Neurodegenerative Diseases

Neurobiology, Pathogenesis and Therapeutics

Neurodegenerative diseases are among the major contributors to disability and disease, with Alzheimer's and Parkinson's diseases the most prevalent among many in this category. This major reference reviews the rapidly advancing knowledge of pathogenesis and treatment of neurodegenerative diseases in the context of a comprehensive survey of each disease and its clinical features. The editors and contributors are among the leading experts in the field internationally.

Covering basic science, diagnostic tools and therapeutic approaches, the book focuses on all aspects of neurodegenerative disease, including the normal aging process. The dementias, prion diseases, Parkinson's disease and atypical parkinsonisms, neurodegenerative ataxias, motor neuron diseases, degenerative diseases with chorea, iron and copper disorders, and mitochondrial diseases, are all methodically presented and discussed, with extensive illustrations. In each case the underlying genetics, neuropathological and clinical issues are fully reviewed, making this the most complete as well as the most authoritative reference available to clinicians and neuroscientists.

M. Flint Beal is Anne Parrish Titzell Professor and Chairman of the Department of Neurology and Neuroscience at the Weill Medical College of Cornell University, and Director of Neurology at the New York Presbyterian Cornell Campus. An internationally recognized authority on neurodegenerative disorders, his research has focused on the mechanism of neuronal degeneration in Alzheimer's disease, Huntington's disease, Parkinson's disease and amyotrophic lateral sclerosis.

Anthony E. Lang is Professor in the Department of Medicine, Division of Neurology, University of Toronto. A founding member of the Parkinson Study Group and the Movement Disorders Society, his research has included clinical trials of poorly recognized neurological disorders, clinical trials of new therapeutic modalities, and studies in molecular biology, neurophysiology, neuropsychology and imaging.

Albert C. Ludolph is Professor of Neurology, Chair of Neurology, and Chairman of the Neuroscience Center of the University of Ulm, Germany. A neurologist and psychiatrist, his major interest is in toxicological models of vulnerability and genetic models for the pathogenesis of neurodegenerative diseases.

Contents

<i>List of contributors</i>	<i>page ix</i>
<i>Preface</i>	<i>xxi</i>

Part I Basic aspects of neurodegeneration

1 Endogenous free radicals and antioxidants in the brain	3
Stefan L. Marklund	
2 Biological oxidants and therapeutic antioxidants	18
John P. Crow	
3 Mitochondria, metabolic inhibitors and neurodegeneration	33
James G. Greene and J. Timothy Greenamyre	
4 Excitotoxicity and excitatory amino acid antagonists in chronic neurodegenerative diseases	44
Chrysanthy Ikonomidou and Lechoslaw Turski	
5 Glutamate transporters	57
Davide Trotti and Stuart L. Gibb	
6 Calcium binding proteins in selective vulnerability of motor neurons	65
László Siklós and Stanley H. Appel	
7 Apoptosis in neurodegenerative diseases	80
Jorg B. Schulz	
8 Neurotrophic factors	94
Michael Sendtner	

9 Protein misfolding and cellular defense mechanisms in neurodegenerative diseases	108	21 Magnetic resonance spectroscopy of neurodegenerative illness	301
Michael Y. Sherman and Alfred L. Goldberg		Bruce G. Jenkins, Ji-Kyung Choi and M. Flint Beal	
10 Neurodegenerative disease and the repair of oxidatively damaged DNA	131	Part III Therapeutic approaches in neurodegeneration	
Marcus S. Cooke		<hr/>	
11 Compounds acting on ion channels	141	22 Gene therapy	329
Holger Lerche and Frank Lehmann-Horn		Chamsy Sarkis and Jacques Mallet	
12 The role of nitric oxide and PARP in neuronal cell death	146	23 Stem cells and cell-based therapy in neurodegenerative disease	347
Mika Shimoji, Valina L. Dawson and Ted M. Dawson		Eva Chmielnicki and Steven A. Goldman	
13 Copper and zinc in Alzheimer's disease and amyotrophic lateral sclerosis	157	24 Necessary methodological and stem cell advances for restoration of the dopaminergic system in Parkinson's disease patients	363
Avi L. Friedlich and Ashley I. Bush		Ole Isacson, Kwang-Soo Kim, Ivar Mendez, Craig van Horne, Lars M. Bjorklund and Rosario Sanchez-Pernaute	
14 The role of inflammation in Alzheimer's disease neuropathology and clinical dementia. From epidemiology to treatment	166	Part IV Normal aging	
Guilio Maria Pasinetti		<hr/>	
15 Selected genetically engineered models relevant to human neurodegenerative disease	176	25 Clinical aspects of normal aging	383
Donald Price, David R. Borchelt, Michael K. Lee and Philip C. Wong		Marilyn S. Albert	
16 Toxic animal models	196	26 Neuropathology of normal aging in cerebral cortex	396
Serge Przedborski and Kim Tieu		John H. Morrison, Patrick Hof and Peter R. Rapp	
17 A genetic outline of the pathways to cell death in Alzheimer's disease, Parkinson's disease, frontal dementias and related disorders	222	Part V Alzheimer's disease	
John Hardy		<hr/>	
18 Neurophysiology of Parkinson's disease, levodopa-induced dyskinesias, dystonia, Huntington's disease and myoclonus	227	27 Mild cognitive impairment	409
Antonio Currà, Rocco Agostino and Alfredo Berardelli		Keith A. Josephs, David F. Tang-Wai and Ronald C. Petersen	
Part II Neuroimaging in neurodegeneration		28 Alzheimer's disease: overview	416
<hr/>		David F. Tang-Wai, Keith A. Josephs and Ronald C. Petersen	
19 Structural and functional magnetic resonance imaging in neurodegenerative diseases	253	29 The neuropathology of Alzheimer's disease in the year 2005	433
Michael Samuel and Alan Colchester		Colin L. Masters and Konrad Beyreuther	
20 PET/SPECT	290	30 Genetics of Alzheimer's disease	441
Maja Trošt, Vijay Dhawan, Andrew Feigin and David Eidelberg		Lars Bertram and Rudolph E. Tanzi	
		31 The role of β-amyloid in Alzheimer's disease	452
		Roger M. Nitsch	
		32 Treatment of Alzheimer's disease	459
		Mary Sano	

Part VI Other dementias

- 33 Dementia with Lewy bodies** 473
Norman Relkin
- 34 Frontotemporal lobar degeneration** 481
Adam L. Boxer, John Q. Trojanowski, Virginia M.-Y. Lee and Bruce L. Miller
- 35 Frontotemporal dementia with parkinsonism linked to Chromosome 17** 494
Mark S. Forman, Virginia M.-Y. Lee and John Q. Trojanowski
- 36 Prion diseases** 512
- I** The clinical approach to human prion disease
- II** The pathogenesis and mechanisms of prion diseases
Adriano Aguzzi, H. Tumani and Albert C. Ludolph

Part VII Parkinson's and related movement disorders

- 37 Approach to the patient presenting with parkinsonism** 551
Katie Kompoliti and Christopher G. Goetz
- 38 Parkinson's disease** 561
Christopher G. Goetz and Katie Kompoliti
- 39 Neuropathology of Parkinson's disease** 575
Dennis W. Dickson
- 40 Genetics of parkinsonism** 586
Thomas Gasser
- 41 Pathophysiology: biochemistry of Parkinson's disease** 598
Daniela Berg, Olaf Riess and Peter Riederer
- 42 Current and potential treatments of Parkinson's disease** 612
Clifford W. Shults
- 43 Multiple system atrophy** 623
Felix Geser, Carlo Colosimo and Gregor K. Wenning
- 44 Progressive supranuclear palsy** 663
Lawrence I. Golbe
- 45 Corticobasal degeneration** 682
Kailish P. Bhatia and Anthony E. Lang

Part VIII Cerebellar degenerations

- 46 Approach to the patient with ataxia** 699
Thomas Klockgether
- 47 Autosomal dominant cerebellar ataxia** 709
Henry L. Paulson
- 48 Friedreich's ataxia and other autosomal recessive ataxias** 719
Hélène Puccio and Michel Koenig
- 49 Ataxia telangiectasia** 738
Richard A. Gatti, Tom O. Crawford, Alan S. Mandir, Susan Perlman and Howard T. J. Mount

Part IX Motor neuron diseases

- 50 An approach to the patient with motor neuron dysfunction** 751
Matthew J. Parton and P. Nigel Leigh
- 51 The genetics of amyotrophic lateral sclerosis** 758
Ammar Al-Chalabi and Robert Brown
- 52 Current and potential therapeutics in motor neuron diseases** 772
Clare Wood-Allum and Pamela J. Shaw
- 53 The hereditary spastic paraplegias** 794
John K. Fink
- 54 Spinal and bulbar muscular atrophy (Kennedy's disease): a sex-limited, polyglutamine repeat expansion disorder** 803
Patrick S. Thomas and Albert R. La Spada
- 55 Spinal muscular atrophies** 817
Klaus Zerres and Sabine Rudnik-Schöneborn
- 56 Western Pacific ALS/parkinsonism-dementia complex** 827
Daniel P. Perl and Patrick R. Hof

Part X Other neurodegenerative diseases

- 57 Huntington's disease** 847
Christoph M. Kosinski and Bernhard Landwehrmeyer

58 Dentatorubral-pallidoluysian atrophy (DRPLA): model for Huntington's disease and other polyglutamine diseases	861	61 Neurological aspects of Wilson's disease	890
Christopher A. Ross, Lisa M. Ellerby, Jonathan D. Wood and Frederick C. Nucifara Jr.		Peter A. LeWitt and George J. Brewer	
59 Neuroanthocytosis	871	62 Disorders of the mitochondrial respiratory chain	909
Alexander Storch		Anthony H. V. Schapira	
60 Brain iron disorders	880	<i>Index</i>	927
Satoshi Kono, Hiroaki Miyajima and Jonathan D. Gitlin

Preface

Neurodegenerative diseases are becoming increasingly prevalent with the aging of the general population. The twentieth century witnessed a significant demographic change in the human population of the industrialized world that is currently followed by a similar shift of life expectancy to upper age ranges in Asia, Africa, and Middle and South America. Quality of life of the aging population of the world is, to a great extent, determined by the normal aging process of neurons in the central nervous system and especially by the occurrence of diseases characterized by accelerated neuronal loss: diseases which are traditionally designated as being neurodegenerative. They are presently amongst the major contributors to disability and disease in human populations.

Alzheimer's disease is the most prevalent of the neurodegenerative diseases followed by Parkinson's disease. Amyotrophic lateral sclerosis and Huntington's disease affect smaller numbers of patients but have devastating consequences. A large number of other rarer neurodegenerative diseases have similar profound effects on the patients and families who are afflicted by these illnesses. Research into the pathogenesis and treatment for these disorders is exploding exponentially. To a great extent this has been fostered by major advances in genetics, since we now know mutations that are associated with a large number of these illnesses. This includes familial forms of Alzheimer's disease, Parkinson's disease, fronto-temporal dementia, ALS, Huntington's disease and a variety of ataxias. Most of the sporadic cases of the common neurodegenerations such as Alzheimer's disease, Parkinson's disease, Amyotrophic lateral sclerosis appear to be polygenetic and are influenced by poorly characterized environmental factors.

The discovery of causative genetic mutations has led to the development of transgenic animal models of these disorders, which has enhanced our understanding of disease pathogenesis. Transgenic models are also

useful for experimental therapeutics. Already, this is having a major impact on the development of novel therapeutic strategies for the treatment of these disorders. The ultimate goal is to either prevent these diseases in at-risk individuals before the onset of clinical manifestations or to develop effective neuroprotective therapies that slow down or halt disease progression in the earliest stages.

Given the pace of research and the burgeoning interest in the field, it appeared to be an auspicious time to put together a major textbook placing the neurodegenerative diseases into modern perspective. The objective of the present text is to present the latest research into the genetics, pathogenesis, biochemistry, animal models, clinical features, and treatment of neurodegenerative diseases. As such, we have been very fortunate to obtain the assistance of an internationally recognized group of authors who are amongst the foremost experts in neurodegenerative diseases.

In the first section we have compiled state-of-the-art chapters that reflect on basic aspects of neurodegeneration, including the roles of free radicals, mitochondria, excitotoxicity, calcium binding proteins, apoptosis, neurotrophins, protein aggregation, DNA repair systems, trace elements, nitric oxide/PARP, and inflammation. We have also obtained outstanding chapters on utilizing diagnostic and therapeutic tools in neurodegenerative diseases. This includes chapters on transgenic animal models, toxic animal models, strategies for molecular genetics, electrophysiological assessment, MRI, PET/SPECT, and MRI spectroscopy. Gene therapy, stem cells and transplantation are also covered.

The book then focuses on major aspects of neurodegenerative diseases, including normal aging of the nervous system. There are specific approaches to diseases dominated by dementia or behavioral disturbances, including Alzheimer's disease, Dementia with Lewy bodies, Pick's disease, fronto-temporal dementias, and fronto-temporal dementia with parkinsonism. There is also a chapter on prion diseases. The approach to the patient presenting with Parkinsonian symptoms is addressed, as well as more detailed chapters dealing with the clinical aspects, neuropathology and treatment of Parkinson's disease. There are also chapters on the so-called "atypical parkinsonisms" including multiple system atrophy, progressive supranuclear palsy and corticobasal degeneration. Subsequent sections deal with the neurodegenerative ataxias, motor neuron diseases, degenerative diseases with chorea (Huntington's disease, DRPLA, neurocanthocytosis), iron and copper disorders and finally mitochondria diseases. In each section we attempted to obtain chapters that detail the genetics and the clinical and neuropathologic features of these illnesses, as well as modern approaches to treatment.

Although the rapid pace of research in the field challenges the ability of any textbook to maintain its currency, we have conscripted a superlative group of contributors and compiled a text that we believe will be the most authoritative in the field for the forthcoming near future. We hope that this text will be useful to both neurologists and neuroscientists who are interested in the pathogenesis, clinical aspects, and treatment of these disorders. We also hope that this work will stimulate the further research necessary to relieve the human suffering caused by these tragic and devastating illnesses.

Basic aspects of neurodegeneration

Endogenous free radicals and antioxidants in the brain

Stefan L. Marklund

Department of Medical Biosciences, Clinical Chemistry, Umeå University Hospital, Sweden

The role of oxygen free radicals and antioxidants in Central Nervous System (CNS) pathology is of major interest for many reasons. While accounting for only 2% of the body weight, the brain uses 20% of the oxygen consumed by the resting body. Polyunsaturated lipids and catecholamines prone to autoxidize are abundant, and since the neurons are postmitotic, efficient protection against oxidants is vital. Accordingly, changes in most antioxidant and prooxidant factors result in phenotypes in the brain, which is exemplified in this chapter. Evidence for attack by oxygen free radicals on lipids, proteins and DNA has also been found in virtually every type of brain disease and in aging. The oxidants also exert signalling effects, but that aspect will not be covered in this chapter.

Formation of oxygen free radicals

Molecular oxygen is chemically a biradical with two unpaired electrons with equal spins in two antibonding Π^*2p orbitals. This has the consequence that oxygen primarily is reduced one step at a time, since reactions with paired electrons are “forbidden.” Reduction of oxygen to water may, in principle, be described in steps:

The results are the intermediates: the superoxide anion radical, hydrogen peroxide and the hydroxyl radical. Hydrogen peroxide is not a free radical but is still reactive, and the intermediates are together often termed reactive oxygen species (ROS). Sometimes peroxy ($\text{LOO}\cdot$) and alkoxyl

($\text{LO}\cdot$) radicals, e.g. formed in lipid peroxidation (below) are included among the ROS. The term is commonly used, because often the actual damaging species in the biological system under study is not well defined.

The bulk of oxygen in the body is reduced in four steps to water in the mitochondrial respiratory chain, without release of intermediates. A few percent of the oxygen consumed is estimated to be reduced stepwise under formation of ROS. With the exception of a few oxidase-catalyzed reactions, the reduction primarily proceeds via formation of superoxide radical.

Superoxide anion radical

Mitochondria

The major source of superoxide radicals in the body is the reaction of oxygen with electrons leaking from the mitochondrial respiratory chain. The major sites of superoxide formation are apparently FeS clusters or semiquinones in complex I and ubisemiquinone in complex III. Studies with depletion of Mn-SOD suggests that complex III superoxide formation may be directed vs. both the inner matrix and the intermembrane space (Raha *et al.*, 2000). From the intermembrane space, the radicals may then enter the cytosol via the voltage-dependent anion channels (VDAC) (Han *et al.*, 2003). Increased mitochondrial superoxide production apparently plays important roles in a variety of pathologies including glutamate-induced excitotoxicity (Nicholls *et al.*, 1999), hyperglycemia (Du *et al.*, 2000), TNF action (Hennet, Richter & Peterhans, 1993), some mitochondrial diseases (McEachern *et al.*, 2000), and ischemia-reperfusion (Li & Jackson, 2002). (See also Chapter 3, Greenamyre and Chapter 62, Shapira.)

The NADPH oxidases

These are membrane-bound complexes that are major sources of superoxide radical in the body. Normally, the activity has useful purposes: in phagocytes for the defense against infections and in other cell types probably for signalling. However, activation of the oxidases may also exert toxic collateral effects. The catalytic subunit gp91phox and p22phox are membrane bound, while there are several cytosolic components that assemble with the membrane-bound components upon activation (Babior, Lambeth & Nauseef, 2002). There are at least five gp91phox homologs (NOX) (Bokoch & Knaus, 2003; Cheng *et al.*, 2001). The most extensively studied is the NOX2 of neutrophils, which also exists in macrophages/microglia. Oxidant production by activated microglia has been implicated in virtually every neurodegenerative disease, e.g. Gao *et al.* (2002). (See also Chapter 14, Pasinetti.) NOX isoforms are also expressed in vascular endothelial and smooth muscle cells (Sorescu *et al.*, 2002), and may be sources of superoxide in pathologies with vascular components, e.g. as induced by peptides derived from APP (Iadecola *et al.*, 1999). Furthermore, components of the NADPH oxidase complex have been demonstrated in cultured cortical neurons and astrocytes, and have been implicated in oxidant production induced by Zn (Noh & Koh, 2000), and neuronal apoptosis following NGF deprivation (Tammariello, Quinn & Estus, 2000).

Autoxidations

Autoxidations generally result in one-step reduction of oxygen to the superoxide radical. Multiple endogenous and exogenous drugs and toxins in the CNS are prone to autoxidation including dopamine, L-DOPA, adrenalin, noradrenalin, 6-OH-dopamine. Most reactions are relatively slow, but are promoted by transition metal ions. Such reactions are suspected to contribute to neurodegeneration, e.g. in Parkinson's disease (Jenner & Olanow, 1996). (See also Chapter 6, Przedborski.)

Xanthine oxidase

This is the final enzyme in the catabolism of purines in humans and catalyzes the stepwise formation of xanthine and urate from hypoxanthine under formation of both superoxide and hydrogen peroxide. Xanthine oxidase is proteolysed from its NADH-accepting form, e.g. following ischemia/reperfusion, which also will lead to increased formation of hypoxanthine. The enzyme has been demonstrated in the brain of some rodents (Patt *et al.*, 1988), but not with certainty in humans. The inhibitor allopurinol (Palmer *et al.*, 1993) or inhibition by pretreatment with

tungsten (Patt *et al.*, 1988) has shown protective effects in some brain i/r models, for example, but many studies have failed to show effects (Nakashima *et al.*, 1999).

Nitric oxide synthase

Under suboptimal concentrations of arginine all nitric oxide synthase isoenzymes generate $O_2^{\cdot-}$ under enzymic cycling (Pou *et al.*, 1992). This side reaction is also influenced by the cofactor tetrahydrobiopterin, which increases the rate of oxygen reduction, but also leads to some direct formation of hydrogen peroxide (Rosen *et al.*, 2002).

Prostanoid metabolism

Both PGH synthase and lipoxygenases release in the presence of NAD(P)H superoxide radical as a byproduct (Kukreja *et al.*, 1986). Such formation has been shown to contribute to microvascular abnormalities in the brain, e.g. induced by hypertension (Kontos *et al.*, 1981).

CYP450

The drug-metabolizing cytochrome P450s leak electrons to oxygen to form the superoxide radical. The 2E1 isoform is particularly prone to form superoxide and occurs in some parts of the brain (Tindberg & Ingelman-Sundberg, 1996). It is induced by ethanol and some xenobiotics, IL-1 β , and ischemia/reperfusion (Tindberg *et al.*, 1996). Whether the activities in the brain are sufficient to exert toxic effects is not known, but 2E1 is strongly implicated in, e.g. liver pathology (Cederbaum *et al.*, 2001).

RAGE

Advanced glycation end products react with a cell surface receptor (RAGE) that transduces proinflammatory signals including formation of oxygen radicals, possibly via activation of NADPH oxidases (Wautier *et al.*, 2001). The receptor exists on microglia, astrocytes and hippocampal neurons and has been implicated in cellular activation, e.g. by A β peptides in Alzheimer's disease (Lue *et al.*, 2001; Sasaki *et al.*, 2001).

Reactions of the superoxide radical

The superoxide radical reacts very rapidly with NO to form peroxynitrite. This reaction is of great importance for the physiology and pathology of both molecules. (See Chapter 2, Crow and Chapter 12, Dawson.) There is also a rapid reaction with ascorbate (Nishikimi, 1975) and a slower complex reaction and interaction with reduced glutathione (Winterbourn & Metodiewa, 1994). The superoxide radical has, however, a low reactivity with most other biomolecules. The most important cellular targets are

proteins with FeS clusters (Gardner & Fridovich, 1991), which occur particularly in mitochondria. The inactivation of the cytosolic and mitochondrial aconitases, which both contain FeS clusters, are useful markers for increased superoxide radical formation (Gardner & Fridovich, 1991; Huang *et al.*, 2002). Participation of superoxide radical in Haber Weiss chemistry may also be of importance, see below. The corresponding acid form, $\text{HOO}\cdot$, is more reactive and may, e.g. initiate lipid peroxidation (Bielski, Arudi & Sutherland, 1983). The acid–base couple has a $\text{p}K_{\text{a}}$ of 4.75, which is why such reactions will increase in importance with decreasing pH. It has been suggested that the superoxide radical can terminate lipid peroxidation chains and there is evidence for the existence of optimal superoxide concentrations in vivo (Nelson, Bose & McCord, 1994). The superoxide radical inhibits glutathione peroxidase (Blum & Fridovich, 1985) and catalase (Kono & Fridovich, 1982). On the other hand, the radical reactivates catalase inhibited by NO (Kim & Han, 2000). There are other in vivo effects of superoxide radical with more undefined mechanisms, but with a neurobiological interest. Thus superoxide activates mitochondrial uncoupling proteins (Echtay *et al.*, 2002), potentiates hippocampal synaptic transmission (Knapp & Klann, 2002) and inactivates a plasma membrane surface glutamate receptor-like complex (Agbas *et al.*, 2002).

Hydrogen peroxide

The major part of the hydrogen peroxide in the body is formed by superoxide dismutase-catalyzed or spontaneous dismutation of the superoxide radical. Some hydrogen peroxide is, however, formed directly by oxidases such as glycolate oxidase, urate oxidase (not in humans) and D-amino acid oxidase, which are localized to peroxisomes. Of particular importance in the CNS are the monoamine oxidases (MAO), situated in the outer membrane of mitochondria. MAO A primarily degrades serotonin and norepinephrine, and MAO B degrades phenylethylamine. Dopamine is metabolized by both (Shih, Chen & Ridd, 1999). Toxic effects may be caused by both the hydrogen peroxide formed upon the oxidative deamination of catecholamines as well as by some of the resulting metabolites. MAO effects have been suggested to contribute to, e.g. the loss of dopaminergic neurons in Parkinson's disease (Jenner & Olanow, 1996), where impairment of mitochondria may contribute (Gluck *et al.*, 2002).

Hydrogen peroxide generally has a low reactivity, but may oxidize some cysteines. Cysteine thiolate anions are readily oxidized to cysteine sulfenic acid, whereas (base)

thiols are very resistant. The thiolate anions exist at physiological pH in cysteines with low $\text{p}K_{\text{a}}$ s caused by adjacent stabilizing positively charged amino acid residues. Protein tyrosine phosphatases can be inactivated by such cysteine oxidation, and this reaction is involved in some of the signaling effects of hydrogen peroxide (Meng, Fukada & Tonks, 2002). Another susceptible target is the active cysteine in glyceraldehyde-3-phosphate dehydrogenase (Brodie & Reed, 1987). This thiol is very susceptible overall for reactions with ROS. Most toxicity of hydrogen peroxide is caused apparently by the interaction with transition metal ions (below).

Hydroxyl radical

The hydroxyl radical reacts at close to diffusion limited rates with most biomolecules and is by far the most reactive of the ROS. It is mainly formed in vivo in the reaction of hydrogen peroxide with reduced forms of transition metal ions:

The most important participating metals in vivo are Cu^+ and Fe^{2+} . The reaction with iron is called the Fenton reaction from its first description (Winterbourn, 1995). For the reactions to occur, the metal ions have to be reduced, e.g. by superoxide:

The sum of the two reactions is called the Haber–Weiss reaction (Halliwell, 1978; McCord & Day, Jr., 1978). The transition metal ion reduction can, however, be accomplished by many other reductants, e.g. ascorbate. Fenton/Haber–Weiss chemistry probably underlies a major part of the toxicity of both hydrogen peroxide and the transition metal ions.

Hydroxyl radical may also be formed from peroxynitrite (Halliwell, Zhao & Whiteman, 1999) and by the reaction of superoxide with hypochlorite (Candeias *et al.*, 1993). HOCl can, for example, be formed from hydrogen peroxide and Cl^- catalysed by myeloperoxidase in neutrophil leukocytes.

Singlet oxygen

An input of energy can transform ground state (triplet) molecular oxygen to singlet oxygen. The physiologically relevant form is called $^1\Delta_{\text{g}}$ singlet oxygen, which has the two antibonding electrons with opposite spins in one of the $\Pi^*2\text{p}$ orbitals. Thereby, spin restrictions for reactions

are removed and singlet oxygen reacts avidly with a wide variety of biomolecules, e.g. those containing double bonds. The reaction with unsaturated fatty acids results in the formation of lipid hydroperoxides, cf. below. Among amino acids residues, methionine and histidine are particularly susceptible, and in DNA the reaction primarily occurs with guanine residues (Sies & Menck, 1992). Singlet oxygen has a very short half-life in water, 3.8 μ s. Protection can be achieved by quenching reactions where the energy is transferred to another molecule, which in turn dissipates it as heat. β -carotene and other carotenoids are efficient singlet oxygen quenchers.

Singlet oxygen can be formed by type II photosensitizing reactions, where molecules excited by light transfer the energy to (triplet) molecular oxygen. Porphyrins and many drugs, e.g. tetracyclins are efficient sensitizers, and singlet oxygen is a major cause of the light-induced skin reactions caused by these compounds. Singlet oxygen is also formed in the reaction between two lipid peroxy radicals, cf. below, and slowly in a reaction between hydrogen peroxide and hypochlorite. Except for photosensitized reactions in the retina, singlet oxygen is probably not a major player in pathology of the nervous system.

Lipid peroxidation and vitamin E

The basis for lipid peroxidation is the labile *bis*-allylic hydrogens (LH below) bound to the methylene carbons between the double bonds in polyunsaturated fatty acids. The process can be initiated, for example, with the reaction of the hydrogen with a hydroxyl radical. Molecular oxygen rapidly adds to the resulting carbon-centred free radical, forming a lipid peroxy radical. This, in turn, abstracts a *bis*-allylic hydrogen from a neighbor fatty acid forming a lipid hydroperoxide and again a carbon-centred free radical. Molecular oxygen adds to this radical resulting in a propagated chain reaction called lipid peroxidation.

The reaction chain can be terminated by the radicals reacting with each other, e.g. the so-called Russel mechanism:

The “phenolic” hydrogen (Toc-OH) on the chroman ring of the lipid-soluble vitamin E (α -tocopherol) efficiently competes with the *bis*-allylic hydrogens for donation to lipid peroxy radicals.

The resulting radical in vitamin E is delocalized and generally does not participate in propagation of lipid peroxidation. The result is termination of the lipid peroxidation chain. Following absorption, vitamin E is transported to the organs of the body via lipoproteins. Vitamin E enters the brain slowly, although this organ seems to be prioritized in vitamin E deficiency (Vatassery *et al.*, 1988). In α - β -lipoproteinemia there is a deficient absorption and transport of vitamin E, which results in neurological deficits that are ameliorated by vitamin E therapy. The secretion of vitamin E from the liver via VLDL is dependent on the α -tocopherol transfer protein. Loss of function mutations in this protein lead to very low plasma vitamin E levels and progressive spinocerebellar ataxia (Gotoda *et al.*, 1995) and retinitis pigmentosa (Yokota *et al.*, 1997).

The *in vivo* initiation mechanisms are not well understood, but commonly may involve reactions of transition metal ions with lipid hydroperoxides, which in turn can be preformed by several mechanisms *in vivo*:

The resulting lipid alkoxy and peroxy radicals then abstract *bis*-allylic hydrogens initiating lipid peroxidation chains.

