section set and some characterization of resonances by codes such as NJOY (McFarlane et al. 1982), AMPX (Greene et al. 1976), or proprietary buffer codes associated with a specific lattice physics code. The many energy-group cross-sections are based upon an assumed flux energy spectrum, e.g., LWR spectrum, with the dependence of the many-group cross-sections on the spectrum assumed decreasing as more energy groups are utilized. In the case of the scattering kernel in the thermal energy range when considering a thermal reactor, it will be generated at several moderator temperatures. Representation of resonance effects has been done in terms of infinitely dilute resonance integrals or resonance probability tables using the many-group structure given as a function of temperature. The specific representation is dependent upon how resonances will be treated in the lattice physics code that the many-group library is being prepared for. Numerous lattice physics calculations are then completed to determine few-group, spatially homogenized cross-sections. Clearly, spatial homogenization does remove details that will need to be recaptured, e.g., pin powers, but it does have the benefit of making the diffusion theory assumption used at the core simulator level more appropriate since strong heterogeneities, e.g., burnable poison rods, have been minimized. Finally, core simulator calculations are completed to evaluate the core's characteristics, normally based upon a few-group neutron diffusion theory model. The following sections provide more details for the lattice physics and core simulator calculations required.

3.6.2 Cross-Section Generation

The goal of lattice physics calculations is to generate the few-group, spatially homogenized cross-sections that are utilized as input to the core simulator. Elsewhere in this handbook is

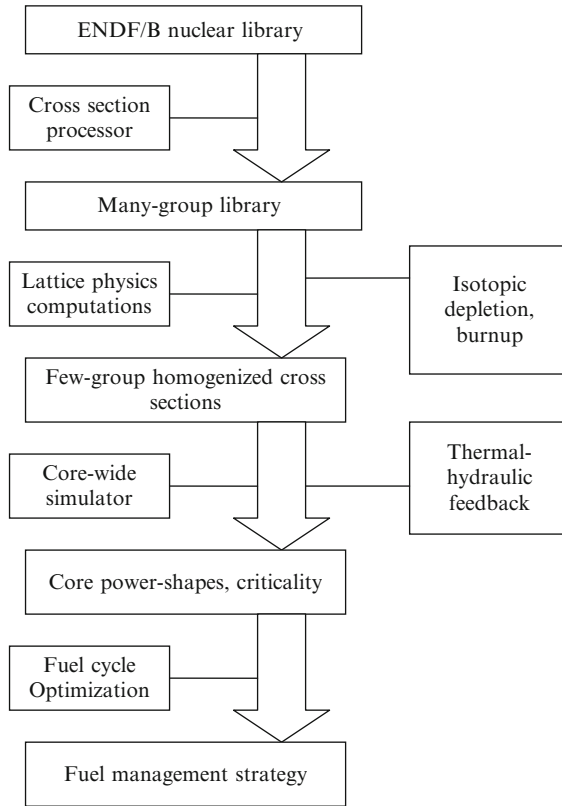

Figure 31
Sequence of calculations required to complete a reload core analysis

presented in detail the methodologies utilized by lattice physics codes. There are a number of assumptions that are generally made in addition to those associated with the numerical solution approach. Some of the key assumptions are:

- Zero current boundary condition used on lattice boundaries
- Two-dimensional radial geometry
- Isotropic or linear anisotropic scattering
- Resonance treatment assumptions, e.g., multiple isotopes additive contributions to resonance self-shielding
- Uniform thermal conditions, i.e., uniform fuel temperature, cladding temperature, and coolant temperature and density.

The validity of these and other assumptions are dependent on the application at hand. For example, the zero current boundary condition assumption appears to work well for LWRs loaded with LEU assemblies for the normal operating range, but mixed LEU-MOX assembly cores require further treatment to minimize the errors introduced by this assumption.

The number of energy groups used and range of spatial homogenization are dependent upon the core type being analyzed. LWRs and HWRs typically utilize two energy groups, thermal gas-cooled reactors may add one or two epithermal groups due to weaker moderation, and finally fast reactors may be using a dozen or more groups. Clearly, fidelity required will influence the number of groups selected to be used. Spatial homogenization for PWRs and BWRs are typically 2×2 and 1×1 , respectively, meshing per lattice when using a nodal method for the core simulator. If a finite difference method is used by the core simulator, which is not common for LWRs, a unit cell mesh would likely be used. Because the unit cell meshing retains strong heterogeneities, which compromises diffusion theory, transport corrected cross-sections would need to be determined and utilized by a diffusion theory-based core simulator. Spatial homogenization across the lattice is typical for fast spectrum cores.

What specific lattice cases need to be executed depends on the core simulator's need and range of applications that the core simulator will have to address, e.g., CZP conditions. Some core simulators utilize a macroscopic cross-section model, i.e., only complete depletion calculations for a limited number of isotopes such as those associated with the transient fission products and burnable poisons, where others utilize a microscopic cross-section model, i.e., complete depletion calculations for the fissile, fertile, selected fission products, and lumped fission products isotopes in addition to those treated by the macroscopic model. The usage of a macroscopic cross-section model could influence the number of history depletion cases that need to be executed. History depletion cases attempt to capture the effects of fuel temperature, coolant temperature and density, control rod insertion, and for PWRs soluble boron concentration, variations throughout the cycle on the isotopic number densities, which originate due to their impact on the neutron energy spectrum. For each history depletion case, there is a need to execute instantaneous branch cases at various burnup points. The instantaneous branch cases utilize fixed isotopic number densities except for the ones that are instantaneously changed. Needless to say, the history and instantaneous branch cases need to be executed for every lattice type, so require a large number of lattice physics calculations. The following are examples of typical cases that may need to be executed for an LWR.

History cases

- Nominal conditions, unrodded depletion
- Nominal conditions, rodded depletion
- Off nominal spectral cases, e.g., coolant density or soluble boron concentration, unrodded depletion
- Off nominal fuel temperature, unrodded depletion

Instantaneous branches cases

- Fuel temperature
- Coolant density (void for BWR and temperature for PWR)
- Rodded to unrodded or unrodded to rodded
- Discrete burnable poison rod pull
- Cold conditions
- Soluble boron for a PWR

The resulting few-group, spatially homogenized cross-sections, whether macroscopic or microscopic, are then characterized in some fashion in terms of history depletion and instantaneous

conditions, e.g., dependence on fuel temperature characterized as square root of absolute fuel temperature. This characterization is either done inside or outside the core simulator. If done inside the core simulator, so-called table sets are prepared from the lattice physics code output and provided as core simulator input. If done outside the core simulator, various fitting coefficients are prepared from the lattice physics code output and provided as core simulator input. In doing this a reference condition for the cross-sections is defined from which corrections to their values for changes in the reference condition are subsequently applied by the cross-section characterization. A typical reference condition would be HFP thermal conditions (fuel temperature, coolant density and temperature), no transient fission products, unrodded state, and for a PWR soluble boron-free.

Clearly given the volume of history depletion and instantaneous branch cases required, this sequence of lattice physics code executions tends to be automated. At the risk of leaving out the reader's favorite lattice physics code, LWR lattice physics codes used commonly today include the following: PARAGON (Ouisloumen et al. 2001), LANCER (Knott et al. 2002), CASMO (Edenius et al. 1995), HELIOS (Casal et al. 1991), APOLLO (Hoffman 1971), WIMS (Halsall 1996), and TRITON (Dehart et al. 2007). For fast spectrum reactors, MC² (Toppel et al. 1967) and APOLLO are examples of applicable lattice physics codes. Needless to say, a Monte Carlo code can serve as a lattice physics code, but given the computational burden per case and the number of cases that need to be run, this approach is rarely utilized in a production environment.

In addition to determining the few-group, spatially homogenized cross-sections, for core simulators based upon a nodal method, discontinuity factors are also determined by the lattice physics code and characterized in some fashion utilizing the history depletion and instantaneous branch cases results. Recall that the discontinuity factors are introduced to correct the spatial homogenization error introduced into the neutron leakage term. When considering the fuel-reflector interface, the discontinuity factors are also correcting the diffusion theory introduced error into the neutron leakage term. Any degree of spatial homogenization beyond the unit cell span implies that pin-wise attributes, such as power and burnup, are no longer available. Since such information is required to evaluate fuel pin and pellet power, burnup, and clad fluence limits, pin reconstruction methods have been developed to be utilized with the information that is available from a coarser mesh core simulator model, typical when using a nodal method. These pin reconstruction methods either utilize the pin-by-pin flux or power predicted by the lattice physics code, combined mathematically with the intra-nodal flux or power available from the coarser mesh core simulator model. Again this pin-by-pin information, referred to as form factors, is characterized in some manner based upon the history depletion and instantaneous branch cases and used by the core simulator. Corner point discontinuity factors may be required in the pin reconstruction to obtain the intra-nodal flux or power. Depending upon the core simulator, other information determined by the lattice physics code will need to be characterized using the history depletion and instantaneous branch cases.

3.6.3 Core Simulation

Core simulation is required to determine whether the values selected for fuel management decision variables, e.g., feed enrichment and loading pattern, minimize/maximize the objectives while satisfying normal operating and safety constraints. In addition, core simulation is required to validate the core simulator utilizing normal operating data and special tests, e.g.,

zero power startup physics tests, and as an aide to the reactor operating staff. Few-group diffusion theory is widely employed to analyze thermal, epithermal, and fast reactor cores. This is due to the computational efficiency of this method and what is considered acceptable fidelity. To minimize modeling-introduced errors, discrete solution of the transport equation or some higher-order approximation to it, e.g., SPN or quasi-diffusion theory, and Monte Carlo may be utilized. The overall benefits so derived in increased fidelity need to be judged in its totality since it may be that cross-section uncertainties dominate the overall uncertainty in a core simulation. Note when utilizing a continuous energy Monte Carlo model or very large number of groups in a many-group transport equation model (or lower order approximation of), with a fine spatial mesh there is no longer a need for lattice physics calculations.

In addition to cross-section and geometry input, core simulators require isotopic and thermal-hydraulic data to be input. For feed fuel, the isotopic data can be passed from the lattice physics code since it is needed to be input to this code. It may be based upon design values, or if the fuel has been fabricated as built values. For the shuffled fuel, the isotopic data is obtained from the previous cycles' core simulations sometimes adjusted to better agree with in-core detector readings. For production quality core simulators, they will have the ability to simulate the fuel shuffle in order to facilitate establishment of the core simulator model for the upcoming reload core. Within the core simulator or coupled to it will be a depletion model that will calculate the isotopics as a function of core lifetime. The capabilities required of the depletion model will be dependent upon whether a macroscopic or microscopic cross-section approach is being utilized. In either instance some form of history depletion model will be needed to utilize the characterized lattice physics produced cross-sections.

For the thermal-hydraulic input data, what are required is dependent upon the thermal-hydraulic model used within or coupled to the core simulator. In many cases a simplified thermal-hydraulic model is utilized since one is mainly interested in using the results of the thermal-hydraulic model to correct cross-sections for thermal-hydraulic feedback, which would have lower fidelity requirements than evaluating whether a thermal limit has been violated. Further, the range of thermal-hydraulic conditions that the core simulator will be utilized to evaluate may be more limiting than those conditions spanned by a complete safety analysis, e.g., core is subcritical during an LOCA. Common to all core types, fuel temperature input to the core simulator for steady-state calculations may consist of tables or functional fits of fuel temperature as a function of power density and burnup for a fixed coolant temperature. The information to provide this input will come from a separate fuel thermal-mechanical code. For transient analysis, more data must be provided as input, such as cladding and fuel thermal conductivity as a function of temperature and burnup, and a gap closure model. Again an external fuel thermal-mechanical model will be used to provide such data. For the hydraulic model, for PWRs it is common to utilize a closed channel, Homogenous Equilibrium Mixture (HEM) model for normal operating conditions. For a BWR, again a closed channel, now accurate if radial meshing is 1×1 for the lattice due to presence of the BWR channel, in conjunction with a drift flux model to capture slip, would be commonly used in core simulators. In addition, by-pass flow and inlet flow redistribution models would be utilized, and a Dryout correlation incorporated to predict the critical power ratio (CPR). Under accident conditions when needed, coupling of the core simulator to a subchannel hydraulic code, such as COBRA (Stewart et al. 1977) or VIPRE (Stewart et al. 1989), has been utilized to more accurately represent the thermal-hydraulic feedback on the cross-sections.

The core simulator cases that must be executed are numerous, as indicated by the following list of intended applications that core simulations must support.

1. Determination of loading pattern, feed enrichments, and for BWRs CRP
2. Determination of core attributes over normal operating range, e.g., power distribution, burnup distribution, reactivity coefficients, transient fission product worths, control rod worths, for PWRs soluble boron worths, and point kinetic parameters
3. Determination of core attributes for safety analysis done by point kinetics via providing point kinetic parameter values outside normal operating range and for unique rodged conditions, e.g., ejected rod, dropped rod, and stuck rod, along with determination of associated power peaking factors and rod worths
4. Three-dimensional core simulation within or coupled to a system transient code for analysis of selected accidents
5. Data to interpret zero power reactor physics and other testing
6. Data to interpret in-core and excore detector readings

Applications 2, 3, and 4 are required to be completed to various degrees to complete Application 1 since they are involved in evaluating whether constraints have been satisfied. What is obvious from the above list of applications is that to complete a first or reload core design, a substantial number of core simulations must be completed. For LWRs where there are numerous reload cores that must be analyzed, in practice automation has been implemented to minimize both the calendar time and core nuclear designer time to complete these simulations. The compression of calendar time is not only beneficial from a cost viewpoint, but also minimizes the uncertainty that the currently operating reload cycle will not operate as assumed in the upcoming reload core design and analysis. Do note that it is a common practice in LWR reload core design to design for a “burnup window” of several weeks shorter or longer than the planned EOC to accommodate this uncertainty.

4 Conclusions

This section presents conclusions regarding the current state of depletion and nuclear fuel management capabilities, and where further enhancements are required to increase capabilities in these areas.

Isotopic depletion modeling capability is well developed. Its major limitation originates not so much from the mathematical limitations of solving the Bateman equation, but from the quality of the input data provided. Nuclear data for certain isotopes and reaction types are not sufficiently accurate to support the needs of nuclear fuel management, particularly for some advanced nuclear systems under consideration, e.g., ARR. As more advanced physics-based models of core materials performance are developed and utilized, very fine spatial and time detail of the isotopic concentrations will be needed. This will produce a heavy computational burden on modeling isotopic depletion. Fortunately, since the spatial component of solving the Bateman equation lends itself to parallel processing, utilization of multi-processor multi-core architectures should be able to address the enhanced computational burden.

Nuclear fuel management practices are very well established for nuclear power plant types that have enjoyed wide deployment, such as PWRs, BWRs, and HWRs. For nuclear power plant types not yet widely deployed, there is considerable opportunity to consider more creative nuclear fuel management practices. VHTRs, whether PBR or PRISMATIC, involve three-dimensional fuel movement, so offer another degree of freedom in in-core nuclear fuel

management. ARRs involve the complexity of feed material of variable elemental and isotopic composition, which can be viewed as a design complexity but offers opportunity due to the increased number of decision variables. For current LWRs and HWRs that elect to employ slightly enriched uranium, nuclear fuel management optimization using mathematical optimization has advanced greatly but still has not addressed the entirely coupled, i.e., out-of-core and in-core, nuclear fuel management problem. The grand challenge for nuclear fuel management optimization remains to address the lattice–assembly–core coupled problem over the multiple cycles in the planning horizon. For closed fuel cycles, one can add additional decisions associated with what elements to recycle, in what quantity, and how to physically introduce them into the core, e.g., heterogeneous or homogenous.

Concerning methods, by the introduction of sufficient margin nuclear fuel management decisions for nearly any nuclear power plant type can be implemented. However, the introduction of margin implies a higher cost, so the focus on methods development in support of nuclear fuel management has been to reduce the uncertainty in predicted core attribute values of importance. This involves not only the methods introduced uncertainties, but also all the other sources of uncertainties, e.g., manufacturing and nuclear data. Here the further development of adaptive simulation capability may play an important role complementary to refinement of models and numerical methods. Also since nuclear fuel management involves multiphysics modeling, e.g., radiation transport, thermal-hydraulics, depletion, and material behavior, a need to understand how all these physics pieces contribute to quantifying uncertainty and approaches to minimizing uncertainty need to be developed.

Abstract: This chapter deals with shielding against nonionizing radiation, specifically gamma rays and neutrons with energies less than about 10 MeV, and addresses the assessment of health effects from exposure to such radiation. The chapter begins with a discussion of how to characterize mathematically the energy and directional dependence of the radiation intensity and, similarly, the nature and description of radiation sources. What follows is a discussion of how neutrons and gamma rays interact with matter and how radiation doses of various types are deduced from radiation intensity and target characteristics. This discussion leads to a detailed description of radiation attenuation calculations and dose evaluations, first making use of the point-kernel methodology and then treating the special cases of “skyshine” and “albedo” dose calculations. The chapter concludes with a discussion of shielding materials, radiological assessments, and risk calculations.

1 Radiation Fields and Sources

The transmission of directly and indirectly ionizing radiation through matter and its interaction with matter is fundamental to radiation shielding design and analysis. Design and analysis are but two sides of the same coin. In *design*, the source intensity and permissible radiation dose or dose rate at some location are specified, and the task is to determine the type and configuration of shielding that is needed. In *analysis*, the shielding material is specified, and the task is to determine the dose, given the source intensity, or the latter, given the former.

The radiation is conceptualized as particles – photons, electrons, neutrons, and so on. The term *radiation field* refers collectively to the particles and their trajectories in some region of space or through some boundary, either per unit time or accumulated over some period of time.

Characterization of the radiation field, for any one type of radiation particle, requires a determination of the spatial variation of the joint distribution of the particle’s energy and direction. In certain cases, such as those encountered in neutron scattering experiments, properties such as spin may be required for full characterization. Such infrequent and specialized cases are not considered in this chapter.

The sections to follow describe how to characterize the radiation field in a region of space in terms of the particle fluence and how to characterize the radiation field at a boundary in terms of the particle flow. The fluence and flow are called *radiometric* quantities, as distinguished from *dosimetric* quantities. The fluence and flow concepts apply both to measurement and calculation. Measured quantities are inherently stochastic, in that they involve enumeration of individual particle trajectories. Measurement, too, requires finite volumes or boundary areas. The same is true for fluence or flow calculated by Monte Carlo methods, because such calculations are, in large part, computer simulations of experimental determinations. In the methods of analysis discussed in this chapter, the fluence or flow is treated as a deterministic point function and should be interpreted as the expected value, in a statistical sense, of a stochastic variable. It is perfectly proper to refer to the fluence, flow, or related dosimetric quantity at a point in space. But it must be recognized that any measurement is only a single estimate of the expected value.

1.1 Radiation Field Variables

1.1.1 Direction and Solid Angle Conventions

The directional properties of radiation fields are commonly described using spherical polar coordinates as illustrated in [Fig. 1](#). The direction vector is a unit vector, given in terms of the orthogonal Cartesian unit vectors \mathbf{i} , \mathbf{j} , and \mathbf{k} by

$$\boldsymbol{\Omega} = \mathbf{i}u + \mathbf{j}v + \mathbf{k}w = \mathbf{i} \sin \theta \cos \psi + \mathbf{j} \sin \theta \sin \psi + \mathbf{k} \cos \theta. \quad (1)$$

An increase in θ by $d\theta$ and ψ by $d\psi$ sweeps out the area $dA = \sin \theta d\theta d\psi$ on a sphere of unit radius. The solid angle encompassed by a range of directions is defined as the area swept out on the surface of a sphere divided by the square of the radius of the sphere. Thus, the differential solid angle associated with the differential area dA is $d\Omega = \sin \theta d\theta d\psi$. The solid angle is a dimensionless quantity. Nevertheless, to avoid confusion when referring to a directional distribution function, units of *steradians*, abbreviated sr, are attributed to the solid angle.

A substantial simplification in notation can be achieved by making use of $w \equiv \cos \theta$ as an independent variable instead of the angle θ , so that $\sin \theta d\theta = -dw$. The benefit is evident when one computes the solid angle subtended by “all possible directions,” namely,

$$\Omega = \int_0^\pi d\theta \sin \theta \int_0^{2\pi} d\psi = \int_{-1}^1 dw \int_0^{2\pi} d\psi = 4\pi. \quad (2)$$

Figure 1

Spherical polar coordinate system for specification of the unit direction vector $\boldsymbol{\Omega}$, polar angle θ , azimuthal angle ψ , and associated direction cosines (u, v, w)

1.1.2 Radiation Fluence

A fundamental way of characterizing the intensity of a radiation field is in terms of the number of particles that enter a specified volume. To make this characterization, the radiometric concept of *fluence* is introduced. The particle fluence, or simply fluence, at any point in a radiation field may be thought of in terms of the number of particles ΔN_p that, during some period of time, penetrate a hypothetical sphere of cross section ΔA centered on the point, as illustrated in  Fig. 2a. The fluence is defined as

$$\Phi \equiv \lim_{\Delta A \rightarrow 0} \left[\frac{\Delta N_p}{\Delta A} \right]. \quad (3)$$

An alternative, and often more useful definition of the fluence, is in terms of the sum $\sum_i s_i$ of path-length segments within the sphere, as illustrated in  Fig. 2b. The fluence can also be defined as

$$\Phi \equiv \lim_{\Delta V \rightarrow 0} \left[\frac{\sum_i s_i}{\Delta V} \right]. \quad (4)$$

Although the difference quotients of (3) and (4) are useful conceptually, beginning in 1971, the ICRU prescribed that the fluence should be given in terms of differential quotients, in recognition that ΔN_p is the expectation value of the number of particles entering the sphere. Thus, $\Phi \equiv dN_p/dA$, where dN_p is the number of particles which penetrate into a sphere of cross-sectional area dA .

The fluence rate, or *flux*, is expressed in terms of the number of particles entering a sphere, or the sum of path segments traversed within a sphere, per unit time, namely,

$$\phi \equiv \frac{d\Phi}{dt} = \frac{d^2 N_p}{dA dt}. \quad (5)$$

 Figure 2

Element of volume ΔV in the form of a sphere with cross-sectional area ΔA . In (a) the attention is on the number of particles passing through the surface *into* the sphere. In (b) the attention is on the paths traveled within the sphere by particles passing through the sphere

1.1.3 Radiation Current or Net Flow

Another radiometric measure of a radiation field is the net number of particles crossing a surface with a well-defined orientation, as illustrated in **Fig. 3**. The *net particle flow* (or simply *net flow*) at a point on a surface is the net number of particles in some specified time interval that flow across a unit differential area on the surface, in the direction specified as positive. As shown in the figure, one side of the surface is characterized as the positive side and is identified by a unit vector \mathbf{n} normal to the area ΔA . If the number of particles crossing ΔA from the negative to the positive side is ΔM_p^+ and the number from the positive to the negative side is ΔM_p^- , then the *net* number crossing toward the positive side is $\Delta M_p \equiv \Delta M_p^+ - \Delta M_p^-$. The net flow at the given point is designated as J_n , with the subscript denoting the unit normal \mathbf{n} from the surface, and is defined as

$$J_n \equiv \lim_{\Delta A \rightarrow 0} \frac{\Delta M_p}{\Delta A} = \frac{dM_p}{dA}. \quad (6)$$

The total flow of particles in the positive and negative directions, J_n^+ and J_n^- , are defined in terms of ΔM_p^+ and ΔM_p^- in a similar manner. The relation between the net flow and the positive and negative flows is $J_n \equiv J_n^+ - J_n^-$.

The net flow *rate* is expressed in terms of the net number of particles crossing an area perpendicular to unit vector \mathbf{n} , per unit area and per unit time, namely, $j_n \equiv j_n^+ - j_n^-$.

The concepts of fluence and particle flow appear to be very similar, both being defined in terms of a number of particles per unit area. However, for the concept of the fluence, the area presented to incoming particles is independent of the direction of the particles, whereas for the particle flow concept, the orientation of the area is well defined.

Figure 3
Element of area ΔA in a surface. Particles cross the area from either side

1.1.4 Directional Properties of the Radiation Field

The computed fluence is a point function of position \mathbf{r} . Measurement of the fluence requires a radiation detector of finite volume; therefore, there is not only uncertainty due to experimental error but also ambiguity in identification of the “point” at which to attribute the measurement. The nature of the particles is implicit, and the argument \mathbf{r} in $\Phi(\mathbf{r})$ is sometimes implicit. With no other arguments, Φ or $\Phi(\mathbf{r})$ represents the total fluence irrespective of particle energy or particle direction, that is, integrated over all particle energies and directions.

In many circumstances, it is necessary to broaden the concept of the fluence to include information about the energies and directions of particles. To do so requires the use of *distribution functions*. Particle energies and directions require, in general, fluences expressed as distribution functions. For example, $\Phi(\mathbf{r}, E) dE$ is, at point \mathbf{r} , the *fluence energy spectrum* – the fluence of particles with energies between E and $E + dE$.

The angular dependence of the fluence is a bit more complicated to write. The angular variable itself is the vector direction Ω . The direction is a function of the polar and azimuthal angles, θ and ψ . Similarly, the differential element of solid angle is a function of the same two variables, namely $d\Omega = \sin \theta d\theta d\psi = d\omega d\psi$. Thus, $\Phi(\mathbf{r}, \Omega) d\Omega$ or $\Phi(\mathbf{r}, \omega, \psi) d\omega d\psi$ is, at point \mathbf{r} , the angular fluence – the fluence of particles with directions in $d\Omega$ about Ω . The joint energy and angular distribution of the fluence is defined in such a way that $\Phi(\mathbf{r}, E, \Omega) dE d\Omega$ is the fluence of particles with energies in dE about E and with directions in $d\Omega$ about Ω .

In the system of notation adopted here, it is necessary that the energy and angular variables appear specifically as arguments of Φ to identify the fluence as a distribution function in these variables. The ICRU notation refers to the energy distribution as the *spectral distribution* and to the angular distribution as the *radiance*.

1.1.5 Angular Properties of the Flow and Flow Rate

Just as it is very often necessary to account for the variation of the fluence with particle energy and direction, the same is true for the flow and flow rate. Treatment of the energy dependence is no different from the treatment used for the fluence, so here only the angular dependence of the flow is examined. With an element of area and its orientation as illustrated in  Fig. 3, it is perfectly proper to define the angular flow in such a way that $J_n(\mathbf{r}, \Omega) d\Omega$ is the flow of particles through a unit area with directions in $d\Omega$ about Ω . The corresponding angular flow rate is written as $j_n(\mathbf{r}, \Omega)$.

 Figure 4 illustrates particles within a differential element of direction $d\Omega$ about direction Ω crossing a surface perpendicular to unit vector \mathbf{n} . Also shown in the figure is a sphere whose surface just intercepts all the particles. It is apparent that if ΔA is the cross-sectional area of the sphere, then the corresponding area in the surface is $\Delta A \sec \theta$, where $\cos \theta = \mathbf{n} \cdot \Omega$. Thus, because the same number of particles pass through the sphere and through the area in $J_n(\mathbf{r}, \Omega) \Delta A = \cos \theta \Delta A \Phi(\mathbf{r}, \Omega)$, or

$$J_n(\mathbf{r}, \Omega) = \mathbf{n} \cdot \Omega \Phi(\mathbf{r}, \Omega). \quad (7)$$

The net flow is given by

$$\begin{aligned} J_n(\mathbf{r}) &\equiv \int_{4\pi} d\Omega J_n(\mathbf{r}, \Omega) \\ &= \int_{4\pi} d\Omega \mathbf{n} \cdot \Omega \Phi(\mathbf{r}, \Omega). \end{aligned} \quad (8)$$

Figure 4
 $J_n(\mathbf{r}, \Omega)$ versus $\Phi(\mathbf{r}, \Omega)$

The fluence is a positive quantity; however, $J_n(\mathbf{r}, \Omega)$ is positive or negative as $\mathbf{n} \cdot \Omega$ is positive or negative. That part of the integral for which $\mathbf{n} \cdot \Omega$ is positive is the flow $J_n^+(\mathbf{r})$, and that part for which $\mathbf{n} \cdot \Omega$ is negative is $-J_n^-(\mathbf{r})$. The algebraic sum of the two parts gives the net flow $J_n(\mathbf{r})$.

1.2 Characterization of Radiation Sources

1.2.1 General Considerations

The most fundamental type of source is a point source. A real source can be approximated as a point source provided that (1) the volume is sufficiently small, that is, with dimensions much smaller than the dimensions of the attenuating medium between the source and detector, and (2) there is negligible interaction of radiation with the matter in the source volume. The second requirement may be relaxed if source characteristics are modified to account for source self-absorption and other source-particle interactions.

In general, a point source may be characterized as depending on energy, direction, and time. In almost all shielding practices, time is not treated as an independent variable because the time delay between a change in the source and the resulting change in the radiation field is usually negligible. Therefore, the most general characterization of a point source used here is in terms of energy and direction, so that $S_p(E, \Omega) dE d\Omega$ is the number of particles emitted with energies in dE about E and in $d\Omega$ about Ω . Common practical units for $S_p(E, \Omega)$ are $\text{MeV}^{-1} \text{sr}^{-1}$ or $\text{MeV}^{-1} \text{s}^{-1}$.

Most radiation sources treated in the shielding practice are isotropic, so that source characterization requires only knowledge of $S_p(E) dE$, which is the number of particles emitted with energies in dE about E (per unit time), and has common practical units of MeV^{-1} (or $\text{MeV}^{-1} \text{s}^{-1}$). Radioisotope sources are certainly isotropic, as are fission sources and capture gamma-ray sources.

A careful distinction must be made between the activity of a radioisotope and its source strength. *Activity* is precisely defined as the expected number of atoms undergoing radioactive transformation per unit time. It is *not* defined as the number of particles emitted per unit time. Decay of two very common laboratory radioisotopes illustrate this point. Each transformation of ^{60}Co , for example, results in the emission of two gamma rays, one at 1.173 MeV and the other at 1.333 MeV. Each transformation of ^{137}Cs , accompanied by a transformation of its decay product ^{137m}Ba , results in emission of a 0.662-MeV gamma ray with probability 0.85.

The SI unit of activity is the becquerel (Bq), equivalent to 1 transformation per second. In medical and health physics, radiation source strengths are commonly calculated on the basis of *accumulated activity*, Bq s. Such time-integrated activities account for the cumulative number of transformations in some biological entity during the transient presence of radionuclides in the entity. Of interest in such circumstances is not the time-dependent dose rate to that entity or some other nearby region, but rather the total dose accumulated during the transient. Similar practices are followed in dose evaluation for reactor transients, solar flares, nuclear weapons, and so on.

Radiation sources may be distributed along a line, over an area, or within a volume. Source characterization requires, in general, spatial and energy dependence, with $S_l(\mathbf{r}, E) dE$, $S_a(\mathbf{r}, E) dE$, and $S_v(\mathbf{r}, E) dE$ representing, respectively, the number of particles emitted in dE about E per unit length, per unit area, and per unit volume. Occasionally, it is necessary to include angular dependence. This is especially true for effective area sources associated with computed angular flows across certain planes. Clearly, for a fixed surface, $S_a(\mathbf{r}, E, \Omega)$ and $J_n(\mathbf{r}, E, \Omega)$ are equivalent specifications.

Energy dependence may be discrete, such as for radionuclide sources, or continuous, as for bremsstrahlung or fission neutrons and photons. When discrete energies are numerous, an energy multigroup approach is often used. The same multigroup approach may be used to approximately characterize a source whose emissions are continuous in energy.

1.2.2 Neutron Sources

Fission Sources

Many heavy nuclides fission after the absorption of a neutron, or even spontaneously, producing several energetic fission neutrons. Fission neutrons may produce secondary radiation sources, such as inelastic-scattering photons and capture gamma photons, and may transmute stable isotopes into radioactive ones.

Almost all of the fast neutrons produced from a fission event are emitted within 10^{-7} s of the fission event. Less than 1% of the total fission neutrons are emitted as *delayed neutrons*, which are produced by the neutron decay of fission products at times up to many minutes after the fission event. Except for very specialized situations, these delayed neutrons, which are emitted with significantly less energy than the prompt neutrons, are of little importance in shield design because of their relatively small yield and low energies.

As the energy of the neutron which induces the fission in a heavy nucleus increases, the average number of fission neutrons also increases. Yields in thermal-neutron induced fission of ^{235}U , ^{239}Pu , and ^{233}U are respectively 2.43, 2.87, and 2.48. See Keepin (1965) for information on epithermal- and fast-neutron induced fission.

Many transuranic isotopes have appreciable, spontaneous fission probabilities; and consequently, they can be used as very compact sources of fission neutrons. For example, 1 g of ^{252}Cf releases 2.3×10^{12} neutrons per second, and very intense neutron sources can be made from this isotope, limited in size only by the need to remove the fission heat through the necessary encapsulation. Properties of the spontaneously fissioning isotopes of greatest importance in spent nuclear fuel are listed in [Table 1](#). Almost all of these isotopes decay much more rapidly by α emission than by spontaneous fission.

The energy dependence of the fission neutron spectrum has been investigated extensively, especially that for ^{235}U . All fissionable nuclides produce a distribution of prompt fission-neutron energies which goes to zero at low and high energies and reaches a maximum at about 0.7 MeV. The fraction of prompt fission neutrons emitted per unit energy about E , $\chi(E)$, can be described quite accurately by a modified two-parameter Maxwellian distribution (a Maxwellian corrected for the average energy of the fission fragments in the laboratory coordinate system), namely,

$$\chi(E) = \frac{e^{-(E+E_\omega)/T_\omega}}{\sqrt{\pi E_\omega T_\omega}} \sinh \sqrt{\frac{4E_\omega E}{T_\omega^2}}. \quad (9)$$

In many shielding applications, the spectrum for thermal-neutron-induced fission of ^{235}U has often been used, at least as a first approximation for other fissioning isotopes, although ^{233}U , ^{239}Pu , and ^{252}Cf have somewhat greater high-energy components; and consequently, their fission neutrons are slightly more penetrating than those of ^{235}U . Please refer to [Table 2](#) for parameter values.

Photoneutrons

A gamma photon with energy sufficiently larger to overcome the neutron-binding energy (about 7 MeV in most nuclides) may cause a (γ, n) reaction. Very intense and energetic photoneutron production can be realized in an electron accelerator where the bombardment of an appropriate target material with the energetic electrons produces intense bremsstrahlung with a distribution of energies up to that of the incident electrons.

Table 1

Selected nuclides which spontaneously fission. All also decay by alpha emission, which is usually the only other decay mode

Nuclide	Half-life	Fission prob. per decay (%)	Neutrons per fission	α per fission	Neutrons per (g s)
^{238}Pu	87.7 y	1.9×10^{-7}	2.28	5.4×10^8	2.7×10^3
^{240}Pu	6569 y	5.7×10^{-6}	2.21	2.0×10^7	920
^{242}Pu	3.76×10^5 y	5.5×10^{-4}	2.24	1.8×10^5	1.8×10^3
^{242}Cm	163 d	6.2×10^{-6}	2.70	1.5×10^7	2.3×10^7
^{244}Cm	18.11 y	1.37×10^{-4}	2.77	7.5×10^5	1.1×10^7
^{246}Cm	4730 y	0.02615	2.86	3.8×10^3	8.5×10^6
^{252}Cf	2.645 y	3.092	3.73	31	2.3×10^{12}

■ **Table 2**

Parameters for the Watt approximation for the prompt fission-neutron distribution for various fissionable nuclides. Values for ^{252}Cf are from Fröhner (1990). The other values were obtained by a logarithmic fit of the Watt formula to the calculated spectra by Walsh (1989)

Nuclide	Type of fission	Equation (9)	
		E_w	T_w
^{233}U	Thermal	0.3870	1.108
^{235}U	Thermal	0.4340	1.035
^{239}Pu	Thermal	0.4130	1.159
^{232}Th	Fast (2 MeV)	0.4305	0.971
^{238}U	Fast (2 MeV)	0.4159	1.027
^{252}Cf	Spontaneous	0.359	1.175

■ **Table 3**

Important nuclides for photoneutron production

Nuclide	Threshold E_t (MeV) ($-Q$ value)	Reaction
^2H	2.225	$^2\text{H}(\gamma, n)^1\text{H}$
^6Li	3.698	$^6\text{Li}(\gamma, n + p)^4\text{He}$
^6Li	5.664	$^6\text{Li}(\gamma, n)^5\text{Li}$
^7Li	7.251	$^7\text{Li}(\gamma, n)^6\text{Li}$
^9Be	1.665	$^9\text{Be}(\gamma, n)^8\text{Be}$
^{13}C	4.946	$^{13}\text{C}(\gamma, n)^{12}\text{C}$

In reactor shielding analyses, the gamma photons encountered have energies too low, and most materials have a photoneutron threshold too high for photoneutrons to be of concern. Only for a few light elements, listed in [Table 3](#), are the thresholds for photoneutron production sufficiently low that these secondary neutrons may have to be considered. In heavy water- or beryllium-moderated reactors, the photoneutron source may be very appreciable, and the neutron-field deep within a hydrogenous shield is often determined by photoneutron production in deuterium, which constitutes about 0.015 at% of the hydrogen. Capture gamma photons arising from neutron absorption have particularly high energies and, thus, may cause a significant production of energetic photoneutrons.

The photoneutron mechanism can be used to create laboratory neutron sources by mixing intimately a beryllium or deuterium compound with a radioisotope that decays with the emission of high-energy photons. Alternatively, the encapsulated radioisotope may be surrounded

by a beryllium- or deuterium-bearing shell. One common laboratory photoneutron source is an antimony–beryllium mixture, which has the advantage of being rejuvenated by exposing the source to the neutrons in a reactor to transmute the stable ^{123}Sb into the required ^{124}Sb isotope (half-life of 60.2 days). Other common sources are mixtures of ^{226}Ra and beryllium or heavy water.

One very attractive feature of such (γ, n) sources is the nearly monoenergetic nature of the neutrons if the photons are monoenergetic. However, in large sources, the neutrons may undergo significant scattering in the source material, and thereby degrade the nearly monoenergetic nature of their spectrum. These photoneutron sources generally require careful usage because of their inherently large, photon emission rates. Because only a small fraction of the high-energy photons (typically, 10^{-6}) actually interact with the source material to produce a neutron, these sources generate gamma rays that are of far greater biological concern than the neutrons.

Neutrons from (α, n) Reactions

Many compact neutron sources use energetic alpha particles from various radioisotopes (*emitters*) to induce (α, n) reactions in appropriate materials (*converters*). Although a large number of nuclides emit neutrons if bombarded with alpha particles of sufficient energy, the energies of the alpha particles from radioisotopes are capable of penetrating the Coulombic potential barriers of only the lighter nuclei.

Of particular interest are those light isotopes for which the (α, n) reaction is exothermic ($Q > 0$) or, at least, has a low threshold energy (see [Table 4](#)). For endothermic reactions, the threshold alpha energy is $-Q(1 + 4/A)$. Thus, for an (α, n) reaction to occur, the alpha particle must (1) have enough energy to penetrate the Coulomb barrier, and (2) exceed the threshold energy. Alpha particles emitted by uranium and plutonium range between 4 and 6 MeV and can cause (α, n) neutron production when in the presence of oxygen or fluorine. Neutrons from (α, n) reactions often exceed the spontaneous fission neutrons in UF_6 or in aqueous mixtures of uranium and plutonium such as found in nuclear waste (Reilly et al. 1991).

A neutron source can be fabricated by mixing intimately one of the converter isotopes listed in [Table 4](#) with an alpha-particle emitter. Most of the practical alpha emitters are actinide elements, which form intermetallic compounds with beryllium. Such a compound (e.g., PuBe_{13})

■ **Table 4**

Important (α, n) reactions

Target	Natural abundance (%)	Reaction	energy (MeV) (Q value)	Threshold energy (MeV)	Coulomb barrier (MeV)
^9Be	100	$^9\text{Be}(\alpha, n)^{12}\text{C}$	5.702	Exothermic	2.6
^9Be	100	$^9\text{Be}(\alpha, n)3\alpha$	-1.573	2.272	2.6
^{10}B	19.8	$^{10}\text{B}(\alpha, n)^{13}\text{N}$	1.060	Exothermic	3.2
^{11}B	80.2	$^{11}\text{B}(\alpha, n)^{14}\text{N}$	0.157	Exothermic	3.2
^{18}O	0.2	$^{18}\text{O}(\alpha, n)^{21}\text{Ne}$	-0.697	0.852	4.6
^{19}F	100	$^{19}\text{F}(\alpha, n)^{22}\text{Na}$	-1.950	2.361	5.1

ensures both that the emitted alpha particles immediately encounter converter nuclei, thereby producing a maximum neutron yield, and that the radioactive actinides are bound into the source material, thereby reducing the risk of leakage of the alpha-emitting component. Some characteristics of selected (α, n) sources are listed in ► [Table 5](#).

The neutron yield from an (α, n) source varies strongly with the converter material, the energy of the alpha particle, and the relative concentrations of the emitter and converter elements. The degree of mixing between the converter and emitter, and the size, geometry, and source encapsulation may also affect the neutron yield.

The energy distributions of neutrons emitted from all such sources are continuous below some maximum neutron energy with definite structure at well-defined energies determined by the energy levels of the converter and the excited product nuclei. The use of the same converter material with different alpha emitters produces similar neutron spectra with different portions of the same basic spectrum accentuated or reduced as a result of the different alpha-particle energies.

Generally, neutrons emitted from the ${}^9\text{Be}(\alpha, n)$ reaction have higher energies than those produced by other (α, n) sources because Be has a larger Q value than that of other converters. The structure in the Be-produced neutron spectrum above 1 MeV can be interpreted in terms of structure in the ${}^9\text{Be}(\alpha, n){}^{12}\text{C}$ cross section, which in turn depends on the excitation state in which the ${}^{12}\text{C}$ nucleus is left. A large peak below 1 MeV in the Be neutron spectrum arises not from the direct (α, n) reaction, but from the “breakup” reaction ${}^9\text{Be}(\alpha, \alpha'){}^9\text{Be}^* \rightarrow {}^8\text{B} + n$. As the alpha-particle energy increases, both the fraction of neutrons emitted from the breakup reaction ($E_n < 1$ MeV) and the probability that the product nucleus is left in an excited state ($E_n < 6$ MeV) increase, thereby decreasing slightly the average neutron energy (see ► [Table 5](#)).

In all (α, n) sources, there is a maximum neutron energy corresponding to the reaction in which the product nucleus is left in the ground state and the neutron appears in the same direction as that of the incident alpha particle ($\theta = 0$). Thus, unlike fission neutron sources, there are no very high energy neutrons generated in an (α, n) source.

■ **Table 5**
Characteristics of some (α, n) sources

Source	Half-life	Principal alpha energies (MeV)	Average neutron energy (MeV)	Optimum neutron yield per 10^6 primary alphas ^a

^aYield for alpha particles incident on a target thicker than the alpha-particle ranges

^bYield is dependent on the proportion of daughters present. Value for ${}^{226}\text{Ra}$ corresponds to a 22-year-old source (50% contribution for ${}^{210}\text{Po}$)

With appropriate (α, n) cross-section data for a converter, ideal neutron energy spectra can be calculated for the monoenergetic alpha particles emitter by different alpha emitters (Geiger and Van der Zwan 1975). However, these ideal spectra are modified somewhat in actual (α, n) sources. The monoenergetic alpha particles lose variable amounts of energy through ionization interactions in the source material before inducing an (α, n) reaction. This effectively continuous nature of the alpha-particle energy spectrum tends to smooth out many of the fine features of the ideal neutron spectrum. Further, if the source is physically large as a result of requiring a large activity (e.g., a $^{239}\text{Pu}/\text{Be}$ source emitting 10^7 neutrons per second requires about 73 g of plutonium), neutron interactions within the source itself may alter the emitted neutron spectrum. Neutron scattering, $(n, 2n)$ reactions with beryllium, and even neutron-induced fission of the actinide converter change the neutron energy spectrum slightly. Finally, impurity nuclides, which also emit alpha particles, as well as the buildup of alpha-emitting daughters, affect the neutron energy spectrum. In general, the neutron energy spectrum as well as the yield depend in a very complicated manner on the composition, size, geometry, and encapsulation of the source. Fortunately, in most shielding applications only approximate energy information is needed and idealized spectra are often adequate.

Activation Neutrons

A few highly unstable nuclides decay by the emission of a neutron. The delayed neutrons associated with fission arise from such decay of the fission products. However, there are nuclides other than those in the fission-product decay chain which also decay by neutron emission. Only one of these nuclides, ^{17}N , is of importance in shielding situations. This isotope is produced in water-moderated reactors by an (n, p) reaction with ^{17}O (threshold energy, 8.0 MeV), with a small cross section of about $5.2 \mu\text{b}$ averaged over the fission spectrum. The decay of ^{17}N by beta emission (half-life 4.4 s) produces ^{17}O in a highly excited state, which in turn decays rapidly by neutron emission. Most of the decay neutrons are emitted within ± 0.2 MeV of the most probable energy of about 1 MeV, although a few neutrons with energies up to 2 MeV may be produced.

Fusion Neutrons

Many nuclear reactions induced by energetic charged particles can produce neutrons. Most of these reactions require incident particles of very high energies for the reaction to take place and, consequently, are of little concern to the shielding analyst. Only near accelerator targets, for example, would such reaction neutrons be of concern.

From a shielding viewpoint, one major exception to the insignificance of charged particle-induced reactions are those fusion reactions in which light elements fuse exothermally to yield a heavier nucleus and which are accompanied quite often by the release of energetic neutrons. The resulting fusion neutrons are usually the major source of radiation to be shielded against. Prompt gamma photons are not emitted in the fusion process, and the bremsstrahlung produced by charged-particle deflections are easily shielded by any shielding adequate for protection from the neutrons. On the other hand, activation and capture gamma photons may arise as a result of neutrons being absorbed in the surrounding material. Cross sections for the two neutron-producing fusion reactions of most interest in the development of thermonuclear fusion power are illustrated in  Fig. 5. In the D-D reaction and D-T reactions, 2.45 and 14.1 MeV neutrons, respectively, are released.

■ Figure 5

Cross sections for the two most easily induced thermonuclear reactions as a function of the incident deuteron energy. Tritium data are from ENDF/B-VI.8 and deuterium data from ENDF/B-VII.0

1.2.3 Gamma-Ray Sources

Radioactive Sources

There are many data sources for characterizing such sources. Printed documents include compilations by Kocher (1981), Weber et al. (1989), Eckerman et al. (1994), and Firestone et al. (1996). There are also many online data sources. One is the NuDAT (nuclear structure and decay data) and Chart of the Nuclides, www.nndc.bnl.gov, supported by the National Nuclear Data Center at Brookhaven National Laboratory. Another is the WWW table of radioisotopes (TORI) <http://nucleardata.nuclear.lu.se/nucleardata/toi> supported by the Lund/LBNL Nuclear Data Search. For detailed information on secondary X-rays and Auger electrons, the computer program of Dillman (1980) is invaluable.

Prompt Fission Gamma Photons

The fission process produces copious gamma photons. The *prompt fission-gamma photons* are released in the first 50 ns after the fission event. Those emitted later are the *fission product gamma photons*. Both are of extreme importance in the shielding and gamma-heating calculations for a reactor.