The lipid peroxidation results in detrimental structural changes of membranes and lipoproteins. The peroxidation-modified lipids degrade further to form a wide variety of toxic reactive compounds such as 4-OH-nonenal and malondialdehyde.

Transition metal ions

Transition metal ions are toxic, e.g. by participating in the Haber–Weiss reaction and in initiation of lipid peroxidation, and therefore have to be tightly controlled *in vivo*. In plasma, binding of Fe to transferrin prevents the reactivity, and normally less than 50% of the capacity is occupied. In the cytosol, storage in ferritin is protective. The form and mechanism of transit of Fe between intracellular pools and proteins, however, is not well defined, but there may be a 0.7–0.9 μ M “labile” iron pool (Konijn *et al.*, 1999). Increased amounts of reactive iron may occur following release from ferritin by the superoxide radical (Biemond *et al.*, 1988) and some redox-cycling toxins (Winterbourn, Vile & Monteiro, 1991), disruption of FeS clusters, e.g. by superoxide radicals (Gardner & Fridovich, 1991), and degradation of heme from denatured hemoproteins. Heme itself is also prooxidant (Gutteridge & Smith, 1988).

The intracellular transit of Cu is better understood and involves different “Cu-chaperones” for different Cu protein targets (Huffman & O’Halloran, 2001). SOD1 is, for example, charged by a Cu-chaperone for SOD (Wong *et al.*, 2000). The intracellular concentration of “free” Cu has been estimated to be less than 1 molecule per cell (Rae *et al.*, 1999). Excess Cu (and Zn) in cells may be scavenged by metallothioneins (Hidalgo *et al.*, 2001). (See also Chapter 13, Bush, Chapter 60, Gitlin, and Chapter 61, Lewitt.)

Hemoprotein peroxidases and oxidants

Mammals contain at least four peroxidases with heme prosthetic groups; myeloperoxidase, eosinophil peroxidase, lactoperoxidase and thyroid peroxidase. Like the ubiquitous plant hemoperoxidases, they have the ability to catalyze the oxidation of a wide variety of phenolic and other substrates by hydrogen peroxide. In vivo, however, the mammalian peroxidases primarily oxidize halides.

Myeloperoxidase exists in granules of neutrophils, monocytes and can also be induced in tissue macrophages/microglia (Sugiyama *et al.*, 2001). Upon activation these cells produce hydrogen peroxide via NADPH oxidase, which myeloperoxidase uses to oxidize Cl⁻ to the strong oxidant hypochlorite.

The hypochlorite is not essential for, but contributes to, the killing of bacteria by the neutrophils (Hampton, Kettle & Winterbourn, 1996). Myeloperoxidase apparently can also catalyze the hydrogen peroxide-dependent oxidation nitrite to a nitrating species (Pfeiffer *et al.*, 2001). This leads to the formation protein-bound nitrotyrosine, previously thought to be a specific marker for the reaction product between superoxide radical and NO, peroxynitrite.

The peroxidase of eosinophil leukocytes can also produce hypochlorite, but seems primarily to oxidize bromide ions to hypobromite (Weiss *et al.*, 1986). The lactoperoxidase of tears, saliva and milk oxidizes thiocyanate to the bacteriostatic hypothiocyanate. The thyroid peroxidase iodinates and condensates tyrosine residues in thyroglobulin to form the thyroid hormones.

Myeloperoxidase has been demonstrated in microglia close to plaques in Alzheimer’s disease and also in the β -amyloid, suggesting a potential involvement in the disease (Reynolds *et al.*, 1999). The enzyme may, however, also have a modulating effect on inflammatory reactions, since mice lacking myeloperoxidase are more susceptible

to experimental autoimmune encephalitis (Brennan *et al.*, 2001a) and atherosclerosis (Brennan *et al.*, 2001b).

Low-molecular weight scavengers

Endogenous

GSH

The tripeptide glutathione, L- γ -glutamyl-L-cysteinylglycine (GSH) reaches cellular concentrations of several mmol/l, and is generally the most abundant low-molecular weight antioxidant in the body. GSH aids in metabolizing hydroperoxides by being the reducing substrate of the glutathione peroxidases (below), and of some of the peroxyredoxins (below). GSH can also directly reduce some free radical targets in biomolecules (Biaglow *et al.*, 1989). The reactions mostly result in formation of the disulfide oxidized glutathione (GSSG), which is in turn reduced back to GSH by glutathione reductase. The enzyme uses NADPH, derived from the glucose-6-phosphate dehydrogenase, the cytosolic (Jo *et al.*, 2002) and the mitochondrial (Jo *et al.*, 2001) NADP-dependent isocitrate dehydrogenase isoenzymes. These dehydrogenases thus form important parts of the antioxidant defence. GSH can also react with oxidized cysteines in proteins forming mixed disulfides. Increased concentrations of these are found in oxidant stress (Cotgreave & Gerdes, 1998). GSH is also used for conjugation of xenobiotics and other molecules catalyzed by glutathione transferases, and direct reaction with free radical intermediates, e.g. from dopamine and L-DOPA can also occur (Spencer *et al.*, 1998). These reactions can, however, also lead to depletion of GSH, causing toxic effects on tissues.

GSH is formed from its constituent amino acids in two steps synthesized by γ -glutamyl-cysteine-synthase and glutathione synthase. Cysteine may be limiting for the synthesis, and can experimentally and therapeutically be supplied by *N*-acetylcysteine or by 2-oxothiazolidine-4-carboxylate (Gwilt *et al.*, 1998). GSH can be exported over the plasma membrane and will then be hydrolyzed to γ -glutamine and cysteinylglycine by the ectoenzyme γ -glutamyltranspeptidase. The dipeptide is then hydrolyzed by dipeptidases. The constituent amino acids can then be taken up intracellularly for GSH resynthesis.

In the brain, the concentration of GSH appears to be higher in astrocytes (4 mmol/l) than in neurons (2.5 mmol/l) and other glial cells. Astrocytes can apparently protect neurons by degrading the diffusible hydrogen

peroxide, and also supply neurons with the substrates for GSH synthesis by export of GSH (Dringen, Gutterer & Hirrlinger, 2000).

Bilirubin and heme oxygenases

Heme is degraded to biliverdin and the transmitter substance CO by the heme oxygenases (HO), the inducible HO-1 and the constitutive HO-2. HO-2 is the most abundant in the CNS. Biliverdin is then reduced by biliverdin reductase and NADPH to bilirubin. Since heme, that for example, can be released from denatured hemoproteins, is prooxidant (Gutteridge & Smith, 1988), the heme oxygenases may exert antioxidant roles, provided that the released iron is efficiently sequestered. Bilirubin, in addition, efficiently scavenges some reactive oxygen species such as singlet oxygen and peroxy radicals, forming biliverdin again. Bilirubin has shown in vitro neuroprotective action (Dore *et al.*, 1999), and a protective cycle involving biliverdin reductase can be envisioned. The β -amyloid precursor protein inhibits HO, and Alzheimer-linked mutant protein causes stronger inhibition. This effect has been suggested to contribute to the pathology in Alzheimer's disease (Takahashi *et al.*, 2000).

Urate

This is the end product of purine catabolism in humans, who have an inactive urate oxidase. In most other species allantoin is formed by urate oxidase. The concentration of urate in humans furthermore is kept high by tubular reabsorption in the kidney. Urate can scavenge a variety of oxidants such as ROO \cdot , ONOO $^-$, NO $_2$ and O $_3$ (Becker *et al.*, 1991) to form allantoin, parabanic acid and some other compounds. Urate at concentrations found in humans furthermore has been shown to protect the Cu-containing SOD1 and SOD3 in vivo against inactivation by (presumably) hydrogen peroxide (Hink *et al.*, 2002). Administration of urate protects, for example, against experimental autoimmune encephalitis (Kastenbauer *et al.*, 2001), and increased levels of the oxidized metabolites in CSF have, for example, been observed in humans with meningitis (Kastenbauer *et al.*, 2002), suggesting a protective role of the compound in the CNS.

Exogenous

Ascorbate

This and vitamin E (see above) are the major dietary antioxidants in humans. Other mammals, with the exception of guinea pigs, synthesize ascorbate in the liver. Ascorbate occurs in 10–100-fold higher concentration in cells

compared with blood plasma. In addition to participation in multiple metabolic reactions, ascorbate is an important antioxidant that reacts rapidly with superoxide radical, other free radicals and peroxynitrite and can also regenerate oxidized vitamin E (Chan, 1993). Ascorbate on the other hand can also reduce ferric iron and other oxidized transition metal ions and thereby promote Fenton-type reactions. Ascorbate easily autooxidizes, catalyzed by transition metal ions under oxygen radical formation (Buettner & Jurkiewicz, 1996). The importance of these prooxidant reactions may, however, be small in vivo where transition metal ions are mostly tightly controlled.

The reaction of ascorbate with oxygen free radicals primarily results in formation of semidehydroascorbate that disproportionates rapidly to dehydroascorbate and ascorbate. Semidehydro- and dehydroascorbate are reduced back rapidly to ascorbate by multiple mechanisms including GSH, thioredoxin reductase (Arrigoni & De Tullio, 2002; Nordberg & Arner, 2001), and a GSH-dependent dehydroascorbate reductase localized to the grey matter (Fornai *et al.*, 1999).

Ascorbate reaches the brain primarily via the CSF. It is actively transported from blood plasma in the choroid plexus into the CSF via a Na-coupled transporter, SVCT2, to result in high extracellular concentrations in the brain, around 200–400 μ mol/l (Rice, 2000). This concentration apparently is controlled, suggesting an extracellular antioxidant role. Neurons take up ascorbate via SVCT2 and contain around 10 mmol/l. Astrocytes contain much less, around 2 mmol/l. The mechanism of loss of ascorbate from neurons is not fully understood, but may include a heteroexchange mechanism with glutamate, and an export of dehydroascorbate via the glucose transporter Glut 3. It is suggested that astrocytes acquire dehydroascorbate by Glut 1, reduce it and secrete ascorbate again. This may serve as a supply mechanism for neurons (Rice, 2000). The presence in all cells of glucose transporters (Glut) that also allow transport of dehydroascorbate, coupled with efficient intracellular reduction, seems to account for a significant part of the cellular ascorbate uptake. Such uptake is enhanced by extracellular ascorbate oxidation via, for example, superoxide radicals (Nualart *et al.*, 2003).

Flavonoids and other plant antioxidants

Dietary and intervention studies have indicated that fruit and vegetable consumption is important for neuronal health (Galli *et al.*, 2002). Plants contain multiple potential active components, and mostly the actual active compounds are not identified with certainty. Many beneficial effects are presumed to be derived from a family of polyphenolic compounds called flavonoids, which occur

abundantly in plants and are major constituents of many formulations, for example, from ginseng and *Ginkgo biloba*. Owing to their polyunsaturated substituted cyclic structures, the compounds function as reducing antioxidants, and have been shown to exert cytoprotective actions in a variety of experimental systems. The compounds may also reduce oxygen (autoxidize) under formation of oxygen radicals and thereby function as prooxidants. Many of the compounds show poor absorption and the extent of passage through the blood–brain barrier is little known. Their importance for the basal CNS integrity in humans is therefore not well established (Youdim *et al.*, 2002). Carotenoids, many of which are precursors of vitamin A, are efficient scavengers of singlet oxygen. Garlic extracts containing S-allylcysteine, S-allylmercaptocysteine, allicin and diallylsulfides have been shown to delay cognitive impairment in a senescent accelerated mouse model (Youdim & Joseph, 2001).

Antioxidant proteins and enzymes

Superoxide dismutases (SOD)

These dismutate the superoxide radical under formation of molecular oxygen and hydrogen peroxide.

Since this reaction occurs rapidly and spontaneously, the SODs generally do not alter the hydrogen peroxide formation, but rather reduce the steady-state concentration of the superoxide radical. When there are major competing reactions that reduce the radical (e.g. with ascorbate) SOD will decrease hydrogen peroxide formation and, if competing reactions oxidize the radical, SOD will tend to increase the hydrogen peroxide formation. If SOD competes with NO for reaction with the superoxide radical, hydrogen peroxide formation will also be increased by the enzyme (Gardner, Salvador & Moradas-Ferreira, 2002).

There are three different SODs with different locations and different roles in the body. The phenotypes of knock-outs are very different (Carlsson *et al.*, 1995; Li *et al.*, 1995; Reaume *et al.*, 1996), and so far there is no evidence that the isoenzymes can complement each other (Copin, Gasche & Chan, 2000). One reason apparently is the poor penetration of the superoxide radical through biological membranes (Winterbourn & Stern, 1987).

The first discovered (McCord & Fridovich, 1969) and most extensively studied is CuZn–SOD (SOD1). It is a homodimeric enzyme with each 15 kDa subunit containing one Cu and one Zn atom. The Cu is liganded by 4 His and the

Zn by 3 His and one Asp residue (Tainer *et al.*, 1982). SOD1 physically is a very stable protein. SOD1 is charged with Cu by the Cu-chaperone for superoxide dismutase (CCS) (Huffman & O'Halloran, 2001). Whereas CCS is essential in yeast, some residual SOD1 activity exists in mice lacking CCS (Wong *et al.*, 2000), suggesting additional ways of charging the enzyme with Cu in mammals. The major location of SOD1 is the cytosol, but the enzyme also occurs in the nucleus (Chang *et al.*, 1988) and in the intermembrane space of mitochondria (Weisiger & Fridovich, 1973). A location for peroxisomes has also been discussed (Keller *et al.*, 1991; Liou *et al.*, 1993). Whereas the other SOD isoenzymes are widely regulated, SOD1 is essentially a constitutive enzyme with tissue-specific differences in concentration (Marklund, 1984). All the cultured or isolated cell types studied so far have contained the enzyme and generally there are rather small differences between various cell types (Marklund, 1984, 1990). Overall the brain contains intermediate levels of SOD1 compared with other tissues, with slightly more in grey matter than in white (Marklund, 1984). SOD1 is an abundantly expressed enzyme and the level in grey matter corresponds to 0.3% of the soluble protein (Marklund, 1984). By immunohistochemistry, spinal motor neurons appear to contain more SOD1 than most other cells in the CNS (Shaw *et al.*, 1997), but a likely proposition is that all other cell types in the CNS also contain sizeable levels of SOD1. More than 100 different mutations in the SOD1 gene have been linked to heritable amyotrophic lateral sclerosis (ALS) (Andersen *et al.*, 2003; Rosen *et al.*, 1993). ALS is caused by the gain of a toxic property of mutant SOD1, and mice lacking SOD1 do not develop motor neuron degeneration or show any other obvious phenotype (Reaume *et al.*, 1996). Closer inspection, however, reveals axonopathy (Shefner *et al.*, 1999), and the mutant mice also show increased susceptibility to, e.g. the neurotoxin MPTP (Zhang *et al.*, 2000), and to ischemia/reperfusion of the CNS (Kondo *et al.*, 1997).

The mammalian Mn-SOD (SOD2) is homotetrameric, with each subunit liganding one Mn atom (Borgstahl *et al.*, 1992). The subunits are synthesized in the cytosol with a signal peptide with direct import into the mitochondrial matrix where the enzyme is matured by proteolysis and equipped with Mn atoms. The latter reaction may be accomplished by a specific Mn-transfer protein (Luk *et al.*, 2003). The severe phenotype of mice lacking SOD2 suggests that the enzyme is essential for mitochondrial integrity (Lebovitz *et al.*, 1996; Li *et al.*, 1995). Mitochondrial factors containing superoxide-susceptible FeS clusters are apparently major targets in SOD2 null mice. Brain grey matter contains high levels of Mn-SOD, whereas the level in white matter is threefold lower (Marklund, 1984).

Apparently, the high levels in the brain are important since CNS injury is a prominent feature of Mn-SOD null mice (Lebovitz *et al.*, 1996). Mice heterozygous for the SOD2 null allele show increased susceptibility to the neurotoxic mitochondrial toxins, malonate, 3-nitropropionic acid and MPTP (Andreassen *et al.*, 2001), and are more susceptible to ALS-linked mutant SOD1 (Andreassen *et al.*, 2000). SOD2 is widely regulated by a variety of inflammatory cytokines (Marklund, 1992; Wong & Goeddel, 1988) and somewhat less so by oxidant stress (Stralin & Marklund, 1994).

Extracellular-SOD (EC-SOD, SOD3) is a homotetrameric secreted glycoprotein (Marklund, 1982). The subunits are synthesized with a signal peptide, which is cleaved upon maturation. They ligand Cu and Zn and the sequence is similar to that of SOD1 in the part that defines the active site (Hjalmarsson *et al.*, 1987). SOD3 shows high affinity for heparin and heparan sulfate, conferred by the highly positively charged C-terminal end of the subunits. In vivo the enzyme is anchored primarily to heparan sulfate proteoglycans in the interstitial matrix of tissues (Karlsson *et al.*, 1994). In the vasculature, SOD3 forms an equilibrium between the plasma phase and the endothelial cell surfaces. The brain contains little SOD3, both in humans (Marklund, 1984) and in mice (Carlsson *et al.*, 1995). However, in the brain the enzyme is localized to neurons in a few discrete areas, and in addition is apparently mainly intracellular (Oury, Card & Klann, 1999). This intracellular location has also been observed in some other tissues and suggests that the enzyme may have an intracellular role or is stored for secretion under some circumstances. The enzyme may thus exert some specific roles in the CNS. SOD3 null mice do not show any spontaneous CNS or other phenotypes, but the lungs are highly susceptible to high oxygen tension (Carlsson, Jonsson, Edlund & Marklund, 1995). Impaired memory (Levin *et al.*, 1998), and enhanced injury in stroke models (Sheng *et al.*, 1999) has also been observed in SOD3 null mice. SOD3 is a highly regulated enzyme and the synthesis is influenced by inflammatory cytokines (Marklund, 1992), vasoactive factors and some sulphated glycosaminoglycans (Stralin & Marklund, 2001), but hardly by oxidant stress (Stralin & Marklund, 1994).

Catalase

The homotetrameric hemoprotein catalase catalyzes the dismutation of hydrogen peroxide.

The catalysed reaction is first order in hydrogen peroxide at all physiological concentrations, and unlike glutathione peroxidase catalase is equally efficient at all

hydrogen peroxide concentrations. Except for erythrocytes, the enzyme is intracellularly localized to peroxisomes. Overall, the brain contains little catalase activity. Both grey and white matter of the human brain contains so little catalase that it is difficult to measure reliably due to contamination of the catalase-rich erythrocytes (Marklund *et al.*, 1982). In the rat brain catalase shows a widespread distribution, both to neurons and to glia (Moreno, Mugnaini & Ceru, 1995). Since hydrogen peroxide easily penetrates membranes (Winterbourn & Stern, 1987), the catalase-rich erythrocytes in the vasculature may degrade some of the hydrogen peroxide formed in the brain. In rats, an age-dependent decline in the catalase activity in various parts of the brain has been observed (Ciriolo *et al.*, 1997).

Glutathione peroxidases (GPX)

There are four GPX isoenzymes, all with selenocysteine in the active sites (Brigelius-Flohe, 1999). The highest activity is generally shown by the cytosolic GPX, which probably is expressed by all cells in the body. This cGPX also occurs in the mitochondria (Esworthy, Ho & Chu, 1997). The phospholipid hydroperoxide (PH) GPX also shows a wide distribution. There is an extracellular plasma GPX that is mainly secreted by the kidney, but which also is expressed in the CNS (Maser, Magenheimer & Calvet, 1994). The fourth isoenzyme is the gastrointestinal (GI) GPX. All GPXs reduce H_2O_2 and some organic hydroperoxides at the expense of reduced glutathione:

In addition, PHGPX reduces a variety of complex lipidhydroperoxides and hydroperoxy groups on other biological compounds. Plasma GPX can also use thioredoxin as a reductant.

The human brain contains relatively low levels of GPX activity compared with other tissues (Marklund *et al.*, 1982), which, together with the low catalase activity, suggests that the organ may be vulnerable to increased formation of hydrogen peroxide. Note that the cGPX activity in the brain is, unlike in other organs, spared in selenium deficiency (Brigelius-Flohe, 1999). The enzyme appears to be mainly expressed in glial cells (Damier *et al.*, 1993). CGPX null mice do not show any spontaneous phenotype, but display an increased infarct size in a brain ischemia-reperfusion model (Crack *et al.*, 2001). They also show increased sensitivity to the neurotoxins: malonate, 3-nitropropionic acid and 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (Klivenyi *et al.*, 2000; Zhang *et al.*, 2000).

Thioredoxin, glutaredoxin, and thioredoxin reductase

The major cytosolic thioredoxin (Trx-1) is a 12 kDA protein with a –Cys–Gly–Pro–Cys– active site motif, which is easily oxidized to a disulfide. Trx possesses potent protein disulfide oxidoreductase activity, and is involved in protein folding (Nordberg & Arner, 2001). Mitochondria contain another isoform, Trx-2. Reduced Trxs also serve as a substrate for the peroxylredoxin isoenzymes, see below. Trx-1 is widely expressed in neurons in the brain (Lippoldt *et al.*, 1995), and overexpression has been shown to protect against, for example, brain ischemia-reperfusion damage (Takagi *et al.*, 1999). Likewise, Trx-2 shows a wide distribution in the brain, apparently primarily to neurons (Rybnikova *et al.*, 2000).

Glutaredoxin (thioltransferase) shows functions overlapping with the Trxs. Unlike these, glutaredoxin can be reduced by glutathione, and it can also reduce protein-GSH-mixed disulfides (Nordberg & Arner, 2001). This effect is, for example important in recovery of mitochondrial function following excitotoxic insult (Kenchappa *et al.*, 2002).

Oxidized Trxs are reduced by thioredoxin reductases (TrxR) using NADPH as reductant (Nordberg & Arner, 2001). The TrxRs are flavoproteins containing active site selenocysteines, which occur in different isoforms in the cytosol and mitochondria (Nordberg & Arner, 2001). The TrxRs show wide substrate specificity and can, in addition to Trx, reduce GSH, dehydroascorbate and semidehydroascorbate, hydroperoxides including lipid hydroperoxides and protein disulfide isomerases (Nordberg & Arner, 2001). The main function of protein disulfide isomerases is to oxidize cysteines to form disulfide bonds during protein folding.

Methionine is easily oxidized by various oxidants to the sulfoxide form and is reduced back by methionine sulfoxide reductase. This enzyme uses the NADPH/Trx/TrxR system for reduction of its active site (Weissbach *et al.*, 2002). Overexpression of methionine sulfoxide reductase predominantly in the brain of *Drosophila* prolongs the lifespan (Ruan *et al.*, 2002). This suggests a role of methionine oxidation in aging.

Peroxyredoxins

In mammals the peroxyredoxins (Prx) comprise a family of six isoenzymes with structural and some functional similarities. The Prx isoenzymes are localized to different compartments with Prx1 and Prx2 in the cytosol, Prx3 in the mitochondria, Prx4 in the plasma membrane, Prx5 in mitochondria, peroxisomes and cytosol, while Prx6 has an extracellular location (Fujii & Ikeda, 2002). The Prx isoenzymes catalyze the reduction of hydrogen peroxide and organic hydroperoxides with all, except Prx6, using thioredoxin

as the reductant. Prx1, 4 and 6 can also use GSH (Fujii & Ikeda, 2002). Notably, a bacterial peroxyredoxin has shown peroxynitrite reductase activity, which might be shared by the mammalian isoforms (Bryk, Griffin & Nathan, 2000). Unlike other enzymes that degrade hydroperoxides, the activities of Prx1 and 2 can be regulated (by phosphorylation), suggesting active involvement in cellular signaling by hydrogen peroxide (Chang *et al.*, 2002). The Prx isoenzymes are generally highly expressed and show wide tissue distributions with comparatively high expression throughout the brain (Rhee *et al.*, 2001). Given the low catalase and glutathione peroxidase activities, the Prx isoenzymes may conceivably exert particularly important roles in the CNS.

Markers of free radical damage

Chemical analysis

There are numerous relatively stable small molecules and protein and DNA modifications formed in reactions with oxygen free radicals, which can be used as markers for oxidant injury.

Peroxidative attack on polyunsaturated fatty acids results in the formation of various classes of isoprostanes, which are regarded as the most reliable markers of lipid peroxidation. The most widely studied is the F2 isoprostane 8-isoPGF₂ α , which derives from arachidonic acid. The isoprostanes are stable and have been determined, e.g. in brain extracts, cerebrospinal fluid, blood plasma and urine, and appear to parallel the peroxidation intensity (Greco, Minghetti & Levi, 2000; Janssen, 2001).

Malondialdehyde is a late breakdown product from peroxidized lipids and is generally detected as a reaction product with thiobarbituric acid (TBARS). The TBARS can be analysed by spectrophotometry, fluorimetry and by HPLC with increasing specificity (Moore & Roberts, 1998). A variety of other aldehydes and molecules can react with TBA, however, and MDA is also formed in prostanoid synthesis. The TBARS reaction therefore, has a very limited specificity and utility in complex matrices such as tissue extracts, plasma and CSF.

A major cytotoxic degradation product from peroxidized lipids is 4-hydroxynonenal. It easily forms thioether adducts and adducts with free amino groups in proteins. It is much less often analyzed than MDA (Moore & Roberts, 1998), but has a greater utility as a marker for immunohistochemical analysis.

Numerous oxidant-induced protein modifications are used as markers. The most commonly analyzed

are carbonyls detected by the reaction with 2,4-dinitrophenylhydrazine. The carbonyls can be formed by OH-radical generated by the Fenton reaction, ionizing radiation, peroxynitrite, lipid peroxidation metabolites and glycooxidation (Berlett & Stadtman, 1997). The carbonyls are commonly detected by photometry in extracts and by histochemical analysis (Smith *et al.*, 1998), and should be considered as general markers of oxidant stress with limited information as to underlying oxidant mechanisms.

Oxidants are major endogenous mutagens and attack the bases in DNA under formation of a variety of modified forms. The most widely analysed is the mutagenic 8-OH-deoxyguanosine (Dizdaroglu *et al.*, 2002). The DNA is rapidly repaired by various excision mechanisms, and the concentration of modified bases thus represents a steady state between formation and excision. The rate of repair is induced in a variety of situations. On the other hand, the concentration of excised modified bases in extracellular fluids and the excretion in urine should be more proportional to the rate of oxidant injury. Increased levels have been found, for example, in CSF in ALS (Bogdanov *et al.*, 2000) and in various areas of the brain in Alzheimer's disease (Gabbita, Lovell & Markesbery, 1998). The results in different studies vary considerably, due to technical differences and the problem of artifactual base oxidation during sample preparation and analysis. (See also Chapter 10, Rølig.)

Modified low-molecular weight compounds are also analysed. In humans urate is oxidized to several different compounds (Becker *et al.*, 1991). The metabolites, allantoin and parabanic acid have been used as oxidant stress markers in humans, e.g. in brain microdialysis (Hillered & Persson, 1995; Marklund *et al.*, 2000) and in cerebrospinal fluid (Kastenbauer *et al.*, 2002).

Salicylate, which permeates tissues rapidly, is oxidized by hydroxyl radicals to 2,3- and 2,5-dihydroxybenzoic acid. The 2,3-compound is apparently specific for the hydroxyl radical, is easily extracted from tissues and can be analyzed by HPLC. Increases have, e.g. been shown in brain ischemia/reperfusion damage (Floyd, 1999).

Cellular and histochemical analyses

Histochemical analysis of oxidant stress markers has been widely employed and offers the advantage of cellular and subcellular location of the processes.

Vital staining for hydrogen peroxide formation can be accomplished via the reaction with Ce ions, which results in precipitation of electron-opaque cerium perhydroxides. Superoxide formation can be visualized with

the Mn²⁺/diaminobenzidine assay (Karnovsky, 1994). Another common vital stain is 2,7-dichlorofluorescein diacetate, which following intracellular hydrolysis of the acetate groups is oxidized to a fluorescent compound by "oxidants." The oxidation is caused primarily by hydrogen peroxide catalysed by hemoproteins. The fluorescent staining thus occurs at the location of the catalytic hemoproteins and not the site of formation of the diffusible hydrogen peroxide. Peroxynitrite, and possibly RO·, ROO· and HOCl will also oxidize DCF. Further complicating interpretation is the fact that DCF in the presence of peroxidases can engage in autooxidations artifactually generating hydrogen peroxide and fluorescence (Rota, Chignell & Mason, 1999).

Lipid peroxidation is most commonly studied with antibodies raised against malondialdehyde- and 4-hydroxynonenal-induced epitopes. These have been widely employed in studies of CNS pathology, e.g. Yoritaka *et al.* (1996). Advanced glycation end products are most commonly demonstrated with antibodies versus *N-E*-carboxymethyl-lysine adducts, a major end product of glycooxidation (Schleicher, Wagner & Nerlich, 1997). Oxidative damage to DNA and RNA has been demonstrated with antibodies vs., e.g. 8-OH-guanosine (Zhang *et al.*, 1999). Increased levels have, for example, been found in ALS (Shibata *et al.*, 2002).

Biological oxidants and therapeutic antioxidants

John P. Crow

Department of Pharmacology and Toxicology, College of Medicine, University of Arkansas, Little Rock, AR, USA

Introduction

A book chapter represents a special type of literature overview, which offers the promise of covering topics and addressing issues which are relevant and topical but which will also stand the test of time. It is appealing to focus on topical issues, which will hopefully provide some immediate insight into problems and questions confronting investigators in the field. However, undue focus on topical issues predisposes the discussion to becoming dated prior to, or shortly after, appearing in print. Thus, the expressed purpose of this chapter will be to deal with broader concepts which will, hopefully, provide stable foundations to interpret results and permit better comprehension of both current and future topical issues relating to nitrogen oxide-derived oxidative injury relevant to neurodegenerative disease. The author's training and research background is in the chemistry and biochemistry of biologically produced oxidants, biochemical mechanisms of oxidative injury, and the pharmacology of endogenous and synthetic antioxidants. Thus, these perspectives will be emphasized, leaving the broader issues of neuroscience to the preeminent neuroscientists elsewhere in this volume. Also, because entire chapters could be devoted to many of the topics covered, citations for relevant literature reviews will be emphasized and the primary literature cited only when necessary.

Why is identification of reactive species and biomolecular targets so difficult?

For many decades, it has been understood that oxidative injury, both acute and chronic, plays a central role in numerous human disease processes and aging, yet major advances in identifying specific reactive species and/or the specific biomolecular targets responsible for cell injury and

death have been few and far between. Reasons for the slow pace of progress abound, but the fundamental problem is rapid transmutation (spontaneous and/or enzymatic) of primary reactive species into secondary and even tertiary species, each with different reactivity profiles and targets. Since the seminal discovery of Cu,Zn superoxide dismutase by Joe McCord and Irwin Fridovich in 1969, overwhelming evidence has accumulated that scavenging of superoxide can, in many instances, prevent oxidative injury. However, superoxide itself is not a good oxidant and few direct reactions of superoxide (with biomolecular targets) have been identified that could readily account for oxidative injury. Logically, superoxide must, under some conditions, be transformed into something else. Besides rapid transmutations, reactive species are, by definition, short-lived and have defied direct measurement in most instances. Thus, it is necessary to rely on stable end-product analysis to infer both the species involved and the mechanisms by which they are formed – a process wrought with uncertainty. The notion that the devil is in the details certainly applies to the study of reactive species in biology. The discovery, some 15 years ago, that nitric oxide (NO) was formed in mammalian systems has opened new avenues of research into reactive species and oxidative injury and, while adding a host of heretofore unconsidered reactive nitrogen species to the fray, it may have, paradoxically, simplified many issues relating to superoxide-mediated toxicity.

The expressed purpose of this chapter is to discuss how, and under what conditions, NO is transformed from a benign second messenger to an aggressive neurotoxin and how pharmacological interventions may limit the latter effects of NO-derived species without altering the beneficial physiological effects of NO itself. To accomplish this goal, it will be necessary to examine some of the essential chemical and biophysical properties of NO, provide a

rationale for the predominant species thought to mediate NO-derived toxicity, and characterize the broad classes of novel antioxidants that may act to prevent oxidative neuronal injury. Along the way, some fundamental principles of oxidant scavenging will be outlined, potential mechanisms of oxidative injury will be discussed, the relevance of some oxidative markers will be assessed, and the potential contribution of endogenous metalloproteins in oxidative injury will be examined. Mutant forms of Cu,Zn superoxide dismutase (SOD1) are known to cause some forms of familial amyotrophic lateral sclerosis (FALS), and recent evidence suggests that both beta amyloid peptide (Alzheimer's disease) and prion protein (bovine spongiform encephalopathy) bind the redox active metal copper. Recognition that these proteins can bind copper and potentially allow it to redox cycle, thereby producing oxidants that can injure neurons directly and/or modify proteins, may prove critical to solving the mysteries of how they are neurotoxic.

The good, the bad, and the unknown of NO

The fact that nitric oxide (NO) is produced enzymatically in mammalian systems and acts as a unique type of second messenger has been known for roughly 15 years. Almost from the beginning, it became clear that NO had a dark side: while it regulates numerous physiological processes, it can also contribute to oxidative injury. The simplest explanation for the duplicitous behavior of NO is that it can undergo chemical transformations and form reactive intermediates with very different properties. All NOS isoforms make at least some free NO, and free NO is what binds to the heme prosthetic group of guanylate cyclase (GC) and initiates cGMP production which, in turn, activates numerous physiological processes. What happens to NO in the interim – after its release from NOS and before it binds to GC – remains the subject of much debate, and intermediate chemical transformation is likely to be the primary determinant in whether or not NO participates in oxidative injury. In the beginning, most of what was known about NO chemistry came from work on atmospheric nitrogen oxides and their roles in air pollution. In recent years, that knowledge base has been extended to the solutional chemistry of NO; however, many of these studies have involved the use of relatively high concentrations of NO and the chemistry of NO changes dramatically as its concentration increases. Normal *in vivo* concentrations of NO are in the submicromolar range (GC is maximally stimulated by low nanomolar levels of NO) where the chemistry is less likely to be governed by reactions with itself or other NO-derived radicals, but where detection sensitivity limits the ability to

identify reactive intermediates in real time. Thus, like most reactive species, it is necessary to analyze the stable end products and attempt to deduce the mechanisms by which they were formed. The limited scope of this chapter dictates that we focus on those NO-derived species (i) that are most likely to form under physiological conditions, and (ii) that can account for the oxidative modifications and cellular injury seen. This “Occam's Razor” approach has the dual advantage of limiting the number of possibilities that must be considered and of focusing on those possibilities that are most likely to be pathologically relevant.

Interminable terminology

Prior to the introduction of NO, perhaps the most commonly used descriptor was “reactive oxygen species” or ROS. ROS has evolved to include “reactive nitrogen species” (RNS) as well as terms like “nitrative” and “nitrosative” stress to the previously used catchall phrase “oxidative stress.” The introduction of NO into the field of free radical/oxidant-mediated cell injury and pathology has had the dual effect of providing alternative (and arguably more tenable) mechanistic explanations for such injury, while simultaneously complicating attempts to identify specific species and sources of reactive species. Adding NO to the fray also creates entirely new categories of terminology to an already bloated and confusing list. “Free radicals” refer to a specific type of reactive species that possess at least one unpaired electron and are, therefore, inherently unstable, although some free radicals – such as NO – are remarkably stable. Not all free radicals are oxidants and superoxide is a much better reductant than oxidant. Thus, it is imperative to provide some terms (and definitions) that encompass all biologically relevant reactive species in ways that the terms “free radical” or “reactive oxygen species” cannot do. Potent reductants such as glutathione (GSH) and ascorbic acid (vitamin C) can rightly be referred to as “reactive species,” but in a different sense from that usually intended. Fortunately, the limited scope of this chapter allows/forces us to its focus on NO-derived reactive species and, for that, we will use the term “NO-derived oxidant” or “NODO.” “NO” will refer specifically to the free radical nitric oxide (properly designated as $\cdot\text{N}=\text{O}$), and “peroxynitrite” (the product of NO and superoxide) will refer to either peroxynitrite anion or the more reactive protonated form, peroxynitrous acid. In addition, “oxidative stress” will be used to refer to cellular production of oxidants which does not exceed the threshold of acute repair. “Oxidative injury” will refer to oxidant production that exceeds the threshold of acute repair and produces discernable impairment of some critical

cellular processes; if continued unabated, oxidative injury ultimately will lead to cell death.

Common oxidative pathways

Many exogenous compounds become toxicants by first being reduced enzymatically, and then spontaneously (i.e. non-enzymatically) reoxidizing to generate reactive oxygen species – initially superoxide.¹ Superoxide then becomes the starting material for the production of overtly injurious species. Thus, many different redox active toxicants may act via common pathways. By focusing on intercepting/scavenging these common intermediates, it may be possible to design compounds which would be beneficial in a number of different disease conditions. For many reasons, the CNS is particularly susceptible to oxidative injury from exogenous toxicants as well from biologically produced oxidants. This is due, in part, to the relative inability of neurons to replenish injured cells and to the very high metabolic demand of neurons (Halliwell, 2001). It has been estimated that the brain accounts for 20% of total body oxygen consumption (Halliwell, 2001). Because oxygen consumption occurs in the mitochondria, high oxygen consumption reflects the second-to-second dependence of neurons on mitochondria. Many generic mitochondrial toxins (e.g. MPP⁺ derived from MPTP, 3-nitropropionic acid, barbiturates, rotenone, etc.) affect the CNS first, not so much because they are taken up specifically by neuronal mitochondria, but because the high energy demands of neurons make them more susceptible to even momentary decreases in electron transport and subsequent ATP production. Creatine may boost athletic performance and slow neurodegenerative processes by providing mitochondria with an alternate energy source (creatine phosphate) to buffer against momentary decreases in ATP.

Mitochondria as primary source of ROS

Given the oxygen handling by mitochondria, it is not surprising that they are the major source of reactive oxygen species in virtually all cell types. The mitochondrial electron transport chain is designed to store four electrons and pass them off to molecular oxygen to produce two molecules of water. However, this process is not 100% efficient and, even under normal physiological conditions, as much as 1% of total oxygen consumption results in incompletely reduced oxygen species including superoxide, hydrogen peroxide, and hydroxyl radical (the products of one, two, and three electron reductions of oxygen, respectively). A dizzying array of biochemical processes involving several multi-subunit copper- and iron-

containing proteins as well as multiple redox active substrates must interact in a highly coordinated fashion to maintain proper electron flow through the system and avoid inadvertent transfer of single electrons to oxygen. Given this inherent complexity, the fact that the electron transport system functions with 99% efficiency is more incredible than a 1% misfire rate. Coincidentally, the fact that the proteins, enzymes, and substrates of the electron transport chain are redox active makes them more likely to be attacked by oxidants (electricians are more likely to get shocked than plumbers) and more likely to be inactivated by oxidants (e.g. electricians with weak hearts). Abnormal oxidative modifications frequently occur at several points along the chain and, in general, the more downstream the malfunction, the more likely that electron-charged enzymes and substrates upstream will accumulate and release single electrons prematurely. The fact that mitochondria require their own specific isoform of SOD (manganese superoxide dismutase, MnSOD, or SOD2) and that MnSOD is absolutely essential for life (Li *et al.*, 1995; Copin *et al.*, 2000), whereas the cytosolic form (Cu,Zn SOD or SOD1) is not (Reaume *et al.*, 1996), provide strong circumstantial evidence: (i) that superoxide is normally produced in mitochondria, (ii) that mitochondria are the principal source of ROS, and (iii) that critical targets susceptible to oxidative inactivation exist within mitochondria. The essential role of MnSOD and how its paradoxical susceptibility to oxidative inactivation may be pivotal to mitochondrial death will be discussed more fully later on.

How can superoxide be toxic?

Prior to the discovery that NO was produced enzymatically *in vivo*, free radical/oxidant-mediated injury was thought to involve primarily superoxide, hydrogen peroxide (H₂O₂), and hydroxyl radical. The fundamental problem was that, of these three species, hydroxyl radical was the only strong oxidant; superoxide and H₂O₂ are very weak oxidants and, in the absence of transition metals like copper, iron and manganese, relatively unreactive.² Yet it was clear from studies with superoxide dismutases, catalase and glutathione peroxidase (the primary H₂O₂ decomposing enzyme in mitochondria) that, not only could oxidative injury be largely prevented by scavenging superoxide and H₂O₂, but also that stable end-products associated with hydroxyl radical production (e.g. aromatic hydroxylation) could be measured in affected tissues. This led to the proposal of a three-tiered reaction cascade involving reduction of redox active Fe(III) to Fe(II) by superoxide, followed by reaction of Fe(II) with H₂O₂ (derived from the dismutation of superoxide) to produce hydroxyl

radical. There are numerous problems with this mechanism, including relatively slow reaction rates and the need for simultaneous production and localization of all three reactants in biological systems containing redundant systems designed to keep all three reactants at extremely low concentrations (Kehrer, 2000; Koppenol, 2001). Equally important is the fact that hydroxyl radical is such a potent oxidant and so indiscriminately reactive that it can only diffuse a few angstroms before reacting with some molecular target. Thus, enthusiasm for hydroxyl radical as a predominant mediator of oxidative injury is dampened by the fact that (via the Fenton reaction) it is difficult to produce and any resulting damage is restricted to the site of production. In this context, the realization that peroxynitrite forms quite readily, possesses hydroxyl radical-like reactivity, and is capable of diffusing considerable distances before “detonating,” becomes very significant (see below).

Reactive oxygen versus reactive nitrogen species

The seminal discoveries that NO is produced in vivo and that it reacts with superoxide extremely rapidly (rate constant $\sim 10^{10} \text{ M}^{-1} \text{ s}^{-1}$) (Kissner *et al.*, 1997) to form a species – peroxynitrite – that has hydroxyl radical-like reactivity, have caused some serious rethinking of the original, fundamental in vivo mechanisms of oxidant production. If the NO/superoxide reaction had been known 30 years ago, the so-called Fenton Reaction (to produce hydroxyl radical) might never have gained such prominence in biology. That is not to say that reactive oxygen species cannot produce oxidative injury in the absence of NO; only that the species produced and mechanisms involved become more straightforward when NO is present, because the only two reactants required are superoxide and NO; redox active metals can interact with peroxynitrite and alter/exacerbate its reactivity, but are not required. It must be emphasized that many of the reactive species produced under biological conditions are too short-lived to be measured directly and that most of what we know about their production has been gleaned from analysis of products which may, or may not, be specific for any given reactive species. Because of the critical importance of product analysis (to assess production of reactive species), we will discuss this at greater length later on. First, it is necessary to examine some of the chemical and biophysical properties of NO, its reaction with superoxide, and the reactivity of peroxynitrite in order to understand how NODOs can account for many of the abnormal oxidative products measured in tissues as well as oxidative injury itself.

Why does “how” matter?

Considerable debate centers around the basic chemistry of NO and NO-derived species – debates which frequently generate considerably more heat than light. Quite often, the biologists seek to avoid such issues and focus on “bottom line” issues related to the end result of NO-mediated toxicity, i.e. “just tell me what happens and don’t bother me with the chemistry that underlies it.” While this approach has some practical merit, the basic chemistry and biophysical properties of NO cannot be ignored if one seeks to successfully intervene pharmacologically. Many potent NOS inhibitors are currently available and it is a simple matter to inhibit all NO production with non-selective inhibitors. However, inhibiting all NO production to prevent oxidative injury is like disconnecting the water source to your house to stop a leaky faucet; the gain will be overwhelmed by the loss.

Physical/chemical properties of nitric oxide

NO is a unique second messenger molecule and an understanding of its biophysical and chemical properties is essential to an understanding of how it can be a benign physiological messenger under some conditions while giving rise to potent oxidizing, nitrating (addition of an $-\text{NO}_2$ group), and nitrosating (addition of an $-\text{NO}$ group) species under other conditions. The singular biophysical property of NO that makes it truly unique is its diffusability; lipid membranes are no barrier to NO and it will diffuse through cell membranes virtually as fast as it diffuses through free aqueous solution (Liu *et al.*, 1998).³ This effectively means that NO produced by one cell will affect physiological and pathological processes in cells far removed from the site of production – a phenomenon that has important implications both in terms of probing biochemical mechanisms and in terms of inhibiting NO-related processes. The extremely efficient diffusability of NO means that selective inhibition (or genetic knockout) of one NOS isoform may or may not have any discernable effect; NO is NO regardless of whether it’s made by nNOS, eNOS, or iNOS, and other isoforms can be up-regulated to compensate for the loss of one isoform. Thus, selective inhibition of a given NOS isoform may have short-term effects that are lost over a period of hours as other isoforms are biosynthesized *de novo*. To categorically rule out involvement of NO in any given physiological or pathological process, it is necessary non-specifically to inhibit all isoforms simultaneously. This may be accomplished successfully in cultured cells, but in whole animals inhibition of all NO production is inconsistent with life. Thus, it is not

possible genetically to knock out all NOS isoforms, nor is it practical to attempt to prevent NO-mediated oxidative injury by chronically inhibiting all NO production with non-selective NOS inhibitors.

Nitric oxide does not react directly with thiols

One important chemical property of NO is its relative lack of reactivity with anything except other radicals⁴ and with metalloproteins that retain some radical character. For example, the essential second messenger function of NO is a consequence of its binding to iron in the heme prosthetic group of guanylate cyclase which, in turn, is activated to produce cGMP. Likewise, NO binds to oxyhemoglobin to yield innocuous nitrate; the high rate constant for this reaction and the enormous concentration of oxyhemoglobin in the blood argue that this is the primary pathway for normal physiological scavenging of NO that reaches the vasculature. We will provide a rationale for why the reaction of NO with the radical superoxide (to yield peroxynitrite) may be the predominant pathological reaction pathway for NO, but one thing that NO does not do is to react directly with thiols such as glutathione (GSH) or cysteine residues in proteins; this fact makes it difficult to reconcile the apparent production of nitrosothiol-containing compounds in vivo (Thomas *et al.*, 2001) without invoking an, as yet undiscovered, reaction pathway. Given sufficient time, NO will react with oxygen to form N₂O₃ and other species that can react directly with thiols, but, at physiological concentrations of NO and oxygen, this reaction is much too slow to be of much biological relevance.⁵ The half-life of NO in biological systems ranges from 0.09 to 2 seconds (Thomas *et al.*, 2001). This short biological half-life places limits on which reactions NO can undergo and which species can be formed. One of the few known reactions of NO that is fast enough to occur within this half-life window is its reaction with superoxide to form peroxynitrite. It should be emphasized that the reaction between superoxide and NO is so fast ($\sim 10^{10} \text{ M}^{-1} \text{ s}^{-1}$) (Kissner *et al.* 1997), that virtually every collision between these two radicals would result in covalent combination to form peroxynitrite; this reaction is roughly five times faster than superoxide can be scavenged by any superoxide dismutases (SODs). Thus, SODs can, at best, only limit peroxynitrite formation, but cannot eliminate it. We will explore the fundamental relationship between SODs, superoxide, H₂O₂, NO and peroxynitrite immediately after examining some of the properties of peroxynitrite that make it the ideal biological oxidant and nitrating agent.

Peroxynitrite – the predominant NO-derived oxidant (NODO)

Peroxynitrite was first described as a chemical entity in the early 1900s and characterized thoroughly as an oxidant and phenolic nitrating agent in the 1960s (Ray, 1962; Hughes & Nicklin, 1968). In the early 1990s, Dr Joseph Beckman suggested that peroxynitrite could be formed in vivo via the reaction of superoxide and NO (Beckman *et al.*, 1990). The first compelling measurement of the rate constant for this reaction was made by Huie and Padmaja in 1993 (Padmaja & Huie, 1993); their rate constant of $6.7 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ has recently been revised upward to greater than $10^{10} \text{ M}^{-1} \text{ s}^{-1}$ (Liu *et al.*, 1998). The reaction between superoxide and NO ranks among the fastest reactions known in biology and approaches the fastest rates that any two molecules can interact; hence the term “diffusion-limited” reaction. One does not need to be a physical chemist to appreciate that a reaction which occurs this rapidly is virtually assured to occur whenever NO and superoxide are produced simultaneously (the rate constant for oxidation of target molecules by hydroxyl radical – the most reactive species known in biology – is in the range of $10^{10} \text{ M}^{-1} \text{ s}^{-1}$ to $10^{11} \text{ M}^{-1} \text{ s}^{-1}$). To argue that peroxynitrite is not formed in vivo is to ignore the simple physical and chemical laws which govern bimolecular reactions in aqueous solution. Aside from the simple reality of a diffusion-limited rate constant, the very first descriptions of endothelium-derived relaxing factor (EDRF/NO) indicated that its biological half-life was enhanced by the addition of SODs – compelling evidence that NO is continuously reacting with superoxide to form peroxynitrite in biological systems (Gryglewski *et al.*, 1986; Rubanyi & Vanhoutte, 1986).

Peroxynitrite anion is the product formed initially from the radical/radical reaction of superoxide and NO; the anion becomes protonated at physiological pH ($pK_a \sim 7.0$) and, in the absence of oxidizable targets, will rearrange spontaneously to nitrate (NO₃⁻) with a half-life of $\sim 1 \text{ s}$ at pH 7.4 and 37 °C (Beckman *et al.*, 1990). However, in the milieu of a cell, peroxynitrite anion will react with a wide array of functional groups on proteins, DNA, lipids, and various low molecular weight compounds such as glutathione (see Scheme 1). Peroxynitrite anion reacts directly with carbon dioxide to increase the yield of a nitrating species and this reaction (with CO₂) may largely govern its reactivity in vivo (Denicola *et al.*, 1996). At the very least, it means that scavengers of peroxynitrite will be effective only if they can out-compete the reaction (of peroxynitrite) with CO₂ and/or react with the peroxynitrite/CO₂ adduct that is formed. Oshima and coworkers (1990) were the first to measure nitrotyrosine (and its deaminated

metabolite nitro-hydroxyphenylacetic acid) in the urine of smokers; however, the source of urinary nitrotyrosine was unknown at that time. Beckman and coworkers verified the *in vivo* formation of peroxynitrite by making an antibody to protein-bound nitrotyrosine and using that antibody to show that proteins in human ARDS lung contained tyrosyl residues that had been nitrated (Crow *et al.*, 1994). Since that time, nitrated proteins (as well as free nitrotyrosine and metabolites) have been shown to occur in many different human disease conditions including ALS, Alzheimer's disease, Parkinson's disease, and prion protein-related diseases as well as in experimental animals (for review, see Beckman, 2002). Whether nitration of proteins *per se* is fundamental to oxidative injury remains to be established. However, it should be emphasized that all work to date reveals a striking selectivity of nitration such that only a few proteins appear to be targets of nitration and that, as such, a high percentage of those specific protein target molecules may be nitrated even though the total cellular nitration, as a function of total protein-bound tyrosine, may be relatively low (0.01% to 1.0% of total tyrosine).

Nitrotyrosine as marker of NODOs

Nitrotyrosine is a stable modification, which is relatively specific for peroxynitrite. Nitrotyrosine has been measured with immunological techniques and by HPLC, validated via GC-MS and LC-MS (Beckman, 2002). However, it must be emphasized that peroxynitrite can modify a number of biomolecular targets in ways that may be more critical to oxidative cell injury and death, particularly within the CNS (see Scheme 1). Peroxynitrite can oxidize critical thiols of enzymes, metal centers in proteins, lipids, nucleic acids, as well as nitrate and hydroxylate phenolics like tyrosine, tryptophan (serotonin), and catecholamines such as dopamine (Daveu *et al.*, 1997; Riobo *et al.*, 2002).⁶ Many of these modifications are irreversible under physiological conditions and can be readily measured; however, it is considerably more difficult to ascribe non-nitration modifications exclusively to peroxynitrite since other reactive species can produce some of these modifications, at least *in vitro*. Only when these modifications occur concomitantly with tyrosine nitration can they be attributed to peroxynitrite. The inability to assign specific reaction products to specific oxidants continues to confound attempts to identify precise reactive species and thereby design specific scavenger molecules as therapeutics. For this and many other reasons, the emphasis, in terms of therapeutic antioxidant drug design, is toward multifunctional agents and combination therapy which includes several compounds, each with specific scavenger profiles. It is important to point out that

Scheme 1 Known reaction pathways for peroxynitrite.

peroxynitrite is capable of producing virtually all of the products previously ascribed to hydroxyl radical. This further illustrates how formation of NODOs – specifically peroxynitrite – may actually simplify efforts to define mechanisms of oxidant formation *in vivo* and simplify the search for the elusive endogenous oxidants most responsible for oxidative injury.

Other oxidative modifications by peroxynitrite

Oxidative modifications to biomolecules, whether by peroxynitrite, other NODOs, or other reactive oxygen species, almost always will be limited to a few particularly susceptible targets and then (with some notable exceptions), to only a small percentage of the total molecules making up that target. For example, activity measurements of enzymes known to be sensitive to oxidative inactivation may reveal that only a small percentage of the total enzyme activity is lost. Thus, questions naturally arise as to how modification of a small percentage of a few select targets can translate into significant oxidative injury. One example would be the oxidative *activation* of an enzyme; activation of even a very small fraction of an important tyrosine kinase (e.g. c-Src kinase (MacMillan-Crow *et al.*, 2000)) could trigger an inappropriate cascade of phosphorylation reactions leading to uncontrolled cell proliferation and tumorigenesis. A similar situation, of uncontrolled or inappropriately prolonged phosphorylation, could result from the inactivation of a phosphatase. Some of the fastest reactions yet described for peroxynitrite occur with the active site thiolates of the tyrosine phosphatases CD45, LAR, and PTP1B (Takakura *et al.*, 1999); because of their low cellular concentrations and extremely fast rate constants, a large fraction of

the total tyrosine phosphatase activity may be lost in a short time. Physiological concentrations (nanomolar) of peroxynitrite irreversibly inactivate these three tyrosine phosphatases *in vitro*, and treatment of cells with peroxynitrite has been shown to produce a prolonged, hyperphosphorylation state (Mondoro *et al.*, 1997; Mallozzi *et al.*, 1997) – evidence suggesting that a large fraction of total tyrosine phosphatase activity was inhibited. Although other mechanisms have been proposed for hyperphosphorylation of tau protein in Alzheimer's and neurofilaments in amyotrophic lateral sclerosis (ALS), mechanisms involving oxidative activation of kinases and/or oxidative inactivation of thiol-dependent phosphatases in these diseases are possibilities which remain largely unexplored.

Hydroxylation of dopamine by peroxynitrite forms 6-hydroxydopamine (6-OHDA) – a well-characterized neurotoxin which readily kills neurons within the substantia nigra (Daveu *et al.*, 1997; Riobo *et al.*, 2002 and J. P. Crow, unpublished observations). Because neuronal lesions by 6-OHDA are irreversible, formation of even minute amounts of 6-OHDA over time could cause cumulative neuronal injury. The structural protein neurofilament L (NFL) is particularly susceptible to nitration by peroxynitrite and *in vitro* studies indicate that one nitrated tyrosyl residue on every tenth NFL molecule is sufficient to prevent self-assembly (Crow *et al.*, 1997). Nitration of only a few subunits of actin or tubulin (Eiserich *et al.*, 1999; Kalisz *et al.*, 2000; Giannopoulou *et al.*, 2002) could also disrupt assembly of these structural proteins via a process analogous to inserting a defective link into a chain. Unequivocal cause-and-effect relationships between these biochemical events and oxidative injury *in vivo* have not been established; they are used solely as examples of how low level modifications could, in theory, have dramatic effects either by inappropriate amplification of a signal (e.g. phosphorylation), by accumulation of damage (6-OHDA), or by interference with a sequential structural protein assembly process such as occurs with neurofilaments, actin, and tubulin. Considering that all of these biochemical insults could occur simultaneously, it is not difficult to envision how oxidative stress can overwhelm cellular repair mechanisms and escalate into oxidative injury.

MnSOD is a ubiquitous target of peroxynitrite *in vivo*

Nitration and inactivation of the mitochondrial form of manganese superoxide dismutase (MnSOD) represents one mechanism of oxidative injury where the consequences are more straightforward and quite profound. Studies with genetic knockouts for MnSOD reveal that it

is essential for life (Li *et al.*, 1995; Copin *et al.*, 2000). Thus, it is possible to extrapolate that an acute loss of MnSOD activity (within a time frame which does not allow for compensation via *de novo* biosynthesis) could, in and of itself, lead to cell death. It stands to reason that loss of MnSOD activity *per se* would not be lethal but, instead, must be related to the increase in levels of reactive species secondary to loss of superoxide scavenging activity. MnSOD has been shown to be particularly susceptible to nitration/inactivation by peroxynitrite (MacMillan *et al.*, 1996, 1998) in a number of human disease conditions including ALS (Aoyama *et al.*, 2000). *In vitro* studies reveal that loss of MnSOD enzyme activity is a consequence of both nitration and other oxidative modifications including inter-subunit formation of dityrosine crosslinks (MacMillan *et al.*, 1998). When MnSOD is found to be nitrated, it is possible to infer that it is also oxidatively inactivated and activity assays have confirmed this in many instances. Thus, this represents a classic example of where nitration may serve as a marker for a more pernicious modification that is less apparent but nonetheless significant in terms of loss of enzyme activity. The fact that MnSOD is inactivated so readily by the very oxidant that it acts to prevent is paradoxical and suggests that this process may serve as an oxidant sensing mechanism in mitochondria, i.e. to signal the cell that oxidative injury has crossed some critical threshold and perhaps to initiate active apoptosis. Because mitochondria in all cell types possess and require MnSOD, acute loss of MnSOD activity may serve as a generic cell death mechanism.