Investigations of prompt fission-gamma photons have centered on the thermal-neutron-induced fission of ^{235}U . For this nuclide, it has been found that the number of prompt fission photons is 8.13 ± 0.35 photons per fission over the energy range of 0.1 to 10.5 MeV, and the energy carried by this number of photons is 7.25 ± 0.26 MeV per fission (Peele and Maienschein 1970). In ► Fig. 6, the measured prompt fission-photon spectrum per thermal fission is shown for thermal fission of ^{235}U . The large peaks observed at 15 and 30 keV are X-rays emitted by the light- and heavy-fission fragments, respectively. Although some structure is evident between

■ Figure 6

Energy spectrum of prompt fission photons emitted within the first 69 ns after the fission of ^{235}U by thermal neutrons. Data are from Peele and Maienschein (1970) and the line is the fission-spectrum approximation of (10)

0.1 and 0.6 MeV, the prompt fission-gamma spectrum is approximately constant at $6.6 \text{ photons MeV}^{-1} \text{ fission}^{-1}$. At higher energies, the spectrum falls off sharply with increasing energy. For shielding purposes, the measured energy distribution shown in [Fig. 6](#) can be represented by the following empirical fit over the range of 0.1 to 10.5 MeV (Peele and Maienschein 1970):

$$N_{py}(E) = \begin{cases} 6.6 & 0.1 < E < 0.6 \text{ MeV} \\ 20.2e^{-1.78E} & 0.6 < E < 1.5 \text{ MeV} \\ 7.2e^{-1.09E} & 1.5 < E < 10.5 \text{ MeV,} \end{cases} \quad (10)$$

where E is in MeV and $N_{py}(E)$ is in units of $\text{photons MeV}^{-1} \text{ fission}^{-1}$. The low-energy prompt fission photons (i.e., those below 0.6 MeV) are not of concern for shielding considerations, although they may be important for gamma-heating problems. For this purpose, 3.74 photons with an average energy of 0.324 MeV may be considered as emitted below 0.6 MeV per fission. Relatively little work has been done to determine the characteristics of prompt fission photons from the fission of nuclides other than ^{235}U , but it is reasonable for shielding purposes to use ^{235}U spectra to approximate those for ^{233}U , ^{239}Pu , and ^{252}Cf .

Gamma Photons from Fission Products

One of the important concerns for the shielding analyst is the consideration of the very long lasting gamma activity produced by the decay of fission products. The total gamma-ray energy released by the fission product chains at times greater than 50 ns after the fission is comparable with that released as prompt fission gamma photons. About three-fourths of the delayed gamma-ray energy is released in the first thousand seconds after fission. In the calculations

involving spent fuel, the gamma activity at several months or even years after the removal of fuel from the reactor is of interest and only the long-lived fission products need be considered.

The gamma energy released from fission products is not very sensitive to the energy of the neutrons causing the fissions. However, the gamma-ray energy released and the photon energy spectrum depend significantly on the fissioning isotope, particularly in the first 10 s after fission. Generally, fissioning isotopes having a greater proportion of neutrons to protons produce fission-product chains of longer average length, with isotopes richer in neutrons and hence, with greater available decay energy. Also, the photon energy spectrum generally becomes "softer" (i.e., less energetic) as the time after the fission increases. Fission products from ^{235}U and ^{239}Pu release, on average, photon energy of 6.84 and 6.15 MeV/fission, respectively (Keepin 1965).

For very approximate calculations, the energy spectrum of delayed gamma photons from the fission of ^{235}U , at times up to about 500 s, may be approximated by the proportionality

$$N_{dy}(E) \sim e^{-1.1E}, \quad (11)$$

where $N_{dy}(E)$ is the delayed gamma yield (photons MeV^{-1} fission $^{-1}$) and E is the photon energy in MeV. The time dependence for the total gamma photon energy emission rate $F_T(t)$ (MeV s^{-1} fission $^{-1}$) is often described by the simple decay formula

$$F_T(t) = 1.4t^{-1.2}, \quad 10 \text{ s} < t < 10^8 \text{ s}, \quad (12)$$

where t is in seconds. More detailed, yet conservative expressions are available in the industrial standards [ANSI/ANS 2005]. ^{235}U and ^{239}Pu have roughly the same total gamma-ray-energy decay characteristics for up to 200 days after fission, at which time ^{235}U products begin to decay more rapidly until at 1 year after fission, the ^{239}Pu gamma activity is about 60% greater than that of ^{235}U .

Gamma-photon source data for the use in reactor design and analysis are readily available from software such as the ORIGEN code, which accounts for mixed oxide fuels and differing operating conditions, namely, BWR, PWR, or CANDU concentrations and temperatures. Activation products are also taken into account, as are spontaneous fission. Both gamma-photon and neutron spectra are available at user-selected times and energy group structures. As of this writing, the ORIGEN code is available as code package C00732 SCALE5.1/ORIGEN from the Radiation Safety Information Computational Center, Oak Ridge National Laboratory, Oak Ridge, Tennessee.

Sample ORIGEN results are given in [Table 6](#) for two extreme cases: time dependent (a) gamma-ray decay power from fission products created by a single fission event, and (b) gamma-ray decay power from fission products created during a 30,000-h period of operation at a constant rate of one fission per second. These particular results are for fission products only and are for fission of ^{235}U . The results do not account for bremsstrahlung or for neutron absorption, during operation, by previously produced fission products.

With these or similar results, the gamma-energy emission rate can be calculated for a wide variety of operation histories and decay times. Let $F_j(t)$ be the rate of energy emission via gamma photons in energy group j from fission products created by a single fission event t seconds earlier. Then, the photon energy emission rates can be calculated readily in terms of $F_j(t)$ for a sample of fissionable material which has experienced a prescribed power or fission history $P(t)$. Data fits are provided by George et al. (1980) and Labauve et al. (1982) for both ^{235}U and

Table 6

Fission-product gamma-photon energy release rates (MeV/s) for thermal fission of ^{235}U , computed using the ORIGEN code (RSIC 1991), Hermann and Westfall (1995)

²³⁹Pu and for all fission products or gaseous products only. Shultis and Faw (2000) reproduce the data and address procedures in detail. Calculations mirroring the data of Table 6 are illustrated in Figs. 7 and 8.

Capture Gamma Photons

The compound nucleus formed by neutron absorption is initially created in a highly excited state with excitation energy equal to the kinetic energy of the incident neutron plus the neutron-binding energy, which averages about 7 MeV. The decay of this nucleus, within 10^{-12} s and usually by way of intermediate states, typically produces several energetic photons. Such capture photons may be created intentionally by placing a material with a high thermal-neutron (n, γ) cross section in a thermal-neutron beam. The energy spectrum of the resulting capture gamma photons can then be used to identify trace elements in the sample. More often, however, capture gamma photons are an undesired secondary source of radiation encountered in neutron shielding. The estimation of the neutron absorption rate and the subsequent production of the capture photons is an important aspect of shielding analyses.

To calculate at some position in a shield the total source strength per unit volume of capture photons of energy E_γ , it is first necessary to know the energy-dependent fluence of neutrons, $\Phi(E)$, and the macroscopic absorption coefficient, $N^i \sigma_\gamma^i(E)$, where N^i and σ_γ^i are the atomic density and microscopic, radiative-capture cross section for the i th type of nuclide in the shield medium. If $F^i(E, E_\gamma) dE_\gamma$ represents the probability of obtaining a capture photon with energy in dE_γ about E_γ when a neutron of energy E is absorbed in the i th-type nuclide, the production, per unit volume, of capture photons with energy in unit energy about E_γ is

$$S_v(E_\gamma) = \sum_{i=1}^n \int_0^{E_{\max}} dE F^i(E, E_\gamma) N^i \sigma_\gamma^i(E) \Phi(E), \quad (13)$$

where E_{\max} is the maximum neutron energy and n is the number of nuclide species in the shield material. The evaluation of (13) can be accomplished only by using sophisticated computer codes for neutron transport calculations.

■ Figure 7

Total gamma-ray (G) and beta-particle (B) energy emission rates as a function of time after the thermal fission of ^{235}U . The curves identified by the numbers 1–6 are gamma emission rates for photons in the energy ranges 5–7.5, 4–5, 3–4, 2–3, 1–2, and 0–1 MeV, respectively

Fortunately, in most shielding situations, the evaluation of the capture photon source can be simplified considerably. The absorption cross sections are very small for energetic neutrons, typically no more than a few hundred millibarns for neutrons with energies between 10 keV and 10 MeV, and they are known with far less certainty than the scattering cross sections. The scattering cross-section for fast neutrons is always at least an order of magnitude greater than the absorption cross-section and, thus, in shielding analysis, the absorption of neutrons while they scatter and slow down is often ignored. Except in a few materials with isolated absorption resonances in the range of 1–100 eV, most of the neutron absorption occurs after the neutrons have completely slowed and assumed a speed distribution which is in equilibrium with the thermal motion of the atoms of the shielding medium. The thermal-neutron (n, γ) cross sections may be very large and in practice, the capture-gamma source calculation is usually based only on the absorption of thermal neutrons, with the epithermal and high-energy absorptions being neglected. Thus, (13) reduces to

$$S_v(E_\gamma) \simeq \sum_{i=1}^n F_{th}^i(E_\gamma) \bar{\sigma}_\gamma^i N^i \Phi_{th}, \quad (14)$$

■ Figure 8

Total gamma-ray (G) and beta-particle (B) energy-emission rates from a ^{235}U sample that has experienced a constant thermal-fission rate of one fission per second for effectively an infinite time so that the decay and production of fission products are equal. These data thus represent the worst-case situation for estimating radiation source strengths for fission products. The curves identified by the numbers 1–6 are gamma-emission rates for photons in the energy ranges 5–7.5, 4–5, 3–4, 2–3, 1–2, and 0–1 MeV, respectively

where F_{th}^i is the capture gamma spectrum arising from thermal neutron (n, γ) reactions and Φ_{th} is the neutron fluence integrated over all thermal energies. The thermal-averaged cross section $\bar{\sigma}_\gamma^i$ may be related to the 2200-m/s cross sections σ_γ^i given in ► Table 7 for selected elements, by $\bar{\sigma}_\gamma^i \approx \sqrt{\pi} \sigma_\gamma^i / 2$ (Lamarsh 1966). Capture cross sections and energy spectra of the capture photons, $F_{th}^i(E_\gamma)$ are given in ► Table 7 for selected elements.

Gamma Photons from Inelastic Neutron Scattering

The excited nucleus formed when a neutron is inelastically scattered decays to the ground state within about 10^{-14} s, with the excitation energy being released as one or more photons. Because of the constraints imposed by the conservation of energy and momentum in all scattering interactions, inelastic neutron scattering cannot occur unless the incident neutron energy is greater

Table 7

Radiative capture cross sections σ_y , and the number of capture gamma rays produced in common elements with natural isotopic abundances. The thermal capture cross sections are for 2200 m s^{-1} (0.0253 eV) neutrons in units of the barn (10^{-24} cm^2). Listed are the numbers of gamma rays produced, per neutron capture, in each of 11 energy groups

Source: Lone, Leavitt, and Harrison (1981)

than $(A+1)/A$ times the energy required to excite the scattering nucleus to its first excited state. Except for the heavy nuclides, neutron energies above about 0.5 MeV are typically required for inelastic scattering. The secondary photons produced by inelastic scattering of low-energy neutrons from heavy nuclides are generally not of interest in a shielding situation because of their low energies and the ease with which they are attenuated. Even the photons arising from inelastic scattering of high-energy neutrons (above 1 MeV) are rarely of importance in shielding analyses unless they represent the only source of photons.

The detailed calculation of secondary photon source strengths from inelastic neutron scattering requires knowledge of the fast-neutron fluence, the inelastic scattering cross sections, and spectra of resultant photons, all as functions of the incident neutron energy. Accounting accurately for inelastic scattering can be accomplished only with neutron transport codes using very detailed nuclear data. The cross sections and energy spectra of the secondary photons depend strongly on the incident neutron energy and the particular scattering nuclide. Such inelastic scattering data are known only for the more important nuclides and shielding materials, and even that known data require extensive data libraries such as that provided by

Roussin et al. (1980). Fortunately, in most analyses, these secondary photons are of little importance when compared with the eventual capture photons. Although inelastic neutron scattering is usually neglected with regard to its secondary-photon radiation, such scattering is a very important mechanism in the attenuation of the fast neutrons, better even than elastic scattering in some cases.

Activation Gamma Photons

For many materials, absorption of a neutron produces a radionuclide with a half-life ranging from a fraction of a second to many years. The radiation produced by the subsequent decay of these activation nuclei may be very significant for materials that have been exposed to large neutron fluences, especially structural components in a reactor core. Most radionuclides encountered in research laboratories, medical facilities, and industry are produced as activation nuclides from neutron absorption in some parent material. Such nuclides decay, usually by beta emission, leaving the daughter nucleus in an excited state which usually decays quickly (within 10^{-14} s) to its ground state with the emission of one or more gamma photons. Thus, the apparent half-life of the photon emitter is that of the parent (or activation nuclide), while the number and energy of the photons is characteristic of the nuclear structure of the daughter.

Although most activation products of concern in shielding problems arise from neutron absorption, there is one important exception in water-moderated reactors. The ^{16}O in the water can be transmuted to ^{16}N in the presence of fission neutrons by an (n, p) reaction with a threshold energy of 9.6 MeV. The activation cross section, averaged over the fission spectrum, is 0.019 mb (Jaeger 1968) and although reactions with such small cross sections are rarely important, ^{16}N decays with a 7.4-s half-life emitting gamma photons of 6.13 and 7.10 MeV (yields of 0.69 and 0.05 per decay). This activity may be very important in coolant channels of power reactors.

1.2.4 X-Ray Sources

As photons and charged particles interact with matter, secondary X-rays are inevitably produced. Because X-rays in most shielding applications usually have energies $\lesssim 100$ keV, they are easily attenuated by any shield adequate for the primary radiation. Consequently, the secondary X-rays are often completely neglected in analyses involving higher-energy photons. However, for those situations in which X-ray production is the only source of photons, it is important to estimate the intensity, energies, and the resulting exposure of the X-ray photons. There are two principal methods whereby secondary X-ray photons are generated: the rearrangement of atomic electron configurations leads to characteristic X-rays, and the deflection of charged particles in the nuclear electric field results in bremsstrahlung. Both mechanisms are briefly discussed as follows.

Characteristic X Rays

If the normal electron arrangement around a nucleus is altered through ionization of an inner electron or through excitation of electrons to higher energy levels, the electrons begin a complex series of transitions to vacancies in the lower shells (thereby acquiring higher binding energies) until the unexcited state of the atom is achieved. In each electronic transition, the difference in the binding energy between the final and initial states is either emitted as a photon, called a

characteristic X ray, or given up to an outer electron, which is ejected from the atom and is called an *Auger electron*. The discrete electron energy levels and the transition probabilities between levels vary with the Z number of the atom and, thus, the characteristic X rays provide a unique signature for each element.

The number of X rays with different energies is greatly increased by the multiplicity of electron energy levels available in each shell (1, 3, 5, 7,... distinct energy levels for the K, L, M, N, \dots shells, respectively). Fortunately, in shielding applications such detail is seldom needed, and often only the dominant K series of X rays is considered, with a single representative energy being used for all X rays.

There are several methods commonly encountered in shielding applications, whereby atoms may be excited and characteristic X rays produced. A photoelectric absorption leaves the absorbing atom in an ionized state. If the incident photon energy is sufficiently greater than the binding energy of the K -shell electron, which ranges from 14 eV for hydrogen to 115 keV for uranium, it is most likely (80–100%) that a vacancy is created in the K shell and, thus, that the K series of X rays dominates the subsequent secondary radiation. These X-ray photons produced from photoelectric absorption are often called *fluorescent radiation*.

Characteristic X rays can also arise following the decay of a radionuclide. In the decay process known as *electron capture*, an orbital electron, most likely from the K shell, is absorbed into the nucleus, thereby decreasing the nuclear charge by one unit. The resulting K -shell vacancy then gives rise to the K series of characteristic X rays. A second source of characteristic X rays, which occurs in many radionuclides, is a result of *internal conversion*. Most daughter nuclei formed as a result of any type of nuclear decay are left in excited states. This excitation energy may be either emitted as a gamma photon or transferred to an orbital electron which is ejected from the atom. Again it is most likely that a K -shell electron is involved in this internal conversion process.

Bremsstrahlung

A charged particle gives up its kinetic energy either by collisions with electrons along its path or by photon emission as it is deflected, and hence accelerated, by the electric fields of nuclei. The photons produced by the deflection of the charged particle are called *bremsstrahlung* (literally, “braking radiation”).

The kinetic energy lost by a charged particle of energy E , per unit path length of travel, to electron collisions (which excites and ionizes ambient atoms) and to bremsstrahlung is denoted by L_{coll} and L_{rad} , the collisional and radiative *stopping powers*, respectively. For a relativistic particle of rest mass M (i.e., $E \gg Mc^2$) slowing in a medium with atomic number Z , it can be shown that the ratio of radiative to ionization losses is approximately (Evans 1955)

$$\frac{L_{\text{rad}}}{L_{\text{coll}}} \simeq \frac{EZ}{700} \left(\frac{m_e}{M} \right)^2, \quad (15)$$

where E is in MeV. From this result, it is seen that bremsstrahlung is more important for high-energy particles of small mass incident on high- Z material. In shielding situations, only electrons ($m_e/M = 1$) are ever of importance for their associated bremsstrahlung. All other charged particles are far too massive to produce significant amounts of bremsstrahlung. Bremsstrahlung from electrons, however, is of particular radiological interest for devices that accelerate electrons, such as betatrons and X-ray tubes, or for situations involving radionuclides that emit only beta particles.

For monoenergetic electrons of energy E_o incident on a target thick when compared with the electron range, the number of bremsstrahlung photons of energy E , per unit energy and per incident electron, emitted as the electron is completely slowed down can be approximated by the distribution (Wyrd 1952)

$$N_{br}(E_o, E) = 2kZ \left[\left(\frac{E_o}{E} - 1 \right) - \frac{3}{4} \ln \left(\frac{E_o}{E} \right) \right], \quad E \leq E_o, \quad (16)$$

where k is a normalization constant independent of E . The fraction of the incident electron's kinetic energy that is subsequently emitted as bremsstrahlung can then be calculated from this approximation as

$$Y(E_o) = \frac{1}{E_o} \int_0^{E_o} dE E N_{br}(E_o, E) = \frac{13}{16} kZE_o, \quad (17)$$

which is always a small fraction for realistic shielding situations. For example, only 4% of the energy of a 0.5-MeV electron, when stopped in lead, is converted into bremsstrahlung. Equation (17) can be used to express the normalization constant k in terms of the radiation yield $Y(E_o)$, namely $kZ = 16Y(E_o)/(13E_o)$, where $Y(E_o)$ can be found from tabulated values (ICRU 1984). With this choice for k , the approximation of (16) agrees quite well with the thick-target bremsstrahlung spectrum calculated by much more elaborate methods, such as the continuous slowing-down model.

The electrons and positrons emitted by radionuclides undergoing beta decay produce bremsstrahlung as they slow down in the source material. However, these photons generally are of negligible importance in radiation shielding situations because the gamma and X-ray photons usually produced in radioactive decay are more numerous and penetrating than the bremsstrahlung. Only for the case of pure beta-particle emitters is beta-particle bremsstrahlung possibly of interest.

During the beta-decay process, the beta particle is accelerated, and consequently, a small amount of bremsstrahlung is emitted. These X rays, called "inner" bremsstrahlung, can be ignored in shielding analyses because only a small fraction of the beta-decay energy, on the average, is emitted as this type of radiation.

X-Ray Machines

The production of X-ray photons as bremsstrahlung and fluorescence occurs in any device that produces high-energy electrons. Devices that can produce significant amount of X rays are those in which a high voltage is used to accelerate electrons, which then strike an appropriate target material. Such is the basic principle of all X-ray tubes used in medical diagnosis and therapy, industrial applications, and research laboratories.

The energy spectrum of X-ray photons emitted from an X-ray tube has a continuous bremsstrahlung component up to the maximum electron energy (i.e., the maximum voltage applied to the tube). If the applied voltage is sufficiently high as to cause ionization in the target material, there will also be characteristic X-ray lines superimposed on the continuous bremsstrahlung spectrum. In  Fig. 9, two X-ray energy spectra are shown for the same operating voltage but for different amounts of beam filtration (i.e., different amounts of material attenuation in the X-ray beam). As the beam filtration increases the low-energy X rays are preferentially attenuated, and the X-ray spectrum hardens and becomes more penetrating. Also readily apparent in these spectra are the tungsten $K_{\alpha 1}$ and $K_{\beta 1}$ characteristic X rays.

■ Figure 9

Measured photon spectra from a Machlett Aeromax X-ray tube (tungsten anode) operated at a constant 140 kV potential. This tube has an inherent filter thickness of 2.50-mm aluminum equivalent and produces the spectrum shown by the thick line. The addition of an external 6-mm aluminum filter hardens the spectrum shown by the thin line. Both spectra are normalized to unit area. Data are from Fewell, Shuping, and Hawkins [1981]

Traditionally, the output from a particular X-ray machine is expressed by a parameter K_o ($R\text{ mA}^{-1}\text{ min}^{-1}$), which is the exposure in the beam (expressed in roentgens) at a specified distance from the tube focal spot (usually 1 m) that would be produced by a 1-mA tube current of 1-min duration. This performance parameter is usually assumed to be known when making analyses for X-ray shielding around a particular machine because it depends greatly on the operating voltage and the degree of beam filtering.

2 Conversion of Fluence to Dose

The *dose conversion coefficient* (ICRP 1987) provides the link between the physical description of a radiation field, namely the fluence and some measure of radiation dose or radiation sensor response. There are two main classes of dose conversion coefficients. One class, the *local* conversion coefficient, converts the energy spectrum of the fluence at a point, $\Phi(\mathbf{r}, E)$ to the point value of the dose (kerma, exposure, absorbed dose, or effective dose). The other class of dose conversion coefficients, sometimes called *phantom related*, makes use of local fluences and dose coefficients within geometric or anthropomorphic phantoms to evaluate risk-related average or effective doses of various types. Geometric phantoms are used for evaluation of operational dose quantities such as the ambient dose, which is correlated with monitored occupational exposure. Effective doses associated with anthropomorphic phantoms are used prospectively for planning and optimization of protection, and retrospectively for demonstration of compliance with dose limits or for comparing with dose constraints or reference levels. These phantom related

coefficients account for the relative radiation sensitivities of the various organs and tissues and the relative biological effectiveness of different radiations.

In the extreme, a receiver with volume V might have a sensitivity that depends on the radiation's energy and direction and where in V the radiation interacts, so the dose or response is

$$R = \int_0^\infty dE \int_{4\pi} d\Omega \int_V dV \mathcal{R}(\mathbf{r}, E, \Omega) \Phi(\mathbf{r}, E, \Omega), \quad (18)$$

in which R is the response, $\Phi(\mathbf{r}, E, \Omega)$ is the fluence, and $\mathcal{R}(\mathbf{r}, E, \Omega)$ is the dose conversion coefficient or response function. For many cases, the receiver is a point and the response is isotropic, so that

$$R(\mathbf{r}) = \int_0^\infty dE \mathcal{R}(E) \Phi(\mathbf{r}, E). \quad (19)$$

Fluence-to-dose conversion is accomplished internally within calculations using point-kernel codes such as Isoshield, Microshield, and the QAD series of codes. The same is true for multi-group codes such as the DOORS and PARTISN series and, in general, it is necessary for the user to provide data tables for dose conversion coefficients. With Monte Carlo codes, such as MCNP, the absorbed dose or kerma may be computed directly or the energy-dependent fluence may be first computed and then dose conversion coefficients applied to the results.

2.1 Local Dosimetric Quantities

Dosimetric quantities are intended to provide, at a point or in a region of interest, a physical measure correlated with a radiation effect. The radiometric quantity called the fluence is not closely enough related to most radiation effects to be a useful determinant. Energy fluence appears to be more closely correlated with radiation effect than is fluence alone, because the energy carried by a particle must have some correlation with the damage it can do to material such as biological matter. This choice is not entirely adequate – not even for particles of a single type. One must examine more deeply the mechanism of the effect of radiation on matter in order to determine what properties of the radiation are best correlated with its effects, especially its biological hazards. One must account for energy transfer from the primary radiation, neutrons or photons in this context, to the absorbing medium at the microscopic level. One must then account for the creation of secondary charged particles and, as well, tertiary particles such as X-rays created as charged particles are stopped.

2.1.1 Energy Imparted and Absorbed Dose

For a given volume of matter of mass m , the energy ϵ imparted in some time interval is the sum of the energies (excluding rest-mass energies) of all charged and uncharged ionizing particles entering the volume minus the sum of the energies (excluding rest-mass energies) of all charged and uncharged ionizing particles leaving the volume, further corrected by subtracting the energy equivalent of any increase in rest-mass energy of the material in the volume. Thus, the energy imparted is that which is involved in the ionization and excitation of atoms and molecules within the volume and the associated chemical changes. This energy is eventually degraded almost entirely into thermal energy. The *specific energy* $z \equiv \epsilon/m$, the energy imparted per unit mass, leads to the absorbed dose quantity.

The *absorbed dose* is the quotient of the *mean* energy imparted $\bar{\epsilon}$ to matter of mass m , in the limit as the mass approaches zero (ICRU 1971). Or it may be written in differential form, namely,

$$D \equiv \lim_{m \rightarrow 0} \bar{z} = \frac{d\bar{\epsilon}}{dm}. \quad (20)$$

The standard unit of absorbed dose is the gray (Gy), 1 Gy being equal to an imparted energy of 1 joule per kilogram. A traditional unit for absorbed dose is the rad, defined as 100 ergs per gram. Thus, 1 rad = 0.01 Gy.

The concept of absorbed dose is very useful in radiation protection. Energy imparted per unit mass in tissue is closely, but not perfectly, correlated with radiation hazard.

2.1.2 Kerma

The absorbed dose is a measurable quantity, but in many circumstances it is difficult to calculate from the incident radiation fluence and material properties because such a calculation would require a detailed accounting of the energies of all secondary particles leaving the volume of interest. A closely related deterministic quantity, used only in connection with indirectly ionizing (uncharged) radiation, is the *kerma*, an acronym for *kinetic energy of radiation produced per unit mass in matter*. If E_{tr} is the sum of the initial kinetic energies of all the charged ionizing particles released by interaction of indirectly ionizing particles in matter of mass m , then

$$K \equiv \lim_{m \rightarrow 0} \frac{\bar{E}_{tr}}{m} = \frac{d\bar{E}_{tr}}{dm}, \quad (21)$$

where \bar{E}_{tr} is the mean or expected energy transferred to the secondary charged particles in the mass m . That some of the initial kinetic energy may be transferred ultimately to bremsstrahlung and lost from m , for example, is irrelevant. The kerma is relatively easy to calculate (requiring knowledge of only the initial interactions), but is hard to measure (because all the initial kinetic energy of the charged particles may not be deposited in m).

The use of the kerma requires the specification of the material present in the incremental volume, possibly hypothetical, used as an idealized receptor of radiation. Thus, one may speak conceptually of tissue kerma in a concrete shield or in a vacuum, even though the incremental volume of tissue may not be actually present.

Absorbed dose and kerma are frequently almost equal in magnitude. Under a condition known as *charged particle equilibrium*, they are equal. This equilibrium exists in an incremental volume about a point of interest if, for every charged particle leaving the volume, another of the same type and with the same kinetic energy enters the volume traveling in the same direction. In many practical situations, this charged particle equilibrium is closely achieved so that the kerma is a close approximation of the absorbed dose.

2.1.3 Exposure

The quantity called *exposure*, with abbreviation X , is used traditionally to specify the radiation field of gamma or X-ray photons. It is defined as the absolute value of the ion charge of one

sign produced anywhere in air by the complete stoppage of all negative and positive electrons, except those produced by bremsstrahlung, that are liberated in an incremental volume of air, per unit mass of air in that volume. The exposure is closely related to air kerma but differs in one important respect. The phenomenon measured by the interaction of the photons in the incremental volume of air is not the kinetic energy of the secondary electrons but the ionization caused by the further interaction of these secondary electrons with air. The SI unit of exposure is coulombs per kilogram. The traditional unit is the roentgen, abbreviated R, which is defined as precisely 2.58×10^{-4} coulomb of separated charge of one sign per kilogram of air in the incremental volume where the primary photon interactions occur.

Kerma in air and exposure are very closely related. A known proportion of the initial kinetic energy of secondary charged particles results in ionization of the air, namely, 33.85 ± 0.15 electron volts of kinetic energy per ion pair (ICRU 1979). The product of this factor and the air kerma, with appropriate unit conversions, is the exposure X . The product, however, must be reduced slightly to account for the fact that some of the original energy of the secondary electrons may result in bremsstrahlung, not in ionization or excitation.

2.1.4 Local Dose Equivalent Quantities

If the energy imparted by ionizing radiation per unit mass of tissue were by itself an adequate measure of biological hazard, absorbed dose would be the best dosimetric quantity to use for radiation protection purposes. However, there are also other factors to consider that are related to the spatial distribution of radiation-induced ionization and excitation. The charged particles responsible for the ionization may themselves constitute the primary radiation, or may arise secondarily from interactions of uncharged, indirectly ionizing, primary radiation.

Relative Biological Effectiveness

In dealing with the fundamental behavior of biological material or organisms subjected to radiation, one needs to take into account variations in the sensitivity of the biological material to different types or energies of radiation. For this purpose, radiobiologists define a *relative biological effectiveness* (RBE) for each type and energy of radiation, and, indeed, for each biological effect or *endpoint*. The RBE is the ratio of the absorbed dose of a reference type of radiation (typically, 250-kVp X-rays or ^{60}Co gamma rays) producing a certain kind and degree of biological effect to the absorbed dose of the radiation under consideration required to produce the same kind and degree of effect. RBE is normally determined experimentally and takes into account all factors affecting biological response to radiation in addition to absorbed dose.

Linear Energy Transfer

As a charged particle moves through matter it slows, giving up its kinetic energy through (a) Coulombic interactions with ambient atomic electrons causing ionization and excitation of the atoms and (b) radiative energy loss by the emission of bremsstrahlung (important only for electrons). The *stopping power* or unrestricted linear energy transfer, LET, L_∞ , often denoted as $-dE/dx$, is the expected energy loss per unit distance of travel by the charged particle.

The larger the LET of a radiation particle the more the ionization, and hence the biological damage, it causes per unit travel distance. Calculation of the LET is accomplished efficiently using one of the STAR Codes (Berger et al. 2005). Representative results are summarized by Shultis and Faw (2000).

Radiation Weighting Factor and Dose Equivalent

The RBE depends on many variables: the physical nature of the radiation field, the type of biological material, the particular biological response, the degree of response, the radiation dose, and the dose rate or dose fractionation. For this reason, it is too complicated a concept to be applied in the routine practice of radiation protection or in the establishment of broadly applied standards and regulations. Since 1964, a surrogate quantity called the *quality factor* Q (not to be confused with the Q value of a nuclear reaction) has been applied to the local value of the absorbed dose to yield a quantity called the *dose equivalent* H , recognized as an appropriate measure of radiation risk when applied to operational dosimetry. As is discussed below, the quality factor is also applied to evaluation of geometric-phantom related doses such as the ambient dose. Note that “the dose equivalent is based on the absorbed dose at a point in tissue which is weighted by a distribution of quality factors which are related to the LET distribution at that point” (NCRP 1993).

Because the spatial density of ionization and excitation along particle tracks is believed to be an important parameter in explaining the variations in biological effects of radiation of different types and energies, and because the density is clearly proportional to linear energy transfer (LET), the quality factor was defined in terms of LET. In particular, because tissue is largely water and has an average atomic number close to that of water, the quality factor was made a mathematical function of the unrestricted LET in water, L_∞ (ICRP 2007).

$$Q(L_\infty) = \begin{cases} 1 & L_\infty < 10 \text{ keV}/\mu\text{m} \\ 0.32L_\infty - 2.2 & 10 \leq L_\infty \leq 100 \text{ keV}/\mu\text{m} \\ 300/\sqrt{L_\infty} & L_\infty > 100 \text{ keV}/\mu\text{m}. \end{cases} \quad (22)$$

To ascribe a quality factor to some particular primary radiation, whether that primary radiation be directly or indirectly ionizing, more information is needed about the nature of the energy deposition. In principle, one must first determine how the absorbed dose is apportioned among particles losing energy at different LETs. One may then account for the variability of Q with L_∞ and determine an average quality factor \bar{Q} .

Quality factors can be ascribed to uncharged ionizing radiation through a knowledge of the properties of the secondary charged particles they release upon interaction with matter. Because secondary electrons released by gamma rays or X-rays are always assigned a quality factor of unity, the same factor applies universally to all ionizing photons. The situation for neutrons is not so simple, and average values must be determined as indicated in the following discussion.

Closely related to the quality factor is the *radiation weighting factor* w_R , introduced by the ICRP in 1991 and modified in 2007, for use with the dose equivalent in tissues of the anthropomorphic phantom and addressed in [2.3.3](#). The SI unit of the dose equivalent H is the sievert, abbreviated as Sv. [Table 8](#) compares quality factors specified by

■ Table 8

Mean quality factors Q or radiation weighting factors w_R adopted by the ICRP (2007) and by the US Nuclear Regulatory Commission (1991), based on NCRP (1971). They apply to the radiation incident on the body or, for internal sources, emitted from the source

^bThe neutron radiation weighting factor is computed from (23)

the US Nuclear Regulatory Commission (NCRP 1971, USNRC 1991) and radiation weighting factors specified by the ICRP (2007). The 2007 formulation computes neutron weighting factors as

$$\omega_R = \begin{cases} 2.5 + 18.2 \exp[-\ln^2(E)/6], & E < 1 \text{ MeV}, \\ 5.0 + 17 \exp[-\ln^2(2E)/6], & 1 \text{ MeV} \leq E \leq 50 \text{ MeV}, \\ 2.5 + 3.25 \exp[-\ln^2(0.04E)/6], & E > 50 \text{ MeV}. \end{cases} \quad (23)$$

2.2 Evaluation of Local Dose Conversion Coefficients

2.2.1 Photon Kerma, Absorbed Dose, and Exposure

If $\mu(E)$ is the total interaction coefficient (less coherent scattering), $f(E)$ is the fraction of the photon's energy E transferred to secondary charged particles and ρ is the material density, the kerma is given by

$$K = \left(\frac{f(E)\mu(E)}{\rho} \right) E\Phi(E). \quad (24)$$

The quantity $f(E)\mu(E)$ is called the linear *energy transfer* coefficient μ_{tr} . For energy E in units of MeV, Φ in units of cm^{-2} , the mass energy transfer coefficient $\mu_{tr}(E)/\rho$ in units of cm^2/g , and the conversion coefficient \mathcal{R}_K in units of Gy cm^2 ,

$$\mathcal{R}_K(E) = 1.602 \times 10^{-10} E \left(\frac{\mu_{tr}(E)}{\rho} \right), \quad (25)$$

in which $\mu_{tr}(E)$ is averaged on the basis of weight fractions of each element in the transport medium at the point of interest.

If the secondary charged particles produce substantial bremsstrahlung, a significant portion of the charged-particles' kinetic energy is reradiated away as bremsstrahlung from the region of interest. Even under charged-particle equilibrium, the kerma may overpredict the absorbed dose. The production of bremsstrahlung can be taken into account by the substitution in (25) of the mass energy absorption coefficient $\mu_{en}/\rho = [1 - G(E)]\mu_{tr}/\rho$, where $G(E)$ is the fraction of the secondary-charged particle's initial kinetic energy radiated away as bremsstrahlung. Then, under the assumptions of charged-particle equilibrium and no local energy transfer from bremsstrahlung,

$$\mathcal{R}_D(E) = 1.602 \times 10^{-10} E \left(\frac{\mu_{en}(E)}{\rho} \right). \quad (26)$$

Extensive table of μ_{en}/ρ values are available on line (Hubbell and Seltzer 2004).

For exposure in units of roentgen, E in MeV, (μ_{en}/ρ) for air in cm^2/g , and Φ in cm^{-2} ,

$$X = 1.835 \times 10^{-8} E \left(\frac{\mu_{en}(E)}{\rho} \right)_{\text{air}} \Phi. \quad (27)$$

2.2.2 Neutron Kerma and Absorbed Dose

Charged particle equilibrium is, in most instances, closely approached in neutron transport, so that the kerma is an excellent approximation of the absorbed dose. The local dose conversion coefficient, in units of Gy cm^2 is given by

$$\mathcal{R}_K(E) = 1.602 \times 10^{-10} \sum_i \frac{N_i}{\rho} \sum_j \sigma_{ji}(E) \epsilon_{ji}(E), \quad (28)$$

■ Figure 10

Kerma dose conversion coefficient for neutron interactions in the ICRU four-element approximation for tissue, with mass fractions: 0.101 H, 0.111 C, 0.026 N, and 0.762 O. Computed using NJOY-processed ENDF/B-V data

in which ρ is the material density (g/cm^3), N_i (cm^{-3}) is the density of atomic species i , $\sigma_{ji}(E)$ is the cross-section (cm^2) for nuclear reaction j with atomic species i , and $\epsilon_{ji}(E)$ (MeV) is the energy transferred to the medium in that same reaction. ➤ Figure 10 illustrates the neutron-kerma dose conversion coefficient for a four-element tissue approximation.

2.3 Phantom-Related Dosimetric Quantities

2.3.1 Characterization of Ambient Radiation

A problem very often encountered in radiation shielding is as follows. At a given reference point representing a location accessible to the human body, the radiation field has been characterized in terms of the fluxes or fluences of radiations of various types computed in the *free field*, that is, in the absence of the body. Suppose for the moment that only a single type of radiation is involved, say either photons or neutrons, and the energy spectrum $\Phi(E)$ of the fluence is known at the reference point. What is needed is the ability to define and to calculate, at *that point* and for *that single type of radiation*, a dose quantity R for a phantom representation of the human subject, which can be calculated using an appropriate conversion coefficient, or response function \mathcal{R} , as

$$R = \int_0^{\infty} dE \mathcal{R}(E) \Phi(E), \quad (29)$$

analogous to (19). Here \mathcal{R} is a phantom-related conversion coefficient and Φ is the fluence energy spectrum, not perturbed by the presence of the phantom. Generation of the conversion coefficient, of course, requires determination of the absorbed dose and accounting for the radiation transport inside a phantom resulting from incident radiation with a carefully defined angular distribution (usually, a parallel beam).

Suppose one knows the angular and energy distributions of the fluence of ionizing radiation at a point in space, that is, the radiation field at the point. Both operational and limiting dose quantities are evaluated as radiation doses in phantoms irradiated by a *uniform* radiation field derived from the actual radiation field at the point. In the *expanded field*, the phantom is irradiated over its entire surface by radiation whose energy and angular distributions are the same as those in the actual field at the point of interest. In the *expanded and aligned field*, the phantom is irradiated by unidirectional radiation whose energy spectrum is the same as that in the actual field at the point.

2.3.2 Dose Conversion Factors for Geometric Phantoms

Of the geometrically simple mathematical phantoms, the more commonly used is the *ICRU sphere* of 30 cm diameter with density 1.0 g/cm^3 and of tissue-equivalent composition, by weight—76.2% oxygen, 11.1% carbon, 10.1% hydrogen, and 2.6% nitrogen. The dose quantity may be the maximum dose within the phantom or the dose at some appropriate depth.

Dose conversion coefficients for the phantoms are computed for a number of irradiation conditions, for example, a broad parallel beam of monoenergetic photons or neutrons. At selected points or regions within the phantom, absorbed-dose values, often approximated by kerma values, are determined. In this determination, contributions by all secondary-charged particles at that position are taken into account; and for each type of charged particle of a given energy, the L_∞ value in water and, therefore, Q are obtained. These are then applied to the absorbed-dose contribution from each charged particle to obtain the dose-equivalent contribution at the given location in the phantom. The resulting distributions of absorbed dose and dose equivalent throughout the phantom are then examined to obtain the maximum value, or the value otherwise considered to be in the most significant location, say at 10 mm depth. The prescribed dose conversion coefficient is then that value of either absorbed dose or dose equivalent divided by the fluence of the incident beam.

These conversion coefficients are intended for operational dose quantities and are designed to provide data for radiation protection purposes at doses well below limits for public exposure. The dose quantities may be treated as point functions, determined exclusively by the radiation field in the vicinity of a point in space. Application of the conversion coefficients for these dose quantities is explained in depth by the ICRU (1988).

Deep Dose Equivalent Index

For this dose quantity, $H_{1,d}$, the radiation field is assumed to have the same fluence and energy distribution as those at a reference point, but expanded to a broad parallel beam striking the phantom. The dose is the maximum dose equivalent within the 14-cm-radius central core of the ICRU sphere. There are difficulties in using this dose quantity when the incident radiation is polyenergetic or consists of both neutrons and gamma rays. The reason is that the depth at

which the dose is maximum varies from one type of radiation to another or from one energy to another. Thus, this quantity is nonadditive.

Shallow Dose Equivalent Index

This dose quantity, $H_{I,s}$, is very similar to the deep dose-equivalent index, except that the dose equivalent is the maximum value between depths 0.007 and 0.010 cm from the surface of the ICRU sphere (corresponding to the depths of radiosensitive cells of the skin).

Ambient Dose Equivalent

For this dose, $H^*(d)$, the radiation field is assumed to have the same fluence and energy distribution as those at a reference point but expanded to a broad parallel beam striking the phantom. The dose equivalent is evaluated at depth d , on a radius opposing the beam direction. This calculated dose quantity is associated with the measured *personal dose equivalent* $H_p(d)$, the dose equivalent in soft tissue below a specified point on the body, at depth d . For weakly penetrating radiation, depths of 0.07 mm for the skin and 3 mm for the lens of the eye are employed. For strongly penetrating radiation, a depth of 10 mm is employed.

Directional Dose Equivalent

For this dose quantity, $H'(d, \Omega)$, the angular and energy distributions of the fluence at a point of reference are assumed to apply over the entire phantom surface. The depths at which the dose equivalent is evaluated are the same as those for the ambient dose equivalent. The specification of the angular distribution, denoted symbolically by argument Ω , requires specification of a reference system of coordinates in which directions are expressed. In the particular case of a unidirectional field, $H'(d, \Omega)$ may be written as $H'(d)$ and is equivalent to $H^*(d)$.

Irradiation Geometries for Spherical Phantoms

Photon and neutron conversion coefficients for deep and shallow indices and for directional dose equivalents at depths of 0.07, 3, and 10 mm have been calculated for radiation protection purposes and have been tabulated by the ICRP (1987) for the following irradiation geometries: (a) PAR, a single-plane parallel beam, (b) OPP, two opposed plane parallel beams, (c) ROT, a rotating-plane parallel beam (i.e., a plane-parallel beam with the sphere rotating about an axis normal to the beam), and (d) ISO, an isotropic radiation field.

For a single plane parallel beam, the more conservative of the irradiation geometries, the conversion coefficients for $H_{I,d}$ and $H^*(d)$ at 10 mm are almost identical for photons. For neutrons, the two differ only at low energies, with the deep dose equivalent index being greater and thus more conservative.

Slab and Cylinder Phantoms

Dose conversion coefficients are also available for plane parallel beams incident on slabs and on cylinders with axes normal to the beam. Slab-phantom deep-dose conversion coefficients are tabulated by the ICRP (1987) for high-energy photons and neutrons. Cylinder-phantom deep-dose coefficients reported by the NCRP (1971) are of special interest in that they are employed in US federal radiation protection regulations (USNRC 1991).

2.3.3 Dose Coefficients for Anthropomorphic Phantoms

The effective dose equivalent H_E and the effective dose \mathcal{E} are limiting doses based on an anthropomorphic phantom for which doses to individual organs and tissues may be determined. Averaging the individual doses with weight factors related to radiosensitivity leads to the effective dose or effective dose equivalent. In many calculations, a single phantom represents the adult male or female. In other calculations, separate male and female phantoms are used. These dose quantities have been developed for radiation-protection purposes in occupational and public health and, to some extent, in internal dosimetry as applied to nuclear-medicine procedures. The dose quantities apply, on average, to large and diverse populations, at doses well below annual limits. Their use in assessment of health effects for an individual subject requires a very careful judgment. One male phantom, Adam, is illustrated in ► Fig. 11. Adam has a companion female phantom, named Eva (Kramer et al. 1982). In yet other calculations (Cristy and Eckerman 1987), a suite of phantoms is available for representation of the human at various ages from the newborn to the adult. The many phantoms used for measurements or calculations are described in ICRU Report 48 (1992).

Anthropomorphic phantoms are mathematical descriptions of the organs and tissues of the human body, formulated in such a way as to permit calculation or numerical simulation of the transport of radiation throughout the body. In calculations leading to conversion coefficients, monoenergetic radiation is incident on the phantom in fixed geometry. One geometry leading to conservative values of conversion coefficients is *anteroposterior* (AP), irradiation from the front to the back with the beam at right angles to the long axis of the body. Other geometries, *posteroanterior* (PA), *lateral* (LAT), *rotational* (ROT), and *isotropic* (ISO) are illustrated in ► Fig. 12. The ROT case is thought to be an appropriate choice for the irradiation pattern experienced by a person moving unsystematically relative to the location of a radiation

■ Figure 11
Sectional view of the male anthropomorphic phantom used in calculation of the effective dose

■ Figure 12

Irradiation geometries for the anthropomorphic phantom. From ICRP (1987)

source. However, the AP case, being most conservative, is the choice in the absence of particular information on the irradiation circumstances.

Effective Dose Equivalent

In 1977, the ICRP introduced the effective dose equivalent H_E , defined as a weighted average of mean dose equivalents in the tissues and organs of the human body, namely,

$$H_E = \sum_T \omega_T D_T Q_T, \quad (30)$$

in which D_T is the mean absorbed dose in organ T and Q_T is the corresponding mean quality factor. If m_T is the mass of organ or tissue T , then

$$Q_T = \frac{1}{m_T} \int dm QD = \frac{1}{m_T} \int dm \int dL_\infty D(L_\infty) Q(L_\infty), \quad (31)$$

in which $D(L_\infty) dL_\infty$ is that portion of the absorbed dose attributable to charged particles with LETs in the range dL_∞ about L_∞ . Tissue weight factors to be used with the effective dose equivalent are listed in [Table 9](#). They are determined by the relative sensitivities for stochastic radiation effects such as cancer and first-generation hereditary illness. The 1977 values are still of importance because of their implicit use in federal radiation protection regulations [USNRC 1991] in the United States.