Protein nitration in neurodegenerative diseases

Nitrated proteins have been identified in affected tissues in Parkinson's Disease (Good *et al.*, 1998; Giasson *et al.*, 2000), in Alzheimer's dementia (Smith *et al.*, 1997; Hensley *et al.*, 1998; Tohgi *et al.*, 1999; Williamson *et al.*, 2002), in ALS (Aoyama *et al.*, 2000; Abe *et al.*, 1995; Beal *et al.*, 1997; Strong *et al.*, 1998; Cassina *et al.*, 2002), and in prion protein-related diseases (Guentchev *et al.*, 2000). Again, the presence of nitrated proteins simply may indicate that peroxynitrite was formed at some stage and modified other critical cellular targets in less discernible but functionally more important ways. Because the magnitude of modification via other pathways may greatly exceed the nitration pathways, the toxicological relevance of peroxynitrite formation may be grossly underestimated if one focuses solely on the extent of protein nitration. By the same token, a lack of clear correlation between the specific proteins which are nitrated and oxidative injury does not preclude peroxynitrite as the mediator of that injury. For example,

the levels of peroxynitrite needed to nitrate 0.05% of the total protein-bound tyrosine in the cell may be sufficient to totally inactivate (via non-nitrative pathways) critical iron-sulfur proteins in the mitochondrial electron transport chain and effectively inhibit mitochondrial energy production. The mechanisms related to peroxynitrite-mediated cytotoxicity are only beginning to be understood and too narrow a focus on the functional consequences of protein nitration alone may be dangerously misleading.

Scavenging of reactive species: basic concepts

Before discussing some of the newer, novel antioxidants that are currently being developed and evaluated as potential human therapeutics, it is important to establish some basic concepts relating to oxidant scavenging (for review, see Crow, 2000). Misconceptions abound as to what constitutes a scavenger of free radicals and/or reactive species, how they work, and their limitations. Exogenously administered scavengers do not magically soak up all reactive species, they merely act as alternate targets. Their overall effectiveness in preventing oxidative injury is a function of several factors including: (i) which species they scavenge, (ii) how fast they react with various injurious species, (iii) their tissue and cellular concentration, and (iv) the mechanism by which they scavenge reactive species. There are few, if any, truly specific scavengers; this may be advantageous from the standpoint of therapeutic antioxidants, but it limits their utility as probes for identifying the specific reactive species responsible for oxidative injury.

With regard to scavenger specificity, it is important to point out that there is no such thing as a “hydroxyl radical scavenger” by virtue of the fact that essentially all biomolecules react with hydroxyl radical at near diffusion-limited rates. Hydroxyl radical is so reactive that it will diffuse only a few angstroms before reacting with any one of a host of target molecules (Kehrer, 2000; Koppenol, 2001). Also, hydroxyl radical production almost invariably requires the presence of redox active iron or copper. Thus, oxidative injury by hydroxyl radical is restricted to a very small radius near the site of production. For example, release of iron from safe storage depots such as ferritin can result in binding of free iron to the phosphate moieties of nucleic acids. Reduction of nucleic acid-bound iron by antioxidants such as ascorbate, followed by diffusion of H_2O_2 to that site can result in hydroxyl radical production, which can oxidize a functional group on that, or an adjacent, nucleic acid, but not targets more than a few angstroms from the site of hydroxyl radical produc-

tion. Several factors, including some discussed earlier, call into question the relevance of hydroxyl radical to oxidative injury. In any case, attempts to employ any compound as a specific “hydroxyl radical scavenger” call into question the comprehension of the investigator.

Direct-acting vs. indirect-acting scavengers

Oxidant and/or free radical scavengers can broadly be grouped as being either direct acting or indirect acting. Direct-acting scavengers, as the name implies, react directly with a reactive species in a bimolecular fashion. This means that, as the concentration of the scavenger is increased, a larger fraction of the reactive molecules will react with it rather than with other biomolecular targets. The fraction of reactive molecules scavenged will be a function of the scavenger concentration and the rate constant for its reaction with the given oxidant: the faster the rate constant, the lower the concentration of scavenger required to be effective. GSH is present in some cells at millimolar concentrations and reacts directly with peroxynitrite, but its effectiveness as an endogenous peroxynitrite scavenger is limited by the fact that the rate constant (for reaction with peroxynitrite) is low relative to other biomolecular targets. Indirect-acting scavengers typically provide electrons to “quench” secondary reactants formed when the primary oxidant attacks a biomolecular target. For example, attack of potent one-electron oxidants such as hydroxyl radical or nitrogen dioxide on tyrosine initially yields a tyrosyl radical, which can then be re-reduced quite effectively by ascorbic acid (vitamin C). By quenching the reactive intermediate (tyrosyl radical), further oxidation/modification of tyrosine is prevented. Ascorbate and tocopherol (vitamin E) are both, for the most part, indirect-acting scavengers which quench reactive intermediates in the cytosol and lipid membrane, respectively. Indirect-acting scavengers display a hyperbolic dose-response relationship (as opposed to a linear dose-response for direct-acting scavengers), meaning that they reach a saturating concentration above which no additional benefit is seen. This may be one reason why little or no additional benefit is seen with megadoses of ascorbate and tocopherol even in situations where oxidative stress is known to play a major role in cell injury.

Sacrificial vs. catalytic scavengers

Direct-acting scavengers can be categorized further as either sacrificial or catalytic. GSH is sacrificial, meaning that one mole of GSH is consumed for every mole of

Based on its reactivity, peroxynitrite (or the protonated form, peroxynitrous acid) can be thought of as a hydroxyl radical bound to nitrogen dioxide (HO--ONO). The central Fe(III) ion of redox active metalloporphyrins like Fe TCPP donates one electron to reduce the "hydroxyl radical end" of peroxynitrite thereby yielding nitrogen dioxide and Fe(IV) porphyrin. Cellular antioxidants rapidly reduce the Fe(IV) back to Fe (III) and also reduce nitrogen dioxide to nitrite, thereby regenerating the reduced porphyrin and simultaneously quenching the secondary reactant. In vivo the Fe ion may be reduced to Fe(II) and thereby become capable of complete two-electron reduction of peroxynitrite, thereby bypassing production of nitrogen dioxide.

Scheme 2 Peroxynitrite scavenging by Fe porphyrins in vitro.

peroxynitrite scavenged. The primary reaction product – GSSG – can be recycled by the NADH-requiring enzyme glutathione reductase; however, this recycling cannot keep pace with GSH oxidation by peroxynitrite in real time, hence the designation sacrificial. Many low molecular weight Mn- and Fe-containing porphyrins are catalytic antioxidants. They can react with peroxynitrite to generate Mn(IV) or Fe(IV) species, which can be re-reduced to their respective +3 (or even +2) forms by ascorbate and GSH even faster than they are initially oxidized by peroxynitrite (for review, see Scheme 2 and Crow, 2000). Thus, they act catalytically in the sense that they are recycled back to their original reduced states in real time. As a general chemical class, many of the Mn and Fe porphyrins currently being investigated were first synthesized and introduced as low molecular weight SOD "mimics" or "mimetics." It is now clear that they are much more effective as peroxynitrite scavengers and that this may be the primary basis for their protective effect, but many are still referred to as SOD mimics and incorrectly used as probes for superoxide-dependent oxidative mechanisms.⁷ Based on new findings of peroxynitrite decomposing activity, hydroperoxide reductase activity, and superoxide oxido-reductase activity of these metalloporphyrins, they have been termed collectively "catalytic antioxidants."

Scavengers based on pharmacophores in proteins

In terms of designing efficient low molecular weight scavengers for use as therapeutics, we can learn a lot from nature. Based on studies with thiol- and metal-containing proteins and enzymes, it is clear that thiol-based compounds hold the greatest promise for effective sacrificial scavengers whereas Mn and Fe porphyrins appear to be the best candidates for exogenously administered peroxynitrite decomposition catalysts. Studies with thiol-containing proteins and low molecular weight complexes indicate that the microenvironment of the thiol can be fine tuned to give reaction rates needed for effective scavenging. For example, the rate constant for GSH or *N*-acetyl cysteine (NAC) reacting with peroxynitrite is $\sim 10^3 \text{ M}^{-1}\text{s}^{-1}$ (Radi *et al.*, 1991). Zinc-thiolate complexes react ~ 100 -fold faster than GSH and the active site thiolate of some tyrosine phosphatase enzymes (e.g. PTP1b, CD45, LAR phosphatases) reacts up to 10 000-fold faster than GSH (Takakura *et al.*, 1999). Based on clinical experience with the thiol-containing compound NAC, it is reasonable to propose that tissue levels of 1–10 μM could be safely achieved. Thiol-based compounds designed to mimic the extraordinarily high reactivity of the active site thiolate of these tyrosine phosphatases effectively would scavenge a high percentage of peroxynitrite formed even at low micromolar concentrations. Such compounds could conceivably be

designed to be substrates for various reductases such that they would be re-reduced (and hence recycled) in vivo.

Metalloporphyrins

The Mn and Fe porphyrins that have been shown to have broad antioxidant properties are, in effect, analogs of naturally occurring heme (iron protoporphyrin IX); the reactivities of the synthetic metalloporphyrins are not constrained by the microenvironment of protein-bound heme. These metalloporphyrins are planar molecules with a central metal ion which can react with peroxynitrite with rate constants in the range of $10^7 \text{ M}^{-1}\text{s}^{-1}$ (Ferrer-Sueta *et al.*, 1999) – fast enough to out-compete most of the known reactions of peroxynitrite with biomolecular targets. Moreover, some metalloporphyrins appear to be capable of scavenging the CO_2 adduct of peroxynitrite as well (Ferrer-Sueta *et al.*, 1999; Crow, 1999). Because these compounds are re-reduced by endogenous antioxidants like ascorbate and GSH in real time, their effective concentration would not be decreased by reaction with peroxynitrite; this is a key pharmacological advantage of the catalytic scavengers. The combination of fast rate constants for reaction with peroxynitrite and fast catalytic recycling means that these agents should be effective – and would continue to be effective – at low micromolar concentrations. Metalloporphyrins have been shown to be protective in a number of cell and animal models of oxidative injury, including ALS (Liu *et al.*, 2002) and models of stroke (Mackensen *et al.*, 2001). Evidence that these redox active porphyrins were working via peroxynitrite scavenging was provided by showing that protein nitration was prevented (Salvemini *et al.*, 1999; Misko *et al.*, 1998). (Prevention of protein nitration strongly suggests that other deleterious reactions of peroxynitrite were also prevented.) However, new evidence suggests that metalloporphyrins have protective effects independent of antioxidant activities, namely that they are potent inducers of heme oxygenases and other heat shock proteins – proteins which are known to enhance survivability to oxidative stress.

Selenium- and tellurium-based scavengers

Selenium and tellurium are in the same chemical family as sulfur and, with regard to reactions with biological oxidants, can be viewed as “hyperactive thiols.” Ebselen is a selenium-containing compound introduced originally as a glutathione peroxidase (GPx) mimic. Much like the metalloporphyrins, ebselen was found to react even more efficiently with peroxynitrite (Sies & Masumoto, 1997). Problems with water solubility and with reactivity toward both

low molecular weight thiols and protein thiols have limited the potential of ebselen as a clinically useful antioxidant. More soluble and less promiscuous compounds such as selenomethione have proved to be effective antioxidants, at least in cell culture models (Briviba *et al.*, 1996) and may have potential as therapeutics in vivo. Compounds like selenium and tellurium which either exist in trace amounts in vivo or not at all, have a high potential for toxicity, particularly if they are released as free metals as a result of oxidation or enzymatic metabolism. New classes of selenium- and tellurium-containing compounds (Jacob *et al.*, 2000) may overcome current limitations and prove to be clinically useful. Metalloporphyrins have the advantage of being remarkably stable toward metal release as the tetra-coordinate porphyrin backbone binds Mn and Fe with very high affinity while permitting the metals to redox cycle.

Superoxide, NO, H_2O_2 , and peroxynitrite are inextricably intertwined with SODs

SODs can catalyze the interconversion between superoxide, NO, H_2O_2 , and peroxynitrite; thus a fundamental relationship exists between these enzymes and the chemical entities that interact with them. This relationship has many important implications including: (i) why it is desirable to scavenge superoxide- and NODOs rather than the primary radicals, (ii) how H_2O_2 -mediated toxicity may be SOD dependent, (iii) how and why SOD mutants cause ALS, (iv) how wild-type SOD may become toxic via the same mechanism as SOD mutants (and thereby cause sporadic ALS), and (v) how binding of copper by amyloid beta and prion protein (PrP) may contribute to Alzheimer's disease and prion-related diseases such as scrapie and bovine spongiform encephalopathies. This topic was reserved for the end because of the need to incorporate several concepts developed earlier.

Why do we need so much SOD activity?

As mentioned earlier, the fundamental problem with superoxide-dependent oxidative injury is that superoxide itself does not do much, i.e. despite its name, it is not a good oxidant and it simply does not react at all with most non-radical biomolecules.⁸ Moreover, superoxide will undergo spontaneous dismutation (transfer an electron from one superoxide to another to yield molecular oxygen and H_2O_2) at a rate which is arguably fast enough to prevent superoxide-mediate modification of the few biomolecular targets that do exist (Gardner & Fridovich, 1992; Hausladen & Fridovich, 1994). So, why do we need superoxide dismutases – enzymes that simply increase the rate of a

reaction that already occurs? Also, why do we need so much SOD (~1% of all soluble protein in the CNS is SOD1)? One possible reason could be the need to compete with NO for available superoxide and thereby prevent formation of peroxynitrite.⁹ The reaction of superoxide with either SOD1 or SOD2 is $2 \times 10^9 \text{ M}^{-1}\text{s}^{-1}$ (Forman & Fridovich, 1973). The reaction of superoxide with NO is ~five-fold faster than that; SODs are already as efficient as nature can make them and they simply cannot react any faster,¹⁰ so biological systems compensate by making more of it and maintaining a very high cytosolic concentration of Cu,Zn SOD (~10 μM of Cu,Zn SOD exists in the cytosol of neurons and most other cell types). The steady-state concentration of superoxide in the cell has been estimated to be in the range of 10 picomolar, or 1 000 000 lower than the concentration of enzyme designed to scavenge it. This extremely high concentration ratio of enzyme to substrate is just the opposite of what exists with most enzymes and has important implications for physiology, pathology, and for the design of therapeutic antioxidants.

More SOD does not mean more H₂O₂

One obvious, yet often unappreciated implication of the 1 000 000:1 molar ratio of SOD1 to superoxide, is that further increasing the concentration of SOD1 will not increase the amount of H₂O₂ formed. The formation of H₂O₂ (via the dismutation of superoxide) is limited by the amount of superoxide formed, not by the rate at which it is converted to H₂O₂. Therefore, in the absence of an increase in superoxide production, merely increasing the concentration of SOD will have absolutely no effect on the amount of H₂O₂ formed. Despite this simple logic, toxicity associated with overexpressing SODs – and particularly SOD2 in the mitochondria – is quite often attributed to increased formation of H₂O₂ (Zhang *et al.*, 2002). This conclusion seems reasonable, based on the fact that overexpression of catalase often abrogates the toxicity associated with SOD overexpression (Zhang *et al.*, 2002). However, such results can also be explained on the basis of SODs catalyzing the reverse reaction whereby H₂O₂ is used as a substrate to produce superoxide (see below). The only conceivable circumstance where higher SOD concentration will lead to more H₂O₂ is when a significant fraction of superoxide is reacting with NO to make peroxynitrite. Under those conditions, increasing the concentration of SODs will “divert” more superoxide (from reacting with NO) to make H₂O₂. However, under these conditions, production of more H₂O₂ is very unlikely to be toxic since this would amount to substituting a very mild cytotoxin (H₂O₂) for a very potent one (peroxynitrite).

In the presence of NO, SODs can use H₂O₂ to run in reverse

Another consequence of overexpressing SODs will be to promote the reverse reaction whereby H₂O₂ becomes a substrate for SODs, resulting in the production of superoxide. SOD, like all enzymes, is capable of catalyzing reactions bidirectionally. The direction of the reaction is dictated by many factors including the relative energy states of substrates and products and by the relative concentrations of substrates and products. In the case of SODs, H₂O₂ would rarely build up to high concentrations because catalase, glutathione peroxidase, and other peroxidases act to decompose H₂O₂ to water and oxygen. However, catalase is primarily localized to peroxisomes and GPx is localized to the mitochondria (Halliwell, 2001). Thus H₂O₂ may accumulate in the cytosol (or other subcellular compartment) to concentrations sufficient to drive the reverse reaction by SODs. Coincidentally, the normal substrate for SODs – superoxide – reacts with NO about five-fold faster than it reacts with SOD itself and NO is small enough to “invade” the active site of SODs. Thus, in the presence of NO, any superoxide produced by SODs can be quickly converted to peroxynitrite and the equilibrium can be “pulled” by NO in the reverse direction. The reverse reaction of SOD is more likely to be important in situations where H₂O₂ is added exogenously, e.g. when H₂O₂ is added to cultured cells. It is quite easy to demonstrate that SODs plus H₂O₂ and NO will yield peroxynitrite *in vitro* and McBride *et al.* have provided compelling evidence for this reaction occurring in cells where H₂O₂ has been added exogenously (McBride & Brown, 1997; McBride *et al.*, 1999).

In the absence of enzyme-bound zinc, Cu,Zn SOD can be reduced to the Cu(I) form by other cellular reductants, thereby eliminating the need for H₂O₂ altogether. Thus, the Cu(I) form of zinc-deficient SOD1 can use ascorbate, GSH, NADH, etc. along with oxygen and NO to make peroxynitrite catalytically. This is the basis for one hypothesis regarding the gained function of SOD1 mutants in ALS and the reader is referred to a review of this mechanism (Beckman *et al.*, 2001). One attractive aspect of this zinc deficiency hypothesis is that it provides a mechanism whereby wild-type SOD1 – via a failure to bind zinc – could become toxic in the same manner as ALS-associated mutants and thereby produce so-called sporadic ALS (Beckman *et al.*, 2001).

The reverse dismutase reaction utilizing H₂O₂ should not be confused with so-called peroxidase activity of SODs. Peroxidase activity of SOD only occurs at extremely high (non-physiological) concentrations of H₂O₂ and inactivates SOD after only a few turnovers (Hodgson & Fridovich, 1975;

Wiedan-Pazos *et al.*, 1996). The reverse reaction of SOD1 occurs at low micromolar concentrations of H_2O_2 and is enhanced in a concentration-dependent manner by NO (Crow *et al.*, unpublished observations).

Copper-binding proteins as a generic mechanism of toxicity in neurodegenerative disease

Much attention has been focused on abnormal aggregation of proteins as the basis for toxicity of beta amyloid peptide in Alzheimer's disease, Huntingtin protein in Huntington's disease, prion protein in Mad Cow disease (bovine spongiform encephalopathy and other prion-related diseases), and SOD1 mutants in ALS. There are many reasons to believe that these proteins are inherently unstable and have a greater tendency to aggregate, particularly in certain conformations or oxidatively modified forms. Binding of non-redox active metals such as zinc and aluminium by these proteins could stabilize abnormal conformations and thereby contribute to toxicity. However, a growing body of evidence suggests that copper binding may be critical to their toxicity, particularly with beta amyloid peptide, prion protein, and SOD1 mutants (Bush, 2000). Copper is inherently toxic due to its ability to steal electrons from cellular reductants such as ascorbate and GSH and hand them off to oxygen to generate superoxide. SOD1 "forces" copper to carry out the opposite reaction – namely to take electrons from superoxide, but abnormal conformations and/or abnormal copper binding by SOD1 mutants could "disinhibit" this inherent property of copper and allow it to become pro-oxidant. There is evidence that beta amyloid and prion protein bind copper in a redox active manner. Oxidants formed in this way could attack critical sites of energy production in mitochondria and/or oxidatively modify the copper binding protein itself, making it resistant to proteolytic degradation and more likely to accumulate and aggregate. Thus, abnormal generation of oxidants via redox cycling of bound copper may turn out to be a generic mechanism contributing to neurodegenerative disease.

ENDNOTES

1. Single, odd electrons could, in theory, be transferred to any molecule capable of accepting them. Odd electrons are transferred to molecular oxygen (to generate reactive species) because oxygen normally has two unpaired electrons and because it is the most abundant, diffusible, and proximal one electron acceptor present.
2. In the absence of redox metal catalysts, significant oxidation of thiols (-SH) such as glutathione by H_2O_2 requires many hours to occur. Superoxide is a much better reductant than oxidant and its ability to reduce Fe(III) cytochrome c serves as the basis for the most commonly used in vitro SOD assay.
3. NO, like oxygen, is lipid soluble and will partition into lipid bilayers. The fact that NO and oxygen accumulate to higher concentrations within lipid bilayers has important implications for NO/oxygen interactions and initiation of lipid peroxidation (Liu *et al.*, 1998).
4. Chemically speaking, the reaction of any radical with any non-radical is electronically unbalanced, thermodynamically unfavourable and, when it does occur, results in a new radical species. Thus, only radicals with very high oxidation potentials will react directly with neutral biological molecules and thereby abstract single electrons. Such electron abstraction neutralizes the oxidizing radical (e.g. hydroxyl radical gets reduced to hydroxide anion or ^-OH) and simultaneously yields a new radical derived from the biomolecular target. The biomolecular radical may be quenched by one electron reductants such as ascorbate or tocopherol (so-called radical termination) or abstract an electron from another target, thereby propagating the radical reaction.
5. The exception to this rule is the reaction of NO with oxygen within a lipid bilayer as mentioned earlier. However, even under these conditions, the reactive species produced will most likely react with electron-rich unsaturated lipids in the bilayer and not escape to interact with soluble biomolecules.
6. Most of the peroxynitrite-mediated modifications that have been studied extensively in vitro are not reversed even by high concentrations of classic reductants such as dithiothreitol. Nitration and hydroxylation of aromatic amino acid residues or low molecular weight compounds represent covalent modifications which could only be reversed only by enzymes in vivo. However, no compelling evidence for reversal of these or other peroxynitrite-mediated modifications in vivo exists.
7. Simple calculations of specific dismutase activity per milligram of porphyrin – compared to true SOD enzyme activity already present in cells – reveals that millimolar concentrations of porphyrins would be needed to enhance total dismutase activity by even a small percentage. Thus, it is exceedingly unlikely that Mn and Fe porphyrins are exerting protective effects via dismutase activity.
8. The notable exception to this rule is iron-sulfur centers in many mitochondrial enzymes such as aconitase (Gardner & Fridovich, 1992; Hansladen & Fridovich, 1994). Iron-sulfur centers retain some degree of radical character and can be oxidized reversibly by superoxide.
9. The amino acid residues which comprise SOD1 support this teleological argument. Most enzymes that peroxynitrite has been shown to inactivate contain critical tyrosine, cysteine, or methionine residues. Human Cu,Zn SOD has only one methionine and two free cysteines – none of which is required for enzyme activity – and no tyrosines. Thus, human Cu,Zn SOD appears to have evolved to be highly resistant to oxidative modification/inactivation by peroxynitrite.
10. Many factors govern whether two molecules will react with each other, but the ultimate limit is imposed by how fast they can

diffuse and randomly collide with each other, i.e. no reaction can occur faster than the rate at which the two reactants can collide. A large protein like SOD cannot diffuse and collide as rapidly as a small molecule like NO. Under physiological conditions, $2 \times 10^9 \text{ M}^{-1}\text{s}^{-1}$ (the rate constant for reaction of superoxide with SOD) is about as fast as a small molecule can collide with a large protein whereas two small molecules can collide from 10 to 100 times faster or 10^{10} to $10^{11} \text{ M}^{-1}\text{s}^{-1}$. Thus, the reaction of superoxide with SOD represents a true diffusion-limited reaction for a protein and a small molecule, and the reaction of superoxide with NO ($\sim 10^{10} \text{ M}^{-1}\text{s}^{-1}$) approaches the diffusion limit for two small molecules.

Mitochondria, metabolic inhibitors and neurodegeneration

James G. Greene¹ and J. Timothy Greenamyre²

¹Center for Neurodegenerative Disease and Department of Neurology, Emory University, Atlanta, GA, USA

²Pittsburgh Institute for Neurodegenerative Diseases, University of Pittsburgh, PA, USA

The role of the mitochondrion in neurodegeneration is a paradox. On the one hand, vital mitochondrial tasks, such as energy production and calcium buffering, provide an important foundation for all neuronal functions. Yet, on the other, mitochondrial free radical production and involvement in cell-death cascades may lead to a neuron's untimely demise.

It is now clear that mitochondria are not merely neuronal “power plants”, but are highly complex, integrated organelles whose function transcends that of simple energy production. In addition to providing the majority of neuronal energy via oxidative phosphorylation, mitochondria play a central role in intracellular ion homeostasis, free radical management, and gene and protein expression.

This chapter will focus on the biology of mitochondrial electron transport, oxidative phosphorylation and other mitochondrial functions, and will discuss the effects of mitochondrial toxins on mitochondrial function and neuronal viability. It will explore briefly one of the main consequences of oxidative metabolism, mitochondrial free radical production and how this and other mitochondrial factors potentially contribute to neuronal death.

Mitochondrial energy production and sites of action for metabolic inhibitors

Mitochondria efficiently convert the potential energy of glucose into a usable cellular energy currency, primarily ATP. Glucose is the primary basis for neuronal energy metabolism; ketone bodies can provide a limited energy source, but only in situations of chronic metabolic imbalance.

Glucose crosses the blood–brain barrier in an insulin-independent manner and is taken up by membrane

transporters. It is phosphorylated almost immediately by hexokinase and enters glycolysis. Iodoacetate (IOA) is an inhibitor of glycolysis that acts by acetylating sulfhydryl groups on glucose-6-phosphate dehydrogenase and other proteins (Hochster & Quastel, 1963). Pyruvate, the end product of glycolysis, is transported through the double-layer mitochondrial membrane into the matrix where it is transformed into acetyl CoA by the pyruvate dehydrogenase complex (PDHC). Lactate, produced from glial metabolism of glucose, is also a significant source of neuronal pyruvate.

Acetyl CoA enters the tricarboxylic acid (TCA) cycle by combination with oxaloacetate to form citrate (Fig. 3.1). The TCA cycle is a sequence of nine reactions that results in the production of high-energy phosphates, reducing equivalents, and oxaloacetate for the next round of the cycle. One important reaction in this sequence is the transformation of succinate to fumarate by succinate dehydrogenase (SDH, complex II). This enzyme contains a flavin prosthetic group that is reduced from FAD⁺ to FADH₂ in the process of succinate metabolism. Malonate is a reversible, competitive inhibitor of SDH (Hochster & Quastel, 1963); 3-nitropropionic acid (3-NP) is a suicide inhibitor of this enzyme (Alston *et al.*, 1977). One mole of glucose produces a net gain of 2 moles each of ATP and NADH in the cytoplasm from glycolysis and 8 moles of NADH, 2 moles of FADH₂, and 2 moles of GTP in the mitochondrial matrix from the TCA cycle.

Since the inner mitochondrial membrane is impermeable to NADH, the reducing equivalents contained in cytosolic NADH are transferred to the mitochondrial matrix by two “shuttles.” The glycerol-3-phosphate shuttle is irreversible and results in one mole of mitochondrial FADH₂ from one mole of cytoplasmic NADH; the malate–aspartate shuttle is reversible and results in one mole of mitochondrial NADH from one mole of cytoplasmic NADH. The

Fig. 3.1 Schematic diagram illustrating various aspects of mitochondrial metabolism. There is significant interaction between energy metabolism, calcium buffering, ROS production, and regulation of neuronal death.

malate–aspartate shuttle, because it requires no net energy expenditure, only operates if the NADH/NAD^+ ratio is higher in the cytoplasm than the mitochondrial matrix. Aminooxyacetic acid (AOAA) inhibits a variety of transamination reactions, including the transamination of oxaloacetate to aspartate in the mitochondrial matrix, which is a key step in the operation of the malate–aspartate shuttle (Kauppinen *et al.*, 1987).

Oxidative phosphorylation transforms the potential energy contained in NADH and FADH_2 into ATP. The electron transport chain (ETC) includes a series of enzymes in the inner mitochondrial membrane, two small electron carriers, and SDH (Fig. 3.1). Electrons from NADH enter the respiratory chain via complex I (NADH dehydrogenase; NADH: ubiquinone oxidoreductase). Rotenone and MPP^+ are inhibitors of this enzyme (Nicklas *et al.*, 1985; Ramsay *et al.*, 1991).

Electrons from complex I are passed to complex III (ubiquinol–cytochrome c oxidoreductase) via the small electron acceptor ubiquinone, also known as coenzyme Q10. Coenzyme Q10 is also the entry point for electrons derived from FADH_2 . Most FADH_2 is generated via the TCA cycle by SDH (complex II; succinate: ubiquinone oxidoreductase), but some comes indirectly from glycolysis via the glycerol-3-phosphate shuttle.

Complex III, which can be inhibited by antimycin (Slater, 1973), donates electrons to a second small electron acceptor, cytochrome c, which passes them to complex IV (cytochrome oxidase). Complex IV transfers electrons to molecular oxygen, the final electron acceptor. Inhibitors of complex IV include cyanide (CN^-) and azide (N_3^-) (Hochster & Quastel, 1963).

Complexes I, III, and IV pump protons from the inner mitochondrial matrix to the outer mitochondrial matrix,

creating potential energy stored in the form of an electrochemical gradient. The establishment of this proton motive force (Δp) is vital to many mitochondrial functions, including ATP synthesis. Δp is a composite of mitochondrial membrane potential ($\Delta\psi$) and ΔpH , with $\Delta\psi$ being the larger contributor to Δp .

The potential energy in Δp is harnessed by complex V (ATP synthase), which produces ATP from ADP and inorganic phosphate when protons flow through the complex back into the mitochondrial matrix. Mitochondrial uncouplers, such as dinitrophenol and carbonyl cyanide trifluoromethoxyphenyl hydrazone (FCCP), disrupt the mitochondrial proton gradient and thereby uncouple electron transport from ATP synthesis (Hochster & Quastel, 1963).