Effective Dose

In 1991, the ICRP recommended a replacement of the effective dose equivalent by the effective dose. This recommendation was endorsed in 1993 by the NCRP in the United States and modified by the ICRP in 2007. The effective dose \mathcal{E} is defined as follows. Suppose that the body is irradiated externally by a mixture of particles of different type and different energy, the different radiations being identified by the subscript R . The effective dose may then be determined as

$$\mathcal{E} = \sum_T \omega_T H_T = \sum_T \omega_T \sum_R \omega_R D_{T,R}, \quad (32)$$

■ **Table 9**

Tissue weight factors adopted by the ICRP (1991, 2007) and the NCRP (1993) for use in determination of the effective dose

Organ	ICRP (1977) USNRC (1991)	ICRP (1991) NCRP (1993)	ICRP (2007)
Gonads	0.25	0.20	0.08
Bone marrow (red)	0.12	0.12	0.12
Lung	0.12	0.12	0.12
Breast	0.15	0.05	0.12
Thyroid	0.03	0.05	0.04
Bone surfaces	0.03	0.01	0.01
Remainder	0.30 ^a	0.05 ^b	0.12 ^c
Colon ^d	–	0.12	0.12
Stomach	–	0.12	0.12
Bladder	–	0.05	0.04
Liver	–	0.05	0.04
Oesophagus	–	0.05	0.04
Skin	–	0.01	0.01
Salivary glands	–	–	0.01
Brain	–	–	0.01

^aA weight of 0.06 is applied to each of the five organs or tissues of the remainder receiving the highest dose equivalents, the components of the GI system being treated as separate organs

^bThe remainder is composed of the following additional organs and tissues: adrenals, brain, small intestine, large intestine, kidney, muscle, pancreas, spleen, thymus, uterus, and others selectively irradiated. With certain exceptions, the weight factor of 0.05 is applied to the average dose in the remainder tissues and organs

^cThe remainder tissues are adrenals, extrathoracic tissues, gall bladder, heart wall, kidneys, lymphatic nodes, muscle, oral mucosa, pancreas, prostate, small intestine, spleen, thymus, and uterus/cervix. The weight factor for the remainder is applied to the average of the male and female remainder doses, each being the unweighted average dose to the 13 organs or tissues appropriate to the male or female

^dIn both the 1991 and 2007 formulations, the dose to the colon is the mass-weighted mean of upper and lower intestine doses

in which H_T is the *equivalent dose* in organ or tissue T , $D_{T,R}$ is the mean absorbed dose in organ or tissue T from radiation R , ω_R is a radiation weighting factor for radiation R as determined from ► [Table 8](#), and ω_T is a tissue weight factor given in ► [Table 9](#). Note that in this formulation, ω_R is independent of the organ or tissue and ω_T is independent of the radiation.

In computing the dose conversion coefficient for the effective dose, one assumes that the phantom is irradiated by unit fluence of monoenergetic particles of energy E . Neither local values nor tissue-average dose equivalents but only tissue-average absorbed doses are calculated. The tissue-average absorbed doses are multiplied by quality factors determined not by the LET distributions in the tissues and organs but by quality factors characteristic of the incident

radiation. This is a fundamental departure from the methodology used in determination of the conversion coefficients for the effective dose equivalent.

2.3.4 Comparison of Dose Conversion Coefficients

► *Figures 13* and ► *14* compare the dose conversion coefficients for photons and neutrons, respectively. At energies above about 0.1 MeV, the various photon coefficients are very nearly equal. This is a fortunate situation for radiation dosimetry and surveillance purposes. Instruments such as ion chambers respond essentially in proportion to absorbed dose in air. Personnel dosimeters are usually calibrated to give responses proportional to the ambient dose. Both the ambient dose and the absorbed dose in air closely approximate the effective dose equivalent. However, below 100 keV the three conversion coefficients are quite different. At the scale of the graph, the 1996 ambient dose coefficients are indistinguishable from the 1987 deep dose index.

The comparison of conversion coefficients for neutrons is not so straightforward. The tissue kerma always has the smallest value, largely because no quality factor is applied to the kinetic energy of a secondary charged particle. Fortunately, the ambient dose and the deep dose equivalent index have conversion coefficients that are very similar at energies above about 5 keV. Therefore, historic dosimetry records based on personnel dosimeters calibrated in terms of the deep dose equivalent index do not diverge significantly from those that would have been recorded using more modern dose standards. Furthermore, the ambient dose coefficient exceeds that for the effective dose equivalent index above about 0.01 MeV. Thus, calibration of personnel dosimeters in terms of ambient dose is a conservative practice. It should be noted that neutron dose conversion factors in the U.S. N.R.C. regulations (10CFR Part 20) are based on very early calculations (NCRP 1971).

■ **Figure 13**

Comparison of photon dose conversion coefficients. Data are from ICRP (1996)

■ Figure 14

Comparison of neutron dose conversion coefficients. Data are from ICRP (1987, 1996, 2007). The 1987 deep dose index and effective dose equivalent are based on quality factors defined prior to ICRP Report 45 (1985)

3 Basic Methods in Radiation Attenuation Calculations

In this section, simplified methods for estimating the dose under specialized source and geometric conditions are reviewed. The methods apply in circumstances in which there is a direct path from source to receiver and a significant portion of the dose is from uncollided radiation. A spatially distributed source is divided conceptually into a set of contiguous small sources, each of which can be treated as a point source. With an *uncollided point kernel*, the uncollided dose can be calculated for each point source. Summation or integration over the source volume then yields the total uncollided dose. In general, a correction factor may be applied to the uncollided point kernel to yield the point kernel for combined uncollided and collided radiation. For monoenergetic gamma rays, the correction factor is referred to as the *buildup factor*. For polyenergetic X-rays, an *attenuation factor* jointly accounts for both collided and uncollided radiation. Similarly, for polyenergetic neutron sources in hydrogenous media, the dose from collided and uncollided fast neutrons is estimated with a total-dose point kernel.

3.1 The Point-Kernel Concept

The fluence or dose at some point of interest is in many situations determined primarily by the uncollided radiation that has streamed directly from the source without any interaction in the surrounding medium. For example, if only air separates a gamma-ray or neutron source from a detector, interactions in the intervening air or in nearby solid objects, such as the ground or

building walls, are often negligible, and the radiation field at the detector is due almost entirely to uncollided radiation coming directly from the source. Scattered and other secondary radiation in such situations is of minor importance. In this section, some basic properties of the uncollided radiation field are presented, and methods for estimating the dose from this radiation are derived.

3.1.1 Exponential Attenuation

The *linear interaction coefficient* for indirectly ionizing radiations such as gamma rays or neutrons, $\mu(E)$, also called the *macroscopic cross section* $\Sigma(E)$, in the limit of small distances, is the probability per unit distance of travel that a particle of energy E experiences an interaction such as scattering or absorption. From this definition, it is easily shown that the probability of a particle traveling a distance x without interaction is given by

$$P(x) = e^{-\mu x}. \quad (33)$$

From this result, the *half-value thickness* x_2 that is required to reduce the uncollided radiation to one-half of its initial value can readily be found, namely, $x_2 = \ln 2/\mu$. Similarly, the *tenth-value thickness* x_{10} , which is the distance the uncollided radiation must travel to be reduced to 10% of its initial value, is found to be $x_{10} = \ln 10/\mu$. The concepts of half-value and tenth-value thicknesses, although stated here for uncollided radiation, are also often used to describe the attenuation of the total radiation dose. The average distance λ that a particle streams from the point of its birth to the point at which it makes its first interaction is called the *mean-free-path length*. It is easily shown that $\lambda = 1/\mu$.

3.1.2 Uncollided Dose from a Monoenergetic Point Source

In the following subsections, basic expressions are derived for the dose from uncollided radiation produced by isotropic point sources.

Point Source in a Vacuum

Consider a point-isotropic source that emits S_p particles into an infinite vacuum as in  Fig. 15a. All particles move radially outward without interaction, and because of the source isotropy, each unit area on an imaginary spherical shell of radius r has the same number of particles crossing it, namely, $S_p/(4\pi r^2)$. It then follows from the definition of the fluence that the fluence Φ^o of uncollided particles at a distance r from the source is

$$\Phi^o(r) = \frac{S_p}{4\pi r^2}. \quad (34)$$

If all the source particles have the same energy E , the response of a point detector at a distance r from the source is obtained by multiplying the uncollided fluence by the appropriate dose-conversion coefficient \mathcal{R} , which usually depends on the particle energy E , namely,

$$D^o(r) = \frac{S_p \mathcal{R}(E)}{4\pi r^2}. \quad (35)$$

■ Figure 15

Point isotropic source (a) in a vacuum, (b) with a slab shield, and (c) with a spherical-shell shield. Point P is the location of the receiver or point detector

Notice that the dose and fluence decrease as $1/r^2$ as the distance from the source is increased. This decreasing dose with increasing distance is sometimes referred to as *geometric attenuation*.

Point Source in a Homogenous Attenuating Medium

Now consider the same point monoenergetic isotropic source embedded in an infinite homogenous medium characterized by a total interaction coefficient μ . As the source particles stream radially outward, some interact before they reach the imaginary sphere of radius r and do not contribute to the uncollided fluence. The number of source particles that travel at least a distance r without interaction is $S_p e^{-\mu r}$, so that the uncollided dose is

$$D^o(r) = \frac{S_p \mathcal{R}(E)}{4\pi r^2} e^{-\mu(E)r}. \quad (36)$$

The term $e^{-\mu r}$ is referred to as the *material attenuation* term to distinguish it from the $1/r^2$ geometric attenuation term.

Point Source with a Shield

Now suppose that the only attenuating material separating the source and the detector is a slab of material with attenuation coefficient μ and thickness t as shown in ► Fig. 15b. In this case, the probability that a source particle reaches the detector without interaction is $e^{-\mu t}$, so that the uncollided dose is

$$D^o(r) = \frac{S_p \mathcal{R}(E)}{4\pi r^2} e^{-\mu(E)t}. \quad (37)$$

This same result holds if the attenuating medium has any shape (e.g., a spherical shell of thickness t as shown in ► Fig. 15c) provided that a ray drawn from the source to the detector passes through a thickness t of the attenuating material.

If the interposing shield is composed of a series of different materials such that an uncollided particle must penetrate a series of thicknesses t_i of materials with attenuation coefficients μ_i before reaching the detector, the uncollided dose is

$$D^o(r) = \frac{S_p \mathcal{R}(E)}{4\pi r^2} \exp(-\sum_i \mu_i(E) t_i). \quad (38)$$

Here $\sum_i \mu_i t_i$ is the total number of mean-free-path lengths of attenuating material that an uncollided particle must traverse without interaction, and $\exp(-\sum_i \mu_i t_i)$ is the probability that a source particle traverses this number of mean-free-path lengths without interaction.

3.2 Uncollided Doses for Distributed Sources

3.2.1 The Superposition Procedure

The results for the uncollided dose from a point source can be used to derive expressions for the uncollided dose arising from a wide variety of distributed sources such as line sources, area sources, and volumetric sources. One widely used approach is to divide the distributed source conceptually into a set of equivalent point sources and then to sum (integrate) the dose contribution from each point source.

The examples presented later for a line source are selected because of their simplicity or utility. In all these examples, it is assumed that the source is monoenergetic and isotropic and the detector is a point isotropic one. For polyenergetic sources, the monoenergetic result can be summed (or integrated) over all source energies.

The superposition technique of decomposing a source into a set of simpler sources is very powerful and has been applied to line, surface, and volumetric sources of complex shapes. Many important practical cases have been examined and generalized results have been published. Among the special cases are cylindrical and spherical surface and volume sources, with and without external shields, and with interior as well as exterior receptor locations. The examples below are but a few of the known results. For other source and shield configurations, the reader is referred to the publications of Rockwell (1956), Blizard and Abbott (1962), Hungerford (1966), Blizard et al. (1968), Schaeffer (1973), Courtney (1975), Chilton et al. (1984), and Shultis and Faw (2000).

3.2.2 Example Calculations for Distributed Sources

The Line Source

A straight-line source of length L emitting isotropically S_1 particles per unit length at energy E is depicted in  Fig. 16. A detector is positioned at point P , a distance h from the source along a perpendicular to one end of the line. Consider a segment of the line source between distance x and $x + dx$ measured from the bottom of the source. The source within this segment may be treated as an effective point isotropic source emitting $S_1 dx$ particles which produces an uncollided dose at P of dD^0 . To obtain the total dose at P from all segments of the line source, one then must sum, or rather integrate, dD^0 over all line segments. Several cases are discussed as follows.

Line Source in a Nonattenuating Medium. In the absence of material interaction () Fig. 16a), the differential uncollided dose produced by particles emitted in dx about x is, from (36),

$$dD^0(P) = \frac{1}{4\pi} \frac{S_1 \mathcal{R} dx}{x^2 + h^2} \quad (39)$$

■ **Figure 16**
Isotropic line source (a) in a homogenous medium and (b) with a slab shield

and thus,

$$D^o(P) = \frac{S_l \mathcal{R}}{4\pi} \int_0^L \frac{dx}{x^2 + h^2} = \frac{S_l \mathcal{R} \theta_0}{4\pi h}. \quad (40)$$

The angle $\theta_0 = \tan^{-1} L/h$ in this result must be expressed in radians.

Line Source in a Homogenous Attenuating Medium. Now suppose that the source and receptor are present in a homogenous medium with a total interaction coefficient μ . Attenuation along the ray from x to P reduces the uncollided dose at P to

$$dD^o(P) = \frac{1}{4\pi} \frac{S_l \mathcal{R} dx}{x^2 + h^2} \exp[-\mu \sqrt{x^2 + h^2}], \quad (41)$$

where \mathcal{R} and μ generally depend on the particle energy E . The total uncollided dose now is described by the integral

$$D^o(P) = \frac{S_l \mathcal{R}}{4\pi h} \int_0^{\theta_0} d\theta e^{-\mu h \sec \theta}. \quad (42)$$

This integral cannot be evaluated analytically. However, it can be expressed in terms of the *Sievert integral* or the *secant integral*, defined as

$$F(\theta, b) \equiv \int_0^\theta dx e^{-b \sec x}. \quad (43)$$

This integral is widely available in the previously cited text and reference works. With it, the dose from a line source may be expressed as

$$D^o(P) = \frac{S_l \mathcal{R}}{4\pi h} F(\theta_0, \mu h). \quad (44)$$

Line Source Behind a Slab Shield. Now suppose that the only material separating the line source and the receptor is a parallel slab or concentric cylindrical-shell shield of thickness t and total attenuation coefficient μ_s , as shown in **► Fig. 16b**. For this case, the analysis above using only attenuation in the slab yields

$$D^o(P) = \frac{S_L \mathcal{R}}{4\pi h} F(\theta_o, \mu_s t). \tag{45}$$

If the shield is made up of layers of thicknesses t_i and attenuation coefficients μ_{si} , then $\mu_s t$ must be replaced by $\sum_i \mu_{si} t_i$, the total mean-free-path thickness of the shield.

A Superposition Procedure for Line Sources. The restriction in the foregoing examples that the detector be perpendicularly opposite one end of the line source is easily relaxed by use of the principle of *superposition of sources*. **► Figure 17** illustrates two receptor points in relation to a line source in a homogenous attenuating medium. Determination of the uncollided dose at either point may be obtained by conceptually decomposing the line source into two adjacent line sources each of which has an end perpendicular to the detector. Point P_1 , for example, is on a normal from the end of a projection of the line source. Were the line source truly of the extended length, then the dose would be given by (44) with angle argument θ_1 . However, that result would be too high by just the amount contributed by a line source of the same strength subtending angle θ_2 . Thus, at point P_1 ,

$$D^o(P_1) = \frac{S_L \mathcal{R}}{4\pi h} [F(\theta_1, \mu h) - F(\theta_2, \mu h)]. \tag{46}$$

By similar reasoning, at point P_2 ,

$$D^o(P_2) = \frac{S_L \mathcal{R}}{4\pi h} [F(\theta_3, \mu h) + F(\theta_4, \mu h)]. \tag{47}$$

As illustrated by these line source examples, the superposition of multiple distributed sources, for each of which the dose is readily calculated, to create a more complex source configuration is an extremely useful procedure that can be used effectively for all types of sources.

► Figure 17
Application of the superposition principle to an isotropic line source

Indeed, part of the art of shield analysis is to devise how to reduce a complex source problem to a set of simpler problems, and the source superposition principle is a valuable tool in this reduction.

4 Photon Attenuation Calculations

This section describes the engineering methodology that has evolved for the design and analysis of shielding for gamma and X-rays with energies from about 1 keV to about 20 MeV. To support this methodology, very precise radiation transport calculations have been applied to a wide range of carefully prescribed situations. The results are in the form of buildup factors, attenuation factors, albedos or reflection factors, and line-beam response functions.

Buildup factors relate the total dose to the dose from uncollided photons alone and are most applicable to point monoenergetic-radiation sources with shielding well distributed between the source point and points of interest. Attenuation factors apply equally well to monoenergetic sources and to polyenergetic sources such as X-ray machines and are most applicable when a shield wall separates the source and points of interest, the wall being sufficiently far from the source that radiation strikes it as a nearly parallel beam. There are many common features of buildup and attenuation factors and it is possible to represent one factor in terms of the other. Albedos, which describes how radiation is reflected from a surface, and line-beam response functions, which are used in skyshine analyses, are taken up in other sections of this chapter.

Discussed first in this section are buildup factors for point isotropic and monoenergetic sources in infinite media. Incorporation of these buildup factors into the uncollided point kernel is treated next. Then addressed are three topics associated with the use of buildup factors. The first is the use of empirical buildup-factor approximations designed to simplify engineering design and analysis. The second is the use of buildup factors with point kernels to treat spatially distributed radiation sources. The third is the application of approximate methods to permit the use of buildup factors in media with variations in composition.

4.1 The Photon Buildup-Factor Concept

Whatever the photon source and the attenuating medium, the energy spectrum of the total photon fluence $\Phi(\mathbf{r}, E)$ at some point of interest \mathbf{r} may be divided into two components. The *unscattered* component $\Phi^o(\mathbf{r}, E)$ consists of just those photons that have reached \mathbf{r} from the source without having experienced any interactions in the attenuating medium. The *scattered* component $\Phi^s(\mathbf{r}, E)$ consists of source photons scattered one or more times, as well as secondary photons such as X-rays and annihilation gamma rays. Accordingly, the dose or detector response $D(\mathbf{r})$ at point of interest \mathbf{r} may be divided into unscattered (primary) and scattered (secondary) components $D^o(\mathbf{r})$ and $D^s(\mathbf{r})$. The buildup factor $B(\mathbf{r})$ is defined as the ratio of the total dose to the unscattered dose, i.e.,

$$B(\mathbf{r}) \equiv \frac{D(\mathbf{r})}{D^o(\mathbf{r})} = 1 + \frac{D^s(\mathbf{r})}{D^o(\mathbf{r})}. \quad (48)$$

The doses may be evaluated using response functions described in [Sect. 2](#), so that

$$B(\mathbf{r}) = 1 + \frac{\int dE \mathcal{R}(E) \Phi^s(\mathbf{r}, E)}{\int dE \mathcal{R}(E) \Phi^o(\mathbf{r}, E)}, \quad (49)$$

in which the integrations are over all possible E .

It is very important to recognize that in (49), the fluence terms depend only on the source and medium, and not on the type of dose or response. The conversion factors or response function $\mathcal{R}(E)$ depends only on the type of dose, and not on the attenuating medium. For these reasons, it is imperative to associate with buildup factors the nature of the source, the nature of the attenuating medium, and the nature of the response.

When the source is monoenergetic, with energy E_o , then $\Phi^o(\mathbf{r}, E) = \Phi^o(\mathbf{r}) \delta(E - E_o)$, so that

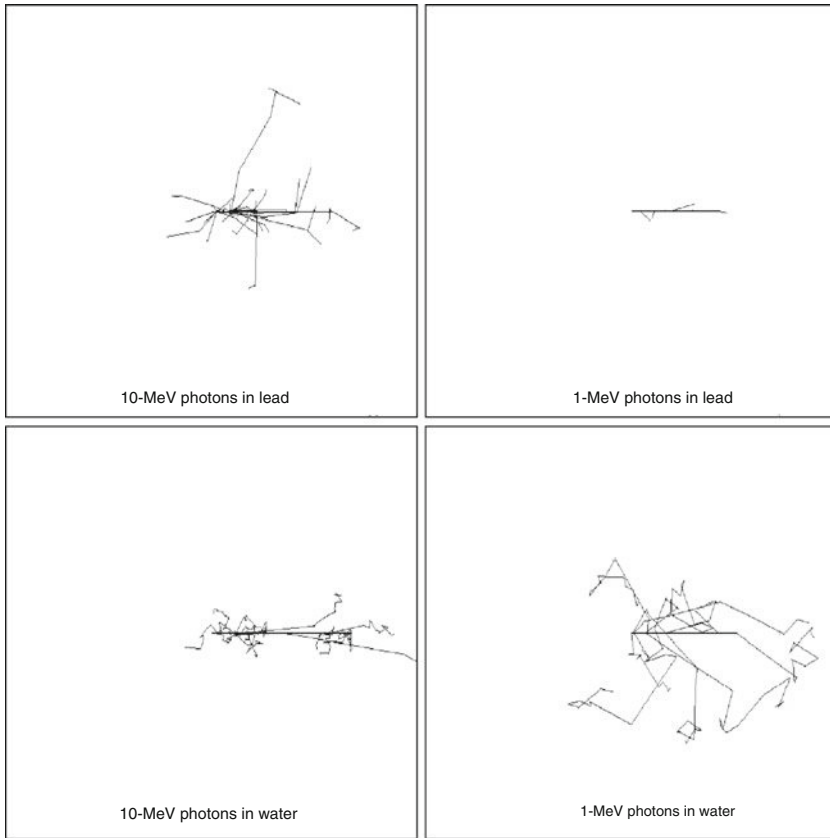

$$B(\mathbf{r}) = 1 + \frac{1}{\Phi^o(\mathbf{r})} \int_0^{E_o} dE \frac{\mathcal{R}(E)}{\mathcal{R}(E_o)} \Phi_s(\mathbf{r}, E). \quad (50)$$

In this case, the response nature is fully accounted for in the ratio $\mathcal{R}(E)/\mathcal{R}(E_o)$.

4.2 Isotropic, Monoenergetic Sources in Infinite Media

By far, the largest body of buildup-factor data is for point, isotropic, and monoenergetic sources of photons in infinite homogenous media. The earliest data (Fano et al. 1959; Goldstein 1959; Goldstein and Wilkins 1954) were based on moments-method calculations (Shultis and Faw 2000) and accounted only for buildup of Compton-scattered photons. Subsequent moments-method calculations (Eisenhauer and Simmons 1975; Chilton et al. 1980) accounted for buildup of annihilation photons as well. Buildup-factor calculations using the discrete-ordinates ASFIT code (Subbaiah et al. 1982) and the integral-transport PALLAS code (Takeuchi, Tanaka, and Kinno 1981) account for not only Compton-scattered and annihilation photons, but also for fluorescence and bremsstrahlung. These calculations, which supplement later moments-method calculations, are the basis for the data prescribed in the American National Standard for buildup factors (ANSI/ANS 1991). Calculation of buildup factors for high-energy photons requires consideration of the paths traveled by positrons from their creation until their annihilation. Such calculations have been performed by Hirayama (1987) and by Faw and Shultis (1993a) for photon energies as great as 100 MeV. Most point-source buildup-factor compilations exclude coherently scattered photons and treat Compton scattering in the free-electron approximation. This is also true for the buildup factors in the standard. Thus, in computing the dose or response from unscattered photons, coherent scattering should be excluded and the total Klein–Nishina cross section should be used. Correction for coherent scattering, significant for only low-energy photons at deep penetration, is discussed in ANSI/ANS (1991).

➤ [Figure 18](#) gives a qualitative impression of the buildup of secondary photons during the attenuation of primary photons. For 10-MeV photons in lead, there is considerable buildup of annihilation photons, which are emitted isotropically, and bremsstrahlung, which deviates little in direction from the path of the decelerating electron or positron. For 1-MeV photons in lead, there is very little buildup of secondary photons, owing to the strong photoelectric absorption of the primary photons. In water, both 1- and 10-MeV photons experience Compton scattering principally. However, for the higher-energy primary photons, the scattering leads to relatively small change in direction. ➤ [Figure 19](#) illustrates the energy spectrum of the energy fluence

■ Figure 18

Comparison of photon transport in lead and water. Each box has 10 mean-free paths on a side. Each depicts the projection in a plane of primary and secondary photon tracks arising from 10 primary photons originating at the box center, moving to the right in the plane of the paper. Tracks computed using the EGS4 code, courtesy of Robert Stewart, Kansas State University

$E\Phi(E)$ of reflected and transmitted photons produced by 2-MeV primary photons, normally incident on a concrete slab two mean free paths in thickness. These fluences are normalized to unit incident flow and, thus, are dimensionless. Note that transmitted photons have energies up to the energy of the primary photons. However, the reflected photons, mostly single scattered, are much more restricted in energy.

Tables of buildup factors are available in standards (ANSI/ANS 1991), the technical literature (Eisenhauer and Simmons 1975; Takeuchi and Tanaka 1984; Goldstein and Wilkins 1954) and many textbooks. Buildup-factor data are generally more broadly applicable than might be thought at first glance. As indicated in (50), it is the ratio $\mathcal{R}(E)/\mathcal{R}(E_o)$ that defines the dependence of the buildup factor on the type of dose or response. For responses such as kerma or absorbed dose in air or water, exposure, or dose equivalent, the ratio is not very sensitive to the type of response. Thus, buildup factors for air kerma may be used with little error for exposure or dose equivalent.

■ Figure 19

Transmitted and reflected energy fluences for 2-MeV photons normally incident on a concrete slab of two mean free path thickness

It can be shown that, for a point isotropic source of monoenergetic photons in an infinite homogenous medium, the buildup factor depends spatially only on the number of mean free paths μr separating the source and the point of interest. Here, μ is the total interaction coefficient (excluding coherent scattering) in the attenuating medium at the source energy, namely $\mu(E_0)$. Thus, we write the buildup factor as $B(\mu r)$, but it must be recognized that there is an implicit dependence on the source energy, the nature of the attenuating medium, and the nature of the response.

► Figure 20 illustrates the buildup factor for concrete, plotted with the photon energy as the independent variable and the number of mean free paths as a parameter. That there are maxima in the curves is due to the relative importance of the photoelectric effect, as compared to Compton scattering, in the attenuation of lower-energy photons and to the very low fluorescence yields exhibited by the low- Z constituents of concrete. ► Figure 21 illustrates the buildup factor for lead, plotted with the number of mean free paths as the independent variable and the photon energy as a parameter. For high-energy photons, pair production is the dominant attenuation mechanism in lead, the cross section exceeding that for Compton scattering at energies above about 5 MeV. The buildup is relatively large because of the production of 0.511-MeV annihilation gamma rays. As may also be seen from the figure, the attenuation factor increases greatly at photon energies just above the 0.088-MeV K -edge for photoelectric absorption, each absorption resulting in a cascade of X-rays. For these reasons, buildup factors may be extraordinarily large, as evidenced by the line for 0.089-MeV photons in ► Fig. 21. At energies below the K -edge, the buildup factors are very small. The importance of fluorescence in the buildup of low-energy photons is addressed by Tanaka and Takeuchi (1986) and by Subbaiah and Natarajan (1987).

4.3 Buildup Factors for Point and Plane Sources

Many so-called “point-kernel codes” finding wide use in radiation shielding design and analysis make exclusive use of buildup factors for point isotropic sources in infinite media. This is true even when the source and shield configuration is quite different from that of an infinite

■ Figure 20

Air-kerma buildup factors for gamma-ray attenuation in concrete, excluding bremsstrahlung, fluorescence, and coherent scattering. Data from Eisenhauer and Simmons (1975)

■ Figure 21

Exposure buildup factors for gamma-ray attenuation in lead, calculated using the PALLAS code, excluding coherent scattering. Data from ANSI/ANS (1991)

medium. A good example is that of a point source and point receptor, each at some distance in air from an intervening shielding wall. Is the use of infinite-medium buildup factors a conservative approximation? That question is addressed in ► [Table 10](#), prepared for shielding of 1-MeV gamma rays by iron. This table lists exposure buildup factors, in some cases for infinite media and in other cases for vacuum-bounded finite media. The first column in the table is the number of mean free paths from source to receptor location. Six columns of buildup factors follow, three for point isotropic (PTI) sources and three for plane monodirectional (PLM) sources.

The PTI source in an infinite medium is the reference case. Data for the PTI source in a finite medium refer to the exposure rate at the surface of a sphere whose radius corresponds to

the mean free path thickness. Data for the PTI source and slab shield are for a point source on one side of a slab of given thickness and a receptor point directly on the opposite side of the slab. Data for the PLM source in an infinite medium are for the buildup factor as a function of distance from a hypothetical plane source emitting a parallel beam of photons perpendicular to the plane. Data for the PLM source in a semi-infinite medium are for the buildup factor as a function of depth in a half-space illuminated by a normally incident parallel beam of photons. Data in the last column, for the PLM source in a finite medium, refer to the exposure on one side of a slab shield of given thickness which is illuminated by a parallel beam of photons normally incident on the opposite side of the slab.

It is apparent from [Table 10](#) that for the cases examined, use of buildup factors for point sources in an infinite medium, with few exceptions, is a conservative approximation in shield design, that is, predicted doses are slightly higher than the actual doses. However, the PLM examples are all for beams *normally* incident on slab shields. When beams are obliquely incident on slab shields, point kernel codes routinely determine the number of mean free paths along the oblique path through the slab shield and apply infinite-medium buildup factors for the corresponding thickness. This practice can underestimate shielding requirements because buildup factors for slant penetration of beams can greatly exceed those for point sources computed at the same optical thicknesses (mean free paths) as is addressed later in this section.

Buildup factors are available for plane isotropic (PLI) and plane monodirectional (PLM) gamma-ray sources in infinite media. Indeed, Fano et al. (1959), Goldstein (1959), and Spencer

(1962), in their moments-method calculations, obtained buildup factors for plane sources first and, from these, buildup factors for point sources. Buildup factors at depth in a half-space shield are also available for the PLM source, that is, normally incident photons (Takeuchi et al. 1981; Takeuchi and Tanaka 1984; Hirayama 1987).

Special methods have been developed for treating buildup when source and receptor are separated by many shielding slabs, such as walls and floors of a structure, at various orientations. For example, Dunn et al. (1992) address shipboard radiation shielding problems and provide buildup factors for common shielding materials.

4.3.1 Empirical Approximations for Buildup Factors

A great deal of effort has been directed toward the approximation of point-source buildup factors by mathematical functions which can be used directly in calculations. These efforts have dealt almost exclusively with buildup factors for point-isotropic and monoenergetic sources in infinite media. Two forms of approximation have been in use for many years. One is the *Taylor form* (Chilton 1977; Foderaro and Hall 1981; Shure and Wallace 1988). The other is the *Berger form* (Chilton 1979; Chilton et al. 1980). While both forms still see a wide application in computer codes used in engineering practice, a more modern, more accurate, but much more complicated approximation is the *geometric progression* (GP) form, and without question it is the preferred approximation to use if possible.

The Geometric Progression Approximation

An extraordinarily precise formulation, called the *geometric progression approximation* of the buildup factor, was developed in recent years (Harima 1986; Harima et al. 1986, 1991). The approximation is in the form

$$B(E_o, \mu r) \simeq \begin{cases} 1 + (b - 1)(K^{\mu r} - 1)/(K - 1), & K \neq 1 \\ 1 + (b - 1)\mu r, & K = 1, \end{cases} \quad (51)$$

where

$$K(\mu r) = c(\mu r)^a + d \frac{\tanh(\mu r/\xi - 2) - \tanh(-2)}{1 - \tanh(-2)}, \quad (52)$$

in which a , b , c , d , and ξ are parameters dependent on the gamma-ray energy, the attenuating medium, and the nature of the response. Example values of the parameters for kerma in air as the response, and for attenuation in air, water, concrete, iron, and lead are listed in [► Tables 11 and 12](#). The parameters are based on PALLAS code calculations (Takeuchi et al. 1981).

4.3.2 Point-Kernel Applications of Buildup Factors

For a distributed source of monoenergetic photons $S_v(\mathbf{r}_s)$ of energy E_o , the dose from uncollided photons at some position \mathbf{r} is

$$D^o(\mathbf{r}) = \int_{V_s} dV_s \frac{S_v(\mathbf{r}_s)\mathcal{R}(E_o)}{4\pi|\mathbf{r}_s - \mathbf{r}|^2} e^{-\ell}, \quad (53)$$

■ Table 11

Source: Extracted from American National Standard ANSI/ANS-6.4.3-1991, *Gamma-Ray Attenuation Coefficients and Buildup Factors for Engineering Materials*, published by the American Nuclear Society. Data are also available from Data Library DLC-129/ANS643, issued by the Radiation Shielding Information Center, Oak Ridge National Laboratory, Oak Ridge, TN

where the integration is over all source locations and ℓ is the optical thickness between \mathbf{r}_s and \mathbf{r} , namely,

$$\ell = \int_0^{|\mathbf{r}_s - \mathbf{r}|} ds \mu(s), \quad (54)$$

with s measured along a straight line from \mathbf{r}_s to \mathbf{r} . To correct for the buildup of secondary radiation, an appropriate buildup factor is included in the integrand of (53). If an infinite-medium, point-source buildup factor is used and the medium is of uniform composition but possibly of variable density, the total dose at \mathbf{r} is

$$D(\mathbf{r}) = \int_{V_s} dV_s \frac{S_v(\mathbf{r}_s) \mathcal{R}(E_o)}{4\pi|\mathbf{r}_s - \mathbf{r}|^2} B(E_o, \ell) e^{-\ell} \equiv \int_{V_s} dV_s S_v(\mathbf{r}_s) \mathcal{G}(\mathbf{r}_s, \mathbf{r}). \quad (55)$$

Here,

$$\mathcal{G}(\mathbf{r}_s, \mathbf{r}) \equiv \frac{\mathcal{R}(E_o)}{4\pi|\mathbf{r}_s - \mathbf{r}|^2} B(E_o, \ell) e^{-\ell} \quad (56)$$

is the dose Green's function or point kernel that gives the dose at \mathbf{r} due to a photon emitted isotropically at \mathbf{r}_s .

From this approximate result, it is seen that the total dose at \mathbf{r} from radiation emitted isotropically from \mathbf{r}_s depends only on the material properties along a line between \mathbf{r}_s and \mathbf{r} and on the distance $|\mathbf{r}_s - \mathbf{r}|$ between these two points. This approximation, based on the infinite-medium, point-source buildup factor, is sometimes called *ray theory*, indicative that the total dose is determined simply by the material and distance along the ray joining the source and detector points. In many situations, it is an excellent approximation and is widely used in photon shielding calculations. To illustrate the use of ray theory, two examples are given as follows.

Line Source in an Infinite Attenuating Medium

With reference to Fig. 16 and (41), one sees that the total dose at detector point P due to photons arising from the differential source length dx is

$$dD(P) = \frac{\mathcal{R}(E_o) S_1 dx}{4\pi(x^2 + h^2)} e^{-\mu\sqrt{x^2 + h^2}} B(E_o, \mu\sqrt{x^2 + h^2}). \quad (57)$$

In analogy to (41), the response due to the entire line source is given by the integral

$$D(P) = \mathcal{R}(E_o) \frac{S_l}{4\pi h} \int_0^{\theta_o} d\theta e^{-\mu h \sec \theta} B(E_o, \mu h \sec \theta). \quad (58)$$

In general, the integral must be evaluated numerically. However, if the Taylor form of buildup-factor approximation is employed, the integral yields a sum of Sievert integrals (Shultis and Faw 2000).

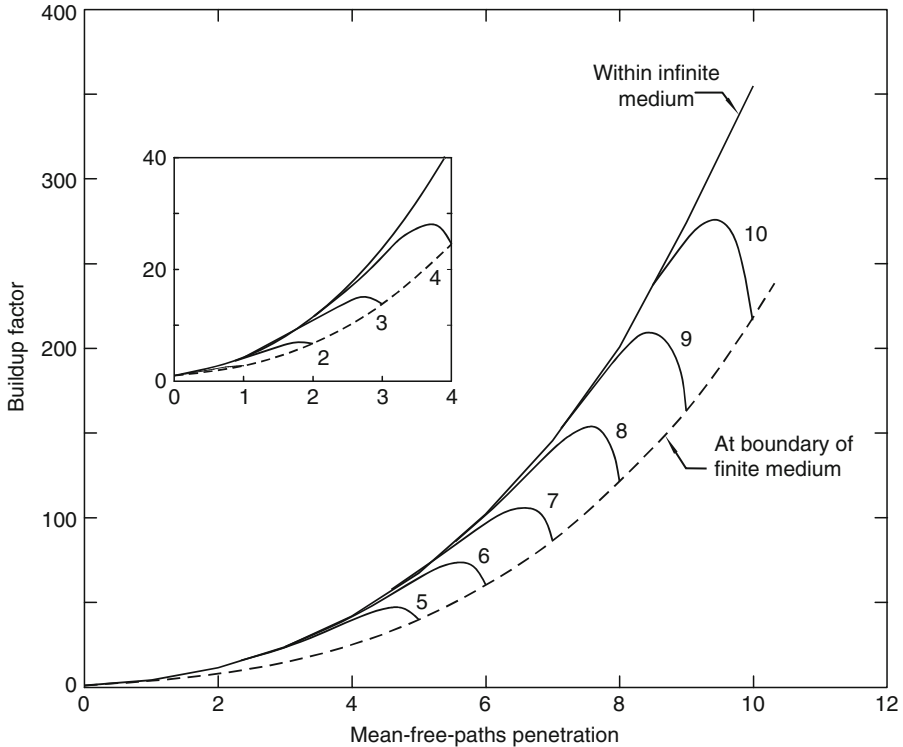

4.4 Buildup Factors for Heterogenous Media

4.4.1 Boundary Effects in Finite Media

Consider a point isotropic source at the center of a finite sphere of shielding material and a dose point at the surface. The sphere is surrounded by air, which may be approximated as a vacuum. The use of an infinite-medium buildup factor in calculating the dose at the boundary leads to an overestimate because, in fact, no photons are reflected back to the sphere from the space beyond the spherical surface. Because the error is on the side of overestimation of the dose, corrections are very often ignored.

► *Figure 22* illustrates the magnitude of the effect of a vacuum interface for a tissue medium. The lower bounding dashed lines are buildup factors for the dose at the surface of a sphere of given radius. The upper bounding solid lines are for the dose at the same radius in an infinite medium. The intervening lines are for points interior to the finite sphere. It is apparent that the effect of the boundary is insignificant for points more than about one mean free path from the surface. Buildup factors at vacuum boundaries of finite media are conveniently presented as the ratio $(B_x - 1)/(B_\infty - 1)$, in which B_x is the finite-medium buildup factor and B_∞ is the infinite-medium buildup factor. This ratio, which is illustrated in ► *Fig. 23*, can be used in many applications, because it has been found to be insensitive to whether the source is a point isotropic, plane isotropic, or plane perpendicular, and to the distance x from the source to the boundary.

Consider the same point isotropic source at the center of a finite sphere of shielding material and a dose point at the surface. The sphere is bounded not by a vacuum but by a tissue medium. This model is appropriate for determination of the phantom dose outside a shielding structure. For use in such calculations, Gopinath et al. (1987) determined adjustment factors to be applied to infinite-medium buildup factors. The adjustment factors, which are listed in ► *Table 13*, were adopted in the ANSI/ANS Standard (1991) for buildup factors. They were computed for parallel beam sources normally incident on shielding slabs, but may be used for point sources as well. The adjustment factor is to be used as follows. For the given shield material, first compute the absorbed dose in tissue at the location of the interface but within an infinite medium of the shielding material. Then multiply the result by the adjustment factor to yield the maximum absorbed dose in the tissue medium surrounding the shielding medium. The adjustment factor is insensitive to the thickness of the shielding medium.

Finite-medium versus infinite-medium buildup factors for a 0.1-MeV point isotropic gamma-ray source in tissue. Calculations performed using the EGS4 code, courtesy of Sherrill Shue (1994), Kansas State University

4.4.2 Treatment of Stratified Media

The use of the buildup-factor concept for heterogenous media is of dubious merit, for the most part. Nevertheless, implementation of point-kernel codes for shielding design and analysis demands some way of treating buildup when the path from source point to dose point is through more than one shielding material. Certain regularities do exist, however, which permit at least an approximate use of homogenous-medium buildup factors for stratified shields. In general, though, the user of a point-kernel code must make the choice of a single material to characterize buildup. That choice is usually either the material with the greatest number of mean free paths between the source and the receiver or the material nearest the receiver.

For hand calculations, greater flexibility may often be used. For example, consider two-layer shields of optical thicknesses (mean free paths) l_1 and l_2 and effective atomic numbers Z_1 and Z_2 , numbered in the direction from source to detector. A commonly applied rule is that if $Z_1 < Z_2$, then the overall buildup factor is approximately equal to the buildup factor B_2 for material 2 evaluated at the total optical thickness $l_1 + l_2$. However, if $Z_1 > Z_2$, then the overall

■ Figure 23

Adjustment factor for the buildup factor at the boundary of a finite medium in terms of the infinite-medium buildup factor for the same depth of penetration. Exposure buildup calculations were performed for point isotropic sources in finite spheres and infinite media, using the EGS4 code, courtesy of Sherrill Shue, Nuclear Engineering Department, Kansas State University

buildup factor is the product $B_1(\ell_1) \times B_2(\ell_2)$. More precise methods have been suggested by Kalos (Goldstein 1959), Broder et al. (1962), Kitazume (1965), Bünemann and Richter (1968), Harima (1983), Su and Jiang (1989), Harima and Hirayama (1993), and Shin and Hirayama (1994, 1995).

4.5 Broad-Beam Attenuation of Photons

4.5.1 Attenuation Factors for Photon Beams

It is often the case in dealing with the shielding requirements for a radionuclide or X-ray source that the source is located some distance in air from a wall or shielding slab, and the concern is with the radiation dose on the exterior (cold) side of the wall. Often too, the source is sufficiently far from the wall that the radiation reaches the wall in nearly parallel rays, and the attenuation in the air is quite negligible in comparison to that provided by the shielding wall. Shielding design and analysis in the circumstances just described, and illustrated in  Fig. 24, are addressed by the National Council on Radiation Protection and Measurements (NCRP 1976) in their widely used Report 49. Attenuation of photons from both monoenergetic and polyenergetic sources can be established in terms of the formula

$$D(P) = D^{\circ}(P)A_f, \quad (59)$$

in which $D(P)$ is the dose or response at point P (the receiver in  Fig. 24), $D^{\circ}(P)$ is the response in the absence of the shield wall, accounting only for the inverse-square attenuation, and A_f is an *attenuation factor* which depends on the nature and thickness of the shielding material, the source energy characteristics, and the angle of incidence θ . The attenuation factor incorporates the response function and combines buildup and exponential attenuation into a single factor A_f .

4.5.2 Attenuation of Oblique Beams of Photons

When monoenergetic beams of gamma rays are obliquely incident on shielding slabs, attenuation-factor and conventional ray-theory methods are not successful. The reason is that

 Figure 24

Attenuation of gamma and X-rays from a point source in air by a shielding wall

the uncollided component of penetrating radiation is likely very small when compared with the collided component, and that the collided component is likely only very weakly dependent on the uncollided component. Obliquely incident beams, however, may be treated using a modified buildup factor that is a function of the angle of incidence. With respect to [Fig. 24](#), the beam attenuation factor in [\(59\)](#) may be written as

$$A_f = B(E_o, \cos \theta, \mu t) e^{-\mu t / \cos \theta}. \quad (60)$$

Values of the special buildup factor $B(E_o, \cos \theta, \mu t)$ are available in Shultis and Faw (2000) for concrete, iron, and lead shields for thicknesses as great as 10 mean free paths for wide ranges of photon energy and angle of incidence. Attenuation factors for concrete are listed in [Table 14](#). Attenuation factors for other materials may be found in the standard ANSI/ANS-6.4 (2006).

4.5.3 Attenuation Factors for X-Ray Beams

The appropriate measure of source strength for X-ray sources is the electron-beam current, and the appropriate characterization of photon energies, in principle, involves the peak accelerating voltage (kVp), the wave form, and the degree of filtration (e.g., mm Al) through which the X rays pass. Although the degree of filtration of the X rays would affect their energy spectra, there is only a limited range of filtrations practical for any one voltage, and within that limited range, the degree of filtration has little effect on the attenuation factor (NCRP 1976). Most diagnostic radiographic procedures for adult patients are conducted with an X-ray-beam quality of 2–3 mm Al half-value-layer (HVL) (Keriakes and Rosenstein 1980), which is consistent with 2.5–3.5 mm Al filtration of the X-ray source. The National Council on Radiation Protection and Measurements (NCRP 1989) requires at least 3.1 mm HVL and 3.1 mm Al filtration for three-phase generators with voltages 90 kVp or greater. Similar requirements are stated for lower voltages and for single-phase generators. Data on energy spectra from a wide variety of X-ray tubes and filtrations are available (Fewell and Shuping 1978; Fewell et al. 1981). For a given voltage, the greatest penetration would occur for a constant potential generator, but it has been found that X rays from modern three-phase generators are very nearly as penetrating (Simpkin 1989; Archer et al. 1994). Less penetrating are X rays from single-phase generators. Conservatism in design, allowing for upgrade in generators, dictates use of attenuation data for multiphase or constant-potential generators. If i is the beam current (mA) and r is the source–detector distance (m), then [\(59\)](#), with dose rate ($cGy \text{ min}^{-1} \simeq R \text{ min}^{-1}$) as the response, takes the form

$$\dot{D}(P) = \frac{i}{r^2} K_o A_f, \quad (61)$$

in which K_o is the *radiation output factor* with units of dose rate in vacuum (or air), per unit beam current at a distance of 1 m from the source in the absence of any shield. The dose unit was recently changed from exposure to air kerma (NCRP 1989). For the same voltage, the radiation output factor for a single-phase generator is less than that for a three-phase generator by a factor of $\sqrt{3}$ (NCRP 1989).

Attenuation factors for X rays normally incident on various shielding materials have been fit by Simpkin (1989, 1995) and by Archer et al. (1994) to the following expression, which was

Table 14

Attenuation factors for monoenergetic beams of gamma rays obliquely incident on slabs of ordinary concrete, expressed as the ratio of transmitted to incident air kerma

Source: MCNP calculations extending the work of Fournie and Chilton (1981) and Chen and Faw (1994)

originally recommended by Archer, Thornby, and Bushong (1983):

$$A_f = \left[\left(1 + \frac{\beta}{\alpha} \right) e^{\alpha y x} - \frac{\beta}{\alpha} \right]^{-1/\gamma}, \quad (62)$$

in which x is the material thickness, in units of millimeters. The coefficients for lead and concrete attenuation factors are listed in [Table 15](#) based on measurements and calculations of Archer et al. (1994), Simpkin (1987a), and Légaré et al. (1977). Conservative values of the output factor K_o given in the table conform to those given by Keriakes and Rosenstein (1980) and in NCRP Report 102 (1989).

In the design and analysis of shield walls for X-ray installations, it is necessary to account for a number of factors: (1) the *maximum permissible dose* for an individual situated beyond the shield wall during some prescribed time interval, such as 1 week, (2) the *workload*, which is the cumulative sum during the prescribed time interval of the product of the beam current and the duration of machine operation, (3) the *use factor*, which is the fraction of machine operation time that the X-ray beam is directed toward the shield wall, and (4) the *occupancy factor*, which is the fraction of the time during which the X-ray machine is in use and the beam is directed toward the shield wall behind which the individual at risk is actually present. All these factors are taken into account in the methodology of NCRP Reports 49 and 147. In addition, that methodology also treats leakage radiation from the X-ray machine and radiation scattered from patients or other objects present in the X-ray beam. The methodology is discussed at length by Simpkin (1987a,b, 1989, 1990) and by Chilton et al. (1984). A computer code for routine X-ray-shielding design and analysis [Simpkin 1987a] is available as code packages CCC-515/KUX and CCC-594/CALKUX from the Radiation Safety Information Computational Center, Oak Ridge National Laboratory, Oak Ridge, Tennessee.