The flow of two moles of electrons through complexes I, III, and IV provides energy for each enzyme complex to pump enough protons to make one mole of ATP. Metabolism of one mole of glucose through oxidative phosphorylation generates about 30 moles of ATP.

Under normal circumstances, glycolysis accounts for only about 5% of neuronal energy production, but it provides necessary precursors for the TCA cycle and oxidative phosphorylation. Under hypoxic conditions, NAD^+ may be regenerated via anaerobic mechanisms, such as lactate production, thereby increasing the energy production of anaerobic glycolysis, although the energy production capacity of this mechanism is limited. Regulation of neuronal energy metabolism is a subject beyond the scope of this review, but it is based on cellular energy charge, the need for anabolic precursors, the supply of glucose and oxygen, and second messenger signaling pathways, especially Ca^{2+} (Pulsinelli & Cooper, 1989; Stryer, 1988; Gunter *et al.*, 1994).

Mitochondrial calcium homeostasis

As mentioned above, the potential energy represented by Δp is important for other mitochondrial functions besides ATP production, namely mitochondrial calcium uptake and homeostasis. The inner mitochondrial membrane contains two mechanisms that allow for passage of calcium ions into the mitochondrial matrix, the calcium uniporter and RaM. Calcium uptake is driven primarily by $\Delta\psi$. These uptake mechanisms have a low affinity for calcium, so they are only activated above a certain set-point calcium concentration (typically 500–1000 nM); however, mitochondria have an extremely high capacity for calcium uptake once that set point is reached (Gunter & Gunter, 2001).

Mitochondrial calcium is extruded by sodium-dependent and sodium-independent mechanisms. Sodium-dependent efflux is modulated by a Na^+/H^+ antiporter that extrudes sodium from the mitochondrial matrix at the expense of ΔpH . Sodium-independent efflux appears to depend on ΔpH as well, in the form of active Ca/H exchange. Thus, the proton-motive force mediates both mitochondrial uptake and release of calcium (Pfeiffer *et al.*, 2001).

As might be imagined, due to their link through the proton motive force, not only does mitochondrial metabolism affect calcium flux, calcium flux modulates mitochondrial metabolism. Small increases in intramitochondrial calcium, such as would be seen with modest neuronal stimulation, act as an intracellular signal to produce increases in mitochondrial respiration. Higher levels of calcium sequestration are thought to induce Ca^{2+} -dependent Ca^{2+} release and propagation of further intracellular calcium signals (Ichas *et al.*, 1997).

Under situations of extreme stress, large amounts of calcium can be sequestered in mitochondria. This serves as a valuable protective mechanism by maintaining cytosolic calcium in the physiologic range, but when overwhelmed, high levels of intramitochondrial calcium have deleterious effects. These include metabolic inhibition, dissipation of $\Delta\psi$, and increased ROS generation (Murphy *et al.*, 1999; Ichas *et al.*, 1997; Stout *et al.*, 1998).

Mitochondrial free radical production

One of the inherent dangers in oxidative metabolism is ROS generation. Superoxide radical is produced by reduction of molecular oxygen by one electron. In mitochondria, this is most likely to occur when elements of the electron transport chain are in a highly-reduced state and, as such, more easily oxidizable. The physiological state during which this is most likely to occur is when matrix ADP concentration is low, resulting in a “bottleneck” at ATP synthase (state IV respiration). A similar highly-reduced state occurs when inhibitors of the electron transport chain are present, resulting in a “backup” of electrons. Under these circumstances oxygen accepts electrons from components other than complex IV. Furthermore, any event that enhances oxidative metabolism, thereby increasing electron flux, may cause an increased likelihood of superoxide generation. Conversely, mitochondrial ROS production is lowest during state III respiration, when ADP is plentiful and electrons proceed unimpeded through the chain (Boveris & Turrens, 1980; Boveris *et al.*, 1972; Loschen *et al.*, 1974). Superoxide production is most likely to

occur at complex I and ubiquinone (Raha & Robinson, 2001).

Superoxide is converted to hydrogen peroxide (H_2O_2) by intramitochondrial manganese superoxide dismutase (Mn-SOD). H_2O_2 is reduced to water by glutathione peroxidase or catalase (Fridovitch, 1995). However, in the presence of reduced iron, such as that present in electron transport chain enzymes, H_2O_2 may be converted to the indiscriminate, highly reactive hydroxyl radical ($\cdot OH$) (Raha and Robinson, 2001) (Fig. 3.1). Accordingly, if mechanisms of superoxide detoxification are not functional or become overwhelmed, production of hydroxyl radical may increase. In addition, the iron-sulfur centers in electron transport chain enzymes are sensitive targets for ROS damage. This may, in turn, result in further mitochondrial inhibition and a vicious cycle of enhanced ROS production.

Mitochondrial permeability transition

One more aspect of mitochondrial physiology to discuss at this point is the mitochondrial permeability transition, which is characterized by sudden increased permeability of the inner membrane to ions and small molecules. This results in osmotic swelling of the mitochondrion and disruption of outer membrane integrity, leading to release of contents from the mitochondrial intermembrane space into the cytosol. This transition is mediated by a pore complex (mtPTP), the molecular composition of which is uncertain (Crompton, 1999). The probability of PTP opening is increased by many factors, including high ADP/ATP ratio, increased mitochondrial Ca^{2+} , and enhanced oxidative stress. This transition can be reversible, and it is inhibited by high mitochondrial membrane potential (Pfeiffer *et al.*, 2001). Several pharmacologic agents, including cyclosporin A, inhibit the mitochondrial permeability transition (Bernardi *et al.*, 1994).

It is worthwhile to note here that, although energy production, calcium buffering, ROS generation, and permeability transition are inextricably linked as aspects of mitochondrial function, mitochondrial deficits may be more pronounced in one aspect of function than another. For example, while a relatively severe complex I deficit may be required to produce noticeable effects on mitochondrial respiration and ATP production, much less intense inhibition of the same enzyme is sufficient to produce significant mitochondrial ROS generation and evidence of oxidative damage (Davey *et al.*, 1998; Betarbet *et al.*, 2000).

Mitochondria and cell death: necrosis

It is not surprising that malfunction of so central an organelle as the mitochondrion would result in cellular injury and possibly death. It is perhaps more intriguing to speculate that one of the functions of mitochondria in certain circumstances may be to induce cell death.

Historically, cellular death has been divided into two categories, and mitochondria may play a role in both types. Necrosis is typically described as a passive process that includes morphological features such as large-scale cellular swelling and rupture associated with inflammation. Apoptosis is an active, regulated form of “programmed” cell death that classically manifests cell shrinkage, chromatin condensation and fragmentation, and the formation of apoptotic bodies that are phagocytosed with little or no resultant inflammatory response (Kerr *et al.*, 1972).

The type of neuronal cell death that occurs in chronic neurodegenerative diseases is unclear. The focused death of individual neurons and neuronal subpopulations with minimal inflammatory response is suggestive of apoptosis, but necrosis on a neuron level cannot be ruled out. Study of this question is complicated in humans by the long duration of illness and poorly defined onset of neurodegenerative disease. It is also confounded by the relatively short time course of neurodegeneration in experimental models.

Necrosis can result from ATP depletion, calcium overload, and ROS generation, among other things, and as noted above, mitochondria are central to all three of those systems. A major fraction of ATP produced (approximately 40%) is consumed by the Na-K ATPase to maintain neuronal membrane potential during the resting state; this proportion increases during neuronal activation (Astrup *et al.*, 1981; Mata *et al.*, 1980). Preservation of sodium and potassium gradients is not only important to keep the neuron in the polarized state for neurotransmission, but the potential energy stored in that gradient is vital for calcium, pH and volume homeostasis.

During situations when mitochondrial capacity is overwhelmed by energy demand, either due to mitochondrial dysfunction or extreme neuronal stress, the ability of a neuron to maintain a polarized state might be compromised (Erecinska & Dagan, 1990). For example, mitochondrial complex II inhibition by 3-NP, markedly diminishes ATP levels in cultured striatal neurons. This diminished mitochondrial capacity is accompanied by depolarization of the resting neuronal membrane potential to 60% of its normal value (Greene *et al.*, 1998). Depolarization of the cellular membrane has a myriad of potential consequences, including excessive NMDA receptor activation (“indirect

excitotoxicity”) and activation of voltage-dependent calcium channels. Excessive NMDA receptor activation may be particularly devastating due to the apparent greater toxicity associated with NMDA receptor-dependent calcium loads, as opposed to other mechanisms of calcium influx (Kiedrowski & Costa, 1995; Peng & Greenamyre, 1998). This can result in dysregulation of neuronal calcium levels and potentially cause non-specific activation of calcium-dependent proteases and other enzymes, leading to rapid cell death in a necrotic manner.

Because the neuronal sodium gradient is dissipated by ATP depletion, secondary active transport via this gradient will stall. Since glutamate reuptake is a Na-dependent process, ATP depletion may result in massive increases in extracellular glutamate concentration and potential for excitotoxic damage (Cousin *et al.*, 1995). Impaired Na/H exchange at the neuronal membrane may have significant effects on cytoplasmic pH, resulting in intraneuronal acidification and an accompanying rise in intraneuronal calcium (Koch & Barrish, 1994). Intraneuronal calcium levels may also increase dramatically due to impairment of Na/Ca exchange at the neuronal membrane. It is thought that this exchange is particularly important in the removal of calcium loads as opposed to the maintenance of resting calcium levels, similar to mitochondrial calcium buffering (Blaustein, 1988). Under circumstances when intraneuronal calcium load is increasing rapidly due to excess NMDA receptor activation, inhibition of Na/Ca exchange may be singularly damaging (Andreeva *et al.*, 1991). The large sodium current associated with NMDA receptor activation only further short-circuits the neuronal sodium gradient and magnifies the effects of the NMDA calcium current (Kiedrowski *et al.*, 1994).

Breakdown of the sodium gradient is essentially due to a large net influx of sodium ions from the extracellular space. This is a significant osmotic load that results in neuronal swelling which can cause, at the least, significant mechanical disturbance of cellular machinery and, at the worst, neuronal rupture.

In addition, ATP depletion will affect any energy-dependent neuronal process such as axonal transport, neurotransmitter uptake, release and reuptake, and ATP dependent calcium sequestration into ER. Furthermore, countless kinase-phosphatase reactions will be deranged, throwing the entire neuronal enzymatic machinery into disarray.

Since all mitochondrial functions are so intimately inter-related, it is difficult experimentally to separate individual mitochondrial functions to explore their specific contribution to cell survival and death. Be that as it may, strategies

that support neuronal ATP production have been shown to limit neuronal death in certain models. Support of brain ATP levels by administration of creatine or cyclocreatine produces significant neuroprotection from the damage resulting from multiple types of mitochondrial inhibition (Matthews *et al.*, 1998a; Carter *et al.*, 1995).

From the preceding discussion, it is apparent that ATP depletion leads to far-reaching neuronal effects that may contribute to neuronal necrosis. A central mediator in those pathways is calcium, which has long been thought to be a key mediator of necrosis. As such, overwhelming both mitochondrial energy production and calcium buffering may have a synergistic effect to damage neuronal calcium homeostasis resulting in accelerated neuronal death.

Mitochondria are important for buffering both physiologic and toxic calcium loads, and mitochondrial ETC dysfunction decreases mitochondrial calcium uptake capability by decreasing $\Delta\psi$ (Gunter & Gunter, 2001). This system has a high capacity for calcium uptake that is not easily exceeded, but calcium entering through NMDA receptors may have privileged access to mitochondria potentially resulting in impaired calcium homeostasis even with intact neuronal mitochondria (Peng & Greenamyre, 1998; Tymianski *et al.*, 1993). Not only might this produce elevation in cytosolic calcium, but calcium-induced activation of the mtPTP (Pfeiffer *et al.*, 2001). This may cause further rise in cytosolic calcium, and further impairment of mitochondrial function. In addition to nonspecific protease activation, calcium overload can induce ROS production via the arachadonic acid and nitric oxide pathways (Gunasekar *et al.*, 1995).

Mitochondrial ROS production may also feed into this spiral toward neuronal necrosis. The most intuitive mechanism for this is non-specific oxidative damage to neuronal components, including nucleic acids, protein, and lipids. This damage can be additive or synergistic with that caused by destructive nonspecific enzyme activation associated with calcium overload.

In addition, since mitochondrial enzymes are ripe targets for ROS-induced damage, production of ROS may lead to further impairment of mitochondrial function (Flint *et al.*, 1993; Yan *et al.*, 1997; Zhang *et al.*, 1990). This leads to ATP depletion, poor calcium handling, and yet more free radical production.

A free radical spin trap (*N*-tert-butyl- α -(2-sulfophenyl)-nitron) has been shown to attenuate metabolic inhibitor-induced neurotoxicity without affecting ATP levels (Schulz *et al.*, 1995). Free radical scavengers are also effective neuroprotectants in models of ischemic neuronal death, which is typically necrotic in the acute period (Yue *et al.*, 1992;

Cao & Phillis, 1994). Additional evidence for the involvement of free radicals in the neurotoxicity induced by metabolic inhibition is the finding that 3-NP toxicity is attenuated in mice transgenic for human copper/zinc superoxide dismutase (Beal *et al.*, 1995). Finally, antioxidants such as ubiquinone and lipoic acid derivatives are protective against acute mitochondrial inhibition *in vivo* (Matthews *et al.*, 1998a; Greenamyre *et al.*, 1994).

Mitochondrial and cell death: apoptosis

Because the neurodegeneration seen in human disease and animal models thereof typically does not fit cleanly into either the necrosis or apoptosis category, the separation of this discussion is somewhat artificial. However, there are some differences between massive mitochondrial dysfunction leading to nonspecific necrosis and more subtle abnormalities that may result in death that is more toward the apoptosis side of the continuum.

Apoptosis, as opposed to necrosis, is an active process. To a certain extent, this process is dependent on intracellular ATP levels, and it has been proposed that whether a cell undergoes necrosis or apoptosis depends on the intracellular ATP concentration (Ankarcrona *et al.*, 1995; Leist *et al.*, 1997; Volbracht *et al.*, 1999). As such, in order for a neuron to undergo apoptosis, mitochondria must be at least partly, if not fully, functional. As mentioned earlier, partial mitochondrial inhibition may have dramatic effects on certain aspects of mitochondrial function with minimal effects on respiration (Davey *et al.*, 1998). It follows that, while severe mitochondrial impairment may result in necrosis, more subtle defects may cause apoptosis.

The cell biology of apoptotic pathways is complicated, interrelated, and incompletely understood, but mitochondria are now recognized to be central mediators of apoptosis (Kroemer & Reed, 2000; Ravagnan *et al.*, 2002). The majority of apoptotic pathways depend on release of mitochondrial intermembrane proteins that activate effectors of apoptotic cascades. Mitochondrial proteins described to be regulators of apoptosis include cytochrome c, AIF (apoptosis inducing factor), endonuclease G, Smac (second mitochondrial activator of caspases), DIABLO (direct IAP binding protein with low *pI*), HtrA2/Omi, and procaspases 2, 3, and 9 (Liu *et al.*, 1996; Ravagnan *et al.*, 2002).

A family of Bcl-2-like proteins modulates release of intermembrane proteins. This protein family includes both promoters (Bax, Bak, Bcl-x-s, Bad, Bim, Bid) and preempts (Bcl-2, Bcl-x-l, Bcl-w) of apoptosis (Ravagnan *et al.*, 2002).

Release of intermembrane space proteins is dependent on pore formation in the mitochondrial membrane. Two possible mechanisms have been described. The first involves oligomerization of Bax or Bak or formation of a Bax-VDAC complex that spans the inner and outer mitochondrial membrane (Antonsson *et al.*, 2001). Anti-apoptotic Bcl-2-like proteins may prevent formation of this pore by heterodimerization with Bax or Bak (Shimizu *et al.*, 1999; Vander Heiden *et al.*, 1999).

The second possible mechanism revolves around the mtPTP (Fig. 3.1). As discussed above, the mtPTP mediates the mitochondrial permeability transition, which may cause outer membrane rupture followed by release of intermembrane space proteins. As such, any stimulus that facilitates mtPTP opening (high ADP/ATP ratio, mitochondrial calcium, mitochondrial ROS) may cause induction of the apoptotic cascade. Binding of cyclophilin D to the ANT can also facilitate pore opening (Crompton *et al.*, 1998; Woodfield *et al.*, 1998). As further evidence of the interconnected nature of these pathways, it has recently been described that Bax translocation to mitochondria increases mitochondrial ROS production and that blocking ROS production prevents cell death (Kirkland *et al.*, 2002, Narita *et al.*, 1998).

The cellular signals that result in mitochondrial protein release are varied. Withdrawal of growth factors, UV damage, free radical production, and cytokine signals may all cause induction of p53, a key cell cycle regulator (Vogelstein *et al.*, 2000). p53 can activate Bax and caspase 8 (Ding & Fisher, 1998). It can also activate a protein called PIG3, which, similar to Bax, can stimulate mitochondrial ROS production (Polyak *et al.*, 1997).

Other cellular signals, including cytoskeletal disruption, TNF receptor activation, or elevated intracellular calcium may cause translocation of proapoptotic Bcl-2-like proteins to the mitochondria and facilitate protein release (Hengartner, 2000; Luo *et al.*, 1998; Puthalakath *et al.*, 1999).

In addition, anything that induces the mtPTP may result in release of mitochondrial proteins and activation of apoptotic cascades. This would include dysfunction of respiration and mitochondrial calcium overload, as well as mitochondrial inhibition and ROS production.

Mitochondrial protein release causes downstream activation of multiple apoptotic effector molecules. Cytochrome c and procaspase 9 released from the intermembrane space combine with the cytosolic protein APAF-1 to form a complex termed the apoptosome (Ravagnan *et al.*, 2002). Formation of the apoptosome results in activation of caspase 9 which cleaves procaspase 3 to activate caspase 3. Caspase 3 has been shown to be an important effector of apoptosis and acts via CADNase

(caspase-activated DNase) and ACINUS (apoptotic chromatin condensation inducer in the nucleus) to provoke chromatin condensation and DNA fragmentation (Hengartner, 2000; Ravagnan *et al.*, 2002).

Smac/DIABLO, when released from the intermembrane space, bind to and inhibit several inhibitors of apoptosis proteins (IAPs) in the cytosol, including XIAP and cIAP1 and 2, thus promoting apoptosis (Du *et al.*, 2000; Ekert *et al.*, 2001). HtrA2/Omi also inhibits IAPs, and it further enhances apoptosis independent of its IAP inhibition through its serine protease activity (Verhagen *et al.*, 2002).

AIF and Endonuclease G act in a caspase-independent manner to cleave nuclear DNA into high molecular weight fragments following mitochondrial release (Li *et al.*, 2001; Zamzami *et al.*, 1996).

There are many other proposed enzymatic pathways that contribute to the apoptotic cascade. The majority of them depend in some way on mitochondrial protein release for initiation or continuation. As such, functioning and malfunctioning mitochondria play a central role in cellular death by apoptotic mechanisms.

Mitochondrial inhibition and neurodegeneration

The previous sections have reviewed mitochondrial biology and the ways in which perturbation of this biology may cause neuronal death. The question as to whether or not mitochondria are involved in the pathogenesis and pathophysiology of human neurodegenerative disease has received extensive attention for more than a decade (Fiskum *et al.*, 1999). It has now been convincingly described that there is impaired mitochondrial function in many neurodegenerative diseases not traditionally thought to be mitochondrial in nature (Orth & Schapira, 2001). Further exploration of the consequences of this decrease in ETC activity has involved extensive use of mitochondrial inhibitors *in vitro* and *in vivo*.

For example, decreased complex I activity has been described in substantia nigra and platelets from Parkinson's disease patients (Schapira *et al.*, 1989, 1990; Parker *et al.*, 1989). Cybrid cell lines made from Parkinson's disease mitochondria exhibit complex I deficiency, impaired calcium homeostasis, and increased ROS (Swerdlow *et al.*, 1998; Sheehan *et al.*, 1997b). The finding that led to investigation of complex I activity in Parkinson's disease patients was the discovery that MPP⁺, the active metabolite of MPTP, inhibits complex I (Nicklas *et al.*, 1985; Ramsay *et al.*, 1991).

Since MPP⁺ is taken up selectively into dopaminergic neurons, it is a poor model for a diffuse complex I defect.

Rotenone is a hydrophobic compound, used sometimes as a pesticide, which produces a generalized complex I inhibition when administered to rodents. This compound has been shown to mimic many of the behavioral and pathological hallmarks of Parkinson's disease, including symptomatic Parkinsonism, specific dopaminergic neuronal degeneration, protein aggregation, oxidative protein damage, and microglial activation. These effects occur in the presence of a rotenone concentration that produces complex I inhibition with minimal effect on mitochondrial respiration (Betarbet *et al.*, 2000).

Rotenone has been shown to markedly enhance H₂O₂ production (Hensley *et al.*, 1998). In addition, rotenone *in vitro* depletes neuronal glutathione, causes oxidative damage to protein and DNA, stimulates mitochondrial release of cytochrome c, and activates caspase 3 (Sherer *et al.*, 2002). These data suggest that inhibition at complex I produces a behavioral and neuropathological model of Parkinson's disease and that mitochondrial dysfunction at complex I may play a significant role in the pathophysiology of Parkinson's disease.

In Huntington's disease, PET scanning has revealed decreased glucose utilization in cerebral cortex and basal ganglia in Huntington's disease patients and also in at-risk individuals (Mazziotta *et al.*, 1987; Kuhl *et al.*, 1982). *In vivo* magnetic resonance spectroscopy has revealed increased lactate in Huntington's disease basal ganglia and cortex, suggesting a shift toward anaerobic metabolism, and thus an oxidative defect (Jenkins *et al.*, 1998). Several specific enzyme defects have been reported in Huntington's disease, including in complexes II, III, and IV (Beal, 1998 for review see). In addition, Huntington's disease mitochondria are less polarized (lower $\Delta\psi$) and handle calcium loads less efficiently than controls; it appears that this is a direct effect of polyglutaminated mutant huntingtin on the mitochondrion. This mitochondrial deficiency was observed in transgenic animals prior to clinical evidence for disease (Panov *et al.*, 2002).

Local or systemic administration of complex II inhibitors (malonate or 3-NP) produces a behavioural and neuropathological syndrome similar to Huntington's disease in rodents and nonhuman primates. Hallmarks include chorea and bradykinesia, weight loss, specific degeneration of striatal projection neurons, sparing of striatal interneurons, and oxidative damage (Beal *et al.*, 1993; Brouillet *et al.*, 1995). Neurodegeneration is associated with perturbation of multiple mitochondrial functions, and it is prevented by manipulation of these functions, including support of neuronal ATP levels and free radical trapping (Matthews *et al.*, 1998a,b; Schulz *et al.*, 1995). Downstream modulation of effectors of neuronal death, such as membrane

hyperpolarization or inhibition of the NMDA receptor is also an effective neuroprotective strategy (Greene & Greenamyre, 1995, 1996). Deficiency of MnSOD enhances and overexpression of Bcl-2 attenuates neurodegeneration seen in these models, consistent with an apoptotic process (Andreassen *et al.*, 2001; Bogdanov *et al.*, 1996). These data show that mitochondrial inhibition at complex II can replicate Huntington's disease pathology in animal models and suggest that mitochondrial dysfunction at complex II may play a significant role in the pathophysiology of Huntington's disease.

In Alzheimer's disease, several studies have revealed evidence of various energetic defects in autopsy and post-mortem tissue (Beal, 1998, for review). Experiments using cybrid cells constructed with Alzheimer's disease mitochondria have revealed complex IV defects, abnormal calcium homeostasis, and increased production of ROS, although the existence of a specific mitochondrial deficit in Alzheimer's disease is controversial (Swerdlow *et al.*, 1997; Sheehan *et al.*, 1997a).

Inhibition of complex IV in model systems by cyanide or azide also produces neuropathological sequelae, although this has been more extensively studied *in vitro* than *in vivo*. Complex IV inhibition has been shown to produce excitotoxic lesions *in vivo* and administration of complex IV inhibitors also produces deficits in learning and spatial memory (Bennett *et al.*, 1996; Brouillet *et al.*, 1994).

Azide and cyanide have also been used to replicate the mitochondrial dysfunction that occurs during hypoxic-ischemic events since the lack of oxygen occurring during these events represents *de facto* complex IV inhibition. Generalization from the acute neurodegeneration produced by hypoxia-ischemia to the chronic neuronal death seen in neurodegenerative disease is fraught with complication, but many of the mitochondrial mechanisms discussed above may be active (see Wieloch, 2001, for review).

Concluding remarks

Mitochondria are central neuronal organelles that play a vital role in neuronal life and death. Both mitochondrial dysfunction and proper function are essential components in neurodegeneration. Further elucidation of the mechanisms of interaction between mitochondria and neuronal death will allow better description of the pathogenesis of neurodegenerative diseases and provide potential targets for therapeutic intervention.

Excitotoxicity and excitatory amino acid antagonists in chronic neurodegenerative diseases

Chrysanthy Ikonomidou¹ and Lechoslaw Turski²

¹Department of Pediatric Neurology, Carl Gustav Carus University, Dresden, Germany

²Solvay Pharmaceuticals Research Laboratories, Weesp, the Netherlands

Introduction

In 1935 Krebs discovered that the amino acid glutamate increases metabolism in the isolated retina and that it is concentrated in the cerebral gray matter (Krebs, 1935). Hayashi (1952, 1958) first reported on excitatory properties of glutamate on neuronal tissue. Local administration of glutamate on the motor cortex of dogs and primates resulted in motor seizures. Curtis *et al.* (1959) subsequently demonstrated that glutamate and aspartate, when applied iontophoretically to the cat spinal cord, depolarized neurons. Since the 1960s there has been appreciation of the role of glutamate in the nervous system, and today it is considered the major excitatory neurotransmitter (Fonnum, 1984). It is essential for learning and memory, synaptic plasticity, neuronal survival and, in early development, for proliferation, migration and differentiation of neuronal progenitors and immature neurons (Guerrini *et al.*, 1995; Ikonomidou *et al.*, 1999; Komuro & Rakic, 1993).

Glutamate fulfils its various functions due to its compartmentalization (Fonnum, 1984). The largest pool of glutamate is the metabolic pool. The neuronal pool is located in nerve endings and represents the neurotransmission pool. A separate pool is located in glia and serves the recycling of transmitter glutamate. The smallest glutamate pool is involved in synthesis of the inhibitory neurotransmitter γ -aminobutyric acid (GABA). Glutamate is released from presynaptic terminals by a calcium-dependent mechanism, is removed subsequently by uptake into the surrounding glial cells and aminated to glutamine.

When released into the synaptic cleft, glutamate acts at the postsynaptic site on receptors (Hollmann & Heinemann, 1994; Nakanishi, 1992). These include the *N*-methyl-D-aspartate (NMDA), kainate, the α -amino-3-hydroxy-5-methylisoxazole-propionate (AMPA) and the metabotropic

receptors. The first three are coupled to ion channels and are therefore called ionotropic glutamate receptors. Metabotropic glutamate receptors mediate their actions through G-proteins.

Receptor subtypes for both ionotropic and metabotropic glutamate receptors have been cloned and characterized (Hollmann & Heinemann, 1994).

Antagonists to these receptors were synthesized, enabling studies of the physiology of glutamate and opening perspectives pertaining to potential therapeutic applications of such compounds in human neurologic diseases.

NMDA receptors

NMDA receptors represent tetrameric heteromeric subunit assemblies whose physiological and pharmacological properties depend upon their subunit composition. Two major subunit families, NR1 and NR2 (A–D) have been cloned (Burnashev *et al.*, 1992; Monyer *et al.*, 1992). Recently NR3A and NR3B receptor subunits were characterized (Anderson *et al.*, 2001; Chatterton *et al.*, 2002; Das *et al.*, 1998; Matsuda *et al.*, 2002). Most NMDA receptors in the CNS are formed from NR1 and NR2 subunits. Alternative splicing results in 8 isoforms of NR1. The NR2 subunit family consists of four individual subunits termed NR2A–D (Hollmann & Heinemann, 1994; Monyer *et al.*, 1991; 1994). Different NR2 subunits result in different Ca^{2+} -permeability of the NMDA receptor channel, different gating properties and magnesium sensitivity (Monyer *et al.*, 1991, 1994).

Glycine is a coagonist at NMDA receptors and polyamines positive modulators (McBain and Mayer, 1994; Ozawa *et al.*, 1998). Physiological concentrations of glycine reduce the relatively rapid NMDA receptor desensitization. Another coagonist at NMDA receptors is D-serine.

Glycine shows different affinities at NMDA receptor subtypes. This affinity depends on the NR1 isoform and also the NR2 subunit composition of the receptor complex which allosterically influences the glycine recognition site located on the NR1 subunit (Monyer *et al.*, 1992; Woodward *et al.*, 1995).

Non-NMDA ionotropic glutamate receptors

AMPA receptors are composed of four subunits, GluR1–GluR4 (GluRA–GluRD). They are widely distributed throughout the mammalian central nervous system and mediate fast glutamatergic neurotransmission. The type of subunits within a tetrameric assembly determines biophysical and pharmacological profile of AMPA receptors. Two splice variants for GluR subunits have been described, *flip* and *flop*; these differ in their expression between brain regions and developmental stages. Other non-NMDA receptor subunits are designated GluR5, GluR6, GluR7, KA1 and KA2, and these form high affinity kainate receptors (Herb *et al.*, 1992, 1996; Hollmann & Heinemann, 1994).

The GluR2 subunit determines Ca²⁺ permeability of AMPA receptor channels. Receptors containing the GluR2 subunit show low Ca²⁺ permeability.

Metabotropic glutamate receptors

These are built from eight subunits, mGluR1–8. Within the mGluR-receptor family the sequence identity varies. Classification into three subclasses (I–III) has been proposed (Nakanishi, 1992; Pin & Duvoisin, 1995). Within each class the amino acid sequence identity is 70% and between classes 45%. mGluR1 and mGluR5 belong to Class I, mGluR2 and mGluR3 to class II, mGluR4 and mGluR6–8 to class III. Different transduction mechanisms are activated by each class. Class I activates phospholipase C, increases phosphoinositide turnover and Ca²⁺ release from internal stores and leads to formation of diacylglycerol which then might activate protein kinase C. Class II and III are coupled negatively to adenylate cyclase and reduce the intracellular amount of cAMP. Class II and III differ in their pharmacological profile against specific agonists (Pin & Duvoisin, 1995).

The neurotoxin glutamate

Excitotoxicity, a phenomenon originally discovered in the 1950s and extensively investigated and characterized in the 1970s and 1980s, describes a process in which an excess of the endogenous excitatory amino acid neurotransmitter glutamate causes overstimulation of glutamate receptors and destroys central neurons. Lucas and

Newhouse (1957) first described that systemic administration of monosodium glutamate results in degeneration of retinal ganglion cells. Olney and colleagues (Olney, 1969, 1971; Olney & Ho, 1970; Olney *et al.*, 1972) subsequently observed that excitatory amino acids, when given to infant rodents and primates, cause neurodegeneration in brain areas that lack blood–brain barrier. The ability of acidic amino acids to destroy neurons correlates with their excitatory potencies (Olney, 1969, 1971; Olney & Ho, 1970; Olney *et al.*, 1972). This interaction was termed neuroexcitotoxicity. Both ionotropic and metabotropic glutamate receptors can mediate excitotoxicity (McDonald & Schoepp, 1992; Schoepp *et al.*, 1995).

The mechanisms that mediate excitotoxicity have been studied extensively since the 1960s. The acute component of glutamate toxicity is mediated through a massive influx of sodium and chloride ions into the cell (Choi *et al.*, 1987; Rothman, 1985). A second component of glutamate neurotoxicity is Ca²⁺-dependent and mediated through activation of Ca²⁺-sensitive proteases. (Choi, 1987; Frandsen & Shousboe, 1991, 1992; Tymianski *et al.*, 1993). Calpains and other proteases that degrade neurofilaments seem to be involved in the late phase of the calcium activated excitotoxic cascade (Bartus *et al.*, 1994; Lee *et al.*, 1991; Manev *et al.*, 1991). Another category of enzymes with potentially self-digesting properties are the phospholipase A2 and other lipases, also activated by elevations of intracellular calcium (Rordorf *et al.*, 1991; Rothman *et al.*, 1993). Agents which inhibit phospholipases can partially attenuate some forms of excitotoxic injury (Rothman *et al.*, 1993). Similarly, endonuclease and protease C inhibitors (Favaron *et al.*, 1990; Samples & Dubinski, 1993) have been shown to inhibit glutamate toxicity in cultures.

Nitric oxide is a potent second messenger implicated in pathogenesis of excitotoxic neuronal death (Dawson *et al.*, 1991). One mechanism that mediates the toxic effect of nitric oxide is the non-enzymatic reaction of nitric oxide with the superoxide anion and the formation of peroxynitrite (ONOO⁻) (Beckman *et al.*, 1992; Ischiropoulos *et al.*, 1992). Peroxynitrite is a highly reactive molecule, which initiates lipid peroxidation in biologic membranes, hydroxylation and nitration of aromatic amino acid residues and sulfhydryl oxidation of proteins (Radi *et al.*, 1991a, b). These reactions can occur in vivo and are important in excitotoxic neuronal damage (Schulz *et al.*, 1995).

The second mechanism that mediates nitric oxide toxicity is via interaction with numerous cytosolic, mitochondrial and nuclear enzymes. Nitric oxide reacts with non-heme iron and causes inactivation of key mitochondrial enzymes such as mitochondrial aconitase and complex I and II of the mitochondrial electron transport chain

(Nathan, 1992; Pantopoulos & Hentze, 1995). It depletes intracellular glutathione levels (Clancy *et al.*, 1994), deaminates nucleotide bases and damages DNA, decreases intracellular levels of nicotinamide-adenine dinucleotide (NAD) and adenosine triphosphate (ATP) (Zhang *et al.*, 1994). Nitric oxide also inhibits the enzyme glyceraldehyde-3-phosphate dehydrogenase, which plays a key role during glycolysis and in the hexose monophosphate shunt and is involved in synthesis of the oxidized form of nicotinamide-adenine dinucleotide phosphate (NADP⁺) and maintenance of glutathione levels (Brune & Lapetina, 1989).

Slow onset excitotoxicity

The concept of slow excitotoxicity arose from observations made by Novelli and coworkers showing that inhibitors of oxidative phosphorylation or of the Na⁺/K⁺ pump allow glutamate or NMDA to become neurotoxic (Novelli *et al.*, 1988). Subsequently, Zeevalk and Nicklas showed that cyanide triggers excitotoxic lesions sensitive to NMDA antagonists in the chick embryo retina (Zeevalk & Nicklas, 1991). Toxicity induced by metabolic inhibition can be mimicked by membrane depolarization with potassium or by relieving the Mg²⁺-block of the NMDA receptor (Zeevalk & Nicklas, 1991). These observations were extended by findings in *in vivo* models showing that mitochondrial toxins (aminooxyacetic acid, an inhibitor of the maleate-aspartate shunt; 1-methyl-pyridine, a mitochondrial complex I toxin; 3-nitropropionic acid and malonic acid, inhibitors of mitochondrial complex II; the nicotinamide antagonist 3-acetylpyridine) produce axon sparing, excitotoxic lesions in the mammalian central nervous system, which can be blocked by NMDA and AMPA antagonists, glutamate release inhibitors and prior decortication (Beal *et al.*, 1991a, b; 1993a, b; Greene *et al.*, 1993; Henshaw *et al.*, 1994; McMaster *et al.*, 1991; Schulz *et al.*, 1994; Srivastava *et al.*, 1993; Urbanska *et al.*, 1991; Wüllner *et al.*, 1994). These observations led to the hypothesis that energy impairment at the postsynaptic site of glutamatergic synapse causes membrane depolarization, alleviation of the Mg²⁺-block of the NMDA receptors and heightened neuronal vulnerability towards physiological concentrations of glutamate (Beal, 1992a; Ikonomidou & Turski, 1996).

Excitotoxicity and neurodegenerative diseases

Morphological changes produced by excitotoxic compounds in the brain and spinal cord in many aspects resemble those observed in the context of chronic neurodegenerative diseases, such as Parkinson's disease, Huntington's

disease and amyotrophic lateral sclerosis. Therefore, it has been suggested that excitotoxic mechanisms may mediate these disorders (Beal, 1992b). Especially slow excitotoxicity, triggered by impairment of mitochondrial energy metabolism, has been implicated. It is conceivable that glutamate overactivity caused by exogenous or endogenous factors is an etiological factor for slow progressive death of vulnerable neuronal populations in chronic neurodegenerative diseases or contributes to their natural history and progression. Exogenous or endogenous compounds may activate glutamate receptors, may increase glutamate synthesis, release or reuptake, interfere with glutamate-linked ion channels or enhance glutamate-linked second messenger systems.

Although the genetic basis for some of these diseases has been defined in recent years, the actual mechanism(s) leading to neurodegeneration are still not understood. Slow excitotoxicity may constitute a contributing factor in pathogenesis of neuronal death that could be amenable to pharmacological treatment.

Excitotoxicity and Parkinson's disease

Parkinson's disease, one of the major neurodegenerative disorders of middle and old age, is associated with degeneration of dopaminergic neurons in the ventral mesencephalon. Clinical symptoms consist of tremor, rigidity, bradykinesia, postural deficits and impaired gait.

A gradual decline of dopaminergic neurons of the substantia nigra pars compacta and dopamine content with age is common in the general population. In Parkinson's disease there may be an accelerated rate of cell death, so that a critical level of dopaminergic cell loss (50–70% of neurons) is reached during normal lifespan and neurological symptoms of Parkinson's disease become obvious (Bernheimer *et al.*, 1973; Fearnley & Lees, 1991; McGeer *et al.*, 1989). It is also possible that an exogenous insult, such as an environmental toxin, may cause a partial loss of substantia nigra dopaminergic neurons which will be followed by further "physiological" decline with age (Calne & Langston, 1983). Careful neuropathological studies, serial positron emission tomography (PET) and single photon emission spectroscopy (SPECT) demonstrate a more rapid decline of dopaminergic neurons in the substantia nigra of Parkinson patients as compared to control aging subjects (Brooks, 1998; Fearnley & Lees, 1991; McGeer *et al.*, 1989). Such findings indicate that idiopathic Parkinson's disease is an active disease process in which nigral cell death is accelerated markedly.

The mechanisms by which these neurons degenerate are poorly understood but there is some evidence implicating excitotoxicity as one contributing mechanism to pathogenesis of Parkinson's disease. Initial observations linking excitotoxicity to Parkinson's disease were made by Spencer and colleagues (Spencer, 1987). They reported that the excitatory amino acid α -amino- β -methylaminopropionic acid (BMAA) is linked to Guam ALS-parkinsonism dementia syndrome. This observation became controversial because others found only low levels of BMAA in ingested cycad flour.

MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) and its metabolite MPP⁺ have been used to model Parkinson's disease, since it was discovered that MPTP can cause Parkinson's disease in man (Davis *et al.*, 1979; Langston *et al.*, 1983). The first report suggesting that excitotoxicity may play a role in the pathogenesis of MPTP-induced Parkinson's disease was made by Turski and colleagues (1991), who demonstrated that neurotoxicity of MPP⁺, the active metabolite of MPTP, can be blocked in the substantia nigra with both competitive and non-competitive NMDA receptor antagonists. Such results could be reproduced by other groups (Brouillet & Beal, 1993; Chan *et al.*, 1993; Jones-Humble *et al.*, 1994; Santiago *et al.*, 1992; Srivastava *et al.*, 1993). Subsequent studies in primates confirmed that NMDA antagonists attenuated MPTP-induced depletion of substantia nigra dopaminergic neurons (Lange *et al.*, 1993; Zuddas *et al.*, 1992). In support of this hypothesis, both glutamate receptor blockers and neuronal NOS inhibitors have been reported to attenuate degeneration of dopamine neurons in MPTP-treated primates (Blum *et al.*, 2001).

Considerable evidence exists implicating mitochondrial dysfunction in Parkinson's disease. Chronic systemic exposure to the lipophilic pesticide rotenone leads to inhibition of mitochondrial complex I and reproduces features of Parkinson's disease in rats, including accumulation of fibrillar cytoplasmic inclusions that contain ubiquitin and α -synuclein (Betarbet *et al.*, 2000). Studies of the electron transport enzymes have been carried out in lymphocytes, platelets, muscle tissue and postmortem brain tissue from Parkinson's disease patients (DiDonato *et al.*, 1993; Di Monte *et al.*, 1991, 1993; Hattori *et al.*, 1991; Janetzky *et al.*, 1994; Mann *et al.*, 1992; Nakagawa-Hattori *et al.*, 1992; Schapira *et al.*, 1990a, b). Decrease in complex I activity was found in brain, muscle tissue and platelets of Parkinson's disease patients compared to control subjects. Some studies also reported impaired activity of complexes II–IV in muscle tissue and complex II in lymphocytes of Parkinson's disease patients. A nuclear magnetic resonance spectroscopy study to measure occipital lobe lactate concentration revealed a highly significant increase of

lactate concentrations in Parkinson's disease patients with the largest increases in Parkinson's disease patients with dementia (Bowen *et al.*, 1994). Similar findings indicating increased lactate levels were reported for the striatum of Parkinson's disease patients (Chen *et al.*, 1994; Taylor *et al.*, 1994).

Impaired mitochondrial function may increase vulnerability of affected neurons towards physiological concentrations of glutamate (slow excitotoxicity). Given the fact that the substantia nigra receives rich glutamatergic inputs from neocortex and the subthalamic nucleus, contribution of slow excitotoxicity to the pathogenesis of this disease in the context of energy failure becomes a very attractive hypothesis.

There is evidence indicating that parkinsonian symptoms are caused by glutamatergic overactivity (cortico-striatal pathway, subthalamopallidal pathway) (Schmidt & Kretschmer, 1997). Milacemide, a glycine prodrug, which enhances NMDA receptor function, worsens parkinsonian symptoms (Giuffra *et al.*, 1993), whereas NMDA receptor antagonists elicit antiparkinsonian like activity in animal models in rodents and primates (Schmidt & Kretschmer, 1997; Uitti *et al.*, 1996; Ossowska *et al.*, 1994).

Antiparkinsonian activity was observed with the non-competitive NMDA antagonist dextromethorphan (Montastruc *et al.*, 1994) and in initial trials with the glutamate release inhibitor lamotrigine (Zipp *et al.*, 1993), but these findings could not be confirmed in subsequent studies (Montastruc *et al.*, 1997; Zipp *et al.*, 1995). So far, the only compounds with antiglutamatergic properties that are used for the treatment of patients with Parkinson's disease are amantadine, memantine and bupropion (Adler *et al.*, 1997; Schwab *et al.*, 1969; Rabey *et al.*, 1992). They are used to ameliorate clinical symptoms but there is no clinical evidence indicating that they influence the course of the disease due to neuroprotective properties. There is only one study by Uitti and coworkers who found that amantadine treatment is an independent predictor of improved survival in Parkinson's disease (Uitti *et al.*, 1996). Studies with remacemide and bupropion have demonstrated efficacy of these compounds alone and in combination with dopaminergic agents in relief of parkinsonian symptoms (Greenamyre *et al.*, 1994; Malsch *et al.*, 2001; Parkinson's Study Group, 2000, 2001; Parsons *et al.*, 1998; Przuntek & Muller, 1999; Przuntek *et al.*, 2002; Spieker *et al.*, 1999; Verhagen *et al.*, 1998). It should be noted though, that all NMDA antagonist drugs used in the therapy of Parkinson's disease have pharmacological functions in other neurotransmitter systems as well, thus the conclusion that their antiparkinsonian activities are due to NMDA antagonist properties is not necessarily correct.

There have been reports that the AMPA receptor antagonist NBQX improves symptoms and enhances the effect of L-DOPA in MPTP-treated monkeys (Klockgether *et al.*, 1991; Wachtel *et al.*, 1992) but these findings could not be replicated (Gossel *et al.*, 1995; Luquin *et al.*, 1993; Papa *et al.*, 1993; Zadow & Schmidt, 1994). Owing to such inconsistencies, AMPA receptor antagonists have not made their way into the clinical treatment of Parkinson's disease.

Huntington's disease

Huntington's disease is inherited as an autosomal dominant disease that gives rise to progressive, selective (localized) neural cell death associated with choreic movements and dementia. The disease is associated with increases in the length of a CAG triplet repeat present in a gene called "huntingtin" located on chromosome 4p16.3. The classic signs of Huntington's disease are progressive chorea, rigidity and dementia, frequently associated with seizures. A characteristic atrophy of the caudate nucleus is seen radiographically. There is a prodromal phase of mild psychotic and behavioural symptoms, which precedes frank chorea by up to 10 years.

Initial efforts to model this disease before the genetic defect had been discovered were made by Schwarcz *et al.*, who injected quinolinic acid (an NMDA agonist) into the striatum and produced loss of GABAergic output neurons sparing interneurons containing somatostatin-NPY (Schwarcz & Kohler, 1983; Schwarcz *et al.*, 1983). This neuropathological pattern resembles that seen in Huntington's disease brains (Beal *et al.*, 1986; Schwarcz & Kohler, 1983; Schwarcz *et al.*, 1983). Based on these findings, an excitotoxicity hypothesis for the pathogenesis of Huntington's disease was formulated.

Administration of the mitochondrial toxin 3-NP to rodents produces pathology resembling Huntington's disease (Borlongan *et al.*, 1997; Brouillet *et al.*, 1995; Palfi *et al.*, 1996). Striatal toxicity of 3-NP can be ameliorated by NMDA receptor antagonists, such as memantine (Wenk *et al.*, 1996), and glutamate release inhibitors, such as riluzole (Guyot *et al.*, 1997). Similarly, striatal toxicity of malonate, a complex II–III inhibitor, was prevented by NMDA receptor antagonists MK-801 and memantine and by the glutamate release inhibitor lamotrigine (Greene & Greenamyre, 1995). Thus, it has been postulated that mitochondrial dysfunction in Huntington's patients may be a trigger that constitutes striatal neurons prone to excitotoxicity. This hypothesis is supported by findings from Greenamyre's group, who reported increased apoptosis in Huntington's disease lymphoblasts associated with repeat length-dependent

mitochondrial depolarization, which correlated with increased numbers of glutamine repeats (Sawa *et al.*, 1999; Panov *et al.*, 2002).

To gain insight into the pathogenesis of Huntington's disease, Schilling *et al.* (1999) generated transgenic mice that expressed a cDNA encoding an N-terminal fragment (171 amino acids) of huntingtin with 82, 44, or 18 glutamines. Mice expressing relatively low steady-state levels of N171 huntingtin with 82 glutamine repeats (N171–82Q) developed behavioural abnormalities, including loss of coordination, tremor, hypokinesia, and abnormal gait, before dying prematurely. In mice exhibiting these abnormalities, diffuse nuclear labeling, intranuclear inclusions, and neuritic aggregates, all immunoreactive with an antibody to the N-terminus (17 amino acids) of huntingtin, were found in multiple populations of neurons. None of these behavioural or pathologic phenotypes were seen in mice expressing N171–18Q. The authors considered these findings to be consistent with the idea that N-terminal fragments of huntingtin with a repeat expansion are toxic to neurons, and that N-terminal fragments are prone to form both intranuclear inclusions and neuritic aggregates.

The mechanism through which the widely expressed mutant Huntington's disease gene mediates a slowly progressing striatal neurotoxicity is unknown. Glutamate receptor-mediated excitotoxicity has been hypothesized to contribute to Huntington's disease pathogenesis. However, inconsistent with this hypothesis, Hansson *et al.* (1999) showed that transgenic Huntington's disease mice expressing exon 1 of the human Huntington's disease gene with an expanded number of CAG repeats are strongly protected from acute striatal excitotoxic lesions. Intrastriatal infusions of quinolinic acid, the agonist of the *N*-methyl-D-aspartate (NMDA) receptor, caused massive striatal neuronal death in wildtype mice, but no damage in transgenic Huntington's disease littermates. The remarkable neuroprotection in transgenic Huntington's disease mice occurred at the stage when they had not developed any neurologic symptoms caused by the mutant Huntington's disease gene. At this stage, there was no change in the number of striatal neurons and astrocytes in untreated transgenic mice, although the striatal volume was decreased by 17%. Hansson *et al.* (1999) proposed that the presence of exon 1 of the mutant Huntington's disease gene induces profound changes in striatal neurons that render these cells resistant to excessive NMDA receptor activation.

The antiglutamatergic compound remacemide, tested in a double-blind placebo controlled study in Huntington's disease patients showed only a trend towards symptomatic improvement (Kieburz *et al.*, 1996). Ketamine failed to show any symptomatic improvement (Murman *et al.*, 1997). Thus, there is so far no evidence that symptomatic improvements should be expected by the use

of antiglutamatergic compounds in Huntington's disease patients. Whether antiglutamatergic agents can be used as neuroprotectants remains controversial. As mentioned above, Hansson *et al.* demonstrated resistance of striatal neurons carrying exon 1 of the mutant Huntington's disease gene to NMDA receptor activation (Hansson *et al.*, 1999). Worrisome are also experimental findings demonstrating that slow neurotoxicity of 3-NP can be enhanced by NMDA antagonists in rats (Ikonomidou *et al.*, 2000).

Glutamate in Alzheimer's disease

Alzheimer's disease is by far the most common cause of dementia. Terry and Davies (1980) pointed out that the presenile form (with onset before age 65) is identical to the most common form of senile dementia. They recommended the term senile dementia of the Alzheimer type (SDAT). Senile (neuritic) plaques and neurofibrillary tangles comprise the major neuropathological lesions in Alzheimer's disease brains. Neuritic plaques are spherical lesions and are found in moderate or large numbers in limbic structures and association neocortex. They contain extracellular deposits of amyloid- β protein. Degrating axons and dendrites are present within and around the amyloid deposits (Selkoe, 1999; Terry & Davies, 1980).

Neurofibrillary tangles are intraneuronal cytoplasmic lesions consisting of paired, helically wound, 10 nm filaments. They occur in large numbers in Alzheimer's disease brains in limbic structures and association cortices of the parietal, frontal and temporal lobes. The subunit protein of neurofibrillary tangles is a hyperphosphorylated, insoluble form of the microtubule associated protein, tau. Insoluble tau accumulates in the tangles after conjugation to ubiquitin (Selkoe, 1999).

It has been known for decades that Alzheimer's disease can occur in a familial form that transmits in an autosomal dominant trait. As more and more mutations are identified, the idea that almost all cases of Alzheimer's disease have genetic determinants is being confirmed (Selkoe, 1999). There are, however, also indications that glutamate and the mechanism of excitotoxicity may be involved in pathogenesis and progression of Alzheimer's disease. Constituents of senile plaques stimulate production by microglia of an unknown NMDA agonist (Giulian *et al.*, 1995) as well as production of nitric oxide (NO), known to enhance glutamate release and inhibit its uptake (Goodwin *et al.*, 1995; Lees, 1993). β -Amyloid enhances glutamate toxicity (Brorson *et al.*, 1995; Mattson and Goodman, 1995), enhances depolarization dependent glutamate release (Arias *et al.*, 1995) and inhibits its glial uptake (Harris *et al.*, 1996).

There is decrease in astroglial glutamate EAA2 carrier in the frontal cortex of Alzheimer's disease patients. Colocalization of glutamate neurons and neurofibrillary tangles was reported in Alzheimer's disease brain (Braak *et al.*, 1993; Francis *et al.*, 1992). Finally, intracerebroventricular administration of β -amyloid produced long-lasting depression of EPSP that was prevented by the NMDA antagonist CPP (Cullen *et al.*, 1996), whereas subcutaneous administration of memantine prevented pathological alterations in the hippocampus produced by direct injection of β -amyloid.

Memantine has shown efficacy and has been approved for use in the treatment of dementia in Germany for over 10 years (Jain, 2000; Winblad & Poritis, 1999). Based on successful clinical trials, an application was filed to the EU Commission in 2002 to approve memantine for treatment of moderately-to-severe Alzheimer's disease (Kilpatrick & Tilbrook, 2002).

Another hypothesis describing a link between glutamate and Alzheimer's disease postulates that NMDA receptor hypofunction may be involved mechanistically. There is evidence that the NMDA receptor system becomes hypoactive with advancing age. Olney and colleagues demonstrated repeatedly that NMDA receptor hypofunction in the adult mammalian brain triggers a disinhibition syndrome in which low grade chronic excitotoxic activity (fuelled by acetylcholine and glutamate) causes a widespread pattern of neurodegeneration resembling that seen in Alzheimer's disease. The authors postulate that, in Alzheimer's disease brains, genetic and/or environmental factors may lead to much earlier and more profound NMDA receptor hypoactivity state than in "normal" aging brains, thus increasing the likelihood that widespread neurodegeneration will occur (Farber *et al.*, 1998; Olney *et al.*, 1997; Wozniak *et al.*, 1998).

Amyotrophic lateral sclerosis

Amyotrophic lateral sclerosis (ALS) is the most common motor neuron disease in adults. It is characterized by selective degeneration of upper and lower motor neurons, progressive weakness and paralysis of all muscles and spasticity (Cleveland & Rothstein, 2001). Over 90% of cases occur sporadically, in 5–10% of cases the disease is inherited in a dominant mode (familial ALS).

ALS is a heterogeneous disorder and several pathogenetic mechanisms have been suggested. These include oxidative damage, neurofilament disorganization and subsequent axonal damage, toxicity from intracellular aggregates and excitotoxicity (Cleveland & Rothstein, 2001).

There is unquestionable and landmark evidence, that familial ALS and some forms of sporadic ALS are caused by mutations in the Cu/Zn superoxide dismutase (SOD1) gene (Andersen, 2001; Andersen *et al.*, 2001; Gaudette *et al.*, 2000). More than 90 mutations have been identified so far and almost all provoke a dominantly inherited disease. It appears that changes in activity level of the enzyme are not the key factor for the disease but rather that the mutated enzymes have acquired toxic properties, the nature of which still remains unresolved. The final event, however, has been shown to be activation of caspase 3, leading to active cell death (Li *et al.*, 2000; Pasinelli *et al.*, 2000; Vukosavic *et al.*, 2000). Activation of caspase 3 is preceded by activation of caspase 1 (Pasinelli *et al.*, 2000; Vukosavic *et al.*, 2000).

One hypothesis to explain toxicity of SOD1 mutations is that such mutated forms release copper and allow it to catalyse oxidative reactions (Corson *et al.*, 1998). Another one postulates that Zn-deficient SOD1 mutants facilitate conversion of oxygen to superoxide, which binds to nitric oxide and produces peroxynitrite.

Debate on involvement of excitotoxicity in ALS is based on studies suggesting that the metabolism of glutamate is abnormal in patients with ALS. Rothstein *et al.* (1992) postulated that the high-affinity glutamate transporter is the site of the defect at least in some forms of the disease. The primary mechanism for the inactivation of glutamate and aspartate is their removal from the extracellular space by a sodium-dependent transport system in astrocytes and neurons. This transport system has both high-affinity and low-affinity carriers for the two molecules. The low-affinity carrier subserves general metabolic activities. The high-affinity carrier is a component of the glutamate neurotransmitter system and is responsible for clearance of the neurotransmitter glutamate from the synaptic cleft. The inhibition of glutamate transport is toxic to neurons, due to persistent elevation of extracellular glutamate. A possible mechanism for the elevated cerebrospinal fluid concentrations of glutamate and aspartate in patients with ALS could be deficient transport into cells. Studying synaptosomes from neural tissue obtained from 13 patients with ALS as well as from controls, Rothstein *et al.* (1992) found that ALS patients showed a marked diminution in the maximal velocity of transport for high-affinity glutamate uptake in synaptosomes from spinal cord, motor cortex, and somatosensory cortex, but not in those from visual cortex, striatum, or hippocampus. This diminution was the result of a pronounced loss of the astroglial EAAT2 protein (Rothstein *et al.*, 1995). Transport of other molecules (gamma-aminobutyric acid and phenylalanine) was normal in patients with ALS.

Fact is that in about one third of ALS patients glutamate concentrations are increased in the cerebrospinal fluid (Shaw *et al.*, 1995), whereas intracellular glutamate concentrations are decreased (Ludolph *et al.*, 1998; Perry *et al.*, 1987; Young, 1990). Cerebrospinal fluid from ALS patients is toxic to hippocampal neurons via stimulation of AMPA receptors (Couratier *et al.*, 1993). The glutamate release inhibitor riluzole attenuates damage induced by ALS CSF (Couratier *et al.*, 1994; Terro *et al.*, 1996). These findings, along with experimental evidence implicating selective vulnerability of spinal motoneurons to AMPA/kainate-receptor agonists (Hugon *et al.*, 1989; Ikonomidou *et al.*, 1996; Williams *et al.*, 1997), implicate that glutamate, acting on AMPA/kainate receptors may be pathogenetically involved in motor neuron degeneration in ALS.

Excitotoxicity has been implicated in two other neurological disorders that resemble ALS, the Guam ALS-Parkinsonism dementia syndrome and a disease described in the Kii peninsula of Japan. These two disorders have been linked to food excitotoxins (Spencer *et al.*, 1986, 1993).

Along with the finding that SOD1 mutants, when expressed in mice, lead to functional loss of EAAT2 (Nagano *et al.*, 1996), it seems likely that deficient glutamate uptake may contribute to pathogenesis of some forms of ALS.

Several agents have been tested in ALS patients for potential neuroprotective properties, these include brain derived neurotrophic factors (The BDNF Study Group, 1999), ciliary neurotrophic factor (Akbar *et al.*, 1997), insulin like growth factor (Borasio *et al.*, 1998; Lai *et al.*, 1997), various antioxidants, antiinflammatory agents, antibiotics, calcium regulators (Cleveland & Rothstein, 2001) and riluzole. Of all those agents, only riluzole, a glutamate-release inhibitor, achieved a modest effect at increasing survival in two independent trials (Bensimon *et al.*, 1994; Lacomblez *et al.*, 1996) and has been approved for the treatment of ALS, although patients do not experience slowing in disease progression.