4.5.4 The Half-Value Thickness

The half-value thickness, or half-value layer (HVL), is defined in terms of the attenuation of a parallel beam gamma or X rays, namely,

$$\text{HVL}(x) = \frac{-\ln 2}{d \ln A_f(x)/dx}. \quad (63)$$

For the special case of uncollided monoenergetic photons, $A_f(x) = e^{-\mu x}$, and

$$\text{HVL} = \frac{-\ln 2}{d \ln A_f/dx} = \frac{\ln 2}{\mu}. \quad (64)$$

However, when dealing with X rays or accounting for scattered gamma rays, the half-value thickness is a function of the depth of penetration, namely,

$$\text{HVL}(x) = \frac{-\ln 2}{d \ln A_f(x)/dx}. \quad (65)$$

At shallow penetrations, lower-energy photons are selectively removed and the HVL is relatively small. As the beam spectrum “hardens” with increasing penetration, the HVL increases. As may be shown from (62), the following relationships apply to X-ray data fit by that equation:

$$\lim_{x \rightarrow 0} \text{HVL} = \frac{\ln 2}{\alpha + \beta} \quad (66)$$

and

$$\lim_{x \rightarrow \infty} \text{HVL} = \frac{\ln 2}{\alpha}. \quad (67)$$

One other important application of the HVL. Values of the HVL at shallow penetration, usually for aluminum or copper, are widely used to characterize the penetration ability of X rays and as a parameter in the assessment of radiation doses from medical X rays. HVL data for a wide variety of materials and a wide variety of gamma- and X-ray source energies may be found in NCRP Reports 49 and 147 (1976, 2005).

4.6 Shield Heterogeneities

Occasionally, an analyst encounters a shield that includes regions of composition different from the bulk shield material. These regions may be large with a well-defined geometry, such as embedded pipes or instrumentation channels transverse to the direction of radiation penetration. By contrast, there may be incorporated into the shield material small irregularly shaped and randomly distributed voids or lumps of other material, such as pieces of scrap iron used to increase the effectiveness of a concrete shield against gamma radiation. For a large, well-defined heterogeneity in the shield (most often a single void or region of low-interaction coefficient), ray theory can often be used effectively. For simple geometry (e.g., a spherical or cylindrical void in a slab shield), (53) can be evaluated analytically. Otherwise, numerical integration techniques are used. Examples are given by Rockwell (1956), Burrus (1968b), and Chilton et al. (1984).

Rigorous calculation of the effect of such heterogenous regions in a shield usually requires Monte Carlo techniques. In this section, some simplified techniques, based on ray theory, illustrate the effect of shield heterogeneities.

Consider two rays through a shield (see  Fig. 25) containing randomly distributed small voids in a continuous phase which has an effective linear attenuation coefficient μ . Ray 1 travels a distance t with transmission probability $T_1 = e^{-\mu t}$. Ray 2 travels a distance $t - \delta$ with transmission probability $T_2 = e^{-\mu(t-\delta)}$. The average path length for these two rays is $\bar{t} = t - \delta/2$, and the average transmission probability is

$$\bar{T} = \frac{1}{2}(T_1 + T_2) = e^{-\mu \bar{t}} \cosh(\mu \delta/2) > e^{-\mu \bar{t}}. \quad (68)$$

Thus, it is seen that the use of the average path length of a ray through the shield material underpredicts the average transmission probability. If the voids are replaced by a material with an attenuation coefficient different from that of the shield material, a similar analysis shows that use of the average path length (in mean free paths) also underestimates the average transmission probability. This effect is known as *channeling* and its neglect leads to an overestimation of the effectiveness of a shield. Channeling is seen in shields with randomly included heterogeneities as well as in shields with well-defined placement of voids and heterogenous regions.

4.6.1 Limiting Case for Small Discontinuities

Suppose in (68) that $\delta \ll \mu^{-1}$, that is, the lumps or voids are much smaller in size than the radiation mean free path length in the continuous phase. In this case, the channeling effect is negligible, and shield transmission factors may be estimated using an average mass attenuation coefficient $\bar{\mu}/\rho$. Suppose that μ , ρ , and w are the effective linear attenuation coefficient, density,

 **Figure 25**
Shield containing randomly distributed voids

and weight fraction of the continuous phase, and μ' , ρ' , and w' are the same quantities for the discontinuous phase. If v is the volume fraction of the voids or lumps in the shield and $\bar{\rho}$ is the average shield density, the average mass attenuation coefficient is

$$\overline{\mu/\rho} = \omega \left(\frac{\mu}{\rho} \right) + \omega' \left(\frac{\mu'}{\rho'} \right) = \frac{\rho(1-v)}{\bar{\rho}} \left(\frac{\mu}{\rho} \right) + \frac{\rho'v}{\bar{\rho}} \left(\frac{\mu'}{\rho'} \right), \quad (69)$$

and the transmission probability is thus

$$T(t) = e^{-(\overline{\mu/\rho})\bar{\rho}t} = e^{-(1-v)\mu + v\mu'}t} = e^{-\mu t} e^{-(\mu' - \mu)v t}. \quad (70)$$

This transmission probability is the same as if the shield materials (continuous and discontinuous components) were conceptually homogenized and the average attenuation coefficient for the homogenous mixture was used.

4.6.2 Small Randomly Distributed Discontinuities

Channeling effects have been treated by a statistical technique attributed to Coveyou (Burrus 1968a). Consider an infinite slab shield of thickness t , uniformly and normally illuminated on one side by radiation. The shield contains randomly distributed lumps with a different linear attenuation coefficient (μ') from that of the shield material (μ). Suppose that the mean chord length through a lump is δ . Then it can be shown that

$$T(t) = e^{-\mu t} e^{-(\mu' - \mu)v t / c_o}. \quad (71)$$

Here, c_o is the *cross-section effectiveness ratio*, namely,

$$c_o = \frac{-(\mu' - \mu)v\delta}{\ln[(1-v) + v e^{-(\mu' - \mu)\delta}]}. \quad (72)$$

For an arbitrary convex lump, the mean chord length is just four times the volume/surface area ratio. For concave and irregularly shaped lumps, the value of δ must be determined by specific calculation or by measurement of slices of the shield material.

5 Neutron Shielding

Neutron shielding analysis is often quite complex, involving not only attenuation of primary or source neutrons but also production and attenuation of secondary particles. These associated problems include the production of photons from neutron inelastic scattering, slowing down and thermalization of neutrons, capture of thermal neutrons leading to capture gamma photons, and even production of secondary neutrons as a result of fission or ($n, 2n$) reactions. Moreover, none of these associated problems is accurately solved using elementary techniques. To obtain accurate results with errors of only a few percentage, it is necessary to use sophisticated numerical techniques based on the exact descriptions of photon and neutron transport in the shield.

In this section, several of the simplified techniques developed for neutron shielding over the past 50 years are reviewed. Although these techniques are seldom used directly in modern shield analysis, the ideas behind them provide an insight into important mechanisms that determine the effectiveness of a neutron shield. Such insight allows the analyst to interpret and assess more critically results obtained with large computer codes.

5.1 Neutron Versus Photon Calculations

The development of simplified techniques for neutron shielding analysis is considerably more difficult than for photon shielding. The use of buildup factors, while theoretically applicable to any type of indirectly ionizing radiation, is much more difficult to apply to the neutron problem. The buildup of scattered neutrons depends strongly on the isotopic composition of the medium, on the neutron energy spectrum, and above all, on the problem geometry. Near a free surface, neutron densities generally decrease much more dramatically than in the photon case. Consequently, the use of infinite-medium buildup factors, which work so well for photon analyses, may introduce serious errors for neutron analyses.

Another serious difference between photon and neutron calculations arises from the evolution of thinking about fluence-to-dose conversion coefficients. Many different response-function sets have been issued by various national and international institutions over the past 50 years. Because the photon quality factor is independent of the photon energy, the ratio of different conversion coefficients, except at very low energies, is nearly constant, as is seen in [▶ Fig. 13](#). Thus, measured or calculated photon doses based on one conversion coefficient can be converted easily to another type of dose by an appropriate multiplicative constant. By contrast, the many neutron response functions that have been used at one time or another are not simply related to each other by a multiplicative constant (see, for example, [▶ Fig. 14](#)). Thus, much neutron shielding data (e.g., point kernels, albedos, transmission factors, etc.) reported in obsolete units cannot be rigorously used in modern shielding analysis. At best, only approximate conversions can be made; and if accurate results are needed, then there is no recourse but to repeat the original calculations or measurements using modern dose units.

5.2 Fission Neutron Attenuation by Hydrogen

There is one widely encountered situation for which the attenuation of a fast-neutron beam can be expected to be somewhat insensitive to the buildup of scattered neutrons. Elastic scattering from light elements results in a significant portion of the neutron's kinetic energy being lost, on the average, in a single scatter. In particular, for scattering from hydrogen the average energy loss is one-half of the initial neutron energy and, consequently, the scattering of a fast neutron on hydrogen acts essentially as an effective absorption or removal interaction because the neutron is, on the average, removed from the fast-neutron energy region by a single scatter. Thus, for the deep penetration of fast neutrons, the fast-neutron fluence might be expected to be very nearly equal to that of uncollided fast neutrons deep in an hydrogenous medium. In addition, the cross section for hydrogen in the MeV-energy region increases as the neutron energy decreases; hence, a low-energy neutron is much more likely to scatter from hydrogen than is a high-energy neutron. In effect, this characteristic of the hydrogen cross section implies

that, once a fast neutron interacts in an hydrogenous medium, the subsequent scattering or slowing-down interactions occur relatively near the point of the first scattering interaction.

From these arguments, it is then possible to derive a point kernel for the uncollided fast-neutron fluence in an infinite hydrogenous medium (Albert and Welton 1950). Consider a point-fission source which emits S_p fission neutrons with an energy spectrum given by $\chi(E)$ in an infinite hydrogenous medium with a hydrogen atom density of $N_H \text{ cm}^{-3}$. The uncollided fluence $\Phi_H^o(r, E)$ at distance r from the source, if one neglects any nonhydrogen collisions, is

$$\Phi_H^o(r, E) = \frac{S_p \chi(E)}{4\pi r^2} \exp[-N_H \sigma_H(E)r]. \quad (73)$$

Because the total fast-neutron fluence is of interest, (73) must be integrated over all fission energies. To perform such an integration, the functional form of $\chi(E)$ and $\sigma_H(E)$ must be used, and because the fast fluence is dominated by those neutrons with energies greater than 4 MeV, a simpler form from that of (9) may be used, namely,

$$\chi(E) \simeq A e^{-aE}, \quad (74)$$

where the parameters A and a depend on the fissile isotope and the energy range of the fit. For the energy range 2–12 MeV, the hydrogen total cross section (which is essentially the scattering cross section) may be approximated by (Blizard 1962)

$$\sigma_H(E) \simeq B E^{-b}, \quad (75)$$

where $B = 5.13 \times 10^{-24}$, $b = 0.725$, and σ_H is in units of cm^2 when E is in units of MeV.

As is shown by Chilton, Shultis, and Faw (1984), integration of (73) over all energy yields

$$\Phi_H^o(r) = \frac{S_p A \beta}{4\pi r^2} r^{\gamma/2} \exp(-\alpha r^\gamma), \quad (76)$$

where

$$\gamma \equiv 1/(1+b), \quad (77)$$

$$\beta \equiv \left[\frac{2\pi\gamma(N_H B b)^\gamma}{a^{1+\gamma}} \right]^{1/2}, \quad (78)$$

and

$$\alpha \equiv \frac{1}{\gamma} \left(\frac{a}{b} \right)^{b\gamma} (N_H B)^\gamma. \quad (79)$$

The presence of heavier components in the attenuating medium (e.g., the oxygen in a water shield) also degrades the fast neutrons in energy, although not nearly as well as the hydrogen. Many experiments have been performed to measure the attenuation of fast fission neutrons in hydrogenous media. Experimentally, it is found that the fast-neutron fluence falls off slightly faster with increasing distance from the source than (76) would indicate. In particular, experimental data for attenuation in water reveal that the spatial distribution of the total fast-neutron fluence can be related to that in hydrogen by

$$\Phi^o(r) = \Phi_H^o(r) \exp(-\mu_{r,O} r); \quad (80)$$

that is, the nonhydrogen component (oxygen) contributes an exponential attenuation factor. The constant $\mu_{r,O}$, although given the symbol of an attenuation coefficient, is an empirically derived constant to account for the nonhydrogen attenuation. Because of the similarity of this constant to the coefficient in the usual exponential attenuation of uncollided radiation, it is called the *removal coefficient*, although numerically it is usually significantly less than the actual total attenuation coefficient. More is said in the next section about the physical basis of the removal coefficient. Thus, by correcting for the attenuation of the oxygen, the fast-neutron fluence in water for a point fission source may be written as

$$\Phi^o(r) = \frac{A\beta S_p}{4\pi r^2} r^{\gamma/2} \exp(-\alpha r^\gamma - \mu_{r,O}r). \quad (81)$$

It should be emphasized at this point that the fast-neutron fluence kernel obtained from (81), with $S_p = 1$, is not adequate for detector-response evaluation because no account is taken of the buildup of small-angle-scattered neutrons which have lost very little energy. The usefulness of the kernel, however, is to suggest how the uncollided fluence (and hence, dose) can be expected to vary with distance from the source. Consequently, by fitting the functional form of the kernel to experimental data, one could expect to obtain a reasonably accurate semiempirical result. Such a fitting technique could be expected to lead to better agreement with experiment because the buildup of fast neutrons could be incorporated empirically. One widely used result is due to Casper (1960), who obtained the following fast-neutron tissue-absorbed-dose kernel for a point ^{235}U fission source in water:

$$\mathcal{G}(r) = \frac{5.39 \times 10^{-11}}{4\pi r^2} r^{0.349} \exp(-0.422r^{0.698} - 0.0308r), \quad (82)$$

where r has units of centimeters and \mathcal{G} has units of Gy for a source strength of one fission neutron.

Other functional forms have been fit to experimental dose data or to values calculated by the more elaborate neutron transport techniques. One particularly simple form for a ^{235}U fission source, which can be readily incorporated into analytical kernel calculations, expresses the fast-neutron tissue-absorbed dose kernel for water in terms of exponential functions (Grotenhuis 1962; Glasstone and Sesonske 1963), in the same units as used above, as

$$\mathcal{G}(r) = \frac{10^{-12}}{4\pi r^2} (23.9e^{-0.129r} + 2.89e^{-0.091r}). \quad (83)$$

Another empirical result, with the same units, which fits the experimental water kernel for absorbed dose in tissue more accurately than do the previous two results and which is valid over a much wider range of r ($0 \leq r \leq 300$ cm), is given by Brynjolfsson [1975] as

$$\mathcal{G}(r) = \frac{2.6 \times 10^{-11}}{4\pi r^2} e^{-br}, \quad (84)$$

where

$$b = \left[0.126 - 0.0001773 \left(r - \frac{r^2}{600} \right) \right] \left[1 - \left(2 + \frac{r^4}{5000} \right)^{-1} \right]. \quad (85)$$

A comparison of the foregoing three empirical tissue-absorbed dose-point-kernels in water with accurately calculated values is presented in [Table 16](#).

■ Table 16

Absorbed dose kernels in tissue from a point ^{235}U fission source in water (\mathcal{G}_o) obtained by the moments method (Goldstein 1959)

5.3 Removal Cross Sections

In many realistic situations, fission neutrons are attenuated not only by an hydrogenous medium but also by an interposed nonhydrogenous shield such as the wall of a steel pressure vessel. Many experimental data have been obtained for such situations; and under special circumstances, the effect of the nonhydrogen component can be very simply accounted for by an exponential attenuation factor, much as was done for the oxygen correction examined in the preceding section.

An idealized fast-neutron attenuation experiment is shown in ► Fig. 26. A point isotropic fission source in an infinite homogenous hydrogenous medium is surrounded by a spherical shell of thickness t composed of a nonhydrogenous material. Experimental results reveal that under certain circumstances, the tissue-absorbed dose D' with the shell in position (i.e., at a distance $r_1 + r_2$ of hydrogenous medium plus a thickness t of the nonhydrogenous component) is related to the dose D at a distance $r = r_1 + r_2$ from the source, without the shell, by

$$D' = D \left(\frac{r}{r+t} \right)^2 e^{-\mu_r t}, \quad (86)$$

where μ_r is called the *removal coefficient* and is a constant characteristic of the nonhydrogenous component for a given fission-neutron energy spectrum.

Two important restrictions on the experimental arrangement are required for the validity of (86). First, it is important that there be at least 6 g cm^{-2} of hydrogen, equivalent to 50 cm of water, between the nonhydrogenous component and the observation position. Second, the thickness t must be such that $\mu_r t$ is less than about 5.

Although the factor $\exp(-\mu_r t)$ in (86) appears to indicate that absorption of neutrons is taking place in the nonhydrogenous component, the principal interactions are scattering interactions in which the fission neutrons are degraded in energy only slightly. However, the

Figure 26

Idealized experimental geometry for the measurement of the removal cross-section in which a nonhydrogenous shield of thickness t is placed between the point-fission source and the detector in an infinite hydrogenous medium

hydrogen in the material following the nonhydrogenous component (one of the two experimental restrictions) moderates or removes the slightly slowed-down neutrons more quickly than those neutrons which traverse the nonhydrogenous component without any energy loss. If, following the nonhydrogenous component, there is sufficient hydrogen to effect the removal of the neutrons which are slightly moderated, the spatial variation of the fast-neutron tissue-absorbed dose D can be obtained from one of the kernels of (82) to (84), for the case that the hydrogenous medium is water.

If a series of different materials is inserted into the hydrogenous medium, the removal term $\exp(-\mu_r t)$ of (86) becomes simply $\exp(-\sum_i \mu_{r,i} t_i)$, where $\mu_{r,i}$ is the removal coefficient for the i th slab of thickness t_i . Similarly, if a slab of a mixture of elements is inserted, the removal coefficient μ_r for the slab is given by $\sum_i N_i \sigma_{r,i}$, where N_i is the atom density of the i th element with microscopic removal cross section $\sigma_{r,i}$. This additive nature of the relaxation lengths for the nonhydrogen components, which is a direct consequence of (86), has generally been supported by experiment, although some deviations have been noted.

The (n, γ) absorption cross-section for most materials in the MeV-energy region is negligible and plays no significant role in the removal of fast neutrons. Conceptually, the removal cross-section is that fraction of the total fast-neutron cross section, averaged over energies of fission neutrons, representing inelastic and elastic scattering through a large scattering angle (i.e., scattering in which there is significant energy loss). Thus, the removal cross section can be expected to be somewhat less than the total cross section. As an approximation, $\mu_r \approx \frac{2}{3} \bar{\mu}_t$, where $\bar{\mu}_t$ is the average total attenuation coefficient in the energy range 6–8 MeV (Goldstein and Aronson 1954).

There is no firm theoretical reason for the removal cross section to be a material constant, and indeed, it might be expected to vary with the fission neutron energy spectrum, the thickness of the nonhydrogenous shield, amount of hydrogenous material on either side of the slab, and the geometry of the experiment. However, experimental results have shown that for most situations (provided that the slab is less than five removal relaxation lengths thick), μ_r can often be taken as a constant for a given incident fission spectrum. In Table 17, the measured values of removal cross sections for several materials are presented. To obtain removal cross sections

■ Table 17

Measured microscopic removal cross sections of various elements and compounds for ^{235}U fission neutrons

Material	σ_r (b/atom)	Material	σ_r (b/atom)

Source: Blizard (1962); Chapman and Storrs (1955)

for other elements, the following empirical formulas (in units of cm^2/g) have been obtained to permit interpolation between these measured values (Zoller 1964):

$$\frac{\mu_r}{\rho} = \begin{cases} 0.190Z^{-0.743} & Z \leq 8 \\ 0.125Z^{-0.565} & Z > 8 \end{cases} \quad (87)$$

or

$$\frac{\mu_r}{\rho} = 0.206A^{-1/3}Z^{-0.294}, \quad (88)$$

where A and Z are the atomic mass and atomic number, respectively, for the element of concern.

5.4 Extensions of the Removal Cross Section Model

5.4.1 Effect of Hydrogen Following a Nonhydrogen Shield

In the preceding section, it was emphasized that the applicability of the removal cross section model of (86) was dependent on whether there is sufficient hydrogen following the nonhydrogenous component to complete the removal of neutrons which have been degraded slightly in energy by the nonhydrogen component. If there is insufficient hydrogen following the

nonhydrogenous component, not all the neutrons are removed, and the removal cross-section appears to have a smaller value. In such a situation, the removal cross-section is no longer simply a material property, but it is also a function of the hydrogen thickness following the nonhydrogen component (Shure et al. 1969).

Values of removal cross sections are insensitive to the lower cutoff energy used to define the lower limit of the fast-neutron fluence. However, for hydrogen-deficient shields, the lower cutoff energy yields slightly smaller values for the removal cross section, as would be expected, because the limited hydrogen available is unable to remove all the degraded neutrons and consequently, leaves relatively more fast neutrons to penetrate the shield.

5.4.2 Homogenous Shields

For homogenous systems in which the nonhydrogen material is uniformly dispersed in a hydrogenous medium such as concrete, the removal cross section concept can also be applied if the hydrogen concentration is sufficiently high. For such situations, the fast-neutron tissue-absorbed dose $D(r)$ from a point fission source of strength S_p can be related to the dose $D_H(r)$ in a pure hydrogen medium of equivalent hydrogen density by the equation

$$D(r) = D_H(r) \exp\left(-\sum_{i=1}^N N_i \sigma_{r,i}^{\text{homo}} r\right), \quad (89)$$

where $\sigma_{r,i}^{\text{homo}}$ is the microscopic removal cross section of the i th nonhydrogen component for a fission neutron source, and N_i is the atom density of the i th nonhydrogen species. The pure hydrogen dose $D_H(r)$ in this result can be calculated in terms of a point-source dose kernel $\mathcal{G}_H(r)$ as $D_H(r) = S_p \mathcal{G}_H(r)$, where $\mathcal{G}_H(r)$ can be inferred from the water kernels of (82) to (85) by eliminating the oxygen contribution and correcting for the different hydrogen atomic density. For example, using Casper's semiempirical kernel of (82), with the oxygen removal term eliminated, $\mathcal{G}_H(r)$ can be expressed as

$$\mathcal{G}_H(r) = \frac{5.39 \times 10^{-11}}{4\pi r^2} \left\{ (Yr)^{0.349} \exp[-0.422(Yr)^{0.698}] \right\}, \quad (90)$$

where Y is the ratio of the hydrogen atom density in the mixture to that in pure water. For most elements, the homogenous removal cross sections in (89) can be taken equal to the heterogenous removal cross section (see [Table 17](#)); although for lighter elements, the homogenous removal cross sections appear to be 5–10% smaller than those for heterogenous media (Tsy-pin and Kukhtevich 1968).

For (89) to be valid, it is imperative that there be sufficient hydrogen present to remove neutrons degraded in energy by collisions with the heavy component. In [Fig. 27](#), the lowest concentration of water required for the validity of (89) is presented as a function of the atomic mass of the nonwater component. Note that the heavier the nonhydrogen component, the more the water is required. It should also be noted that the concrete, which is a very important neutron-shielding material, is just barely able to pass this criterion. One should be cautious therefore in the application of (89) to a very dry concrete.

■ Figure 27

Lowest volume concentration of water in a homogenous mixture containing heavy components with an average atomic mass A for (89) to be valid. From Tsypin and Kukhovich (1968)

5.4.3 Energy-Dependent Removal Cross Sections

In many situations, the neutron spectrum incident on an hydrogenous shield is not that of a fission source, but may have a completely different energy dependence, $\chi(E)$, as a result of penetration through other materials or from a difference in the physical source of the fast neutrons (e.g., a fusion reaction). In such situations, the removal concept can again be used by employing energy-dependent removal cross sections. As with the fission-spectrum case, it is important that sufficient hydrogen be present to remove those neutrons which have been slightly degraded by collisions with the nonhydrogenous components in the shield. For any point isotropic source of strength S_p and energy spectrum $\chi(E)$, the tissue-absorbed dose in a distance r away from the source in an infinite homogenous medium can, by analogy with our previous results, be written as

$$D = \int_0^{\infty} dE S_p \chi(E) \mathcal{G}_H(r, E) \exp\left[-\sum_{i=1}^N N_i \sigma_{r,i}(E) r\right], \quad (91)$$

where $\mathcal{G}_H(r, E)$ is the neutron dose kernel at a distance r from a unit-strength isotropic source emitting neutrons of energy E in a pure hydrogen medium of density equivalent to that in the shield material; $\sigma_{r,i}(E)$ is the microscopic removal cross section of the i th nonhydrogen shield component for neutron energy E ; and N_i is the atom density of the i th shield component.

The use of (91) to calculate the dose depends on two crucial pieces of information: the hydrogen dose kernel $\mathcal{G}_H(r, E)$ and the energy-dependent removal coefficient $\mu_{r,i}$. As a rough approximation for the energy-dependent hydrogen dose kernel, one may use the following result [Tsypin and Kukhovich 1968]:

$$\mathcal{G}_H(r, E) = \frac{1}{4\pi r^2} \exp[-\mu_H(E)r][1 + \mu_H(E)r]\mathcal{R}_D(E), \quad (92)$$

which is simply the uncollided dose kernel times an approximate buildup-factor correction, $[1 + \mu_H(E)r]$, times the tissue-absorbed dose-response function $\mathcal{R}_D(E)$. Here $\mu_H(E)$ is

the total hydrogen attenuation coefficient at energy E . An alternative is to use the following empirical result for the tissue-absorbed dose kernel (Shultis and Faw 2000) as

$$\mathcal{G}_H(r, E) = \frac{A_0(E)}{4\pi r^2} \exp[-A_1(E)Yr - A_2(E)(Yr)^2 + \mu_{r,O}(E)Yr], \quad (93)$$

in which Y is the ratio of the hydrogen atom density to that in water, and $\mu_{r,O}(E)$ is the energy-dependent removal coefficient for oxygen in water. The parameters $A_0(E)$, $A_1(E)$, and $A_3(E)$ are given in ► [Table 18](#).

A more severe limitation of the energy-dependent removal-cross-section theory is the availability of values for removal cross sections. Only sparse experimental data are available, and those have rather large associated uncertainties (Gronroos 1968; Tsypin and Kukhtevich 1968). In many cases, it is necessary to use theoretical values of removal cross sections. Generally, the lack of information about energy-dependent removal cross sections as well as a lack of an accurate hydrogen-attenuation dose kernel limit the use of removal-cross-section theory for dose calculations. Of particular concern in shield calculations are those energy regions for which these removal cross-sections have minima, that is, those energies for which neutrons can stream through the shield material with a little chance of being removed. To obtain accurate results for nonfission spectra, more elaborate transport-theory based methods are called for. However, for an approximate calculation, (91) may be useful.

5.5 Fast-Neutron Attenuation without Hydrogen

In nonhydrogenous material, accurate calculation of the attenuation of fast neutrons requires numerical procedures based on transport theory or removal-diffusion theory. For rough estimates of fast-neutron penetration, however, a few empirical results have been obtained and are summarized in this section.

■ **Table 18**

Constants for the empirical fit of the tissue-absorbed dose kernel for a point-monoenergetic neutron source in water as given by (93).^a

Source energy (MeV)	A_0 (Gy cm ²)	A_1 (cm ⁻¹)	A_2 (cm ⁻²)	Range of fit (cm)
2	7.31×10^{-11}	0.1716	6.274×10^{-4}	10 to 80
4	9.55×10^{-11}	0.1115	3.792×10^{-4}	10 to 110
6	8.63×10^{-11}	0.07953	1.913×10^{-4}	10 to 140
8	7.04×10^{-11}	0.06362	1.634×10^{-4}	10 to 140
10	6.09×10^{-11}	0.05723	1.414×10^{-4}	10 to 140
14	5.42×10^{-11}	0.04925	1.318×10^{-4}	10 to 140

^aThese values were obtained by a least-squares fit to the results of moments calculations (Brynjolfsson 1975; Goldstein 1959). Agreement is within $\pm 10\%$ over the indicated range of each fit

Important nonhydrogenous materials frequently encountered in shield design include iron, lead, and aluminum used as structural material or for photon shielding. Fast neutrons are attenuated very poorly by these materials. For Po–Be neutrons, relaxation lengths are found to be 16 cm for iron, 24 cm for lead, and 30 cm for aluminum (Dunn 1957). Hence, fast-neutron attenuation through only a few centimeters of these materials can be neglected for practical purposes.

However, for thick nonhydrogenous shields, fast neutrons may be appreciably attenuated. Beyond a few mean-free-path lengths from a fast-neutron source in an infinite nonhydrogenous medium, the fast-neutron fluence has been observed to decrease exponentially. However, the relaxation length is a characteristic not only of the material but also of the source energy and the low-energy limit used to define the fast-neutron region (i.e., the “fast group” of neutrons). Specifically, the total fast-neutron fluence $\Phi_\alpha(r)$ above some threshold energy E_α at a distance r greater than three mean-free-path lengths from a point monoenergetic source of strength S_p and energy E_o in an infinite homogenous medium, can be calculated by (Broder and Tsy-pin 1968)

$$\Phi_\alpha(r) \simeq \int_{E_\alpha}^{E_o} \Phi(r, E) dE = \frac{S_p B_o}{4\pi r^2} \exp(-r/\lambda_r). \quad (94)$$

The factor B_o corrects for the initial buildup of scattered fast neutrons and, after a few mean-free-path lengths, becomes a constant. Both the initial buildup factor and the relaxation length λ_r are empirical constants and depend on the attenuating material, the source energy, and the threshold energy E_α . In \blacklozenge Table 19, values of B_o and λ_r are presented for a few materials.

If the fast-neutron source is distributed in energy, the technique above can still be applied by dividing the source energy region into several contiguous narrow energy ranges and then treating the neutrons in each range as monoenergetic neutrons, governed by (94). Thus,

$$\Phi_\alpha = \frac{S_p}{4\pi r^2} \sum_i f_i B_o^i \exp(-r/\lambda_r^i), \quad (95)$$

where f_i is the fraction of neutrons emitted in the i th energy range and B_o^i and λ_r^i are the initial buildup factor and relaxation length, respectively, for neutrons at the mean energy of the i th

\blacksquare **Table 19**
Initial Buildup Factors and Relaxation Lengths in Different Media for Monoenergetic Neutron Sources. The energy range for the fast-neutron flux density is 1.5 MeV to E_o

Medium	Density (g cm ⁻³)	$E_o = 4$ MeV		$E_o = 14.9$ MeV	
		B_o	λ_r (cm)	B_o	λ_r (cm)

Source: Broder and Tsy-pin (1968)

energy range. At large distances into the shield, only a few terms in the summation of (95) are significant, those corresponding to neutrons whose energies are at minima in the total effective nuclear cross section.

The exponential attenuation of the fluence given empirically by the equations above can also be applied to media composed of a mixture of elements by using a weighted average of the relaxation lengths for the individual components, that is,

$$\lambda_r = \left(\sum_i \frac{\rho'_i}{\rho_i} \frac{1}{\lambda_r^i} \right)^{-1}, \quad (96)$$

where λ_r^i is the relaxation distance of the i th material at density ρ_i , and ρ'_i is the actual density of the i th material in the mixture, which may be different from ρ_i .

One of the major difficulties in applying the above technique is the lack of empirical data for initial buildup or, more important, for values of the relaxation lengths. Often, values for λ_r are chosen as the reciprocal of the removal coefficient μ_r for neutrons above 3 MeV. In reality, one can expect the relaxation length to be somewhat larger because hydrogen is not present to remove the slightly degraded neutrons. Typically, the removal coefficient should as a rule of thumb be reduced by a factor of about 2 to compute λ_r . However, the use of such inferred values for the relaxation lengths introduces a great deal of uncertainty in the fast-neutron fluences calculated, and consequently, such estimates must be used cautiously.

The procedures described here for estimating the fast-neutron fluence are, at best, only approximate. For design work, it is necessary to employ more elaborate methods based on the neutron-transport equation.

5.6 Intermediate and Thermal Fluences

The attenuation of fast neutrons in a shield necessarily leads to neutrons with intermediate and, eventually, thermal energies. The resulting intermediate-energy neutrons can contribute appreciably to the transmitted neutron dose in a shield, and the thermal neutrons, which are readily absorbed in the shield material, lead to the production of high-energy capture gamma photons. In many instances, the capture gamma-ray dose at the shield surface is the dominant consideration in the shield design. Thus, an important aspect of neutron shield analyses is the calculation of thermal and intermediate neutron fluences.

The thermal and intermediate neutrons in a shield arise from the thermalization of fast neutrons as well as from thermal and intermediate-energy neutrons incident on the shield's surface. Many elaborate techniques have been developed to compute accurately the thermal and intermediate neutron fluences; however, two simplified methods, based on diffusion and Fermi age theory, are first presented.

5.6.1 Diffusion Theory for Thermal Neutron Calculations

For hydrogenous shields, the fast neutrons are rapidly thermalized once they are removed from the fast group, as a result of the higher hydrogen cross section experienced by the neutrons removed. Consequently, as a rough approximation, the neutrons can be assumed to become

thermalized at the point at which they are removed from the fast group. In effect, the migration of intermediate-energy neutrons is neglected. The diffusion of the thermal neutrons then establishes the thermal-neutron fluence inside the shield. The thermal neutron flux density Φ_{th} can be calculated by use of the steady-state, one-speed, diffusion model for neutron transport (Lamarsh 1966),

$$D\nabla^2\Phi_{th}(\mathbf{r}) - \mu_a\Phi_{th}(\mathbf{r}) + S_{th}(\mathbf{r}) = 0, \quad (97)$$

where D and μ_a are the diffusion coefficient and linear absorption coefficient (macroscopic absorption cross section), respectively, for thermal neutrons.

Neutrons appear in the thermal group as they are lost from the fast group. Thus, the thermal neutron source term in (97) can be determined from the spatial rate of change of the fast neutrons traveling in direction Ω , namely,

$$S_{th}(\mathbf{r}) = -\nabla \cdot \int_{4\pi} d\Omega \Omega \Phi_f(\mathbf{r}, \Omega). \quad (98)$$

To a good approximation, the fast neutrons can be considered to be moving directly away from their source because there is little change in direction from the time the neutron leaves the source until it is removed from the fast region. Also, far from the fast neutron sources, the fast neutrons are all traveling in approximately the same direction \mathbf{n} directly away from their source, so that $\int_{4\pi} d\Omega \Omega \Phi_f(\mathbf{r}, \Omega) \simeq \mathbf{n}\Phi_f(\mathbf{r})$. Thus, the source of the thermal neutrons can be estimated from the fast-neutron fluence as

$$S_{th}(\mathbf{r}) \simeq -\nabla \cdot \mathbf{n}\Phi_f(\mathbf{r}). \quad (99)$$

The vector \mathbf{n} is a unit vector directed away from the fast-neutron source in the direction of fast-neutron travel or, equivalently, the direction in which the fast fluence decreases the most rapidly (i.e., opposite to the direction of the gradient of Φ_f).

For example, consider a plane shield ($0 < x < T$) in which the fast-neutron fluence is represented by an exponential function, or more generally, by a sum of N exponentials; that is,

$$\Phi_f(x) = \sum_{i=1}^N \Phi_f^i(0) \exp[-k_f^i x], \quad (100)$$

where $\Phi_f^i(0)$ and k_f^i are adjusted to give the best fit to the given fast-neutron fluence. For this case, the diffusion equation becomes

$$\frac{d^2\Phi_{th}(x)}{dx^2} - \frac{\mu_a}{D}\Phi_{th}(x) = -\frac{1}{D} \sum_{i=1}^N k_f^i \Phi_f^i(0) \exp[-k_f^i x], \quad (101)$$

whose general solution is

$$\Phi_{th}(x) = Ae^{-x/L} + Ce^{x/L} - \sum_{i=1}^N \frac{k_f^i \Phi_f^i(0)}{(k_f^i)^2 D - \mu_a} \exp[-k_f^i x], \quad (102)$$

where $L \equiv \sqrt{D/\mu_a}$. The constants A and C are then evaluated from the presumably known thermal neutron fluence incident at $x = 0$, and by setting Φ_{th} to zero at the outer surface of the shield, or, for thick shields, setting C equal to zero.

Instead of representing the fast-neutron fluence by a sum of exponentials as in (8.39), the shield could be divided into contiguous regions, with the fluence in each region represented by a single exponential, that is,

$$\Phi_f(x) = \Phi_f(x_j) \exp[-k_f^i(x - x_j)], \quad x_j < x < x_{j+1}. \quad (103)$$

Such a fit is easily performed by a series of straight-line fits to a plot of $\ln \Phi_f(x)$ versus x , and the relaxation constant k_f^j is obtained from

$$k_f^j = \frac{1}{x_j - x_{j+1}} \ln \left[\frac{\Phi_f(x_{j+1})}{\Phi_f(x_j)} \right]. \quad (104)$$

Once the exponential fit of the fast-neutron fluence is obtained for each region, the thermal neutron diffusion equation is solved in each region. The constants of integration are evaluated by requiring the solution and its first derivative to be continuous at the interfaces x_j or equal to specified values of the thermal neutron fluence at the shield surfaces. For preliminary analyses, it is often sufficient to fit the fast-neutron fluence by a single exponential over the whole shield volume. In **Table 20**, values for D and μ_a are presented for a few important shield materials, together with values of k_f for attenuation of fast neutrons.

5.6.2 Fermi Age Treatment for Thermal and Intermediate-Energy Neutrons

A refinement of the diffusion-theory procedure is to use Fermi age theory to correct for the migration of neutrons as they slow down to thermal energies (Blizard 1962). Age theory describes the slowing down of neutrons by a continuous energy-loss process which results in the same average energy loss as in the actual discrete energy losses from each scattering interaction. With this theory, neutrons are found to be distributed spatially in a Gaussian manner about the point at which they begin to slow down.

Table 20

Neutron properties of hydrogenous shield materials

Material	Density (g cm ⁻³)	k_f (cm ⁻¹) ^a	D (cm)	μ_a (cm)
Water	1.0	0.14	0.17	0.022
Ordinary concrete	2.35	0.085	0.65	0.0094
Barytes	3.50	0.125	0.44	0.019
Iron concrete	4.30	0.16	0.29	0.081

^aApproximate value for fast-neutron attenuations for a single exponential fit by (100). Actual fit values should be used whenever available.

Source: Glasstone and Sesonske (1963)

The number of fast neutrons reaching thermal energies per unit time at some point x inside the shield, $S_{th}(x)$, can be shown to be (Shultis and Faw 2000)

$$S_{th}(x) \simeq k_f \Phi_f(0) \exp[-k_f(x - k_f \tau_{th})], \quad (105)$$

where τ_{th} is the age to thermal energy. This result is valid for a shield whose thickness $T \gg \sqrt{\tau_{th}}$.

If the thermal neutrons are absorbed near the point at which they reach thermal energies, then under steady conditions the number absorbed, $\mu_a \Phi_{th}(x)$, must equal the number thermalized, $S_{th}(x)$. Thus, from (105),

$$\Phi_{th}(x) \simeq \frac{k_f}{\mu_a} \Phi_f(0) \exp[-k_f(x - k_f \tau_{th})] = \frac{k_f}{\mu_a} \Phi_f(x - k_f \tau_{th}). \quad (106)$$

This result implies that inside the shield the thermal neutron fluence is proportional to the fast-neutron fluence displaced toward the source by a *displacement distance* $k_f \tau_{th}$. The thermal neutron fluence inside a shield can thus be expected to parallel the fast-neutron fluence – a result usually observed.

5.6.3 Removal-Diffusion Techniques

Although diffusion theory can be used for initial estimates, more accurate techniques are often needed without the effort and expense of a full-scale multigroup transport calculation. Multigroup diffusion theory, which is considerably less expensive and complex to use than the transport theory, is remarkably successful at describing the slowing down and thermalization of neutrons in a reactor core. However, for describing neutrons deep within a shield, it has met with only limited success (Taylor 1951), although better accuracy has been obtained by introducing extraneous renormalization techniques to describe the penetration of the fast neutrons (Anderson and Shure 1960; Haffner 1968). That strict diffusion models should be of limited use to describe fast-neutron penetration, and subsequent thermalization is not surprising since diffusion theory requires both the differential scattering cross sections, and the angular fluence to be well described by first-order Legendre expansions. Such conditions usually hold in a reactor core where the neutron fluence is approximately isotropic; however, the fluence deep within a shield is determined by those very energetic neutrons which are highly penetrating and whose angular distribution is therefore highly anisotropic.

The penetrating fast neutrons are described very successfully by removal theory. The migration of the neutrons, once they are removed from the anisotropic fast group and begin to thermalize, is small compared to the distance traveled by the unremoved neutrons. Further, during thermalization, the fluence becomes more isotropic as more scatters occur. Consequently, one would expect multigroup diffusion theory to be applicable for the description of the slowing-down process and the subsequent diffusion at thermal energies. One approach to compute the buildup of low-energy neutrons inside a shield is to combine removal theory (to describe the penetration of fast neutrons) with multigroup diffusion theory (to describe the subsequent thermalization and thermal diffusion). This combination of removal and diffusion theory, in many formulations, has proved very successful.

Original Spinney Method

The first wedding of removal theory to diffusion theory was introduced by Spinney in 1958 (Avery et al. 1960). In the original formulation, the fast-source region, 0–18 MeV, is divided into 18 equal-width energy bands. The source neutrons in each band penetrate the shield in accordance with the removal theory. The density of removal collisions from all bands is then used as the source of neutrons in the first diffusion group. Explicitly, this diffusion source density at \mathbf{r} is given by

$$S_d(\mathbf{r}) = \sum_{i=1}^{18} \int_V \frac{S_v(\mathbf{r}') \chi_i \mu_{r,i} \exp(-\mu_{r,i} |\mathbf{r} - \mathbf{r}'|)}{4\pi |\mathbf{r}' - \mathbf{r}|^2} dV(\mathbf{r}'), \quad (107)$$

where $S_v(\mathbf{r}')$ is the production of source neutrons per unit volume at \mathbf{r}' in the source region, χ_i is the fraction of source neutrons in the i th removal band, and $\mu_{r,i}(\mathbf{r})$ is the removal coefficient for the i th band at position \mathbf{r} . The term $\mu_{r,i} |\mathbf{r} - \mathbf{r}'|$ is the total number of removal relaxation lengths between \mathbf{r} and \mathbf{r}' for a fast neutron in the i th band.

These removal neutrons are inserted as source neutrons into the top energy group of five energy groups, with the fifth group representing the thermal neutrons. The transfer of neutrons from one diffusion group to another diffusion group is determined by Fermi age theory (Lamarsh 1966), a continuous slowing-down model, and consequently neutrons can be transferred only to the energy group directly below. Thus, the diffusion group equations are written as

$$\nabla^2 \Phi_i(\mathbf{r}) - \frac{\mu_{a,i}}{D_i} \Phi_i(\mathbf{r}) - \frac{1}{\tau_i} \Phi_i(\mathbf{r}) = -\frac{S_i(\mathbf{r})}{D_i}, \quad (108)$$

where Φ_i is the fluence for group i , $\mu_{a,i}$ is the linear absorption coefficient for group i , D_i is the i th group diffusion coefficient, and τ_i is the square of the slowing-down length from group i to the next lower group $i + 1$, or equivalently, the Fermi age of neutrons starting from group i and slowing down to group $i + 1$ (for the thermal group, $\tau_i^{-1} = 0$).

The source term for the i th diffusion group is then given by

$$S_i(x) = \begin{cases} S_d(\mathbf{r}) & \text{from (107), } i = 1, \\ D_{i-1} \tau_{i-1}^{-1} \Phi_{i-1}(\mathbf{r}), & i > 1. \end{cases} \quad (109)$$

Improved Removal-Diffusion Methods

The original Spinney method, just described, was quite successful in predicting the low-energy neutron fluences in the concrete shields around early graphite reactors. However, to obtain better accuracy for a wider range of shield configurations, several obvious improvements could be made. First, more diffusion groups could be used to better describe the continuous slowing-down model implied by Fermi age theory. Second, neutrons should be allowed to transfer past intermediate diffusion groups in a single step to account for the possibility of large energy losses in inelastic scattering or elastic scattering from light nuclei. Third, more detail should be given for the removal of fast neutrons from the removal bands to the diffusion groups. Fast-neutron diffusion cannot be neglected altogether; and hence, the upper diffusion groups should overlap the same energy region spanned by the lower-energy removal bands. Further, when neutrons suffer a removal interaction, they should be allowed to enter any one of several diffusion groups, depending on the severity of the removal interaction. This improved description of the removed neutrons would give more information about the fast-neutron fluence, an important consideration for radiation damage studies.

Shortly after the introduction of the Spinney method, several variations of it were introduced which implement some or all of the improvements described above. Three such codes are RASH-E (Bendall 1962), MAC (Peterson 1962), and NRN (Hjärne 1964).

For thick shields with attenuation factors as low as 10^{-12} , this removal-diffusion method gives very accurate results even for layered shields, provided that penetration takes place mainly at the source energies (Peterson 1962). It is least accurate when significant attenuation occurs after diffusion (e.g., water followed by a thick iron shield). The greatest disadvantage of this method is the need to calculate many energy-group and removal-band constants (although considerably fewer than are needed for multigroup transport calculations). The removal-diffusion technique is a very powerful tool for the reactor designer, offering accuracies for many shield configurations comparable to those of the much more computationally expensive neutron transport methods.

With the advent of computing power undreamed of only decades ago, the use of removal-diffusion theory has waned and transport theory codes are now almost universally used in place of removal-diffusion codes. However, we include this section, not only for historical completeness, but for the insight it affords the analyst on how fast neutrons migrate through a shield.

5.7 Capture-Gamma-Photon Attenuation

Often, a significant contribution to the total dose at the surface of a shield is made by capture gamma photons produced deep within the shield as a result of neutron absorption. Another source of secondary photons arises from the inelastic scattering of fast neutrons. The resulting photons generally have much lower energies than the capture gamma photons (see [Table 7](#)) and are frequently ignored in the analysis of thick shields.

Most neutrons are not absorbed until they are thermalized, and consequently, one needs to consider only the absorption of thermal neutrons in most shield analyses. For this reason, it is important to calculate accurately the thermal neutron fluence $\Phi_{th}(\mathbf{r})$ in the shield. The volumetric source strength of capture photons per unit energy about E is, thus, given by (13), namely

$$S_{\gamma}(\mathbf{r}, E) = \Phi_{th}(\mathbf{r})\mu_{\gamma}(\mathbf{r})f(\mathbf{r}, E), \quad (110)$$

where $\mu_{\gamma}(\mathbf{r})$ is the absorption coefficient at \mathbf{r} for thermal neutrons and $f(\mathbf{r}, E)$ is the number of photons produced in unit energy about E per thermal neutron absorption at \mathbf{r} . Although the capture-photon-energy distribution for any material is composed of a set of monoenergetic photons, a great many different energies can generally be expected as a result of multiple nuclear transitions following neutron capture and the usual presence of many different nuclear species in the shield material. Consequently, the capture-gamma-photon yield is usually “binned” into energy groups. Thus, the source strength for the i th energy group of width ΔE_i is

$$S_{\gamma i}(\mathbf{r}) \equiv \int_{\Delta E_i} S(\mathbf{r}, E) dE = \Phi_{th}(\mathbf{r})\mu_{\gamma}(\mathbf{r})f_i(\mathbf{r}), \quad (111)$$

where f_i is the number of photons produced in group i per thermal neutron absorbed at \mathbf{r} , averaged over all isotopes at \mathbf{r} , namely,

$$f_i(\mathbf{r}) = \frac{1}{\mu_{\gamma}(\mathbf{r})} \sum_m \mu_{\gamma}^m(\mathbf{r})f_i^m, \quad (112)$$

where the superscript m refers to the m th nuclide and summation is over all nuclear species. The quantity f_i^m is the number of capture photons emitted in group i arising from the absorption of a thermal neutron by the m th nuclide (see [Table 7](#)).