Conclusions

There is evidence supporting the notion that excitotoxicity mediated by glutamate constitutes a contributing factor in the pathogenesis of chronic neurodegenerative diseases. Budipine, amantadine and memantine are in use for therapy of parkinsonism. Memantine is effective in therapy of Alzheimer's dementia and riluzole showed some efficacy in ALS. There is, however, evidence indicating that NMDA antagonists can be detrimental for neuronal survival in chronic models of neurodegeneration (Ikonomidou *et al.*, 2000). Riepe *et al.* developed the paradigm of chemical

preconditioning, in which they studied mechanisms of excitotoxicity hours to days after a conditioning excitotoxic stimulus (Riepe *et al.*, 1995, Riepe & Ludolph, 1997; Ludolph *et al.*, 1998). Chemical preconditioning is a neuroprotective strategy, which involves the activation of NMDA receptors (Kasischke *et al.*, 1996). If similar endogenous neuroprotective mechanisms become operant in the context of chronic neurodegenerative diseases, then perhaps blocking NMDA receptors may not be the right therapeutic strategy to pursue, despite the fact that these compounds are protective in acute models of neurodegeneration which we use to study these diseases in rodents and primates. Perhaps targeting non-NMDA receptor mediated excitotoxicity would be the better way to go and could better enable that these devastating diseases become amenable to neuroprotective treatment.

Glutamate transporters

Davide Trotti and Stuart L. Gibb

Department of Neurology, Massachusetts General Hospital
Harvard Medical School, Charlestown, MS, USA

Introduction

In the central nervous system (CNS) of mammals, glutamate acts as a chemical transmitter of excitatory signals by binding to different glutamate receptors and activating a multitude of highly integrated molecular pathways. Termination of this excitatory neurotransmission occurs via re-uptake of glutamate by specialized high affinity transporters capable of maintaining glutamate at $\sim 1 \mu\text{M}$ levels in the synaptic cleft. At higher concentrations, glutamate can also act as neurotoxin causing degeneration and death of neurons (Choi, 1992). This event is known as excitotoxicity and contributes to many chronic and acute neurodegenerative diseases. Therefore, glutamate homeostasis and the regulation of glutamate transporter abundance and function are a key element for the normal brain function.

High affinity, Na^+ -dependent glutamate transporters: localization, functional properties and topology

Molecular cloning has identified five different subtypes of Na^+ -dependent glutamate transporters, termed EAAT1–5 (excitatory amino acid transporters 1–5; nomenclature used for human subtypes). At present, two different nomenclatures are in use in the literature to indicate human and rodent isoforms (Table 5.1). However, the homologues show a high degree of interspecies conservation (>95%) and do not differ functionally. The gene names for the human transporter are as follows: EAAT3 or SLC1A1; EAAT2 or SLC1A2; EAAT1 or SLC1A3; EAAT4 or SLC1A4; EAAT5 or SLC1A5. The acronym SLC1 refers to ‘Solute Carrier family’ number 1 and A1 to family member number 1.

Localization

Immunohistochemistry studies revealed that the glutamate transporters EAAT1 and EAAT2 are localized to astroglial membranes that immediately oppose synaptic cleft regions of the neuropil. EAAT3–4 are expressed in neuronal membranes in a perisynaptic distribution with the highest concentration at the edge of postsynaptic densities, rather than within the synaptic cleft, and in general are expressed in a somatodendritic fashion on post-synaptic spines and somas. The glial transporter EAAT1 is highly expressed in the molecular layer of the cerebellum and less in the hippocampus, superior colliculus, and *substantia gelatinosa* of the spinal cord. In contrast, EAAT2 expression is generally high throughout all brain regions and the spinal cord but it is largely absent from the white matter tracts. EAAT3 is selectively enriched in neurons of the hippocampus, cerebellum, and basal ganglia, whereas EAAT4 is confined largely to the soma and dendrites of the Purkinje cells of the cerebellum. EAAT5 is located in retinal ganglion cells (for a detailed review, see Danbolt, 2001) (Table 5.1). Recent studies reported the cloning of a variant form of EAAT2 from rat forebrain neuronal cultures that localizes in the presynaptic terminals and dendritic shafts of neurons as well as in astrocytes (Chen *et al.*, 2002; Schmitt *et al.*, 2002).

Functional properties

Glutamate transporters are coupled to the inwardly directed electrochemical gradients of Na^+ and H^+ , and to the outwardly directed gradient of K^+ . This unique coupling stoichiometry allows efficient removal of glutamate from extracellular compartments. The coupling stoichiometry of EAAT2 and EAAT3 was examined in detail and the studies revealed that 3 Na^+ ions and 1 H^+ are co-transported with

Fig. 5.1 Stoichiometry of the glutamate transporters. Glutamate transport involves loading of the empty carrier with glutamate⁻/H⁺ and 3 Na⁺, following the translocation of the fully loaded carrier across the plasma membrane and release of the cotransported ions at the intracellular space. Thereafter, 1 K⁺ binds to the carrier inside and promotes the relocation of the empty carrier. This implies that 2 positive net charges are moved inside the cell for each glutamate molecule taken up and the process can be monitored by electrophysiological techniques. The insert of the figure shows a representative recording of glutamate-mediated uptake current performed in a *Xenopus* oocyte expressing EAAT2. For net uptake of glutamate, the transporters must complete this cycle. If K⁺ does not bind, the transporter does not enter the relocation step, binds Na⁺ and glutamate⁻ at the inside of the cell and translocates back in the reverse direction. In this case, the transporter behaves like an exchanger. The net uptake of glutamate is also accompanied by a chloride conductance, the extent of which varies among glutamate transporter subtypes.

each glutamate molecule, whereas 1 K⁺ is transported in the opposite direction (Levy *et al.*, 1998a; Levy *et al.*, 1998b; Zerangue and Kavanaugh, 1996) (Fig. 5.1). This implies that two positive charges are translocated with each glutamate molecule. Functional analysis of EAAT4 has led to the identification of a substrate gated chloride conductance associated to the transport of glutamate. This feature is also displayed by other glutamate transporter family members, with the anion permeability decreasing in the order EAAT5-4 >> EAAT1 > EAAT3 >> EAAT2 (Seal & Amara, 1999).

Table 5.1. Distribution of glutamate transporters in the nervous system

Glutamate transporter	Rodent homologue	Cell type	Distribution
EAAT1	GLAST	Astrocyte	Highly expressed in cerebellum. Brain and spinal cord
EAAT2	GLT1	Astrocyte	All brain and spinal cord
EAAT3	EAAC1	Neuron	Hippocampus, cerebellum, basal ganglia
EAAT4	EAAT4	Neuron	Purkinje cells of cerebellum
EAAT5	EAAT5	Neuron	Retina

Topology

Recently, crystallographic studies have shed light on the molecular architecture of glutamate transporters. Yernool and colleagues (Yernool *et al.*, 2004) crystallized a glutamate transporter (Glt_{ph}) from the obligate anaerobe, *Pyrococcus horikoshii*. Glt_{ph} shares 37% homology with the eukaryotic EAAT2 glutamate transporter. Protomer structure contains eight transmembrane regions which are predominantly α -helical (regions 4 and 7 are segmented α -helices), a large extracellular loop connecting transmembrane regions 3 and 4, and two hairpin regions. A schematic representation is shown in Fig. 5.2. The Glt_{ph} study also provided data on the residues mediating interactions between a homotrimeric functional complex. The first six transmembrane regions of Glt_{ph} form a cylinder, the outer surface of which mediates intersubunit contact within the trimer complex. The remaining C-terminal residues form a structure within the cylinder that is implicated in substrate transport. Although there may be differences between this model and the structure of other glutamate transporter isomers, it is reasonable to expect that their structures will be similar. However, in models of three-dimensional topology, differences do exist. The crystal structure of Glt_{ph} indicates that it exists as a trimer, stoichiometry which has previously been reported for other prokaryotic transporters. Furthermore, the study suggests that eukaryotic transporters such as EAAT2 also exist as a homotrimer. When EAAT2 was overexpressed in HEK cells and cross linked with glutaraldehyde, a banding pattern consistent with trimer formation was observed. In a different study and using a variety of different approaches, Gendreau and colleagues, demonstrated that a bacterial glutamate transporter from *Escherichia coli* and the human glutamate transporter EAAT2 assemble as homotrimers,

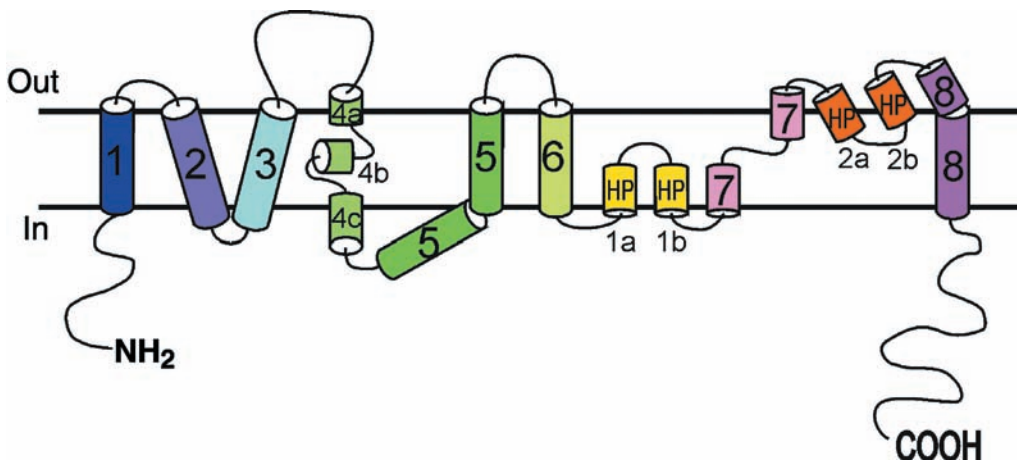

Fig. 5.2 Schematic representation of a glutamate transporter topology.

demonstrating an evolutionary conserved trimeric quaternary structure of glutamate transporter (Gendreau *et al.*, 2004). This is in contrast to data provided by freeze–fracture electron microscopy. Eskandari and colleagues reported that expressing EAAT3 in *Xenopus* oocytes revealed the presence of distinct 10 nm pentagonal particles, in which five well-defined domains could be identified. According to these observations, the functional EAAT3 complex was predicted to be a pentamer in the appearance of a penton-based pyramid (Eskandari *et al.*, 2000).

Regulation of glutamate transporters

Glutamate transporter levels and activity are subject to complex regulation by a variety of endogenous factors. There is evidence for neuronal and non-neuronal factors inducing upregulation of transporter levels as well as for substrate-mediated increase in transport activity (Poitry-Yamate *et al.*, 2002). Several hormones, growth and trophic factors, signaling molecules like reactive oxygen and nitrogen species, arachidonic acid and poly-unsaturated fatty acids or protein kinase C activity are capable of regulating expression, trafficking and activity of glutamate transporters (for review see Robinson, 2002). In addition, their associating proteins also regulate glutamate transporter activity. Two proteins, GTRAP41 and GTRAP48 specifically interact with the intracellular carboxy-terminal domain of EAAT4 and modulate its activity (Jackson *et al.*, 2001). The expression of either GTRAP41 or GTRAP48 resulted in the increase in the V_{max} of the transport without altering glutamate affinity. It is speculated that GTRAP41 couples EAAT4 to actin and GTRAP48 to a Rho GTPase signaling system. A completely different protein named GTRAP3-18 (Lin

et al., 2001) interacts with the intracellular carboxy-terminal domain of EAAT3. GTRAP3-18 is a predicted 188 amino acid hydrophobic protein with four possible transmembrane domains, which possesses a sequence identity (95%) to E18, a protein encoded by a vitamin-A-responsive gene. In contrast to the effect exerted by GTRAP41 and GTRAP48 on EAAT4, GTRAP3-18 reduces the transport activity of EAAT3 by decreasing the affinity of glutamate to the transporter.

Excitatory neurotransmission and glutamate transporters

The concept that glutamate transporters control the termination of glutamatergic neurotransmission is based on the evidence that synaptically released glutamate is not inactivated by enzymatic degradation because of the lack of a specific enzyme in the synaptic cleft. Clements and colleagues empirically estimated the time course of decay of glutamate in the synaptic cleft and found that it is slower than that derived from theoretical calculation based on a simple diffusion model (Clements *et al.*, 1992). Consequently, these investigators proposed that neighboring structures restricted the diffusion of glutamate. This suggested that altering the location, density, and/or the function of glutamate transporters could influence the time course of the transmitter clearance in the synaptic cleft. The turnover rate of EAAT2 for a complete cycle of transport at -80 mV and 22 °C was found to be approximately 70 ms (Wadiche *et al.*, 1995) and 20 ms for EAAT1 (Wadiche & Kavanaugh, 1998). This is significantly slower than the estimated glutamate decay time constant in hippocampal synapses which is 1–2 ms (Clements *et al.*, 1992). This

difference was predicted also to be true at physiological temperatures. Therefore, it can be argued as to whether glutamate transporters really constitute a major mechanism for removing released glutamate. Binding of glutamate to the transporters, however, exhibits fast kinetics. By applying glutamate with a time resolution of 100 microseconds using the laser-pulse photolysis technique of caged glutamate, the binding kinetics of the glutamate transporter EAAT3 occurred on a submillisecond time scale and preceded the subsequent slower glutamate translocation across the membrane by a few milliseconds after binding (Grewer *et al.*, 2000). Thus, even though the turnover rate is low, the glutamate binding step itself is thought to be fast enough to participate in the removal of glutamate released in the synaptic cleft.

As suggested by experimental evidence (Lehre & Danbolt, 1998; Lehre & Rusakov, 2002), the geometry of the synapse is also an important determinant of the shaping of the glutamate-mediated neurotransmission (for review, see Rusakov & Lehre, 2002). The spatial confinement of glutamate in the synaptic cleft is not absolute as the cleft in which the neurotransmitter is released forms a continuum with the extracellular space. A glutamate molecule leaving the cleft is likely to be taken up by transporter proteins concentrated around the cleft on cell membranes of glia and neurons. However, experimental findings have suggested that glutamate molecules can exit the synaptic cleft, elude glutamate transporters and interact with glutamate receptors, such as metabotropic glutamate receptors (mGluRs) located perisynaptically (Brasajo & Otis, 2001; Tempia *et al.*, 1998).

Excitotoxicity and glutamate transporters

Based on the stoichiometry of glutamate transport and the prevailing ionic environment in which the transporters operate, it can be calculated that these proteins concentrate glutamate more than 10 000-fold across cell membranes (Levy *et al.*, 1998b). Because of this high concentrating capacity, glutamate transporters are thought to play a major role in maintaining the extracellular glutamate concentration at low levels to protect neurons from excitotoxicity. This has been experimentally demonstrated both *in vitro* and *in vivo*. Protection of neurons by glutamate transporters from glutamate-mediated excitotoxicity was first demonstrated *in vitro* in organotypic rat spinal cord cultures using the glutamate transporter blockers. Treatment with these compounds generally resulted in elevated extracellular accumulation of glutamate that correlated with increased excitotoxic cell death (O'Shea *et al.*, 2002;

Rothstein *et al.*, 1993). *In vivo*, of particular note is the work of Rothstein and coworkers, who applied antisense oligonucleotides directed at glutamate transporters to the cerebroventricle of alert rats. Administration of antisense EAAT2 or EAAT1 oligonucleotides resulted in the degeneration of neurons whereas EAAT3 antisense oligonucleotides did not induce neurodegeneration, suggesting that the glial but not the neuronal glutamate transporters protect neurons from excitotoxicity. Complementary findings were obtained in EAAT1 and EAAT2 knockout mice which exhibited increased susceptibility to glutamate-mediated brain injury and suffered from lethal spontaneous seizures, whereas EAAT3 knockout mice did not show neurodegeneration (Peghini *et al.*, 1997; Tanaka *et al.*, 1997; Watanabe *et al.*, 1999). The prevailing role of glial glutamate transporters in protecting neurons from excitotoxic insults stems from the different functional role that glial and neuronal glutamate transporters play in the CNS. In neurons, the intracellular glutamate concentration is ~10 mM. Considering the extracellular glutamate concentration of ~1 μ M, this results in a steep gradient across neuronal cell membranes, which is essentially equal to the maximal concentration capacity of the high affinity glutamate transporters. Consequently, under normal conditions, neuronal glutamate transporters are almost at equilibrium and have little functional capacity. It is therefore not too surprising that the knockout of neuronal EAAT3 did not induce neurodegeneration. In glial cells, however, glutamate is taken up continuously and is then rapidly converted to glutamine by glutamine synthetase, a glial enzyme that maintains the concentration of glutamate as low as ~50 μ M. Therefore, glial glutamate transporters are not at equilibrium and keep pumping glutamate into glial cells, generating a continuous stream of the neurotransmitter from glutamatergic synapse to glial cells.

Neurodegenerative diseases and glutamate transporters

Impairment in glutamate transporters has been reported in a number of acute and chronic neurodegenerative pathologies. However, in most cases it is not clear whether this impairment represents a primary defect, an event secondary to the primary insult, or both.

Amyotrophic lateral sclerosis (ALS)

Increased glutamate levels followed by excitotoxicity has been indicated as one possible pathogenic event occurring

in ALS (Rothstein, 1995a, b), a neurodegenerative disorder of motor neurons in the spinal cord, motor cortex and brain stem. Reduced glutamate uptake and loss of the glutamate transporter EAAT2 has been observed in motor cortex from postmortem brains of ALS patients (Rothstein *et al.*, 1992, 1995). Similarly, a reduction in EAAT2 was found in the spinal cord of transgenic mice models of ALS, as well as elevation of extracellular glutamate levels (Bruijn *et al.*, 1997), suggesting that glutamate transport impairment is a common component in the pathway to motor neuron degeneration. The molecular mechanisms leading to EAAT2 loss in ALS are not yet understood. Levels of EAAT2 mRNA are unchanged (Bristol & Rothstein, 1996), suggesting that the reduction of EAAT2 is not due to decreased transcription of mRNA, but rather to an irreversible event at the translation or post-translation level. In a subset of sporadic ALS patients, abnormal EAAT2 mRNA editing and the presence of aberrant spliced forms with manifested dominant negative properties were found (Lin *et al.*, 1998). However, other investigators failed to find a correlation between the presence of aberrant EAAT2 transcripts and ALS, as these transcripts were also detected in tissue specimens from control and Alzheimer's disease subjects (Flowers *et al.*, 2001; Meyer *et al.*, 1999). The case of ALS illustrates the involvement of glutamate transporters in a neurodegenerative pathology that is also characterized by oxidative stress. Studies by Rosen and colleagues (Rosen *et al.*, 1993) showed that about 20% of familial ALS patients carry missense mutations in the gene encoding Cu²⁺/Zn²⁺ superoxide dismutase (SOD1). Mutations in SOD1 catalyze the formation of deleterious oxidants, such as hydroxyl radical or peroxynitrite. Several lines of evidence suggested a link between SOD1 mutants and excitotoxicity-mediated neuronal death. A loss of EAAT2 has been reported in the spinal cord of transgenic ALS mice and rats. In a *Xenopus* oocyte model, coexpression of some of the mutant forms of human SOD1 protein and EAAT2 caused inactivation of the transporter molecule (Trotti *et al.*, 1999). Therefore, it is possible that the inactivation and loss of EAAT2 may be related to the properties of the SOD1 mutation.

Using single-strand conformation polymorphism analysis of genomic DNA, Brown and colleagues reported a mutation in the EAAT2 gene associated with sporadic ALS. This mutation substitutes an asparagine for a serine at position 206 (N206S) (Aoki *et al.*, 1998) and avoided the glycosylation of the carrier at that site. It was also found that the EAAT2-N206S mutant had a pronounced reduction in the transport rate and a substantial dominant negative impact on the wild-type activity. The decreased rate of transport was because of decreased trafficking of the mutated carrier to the plasma membrane. Moreover, the EAAT2-N206S

exhibited an increased reverse transport capability (Trotti *et al.*, 2000). These combined effects significantly impair the ability of EAAT2 to clear glutamate at the synaptic cleft of neurons.

Alzheimer's disease

Alzheimer's disease is a chronic degenerative neurological disorder. Hallmarks of the disease are accumulation of β -amyloid peptide, a major constituent of the amyloid plaques characteristic of the disease, as well as widespread oxidative injury. The role of β -amyloid peptide in the neuropathology of Alzheimer's disease, including free radical injury and excitotoxicity is well documented. Treatment of neuron/astrocyte co-cultures with high concentrations of β -amyloid peptide increases the vulnerability of neurons to glutamate-induced cell death, probably due to the inhibition of astrocytic glutamate transporters (Harris *et al.*, 1996). Two recent studies showed that, at concentrations compatible to those found in Alzheimer's disease brains, the β -amyloid peptide causes instead a substantial increase in glutamate uptake in astrocytes and attenuates synaptic efficacy (Abe & Misawa, 2003; Ikegaya *et al.*, 2002). These findings are also supported by an electrophysiological study done in cultured microglia in which chronic treatment with low concentrations of β -amyloid peptide enhanced glutamate transport currents (Noda *et al.*, 1999). An excessive removal of glutamate may cause depressed glutamatergic neurotransmission which is at the basis of the amnesia in Alzheimer's disease. A different study based on antibodies reported reduced levels of EAAT2 protein in frontal cortex of Alzheimer's patients but normal levels of EAAT2 mRNA as well as of EAAT1 and EAAT3 (Li *et al.*, 1997). Note that transgenic mice expressing mutant amyloid precursor protein appear to have reduced EAAT2 and EAAT1 protein levels (Masliah *et al.*, 2000).

Huntington's disease

Huntington's disease is a late-onset neurodegenerative disease for which the mutation is CAG/polyglutamine repeat expansion. The R6 mice expressing an N-terminal fragment of mutant huntingtin develop a movement disorder that is preceded by the formation of neuronal polyglutamine aggregates. The phenotype is probably caused by a widespread neuronal dysfunction, whereas neuronal cell death occurs late and is very selective. Decreased mRNA and protein levels of the major astroglial glutamate transporter EAAT2 in the striatum and cortex of these mice is accompanied by a concomitant decrease in glutamate uptake (Behrens *et al.*, 2002; Lievens *et al.*, 2001).

In contrast, the expression of the glutamate transporters EAAT1 and EAAT3 remained unchanged. These changes in expression and function occurred prior to any evidence of neurodegeneration and suggest that a defect in astrocytic glutamate uptake may contribute to the phenotype and neuronal cell death in Huntington's disease.

Parkinson's disease

Indirect observations suggested a possible malfunctioning of glutamate transporters in the pathogenesis of Parkinson's disease. 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a neurotoxin known to target dopaminergic neurons in Parkinson's disease, reversibly inhibits astroglial glutamate uptake in cultured astrocytes (Hazell *et al.*, 1997).

Ischemia

Reversed operation of glutamate transporters appears to contribute to the rise in extracellular glutamate and the excitotoxicity that occurs during an ischemic insult (Rossi *et al.*, 2000). Because glutamate uptake is driven by the energy stored in the form of electrochemical gradients across the plasma membranes, the impairment of the ionic gradients caused by insufficient energy supply, which occurs during brain ischemia, results in a decrease in concentrating capacity of glutamate transporters and favors their reversed operation. Neurons have a much higher content of glutamate than glial cells; therefore neuronal glutamate transporters are more likely to run in reverse in ischemia and to contribute to the extracellular rise in glutamate to excitotoxic levels (Hamann *et al.*, 2002; Rossi *et al.*, 2000). During ischemia, glutamate transporter expression is also altered (An *et al.*, 2002; Rao *et al.*, 2001) and their activity can be further downregulated by polyunsaturated fatty acids, particularly by arachidonic acid, and reactive oxygen species (ROS), both of which are produced in response to excessive glutamate receptor activation (Volterra *et al.*, 1994).

Glutamate transporters and mercury neurotoxicity

Sensory disturbance and ataxia were described in a number of neurological cases attributed to the ingestion of fish contaminated with methylmercury (MeHg) (Harada, 1995; Malm *et al.*, 1995). Poisoning with elementary mercury (Hg^0) vapours was also shown to produce similar neurological symptoms. Several lines of evidence indicate that glutamate-mediated excitotoxicity is probably involved. For example, glutamate receptor (NMDA type)

antagonists effectively blocked the neurotoxic action of mercury in cerebral neuronal cultures (Park *et al.*, 1996). MeHg and Hg^0 would act, at least in part, through the common oxidation product mercuric mercury (Hg^{2+}). Submicromolar concentrations of Hg^{2+} were found to inhibit selectively the uptake of excitatory amino acids in cultured astrocytes. MeHg mimicked this effect but not other divalent cations (Aschner, 1996; Aschner, 2001; Aschner *et al.*, 2000). It was also shown that mercuric chloride uncouples glutamate uptake from the co-transport of 1H^+ (Nagaraja & Brookes, 1996), and that micromolar concentrations of it is sufficient to induce a dramatic inhibition of the glutamate transporters EAAT1-T3 (Trotti *et al.*, 1997).

Concluding remarks

Regulation of glutamate transporter abundance and function is a very important element in the normal brain function as impairment in glutamate uptake is associated with many neurodegenerative diseases. This has also led to the identification of the glutamate transport system as a desirable therapeutic target. In recent years, important advances have been made in understanding basic molecular and cellular mechanisms governing the expression and regulation of glutamate transporters. These achievements are expected to facilitate further studies on the roles of individual transporter subtypes and to develop new strategies for the diagnosis and treatment of diseases associated with the malfunctioning of glutamate transporters.

Calcium binding proteins in selective vulnerability of motor neurons

László Siklós¹ and Stanley H. Appel²

Introduction

Since the mid-1990s, the specific etiologies and mechanisms leading to dysfunction and loss of motor neurons in ALS have been under intensive investigation. No single mechanism appears to explain the devastating and inexorable injury to motor neurons. What appears far more likely is a convergence of a number of different mechanisms that collectively or sequentially impair motor neuron structure and function. Among the various proposals implicated, increased free radicals and oxidative stress, increased glutamate excitotoxicity, increased cellular aggregates and increased intracellular calcium have received the most attention (Rothstein, 1995; Cleveland, 1999; Shaw & Eggett, 2000; Rowland, 2000; Julien, 2001; Rowland & Shneider, 2001; Cleveland & Rothstein, 2001). None of these mechanisms is mutually exclusive and altered calcium homeostasis, free radicals, and glutamate excitotoxicity may all participate in the cell injury cascade leading to motor neuron death. Alterations in one parameter can lead to alterations in other parameters, and each can enhance and propagate the injury cascade. Such perturbations could critically impair motor neuron mitochondria and neurofilaments, compromise energy production and axoplasmic flow, and impair synaptic function. However, these alterations would be expected to adversely affect most neurons, and the critical question is why motor neurons are uniquely sensitive to injury in ALS, and why some motor neurons are relatively resistant to injury. Our own hypothesis focuses on the critical role of intracellular calcium and the inability of vulnerable motor neurons to handle an increased intracellular calcium load, possibly related to the relative paucity of the calcium binding proteins, calbindin D_{28k} and parvalbumin. With this hypothesis, impaired calcium homeostasis is considered a “final common pathway” leading to motor neuron injury through

a calcium-dependent positive feedback loop (Appel *et al.*, 2001).

Intracellular ionized calcium $[Ca^{2+}]_i$ is a ubiquitous second messenger, which plays an important role in a variety of neuronal functions in physiological as well as pathological states (Berridge *et al.*, 1998; Berridge *et al.*, 2000). Unlike other second messengers, ionic calcium cannot be metabolized, thus numerous mechanisms have evolved to regulate $[Ca^{2+}]_i$ and prevent toxicity (Clapham, 1995). Calcium can enter the cell from the extracellular space through various Ca channels including voltage-gated and ligand-gated channels, and can be actively extruded from the cell by calcium pumps and Na/Ca-exchangers (Carafoli & Stauffer, 1994). Calcium can also be released from high affinity intracellular stores through inositol triphosphate or ryanodine receptors, and can be taken up into these stores by Ca pumps (Pozzan *et al.*, 1994). Mitochondria also accumulate calcium through a passive low-affinity uniporter and release calcium through Na-dependent and Na-independent pathways (Gunter *et al.*, 1998). Perturbations in calcium homeostasis can have significant untoward effects on cell function, which could lead to irreversible cell injury. However, it is also possible that increased intracellular calcium is a marker of motor neuron degeneration rather than the cause of motor neuron degeneration. In the discussion that follows, we marshal the evidence that increased intracellular calcium within motor neurons may contribute to motor neuron injury as well as act as a secondary marker of motor neuron injury.