The calculation of the dose from capture gamma photons is based on the distributed source of (111). The calculational procedure is illustrated for an infinite slab shield in which the thermal-neutron fluence has been previously obtained (see [Fig. 28](#)). The slab is generally composed of laminates, that is, a series of adjacent homogenous regions. If the thermal-neutron fluence depends only on the distance into the slab (plane geometry), then with the technique involving the point kernel and point-source buildup factors, the dose or detector response $D(t)$ at the shield surface from capture-gamma photons in all G groups is

$$D(t) = \sum_{i=1}^G \mathcal{R}_i \int_0^t dx S_{\gamma i}(x) \int_0^\infty d\rho 2\pi\rho B_i(r) \frac{\exp[-\mu_i r]}{4\pi r^2}, \quad (113)$$

where \mathcal{R}_i is a fluence-to-dose conversion factor for photons in energy group i , B_i is a composite buildup factor for photons in group i traveling from the source to the detector through the various interposed laminates, and $\mu_i r$ is the total number of mean free paths for photons in group i between the source and the detector.

[Equation \(113\)](#) could be evaluated numerically for a given B_i and $S_{\gamma i}$; however, considerable simplification is possible if we assume functional forms for these two quantities that allow analytical evaluation of the integrals. In particular, the shield is subdivided into N contiguous regions such that each region is composed of a single material and over which the thermal-neutron fluence could be fit reasonably well by a single exponential (see [Fig. 28](#)). Thus, for

■ **Figure 28**

Profile of the thermal neutron fluence in a multilaminar shield showing the coordinate system used for calculation of the capture-gamma-photon dose at the shield surface

the j th region bounded by x_j and x_{j+1} , the thermal-neutron fluence is represented by

$$\Phi_{th}^j(x) \simeq \Phi^j \exp[-k^j x], \quad x_j < x < x_{j+1}, \quad (114)$$

where Φ^j and k^j are constants. Thus, the capture-gamma-source strength for the i th energy group is

$$S_{\gamma i}^j(x) = C_i^j \exp[-k^j x], \quad (115)$$

with $C_i^j \equiv \Phi^j \mu_{\gamma i}^j f_i^j$, where the superscript j refers to material properties in the j th region and the subscript i refers to the energy group of the photons. Equation (113) can then be evaluated analytically for the uncollided dose ($B = 1$), and for the collided dose, if the Berger-buildup factor approximation is used (Stevens and Trubey 1968).

5.8 Neutron Shielding with Concrete

Of all shielding materials, concrete is probably the most widely used because of its relatively low cost and the ease with which it can be cast into large and variously shaped shields. Concrete is prepared from a mixture, by weight, of about 13% cement, 7% water (including water in the aggregate), and 80% aggregate. Many different types of concrete can be prepared by varying the nature of the aggregate. For example, to improve photon-attenuation properties, scrap iron or iron ore may be incorporated into the sand-and-gravel aggregate.

The amount of hydrogen in concrete strongly influences its effectiveness for shielding against neutrons. Generally, the more water content, the less concrete is needed to thermalize and absorb incident-fast neutrons. Virtually, all the hydrogen in concrete is in the form of water, which is present not only as *fixed water* (i.e., water of hydration in the cement and aggregate) but also as *free water* in the pores of the concrete. At elevated temperatures, both may be lost, thereby greatly reducing the ability of the concrete to attenuate fast neutrons. Even at ambient temperatures, free water may be lost slowly over time by diffusion and evaporation. Typically, the free water is initially about 3% by weight of the concrete, and this water is lost by evaporation during curing of the concrete. Over a 20- to 30-year period at ambient temperatures, half the fixed water may be lost.

Neutron attenuation calculations for concrete, especially by the simplified methods presented in this chapter, are usually problematic, partly as a result of the variation in elemental compositions of different concretes, and partly because the hydrogen content of many concretes is only marginal for the application of removal theory. Neutron transport methods generally must be used if accurate results are desired.

5.8.1 Concrete Slab Shields

A particularly important shielding geometry is that of a plane slab of ordinary concrete on which a monoenergetic, broad, parallel beam of neutrons is normally incident. This problem has been studied in some detail (Alsmiller et al. 1969; Chilton 1971; Roussin and Schmidt 1971; Roussin et al. 1973; Wyckoff and Chilton 1973; Wang and Faw 1995). Extensive tables of dose transmission factors $\tau_i(t, E, \cos \theta)$ are available for neutrons ($i = n$) and the secondary photon

dose ($i = p$), for plane parallel beams of neutrons of energy E incident at the concrete slab (NBS Type 04), at an angle θ with respect to the slab normal (ANSI/ANS-2006). The transmitted dose rates for a neutron flux of Φ is then simply calculated as

$$D_i(t) = \Phi \cos \theta \tau_i(t, E, \cos \theta), \quad i = n, p. \quad (116)$$

Effect of Water Content

If the proportion of water is changed in concrete, the concrete's attenuation ability also changes, especially for thicker shields. An example of the effect of water content in ordinary concrete (NBS Type 04 of [Table 24](#)) is shown in [Fig. 29](#). Detailed data must be obtained from the literature (Chilton 1971); but as an example, it can be shown that a reduction from 5.5% water to 4.5% water requires that the prescribed dose-equivalent values be multiplied by a factor of about 1.6 for incident neutrons in the energy range 1–15 MeV and for a shield thickness of about 400 g cm^{-2} . A reduction to 3.5% requires a multiplicative factor of about 2.6 under these circumstances; and a reduction to 2.5% implies a factor of about 4.1 (NCRP 1977).

■ Figure 29

Transmitted dose equivalent per unit incident fluence for neutrons, normally incident on slabs of ordinary concrete (NBS Type 04), with two thicknesses and four water contents (by weight). Response functions used are for the deep dose index (PAR) as specified by the ICRP (1987). Data courtesy of X. Wang, Kansas State University

Effect of Slant Incidence

Data are also available for neutron penetration through concrete slabs under slant incidence conditions (Chilton 1971; Wang and Faw 1995; ANS/ANSI 2006). In [▶ Fig. 30](#), the transmitted phantom-related dose equivalent for several slab thicknesses and incident angles is shown for a slab composed of a 5.5%-water calcareous concrete. These dose-equivalent results, which also included the capture-photon contribution, are normalized to a unit incident flow on the slab surface; that is, to an incident beam that irradiates each square centimeter of the surface with one neutron regardless of the beam direction. The transmitted dose equivalent when normalized this way is called the *transmission factor*. In ANSI/ANS-6.4-2006, tables are provided for the neutron and secondary-photon transmission factors for several thicknesses of concrete slabs uniformly illuminated by monoenergetic and monodirectional neutrons. Data for different concretes, incident energies, and incident directions can be found in the literature cited.

The transmission factor for a given slab thickness is seen from [▶ Fig. 30](#), to decrease by a multiplicative factor of between only 2–5 as the incident beam changes from normal incidence to a grazing incidence of 75° (from the normal), for a wide range of incident neutron energies. This variation of the transmission factor for neutrons, while appreciable, is not nearly as severe as it is for photons (see [▶ Table 14](#)).

Effect of the Aggregate

Aside from water variation, the other major change possible in the composition of ordinary concrete is the use of quartz-based sand and aggregate (SiO_2), instead of limestone in ordinary concrete. This siliceous type of concrete allows more dose-equivalent penetration than does the same mass thickness of calcareous concrete with the same water content; in general, it has neutron shielding properties about the same as calcareous concrete with about 2% less water (i.e., as if a 5.5% water content had been reduced to 3.5%) (Chilton 1971; Wyckoff and Chilton 1973).

It should be noted that none of the data presented in this section apply to “heavy concretes,” that is, to concretes with minerals containing high- Z elements included as part of the aggregate, nor to any other concrete of a composition deviating markedly from those proportions considered “ordinary.”

Effect of the Fluence-to-Dose Conversion Factor

Finally, the dose units used to measure the transmitted dose can have an appreciable effect on the transmission factor, far more so for neutrons than for photons. In [▶ Fig. 31](#), the neutron and secondary-gamma-ray transmission factors are shown for four response functions. It is seen that the transmitted secondary-photon dose is insensitive to the type of response function when compared with the neutron dose. For this reason, it is very important to pay careful attention to the dose-conversion coefficient used when trying to apply results found in the literature to a particular neutron shielding problem.

One final comment on the data presented in this section is appropriate as a cautionary statement. The data presented here are based on results of theoretical calculations. No experimental verification is available. Under such circumstances, the data should be used with some caution, especially for the greater thicknesses, and a factor of safety of at least two in dose is advised.

■ Figure 30

Transmitted deep dose equivalent (including the capture-gamma-photon contribution) through a concrete slab illuminated obliquely at four angles as a function of the incident neutron energy. The transmitted dose is normalized to a unit flow on the slab surface. Note that the curves at $x = 200$ cm and $x = 400$ cm have been multiplied by factors of 10^2 and 10^6 , respectively. Concrete composition (in 10^{21} atoms cm^{-3}): H, 8.50; C, 20.20; O, 35.50; Mg, 1.86; Al, 0.60; Si, 1.70; Ca, 11.30; and Fe, 0.19; density is 2.31 g cm^{-3} and water (percent by weight) is 5.5%. From data of Chilton (1971)

6 The Albedo Method

The calculation of how radiation incident on a surface is reemitted through the surface toward some point of interest is a frequently encountered problem in radiation shielding. Transport techniques are generally required for detailed estimation of reflected doses. But under certain circumstances, a simplified approach based on the albedo concept can be used with great effect. These conditions are (1) that the displacement on the surface between the entrance and exit of the radiation is very small when compared with the problem dimensions, (2) that the reflecting medium is about two or more mean free paths thick, and (3) that scattering between the radiation source and surface and between the surface and point of interest is insignificant.

Of course, reflection does not take place exactly at the point of incidence, but results from scattering by nuclei or electrons within the medium, with perhaps very many interactions taking place before an incident particle emerges or is “reflected” from the surface, as indicated in ► Fig. 32. Nevertheless, in radiation shielding calculations in which the character of the incident radiation does not change greatly over the surface in distances of about one mean free path, as measured in the reflecting medium, a reasonably accurate assumption can be made that the particles emerging from an incremental area result directly from those incident on that same area. Similarly, it has been found that for a reflecting medium thicker than about two mean free paths, it is an excellent approximation to treat the medium as a half-space. For discussion of these approximations and for more advanced treatments, the reader is referred to Leimdorfer (1968) and Selph (1973). The use of albedo techniques is central to many radiation-streaming codes and has been widely used as an alternative to much more expensive transport calculations.

Figure 32
Particle reflection from a scattering medium

Figure 33
Angular and energy relationships in the albedo formulation

6.1 Differential Number Albedo

Radiation reflection may be described in terms of the geometry shown in Fig. 33. Suppose that a broad beam of incident particles, all of energy E_0 and traveling in the same direction, strike area dA in the reflecting surface at angle θ_0 measured from the normal to the surface. If Φ_0 is the fluence of the incident particles and J_{n0} is the corresponding flow, the number of incident particles striking dA is $dA J_{n0} = dA \Phi_0 \cos \theta_0$. Suppose that the energy spectrum of the angular distribution of the fluence of reflected particles emerging from the surface with energy E and direction characterized by angles θ and ψ is $\Phi_r(E, \theta, \psi)$ and the corresponding differential flow is $J_{nr}(E, \theta, \psi)$. The number of particles emerging from dA with energies in dE about E and with directions in solid angle $d\Omega$ about direction (θ, ψ) is $dA J_{nr}(E, \theta, \psi) dE d\Omega = dA \cos \theta \Phi_r(E, \theta, \psi) dE d\Omega$. The *number albedo* $\alpha(E_0, \theta_0; E, \theta, \psi)$ is defined as

$$\alpha(E_0, \theta_0; E, \theta, \psi) \equiv \frac{J_{nr}(E, \theta, \psi)}{J_{n0}} = \frac{\cos \theta \Phi_r(E, \theta, \psi)}{\cos \theta_0 \Phi_0}. \quad (117)$$

6.2 Integrals of Albedo Functions

Occasionally of interest as reference albedos or in verification of particle conservation in transport calculations are the following integrals over all possible energies and all possible directions:

$$\alpha_N(E_o, \theta_o; \theta, \psi) \equiv \int_0^{E_o} dE \alpha(E_o, \theta_o; E, \theta, \psi) \quad (118)$$

and

$$A_N(E_o, \theta_o) \equiv \int_0^{2\pi} d\psi \int_0^1 d(\cos \theta) \alpha_N(E_o, \theta_o; \theta, \psi). \quad (119)$$

Of much more interest and utility is the *differential dose albedo*, defined as the ratio of the reflected flow, in dose units, to the incident flow, also in dose units. If $\mathcal{R}(E)$ is the dose-conversion coefficient, then

$$\alpha_D(E_o, \theta_o; \theta, \psi) \equiv \frac{\int_0^{E_o} dE \mathcal{R}(E) J_{nr}}{\mathcal{R}(E_o) J_{no}} = \int_0^{E_o} dE \frac{\mathcal{R}(E)}{\mathcal{R}(E_o)} \alpha(E_o, \theta_o; E, \theta, \psi). \quad (120)$$

It is important to recognize that dose-conversion coefficients affect $\alpha_D(E_o, \theta_o; \theta, \psi)$ only in the *ratio* $\mathcal{R}(E)/\mathcal{R}(E_o)$. For this reason, the photon dose albedo is not strongly dependent on the nature of the response. Photon albedos are commonly evaluated for exposure as the dose, but used in estimation of dose-equivalent or even effective dose. However, greater care must be taken with neutron albedos because $\mathcal{R}(E)/\mathcal{R}(E_o)$ can be quite different for different conversion coefficients.

6.3 Application of the Albedo Method

Refer to  [Fig. 33](#) and suppose that a point isotropic and monoenergetic photon source of strength S_p is located at distance r_1 from area dA along incident direction Ω_o and that a dose point is located distance r_2 from area dA along emergent direction Ω . Suppose that an isotropic radiation detector at the dose point is a vanishingly small sphere with cross-sectional area δ . At area dA , the flow of incident photons is $J_{no} = (S_p/4\pi r_1^2) \cos \theta_o$. Since the solid angle subtended by the detector at dA is δ/r_2^2 , the number of photons emerging from dA with energies in dE and with directions intercepting the detector is $J_{nr}(E, \theta, \psi) dA (\delta/r_2^2)$. This quantity, divided by the cross-sectional area of the spherical detector, is just that part of the energy spectrum of the fluence at the detector attributable to reflection of photons from area dA , namely,

$$d\Phi(E) dE = J_{nr}(E, \theta, \psi) \frac{dA}{r_2^2} dE = J_{no} \alpha(E_o, \theta_o; E, \theta, \psi) \frac{dA}{r_2^2} dE \quad (121)$$

or

$$d\Phi(E) dE = \frac{S_p \cos \theta_o}{4\pi r_1^2} \alpha(E_o, \theta_o; E, \theta, \psi) \frac{dA}{r_2^2} dE. \quad (122)$$

That part dD_r of the dose D_r owing to reflection of photons from dA is $\int dE \mathcal{R}(E) d\Phi(E)$, namely,

$$dD_r = \frac{S_p \cos \theta_o}{4\pi r_1^2} \frac{dA}{r_2^2} \int_0^{E_o} dE \mathcal{R}(E) \alpha(E_o, \theta_o; E, \theta, \psi) \quad (123)$$

or

$$dD_r = \left[\frac{S_p \mathcal{R}(E_o)}{4\pi r_1^2} \right] \frac{dA \cos \theta_o}{r_2^2} \alpha_D(E_o, \theta_o; \theta, \psi). \quad (124)$$

If the source were not isotropic but had an angular distribution $S(\Omega)$, then

$$dD_r = \left[\frac{S(\theta_o) \mathcal{R}(E_o)}{r_1^2} \right] \frac{dA \cos \theta_o}{r_2^2} \alpha_D(E_o, \theta_o; \theta, \psi), \quad (125)$$

in which $S(\theta_o)$ denotes symbolically the source intensity per steradian, evaluated at the direction from the source to reflecting area dA . Note that the bracketed term on the right side of either of the two previous equations is just the dose D_o at dA due to incident photons. Thus,

$$dD_r = D_o \alpha_D(E_o, \theta_o; \theta, \psi) \frac{dA \cos \theta_o}{r_2^2}. \quad (126)$$

Determination of the total reflected dose D_r requires an integration over the area of the reflecting surface. In doing such an integration, it must be remembered that as the reflecting location on the surface changes, all the variables θ_o , θ , ψ , r_1 , and r_2 change as well.

6.4 Albedo Approximations

Key to the albedo technique is the availability of either a large set of albedo data or, preferably, an empirical formula that approximates the albedo over the range of source energies and incident and exit radiation directions involved in a particular problem. Many albedo approximations have been proposed over the past four decades. However, many of these must be used with caution because they are based on limited energy-angular ranges, a single reflecting material, old cross section data, and, for neutron albedos, obsolete fluence-to-dose conversion factors.

6.4.1 Photon Albedos

A two-parameter approximation for the photon-dose albedo was devised by Chilton and Huddleston (1963), later extended by Chilton, Davisson, and Beach (1965), in the following form:

$$\alpha_D(E_o, \theta_o; \theta, \psi) \approx \frac{C(E_o) \times 10^{26} [\sigma_{ce}(E_o, \theta_s)/Z] + C'(E_o)}{1 + \cos \theta_o / \cos \theta}, \quad (127)$$

in which $C(E_o)$ and $C'(E_o)$ are empirical parameters that depend implicitly on the composition of the reflecting medium. Here, θ_s is the scattering angle, whose cosine is

$$\cos \theta_s = \sin \theta_o \sin \theta \cos \psi - \cos \theta_o \cos \theta \quad (128)$$

and $\sigma_{ce}(E_o, \theta_s)$ is the Klein–Nishina *energy scattering* cross section

$$\sigma_{ce}(E, \theta_s) = Zr_e^2 q^2 [1 + q^2 - q(1 - \cos^2 \theta_s)]/2, \quad (129)$$

where $q = E/E_o$, r_e is the classical electron radius, and Z is the atomic number of the medium. The approximation of (127) was fit to data obtained by Monte Carlo calculations using modern dose units to produce the albedo parameters shown in ► Table 21.

Chilton (1967) found that albedo data for concrete could be fit even better by the formula

$$\alpha_D(E_o, \theta_o; \theta, \psi) = F(E_o, \theta_o; \theta, \psi) \frac{C(E_o) \times 10^{26} [\sigma_{ce}(E_o, \theta_s)/Z] + C'(E_o)}{1 + (\cos \theta_o / \cos \theta)(1 + 2E_o \text{ vers } \theta_s)^{1/2}}, \quad (130)$$

in which the factor F is a purely empirical multiplier, given by

$$F(E_o, \theta_o; \theta, \psi) = A_1(E_o) + A_2(E_o) \text{ vers}^2 \theta_o + A_3(E_o) \text{ vers}^2 \theta + A_4(E_o) \text{ vers}^2 \theta_o \text{ vers}^2 \theta + A_5(E_o) \text{ vers } \theta_o \text{ vers } \theta \text{ vers } \psi, \quad (131)$$

in which $\text{vers } \theta = 1 - \cos \theta$. The seven parameters in this approximation are tabulated by Shultis and Faw (2000).

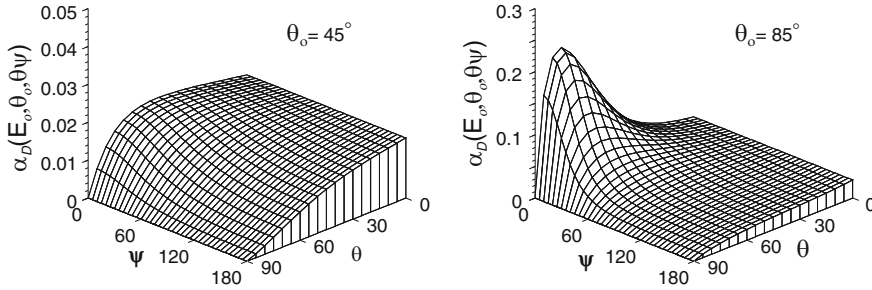

It should be emphasized that, to estimate an albedo for a photon energy between the tabulation energies, the interpolation should *not* be made with interpolated values of the parameters; rather, an interpolation of calculated albedos obtained with coefficients at bracketing tabulated energies should be used. Examples of the dose albedo from (130) are shown in ► Fig. 34.

Ambient-dose-equivalent albedos for reflection of 1.25-MeV photons from concrete

6.4.2 Neutron Albedos

There is much data in the literature for neutron albedos and for the associated secondary-photon doses. For a review of these earlier studies, see Shultis and Faw (2000) and Brockhoff and Shultis (2007). Unlike compilations or formulas for albedos for monoenergetic incident photons, it is difficult to interpolate similar neutron albedos because of the many resonances in the neutron cross sections. To account for the usual continuous distribution of fast or intermediate-energy neutrons, it is preferable to obtain albedos for incident neutrons in various contiguous energy bins. However, many early albedo studies are for monoenergetic sources, and hence, are of limited practical utility. Moreover, most neutron-albedo approximating formulas are based on the very old neutron-interaction data, on only a few incident directions, and are available only for a single reflecting material. With rare exception, neutron-albedo studies consider only concrete, the material most frequently subject to reflection analyses.

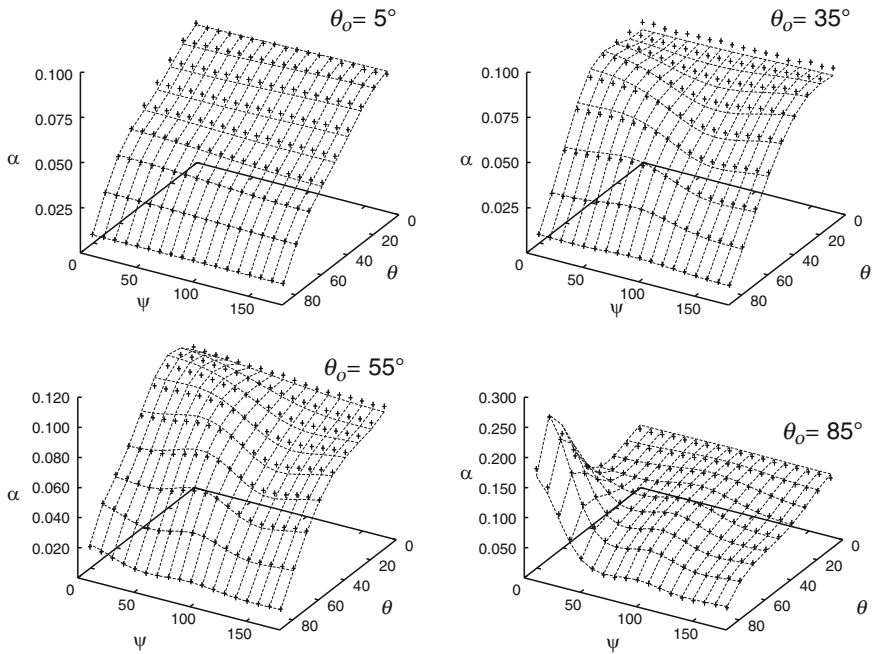

Recently, neutron dose albedos have been calculated for reflection from concrete, water, iron, and lead (Brockhoff and Shultis 2007). From these data, a variety of approximating formulas were adjusted to the calculated data. The formula that best fit the data for all materials and energy groups was

$$\alpha_D(\Delta E_o, \theta_o; \theta, \psi) = \frac{H(\kappa_1, \cos \theta_o)H(\kappa_2, \cos \theta)}{1 + K_1(E_o, \theta_o; \theta) / \cos \theta} \sum_{i=0}^N B_i P_i(\cos \theta_s), \quad (132)$$

where

$$K_1(E_o, \theta_o; \theta) = \sum_{i=0}^2 \cos^i \theta \sum_{j=0}^2 A_{ij} \cos \theta_o^j. \quad (133)$$

The number of fitting parameters is $N+12$ [κ_1 , κ_2 , $9 A_{ij}$, and $(N+1) B_i$]. The number of terms used in the Legendre expansion, $N+1$, determines the accuracy of the approximation. For most reflecting media and neutron energies, the use of a 9-term expansion results in fits with a maximum deviation of less than 10%. However, for extreme cases such as 8–10 MeV neutrons incident on concrete, water, iron, and lead, an $N = 13$ (24 parameters) results in maximum deviations of 6.95, 9.08, 8.97, and 8.13% for the four reflecting media, respectively. Besides approximating the albedo for all the discrete fast-energy groups, the 24-parameter formula also worked well for thermal neutrons, ^{252}Cf fission neutrons, and 14-MeV neutrons. Tabulations of the 24 parameters are provided by Brockhoff and Shultis (2007) and by ANS/ANSI (2006). A sample comparison between the calculated albedo data and approximation is shown in ► [Fig. 35](#).

■ Figure 35

Neutron differential ambient-dose equivalent albedo $\alpha_D(E_o, \theta_o; \theta, \psi)$ for 6–8 MeV neutrons, incident on a slab of concrete for $\theta_o = 5, 35, 55,$ and 85 degrees. Comparison of MCNP results (crosses) and the results obtained using the approximation of (132) (surface)

Secondary-Photon Albedos

The secondary albedo arises from the production of inelastic and capture gamma rays that are radiated from the reflecting surface. In general, the secondary-photon albedo is independent of the azimuthal angle as a consequence of the isotropic emission of secondary gamma rays. Also of note is that the magnitude of the secondary-photon dose albedo is usually considerably less than that of the neutron dose albedo and, consequently, a high accuracy for the secondary-photon albedo is generally not needed.

Maerker and Muckenthaler provided detailed calculations for thermal neutrons incident on concrete, and proposed a relation to approximate the secondary-photon albedo, namely, (Maerker and Muckenthaler 1965)

$$\alpha_{D_2}^{(n,\gamma)}(\theta_o, \theta) = \cos^{A_1}(\theta) [A_2 + A_3 \cos(\theta_o) + A_4 \cos^2(\theta_o)] A_5, \quad (134)$$

where the parameters $A_1, A_2, A_3, A_4,$ and A_5 are functions of the reflecting media and the energy of the incident neutrons. This approximation was used by Shultis and Brockhoff (2007) to approximate their calculated secondary-photon albedos.

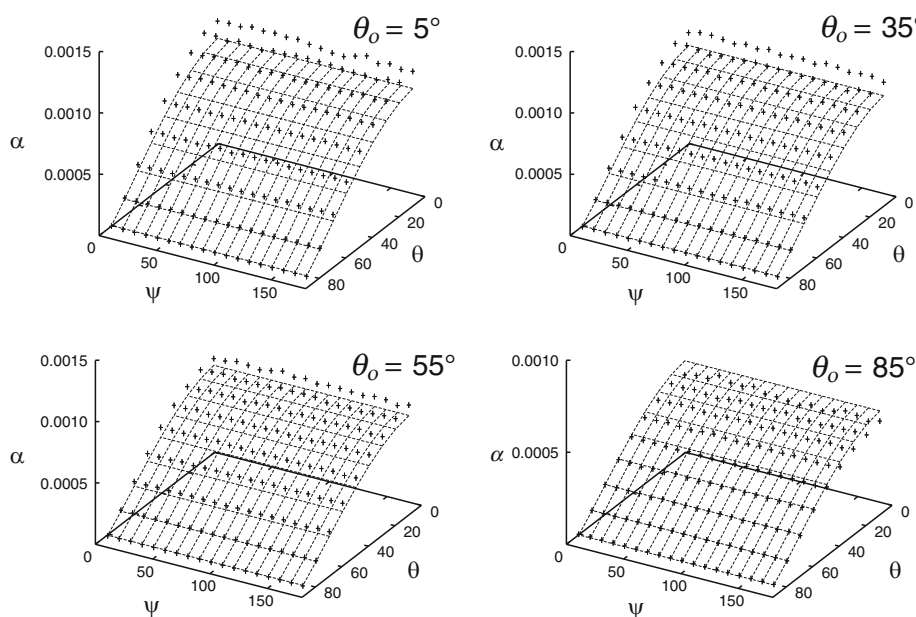

This approximation is not as accurate as the approximations presented for the neutron albedo. Use of this approximation can result in deviations in excess of 20% in some cases. Therefore, for problems in which the secondary-photon albedo needs to be calculated accurately over a small range of reflected directions, (134) should be used carefully. For most problems,

the secondary-photon albedo is usually small in comparison with the neutron albedo; and the use of this approximation should yield acceptable results. A sample comparison between the calculated albedo data and approximation is shown in  Fig. 36.

7 Skyshine

In many facilities with intense localized sources of radiation, the shielding against radiation that is directed skyward is usually far less than that for the radiation emitted laterally. However, the radiation emitted vertically into the air undergoes interactions and some secondary radiation is reflected back to the ground, often at distances far from the source. This atmospherically reflected radiation, referred to as *skyshine*, is of concern both to workers at a facility and to the general population outside the facility site.

A rigorous treatment of the skyshine problem requires the use of computationally expensive methods based on multidimensional transport theory. Alternatively, several approximate procedures have been developed for both gamma-photon and neutron-skyshine sources. See Shultis et al. (1991) for a review. This section summarizes one approximate method, which has been found useful for bare or shielded gamma-ray and neutron skyshine sources. This method, termed the *integral line-beam skyshine method*, is based on the availability of a *line-beam response function* (LBRF) $\mathcal{R}(E, \Phi, x)$ that gives the dose at a distance x from a point source

 **Figure 36**

The differential secondary-photon effective-dose-equivalent (AP) albedo $\alpha_D(E_o, \theta_o; \theta, \psi)$ for 1–2 MeV monidirectional neutrons, incident on a slab of concrete for $\theta_o = 5, 35, 55,$ and 85 degrees. Comparison of MCNP results (crosses) and the results obtained using the approximation of (134) (surface)

emitting a particle (neutron or photon) of energy E , at an angle Φ from the source-to-detector axis into an infinite air medium.

To obtain the skyshine dose $D(d)$ at a distance d from a bare collimated source, the line-beam response function, weighted by the energy and angular distribution of the source, is integrated over all source energies and emission directions. Thus, if the collimated source emits $S(E, \Omega)$ particles, the skyshine dose is

$$D(d) = \int_0^\infty dE \int_{\Omega_s} d\Omega S(E, \Omega) \mathcal{R}(E, \Phi, d), \quad (135)$$

where the angular integration is over all emission directions allowed by the source collimation Ω_s . Here Φ is a function of the emission direction Ω . To obtain this result, it has been assumed that the presence of an air-ground interface can be neglected by replacing the ground by an infinite air medium. The effect of the ground interface on the skyshine radiation, except at positions very near to a broadly collimated source, has been found to be small. At positions near the source (near-field), the ground augments slightly the dose, although at large distances from the source; it depresses slightly the dose when compared with results obtained with the infinite-air approximation. To account for the generally small air-ground interface effect, empirical *ground correction factors* are available to correct the infinite-air result of (135) (Kahn 1994; Gui, Shultis and Faw 1997a and 1997b).

Implicit in the integral line-beam approach is the assumption that the radiation source can be treated as a point source and that the source containment structure has a negligible perturbation on the skyshine radiation field, that is, once source radiation enters the atmosphere, it does not interact again with the source structure. With this assumption, the energy and angular distribution of source radiation penetrating any overhead source shield or escaping from the containment structure is independent of the subsequent transport of the radiation through the air to the detector. In most skyshine calculations at distances far from the source, this is true; however, for detectors near the source, this second assumption is not always valid.

7.1 Approximations for the LBRF

The LBRF for both photons, neutrons, and secondary photons from neutron interactions in the air can all be approximated over a large range of x by the following three-parameter empirical formula, for a fixed value of E and Φ (Lampley et al. 1988):

$$\mathcal{R}(x, E, \Phi) = \kappa E(\rho/\rho_o)^2 [\rho x/\rho_o]^b \exp[a - (c\rho x/\rho_o)], \quad (136)$$

in which ρ is the air density in the same units as the reference density $\rho_o = 0.0012 \text{ g cm}^{-3}$ and κ is a constant that depends on the dose unit used. The parameters a , b , and c depend on the neutron or photon source energy E (in MeV), the emission direction Φ , and dose unit employed. Various compilations of the parameters a , b , and c have been produced by fitting (136) to results of Monte Carlo calculations of the LBRF.

A double linear interpolation scheme can be used to obtain the logarithm of $\mathcal{R}(E, \Phi, x)$ for any E or Φ in terms of values at the discrete tabulated energies and angles. In this way, the approximate line-beam response function can be rendered completely continuous in the x , E , and Φ variables. With these approximate LBRFs, the skyshine dose is readily evaluated from (135) using standard numerical integration.

7.1.1 Photon LBRF Approximation

Tables of the parameters for (136), suitable for estimating the LBRF $\mathcal{R}(E, \Phi, x)$, were provided first by Lampley et al. (1988) and later, in more modern dosimetric units, by Shultis and Faw (1994) for a source-to-detector range of about $1 \text{ m} < x < 3000 \text{ m}$ for 12 discrete energies from 0.04 to 10 MeV and for 20 discrete angles Φ are available. Brockhoff et al. (1996) later extended to the energy range from 20 to 100 MeV. These later compilations are available from the Radiation Safety Information Computational Center (RSICC) as part of the Data Library Collection DLC-188/SKYDATA-KSU. \blacktriangleright Figure 37 illustrates $\mathcal{R}(E, \Phi, x)$ for 6.13-MeV photons. Such high-energy photons arise from decay of ^{16}N and are important in the design of water-cooled nuclear power plants.

7.1.2 Neutron LBRF Approximation

The neutron and secondary-photon LBRFs have been evaluated with the MCNP code at 14 discrete energies from 0.01 to 14 MeV, at 18 emission angles from 1 to 170 degrees, and at 24 source-to-detector distances from 10 to 2450 m (Gui et al. 1997a). Equation (136) was fit to these data and a compilation of the fitting parameters for modern neutron dosimetry units produced and is also part of the RSICC Data Library Collection DLC-188/SKYDATA-KSU. Examples of these approximate neutron LBRFs are shown in \blacktriangleright Fig. 38.

7.2 Open Silo Example

The general result of (135) can be reduced to explicit forms suitable for calculation for special geometries and source characteristics (Shultis et al. 1991). As an example, consider the case in which an isotropic, monoenergetic point source [(i.e., $S(E', \Omega) = S_p \delta(E' - E)/4\pi$], is located on the vertical axis of a cylindrical-shell shield (silo) of inner radius r (see \blacktriangleright Fig. 39). The wall of the silo is assumed to be *black* (i.e., no source radiation penetrates it). The source is distance h_s

\blacksquare Figure 37

Line-beam response function for 6.13-MeV photons in the atmosphere

Figure 38

The neutron line-beam response functions (Sv/source-neutron) for a 14-MeV source in an infinite air medium. The left figure shows the neutron dose as a function of the source-to-detector distance and the angle of neutron emission with respect to the source–detector axis. The right figure shows the dose from secondary photons

Figure 39

Geometry for skyshine analysis of an isotropic point source in an open silo

below the horizontal top of the silo which collimates the emergent radiation into a cone with a polar angle θ_{max} measured from the vertical axis and defined by

$$\omega_o \equiv \cos \theta_{max} = 1 / \sqrt{1 + r^2 / h_s^2}. \tag{137}$$

A detector (dose point) is located in air at radial distance x from the silo axis and at distance h_d below the silo top. If h_d is above the top of the silo wall, this distance is negative. The distance

from the source to the detector is

$$d = \sqrt{x^2 + (h_s - h_d)^2} \quad (138)$$

and the angle ζ between the horizontal and the source-to-detector axis is

$$\zeta = \tan^{-1}[(h_s - h_d)/x]. \quad (139)$$

Consider a particle emitted at polar angle θ , measured from the silo axis, and at azimuthal angle ψ , measured from the vertical plane through the source and detector. The cosine of the angle of emission Φ between the photon direction and the source–detector axis is the dot product of the unit vector in the emission direction and a unit vector along the source–detector axis, namely,

$$\cos \Phi = \sin \theta \cos \psi \cos \zeta + \cos \theta \sin \zeta. \quad (140)$$

For this unshielded-silo, monoenergetic-source problem, the skyshine dose at the detector is given by (135), which, upon using the azimuthal symmetry of the geometry and the monoenergetic nature of the source, reduces to

$$D(d) = \frac{S_p}{2\pi} \int_0^\pi d\psi \int_{\omega_o}^1 d\omega \mathcal{R}(E, \Phi, d). \quad (141)$$

This double integral is readily evaluated using standard numerical integration techniques.

7.3 Shielded Skyshine Sources

Most skyshine sources have some shielding over them, for example, a building roof, that reduces the amount of radiation escaping into the atmosphere. Such shielding causes some of the source radiation penetrating the shield to be degraded in energy and angularly redirected before entering the atmosphere. The effect of an overhead shield on the skyshine dose far from the source can be accurately treated by a two-step hybrid method (Shultis et al. 1991; Stedry et al. 1996; Shultis 2000). First, a transport calculation is performed to determine the energy and angular distribution of the radiation penetrating the shield, and then, with this distribution as an effective point, bare, skyshine source, the integral line-beam method is used to evaluate the skyshine dose at distances far from the source.

Although the two-step hybrid method can give very accurate results (e.g., Hertel et al. (2005)) the shield transport calculation requires considerable effort when compared with the subsequent integral line-beam calculation. A simpler, albeit less-accurate method to account for an overhead shield for photon skyshine is to assume that source photons are exponentially attenuated and that the buildup of secondary radiation can be estimated by an infinite-medium buildup factor for the source-energy photons (Shultis et al. 1991). In this simplified method, the energy and angular redistribution of the photons scattered in the shield is ignored (i.e., the scattered photons are assumed to emerge from the shield with the same energy and direction as the uncollided photons). The skyshine dose rate for a shielded source is thus

$$D(d) = \int_0^\infty dE \int_{\Omega_s} d\Omega e^{-\lambda} B(E, \lambda) S(E, \Omega) \mathcal{R}(E, \Phi, d), \quad (142)$$

where λ is the mean-free-path length that a photon emitted in direction Ω travels through the shield without collision. Clearly, when there is no source shielding ($\lambda = 0$), this result reduces to the unshielded result of (135).

An alternative approach for skyshine sources of photons shielded by a horizontal slab shield is to use a simple one-dimensional Monte Carlo calculation to determine the scattered and annihilation photons that subsequently escape into the atmosphere. These escaping photons are then transported through the air with the LBFR to the point of interest far from the source (Stedry et al. 1996). In this approach, the exact energy and angular distributions of the photons are used and very accurate results can be obtained with minimal computational effort.

The integral line-beam method for photon and neutron skyshine calculations has been applied to a variety of source configurations and found to give generally an excellent agreement with benchmark calculations and experimental results (Shultis et al. 1991; Shultis and Faw 1994; Hertel et al. 2005).

7.4 Computational Resources for Skyshine Analyses

As an alternative to computationally expensive transport calculations of far-field skyshine doses, several codes, based on the line-beam response function, are available that allow evaluation of skyshine doses with minimal computational effort. SKYSHINE-III, developed by Lampley, Andrews, and Wells (1988), is the original photon LBRF code, and can be obtained from RSICC. MicroSkyshine is a commercially available code (Grove 1987) for photon skyshine using improved LBRFs (Shultis and Faw 1987). More recent photon skyshine codes include SKYDOSE, which treats source energies between 0.4 and 100 MeV and distances out to 2500 m, and McSKY, which treats shielded skyshine sources by the Monte Carlo shield approach discussed above. For neutron skyshine problems there is SKYNEUT, which computes skyshine dose out to 2500 m from an arbitrary spectrum of neutron energies, and SKYCONES, which treats sources with polar angle variations and is used in the hybrid method discussed in the previous section. With the exception of MicroSkyshine, all these codes are available from RSICC.

8 Radiation Streaming Through Ducts

Except for the simplest cases, the analysis of radiation streaming through gaps and ducts in a shield requires advanced computational procedures. Because neutron albedos, especially for thermal neutrons, are generally much higher than those for photons, multiple scattering from duct walls is more severe for neutrons than for photons, for which a single scatter analysis is often sufficient. Moreover, placing bends in a duct, which is very effective for reducing gamma-ray penetration, is far less effective for neutrons. Fast neutrons entering a duct in a neutron shield become thermalized and, thereafter, are capable of scattering many times, allowing neutrons to stream along the duct, even one with several bends. Also, unlike gamma-ray streaming, the duct need not be a void (or gas filled) but can be any part of a heterogenous shield that is “transparent” to neutrons. Neutrons can navigate many bends and twists of the streaming channel, and consequently, the design of neutron shields containing ducts or regions with low hydrogen content must be done with great care.

The albedo concept has been found useful for simple duct analyses, and even for more complex geometries in which Monte Carlo techniques are used. Albedo methods are widely used in

the treatment of streaming, and special data sets, primarily for photons, have been developed for such use. Among these are SAIL (Simmons et al. 1979) and BREESE-II (Cain and Emmett 1979). The STORM method (Gomes and Stevens 1991) was especially devised to account for random variations in the displacement between point of entry and point of emergence in particle reflection, an important consideration in the analysis of radiation streaming. Among the few codes that deal exclusively with radiation streaming through ducts are DCTDOS (Spencer 1987) and ALBEDO/ALBEZ (Baran and Grun 1990).

This section provides an introduction to the topic of radiation streaming through ducts, with emphasis on axisymmetric illumination of straight cylindrical ducts and two-legged ducts void of any attenuating medium. First addressed are techniques that can be applied to both neutrons and photons, and then later methods are presented that were developed for a specific type of radiation.

8.1 Characterization of Incident Radiation

Here it is assumed that radiation incident upon a duct is uniform across the entrance plane (☛ Fig. 40). The incident radiation intensity may vary with polar angle θ , but it is assumed that it does not vary azimuthally about the duct axis. The natural polar axis for describing the angular variation is the duct axis. If the angular fluence of the incident radiation at the duct entrance plane is $\Phi_o(\theta)$, then the angular flow in the plane is just $J_{no}(\theta) = \cos \theta \Phi_o(\theta)$. It is often useful to use $\omega \equiv \cos \theta$ rather than θ as the independent angular variable so that $J_{no}(\omega) = \omega \Phi_o(\omega)$. Note that θ varies from 0 to $\pi/2$ and ω from 0 to 1. The flow J_n^+ within this range, which is the total flow into the duct (per unit area of the entrance plane), is given by

$$J_n^+ = 2\pi \int_0^1 d\omega J_{no}(\omega) = 2\pi \int_0^1 d\omega \omega \Phi_o(\omega), \quad (143)$$

in which the positive superscript designates directions within the hemisphere toward the duct entrance.

■ Figure 40
Detector response at point P on duct axis due to passage of particles through area dA in duct-entrance plane

Now suppose that the incident angular flow $J_{no}(\omega)$ is expanded in a power series. Each portion of the incident radiation characterized by a single term in a power series may be treated independently. Thus, suppose that $J_{no}(\omega) = (m+1)\omega^m J_n^+ / 2\pi$. The corresponding angular fluence is $\Phi_o(\omega) = (m+1)\omega^{m-1} J_n^+ / 2\pi$. Also, suppose that the incident radiation has energy E_o . The dose at the entrance plane is denoted by $D^o(0)$, where the superscript denotes incident radiation and the zero argument denotes the entry plane. Here,

$$D^o(0) = 2\pi \mathcal{R}(E_o) \int_0^1 d\omega \Phi_o(\omega) = \frac{m+1}{m} \mathcal{R} J_n^+, \quad (144)$$

where $\mathcal{R}(E_o)$ is the fluence-to-dose conversion factor for particles of energy E_o .

8.2 Line-of-Sight Component for Straight Ducts

Consider a dose point P in the exit plane of a straight duct illustrated in  Fig. 40. The dose at P in the exit plane, caused by radiation incident from an element of area dA in the entrance plane, is $dD^o(P) = \mathcal{R} dA J_{no}(\omega)/r^2$, in which the zero superscript denotes uncollided radiation and r is the distance from dA to point P . The uncollided dose from the entire entrance plane is

$$D^o(P) = \mathcal{R} \int_A \frac{dA}{r^2} J_{no}(\omega), \quad (145)$$

in which the integration is over the total area A of the source plane covering the duct entrance. Because $dA \omega/r^2$ is the solid angle $d\Omega$ subtended by dA at P , the dose can be expressed as an integration over the solid angle Ω subtended by the entrance area A at point P , namely,

$$D^o(P) = \mathcal{R} \int_A d\Omega \omega^{-1} J_{no}(\omega) = \mathcal{R} \int_{\Omega} d\Omega \Phi_o(\omega). \quad (146)$$

It is an important but subtle point that the line-of-sight dose *in the exit plane* of a duct is given by integrating the angular distribution of the fluence *in the entrance plane*.

8.2.1 Line-of-Sight Component for the Cylindrical Duct

Consider a duct of length Z , radius a , and aspect ratio $\beta \equiv a/Z$ as shown in  Fig. 41, but, for the line-of-sight analysis, with $\rho \leq a$, that is, with the element of area $2\pi\rho d\rho$ inside the duct entrance. The dose contribution $dD^o(P)$ at point P due to the differential annular area is $2\pi\rho d\rho \mathcal{R} J_n(\theta)/r^2$. Because $\rho d\rho = r dr$, $r = Z/\omega$, $\omega = \cos \theta$, and $dr = -Zd\omega/\omega^2$, it follows that

$$dD^o(P) = (m+1)J_n^+ \mathcal{R} d\omega \omega^{m-1}, \quad (147)$$

and upon integrating,

$$D^o(P) = (m+1)J_n^+ \mathcal{R} \int_{\omega_o}^1 d\omega \omega^{m-1}. \quad (148)$$

Because $D^o(0) = J_n^+ \mathcal{R}(m+1)/m$ for $m > 0$, this result may be written as

$$\frac{D^o(P)}{D^o(0)} = m \int_{\omega_o}^1 d\omega \omega^{m-1} = 1 - \omega_o^m = 1 - (1 + \beta^2)^{-m/2}. \quad (149)$$

Figure 41
Geometry for evaluation of the line-of-sight and wall-penetration components of dose for a straight cylindrical duct

For the special case of $m = 1$, that is, for isotropic incident fluence, $D^o(P)/D^o(0) = \Omega/(2\pi)$, where Ω is the solid angle subtended by the duct entrance at the center of the duct exit.

The line-of-sight component of the dose at the exit of a cylindrical duct is illustrated in **Fig. 42** and **Fig. 44**. As is quite evident from these figures, for $a \ll Z$, $D^o(P)/D^o(0) \simeq (m/2)\beta^2$, which is just the inverse-square law for attenuation of radiation from a point source.

8.2.2 Line-of-Sight Component for the Rectangular Duct

The line-of-sight component for a rectangular ducts with dimensions $W \times L$, for $J_{no}(\omega) = (m + 1)\omega^m J_n^+ / 2\pi$, is given by (Shultis and Faw 2000)

$$D^o(P) = \frac{2}{\pi} \mathcal{R}(m + 1) J_n^+ \int_0^{L/2} dy \int_0^{W/2} dx Z^m (x^2 + y^2 + Z^2)^{-(m+2)/2}. \quad (150)$$

For the special case of $m = 1$, that is, for isotropic incident fluence and just as for the cylindrical duct, $D^o(P)/D^o(0) = \Omega/(2\pi)$, where Ω is the solid angle subtended by the duct entrance at the center of the duct exit.

8.3 Wall-Penetration Component for Straight Ducts

The following discussion applies to photons, or to fast neutrons penetrating a duct wall with sufficient hydrogen content so that removal theory can be used. In the later case, the photon-attenuation coefficient μ is replaced by the appropriate removal coefficient μ_r . However, for

■ Figure 42

Line-of-sight and wall-transmission components for photons incident with isotropic fluence on a straight cylindrical duct. The independent variable is β , the aspect ratio, and the parameter is the wall thickness expressed as μZ , the number of mean free paths

thermal neutrons emitted by the source plane at the duct entrance, no simple formulas for the wall-penetration component exist.

Consider the cylindrical duct illustrated in [Fig. 41](#). Of interest is the radiation penetrating the wall through the lip of the duct entrance. This component $D^w(P)$ may be evaluated in a way very similar to that for the line-of-sight component, (147) through (149), except that $\rho \geq a$ and attenuation in the wall material must be accounted for, as is illustrated in the figure. Suppose that the effective linear-interaction coefficient for the wall material is μ . Then, the attenuation factor for a ray toward P from radius ρ is $\exp[-\mu(Z \sec \theta - a \csc \theta)]$. The analog of (149) is

$$\frac{D^w(P)}{D^o(0)} = m \int_0^{\omega_0} d\omega \omega^{m-1} \exp\left[-\mu Z \left(\frac{1}{\omega} - \frac{\beta}{\sqrt{1-\omega^2}}\right)\right]. \quad (151)$$

This ratio, which depends on *both* β as well as the mean free paths μZ of wall thickness, is illustrated in [Fig. 42](#). Obviously, for thinner walls and narrower ducts, the wall-penetration component can dominate the dose at the duct exit.

8.4 Single-Scatter Wall-Reflection Component

To evaluate this component, it is assumed that the particles entering the duct at its entrance may be treated as though coming from a point source on the duct axis. Only singly reflected particles are taken into account. Although this is a reasonable approximation for gamma rays, which

experience relatively very low albedos peaked in directions along the duct axis, it is not reasonable for thermal neutrons, which experience relatively very high albedos with more nearly isotropic reflection.

The geometry and notation for duct-wall reflection are illustrated in **Fig. 43**. The equivalent point source on the axis is located at point P_0 at the duct entrance, and dose is evaluated at point P on the axis at the other end of the duct. The source emits $S(\theta)$ monoenergetic particles per steradian, with azimuthal symmetry about the duct axis. If $J_n(\theta) = [(m+1)/2\pi]J_n^+ \cos^m \theta$ is the fluence at the duct-entry plane, then $S(\theta) = \pi a^2 J_n(\theta) = [(m+1)/2]a^2 J_n^+ \cos^m \theta = [(m+1)/2]a^2 J_n^+ \omega^m$. In accord with (124), the incident flow J_{n0} at reflecting area $dA = 2\pi a dz$ is given by $\cos \theta_1 S(\theta)/4\pi r_1^2$, and because $\cos \theta_1 = a/r_1$, it follows that the portion of the dose at P due to reflection from area dA is given by

$$dD^1 = \frac{2\pi a^2 dz \mathcal{R} S(\theta)}{r_1^3 r_2^2} \alpha_D(E_o, \theta_1; \theta_2, 0). \quad (152)$$

Note that all reflections leading to the dose point require zero change in azimuthal angle ψ . The total reflected dose is given by

$$D^1(P) = 2\pi a^2 \mathcal{R} \int_0^Z dz \frac{S(\theta)}{r_1^3 r_2^2} \alpha_D(E_o, \theta_1; \theta_2, 0). \quad (153)$$

By using dimensionless variables, namely, $u \equiv z/Z$ and the *aspect ratio* $\beta \equiv a/Z$, this result can be expressed as

$$D^1(P) = \pi(m+1)J_n^+ \mathcal{R} \beta^4 \int_0^1 du u^m \frac{\alpha_D(E_o, \theta_1; \theta_2, 0)}{(\beta^2 + u^2)^{(m+3)/2} [\beta^2 + (1-u)^2]}. \quad (154)$$

For $m > 0$, this can be expressed in terms of the dose at the source plane $D^0(0)$. From (144), $D^0(0) = [(m+1)/m] \mathcal{R} J_n^+$ for the broadly illuminated duct entrance, and because $\omega = \cos \theta = z/\sqrt{z^2 + a^2} = 1/\sqrt{1 + \beta^2/u^2}$, the ratio of the single-reflection dose at the duct exit to the dose at the center of the broadly illuminated duct entrance is, for $m > 0$,

$$\frac{D^1(P)}{D^0(0)} = \pi m \beta^4 \int_0^1 du u^m \frac{\alpha_D(E_o, \theta_1; \theta_2, 0)}{(\beta^2 + u^2)^{(m+3)/2} [\beta^2 + (1-u)^2]}, \quad (155)$$

Figure 43

Geometry for evaluation of single-wall reflection in a straight cylindrical duct

■ Figure 44

Line-of-sight and single wall-reflection component for photons incident with isotropic fluence on a straight cylindrical duct in a concrete wall. The independent variable is β , the aspect ratio, and the parameter is the photon energy. The data points represent the multiple-reflection dose for a 0.1-MeV equivalent point source at the entry of a cylindrical duct in a 2-m-thick concrete wall, computed using the MCNP Monte Carlo radiation-transport computer code

in which $\theta_1 = \cot^{-1}[\beta/u]$ and $\theta_2 = \cot^{-1}[\beta/(1-u)]$. The reader will note that, for specified photon energy and wall material, the reflection component of the exit dose is a function of only the aspect ratio. Representative results are illustrated in [► Fig. 44](#). Even for concrete, which has higher albedos than iron or lead, the wall-reflection component of the dose is generally much less than the line-of-sight component.

8.5 Photons in Two-Legged Rectangular Ducts

Photon transmission through multiple-legged ducts of arbitrary cross section is beyond the scope of this chapter. However, an albedo approach that might be employed in general cases is illustrated here for a two-legged rectangular duct. Details of this analysis and refinements to account for lip and corner penetration are described by LeDoux and Chilton (1959).

The geometry is illustrated in [► Fig. 45](#). It is assumed here that the lengths of the duct's legs are appreciably greater than the widths and heights of the legs and that the duct walls are of uniform composition and at least two mean-free-path-lengths thick. The dose $D(P)$ is evaluated at the center of the duct exit. Photons entering the duct are approximated by an anisotropic source $S(\theta)$ at the center of the duct entrance. For example, if the axisymmetric angular flow at the duct entrance plane is $J_n(\theta)$ and the cross-sectional area of the duct entrance is A ,

Figure 45 Prime scattering areas in radiation transmission through two-legged rectangular ducts

$S(\theta) = AJ_n(\theta)$. Here a monoenergetic photon source is assumed, although generalization of the method to polyenergetic sources is straightforward.

The analysis by LeDoux and Chilton is based on the approximation that the dose at $P, D(P)$, consists principally of responses to radiation reflected from *prime scattering areas*, that is, areas on the duct walls visible to both source and detector and from which radiation may reach the detector after only a single reflection. There are four prime scattering areas as can be seen in **► Fig. 45**, namely, areas A_1 and A_2 on the walls, and areas A_3 and A_4 on the floor and ceiling (considering the figure to be a plan view). Photon reflection from each area is treated as though it occurred from the centroid of the area. Thus, the transmitted dose may be expressed as

$$D(P) = D_1(P) + D_2(P) + 2D_3(P). \tag{156}$$

According to (124),

$$D_1(P) = \frac{\mathcal{R}A_1S(\pi/2 - \theta'_1) \cos \theta'_1 \alpha_D(E_o, \theta'_1; 0, 0)}{(r_1 r_2)^2}, \quad (157)$$

$$D_2(P) = \frac{\mathcal{R}A_2S(0) \alpha_D(E_o, 0; \theta'_2, 0)}{(r'_1 r'_2)^2}, \quad (158)$$

and

$$D_3(P) = \frac{\mathcal{R}A_3S(\pi/2 - \theta''_1) \cos \theta''_1 \alpha_D(E_o, \theta''_1; \theta''_2, \pi/2)}{(r''_1 r''_2)^2}, \quad (159)$$

in which the various arguments of the albedo function α_D are identified in  Fig. 45. Penetration of radiation through the corner lip can also be estimated in a similar manner (Shults and Faw 2000).

8.6 Neutron Streaming in Straight Ducts

Neutron streaming in straight ducts can be treated in the same context as gamma-ray streaming (see (148) and (150)). Neutron streaming may be treated similarly if the material surrounding the duct is a hydrogenous medium for which removal theory can be applied by replacing the attenuation coefficient μ for photons by the appropriate removal coefficient μ_r . However, for thermal neutrons no simple approximation is available. In this section, the albedo method is used to estimate the wall-scattered component. First, single-wall scattering is considered for neutrons.

Single-Wall Scattering

To describe the neutron albedo from the duct walls, it is assumed that neutrons are reflected partially isotropically and partially with a cosine distribution. In particular, the differential-wall dose albedo is approximated (using the notation of  Fig. 43) as

$$\alpha_D(E_o, \theta_1; \theta_2, 0) \simeq A_D \frac{\gamma + 2(1 - \gamma) \cos \theta_2}{2\pi}, \quad (160)$$

where A_D is the *dose reflection factor*, the fraction of incident dose reemitted in all outward directions from the wall surface, γ is the fraction of neutrons reemitted isotropically, and $(1 - \gamma)$ is the fraction reemitted with a cosine distribution. With this albedo approximation, the single-scatter dose given by (154) can be written as

$$D^1(P) = \frac{1}{2} J_n^+ \mathcal{R} \beta^2 A_D [\gamma I_{0,m} + 2\beta(m+2)(1-\gamma)I_{1,m}], \quad (161)$$

where the $I_{n,m}$ integral is defined for $n = 0, 1$ and $m \geq 0$ as

$$I_{n,m}(\beta) \equiv \beta^2 \frac{m+1}{(m+2)^n} \int_0^1 du \frac{u^m}{(\beta^2 + u^2)^{(m+3)/2} [\beta^2 + (1-u)^2]^{(n+2)/2}}. \quad (162)$$

The integral $I_{n,m}$ approaches unity (Chilton et al. 1984), as the aspect ratio becomes very small (i.e., for $\beta \equiv a/Z \ll 1$). For such ducts, illuminated by an isotropic source plane ($m = 0$), (161) reduces to

$$D^1(P) = \frac{1}{2} J_n^+ \mathcal{R} \beta^2 A_D [\gamma + 4\beta(1 - \gamma)]. \quad (163)$$

This result is known as the Simon and Clifford (1956) single-scatter duct formula.

Multiple-Wall Scattering

Because of the relatively high albedo for neutrons, they can scatter many times from a duct wall before reaching the duct exit. An analytical estimation of the multiple wall-scatter component is a formidable task. Simon and Clifford (1956) showed that, for the albedo of (160) and a long cylindrical duct ($Z \gg a$) illuminated by a source plane with isotropic incident fluence, that the wall-scattered component, including all orders of scatters, is given by (163), with the total albedo A_D replaced by

$$A'_D = 1 + A_D + A_D^2 + A_D^3 + A_D^4 + \dots = \frac{A_D}{1 - A_D}. \quad (164)$$

Thus, the dose from both the line-of-sight and multiple wall-scattered components at the duct exit is

$$D(P) = J_n^+ \mathcal{R} \beta^2 \left\{ 1 + \frac{A_D}{1 - A_D} [\gamma + 4(1 - \gamma)\beta] \right\}. \quad (165)$$

Here the line-of-sight component is obtained by treating the entrance as a disk source of radius a and evaluating the uncollided dose at a distance Z from the disk's center. The result is $D^0(P) \simeq J_n^+ \mathcal{R} \beta^2$ (Shultis and Faw 2000).

The result above holds for cylindrical ducts with a small aspect ratio a/Z . For larger ratios, the importance of the infinite number of internal reflections implied by (164) becomes less. Artigas and Hungerford (1969) have produced a more complicated version of (165), which gives better results for $a/Z > 0.3$ (Selph 1973).

8.7 Neutron Streaming in Ducts with Bends

To reduce radiation reaching the duct exit, shield designers often put one or more bends in the duct. Analyzing the effect of bends is an important but difficult task for the designer. However, a few simplified techniques are available for estimating transmitted neutron doses through ducts with bends. Albedo methods are widely used for treating neutron streaming through bent ducts. These methods range from simple analytical models, such as those presented in this section, to Monte Carlo methods that use albedos to reflect neutrons from duct walls and, thereby, allow them to travel large distances along the duct (Brockhoff and Shultis 2007).

8.7.1 Two-Legged Ducts

Neutron Streaming in a Two-Legged Cylindrical Duct

A two-legged cylindrical duct of radius a , shown in  Fig. 46, is first considered. The two legs are bent at an angle θ such that neutrons emitted from the source plane across the duct

■ **Figure 46**
Geometry for the two-legged duct model

entrance at A cannot stream directly to the duct exit at C . Both legs are assumed to have small aspect ratios, that is, $a/L_1 \ll 1$ and $a/L_2 \ll 1$. The uniform source plane emits neutrons into the duct with a general cosine flow distribution $J_n^+(\psi) = (m+1)J_n^+ \cos^m \psi / (2\pi)$, where ψ is the angle with respect to the normal to the source plane.

The uncollided dose on the duct centerline at the duct bend B arising from the disk source at the duct entrance is, for $a/L_1 \ll 1$, (Shultis and Faw 2000)

$$D^o(B) = (m+1)\mathcal{R}(E_o) \frac{J_n^+}{2} \left(\frac{a}{L_1}\right)^2. \quad (166)$$

Neutrons that reach the bend enter the duct-wall material, interact, and some are scattered back into the duct. Those neutrons reaching the duct exit at C are those that are reradiated from the portion of the duct wall visible from C , namely from the area $A_v = \pi a^2 / \sin \theta$. With the albedo concept [cf. (122)], the reflected or reradiated dose at C can be expressed as (recall that $a/L_2 \ll 1$)

$$D(C) = D^o(B) \cos \xi \widehat{\alpha}_D(\theta_o) \frac{A_v}{L_2^2}, \quad (167)$$

where ξ is some effective incident angle at the bend, and $\theta_o = (\pi/2) - \theta$ is the angle with respect to the normal to A_v at which reradiated neutrons reach the duct exit. Here $\widehat{\alpha}_D$ is a *differential reradiation probability*, analogous to the differential dose albedo. Assume that a fraction γ of the reradiated neutron flow from A_v is isotropic and a fraction $(1-\gamma)$ has a cosine distribution, so that

$$\widehat{\alpha}_D(\theta_o) = \widehat{A}_D \frac{\gamma + 2(1-\gamma) \cos \theta_o}{2\pi}. \quad (168)$$

The quantity \widehat{A}_D is the fraction of all the neutrons incident on the wall surfaces at the bend that are reradiated from A_v .

Finally, substitution of (166) and (168) into (167), along with the relation $\cos \theta_o = \sin \theta$, gives the transmitted dose at C as

$$D(C) = (m+1)J_n^+ K \mathcal{R}(E_o) \left(\frac{a^2}{2L_1^2} \right) \left(\frac{a^2}{2L_2^2} \right) \frac{\gamma + 2(1-\gamma) \sin \theta}{\sin \theta}, \quad (169)$$

where $K \equiv \widehat{A}_D \cos \xi$ is treated as an empirical constant. This result for the case of isotropic source flow ($m = 0$) was first obtained by Simon and Clifford (1956). Although cylindrical ducts have been used in this somewhat heuristic derivation, any simple duct shape could be used and only a slightly different expression would result.

Neutron Streaming in a Two-Legged Rectangular Duct

The LeDoux–Chilton albedo analysis of a two-legged L-shaped duct discussed in Section 8.5 cannot be applied directly to the neutron duct problem because of the importance of multiple scattering from the duct walls for the neutron case. However, Chapman (1962) extended the LeDoux–Chilton model to include second-order scattering effects, and Song (1965) used this refined model successfully to treat neutron transmission.

8.7.2 Neutron Streaming in Ducts with Multiple Bends

The Simon–Clifford model for a two-legged cylindrical duct can be extended to a duct with N legs. With this extension, the dose at the exit of the N th leg is

$$D(L_N) = (m+1)J_n^+ \mathcal{R}(E_o) \left(\frac{a^2}{2L_1^2} \right) \times \prod_{i=2}^N \left[K \left(\frac{a^2}{2L_i^2} \right) \left(\frac{\gamma + 2(1-\gamma) \sin \theta_i}{\sin \theta_i} \right) \right]. \quad (170)$$

This result can be applied to a duct that makes a curved path through the shield by dividing the duct into a series of straight-line segments of length equal to the maximum chord length that can be drawn internal to the duct (Selph 1973). In particular, if the duct is conceptually represented by a series of N equal-length (L) and equally bent (θ) legs, the dose at the duct exit is

$$D(L_N) = (m+1)J_n^+ \mathcal{R}(E_o) \left(\frac{a^{2N} K^{N-1}}{2^N L^{2N}} \right) \left(\frac{\gamma + 2(1-\gamma) \sin \theta}{\sin \theta} \right)^{N-1}. \quad (171)$$

8.8 Empirical and Experimental Results

There is much literature on experimental and calculational studies of gamma-ray and neutron streaming through ducts. In many of these studies, empirical formulas, obtained by fits to the data, have been proposed. These formulas are often useful for estimating duct-transmitted doses under similar circumstances. As a starting point for finding such information, the interested reader is referred to Rockwell (1956), Selph (1973), NCRP (1977, 1984), and Weise (1994).

9 Shield Design

9.1 Shielding Design and Optimization

Shielding design embodies essentially the same considerations as shielding analysis. Both require thorough characterization of radiation sources and receptors as well as comprehensive information on shield properties. Such properties encompass not only the nuclear characteristics but also the thermal properties and certainly, structural properties. Shield optimization may have the goal of minimizing weight, volume, or cost. Minimum weight is a common goal, but it is easy to envision cases where shield volume or shield cost might control.

Source characterization is a major task. Usually, the source emits gamma rays or a mixture of neutrons and gamma rays. In either case, the energy spectra and spatial distributions must be known. On occasion, a surface such as the outside of a nuclear reactor pressure vessel is identified as a “(secondary) source surface.” Then, it is necessary to specify angular distribution as well as energy spectrum. When thermal effects are important, it may be necessary to account for charged particles or low-energy X-rays or Auger electrons released from the primary source. Similarly, such low energy particles may be released in the course of reactions taking place as primary radiations are attenuated.

Receptor characterization is another important task. What are dose and dose rate limitations and are they specified at a point or averaged over a region? Does the dose apply to a physical or anthropomorphic phantom? Is the shielding designed to protect workers, individual members of the public, or population groups? Otherwise, is the shielding designed to protect materials or equipment?

Materials characterization poses broad demands for information ranging from nuclear properties to structural properties. Some materials are effective in attenuating gamma rays but ineffective in attenuating neutrons. Therefore, in many instances, composite materials, perhaps homogenous and perhaps layered, are demanded. Thereby, shield geometry – numbers and thicknesses of layers – enters into the shield-optimization problem. Elemental compositions and densities of material components must be known. Cross sections must be known by element. In some cases, for example, dealing with boron- or lithium-shield components, isotopic compositions and cross sections must also be known. Structural properties, including thermal expansion characteristics, must also be known. Other considerations include sensitivity to heat, relative humidity, and radiation damage. Long-term composition changes such as water loss from concrete may also play a role in material selection and shield optimization.

Shield optimization may well be a “brute force” trial-and-error procedure, tempered by experience. As computational resources continue to improve, the trial-and-error approach gains favor. However, there are elegant, well-known optimization procedures calling on the application of variational principles to find an optimal design for the given design criteria and constraints. Blizard (1962) describes shield optimization by weight using methods of variational calculus. Mooney and Schaeffer (1973) also address variational methods and cite a number of applications. Claiborne and Schaeffer (1973) integrate the many design considerations into a comprehensive review of the three distinct phases in reactor shielding design: (1) preliminary conceptual design, (2) correlation of phase (1) with mechanical design to obtain a final conceptual design, and (3) translation of the final conceptual design into a detailed engineering design. In doing so, they draw on the experience of Hungerford (1966) in the design of the shielding for the Enrico Fermi sodium-cooled nuclear power plant. Hungerford (1968) put forth six

principles of shield design to be followed in developing the shield system for a nuclear power reactor:

1. *Reactor Shield Unity*: A shield is an integral part of a reactor system and must be designed at the same time as, and as an entity with, the overall reactor system.
2. *Shield Integrity*: Adjacent parts of a shield, having the same design criteria, must be designed with equal performance characteristics.
3. *Shield Safety*: Because the reactor shield is a safety device and must be considered as a part of the safety system of the reactor, there can be no compromise with expediency in its design.
4. *Shield Accommodation*: A shield should be adapted to provide for the mechanical requirements of the reactor, its supporting structure, and its component systems, without sacrificing the principles of reactor shield unity, shield integrity, or shield safety.
5. *Shield Economy*: The best possible shield should be designed at the lowest possible cost, consistent with the overall reactor design, without sacrificing safety, integrity, or accommodation.
6. *Shield Simplicity*: A shield should be designed to be as simple in configuration as possible, with the minimum number of voids, ducts, and cutouts for the reactor components and auxiliary systems, consistent with the principle of shield accommodation.

Two comprehensive resources for shielding design are Vols. II and III of the Engineering Compendium on Radiation Shielding (Jaeger et al. 1975, 1970). Volume III (1970) addresses the following individual topics in shielding design: the design of shielding for research and testing reactors, stationary power reactors, and ship-propulsion reactors. Also addressed are the design of shipping and storage containers, hot cells, medical irradiation facilities, accelerators, and nuclear fuel processing plants. In the preface to the volume, Jaeger points out that radiation attenuation analysis is a design tool in two states: first, in an approximate comparative assessment of design alternatives, then, in complex engineering considerations reaching a balance between the aspects of safety and economy and the functional requirements of nuclear facilities. Volume II (1975) provides a wealth of information on mechanical, thermal, and technological properties of gamma-ray and neutron shields, as well as optimal choices of shielding materials. Two American National Standards, ANSI/ANS-6.4-2006 and ANSI/ANS-6.4.2-2006, not only address shielding standards but also provide comprehensive guidance on shielding materials and fabrication, especially for concrete.

9.2 Shielding Materials

In this section, essential properties and compositions of shielding materials are summarized. These materials include natural materials such as air, water, and soil as well as materials of construction. Specialized materials for X-ray facilities are addressed, as are special materials for neutron shielding.

9.2.1 Natural Materials

Air and water, the most natural of materials, require an understanding of their shielding properties. Air properties are critical in dealing with design or analysis involving atmospheric skyshine and when irradiated by neutrons. Dry air, at 1 atmosphere and 20°C has a density of 0.00120 g/cm³. Ordinarily ideal gas laws may be applied to account for different temperatures

or pressures as well as to account for humidity. In dry air, weight fractions by element are N: 0.7553, O: 0.2318, C: 0.0001, and Ar: 0.0128. ⁴⁰Ar, present at 0.996 atomic fraction, captures thermal neutrons with the cross section of 0.66 b. The product ⁴¹Ar decays with a half-life of 110 m, releasing a beta particle and, with 99.6% frequency, a 1.293-MeV gamma ray.

Hydrogen present in water with 0.112 weight fraction, captures thermal neutrons with a cross section of 0.33 b and, in the process, releases a 2.23-MeV-capture gamma ray. In a complementary reaction with 2.23-MeV threshold, photoneutrons are produced in the interaction of gamma rays with deuterium.

Soils often find use as radiation shields; however, water content is highly variable, depending on environmental conditions. ➤ [Tables 22](#) and [23](#) list characteristics of a range of soil types. Similarly, untreated wood, though useful for neutron attenuation, loses water over time and is, therefore, generally found unacceptable as a shield material.

9.2.2 Concrete

Cost, density, compressive strength, ease of placement, and effectiveness in attenuation of both neutrons and gamma rays make concrete a highly desirable shielding material. Neutron shielding by concrete and the importance of water (hydrogen) content are addressed earlier in this chapter and is not repeated here. Types of concrete are characterized by the type of aggregate, *siliceous* referring to quartz based aggregate and *calcareous* referring to limestone based aggregate. Table 24 lists components of three types of “ordinary” concrete: NBS Type 03, Type 04, and the current NIST ordinary concrete (Hubbell & Seltzer 2004). Type 04 is commonly cited and appears to be accepted as “representative.” High-density concrete is often used to provide greater attenuation for a given thickness. Additives for this type of concrete include scrap metal such as steel punchings and metallic ores. Magnetite concrete ($\rho = 3.53 \text{ g/cm}^3$) contains in the mix iron oxide to the extent 4900 lb/yd³. Barite concrete ($\rho = 3.35 \text{ g/cm}^3$) contains barium sulfate ore to the extent 5000 lb/yd³. ANSI/ANS-6.4-2006 lists other high-density concretes plus a low-density ($\rho = 2.1 \text{ g/cm}^3$) serpentine concrete for high temperature applications.

Reinforcing steel, or *rebar*, provides tensile strength and adds density to concrete. For gamma-ray shielding, it is generally satisfactory to conceptually homogenize the reinforced concrete. For neutron shielding, however, channeling effects very often call for treatment of the reinforced concrete as a combination of a continuous concrete phase with steel heterogeneities.

9.2.3 Metallic Shielding Materials

Very often it is necessary to address shielding properties of alloy (carbon) steels and stainless steels. Alloy steel has a nominal density of 7.86 g/cm^3 , contains 0.2 to 0.4% carbon by weight plus varying concentrations of Si, Mn, Cr, Ni, Mo, P, and S. Stainless steel, with density typically $7.9\text{--}8.0 \text{ g/cm}^3$, contains up to about 0.08% carbon by weight and large concentrations of Mn, Cr, Ni, and Mo. In the presence of neutrons, cobalt must be held to the lowest concentration possible to prevent activation yielding the gamma-ray emitter ^{60}Co .

Other important metallic shielding materials are lead, tungsten, and uranium. Next to concrete, lead is no doubt the most common shield material. It has low strength, a low melting point (327°C), and a high density (11.34 g/cm^3). Tungsten has high strength and a high melting point (3410°C). Uranium, especially uranium depleted in ^{235}U , has high strength, intermediate melting point (857°C), and a high density ($18.5\text{--}19.0 \text{ g/cm}^3$).

9.2.4 Special Materials for Neutron Shielding

Shielding of epithermal or fast neutrons requires a two stage process. Fast neutrons can rarely be captured or absorbed; thus, it is first necessary to slow neutrons to thermal energies, as the first step, and then to absorb them. The slowing-down process itself may be in two stages. Neutrons with many MeV of energy may be slowed by inelastic scattering with atoms of, for example, iron. This is the removal process discussed in [5.3](#). At neutron energies below about 6 MeV, the elastic scattering cross section of hydrogen exceeds the inelastic scattering cross section of iron. Thus, in addition to a component such as iron, a hydrogenous component is needed for efficient neutron thermalization. Thermal neutrons are readily captured, unfortunately, in most instances releasing high-energy capture-gamma rays. Thus, for an effective neutron shield, a strong absorber such as boron or lithium, perhaps indium or cadmium, is needed to avoid significant capture-gamma rays.

Boron for Neutron Attenuation

Natural boron contains 19.9 atomic percent ^{10}B and 80.1 percent ^{11}B , the former with a 3840-b (2200-m/s) absorption cross section, the latter with only 5 mb. The absorption of a neutron by ^{10}B releases a 0.48-MeV gamma ray – significant, but of lower energy than most capture gamma rays. Boron shielding materials are available in the form of boron carbide, B_4C , with density 2.51 g/cm^3 , borated graphite, boron carbide mixed in graphite, and boral (a mixture of boron carbide in aluminum cladding). Plates or sheets of boral commonly contain 35% boron by weight and are available up to 1 by 3 m^2 in area and thicknesses of 0.125 and 0.25 in. Boron shielding is also available as borated polyethylene in a wide range of shapes and compositions, in a wide range of boron concentrations, and even in castable form. For mixed neutron and gamma-ray shielding, lead-loaded borated polyethylene is also available.

Lithium for Neutron Attenuation

Natural lithium contains 7.5 atomic percent ^6Li and 92.5 percent ^7Li . The former has an exceptionally high cross section (941 b) for thermal-neutron absorption and

produces no secondary gamma rays. It is light in weight and available enriched in ^6Li . It is offered commercially as lithium polyethylene, with 7.5% lithium by weight and in a variety of shapes.

9.2.5 Materials for Diagnostic X-Ray Facilities

There are six materials of prime concern in the design of diagnostic facilities. Of these, concrete, steel, and lead have already been addressed. Others are wood, plate glass, and gypsum wallboard. Shielding design considerations are documented by Jaeger et al. (1975), Archer et al. (1994), and NCRP (2005).

Depending on hydrogen content, wood density varies from 0.5 to 0.8, nominally 0.55 g/cm^3 , and is essentially cellulose, water, and lignin. Crown glass, a silica soda lime glass, is durable and has a low index of refraction. Density is $2.5\text{--}2.7\text{ g/cm}^3$. Lead oxide may be added at up to about 0.75 weight fraction Pb to yield lead glass with density up to about 6.2 g/cm^3 . Sheets are available with lateral dimensions up to about 140 cm and thicknesses up to about 40 cm. Plaster board, or gypsum wallboard, has a density typically 2.32 g/cm^3 . By weight fraction, gypsum composition is H 0.0234, O 0.5576, S 0.1862, and Ca 0.2328. Typical thickness is 14 mm of gypsum plus 1 mm of paper. Sheets may be lined with lead in thicknesses 1/32 in to 1/8 in.

9.3 A Review of Software Resources

Listed below are selected software packages of interest in shielding design and analysis. All are available from the Radiation Safety Information Computational Center, accessible on line at <http://www-rsicc.ornl.gov/>.

- **QAD-CGGP**: point kernel code featuring combinatorial 3D geometry and source options with geometric progression buildup factors for gamma rays
- **QADMOD-GP**: point kernel code featuring faster 3D geometry and source options with geometric-progression buildup factors for gamma rays
- **G-33**: point kernel code featuring multi-group gamma-ray scattering with QAD geometry and GP-buildup factors
- **ISOSHLD**: point kernel code featuring multiple isotope sources, limited geometry, and source description
- **DOORS**: discrete ordinates code package incorporating ANISN, DORT, and TORT codes for 1, 2, and 3D discrete ordinates calculations
- **PARTISN**: discrete ordinates code featuring multidimensional, time-dependent, multigroup discrete ordinates transport code system
- **COHORT**: Monte Carlo code featuring radiation transport; flexible geometry
- **MORSE**: Monte Carlo code featuring multigroup neutron and gamma-ray transport; combinatorial geometry
- **MCNP**: Monte Carlo code featuring continuous energy, neutral particle transport; flexible geometry
- **ORIGEN**: neutron activation code featuring neutron activation, radioactive decay, and source-term analysis

9.4 Shielding Standards

Listed below are ANSI/ANS standards pertinent to shielding design. Standards 6.4 and 6.4.2 cite standards of other sponsors such as ASME and IEEE as well as selected international standards.

- ANSI/ANS-5.1-2005: Decay Heat Power in Light Water Reactors
- ANSI/ANS-6.1.2-1999: Neutron and Gamma-Ray Cross Sections for Nuclear Radiation Protection Calculations for Nuclear Power Plants
- ANSI/ANS-6.3.1-1987;R1998;R2007 (R=Reaffirmed): Program for Testing Radiation Shields in Light Water Reactors (LWR)
- ANSI/ANS-6.4-2006: Nuclear Analysis and Design of Concrete Radiation Shielding for Nuclear Power Plants
- ANSI/ANS-6.4.2-2006: Specification for Radiation Shielding Materials
- ANSI/ANS-6.6.1-1987;R1998;R2007 (R=Reaffirmed): Calculation and Measurement of Direct and Scattered Gamma Radiation from LWR Nuclear Power Plants
- ANSI/ANS-18.1-1999: Radioactive Source Term for Normal Operation for Light Water Reactors
- ANSI/ANS-19.1-2002: Nuclear Data Sets for Reactor Design Calculations
- ANSI/ANS-19.3.4-2002: The Determination of Thermal Energy Deposition Rates in Nuclear Reactors

10 Health Physics

As it passes through biological tissue, radiation interacts with ambient atoms and produces chemical free radicals that, in turn, cause oxidation–reduction reactions with cell biomolecules. However, how such reactions affect the cell and produce subsequent detrimental effects to an organism is not easily determined. Because of the obvious concern about the biological effects of radiation, much research has been directed toward understanding the hazards associated with ionizing radiation.

There are two broad categories of radiation hazards to humans. *Hereditary effects* result in damage to the genetic material in germ cells that, although not detrimental to the individual exposed, may result in hereditary illness to succeeding generations. *Somatic effects* affect the individual exposed and are further classified by the nature of the exposure, for example, *acute* or *chronic*, and by the time scale of the hazard, for example, short term or long term. The short-term acute effects on the gastrointestinal, respiratory, and hematological systems are referred to as the *acute radiation syndrome*.

The effects of human exposure to ionizing radiation depend on both the exposure as well as its duration. Acute, life-threatening exposures lead to *deterministic* consequences requiring medical treatment. For such exposures, illness is certain, with the type and severity depending on the exposure and the physical condition of the individual exposed.

By contrast, minor acute or chronic low-level exposures produce stochastic damage to cells and subsequent ill effects are quantifiable only in a probabilistic sense; hereditary illness or cancer may or may not occur. Only the probability of illness, not its severity, is dependent on the radiation exposure. Such consequences are, thus, *stochastic* as distinct from *deterministic*. Although the effects of low-level radiation exposures to a large number of individuals can be estimated, the effect to a single individual can be described only probabilistically.

10.1 Deterministic Effects from Large Acute Doses

There are two circumstances under which a person can receive high doses of ionizing radiation. The first is accidental, and most likely involves a single exposure of short duration. The second is from medical treatments, and often involves doses delivered daily for several weeks and which may be delivered under conditions designed to intensify the response of certain organs and tissues to the exposures. Here, only single acute exposures to all or part of the body are considered. Issues such as fractionation and effect modification, which pertain largely to medical exposures, are not addressed.

10.1.1 Effects on Individual Cells

The probability that a particular radiation exposure kills a cell or prevents it from dividing depends on many factors. The two most important factors are the dose rate and the LET of the radiation. Doses delivered at low dose rates allow the cell's natural repair mechanism to repair some of the damage, so that the consequences are generally not as severe as if the doses were delivered at high dose rates. High LET radiation, like alpha particles, creates more ion–electron pairs closer together than does low LET radiation. Consequently, high LET radiation produces more damage to a cell it passes through than would, say, a photon.

The position in a cell's life cycle at the time of exposure also greatly affects the damage to the cell. Cell death is more likely if the cell is in the process of division than if it is in a quiescent state. Thus, radiation exposure results in more cell death in organs and tissues with rapidly dividing cells, such as the fetus (especially in the early stages of gestation), the bone marrow, and the intestinal lining. Whole-body absorbed doses of several Gy are life-threatening largely because of stem cell killing in the bone marrow and lining of the intestines. However, in these tissues and in most other tissues and organs of the body, there are ample reserves of cells, and absorbed doses of much less than one Gy are tolerable without significant short-term effect. Similarly, radiation doses which would be fatal if delivered in minutes or hours may be tolerable if delivered over significantly longer periods of time. Age, general health, and nutritional status are also factors in the course of events following radiation exposure.

For those tissues of the body for which cell division is slow, absorbed doses which might be fatal if delivered to the whole body may be sustained with little or no effect. On the other hand, much higher absorbed doses may lead ultimately to such a high proportion of cell death that, because replacement is so slow, structural or functional impairment appears perhaps long after exposure and persists perhaps indefinitely.

10.1.2 Deterministic Effects in Organs and Tissues

In this section, only deterministic somatic effects – effects in the person exposed – are considered. These effects have well-defined patterns of expression and thresholds of dose, below which the effects do not occur. The severity of the effect is a function of dose. The stochastic carcinogenic and genetic effects of radiation are addressed later.

The risk, or probability of suffering a particular effect or degree of harm, as a function of radiation dose above a threshold dose D_{th} , can be expressed in terms of a 50th-percentile dose D_{50} , or median effective dose, which would lead to a specified effect or degree of harm in half the persons receiving that dose. The D_{50} dose depends, in general, on the rate at which the dose is received. For doses below a threshold dose D_{th} , the effect does not occur.

A summary of important deterministic effects is given in [Table 25](#). Information about these and other effects on particular organs and tissues can be found in the following sources: Information is taken from the following sources: (Langham 1967; Upton and Kimball 1967; Wald 1967; NCRP 1971a; Vogel and Motulsky 1979; Pochin 1983; ICRP 1984, 1991; UN 1988; Shultis and Faw 2008).

10.1.3 Potentially Lethal Exposure to Low-LET Radiation

The question of what constitutes a *lethal dose* of radiation has, of course, received a great deal of study. There is no simple answer. Certainly, the age and general health of the exposed person are key factors in the determination. So, too, are the availability and administration of specialized medical treatment. Inadequacies of dosimetry make interpretation of sparse human data difficult. Data from animal studies, when applied to human exposure, are subject to uncertainties in extrapolation. Delay times in the response to radiation, and the statistical variability in response have led to expression of the lethal dose in the form, for example, $LD_{50/60}$, meaning the dose is fatal to 50% of those exposed within 60 days. The *dose* itself requires a careful interpretation. One way of defining the *dose* is the free-field exposure, in roentgen units, for gamma or

Table 25

Median effective absorbed doses D_{50} and threshold doses D_{th} for exposure of different organs and tissues in the human adult to gamma photons at dose rates $\leq 0.06 \text{ Gy h}^{-1}$

Organ/Tissue	Endpoint	D_{50} (Gy)	D_{th} (Gy)
Skin	Erythema	6 ± 1	3 ± 1

	Diarrhea	3 ± 0.8	1
GI system	Death	15 ± 5	8
	Death	3.8 ± 0.6	1.8 ± 0.3

^aDose rate 0.5 Gy/h

Source: Scott and Hahn (1989)

X-rays. A second is the average absorbed dose to the whole body. A third is the *mid-line* absorbed dose, that is, the average absorbed dose near the abdomen of the body. For gamma rays and X-rays, the mid-line dose, in units of rads, is about two-thirds the free-field exposure, in units of roentgens. The evaluation by Anno et al. (1989) for the lethal doses of ionizing radiation are given in ► [Table 26](#). The effects of large doses below the threshold for lethality are summarized in NCRP Report 38 (1971) and by Anno et al. (1989). For extremely high doses (>500 Gy), death is nearly instantaneous, resulting from enzyme inactivation or possibly from immediate effects on the electrical response of the heart (Kathren 1985). Lesser, but still fatal doses, lead promptly to symptoms known collectively as the *prodromal syndrome*. The symptoms, which are expressed within a 48-h period are primarily gastrointestinal (e.g., nausea, diarrhea, cramps, and dehydration) and neuromuscular (e.g., fatigue, sweating, fever, headache, and hypotension). For high doses with potential survival, the prodromal stage is followed by a latent stage, a stage of manifest illness, and a recovery stage beyond 6–8 weeks post-exposure.

10.2 Hereditary Illness

In 1927, Hermann Muller discovered that fruit flies receiving high doses of radiation could produce offspring with genetic abnormalities. Subsequent animal and plant studies have demonstrated a nearly linear relationship between dose and mutation frequency, for doses as low as 3 mSv. However, there is almost no evidence of radiation-induced mutations in humans. Indeed, the only unequivocal evidence relates to chromosomal rearrangement in spermatocytes. Nevertheless, animal studies clearly indicate that radiation can produce heritable mutational effects in the humans. Because radiation-induced mutation rates in humans are unknown, even for atom bomb survivors, estimation of risks to human populations are based largely on extrapolation of studies of radiation effects in other mammals, notably the mouse. The estimation of human hereditary risks from animal studies involve many assumptions, and the estimates turn out to be a very small fraction of the natural incidence of such illness, thereby, explaining why radiation-induced hereditary illness has not been observed in humans.

■ **Table 26**
Lethal doses of radiation

Lethality	Mid-line absorbed dose (Gy)
$LD_{5/60}$	2.0–2.5
$LD_{10/60}$	2.5–3.0
$LD_{50/60}$	3.0–3.5
$LD_{90/60}$	3.5–4.5
$LD_{99/60}$	4.5–5.5

10.2.1 Classification of Genetic Effects

► *Table 27* reports estimates of the natural incidence of human hereditary or partially hereditary traits causing serious handicap at some time during life. Inheritance of a deleterious trait results from mutation(s) in one or both maternal and paternal lines of germ cells. Here a mutation is either a microscopically visible chromosome abnormality or a submicroscopic disruption in the DNA making up the individual genes within the chromosomes. Mutations take place in both germ cells and somatic cells, but only mutations in germ cells are of concern here.

Regularly inherited traits are those whose inheritance follows Mendelian laws. These are autosomal dominant, X-linked, and recessive traits. Examples of autosomal dominant disorders, that is, those which are expressed even when the person is heterozygous for that trait, are certain types of muscular dystrophy, retinoblastoma, Huntington's chorea, and various skeletal malformations. Examples of recessive disorders, that is, those which are expressed only when the individual is homozygous for the trait, include Tay-Sachs disease, phenylketonuria, sickle-cell anemia, and cystic fibrosis. X-linked disorders, that is, those traits identified with genes in the X chromosome of the X-Y pair and which are expressed mostly in males, include hemophilia, color blindness, and one type of muscular dystrophy. In the X-Y chromosome pair, otherwise recessive genetic traits carried by the "stronger" maternal X chromosome are expressed as though the traits were dominant. *Chromosome abnormalities* are of two types:

■ **Table 27**

Genetic risks from continuing exposure to low-LET, low-dose, or chronic radiation as estimated by the BEIR and UNSCEAR committees on the basis of a doubling-dose of 1 Gy

Type of Disorder	Per million progeny		
	Natural frequency	Cases/Gy in first generation	Cases/Gy in second generation ^a
Mendelian autosomal			
Dominant and X-linked	16,500	750–1500	1300–2500
Recessive	7,500	0	0
Chromosomal	4,000	^b	^b
Irregularly inherited traits			
Chronic multifactorial	650,000	250–1200	250–1200
Congenital abnormalities	60,000	2000	2400–3000
Total	738,000	3000–4700	3950–6700
Total risk (% of baseline)		0.41–0.64	0.53–0.91

^aRisk to the second generation includes that to the first except for congenital abnormalities for which it is assumed that between 20% and 50% of the abnormal progeny in the first generation may transmit the damage to the second post-radiation generation, the remainder causing lethality.

^bAssumed to be included with Mendelian diseases and congenital abnormalities.

Source: UN (2001); adopted by NAS (2006) and ICRP (2007)

those involving changes in the numbers of chromosomes and those involving the structure of the chromosomes themselves. Down syndrome is an example of the former. With natural occurrence, numerical abnormalities are more common. By contrast, radiation-induced abnormalities are more frequently structural abnormalities.

There is a very broad category comprising what are variously called *irregularly inherited traits*, multifactorial diseases, or traits of complex etiology. This category includes abnormalities and diseases to which genetic mutations doubtlessly contribute, but which have inheritances much more complex than result from chromosome abnormalities or mutations of single genes. They are exemplified by inherited predispositions for a wide variety of ailments and conditions. One or more other multifactorial disorders, including cancer, are thought to afflict nearly all persons sometime during life; however, the mutational components of these disorders are unknown even as to orders of magnitude (NAS 1990). Also included in [▶ Table 27](#) is a subgroup of irregularly inherited traits identified as *congenital abnormalities*. These are well-identified conditions such as spina bifida and cleft palate, with reasonably well-known degrees of heritability.

10.2.2 Estimates of Hereditary Illness Risks

[▶ Table 27](#) also summarizes the 2001 UNSCEAR genetic risk estimates. The results are for low LET radiation (quality factor $Q = 1$); thus, the absorbed dose and dose equivalent are the same. These estimates are based on a population-averaged *gonad*-absorbed dose of 1 Gy (100 rad) to the reproductive population which produce one-million live-born. Because of the linearity of the dose-effect models used, these estimated hereditary risks are the same whether the gonad dose is received in a single occurrence or over the 30-year reproduction interval. The population for these results is assumed static in number, so that one million born into one generation replace one million in the parental generation.

Data in [▶ Table 27](#) give the expected number of genetic illness cases appearing in the first and second generations, each receiving radiation exposure. Except as indicated, cases in the second generation include the new cases from exposure of the first generation plus cases resulting from exposure of the previous generation, for example, 550–1000 cases of autosomal dominant and X-linked class and no cases of the autosomal recessive class. The ICRP (2007) suggests overall risk coefficients for heritable disease up to the second generation as 0.002 Sv^{-1} for the whole population and 0.001 Sv^{-1} for adult workers.

10.3 Cancer Risks from Radiation Exposures

A large body of evidence leaves no doubt that ionizing radiation, when delivered in high doses, is one of the many causes of cancer in the human. Excess cancer risk cannot be observed at doses less than about 0.2 Gy and, therefore, risks for lower doses cannot be determined directly (UN 1988). At high doses, in almost all body tissues and organs, radiation can produce cancers that are indistinguishable from those occurring naturally. Consequently, radiation-induced cancer can be inferred only from a statistical excess above natural occurrence. [▶ Table 28](#) summarizes natural incidence and mortality for the male and female. ICRP Report 103 (2007) provides comprehensive age and gender dependent incidence and mortality data for Euro-American and Asian populations.

■ **Table 28**

Annual cancer incidence and death rates per 100,000 population in the 2002 United States population

Primary site	Incidence per 10 ⁵ per year		Deaths per 10 ⁵ per year	
	Males	Females	Males	Females
Leukemia	14.6	8.8	10.1	5.7
Lymphoma	25.1	17.9	10.2	6.5
Respiratory	94.7	55.8	76.2	42.2
Digestive	106.9	71.4	59.1	35.9

Genital	167.3	48.9	28.6	16.7
Urinary	56.3	19.1	13.9	5.3
Other	80.6	58.2	41.8	24.9
Total	545.5	405.0	239.9	162.7

Source: HHS (2005)

There is a large variation in the sensitivity of tissues and organs to cancer induction by radiation. For whole-body exposure to radiation, solid tumors are of greater numerical significance than leukemia. The excess risk of leukemia appears within a few years after radiation exposure and largely disappears within 30 years after exposure. By contrast, solid cancers, which occur primarily in the female breast, the thyroid, the lung, and some digestive organs, characteristically have long latent periods, seldom appearing before 10 years after radiation exposure and continuing to appear for 30 years or more. It is also apparent that age at exposure is a major factor in the risk of radiation-induced cancer. Various host or environmental factors influence the incidence of radiation-induced cancer. These may include hormonal influences, immunological status, and exposure to various oncogenic agents.

10.3.1 Estimating Radiogenic Cancer Risks

Our knowledge about radiation-induced cancer is based on epidemiological studies of people who have received large radiation doses. These populations include atomic bomb survivors, radiation therapy patients, and people who have received large occupational doses. Some 91,000 survivors of the atomic weapon attacks on Hiroshima and Nagasaki and their offspring remain under continuing study, and much of our knowledge about radiation-induced cancer derives from this group. Occupational groups include medical and industrial radiologists and technicians, women who ingested large amounts of radium while painting instrument dials during World War I, and miners exposed to high concentrations of radon and its daughter radionuclides. Finally, radiation therapy patients have provided much information on radiation carcinogenesis. These include many treated with X-rays between 1930 and 1950 for severe spinal arthritis, Europeans given ²²⁶Ra injections, and many women given radiation therapy for cervical cancer.

10.4 The Dose and Dose-Rate Effectiveness Factor

Assessment of cancer risks from radiation exposure is concerned primarily with exposures of population groups to low doses at low dose rates. As just indicated, however, there is little choice but to base risk estimates on consequences of exposures at high doses and dose rates. Furthermore, organizations such as the ICRP and the NCRP have endorsed, and government organizations have agreed, to base risk estimates on a linear no-threshold relationship between cancer risk and radiation dose. An exception applies to radiation-induced leukemia, for which a quadratic, no-threshold relationship has been adopted. How does one reconcile low-dose risk estimates based on high-dose data? The answer is addressed in [Fig. 47](#). Symbols display a limited base of data for high doses and dose rates. A central curved line displays what may be the true dose response (say a linear quadratic relationship). The upper straight line, with slope α_H is the linear, no-threshold approximation for the high-dose data. The lower straight line, with slope α_L is tangent to the true response curve in the limit of low dose and low-dose rate, conditions allowing for partial repair of radiation damage. Risks at low doses and dose rates, if computed on the basis of α_H , need to be corrected by division by the ratio α_H/α_L defined as the *DDREF*, the *dose and dose rate correction factor*.

10.4.1 Dose-Response Models for Cancer

Evidence is clear that absorbed doses of ionizing radiation at levels of 1 Gy or greater may lead stochastically to abnormally high cancer incidence in exposed populations. However, there is no direct evidence that chronic exposure to low levels of ionizing radiation may likewise lead to abnormally high cancer incidence. Risk estimates for chronic, low-level exposure requires extrapolation of high-dose and high-dose-rate response data to low doses. Methods used for extrapolation are often controversial, any one method being criticized by some as overpredictive and by others as underpredictive.

Figure 47
Basis for the dose and dose-rate effectiveness factor

Current risk estimates for cancer have as the basic elements dose responses that are functions of the cancer site or type, the age a_o (y) at exposure, the age a (y) at which the cancer is expressed or the age at death, and the sex s of the subject. The radiogenic cancer risk is expressed as

$$\text{risk} = R_o(s, a) \times EER(D, s, a_o, a). \quad (172)$$

Here, R_o is the natural cancer risk as a function of sex, site, and age at cancer expression, for both incidence and mortality; and EER is the *excess relative risk* function that is determined by fitting a model to observed radiogenic cancer incidence or mortality for cancer at a particular site. For example, the excess relative risk for all solid cancer, except thyroid and nonmelanoma skin cancer, is expressed as (NAS 2006)

$$ERR(D, s, a_o, a) = \beta_s D \exp[e^* \gamma] (a/60)^\eta, \quad (173)$$

in which D is the dose in Sv. In this particular model, the empirical parameter $e^* = (a_o - 30)/10$ for $a_o < 30$ and zero for $a_o \geq 30$. Parameters β_s , γ , and η depend on whether the estimate is for incidence or mortality. For example, for cancer incidence, $\gamma = -0.30$, $\eta = -1.4$, and $\beta_s = 0.33$ for males and 0.57 for females.

To use (172), the natural risk $R_o(s, a)$ for the type of cancer of concern must be known. Data for natural risk are available, but are too extensive to be presented here. They may be found in publications of the Centers for Disease Control (HHS 2005) and on-line at <http://www.cdc.gov/cancer/ncpr/uscs> or <http://seer.cancer.gov/statistics>. For example, US death rates per 100,000 US males, for all races and all cancer sites combined increase from 2.1 for infants to 11.3 at age 30–34, and 520 at age 60–64. For females, the corresponding rates are 1.6, 13.8, and 382, respectively.

It should be emphasized that, in examining these risks of cancer from radiation exposure, one should keep in mind the overall or natural risk of cancer. As indicated in **► Table 28**, two persons per thousand in the United States die each year from cancer. As will be seen in the next section, the overall lifetime risk of cancer mortality is about one in five for males and about one in six for females.

10.4.2 Average Cancer Risks for Exposed Populations

The BEIR-VII Committee of the National Academy of Sciences (NAS 2006) made various estimates of the risk of excess cancer incidence and mortality resulting from low-LET (gamma-ray) exposures. These risks are summarized in **► Table 29** by sex and by age at exposure. Although the data are for conditions of low dose and dose rate, they were generated in large part from cancer incidence and mortality experienced by survivors of atomic weapons at Hiroshima and Nagasaki. At lower doses and dose rates, risks are somewhat less because biological repair mechanisms can repair a greater fraction of the genetic damage produced by the radiation. This effect is accounted for in risk estimates for leukemia, which are based on a linear-quadratic dose–response model. For solid cancers, risks have been modified by application of a dose and dose-rate effectiveness factor, namely, by dividing high-dose and dose-rate data by the DDREF value of 1.5. The ICRP (1991, 2007) continues to recommend a DDREF value of 2.0.

The BEIR-VII Committee also calculated risks to the US population under three low-LET exposure scenarios: (1) single exposure to 0.1 Gy, (2) continuous lifetime exposure to 1 mGy

Table 29

Excess lifetime cancer incidence and mortality for the US population by age at exposure for a whole-body dose of 0.1 Gy (10 rad) from low LET radiation to populations of 10^5 males or females

	Age at exposure (years)								
	0	10	20	30	40	50	60	70	80
Females									
Incidence									
Leukemia	185	86	71	63	62	62	57	51	37

Source: based on (NAS 2006)

per year, and (3) exposure to 10 mGy per year from age 18 to age 65. Results are summarized in Table 30. The first scenario is representative of accidental exposure of a large population (the 1999 US population), the second of chronic exposure, and the third of occupational exposure. For example, for leukemia mortality, with 95% confidence limits (not given in Table 30), for a single exposure of the US population to 0.1 Gy, the risk per 100,000 is 70 (20–220) for the male and 50 (10–190) for the female. For nonleukemia mortality per 100,000 fatalities are 410 (200–830) for the male and 610 (300–1200) for the female. For this case, the total low-dose cancer mortality risk for the US population is $0.5 \times (480 + 660) / (0.1 \text{ Gy} \times 10^5) = 0.057$ per Gy, which can be rounded to 0.05 per Gy, or 5×10^{-4} per rem. This risk should be used as an overall cancer risk factor for environmental exposures, that is, small exposures obtained at low dose rates. The ICRP (2007) nominal risk recommendations are 0.055 Sv^{-1} for the whole population and 0.041 Sv^{-1} for adult workers.

10.5 Radiation Protection Standards

It was recognized near the beginning of the twentieth century that standards were needed to protect workers and patients from the harmful consequences of radiation. Many sets of standards, based on different philosophies, have been proposed by several national and international

■ Table 30

Excess cancer incidence and mortality per 100,000 males and 100,000 females in the stationary US population for three low-dose exposure scenarios

Cancer Type	Cases per 10 ⁵		Deaths per 10 ⁵	
	Males	Females	Males	Females
Single Exposure to 0.1 Gy (10 rad):				
Radiation Induced:				
leukemia	100	70	70	50
nonleukemia	800	1300	410	610
total	900	1370	480	660
Natural Expectation:				
leukemia	830	590	710	530
nonleukemia	45500	36900	22100	17500
total	46330	37490	22810	18030
Continuous Lifetime Exposure to 1 mGy (100 mrad) per year:				
Radiation Induced:				
leukemia	67	51	47	38
nonleukemia	554	968	285	459
total	621	1019	332	497
Continuous Exposure to 10 mGy (1 rad) per year from age 18 to 65:				
Radiation Induced:				
leukemia	360	270	290	220
nonleukemia	2699	4025	1410	2169
total	3059	4295	1700	2389

Source: based on (NAS 2006)

standards groups. The earliest standards were based on the concept of *tolerable doses* below which no ill effects would occur. This was replaced in 1948 by the National Council on Radiation Protection and Measurements (NCRP) in the United States which introduced standards based on the idea of *permissible doses*, that is, a dose of ionizing radiation which was not expected to cause appreciable body injury to any person during his or her lifetime.

10.5.1 Risk-Related Dose Limits

Today it is understood that low-level radiation exposure leads to stochastic hazards and that modern radiation standards should be based on probabilistic assessments of radiation hazards.

This new line of thinking is exemplified by a 1972 report to the ICRP by the Task Group on Dose Limits. Key portions of the report are summarized as follows. It must be noted that the report is unpublished and not necessarily reflective of the official ICRP position. The tentative dose limits examined in the report were not based on explicit balancing of risks and benefits, then thought to be an unattainable ideal. Rather, they were based on the practical alternative of identifying acceptable limits of occupational radiation risk in comparison with risks in other occupations generally identified as having a high standard of safety and also having risks of environmental hazards generally accepted by the public in everyday life.

Linear, no-threshold dose-response relationships were assumed for carcinogenic and genetic effects, namely, a 1×10^{-4} probability per rem whole-body dose equivalent for malignant illness or a 4×10^{-5} probability per rem for hereditary illness within the first two generations of descendants (ICRP 1977). For other radiation effects, absolute thresholds were assumed.

To illustrate the reasoning for risk-based limits, consider the occupational whole-body dose-equivalent limit of 5 rem/y. For occupational risks, it was observed that “occupations with a high standard of safety” are those in which the average annual death rate due to occupational hazards is no more than 100 per million workers. An *acceptable risk* was taken as 50 per million workers per year, or a 40-year occupational lifetime risk of 2 fatalities per 1000 workers, that is, 0.002. It was also observed that in most facilities in which radiation may expose workers, the average annual doses are about 10 percent of the doses of the most highly exposed individuals, with the distribution highly skewed toward the lower doses. To ensure an *average* lifetime risk limit of 0.002, an upper limit of 10 times this value was placed on the lifetime risk for any one individual. The annual whole-body dose-equivalent limit for stochastic effects was thus taken as $(10 \times 0.002)/(40 \text{ y} \times 0.01 \text{ malignancies/Sv}) = 0.05 \text{ Sv}$ (5 rem) per year. Similar reasoning is used to set public dose limits and limits for nonstochastic effects (Shultis and Faw 2008).

10.5.2 The 1987 NCRP Exposure Limits

The concept of “risk-based” or “comparable-risk” dose limits provides the rationale for the 1977 ICRP and the 1987 NCRP recommendations for radiation protection, and which serve as the present basis for the US radiation protection standards. A summary of these dose limits is given in [▶ Table 31](#).

Acknowledgments

The authors of this chapter gratefully acknowledge the guidance and support of their colleagues and mentors in the field of radiation shielding and radiation protection. The late Arthur Chilton, our colleague and friend, will be known to readers of this chapter for his breadth of interest and experience in radiation shielding. He was the coauthor of and the inspiration for our first book on radiation shielding. Of the many who taught us, we particularly acknowledge Lewis Spencer, Martin Berger, Herbert Goldstein, and Norman Schaeffer. We acknowledge the American Nuclear Society too for their continuing publication of our textbooks on radiation shielding and radiological assessment, from which much of the material in this chapter has been taken.

■ **Table 31**
The 1987 NCRP recommendations for exposure limits

Type of Dose	mSv	rem
<i>Occupational exposures (annual):</i>		
1. Limit for stochastic effects	50	5
2. Limit for nonstochastic effects:		
a. Lens of the eye	150	15
b. All other organs	500	50
3. Guidance: cumulative exposure age (y) ×	10	1
<i>Public exposures (annual):</i>		
1. Continuous or frequency exposure	1	0.1
2. Infrequent exposure	5	0.5
3. Remedial action levels	5	0.5
4. Lens of the eyes, skin and extremities	50	5
<i>Embryo–fetus exposure:</i>		
1. Effective-dose equivalent	5	0.5
2. Dose-equivalent limit in a month	0.5	0.05
<i>Negligible individual risk level (annual):</i>		
1. Effective-dose equivalent per source or practice	0.01	0.001

Abstract: The aim of this chapter is to give some key points on the use of high performance computing (HPC) in the field of nuclear engineering.

This chapter is divided into two main parts. This first one is an introduction to parallel computing. In this first part, we will describe not only the main computer and processor architectures which are used today but also some which are not so usual but which will allow the readers to better understand the key point of parallelism from the hardware point of view. Still in this first part, we will continue by describing the main parallelism models, in the same point of view as the description of the parallel architecture. In [Sect. 4](#), we will give some basic ideas on how to design parallel programs. This section is the last of the first part.

The second part is dedicated to the use of high performance computing in nuclear engineering. We will give first the main challenges which can be addressed using HPC. Some of them are illustrated in [Sect. 6](#) on some of the main scientific domains in nuclear engineering (reactor physics, material sciences and thermal-hydraulic). For each of them we have tried to describe the main problems which can be addressed using HPC but some of them remain as scientific and industrial challenges.

1 Introduction

The aim of this chapter is to give some key points on the use of high performance computing (HPC) in the field of nuclear engineering.

In this chapter we will give an introduction to high performance computing, by describing the main computer and processor architectures, parallel programming models, and some elements concerning the design of parallel software.

After this short introduction to parallel computing, we will discuss the main challenges concerning HPC in nuclear engineering and give illustrations of them in three main fields, namely, reactor physics, computational fluid dynamics, and material sciences.

2 Main Computer and Processor Architectures

2.1 Main Architecture Classes for High Performance Computing

One of the main ways to classify the different kinds of architectures is the well-known Flynn's classification (Butenhof 1997; Duncan 1990). Flynn's taxonomy (Flynn 1972) is a classification of computer architectures, proposed by Michael J. Flynn in 1966. The four classifications defined by Flynn are based upon the number of concurrent instruction (or control) and data streams available in the architecture ([Table 1](#)). This classification can be summarized as follows:

- Single Instruction, Single Data stream (SISD): A sequential computer which exploits no parallelism in either the instruction or data streams. Examples of SISD architecture are the traditional uni-processor machines like a PC or old mainframes.
- Single Instruction, Multiple Data streams (SIMD): A computer which exploits multiple data streams against a single instruction stream to perform operations which may be naturally parallelized, for example, an array processor or graphical processor unit (GPU).

Table 1
Flynn's classification

		Data flow	
		Simple	Multiple
Instruction flow	Simple	SISD	SIMD
	Multiple	MISD	MIMD

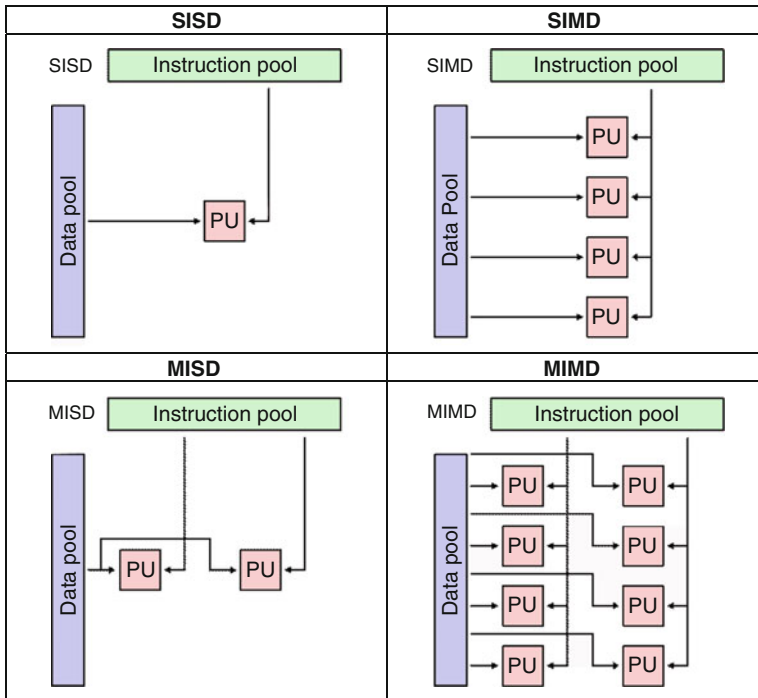

Figure 1
Flynn's classification

- Multiple Instruction, Single Data stream (MISD): This architecture is rarely seen due to the fact that multiple instruction streams generally require multiple data streams to be effective. However, this architecture is used for systems requiring redundant parallelism, as for example on airplanes that need to have several backup systems in case one fails. Some theoretical computer architectures have also been proposed which make use of MISD, but none have entered mass production.
- Multiple Instruction, Multiple Data streams (MIMD): Multiple autonomous processors simultaneously executing different instructions on different data (➤ Fig. 1). Distributed systems are generally recognized to be MIMD architectures, either exploiting a single shared memory space or a distributed memory space.

Today, even PC could not be considered as SISD architecture, since standard processors execute at least two instructions per cycle.

Most of the existing architectures are now MIMD architectures. Some processors, like GPU (Hong and Kim 2009), accelerators, Cell (Gschwind et al. 2006), etc. are considered as SIMD processor architectures.

Concerning today's architecture, other possible classifications exist. One of them is the following:

- Standard components architecture: based on standard processors and interconnection networks
- Semi-custom architectures: based on standard processors and specific interconnection networks
- Full-custom architectures: based on specific processors and interconnection networks

In principle, full-custom architectures should be the most performing but also the most expensive, since the development time is greater, and the market for this kind of architecture is thinner.

The readers can find in (Leighton 1992; King et al. 1988; Hwang 1993) many details and explanations on parallel computer architecture.

2.2 SIMD Architectures

As presented below, SIMD architectures are based on a unique synchronism mechanism (🔍 Figs. 2 and 🔍 Figure 3). At each clock cycle the same instruction is executed by all the processing units on the data located in the processing unit. One of the best examples of this kind of architecture in the past is the CM2 (Hillis 1982; Tucker and Robertson 1988; Trew and Wilson 1991). This kind of architecture is similar to systolic arrays. SIMD architectures had all but disappeared with the emergence of standard component architectures, but they should be reexamined with the emergence of custom processing units, like GPGPU (Hong and Kim 2009).

🔍 Figure 2
SIMD architecture

■ Figure 3
CM2 machine

■ Figure 4
Shared memory MIMD architecture model

2.3 MIMD Architectures

In MIMD architecture, the different computing units are dealing with different instructions and different data at the same time. Moreover, no more global synchronization is needed, since each computing unit is independent.

There exist different architectures based on this model:

- Shared memory multiprocessors (SMP): each computing unit shares the same memory (see [▶ Fig. 4](#))
- Distributed memory multiprocessors: each computing unit has its own memory (see [▶ Fig. 5](#))
- Hybrid MIMD architecture: a combination of the two previous architecture models. Computing units are gathered into shared memory nodes. These nodes are then linked using distributed memory architecture model (see [▶ Fig. 6](#)).

Figure 5
Distributed memory MIMD architecture model

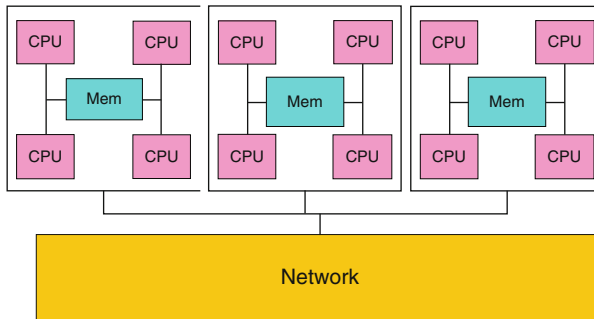

Figure 6
Hybrid MIMD architecture model

2.4 Dataflow and Systolic Architectures: Specialized Architectures Versus Generic Ones

These architectures are potentially more powerful on data flow, SIMD, systolic algorithms, but need customized processors. The relatively long time required to design these custom powerful architectures results in performance increases over time, which lags behind the rate of performance increase seen in commodity components.

However, there are situations where this strategy yields high returns. One of them is to consider architectures where the custom processor is not the main computing element but a coprocessor dedicated to increase the power of the main component. One typical example is the graphical processor unit (GPU). This point will be developed later.

2.5 Vector Architectures

A vector processor, or array processor, is a CPU design where the instruction set includes operations that can perform mathematical operations on multiple data elements simultaneously.

Figure 7
Principle of vector processing

This is in contrast to a scalar processor which handles one element at a time using multiple instructions.

Single instruction results in multiple operands being updated. Scalar processing operates on single data elements. Vector processing operates on whole vectors (groups) of data at a time (see ► [Fig. 7](#)).

In general terms, CPUs are able to manipulate one or two pieces of data at a time. For instance, many CPUs have an instruction that essentially says “add A to B and put the result in C,” while others require two or three instructions to perform these types of operations.

The data for A, B, and C could be – in theory at least – encoded directly into the instruction. However, things are rarely that simple. In general, the data is rarely sent in raw form and is instead “pointed to” by passing in an address to a memory location that holds the data. Decoding this address and getting the data out of the memory takes some time. As CPU speeds have increased, this memory latency has historically become a large impediment to performance.

In order to reduce the amount of time this takes, most modern CPUs use a technique known as instruction pipelining in which the instructions pass through several subunits in turn. The first subunit reads the address and decodes it, the next “fetches” the values at those addresses, and the next does the math itself. With pipelining the “trick” is to start decoding the next instruction even before the first has left the CPU, in the fashion of an assembly line, so that the address decoder is constantly in use. Any particular instruction takes the same amount of time to complete, a time known as the latency, but the CPU can process an entire batch of operations much faster than if it did so one at a time.

Vector processors take this concept one step further. Instead of pipelining just the instructions, they also pipeline the data itself. They are fed instructions that say not just to add A to B, but to add all of the numbers “from here to here” to all of the numbers “from there to there.” Instead of constantly having to decode instructions and then fetch the data needed to complete them, it reads a single instruction from memory, and “knows” that the next address will be one larger than the last. This allows for significant savings in decoding time.

In fact, vector processors work best only when there are large amounts of data to be worked on. For this reason, these sorts of CPUs were found primarily in supercomputers, as the supercomputers themselves were generally found in places such as weather prediction centers and physics labs, where huge amounts of data are “crunched.”

■ Figure 8

Examples of vector architecture – from *top to bottom and left to right*: CRAY 1, CRAY T90, CRAY X1, Fujitsu VPP5000 and NEC SX9

Main examples of these architectures are the Cray supercomputers (Cray 1, YMP, C90, T90, X1), Fujitsu VP family, NEC SX family (see ➤ [Fig. 8](#)).

3 Parallelism Models

3.1 Overview

There are several parallel programming models in common use (Butenhof [1997](#)):

- Shared memory
- Threads
- Message passing
- Data parallel
- Hybrid

Parallel programming models exist as an abstraction above hardware and memory architectures. Although it might not seem apparent, these models are not specific to a particular type of machine or memory architecture. In fact, any of these models can (theoretically) be implemented on any underlying hardware.

Two examples:

- Shared memory model on a distributed memory machine: Kendall Square Research (KSR) (Singh et al. [1993](#); Burkhardt et al. [1992](#)) approach.

Machine memory was physically distributed, but appeared to the user as a single shared memory (global address space). Generically, this approach is referred to as “virtual shared memory.” Note: although KSR is no longer in business, there is no reason to suggest that a similar implementation will not be made available by another vendor in the future.

- Message passing model on a shared memory machine: MPI on SGI Origin

The SGI Origin employed the CC-NUMA (Chapman et al. 2001) type of shared memory architecture where every task has direct access to global memory. However, the ability to send and receive messages with MPI, as is commonly done over a network of distributed memory machines, is not only easily implementable but is widely used.

Which model to use is often a combination of what is available and personal choice? There is no “best” model, although there certainly are better implementations of some models over others.

The following sections describe each of the models mentioned above, and also discuss some of their actual implementations.

3.2 Shared Memory Model

In the shared memory programming model, tasks share a common address space, which they read and write asynchronously. Various mechanisms such as locks/semaphores may be used to control access to the shared memory.

An advantage of this model from the programmer’s point of view is that the notion of data “ownership” is lacking, and so there is no need to specify explicitly the communication of data between tasks. Program development can often be simplified.

An important disadvantage in terms of performance is that it becomes more difficult to understand and manage data locality.

Implementations:

On shared memory platforms, the native compilers translate user program variables into actual memory addresses, which are global.

No common distributed memory platform implementations currently exist.

3.3 Threads Model

In the threads model of parallel programming (Tanenbaum 1992), a single process can have multiple, concurrent execution paths. Perhaps the simplest analogy that can be used to describe threads is the concept of a single program that includes a number of subroutines:

- The main program `a.out` is scheduled to run by the native operating system. `a.out` loads and acquires all of the necessary system and user resources to run.
- `a.out` performs some serial work, and then creates a number of tasks (threads) that can be scheduled and run by the operating system concurrently.
- Each thread has local data, but also, shares the entire resources of `a.out`. This saves the overhead associated with replicating a program’s resources for each thread. Each thread also benefits from a global memory view because it shares the memory space of `a.out`.
- A thread’s work may best be described as a subroutine within the main program. Any thread can execute any subroutine at the same time as other threads.

■ **Figure 9**

Thread programming model

- Threads communicate with each other through global memory (updating address locations). This requires synchronization constructs to insure that no more than one thread is updating the same global address at any time.
- Threads can come and go, but `a.out` remains present to provide the necessary shared resources until the application has completed.

Threads are commonly associated with shared memory architectures and operating systems (👉 [Fig. 9](#)).

Implementations:

From a programming perspective, threads implementation commonly comprises:

- A library of subroutines that are called from within parallel source code
- A set of compiler directives imbedded in either serial or parallel source code

In both cases, the programmer is responsible for determining all parallelism. Threaded implementations are not new in computing. Historically, hardware vendors have implemented their own proprietary versions of threads. These implementations differed substantially from each other making it difficult for programmers to develop portable threaded applications. Unrelated standardization efforts have resulted in two very different implementations of threads: POSIX threads and OpenMP.

- POSIX threads (Butenhof [1997](#))
 - Library based; requires parallel coding.
 - Specified by the IEEE POSIX 1003.1c standard (1995).
 - C Language only.
 - Commonly referred to as Pthreads.
 - Most hardware vendors now offer Pthreads in addition to their proprietary threads implementations.
 - Very explicit parallelism; requires significant programmer attention to detail.
- OpenMP (Chandra [2001](#); Chapman et al. [2007](#))
 - Compiler directive based; can use serial code.
 - Jointly defined and endorsed by a group of major computer hardware and software vendors. The OpenMP Fortran API was released October 28, 1997. The C/C++ API was released in late 1998.
 - Portable/multi-platform, including Unix and Windows NT platforms.

- Available in C/C++ and Fortran implementations.
- Can be very easy and simple to use – provides for “incremental parallelism.”

Microsoft has its own implementation for threads, which is not related to the UNIX POSIX standard or OpenMP.

3.4 Message Passing Model (Roosta 2000)

The message passing model demonstrates the following characteristics:

- Sets of tasks that use their own local memory during computation. Multiple tasks can reside on the same physical machine as well across an arbitrary number of machines.
- Tasks exchange data through communications by sending and receiving messages.
- Data transfer usually requires cooperative operations to be performed by each process (➤ Fig. 10). For example, a send operation must have a matching receive operation.

Implementations:

From a programming perspective, message passing implementations commonly comprise a library of subroutines that are imbedded in source code. The programmer is responsible for determining all parallelism.

Historically, a variety of message passing libraries have been available since the 1980s. These implementations differed substantially from each other making it difficult for programmers to develop portable applications. In 1992, the MPI Forum was formed with the primary goal of establishing a standard interface for message passing implementations (The MPI Forum 1993).

Part 1 of the message passing interface (MPI) was released in 1994. Part 2 (MPI-2) was released in 1996. Both MPI specifications are available on the web at www.mcs.anl.gov/Projects/-mpi/standard.html.

MPI is now the “de facto” industry standard for message passing, replacing virtually all other message passing implementations used for production work. Most, if not all of the popular parallel computing platforms offer at least one implementation of MPI. A few offer a full implementation of MPI-2.

For shared memory architectures, MPI implementations usually do not use a network for task communications. Instead, they use shared memory (memory copies) for performance reasons.

■ Figure 10
Principle of the message passing model

3.5 Data Parallel Model (Roosta 2000)

The data parallel model demonstrates the following characteristics:

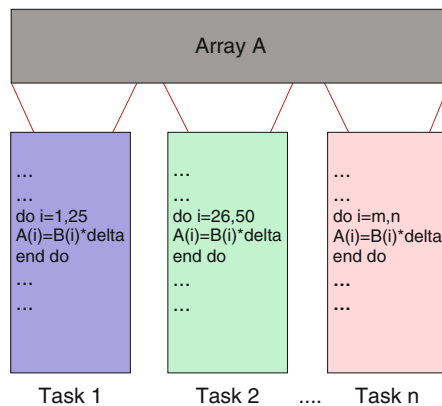

- Most of the parallel work focuses on performing operations on a data set. The data set is typically organized into a common structure, such as an array or cube.
- A set of tasks work collectively on the same data structure; however, each task works on a different partition of the same data structure.
- Tasks perform the same operation on their partition of work, for example, “add 4 to every array element.”

On shared memory architectures, all tasks may have access to the data structure through global memory. On distributed memory architectures the data structure is split up and resides as “chunks” in the local memory of each task (🔗 Fig. 11).

Implementations:

Programming with the data parallel model is usually accomplished by writing a program with data parallel constructs. The constructs can be calls to a data parallel subroutine library or, compiler directives recognized by a data parallel compiler. For example, one can cite:

- Fortran 90 and 95 (F90, F95) (Metcalf and Reid 1999): this is an ISO/ANSI standard extensions to Fortran 77 like pointers and dynamic memory allocation added array processing (arrays treated as objects), recursive and new intrinsic functions, and many other new features. Implementations are available for most common parallel platforms.
- High Performance Fortran (HPF) (H.P.F. Forum 1993): it consists of extensions to Fortran 90 to support data parallel programming. Directives to tell compiler how to distribute data have been added, assertions that can improve optimization of generated code have been added, and data parallel constructs have also been added (now part of Fortran 95). Implementations are available for most common parallel platforms.
- Compiler Directives: Allow the programmer to specify the distribution and alignment of data. Fortran implementations are available for most common parallel platforms.

🔗 Figure 11

Principle of data parallel programming model

Distributed memory implementations of this model usually have the compiler convert the program into standard code with calls to a message passing library (MPI usually) to distribute the data to all the processes. All message passing is done invisibly to the programmer.

3.6 Other Models

Other parallel programming models besides those previously mentioned certainly exist, and will continue to evolve along with the ever changing world of computer hardware and software. Only three of the more common ones are mentioned here.

3.6.1 Hybrid

In this model, any two or more parallel programming models are combined.

Currently, a common example of a hybrid model is the combination of the message passing model (MPI) with either the threads model (POSIX threads) or the shared memory model (OpenMP) (Rabenseifner et al. 2006). This hybrid model lends itself well to the increasingly common hardware environment of networked SMP machines.

Another common example of a hybrid model is combining data parallel with message passing. As mentioned in the data parallel model section previously, data parallel implementations (F90, HPF) on distributed memory architectures actually use message passing to transmit data between tasks, transparently to the programmer.

3.6.2 Single Program Multiple Data (SPMD) (Roosta 2000)

SPMD is actually a “high level” programming model that can be built upon any combination of the previously mentioned parallel programming models (► Fig. 12).

A single program is executed by all tasks simultaneously. At any moment in time, tasks can be executing the same or different instructions within the same program.

SPMD programs usually have the necessary logic programmed into them to allow different tasks to branch or conditionally execute only those parts of the program they are designed to execute. That is, tasks do not necessarily have to execute the entire program – perhaps only a portion of it. All tasks may use different data.

3.6.3 Multiple Program Multiple Data (MPMD) (Roosta 2000)

Like SPMD, MPMD is actually a “high level” programming model that can be built upon any combination of the previously mentioned parallel programming models.

Figure 12
SPMD model

MPMD applications typically have multiple executable object files (programs). While the application is being run in parallel, each task can be executing the same or different program as other tasks. All tasks may use different data (► Fig. 13).

3.7 The Different Levels of Parallelism

3.7.1 First Level: Distributed Computing

This means that “quasi” independent simulation can be achieved in parallel. Only a light central control could be performed in order to control the whole simulation. This is used for all parameterized calculations (uncertainties reduction, design optimization, safety and operating optimization). In this case the major problems to deal with are the dataflow and workflow management (► Fig. 14).

For the distributed level, the architecture of the simulation does not suppose specific constraint on the hardware. The only need is to have a connection between the unit in charge of the control of the simulation and the units in charge of the simulation itself.

3.7.2 Second Level: Coarse Grain Parallel Computing

For this case, we cannot suppose independent simulation. We consider either a unique problem which can be solved by concurrent calculation but needs synchronization and communication

■ Figure 13
MPMD programming model

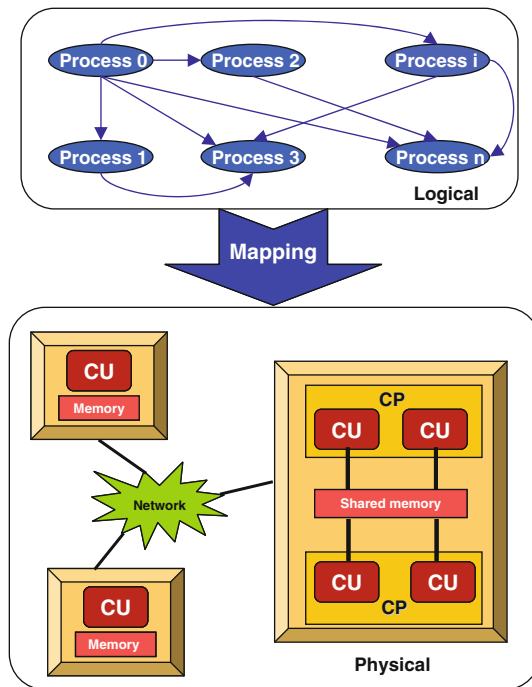

■ Figure 14
Sketch of a distributed computing simulation

between processes. In that case, one can have either a centralized control for the simulation of a distributed one. Of course, since the simulation needs communication, the hardware has a strong influence on the performance of simulation. For this kind of simulation, we consider an ideal parallel machine, that is to say specific communication hardware which minimizes the latency and offers the greater bandwidth as possible.

We have to define the graph of processes (dependency graph) and the communication graph. These two graphs have then to be mapped on the target architecture. We can suppose each process will be mapped on one different computational unit (CU), or many processes could be mapped on the same physical process unit. Moreover, even, we assume that each process is mapped on a different computational unit; the communication media can be different depending on the target architecture. The communication can be achieved either using a communication network between different memory units or through the memory in case of a shared memory machine (► [Fig. 15](#)).

3.7.3 Third Level: Fine Grain Parallel Computing

In this level, we consider the very fine level of parallelism that can be achieved in a single program. Usually this level is implemented using a multithreaded programming model on shared

■ Figure 15

Sketch of a parallel computing simulation – mapping of a logical graph onto a real architecture

memory architecture. This level is not very different from the previous one, but in order to achieve good performance, one has to be cautious in the use of the different memory hierarchies.

The most popular way to implement this model is to use the OpenMP (Chandra 2001) standard, where the parallelism is expressed using directives. So it is quite easy to obtain quite good performances with a moderate effort and reduced modification of the source code.

This model can be used in a standalone way in order to increase performance of a program on a reduced architecture or used in a combined way with coarse grain approach.

This model becomes more and more popular with multicore architectures. Most of the desktops have now between four and eight cores, and server can have up to 32 cores sharing a common memory.

4 Designing Parallel Programs

4.1 Automatic Versus Manual Parallelization

Designing and developing parallel programs has characteristically been a very manual process. The programmer is typically responsible for both identifying and actually implementing parallelism. Very often, manually developing parallel codes is a time consuming, complex, error-prone, and iterative process.

For a number of years now, various tools have been available to assist the programmer with converting serial programs into parallel programs. The most common type of tool used to automatically parallelize a serial program is a parallelizing compiler or preprocessor (Feautrier 2006).

A parallelizing compiler generally works in two different ways:

- Fully automatic
 - The compiler analyzes the source code and identifies opportunities for parallelism.
 - The analysis includes identifying inhibitors to parallelism and possibly a cost weighting on whether or not the parallelism would actually improve performance.
 - Loops (do, for) are the most frequent target for automatic parallelization.
- Programmer directed
 - Using “compiler directives” or possibly compiler flags, the programmer explicitly tells the compiler how to parallelize the code.
 - May be able to be used in conjunction with some degree of automatic parallelization also.

If you are beginning with an existing serial code and have time or budget constraints, then automatic parallelization may be the answer. However, there are several important caveats that apply to automatic parallelization:

- Wrong results may be produced.
- Performance may actually degrade.
- Much less flexible than manual parallelization.
- Limited to a subset (mostly loops) of code.
- May actually not parallelize the code if the analysis suggests there are inhibitors or the code is too complex.

- Most automatic parallelization tools are for Fortran.

The remainder of this section applies to the manual method of developing parallel codes.

4.2 Understand the Problem and the Program

Undoubtedly, the first step in developing parallel software is to first understand the problem that you wish to solve in parallel. If you are starting with a serial program, this necessitates understanding the existing code also.

Before spending time in an attempt to develop a parallel solution for a problem, determine whether or not the problem is one that can actually be parallelized.

Example of parallelizable problem:

Calculate the potential energy for each of several thousand independent conformations of a molecule. When done, find the minimum energy conformation.

This problem is able to be solved in parallel. Each of the molecular conformations is independently determinable. The calculation of the minimum energy conformation is also a parallelizable problem.

Example of a nonparallelizable problem:

Calculation of the Fibonacci series (1, 1, 2, 3, 5, 8, 13, 21, ...) by use of the formula: $F(k + 2) = F(k + 1) + F(k)$

This is a nonparallelizable problem because the calculation of the Fibonacci sequence as shown would entail dependent calculations rather than independent ones. The calculation of the $k + 2$ values uses those of both $k + 1$ and k . These three terms cannot be calculated independently and therefore, not in parallel.

Identify the program's *hotspots*:

- Know where most of the real work is being done. The majority of scientific and technical programs usually accomplish most of their work in a few places.
- Profilers and performance analysis tools can help here.
- Focus on parallelizing the hotspots and ignore those sections of the program that account for little CPU usage.

Identify *bottlenecks* in the program

- Are there areas that are disproportionately slow, or cause parallelizable work to halt or be deferred? For example, I/O is usually something that slows a program down.
- May be possible to restructure the program or use a different algorithm to reduce or eliminate unnecessary slow areas.

Identify inhibitors to parallelism

- One common class of inhibitor is *data dependence*, as demonstrated by the Fibonacci sequence above.

Investigate other algorithms if possible

- This may be the single most important consideration when designing a parallel application.

4.3 Partitioning

One of the first steps in designing a parallel program is to break the problem into discrete “chunks” of work that can be distributed to multiple tasks. This is known as decomposition or partitioning.

There are two basic ways to partition computational work among parallel tasks: *domain decomposition* and *functional decomposition*.

4.3.1 Domain Decomposition (Smith et al. 1996)

In this type of partitioning, the data associated with a problem is decomposed. Each parallel task then works on a portion of the data (see ▶ Fig. 16).

There are different ways to partition data as illustrated on ▶ Fig. 17.

4.3.2 Functional Decomposition (Andrade et al. 2003)

In this approach, the focus is on the computation that is to be performed rather than on the data manipulated by the computation. The problem is decomposed according to the work that must be done. Each task then performs a portion of the overall work (see ▶ Fig. 18).

Functional decomposition lends itself well to problems that can be split into different tasks. For example:

Ecosystem Modeling

Each program calculates the population of a given group, where each group’s growth depends on that of its neighbors. As time progresses, each process calculates its current state, then exchanges

■ Figure 16

Sketch of a domain decomposition technique

Figure 17
Different kinds of data partitioning

Figure 18
Sketch of a functional decomposition technique

information with the neighbor populations. All tasks then progress to calculate the state at the next time step (see Fig. 19).

Signal Processing

An audio signal data set is passed through four distinct computational filters. Each filter is a separate process. The first segment of data must pass through the first filter before progressing to the second. When it does, the second segment of data passes through the first filter. By the time the fourth segment of data is in the first filter, all four tasks are busy (Fig. 20).

Figure 19
Ecosystem modeling

Figure 20
Signal processing parallelization

Climate Modeling

Each model component can be thought of as a separate task. Arrows represent exchanges of data between components during computation: the atmosphere model generates wind velocity data that are used by the ocean model, the ocean model generates sea surface temperature data that are used by the atmosphere model, and so on (► [Fig. 21](#)).

Combining these two types of problem decomposition is common and natural.

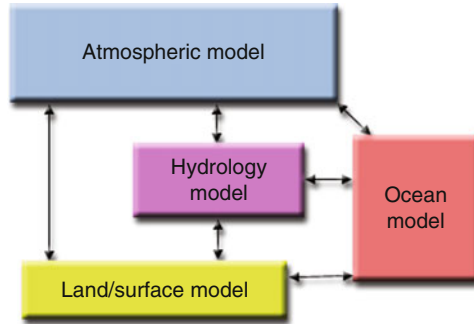

4.4 Communications (Saad and Schultz 1989; Gannon and Rosendale 1984)

4.4.1 Who Needs Communications?

The need for communications between tasks depends upon your problem:

You Do Not Need Communications

Some types of problems can be decomposed and executed in parallel with virtually no need for tasks to share data. For example, imagine an image processing operation where every pixel

■ **Figure 21**
Climate modeling – coupled model components

in a black and white image needs to have its color reversed. The image data can easily be distributed to multiple tasks that then act independently of each other to do their portion of the work.

These types of problems are often called *embarrassingly parallel* because they are so straightforward. Very little inter-task communication is required.

You Do Need Communications

Most parallel applications are not quite so simple, and do require tasks to share data with each other. For example, a 3D heat diffusion problem requires a task to know the temperatures calculated by the tasks that have neighboring data. Changes to neighboring data has a direct effect on that task's data.

4.4.2 Factors to Consider

There are a number of important factors to consider when designing your program's inter-task communications:

Cost of Communications

Inter-task communication virtually always implies overhead. Machine cycles and resources that could be used for computation are instead used to package and transmit data. Communications frequently require some type of synchronization between tasks, which can result in tasks spending time "waiting" instead of doing work. Competing communication traffic can saturate the available network bandwidth, further aggravating performance problems.

Latency Versus Bandwidth

Latency is the time it takes to send a minimal (0 byte) message from point A to point B, commonly expressed as microseconds.

Bandwidth is the amount of data that can be communicated per unit of time, commonly expressed as megabytes/seconds.

Sending many small messages can cause latency to dominate communication overheads. Often it is more efficient to package small messages into a larger message, thus increasing the effective communications bandwidth.

Visibility of Communications

With the Message Passing Model, communications are explicit and generally quite visible and under the control of the programmer.

With the Data Parallel Model, communications often occur transparently to the programmer, particularly on distributed memory architectures. The programmer may not even be able to know exactly how inter-task communications are being accomplished.

Synchronous Versus Asynchronous Communications

Synchronous communications require some type of “handshaking” between tasks that are sharing data. This can be explicitly structured in code by the programmer, or it may happen at a lower level unknown to the programmer.

Synchronous communications are often referred to as *blocking* communications since other work must wait until the communications have completed.

Asynchronous communications allow tasks to transfer data independently from one another. For example, task 1 can prepare and send a message to task 2, and then immediately begin doing other work. When task 2 actually receives the data does not matter.

Asynchronous communications are often referred to as *nonblocking* communications since other work can be done while the communications are taking place.

Interleaving computation with communication is the single greatest benefit for using asynchronous communications.

Scope of Communications

Knowing which tasks must communicate with each other is critical during the design stage of a parallel code. Both of the two scopings described below can be implemented synchronously or asynchronously.

Point-to-point – involves two tasks with one task acting as the sender/producer of data, and the other acting as the receiver/consumer.

Collective – involves data sharing between more than two tasks, which are often specified as being members in a common group, or collective. Some common variations (there are more) are illustrated on  [Fig. 22](#).

Efficiency of Communications

Very often, the programmer will have a choice with regard to factors that can affect communications performance. Only a few are mentioned here.

Which implementation for a given model should be used? Using the Message Passing Model as an example, one MPI implementation may be faster on a given hardware platform than another.

What type of communication operations should be used? As mentioned previously, asynchronous communication operations can improve overall program performance.

Network media – some platforms may offer more than one network for communications. Which one is best?

Figure 22
Main global communication schemes

Finally, realize that this is only a partial list of things to consider!!!

4.5 Synchronization

4.5.1 Types of Synchronization

Barrier

Usually implies that all tasks are involved

Each task performs its work until it reaches the barrier. It then stops, or “blocks.”

When the last task reaches the barrier, all tasks are synchronized.

What happens from here varies. Often, a serial section of work must be done. In other cases, the tasks are automatically released to continue their work.

Lock/Semaphore

- Can involve any number of tasks.
- Typically used to serialize (protect) access to global data or a section of code. Only one task at a time may use (own) the lock/semaphore/flag.
- The first task to acquire the lock “sets” it. This task can then safely (serially) access the protected data or code.
- Other tasks can attempt to acquire the lock but must wait until the task that owns the lock releases it.
- Can be blocking or nonblocking.

Synchronous Communication Operations

Involves only those tasks executing a communication operation. When a task performs a communication operation, some form of coordination is required with the other task(s)

participating in the communication. For example, before a task can perform a send operation, it must first receive an acknowledgment from the receiving task that it is OK to send.

Discussed previously in the [Sect. 4.4](#).

4.6 Data Dependencies

4.6.1 Definition

A *dependence* exists between program statements when the order of statement execution affects the results of the program.

A *data dependence* results from multiple use of the same location(s) in storage by different tasks.

Dependencies are important to parallel programming because they are one of the primary inhibitors to parallelism.

4.6.2 Examples

Loop Carried Data Dependence

```
DO 500 J = MYSTART, MYEND
  A(J) = A(J-1) * 2.0
500 CONTINUE
```

The value of $A(J - 1)$ must be computed before the value of $A(J)$; therefore, $A(J)$ exhibits a data dependency on $A(J - 1)$. Parallelism is inhibited.

If task 2 has $A(J)$ and task 1 has $A(J - 1)$, computing the correct value of $A(J)$ necessitates the following:

- Distributed memory architecture – task 2 must obtain the value of $A(J - 1)$ from task 1 after task 1 finishes its computation.
- Shared memory architecture – task 2 must read $A(J - 1)$ after task 1 updates it.

Loop Independent Data Dependence

task 1	task 2
-----	-----
X = 2	X = 4
.	.
.	.
Y = X**2	Y = X**3

As with the previous example, parallelism is inhibited. The value of Y is dependent on:

- Distributed memory architecture – if or when the value of X is communicated between the tasks
- Shared memory architecture – which task last stores the value of X

Although all data dependencies are important to identify when designing parallel programs, loop carried dependencies are particularly important since loops are possibly the most common target of parallelization efforts.

■ Figure 23

Example of time-dependent diagram of a parallel computation using four tasks. Illustration of load imbalance between tasks

4.6.3 How to Handle Data Dependencies

In distributed memory architectures, communicate required data at synchronization points.
In shared memory architectures, synchronize read/write operations between tasks.

4.7 Load Balancing

Load balancing refers to the practice of distributing work among tasks so that *all* tasks are kept busy *all* of the time. It can be considered a minimization of task idle time.

Load balancing is important to parallel programs for performance reasons. For example, if all tasks are subject to a barrier synchronization point, the slowest task will determine the overall performance (🕒 Fig. 23).

4.7.1 How to Achieve Load Balance

Equally Partition the Work Each Task Receives

For array/matrix operations where each task performs similar work, evenly distribute the data set among the tasks.

For loop iterations where the work done in each iteration is similar, evenly distribute the iterations across the tasks.

If a heterogeneous mix of machines with varying performance characteristics are being used, be sure to use some type of performance analysis tool to detect any load imbalances. Adjust work accordingly.

Use Dynamic Work Assignment

Certain classes of problems result in load imbalances even if data is evenly distributed among tasks:

- Sparse arrays – some tasks will have actual data to work on while others have mostly “zeros.”
- Adaptive grid methods – some tasks may need to refine their mesh while others do not.

- N-body simulations – where some particles may migrate to/from their original task domain to another task's; where the particles owned by some tasks require more work than those owned by other tasks.

When the amount of work each task will perform is intentionally variable, or is unable to be predicted, it may be helpful to use a *scheduler – task pool* approach. As each task finishes its work, it queues to get a new piece of work.

It may become necessary to design an algorithm which detects and handles load imbalances as they occur dynamically within the code.

4.8 Granularity

4.8.1 Computation/Communication Ratio

In parallel computing, granularity is a qualitative measure of the ratio of computation to communication.

Periods of computation are typically separated from periods of communication by synchronization events.

4.8.2 Fine Grain Parallelism

This parallelism is characterized by relatively small amounts of computational work done between communication events and a low computation to communication ratio.

4.9 Limits and Costs of Parallel Programming

4.9.1 Amdahl's Law

Amdahl's Law states that potential program speedup is defined by the fraction of code (P) that can be parallelized:

$$\text{Speedup} = \frac{1}{1 - P}$$

If none of the code can be parallelized, $P = 0$ and the speedup = 1 (no speedup). If all of the code is parallelized, $P = 1$ and the speedup is infinite (in theory).

If 50% of the code can be parallelized, maximum speedup = 2, meaning the code will run twice as fast.

Introducing the number of processors performing the parallel fraction of work, the relationship can be modeled by:

$$\text{Speedup} = \frac{1}{S + (P/N)}$$

where P = parallel fraction, N = number of processors, and S = serial fraction.

It soon becomes obvious that there are limits to the scalability of parallelism. For example, at $P = .50, .90,$ and $.99$ (50%, 90%, and 99% of the code is parallelizable):

N	Speedup		
	$P = .50$	$P = .90$	$P = .99$
10	1.82	5.26	9.17
100	1.98	9.17	50.25
1,000	1.99	9.91	90.99
10,000	1.99	9.91	99.02

However, certain problems demonstrate increased performance by increasing the problem size. For example:

2D Grid calculations	85 s	85%
Serial fraction	15 s	15%

We can increase the problem size by doubling the grid dimensions and halving the time step. This results in four times the number of grid points and twice the number of time steps. The timings then look like:

2D Grid calculations	680 s	75.84%
Serial fraction	15 s	2.16%

Problems that increase the percentage of parallel time with their size are more *scalable* than problems with a fixed percentage of parallel time.

4.9.2 Complexity

In general, parallel applications are much more complex than corresponding serial applications, perhaps in the order of magnitude. Not only do you have multiple instruction streams executing at the same time, but you also have data flowing between them.

The costs of complexity are measured in programmer time in virtually every aspect of the software development cycle:

- Design
- Coding
- Debugging
- Tuning
- Maintenance

Adhering to “good” software development practices is essential when working with parallel applications – especially if somebody besides you will have to work with the software.

4.9.3 Portability

Thanks to standardization in several APIs, such as MPI, POSIX threads, HPF, and OpenMP, portability issues with parallel programs are not as serious as in the past years. However, all

of the usual portability issues associated with serial programs apply to parallel programs. For example, if you use vendor “enhancements” to Fortran, C, or C++, portability will be a problem.

Even though standards exist for several APIs, implementations will differ in a number of details, sometimes to the point of requiring code modifications in order to effect portability.

Operating systems can play a key role in code portability issues.

Hardware architectures are characteristically highly variable and can affect portability.

4.9.4 Resource Requirements

The primary intent of parallel programming is to decrease execution wall clock time; however, in order to accomplish this, more CPU time is required. For example, a parallel code that runs in 1 h on eight processors actually uses 8 h of CPU time.

The amount of memory required can be greater for parallel codes than serial codes, due to the need to replicate data and for overheads associated with parallel support libraries and subsystems.

For short running parallel programs, there can actually be a decrease in performance compared to a similar serial implementation. The overhead costs associated with setting up the parallel environment, task creation, communications, and task termination can comprise a significant portion of the total execution time for short runs.

4.9.5 Scalability

The ability of a parallel program’s performance to scale is a result of a number of interrelated factors. Simply adding more machines is rarely the answer.

The algorithm may have inherent limits to scalability. At some point, adding more resources causes performance to decrease. Most parallel solutions demonstrate this characteristic at some point.

Hardware factors play a significant role in scalability. Examples:

- Memory–CPU bus bandwidth on an SMP machine
- Communications network bandwidth
- Amount of memory available on any given machine or set of machines
- Processor clock speed

Parallel support libraries and subsystems software can limit scalability independent of your application.

5 Use of HPC for Nuclear Energy Application: Overview

As for many scientific and technological fields, high performance computing brings many benefits for nuclear energy domain. As for other fields, basic disciplines, like material sciences, thermo- hydraulics, and structural mechanics, can benefit from HPC. Moreover, typical discipline likes neutronics is very time and memory consuming, and HPC is very important for this kind of simulation.

Of course, one cannot imagine high accuracy simulation without S modeling. So the coupling complexity becomes an added challenge each of the disciplines.

One of main illustration of the need and use of HPC is the Virtual Power Plant Challenge. Even if this goal is not fully reachable, it is interesting to describe it as an illustration of the potential needs in terms of simulation and high performance computing for nuclear energy.

5.1 The Virtual Power Plant Challenge

5.1.1 Description

The virtual power plant is intended to provide 3D, multi-physics, multi-scale simulation tools dedicated to the operation and safety of today's power plants, the design optimization of advanced reactors, the design of next generation systems, and the management of nuclear waste storage. These tools will involve various disciplines such as materials, reactor physics, thermal-hydraulics, thermal-mechanics, fuel management, and geological disposal.

5.1.2 Motivation

For today's power plants (GEN III: PWR, BWR) the challenges are the lifespan extension of nuclear installations, the optimization of the fuel use, and the preparation for their dismantlement. Advanced reactors (GEN III+: EPR) have to be tuned in order to increase their economic competitiveness, safety, and reliability. For next generation systems (GEN IV: SFR, HTR, FGCR) a technological jump has to be achieved in order to enable: the transition away from fossil fuel, the control of waste management, optimization of the use of resources, and the nonproliferation of nuclear material.

The main needs can be grouped along the following lines: coupling models of vibration and structure ageing, simulating the degradation mechanisms of materials under irradiation, guaranteeing optimum use of the fuel, simulating earthquake resistance of cooling towers, using real geometries to study accidental scenario, predicting the life span of vessels, and simulating the geological long-term storage of waste material.

The main disciplines involved are thermal-hydraulics (DNS, LES), thermal-mechanics, material (Ab initio – molecular dynamics – kinetic Monte Carlo/by chemical kinetics – discrete dislocation dynamics – crystal plasticity), neutron physics (deterministic and Monte Carlo simulations), and coupling between these disciplines.

5.1.3 Main Challenges

For the main challenges, we discuss the state-of-the-art, and a possible roadmap for the future.

- Coupled thermo-hydro-mechanical problems: Predicting long-term safety of civil engineering installations, like nuclear power plants containment walls or underground nuclear waste

disposal facilities, requires numerical simulations with the following features:

- 3D geometries due to geometrical configuration of the installations and anisotropic properties of materials.
- Nonlinear coupled problems: multiphase transport phenomenon and mechanical behavior are two examples.
- Wide uncertainties on material data imply parametric studies or inverse problem resolution.

Today, we are able to solve coupled problems in near field which means less than 100 m. Long-term behavior taking care of transport phenomenon and creep effects will need to solve these problems for domains 10 times bigger. Solving such a problem with 30,000 unknowns and 5,000 time steps takes 4 days of calculation on one node today. The target 3D problem will have 600,000 unknowns: with the same machine execution time it would be $500 \times 4 = 2,000$ days = 10 years. Clearly, we expect a gain of a factor between 100 and 500 on the calculation time (👉 Fig. 24).

- Multi-scale modeling of behavior and degradation mechanisms of materials: Detailed prediction of high nonlinear mechanical behavior of metallic materials but also concrete require the introduction of micro structural features into the modeling. This is even more crucial for prediction of degradation due to natural ageing, environment, or irradiation. Following features are required:
 - Very complex 3D geometries to represent real microstructures
 - Calibration of complex mechanical formulation by inverse problem resolution
 - Weak multi-scale coupling between discrete dislocations dynamics (DDD) and finite element (FE) codes

Today, material behavior on the scale of $200 \mu\text{m}^3$ can be computed with a coarse representation of microstructure (500,000 degrees of freedom), which represents 0.1 TeraFlops. Solving real problems without technical rupture (what is this?) will lead to problems with a few millions

■ Figure 24

Material simulation using domain decomposition (figure on the left) and results of the simulation. (EDF courtesy)

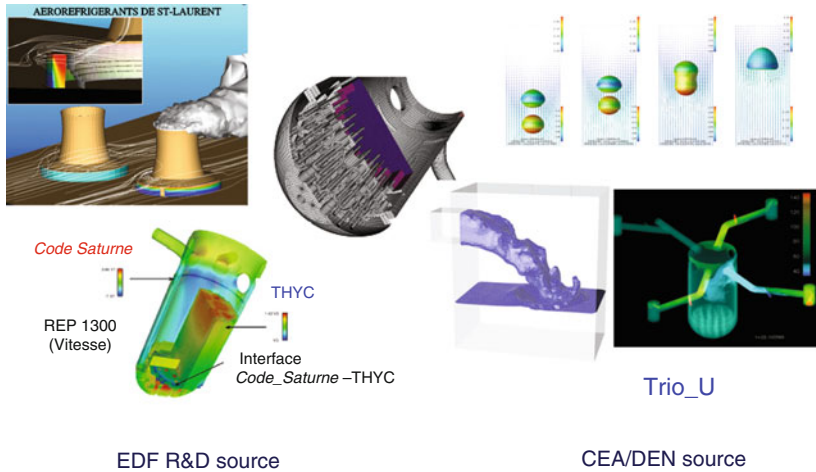

■ Figure 26

Illustration of different neutronic reference calculation using different approaches (Monte Carlo and deterministic) (CEA DEN courtesy)

degrees of freedom and a few TeraFlops. Development and implementation of new computational methods will lead to a few 10 million degrees of freedom and a few 10 TeraFlops (► Fig. 25).

- Neutronics reference calculations: In the field of neutron physics, in order to validate the different models, one needs reference calculations which can be achieved using Monte Carlo simulations and deterministic simulations. An example of what could be achieved is the simulation of one reactor cycle using a probabilistic approach in order to establish reference values concerning the fine 3D power distribution inside a reactor. Such a calculation using a Monte Carlo approach requires about 50 ExaFlops (50.10e18 floating point operations) or 26 PetaFlops (25.10e15 floating point operations) using an unstructured transport solver (► Fig. 26).
- Multi-scale and multi-model simulations: In the field of thermal-hydraulics, the problem can be illustrated by the simulation of two-phase turbulent flows. It implies the coupling of different scales (multi-scale/multi-resolution approaches) and models (two-phase flows and turbulent flows). In order to have a detailed description of the phenomena, it is compulsory to deal with very fine mesh. In the context of power plants, the complexity of geometries combined with fine mesh resolution lead to over $1e9$ meshing elements. It can be considered that one simulation step represents around 10 TeraFlops ($10 \cdot 10^{E12}$ floating point operations).

In the field of thermal-mechanics, the problem is the computation of the whole structure (pipe) and the modeling of much localized damage (thermal fatigue on surface). At the

■ Figure 27

Illustration of different scales for thermal-hydraulic simulations (EDF R&D and CEA DEN courtesy)

finest level, very precise results from thermal-hydraulics are expected and specific complex mechanical formulations are required (🔗 Fig. 27).

- Multi-physics problems: In order to ensure the safety of the installations, the simulation tools have to offer the capability to simulate coupled phenomena (like thermal-hydraulics and neutron physics or thermal-hydraulics and thermal-mechanics) in the transient state. The appropriate level of precision is compulsory for realistic simulations for each physical field. For instance a reference calculation using a Monte Carlo approach has to be coupled with the right level of precision coming from the thermal-hydraulics side. These lead to coupled simulations requiring more than 100 ExaFlops. The different estimates of floating point operations presented above may be reduced by both improved more efficient physical models and better numerical optimizations, but the needs lie between two to three orders of magnitude of what can be handled today. Same coupling schemes and corresponding challenges are required to compute full 3D response of reactor pressure vessel during pressurized thermal shocks or real deformation (due to geometrical evolution under neutron flux, vibration/erosion) of a complete set of fuel assemblies.

5.2 Other Examples and Use

Of course, many other uses of HPC exist. They require the different levels of parallelism described in 🔗 Sect. 3.7.

For example, the first level, distributed computing one, is used for parametric studies or for sensibility calculations. It is also used for embarrassing applications like Monte Carlo simulations in neutronic calculations.

The second level, the coarse grain parallel computing one, is used by all the parallel applications in the different scientific domains involved in nuclear energy simulations: material

sciences, thermo-mechanic, thermo-hydraulic, neutronic, etc. In this case, usually the parallelism is a data parallel one (see ▶ Sects. 3.5 and ▶ 4.3.1). It is also used for coupled simulations like described in ▶ Sect. 4.3.2.

Finally, the third level, the fine grain one, is usually used in combination with the second one for massively parallel applications, or in a stand alone way for applications which do not need massively parallel computations. One can cite some structural mechanic applications, or some solvers in which implementation is much more efficient using a thread model parallelism (see ▶ Sect. 3.3) using a reduced number of threads.

The aim of the next section is to illustrate the use of HPC in some of the basic scientific fields used in nuclear energy simulation.

6 Illustration of HPC Use on Different Applications

The goal of this section is to illustrate the different applications of the use of HPC, and not to deal with the physical part. The goal is not to go deeper into the technical stuff in order to explain how different applications are parallelized but more to explain what are the benefits of using HPC, the main techniques used, the state-of-the-art use of HPC in the different fields, and of course the challenges and needs.

6.1 HPC for Reactor Core Simulation

6.1.1 Introduction

In this section, we will focus on the three main scientific fields involved in the numerical simulation of nuclear reactors, namely: neutronics, thermal-hydraulic, and fuel modeling. Of course, the true modeling of a reactor core is much more complex and should involve many more physical fields (structural mechanics, chemistry, materials); but for a first level of modeling, either the three fields listed above are sufficient or simplified model and embedded modeling are used (for instance, structural mechanics and chemistry in fuel simulation).

Some of these scientific fields are treated in the following sections (material sciences, structural mechanics).

We propose to consider each field independently and then address specific problem of coupling.

6.1.2 Major Challenges

As explained before, we can consider different targets of use for high performance computing in reactor physics. Depending on the target, different level and techniques can be used. Nevertheless, the different techniques will allow us to fall back on to higher level of simulation, like:

- Parameterized calculations: this is the basic technique for optimization. HPC is a great opportunity to take into account more parameters and to reduce “time to market.” This

allows too the use of optimization techniques, like neural networks, in order to find and optimize a set of parameters automatically.

- A high resolution physics: greater memory capacity and greater CPU power are required for more refined models in each discipline, for instance CFD in thermal-hydraulic, instead of porous media modeling, deterministic or Monte Carlo transport instead of few groups diffusion approach.
- A more realistic physics by using systematically real physical model instead of simplified model or pretabulated values. This implies, not only greater CPU power, but robust and easy of use coupled system.
- Real time simulation: this already exists, but we can imagine improving modeling in order to obtain more realistic simulators and decreases the number of assumptions.

All these improvements are needed in order to:

- Increase margin by reducing uncertainties.
- Optimize designs.
- Improve safety.
- Optimize operations.
- Increase physics knowledge.

We are not too far from being able to design a virtual reactor system which allows the virtual design and optimization of existing or new design of reactors or part of reactors.

6.1.3 HPC in Monte Carlo Simulations

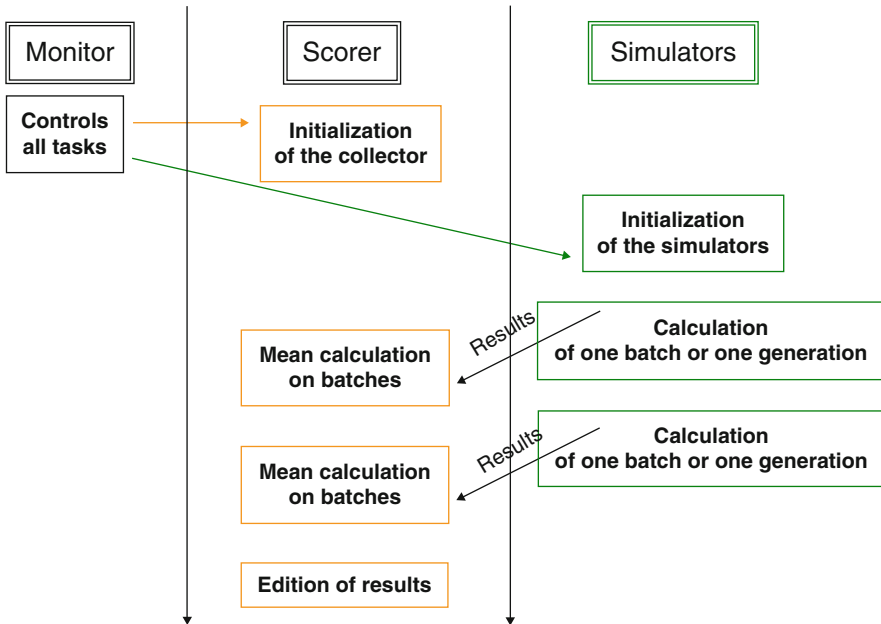

Monte Carlo method to solve the transport equation is the best candidate for parallelism. Since the simulation process is based on a statical approach of independent particle trajectories, each particle can be computed by a different processor. Monte Carlo simulation is embarrassingly parallel (see “Principles for a parallel implementation”).

Principles for a Parallel Implementation

This is for the main principle. For a true implementation, there are some more details. In order to control the simulation process, one needs a monitor which is in charge to control the whole simulation and another process which is in charge to collect the simulations results. These two processes could be executed on a same processor or on different ones. For this implementation part, the model used is an MPMD one (see [Sect. 3.6.3](#)), based on master/slave model with the identification of a master in charge of the simulation control and the separation of simulation process and collector process (Trama and Hugot 2007; Deng and Xie 1999; Goorley et al. 2003).

This implementation principle is used in the TRIPOLI-4^Z (Trama 2008; Hugot et al. 2008; Trama and Hugot 2007) code and is illustrated in [Fig. 28](#).

The main advantages of this model are that it is very easy to implement and port (very basic exchange of information between processes); it is well adapted to independent particles simulation. The last advantage is that this implementation allows fault tolerant simulation. Indeed, if one simulator falls down, either due to a material fault or a numerical one, the monitor can launch the corresponding batches to another simulator. Using these features, even if we lost more than half of the simulators, the whole simulation can still go on.

■ **Figure 28**
Parallel implementation principle in Monte Carlo code

Other features have been also implemented in the TRIPOLI-4^Z, like checkpoint/restart functionalities: the current state of the TRIPOLI-4^Z simulation is stored in different files which allow the restart of the simulation at anytime.

In the area of mathematical and algorithmic development, the main problem concerns the parallel version of the random number generator (Hellekalek 1998). This one has to fulfill the following properties:

- Independent from the number of processors.
- No correlation between suites for different processors.
- On each processor, the generator can be initialized independently (no communication between processes).

One example of this parallel random generator is based on the generalized feedback shift register (GFSR) algorithm (Lewis and Payne 1973). The main advantages of this random number generator are that it is very fast and has very long period (2,607). However, one can have two identical integers before the end of the generator period (which limits to 2^{32} , which is the maximum number of integer) and it is quite tricky to parameter and tune.

Performances

The way for evaluating the parallel performances of Monte Carlo simulations is quite different from the classical speedup of efficiency (see ► Sect. 4.1.1) and is based on the “figure of merit” (FOM) formula. The FOM quantity is defined as follow:

$$Q = \frac{1}{\sigma^2 \times \tau},$$

■ **Figure 29**
FOM of parallel execution of TRIPOLI-4 code

where σ is the standard deviation, τ is the elapsed time

It is expected that the speedup or the FOM is linear with the number of processor (🔍 Fig. 29). It is almost true.

The same behavior has been measured until 1,000 processors using TRIPOLI-4 code with efficiency over 90%.

One of the advantages of the parallel implementation of TRIPOLI-4 code is that the monitor can control dynamically the load balance of each simulator, and the number and size of the batch can be adjusted in order that the simulators are not waiting and thus maximize the global efficiency of the simulation.

However, there are some bottlenecks to obtain ideal efficiency. Even if the performance can be adjusted, the scorer could be a bottleneck to an ideal efficiency for very large number of simulators ($\gg 1,000$). Some solutions could be investigated, like implementing a tree of collector, in order to share the load of collecting results. Another solution could be to avoid the online collecting and accumulate the results after the simulation. One has to be cautious with the amount of data to store.

Future Challenges

Even if, as we have seen, Monte Carlo simulations are embarrassingly parallel, access to petascale class simulation will however be a challenge, as for many other applications.

As we mentioned earlier, we will have to deal with the huge amount of data, either on the network or the file system, in order to store the simulations results.

But if we still increase the complexity of the geometry, the refinement of the details and the amount of computing variables (for instance, detailed reaction rates on a whole core), the storage of all these information in memory will be a problem. Indeed, in the parallelism model described below, all the input (geometry, nuclear data) and output data are duplicated on each processor (see 🔍 Fig. 30).

■ **Figure 30**
Domain replication (particle parallelism)

■ **Figure 31**
Domain decomposition (spatial parallelism)

Thus, the future limit will be not only the CPU time as now, but the memory limit. One solution would be to mix the task parallelism with a data parallelism, and to split the computational domain and distribute it among the different processors (see ➤ [Fig. 31](#)).

■ **Figure 32**

Domain decomposition and domain replication (spatial and particle parallelism)

But, it is against the natural way of parallelizing Monte Carlo simulations and will lead to tricky problems like load imbalance and efficiency decrease due to communications traffic between processors.

In the MERCURY code, both models are implemented (Procassini et al. 2005) in order to take advantage of both spatial and particles parallelism (see ► [Fig. 32](#)).

6.1.4 HPC in Deterministic Simulations

The Different Level of Parallelism

In deterministic simulation, we can consider three main levels of parallelism:

- The first level concerns multiparameterized calculations. This level is typically implanted using a distributed computing approach (see ► [Sect. 3.7.1](#)), since each calculation is an independent one from the other. Classical example is a multiparameter assembly's calculation, where one has to compute different kinds of reactor assemblies for core code calculation.
- The second is what we can call multi-domain calculations. It is implemented using a coarse grain parallelism approach (see ► [Sect. 3.7.2](#)). For example, it concerns all the treatment dealing with cross sections, depletion process, thermal-hydraulic feedback, etc. In this level, usually we can consider that the spatial dependency of the data is very tight and a massively parallel approach is well suited. Concerning the case where the spatial dependency of the data is strong, domain decomposition techniques are used. It concerns, for example, the transport equation resolution.

- The third level is based on a fine grain parallelism model (see [Sect. 3.7.3](#)) and mainly concerns the fine grain parallelization of solvers by exploiting intrinsic parallelism of the involved numerical methods.

In the following we will illustrate these different levels by describing some typical examples.

First Level: Multiparameterized Calculations

The main interest of this level is to use the brute force of HPC to solve problems with huge amount of independent calculation in a “human” time. (Some examples have been presented by Prof. Turinsky in this talk during the M&C-SNA conference in 2007 in Monterey.) Different uses of HPC for reducing uncertainties in simulator predictions of limiting nuclear plant attributes or how to gain margins using optimization techniques are discussed below.

One way to reduce uncertainties is of course to use deterministic (forward and adjoint) approaches. Another way is to use a less-intrusive method and is based on a stochastic (sampling) approach. Of course this approach is challenged in regard to computational resources required. This sampling approach is also very interesting in case of problem where deterministic approach is too complex. One can cite coupled problems (thermo-hydraulic–neutronic) or depletion ones.

Concerning optimization problems, one very good example is fuel optimization. Grand challenge problem attributes include:

- Multiobjective
- Multicycle

Figure 33

Example of set of solutions found by the genetic algorithm depending on different strategies (Pareto front)

■ Figure 34

Illustration of different solutions: Pareto front on the *left* – loading pattern on the *middle* – corresponding power map on the *right*

- Lattice optimization
- Bundle optimization
- Loading pattern optimization
- Excess reactivity control optimization (e.g., BWR: CRP and core flow)

As an example of this topic, one can cite an exercise achieved for fuel loading pattern optimization with genetic algorithm (Do et al. 2009). A tool based on URANIE/VIZIR and APOLLO3² (Golfier et al. 2009) code has been designed and has been successfully applied to the optimization of fuel loading pattern in the case of high heterogeneous LWR cores. This tool allows the evaluation of more than ten million different configuration in less than 10 h using more than 4,000 processors. An illustration of different kinds of solutions is provided in [Fig. 33](#).

The main advantage of this kind of approach is to allow engineers to test many different kinds of configurations and relax some constraints which are not possible without genetic algorithms and HPC. An example of different solutions found is given in [Fig. 34](#).

Second Level: Multi-Domain Calculations

This level is the most classical one. In most of parallel scientific applications this one is used through domain decomposition techniques. To be more precise, one could say that this domain is mainly based on spatial decomposition. Applied to neutronics applications, all the calculations which are spatially independent are included. For instance, in a typical two-stage calculation, at the core level, all the steps concerning cross-sections loading and management,

thermal feedback, isotopic depletion, etc. are local to the cell of the geometrical domain, and thus could be done in parallel. To summarize in a standard deterministic 3D core calculation, all the steps are spatially independent and thus could be done naturally in parallel, except one, the flux calculation. Even if all the precedent steps could be done in parallel, the main problem is still the data flow management and the data distribution between the processes. One has to think about it in the architecture code design in order to have optimum data structures to mitigate this problem.

Concerning the flux calculation itself, classical domain decomposition techniques can be used (see ▶ Sect. 4.3.1, Smith et al. 1996). Concerning the Boltzmann transport equation solver (Roy and Stankovski 1997), other parallelism degree can be found, since the other dimensions of the equations can be used, for instance the angular or energetic ones. Many solvers have been implemented in parallel, exploiting either angular and energetic parallelism (Zeyao and Lianxiang 2004; Stankovski et al. 1997), spatial one (Guérin et al. 2007; Ragusa 2003a, b) or both (Sjoden 1997).

Another degree of parallelism can be used when exploiting multilevel techniques. For instance, fine transport solution on one assembly coupled with full 3D coarse solution. Typical examples of such techniques can be found in the COBAYA code (see ▶ Fig. 35) (Herrero et al. 2007) or applied to the MINOS diffusion solver within an original approach based on a component mode synthesis (Guérin et al. 2005; Guérin et al. 2006).

Multilevel parallelism approach is also well suited for 3D calculations, especially when the method is intrinsically parallel or very difficult to parallelize. One typical example is the method of characteristics solver used to find the solution of the neutron transport equation. Indeed it is possible to parallelize this method, but one needs to employ very advanced parallelism techniques in order to obtain interesting efficiency (Dahmani and Roy 2006; Wu and Roy 2001; Dahmani and Roy 2005). Another way is to couple a 2D approach with a coupling one in the third direction and to compute 2D plans in parallel (see ▶ Fig. 36). This approach is used for instance in the Dekart code (Han Gyu et al. 2004) in UNIC code (Palmiotti et al. 2007).

Third Level: Fine Grain Parallelism Model

This level is usually used on shared memory architecture and exploits intrinsic parallelism of the algorithms. These techniques had a great infatuation in early 2000's with HPF language and after that OpenMP (Ragusa 2003a,b; Coulomb 1997). It becomes more and more interesting in today's computing environment with the many-core architectures which have to be combined with the second level of parallelism in order to improve the overall performances of the algorithm.

6.2 HPC for CFD and DNS

Benoit Mathieu, CEA/DEN/DER/SSTH – CEA Grenoble

6.2.1 Main Industrial Issues

As mentioned in Simulation and Modeling for Advanced Nuclear Energy Systems Workshop, modeling fluid flow and heat transfer is necessary, not only for core modeling, but also for

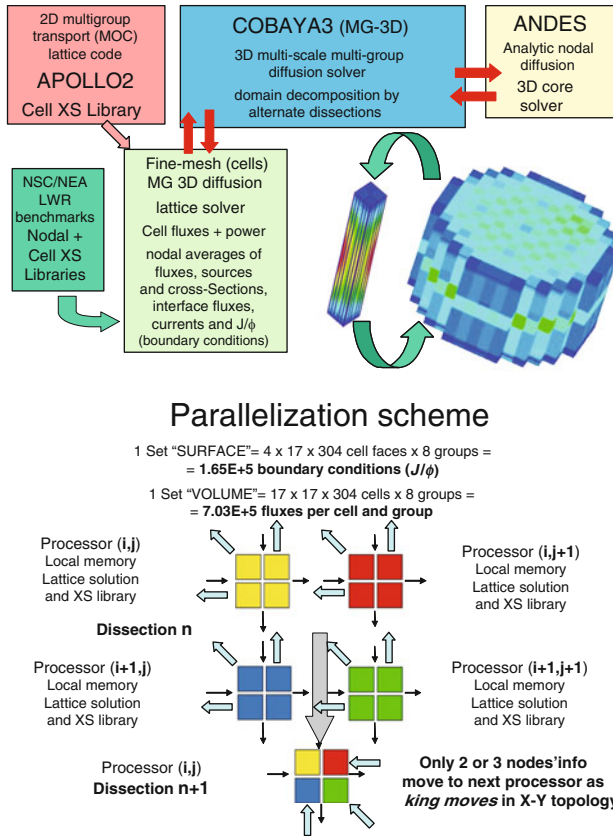

Figure 35

Parallelism principle used in COBAYA code (Courtesy NURESIM project)

the whole plant, including steam generators, pipes, pumps, and condensers. Because of the complexity of the phenomena and geometries involved, current codes often rely on empirical correlations. It is often not clear whether these correlations can be readily extrapolated to new situations. The scientific challenges are in physical modeling, numerical methods, and computer science. Physical modeling must rely on more first principles methods for single-phase and multiphase-multi-fluid flows, for steady and unsteady flows, and with or without heat transfer. Numerical methods must be more robust and provide the optimal mix between accuracy and stability. Codes must deal with billions of mesh elements and enable easy multi-scale and multi-physics coupling.

The main problems to solve in the short term (2–5 years) for light water reactors (LWRs) are pressurized thermal shock, gravity-driven flows, and fluid–structure interactions. For sodium-cooled fast reactors (SFRs) detailed core flow modeling is needed. In the intermediate term (5–10 years) reflooding and thermal fatigue of LWRs and transients and severe accidents for SFRs must be addressed. In the long-term (>10 years) critical heat flux for LWRs and the fluids and heat transfer portion of the numerical reactor simulation for both LWRs and SFRs must be developed. Development is needed in four areas:

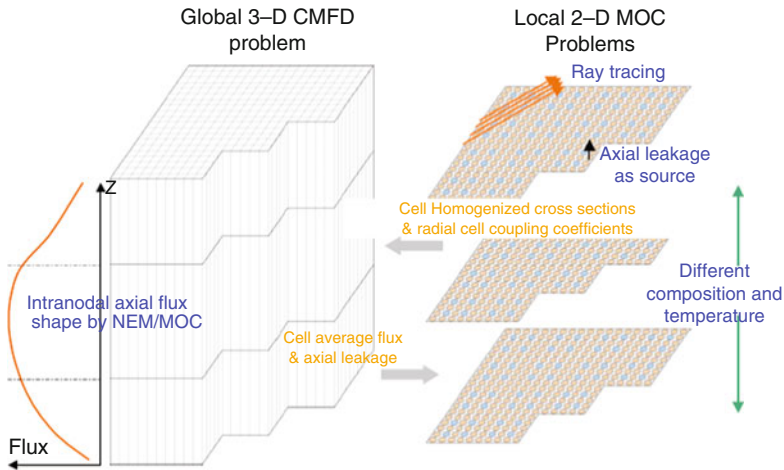

Figure 36
Planar MOC Solution-based 3D CMFD (Downar 2007)

- Direct numerical simulation (DNS), the closest scale to first principles approach: front-tracking, diffuse interface models, particle methods, and lattice Boltzmann techniques
- Computational fluid dynamics (CFD) in open media (detailed calculation within one subchannel or within plena), with a focus on large eddy simulation and high Reynolds numbers
- CFD in porous media (for multichannel analysis)
- System scale (overall plant calculation)

6.2.2 The Multi-Scale Approach

Studies in fluid mechanics for civil nuclear engineering cover a broad range of applications that involve different length scales and time scales. To address these needs, engineers usually use different physical and numerical methods, implemented in various dedicated and sometimes application-specific software packages. In order to provide a unified and comprehensive view of these tools, a framework called “multi-scale approach” has been defined. This framework not only provides a classification of the different modeling scales, but it also suggests a methodology to simultaneously use several of them to solve a given problem. For example, many complex situations cannot be reliably modeled with one single simulation tool without a preliminary qualification process. The multi-scale approach facilitates the selection of an appropriate model as well as the definition of a procedure to qualify for the given application. Moreover, this framework underlines the possibility to couple codes at different scales which extend by several orders of magnitude the range of scales that can be represented within a single simulation. High performance computing can be used at all scales to improve the quality of the results in general or to simulate particularly complex problems (🔗 Fig. 37).

Simulation tools dedicated to the largest scales (system scale or component scale) very often require complex physical models to account for subgrid-scale phenomena. Hence, system-scale

■ Figure 37

The four identified scales of the multi-scale approach for thermal-hydraulics (system scale, component scale, local averaged scale, DNS scale)

codes might use a 1D or 0D descriptions of some system components, together with complex correlations to take into account the different flow patterns that might be found in these components (see, e.g., the CATHARE code (<http://www-cathare.cea.fr/>; Barre and Bernard 1990)). Some of these models do not rely on any mesh convergence property and the mesh can therefore be very coarse. Due to the small number of degrees of freedom (a few thousands in system models), these models can run on single processor computers. HPC is used for these codes though, in order to perform sensitivity analysis by running thousands of simulations.

When the study requires a more accurate representation of the flow pattern at smaller scales, 3D simulations are used and the assessment of the model can partially rely on mesh convergence properties. Therefore, a higher number of degrees of freedom is expected to produce a better result and HPC is massively exploited to run the most refined simulations.

6.2.3 HPC for DNS

DNS stands for direct numerical simulation and traditionally consists in solving the Navier–Stokes equations down to the Kolmogorov scales to achieve mesh convergence of the numerical scheme without any subgrid turbulence model. It is the preferred way to study general properties of turbulent incompressible single-phase flows in academic geometries (infinite 3D periodic domain or channels with flat parallel walls) because it does not rely on any questionable subgrid-scale model but, for a majority of real flows, the physical size of simulated channels cannot exceed a few millimeters.

Despite the academic nature of DNS-based studies, this kind of methodology already provided useful results for the study of turbulent flows, particularly in the field of averaged equations models (closure laws for LES and K-epsilon models, wall laws, etc.).

In the framework of the multi-scale approach, two new fields of research recently arose, for which using DNS is quite natural:

- Porous medium modeling
- Study of two-phase flows and boiling

■ Figure 38

The QLOVICE experiment: pool heating in a transparent test section (CEA/DEN)

Both subjects are treated for the purpose of the multi-scale approach. Porous medium studies with DNS will help tuning the component-scale models that rely on a porous medium description of the component (for instance, the reactor core). Studies of two-phase flows with DNS have at least two purposes:

- Improving models at larger scales (for instance, closure laws for six equations models)
- Studying some complex physical mechanisms like the DNB (departure from nucleate boiling)

If we illustrate the DNB problem, today, we use hundreds of correlations for DNB. Using a multi-scale approach the idea is to better understand the basic phenomena through close interaction between numerical experiments and experimental observations, like coalescence of bubbles, spreading of one bubble (➤ Fig. 38).

Whereas single-phase DNS codes in structured grids are quite simple, DNS of two-phase flows or porous medium face serious algorithmic difficulties which have found satisfactory solutions only recently.

DNS codes for the incompressible Navier–Stokes equations are usually based on efficient FFT-based Poisson solvers to solve for a divergence free velocity field at each time step. For different reasons, both of these two new applications of DNS do not fit very well in this framework and require more complex codes:

- Porous media have a nonregular geometry.
- Two-phase flows need a Poisson solver for nonuniform density, plus a proper treatment of surface tension and jumps of some physical quantities at the interface (density, viscosity, velocity, etc.).

For example, the Trio_U code (CEA) (<http://www-trio-u.cea.fr>; Calvin et al. 2002) implements a sophisticated mixed Lagrangian–Eulerian method to track the interface (➤ Fig. 39).

■ Figure 39

Mixed front-tracking-based DNS method for two-phase flows (Trio_U code). A dynamic surface mesh tracks the phase interfaces

In order to run this method on massively parallel computers, proper algorithms for dynamic load balancing of the Lagrangian mesh must be implemented (Laucoin and Calvin 2004).

In this field of research, meshes typically have 10–100 million elements (Eulerian mesh) and computations typically cost several hundreds of thousand hours of CPU time.

One typical example of actual capabilities is a two-phase flow intermittent, relatively difficult to reproducibly achieve experimentally, and especially difficult to orchestrate. Only some magnitude of most important physical parameters can be measured by direct experiences; these include the interfacial area (total surface interfaces between the liquid and gas), the void fraction (fraction of gas per unit volume), and drag (friction force between the liquid and gas). The numerical model provides much more information such as speed, size, and possible collisions of thousands of gas bubbles from the flow (see ► Fig. 40).

The calculation was performed on 1,000 cores representing 300,000 h of computing total and was executed in 10 days.

6.2.4 HPC for LES

LES stands for Large Eddy Simulation and sits on the next level just above DNS in the multi-scale approach. The goal of LES is to model the effect of small-scale turbulence eddies on the large scales in order to use a coarser mesh, while capturing the nonstationary nature of the flow due to large eddies. It essentially consists of modeling the turbulent viscosity that accounts for the subgrid-scale kinetic energy dissipation. LES will be used at larger scales where an accurate description of the wall geometry must be used. Hence, meshes are usually not regular.

Typical application examples related to the field of nuclear safety include:

Figure 40
Example of DNS simulation, flow bubble column using Trio_U code

- Modeling of thermal oscillations at a T-junction (thermal fatigue) (see Fig. 41)
- Finding absolute extremas of boron concentration (location and value) during a clean water injection (see Fig. 42) (Bieder and Calvin 2003; Calvin 2003)
- Finding peak temperatures in a fuel assembly (see Fig. 43)

Some codes will use hexahedral elements (which sometimes requires a difficult meshing process), while some other rely on tetrahedral elements. Tetrahedral meshes will need more elements to accurately represent channel flows but can be quickly generated even for complex geometries. Moreover, they do not tend to artificially drive the flow in particular directions (e.g., main directions given by mesh lines in hexahedral meshes).

The main issues in LES are:

- Designing wall laws to account for the non-isotropic turbulence at walls
- Obtaining appropriate numerical schemes for unstructured grids (many cell or vertex-based methods require a questionable smoothing step to kill spurious velocity fields that are not seen by the pressure correction step).
- Being able to run unsteady simulations with appropriate meshes (10–100 million mesh elements).

6.2.5 Other Fields

We have illustrated in the previous sections the main fields where HPC is involved in CFD, but lots of other fields can address the use of HPC, like RANS models.

■ Figure 41
Modeling of thermal oscillations at a T-junction

■ Figure 42
Boron dilution in a PWR using LES approach with Trio_U code

Major problems, which one has to deal with are standard ones but have to be addressed in order to progress in the physical modeling of phenomena while conserving very good performances.

Among these problems one can cite implicit methods and code coupling.

6.3 High Performance Computing for Materials Science

Marius Stan and Stephen R. Lee – Los Alamos National Laboratory, Los Alamos, NM 87545, USA.

6.3.1 Introduction

In nuclear reactors, severe radiation environments continuously alter thermo-mechanical properties of nuclear fuels (actinide-based alloys and ceramics) (Olander 1976) and structural materials (alloys) (Hecker and Stan 2008). The physics and chemistry of such materials increase in complexity due to irradiation effects. To address these issues, several projects have been developed all over the world to assess the properties of multicomponent materials.

One of the most challenging aspects of developing a comprehensive understanding of nuclear reactor fuels and structural materials is their complex, evolving composition. The study of multicomponent systems containing U, Np, Pu, Am, Cm or Fe, C, Cr, and their oxides, nitrides, and alloys, is considerably complicated by the presence of fission products such as Xe, Cs, Sr, He, I, and Tc. Most commercial reactor and fuel performance codes assume the reactor materials to be homogenous and average the properties over the computational domain. By including the heterogeneous character of the fuels, the precision and accuracy of predictions can be significantly improved.

There is an increasing need for a multi-physics approach to develop a fundamental understanding of properties of complex nuclear fuel materials in the reactor environment, leading to improved tools for predicting phenomena such as heat transfer, phase stability, species diffusion, and fission products retention.

Recently, combined theoretical, computational, and experimental efforts have provided valuable information about material properties and important phenomena associated with nuclear fuels (Stan et al. 2007). However, as of today, models and simulations are still not regarded as critical tools for fuel design and optimization. One of the reasons is the lack of predictability, often associated with the empirical correlations used in computational tools. The applicability of such correlations is limited to a regime where experimental data is available.

Another reason is the lack of available computational power during previous design eras, which limited the fidelity and reach of simulations.

The idea of replacing empirical correlations with theory-based models for the purpose of improving high performance simulation tools is not new. For example, in USA the last nuclear test was fired in 1992, and shortly thereafter, the Comprehensive Test Ban Treaty was adopted. This led to the creation of the Stockpile Stewardship Program (SSP) and the Advanced Simulation and Computing Initiative (ASCI), started in 1996. The SSP was an integrated program of experimentation and simulation directed to certify the US nuclear weapons stockpile without full nuclear tests. ASCI was the simulation component of the overall SSP. For various reasons, ASCI did not have a counterpart in the nuclear fuels area. However, the ASCI program redefined high performance computing and applications for coupled computational multi-physics problems, all of which are available for advanced nuclear fuel performance codes today, enabling them to incorporate theory-based models and simulations rather than empirical correlations. The ASCI program also affected the type, pace, and ultimately the widespread availability of high performance computing for scientific endeavors.

The definitions below are intended to ensure a coherent framework for the presentation of results and discussions in this section:

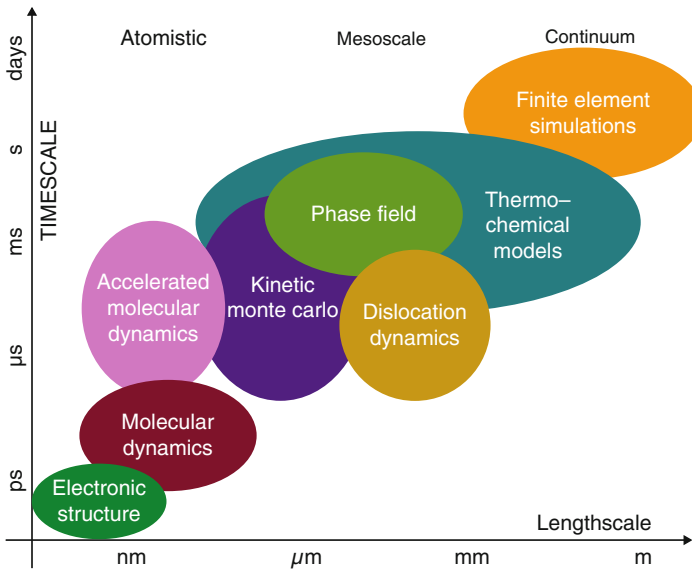

A *model* is a logical description of how a system (nuclear fuel material, in our case) performs. Models are based either on a theory or empirical knowledge and are validated by experiment (rarely by computation). Most models are presented as mathematical expressions. For example, “enthalpy depends linearly on temperature” and “enthalpy is quadratic in temperature” are different models.

Empirical models are collections of experimental observations fitted to mathematical expressions, such as (but not only) polynomial functions. When accurate, they allow for concise descriptions of material properties and are extremely valuable for technological applications. However, empirical models are only valid within the range of parameters and irradiation conditions covered in the data set on which they have been developed. Interpolation and extrapolation of empirical models is a dangerous practice that can lead to errors. Since the uncertainty associated with empirical models is often large, confidence intervals are difficult to calculate. *Theory-based models* are developed to include and explain the physics, chemistry, and materials science of fuel materials. These models are often referred to as “mechanistic” descriptions of properties. They are expected to provide a deeper understanding of the nature of the properties and to have improved predictive character.

A *simulation* is the process of running computer programs to reproduce, in a simplified way, the behavior of a system. Simulations describe the evolution of the system along a certain coordinate, most often the time. For example, a simulation of heat transport in a fuel element can describe the enthalpy content of a specific volume at different moments in time. The simulation is likely to involve a model of enthalpy, similar or more sophisticated than the ones mentioned above.

6.3.2 Theoretical and Computational Methods

To account for all the important material properties and reactor phenomena, models and simulations must address a wide range of space and time scales, starting with the nucleus, the electronic structure, atomistic, nanoscale, mesoscale, all the way to the fuel element size

■ Figure 44

Length and time scales involved in simulating phenomena relevant for nuclear materials as covered by computational methods (Stan et al. 2007)

(centimeters), and from picoseconds to seconds, all the way to the operating and storage characteristic times (months, years). The characteristic time step and space length associated with various phenomena cannot be estimated. For example, diffusion involves the electronic structure properties of the atoms at nanoscale lengths and nanosecond times. Still, the kinetics of bulk diffusion processes can be characterized from a continuum, macroscopic point of view (microns) using characteristic times of minutes, hours, and even days for the fuel-clad interaction.

To address all relevant properties and phenomena that occur in materials in general and nuclear fuels in particular, numerous theoretical and computational methods have been developed. The methods cover various time and space scales, as shown in [Fig. 44](#). The information is transferred between scales via characteristic parameters such as density, energy, temperature, or average grain size.

Nuclear methods are often reviewed as part of reactor physics books (Stacey 2001) and revolve around nuclear reactions and neutron transport theory. Sophisticated mathematical methods and computational techniques are used to calculate nuclear cross sections. Although very important for criticality calculations and reactor energy balance, the nuclear methods have, as of now, little impact on materials models. Since the thermo-mechanical and chemical properties of the nuclear fuels appear to be more influenced by the electron bands rather than the nuclear structure of the atoms, the nuclear data and associated models will not be reviewed in this section.

Atomistic methods account for the evolution of each atom in the computation domain and typically focus on point properties that are then used as a basis for statistical mechanics evaluations of bulk properties.