Increased calcium in motor neurons in ALS

The first direct demonstration of altered intracellular calcium in ALS came from ultrastructural studies of muscle biopsy samples from patients with sporadic ALS

(Siklós *et al.*, 1996). Using oxalate-pyroantimonate fixation to visualize tissue calcium as electron dense deposits, we demonstrated an increased number of calcium precipitates in synaptic vesicles and mitochondria of ALS motor axon terminals, accompanied by an increased number of vesicles and swelling of mitochondria (Siklós *et al.*, 1996). Since many of these biopsies were from patients in early stages of disease, it is unlikely that such findings were a late marker of motor neuron degeneration. Furthermore, the increased calcium in ALS motor axon terminals paralleled the increased intracellular calcium and increased number of synaptic vesicles demonstrated in motor nerve terminals of mice injected intraperitoneally with immunoglobulin G (IgG) from ALS patients (Engelhardt *et al.*, 1995; Pullen & Humphreys, 2000; Pullen *et al.*, 2004). Increased calcium with degenerative changes in the endoplasmic reticulum and Golgi complex was also demonstrated in motor neuron cell bodies in the spinal cord following passive transfer with ALS IgG. In SOD1 transgenic mice with the G^{93A} mutation, a model of the familial form of ALS (Gurney *et al.*, 1994), a robust increase of intracellular calcium was demonstrated in cell bodies of spinal motor neurons and proportional disintegration of the corresponding motor axon terminals was also documented (Siklós *et al.*, 1998).

In cell cultures, glutamate neurotoxicity is mediated by the entry of calcium (Choi *et al.*, 1987; Tymianski *et al.*, 1993). Given the important potential role of glutamate excitotoxicity in motor neuron injury in ALS (Rothstein, 1995), we investigated alterations in calcium distribution in spinal motor neurons following in vivo application of D,L homocysteic acid, a non-specific glutamate agonist (Adalbert *et al.*, 2002). We noted increased accumulation of calcium in the cytoplasm, followed by gradual increases in calcium in degenerating intracellular organelles (endoplasmic reticulum, Golgi complex and mitochondria). Thus calcium is increased in degenerating spinal motor neurons in several different models of both sporadic and familial ALS.

Cellular calcium homeostasis and calcium binding proteins

Since ionic calcium plays a universal second messenger role, its concentration and intracellular distribution require tight regulation (Brini & Carafoli, 2000). A steep concentration gradient of Ca²⁺ can develop across the plasma membrane of neurons, spanning four orders of magnitude. This gradient guarantees fast signal transduction in physiological conditions, but could easily lead to large increases in [Ca²⁺]_i and cellular degeneration, if control mechanisms are compromised (Nicotera & Orrenius, 1998; Sattler & Tymianski, 2000). In the past several years

much has been learned about these control mechanisms, especially the major calcium sequestering organelles: the rapidly exchanging endoplasmic reticulum (Berridge, 1998; Paschen & Doutheil, 1999) and the high buffering capacity of mitochondria (Gunter *et al.*, 1998), and their possible cooperation in regulating calcium signals in health and disease (Meldolesi, 2001; Siesjö *et al.*, 1999).

Within the cell, calcium can interact with numerous proteins. However, the possible geometrical formations of the binding sites are quite limited. The most common calcium binding domain of proteins is the EF-hand motif, which is a helix-loop-helix structure of usually 12 residues with a special sequence, forming a loop that can accommodate calcium ions (Marsden *et al.*, 1990; Lewit-Bentley & Réty, 2000). To date, over 200 proteins are known to be capable of binding Ca²⁺ in one or more EF-hand motifs (Yap *et al.*, 1999). The EF-hand proteins are members of 45 distinct subfamilies, originally identified by functional and/or chemical characteristics of the first known representatives (Kawasaki *et al.*, 1998). Through their Ca²⁺-binding EF-hand motifs, these proteins do influence local concentrations of [Ca²⁺]. For many of the EF-hand proteins such as calmodulin or troponin C, their buffering capacity is far less significant than the regulatory function triggered by calcium-induced conformational changes (Miller, 1995; Yap *et al.*, 1999). Additional studies are necessary to define the actual coordinating function of the majority of EF-hand proteins and how they mediate intracellular calcium signalling. At present, this information is lacking, and most explanations attempt to understand the unique aspects of calcium homeostasis in different cell types based upon the buffering capacity of CaBPs. The limitation of this approach is exemplified by the approximately 10 μM intracellular concentration of calmodulin, which is equipped with four calcium binding motifs and theoretically might possess significant buffering capacity (Brini & Carafoli, 2000). Yet calmodulin appears to function more as a regulatory molecule (Cheung, 1980; Means *et al.*, 1982) than a passive buffer.

The strategic localization of CaBPs in the cytosol appears to be extremely important for influencing calcium homeostasis. For example, distribution of CaBPs in the vicinity of plasmalemmal calcium pumps and channels, as well as around mitochondria and endoplasmic reticulum, might indicate their relevance in calcium-mediated cellular death/life issues (Miller, 1998). In contrast to earlier concepts of active calcium accumulation, it is now clear that mitochondria are equipped with a uniporter for the passive uptake of Ca²⁺ from the cytosol (Gunter & Pfeiffer, 1990; Bernardi, 1999). The rapid flow of Ca²⁺ from the cytoplasm to the mitochondrial matrix ensures that changes in [Ca²⁺]_i, assumed to be proportional to cellular

Fig. 6.1 An overload of intracellular Ca^{2+} may induce injury directly, by activating destructive enzymes (endonucleases, proteases), or indirectly, by activating phospholipases, which generate toxic intermediates. Furthermore, if the capacity of the sequestering organelles, particularly mitochondria, were exceeded, mitochondrial dysfunction would result in energy depletion and increased free radicals. The decreased levels of ATP could impair active defense processes (Ca-extruding mechanisms) and ultimately, collapse the mitochondrial membrane potential, and induce release of apoptotic factors. With high amount of mobile CaBP-s in the cytosol, however, the amplitude of $[\text{Ca}^{2+}]_i$ would be attenuated. The presence of CaBP-s might shortcut Ca^{2+} to the extrusion pumps, or recycle Ca^{2+} to the high affinity ER store before final extrusion, thus prevent or delay the overload of mitochondria.

activity, are quickly copied into corresponding intramitochondrial changes (Werth & Thayer, 1994). The calcium dependence of the activity of certain intramitochondrial enzymes involved in energy metabolism has been implicated in adjusting energy production to the actual demand of the cell under physiological conditions (Cox & Matlib, 1993; Robb-Gaspers *et al.*, 1998). If the system is overwhelmed by large increases in $[\text{Ca}^{2+}]_i$, the special mitochondrial defense system is activated by opening the mitochondrial megachannel (permeability transition pore), leading to the release of substances such as cytochrome *c* and initiating cell injury (Kroemer *et al.*, 1998; Murphy *et al.*, 1999). This mechanism has been implicated in acute lesions as well as chronic degenerative disorders (Schapira, 1998). One role for CaBPs might be to attenuate the amplitude of $[\text{Ca}^{2+}]_i$, and either facilitate the extrusion

of Ca^{2+} or recycle it to the fast exchanging endoplasmic reticulum store. The presence of CaBPs could help keep the relevant cytosolic $[\text{Ca}^{2+}]_i$ in the normal range while the elevation of the total calcium level remains hidden. This phenomenon might provide the basis of the findings of Brini *et al.* (2000), and Mogami *et al.* (1997), without assuming the presence of special intracellular tunnels for Ca^{2+} (Mogami *et al.*, 1997), who reported that, either lowering the calcium level in the endoplasmic reticulum (ER), or replenishing ER stores could occur without detectable changes in the cytosolic calcium level. Thereby, besides decreasing the activation of destructive enzymes by lowering $[\text{Ca}^{2+}]_i$, CaBPs reduce the likelihood of mitochondrial calcium overload, thus decrease the likelihood of megachannel openings and the release of apoptosis-inducing factors (Fig. 6.1) [Brustovetsky *et al.*, 2002].

Calcium binding proteins in motor neurons

One of the unique aspects of amyotrophic lateral sclerosis is that motor neuron pools are affected to differing extents (Swash & Schwartz, 1995). This selectivity, particularly the relative preservation of some motor neuron functions (e.g. voluntary sphincter and oculomotor) has prompted a search for constituents which could provide such protection. The variable content of parvalbumin and/or calbindin-D_{28k} in different motor neuron populations offers one potential explanation. The discovery of calmodulin, the isolation of an increasing number of other calcium binding proteins (CaBPs) (e.g. Waisman *et al.*, 1983) and the first detailed description of the distribution of calbindin-D_{28k} and parvalbumin in the brain and spinal cord of the rat (Celio, 1990), have increased our understanding of the potential functions of CaBPs in the nervous system (Baimbridge *et al.*, 1992). Reports that followed the studies of Celio confirmed the different composition of CaBPs in different populations of motor neurons in the spinal cord of rats (Ren & Ruda, 1994), as well as in the brainstem of primates (Reiner *et al.*, 1995). In rodents, the presence of parvalbumin mRNA was documented to be a marker of ALS-resistant motor neurons (Elliott & Snider, 1995). The most pertinent studies were the demonstrations in human CNS that motor neurons most vulnerable in ALS are relatively deficient in the CaBPs calbindin-D_{28k} and/or parvalbumin, and those motor neurons most resistant in ALS have relatively abundant concentrations in either or both of these CaBPs (Ince *et al.*, 1993; Alexianu *et al.*, 1994).

Not all of the published reports of CaBPs in motor neurons of adult mammalian models agree that the paucity of parvalbumin and/or calbindin-D_{28k} in spinal motor neurons best explains vulnerability in ALS (Laslo *et al.*, 2000). Part of the misleading interpretations may relate to the immunocytochemical techniques used, including differences in the source and type of (monoclonal or polyclonal) primary antibodies and, particularly, the degree of the calcium-binding status of CaBPs, which cannot be always and/or easily controlled (Winsky & Kuznicki, 1996). However, to date, no studies of human CNS (including ALS specimens) have refuted the hypothesis that motor neuron parvalbumin and/or calbindin-D_{28k} play a significant role in resistance or vulnerability to injury in ALS.

AMPA/kainate receptors and selective vulnerability

An alternative approach to explain the calcium-dependent vulnerability of motor neurons in ALS might be based on

the details of the composition of their surface receptors. AMPA/kainate receptors are the major glutamate receptors present on motor neurons, and activation of these receptors would be expected to promote the entry of extracellular calcium and thereby contribute to selective vulnerability (Williams *et al.*, 1997). However, under normal circumstances, the mRNA for the GluR2 subunit of the AMPA/kainate receptor is edited with high efficiency resulting in an arginine in place of a glutamine, and rendering the receptor impermeable to calcium (Puchalski *et al.*, 1994). No differences in GluR2 subunits have been demonstrated in vulnerable compared to resistant motor neurons *in vivo*. In G86R mSOD1 transgenic mice, the distribution and intensity of GluR2 immunoreactivity was not altered between transgenic and control mice, and was equivalent in vulnerable motor neurons and resistant sensory neurons, although editing of the GluR2 was not examined (Morrison *et al.*, 1998). Vandenberghe *et al.* [2000] demonstrated that rat spinal motor neurons were more vulnerable to AMPA and kainate than dorsal horn neurons, despite edited GluR2 being expressed equivalently in both spinal and dorsal horn neurons. Further, whole cell calcium permeability was similar in both neuronal populations. Nevertheless, in tissue culture, both Ca-permeable and Ca-impermeable AMPA receptors have been demonstrated in motor neurons that express GluR2 (Van Den Bosch *et al.*, 2000). However, it is not clear whether the Ca-permeable AMPA receptors in such preparations have absent GluR2, or unedited GluR2. Short exposures of kainate did not affect dorsal horn neurons but did kill motor neurons through Ca-permeable AMPA receptors. Furthermore, both GluR2-containing and GluR2-lacking AMPA receptors coexist in clusters at synapses in motor neurons (Vandenberghe *et al.*, 2001). The key question is whether the Ca-permeable AMPA receptors present in motor neurons *in vitro* are also present in adult human motor neurons *in vivo*.

In human ALS, Takuma *et al.* (1999) demonstrated specific alterations in the AMPA/kainate receptors. They documented reduced efficiency of GluR2 RNA editing, and decreased expression of the GluR2 subunit in the ventral gray of ALS tissue compared to controls. Both of these changes would be anticipated to increase permeability to calcium. However, these results could be the consequence and not the cause of motor neuron injury or selective vulnerability. At present, it is still unclear whether Ca-permeable AMPA/kainate receptors contribute to selective vulnerability and selective resistance in ALS. Are specific Ca-permeable AMPA/kainate receptors present in adult human spinal motor neurons (to explain their vulnerability), and are such receptors relatively absent in eye muscle motor neurons (to explain their resistance)? Recent studies

in rat suggest no differences in the mRNA and protein for the GluR2 subunit of AMPA/kainate receptors in vulnerable hypoglossal motor neurons and resistant oculomotor motor neurons (Laslo *et al.*, 2001). Such studies would suggest that differences in AMPA/kainate R may not be the best explanation for selective vulnerability.

Mechanism of protection of motor neurons by calcium binding proteins: axon terminals

Evidence for the potential importance of CaBPs in selective vulnerability is revealed in the calcium distribution of different motor neurons of SOD1 mutant mice and rats regularly injected with ALS IgG (Siklós *et al.*, 1999). For this comparative analysis of models of sporadic and familial ALS, we selected spinal motoneurons and oculomotor neurons, since their CaBP composition was clearly different (Alexianu *et al.*, 1994; Siklós *et al.*, 1998). In light of earlier data from passive transfer experiments (Engelhardt *et al.*, 1995) we expected major changes at the neuromuscular junction and focused on motor axon terminals in the interosseus- and external eye muscles.

The analysis of motor axon terminals of the interosseus muscle in both models of ALS revealed mitochondrial degeneration and extensive calcium accumulation in mitochondria. These results were in agreement with previous findings obtained by examination of the same muscle after acute IgG treatment of animals (Engelhardt *et al.*, 1995), or by analysis of muscle biopsy samples of sporadic ALS patients (Siklós *et al.*, 1996).

Microscopic examination of the neuromuscular junctions in the external eye muscles also revealed changes different from those seen in the interosseus muscle. The major finding in the neuromuscular junctions in the external eye muscles was the appearance of large vacuolar structures (endosomes) accumulating the majority of intraterminal calcium. Such changes were not noted in neuromuscular junctions of interosseous muscles. The development of calcium filled endosomes was seen in motor nerve terminals of the superior rectus muscle of SOD1 transgenic mice (Siklós *et al.*, 1998), and following injection of IgG from patients with sporadic ALS. Such endosomes were in contact with the extracellular space via a narrow channel. Thus, oculomotor neurons with ample levels of parvalbumin could resist the applied stress conditions, probably by specialized management of intracellular calcium.

The exact origin or identity of endosomes could not be determined. However, their development was probably connected to the peculiar modification of synaptic transmission in the oculomotor synapses. Stimulation of

nerve terminals has been reported to lead to a transient increase of endosome-like organelles, because of the different kinetics of exo- and endocytosis (Takei *et al.*, 1996). Such vacuoles could possess very narrow channels communicating with the extracellular space (Gad *et al.*, 1998), similar to the endosomes documented in our study. Since increased intracellular calcium has been demonstrated to hinder vesicle membrane retrieval in a graded fashion (von Gersdorff & Matthews, 1994; Brodin *et al.*, 1997), differential formation of endosomes in vulnerable and resistant motoneurons could result from different ways of handling intracellular calcium possibly influenced by the calcium binding protein content. Indeed, in a recent study, Burrone and colleagues (2002) demonstrated that intracellular (endogenous) calcium buffers could decrease the release of vesicles towards the active zone, thus decreasing the size of the rapidly releasable pool of vesicles. The consequent saturation of the reserve pool of vesicles may favour a decreased rate of endocytosis and formation of a non-pinched off membrane-enclosed structure, i.e. endosome (Fig. 6.2). Alternatively, endosome-like structures may develop after prolonged stimulation (Leenders *et al.*, 2002). Such stimulation could increase intracellular calcium triggered by increased glutamate excitotoxicity, increased oxidative stress, or ALS IgG (Smith *et al.*, 1992). Thus endosomes may constitute an alternative route for vesicle recycling, probably to compensate for the exhaustion of the releasable pool of vesicles. If calcium binding proteins (i.e. endogenous calcium buffers) were present, the releasable pool would be exhausted faster (Burrone *et al.*, 2002), and endosomes might develop preferentially at those axon terminals with larger calcium buffering capacity. If the membrane of such structures is constituted from that of synaptic vesicles, the incorporated ATP-ase in these structures (Michaelson *et al.*, 1980) would facilitate the removal of the increased calcium load from the intracellular space. Accordingly, the presence of CaBPs could explain the *ex vivo* resistance of extraocular terminals to physiological effects of amyotrophic lateral sclerosis sera, i.e. differences in the frequency of spontaneous transmitter release, compared to motor axon terminals of spinal motor neurons (Mosier *et al.*, 2000). These observations suggest that axon terminals with high CaBP content may develop a specialized mechanism against calcium load, which might be particularly important for motor neurons where axon terminals and cell bodies could be at large distances. However, so far, no direct evidence demonstrates that the presence of parvalbumin (or any other calcium binding protein) in oculomotor neurons is the sole factor responsible for the selective resistance of these motor neurons or their ability to handle an increased intracellular calcium load.

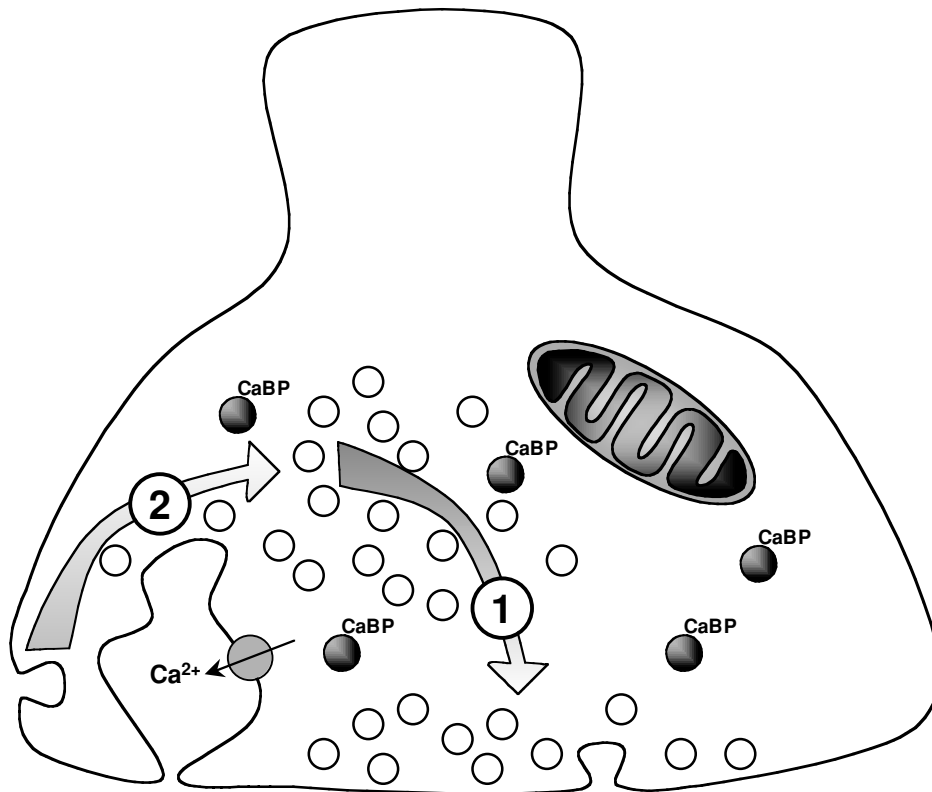

Fig. 6.2 Endogenous calcium buffers (CaBP) in axon terminals could retard vesicle mobilization to the active zone (1). The consequent saturation of the reserve pool of vesicles provides a negative feedback for recycling (2), which, in parallel with the exhaustion of the readily releasable pool of vesicles, facilitate the development of an alternative route of membrane retrieval. The calcium pump of endosomes would help to keep cytoplasmic calcium low.

Mechanism of protection of motor neurons by calcium binding proteins: cell bodies

The basic principles of the protection of motor neurons from calcium-mediated degeneration are summarized in Fig. 6.1, which models the potential neuroprotective effects of CaBPs. Such a model is supported by the differential survival of motor neurons and the parallel levels and distribution of intracellular calcium in the oculomotor nucleus and the spinal motor neurons of mutant SOD1 transgenic mice (Siklós *et al.*, 1998). Although the exact mechanism of mutant SOD1 toxicity is still undefined (Cleveland & Liu, 2000; Cleveland & Rothstein, 2001), the interaction of altered calcium- and free radical homeostasis (Mattson, 1998) suggest that the presence of CaBP could be neuroprotective.

Direct electrophysiological evidence for differences in vulnerable and resistant motor neurons was provided by using the “added buffer” approach of Neher and Augustine (1992). With this technique to monitor “calcium

buffering” Keller’s laboratory was able to document that calcium binding ratios were five- to sixfold greater in oculomotor neurons than in spinal motor neurons (Vanselow & Keller, 2000). Prolonged Ca recovery times were noted in oculomotor neurons, in contrast to spinal motor neurons that had more rapid recovery times.

The proposed synergetic effect of free radical and calcium homeostasis (Mattson, 1998) prompted us to study the calcium distribution in SOD1 knockout animals, which, though, more prone to injury, develop normally (Reaume *et al.*, 1996). We noted a selective age-dependent increase of calcium levels of spinal motoneurons compared with oculomotor neurons in wild-type animals (Siklós *et al.*, 2000), supporting the notion of altered calcium homeostasis with aging (Kirischuk & Verkhratsky, 1996; Verkhratsky & Toescu, 1998). Lack of such changes in oculomotor neurons suggests that stabilization of calcium homeostasis during aging, associated with the presence of calcium binding proteins, might enhance neuroprotection (Clementi *et al.*, 1996).

An unexpected finding of the present experiments was the relative decrease of calcium from the ER stores and the cytoplasm of spinal motor neurons of SOD1 knockout animals compared to age-matched controls. No such changes were noted in oculomotor neurons. These data suggest that decrements in the free-radical defense system could selectively impair calcium homeostasis in neurons with presumably lower calcium buffer capacity. Recent physiological and anatomical characterization of SOD1 knockout mice revealed a slow development of a mild, chronic peripheral hindlimb axonopathy and a moderate decline in motor unit number, suggesting impaired sprouting (D. Flood & J. Shefner, personal communication). This finding is in accord with the reduction of calcium in spinal motor neurons, since suitable intracellular calcium levels and intact intracellular stores are known to be necessary for synapse remodeling and neurite elongation (Kocsis *et al.*, 1993; Mattson & Kater, 1987; Suarez-Isla *et al.*, 1984). The protection of oculomotor neurons, particularly their internal stores from such a decrease of intracellular calcium could be explained on the basis of their higher CaBP content, as proposed by Hofer *et al.* (1998), assuming that Ca^{2+} released from the stores can be captured immediately and recycled into the stores by CaBPs (see Fig. 6.1).

In vitro transfection study

To test the protective effects of CaBP directly, we used our motor neuron cell line (VSC 4.1 cell line) and studied the effects of purified IgG from sporadic ALS patients on cellular viability and physiological properties (Smith *et al.*, 1994). Cytotoxicity of ALS IgG in these cells was associated with increased calcium currents through voltage-gated calcium channels (Mosier *et al.*, 1995). Furthermore, with direct calcium imaging by laser scanning confocal microscopy, it was demonstrated that ALS IgG could induce transient increases in the intracellular calcium level, with amplitudes proportional to the cytotoxic potential of the actual IgG preparation (Colom *et al.*, 1997). The initial transient increase in calcium was clearly different from the later sustained increases in calcium, which appeared to accompany actual cell degeneration. This initial signaling of subsequent cell injury is also a hallmark of glutamate-induced cell degeneration (Tymianski, *et al.* 1993). The cytotoxicity of VSC 4.1 cells with ALS IgG was only noted in differentiated cells with low calbindin- $\text{D}_{28\text{k}}$ content. When calbindin- $\text{D}_{28\text{k}}$ expression was increased following retroviral infection of VSC 4.1 cells, the ALS IgG was no longer toxic. When calbindin- $\text{D}_{28\text{k}}$ antisense oligonucleotides were injected into the cells, the calbindin- $\text{D}_{28\text{k}}$

content was decreased markedly, and the toxic effects of ALS IgG were restored (Ho *et al.*, 1996). Similar neuroprotective effects of calbindin- $\text{D}_{28\text{k}}$ in cell culture were documented by Roy *et al.* (1998). More recently, Van Den Bosch *et al.* (2002) have documented that the application of kainic acid results in marked increases in intracellular calcium leading to subsequent motor neuron death, which can be relatively protected by overexpression of parvalbumin.

In vivo studies

To study the effects of CaBP in vivo, transgenic animals were developed with increased expression of parvalbumin in their motor neurons (Beers *et al.*, 2001). A rat calmodulin II (CaMII) promoter was employed because it has been shown to promote β -galactosidase expression in embryonic and adult mouse neurons. Transgenic lines (two altogether) were bred to homozygosity and determined to contain eight to ten integrated copies of the CaMII/parvalbumin construct. Presence of parvalbumin was confirmed by *in situ* hybridization and immunocytochemistry in ventral horn neurons of the lumbar section of the spinal cord. None of the parvalbumin transgenic mice exhibited ALS-like signs of weakness or paralysis, or died prematurely. When homozygous PV^+ mice (eight to ten copies of parvalbumin construct) were injected intraperitoneally with immunoglobulins from ALS patients, neither elevation of the calcium content of the motor neurons, nor increase in the frequency of the spontaneous transmitter release were noted. Similar treatments increased calcium in wild-type animals. Thus the increased parvalbumin expression in spinal motor neurons completely prevented the increased intracellular calcium noted in motor axon terminals.

When mice with mutant SOD1 (mSOD1) transgenic mice with the $\text{G}^{93\text{A}}$ mutation were bred to the parvalbumin transgenic mice ($\text{PV}^+ \times \text{mSOD1}$), we noted increased preservation of spinal neurons (by approximately 33%), a delayed disease onset (by 17%) and a prolonged survival (by 11%), compared to mSOD1 mice. These modest effects were in marked contrast to the complete blockade of increased calcium following injection of ALS IgG. One potential explanation for the discrepancy may relate to the fact that homozygous PV transgenic mice with high integrated PV copy number were used for the IgG experiments, while hemizygous mice with low integrated PV copy number were studied in the PV/mSOD1 transgenic mice. The moderate protective effect of the upregulation of PV on motoneuron survival in the familial ALS model suggests that a focus on motor neurons alone is insufficient. We must also consider the maintenance of calcium homeostasis in cells such as

neighboring glia which can certainly contribute significantly to motor neuron viability.

Stress-related changes of CaBPs in motoneurons and glial cells

The traditional tool to study physiological and cellular reactions during degeneration – axotomy (Koliatsos & Price, 1996) – revealed that a certain number of the surviving motor neurons in the hypoglossal nucleus (Krebs *et al.*, 1997; Dassesse *et al.*, 1998) and in the spinal cord of the operated rats (Fallah & Clowry, 1999) respond to stress with increased levels of CaBPs. The upregulation of CaBP expression was explained as a self-protective mechanism to facilitate the survival of injured motoneurons by maintaining Ca^{2+} homeostasis. This concept was supported by axotomy experiments in mice (Obál, 2002) correlating changes of calcium- and CaBP levels in the oculomotor neurons (prototype of resistant neurons in ALS) and hypoglossal neurons (representing vulnerable cells in ALS). In the oculomotor nucleus, CaBP-staining was significantly increased in the perikarya, in contrast to the hypoglossal nucleus, in which the elevated staining intensity was localized primarily to the neuropil, with no, or only occasional, staining of the cell bodies. Accordingly, by electron microscopy changes in intracellular calcium in oculomotor neurons were small, demonstrating only a fast transient increase, while in hypoglossal neurons, calcium levels were markedly increased and lasted considerably longer.

There is increasing evidence in ALS that motor neurons do not die by themselves but require other cells: the process is non-cell autonomous (Clement *et al.*, 2003). In mutant SOD1 transgenic mice, which are models of familial ALS, neither the neuron-specific expression of the mutant SOD1 (Lino *et al.*, 2002; Pramatarova *et al.*, 2001), nor astrocyte-specific expression of mSOD1 (Gong *et al.*, 2000) induced the degeneration of motor neurons. Furthermore, studies of chimeric mice confirm the non-cell autonomy of motor neuron cell death, and support the potential participation of glia in motor neuron degeneration (Clement *et al.*, 2003).

Indeed, as demonstrated in the model of fALS, astrocytes are exposed to oxidative stress, leading to their injury and manifested in the loss/inactivation of the (EAAT2) glutamate transporter (Trotti *et al.*, 1999; Howland *et al.*, 2002), which increases the likelihood of further excitotoxicity. The phenotypic transformation of spinal cord astrocytes, triggered either directly by oxidative stress (Cassina *et al.*, 2002), or by excess calcium influx (Du *et al.*, 1999), may lead to a loss of astrocytic functions including buffering

potassium and glutamate, as well as inhibiting feedback control of microglial NO release, and thereby aggravating neuronal damage (Schubert *et al.*, 2001). The importance of calcium influx in altering astrocytic function is highlighted by the findings that astrocytic transformation/reactive gliosis could be minimized by the L-type Ca^{2+} channel blocker, nifedipine (Du *et al.*, 1999). Furthermore, under certain experimental conditions (3-nitropropionic acid stress), astrocytes proved to be even more sensitive to calcium overload than neurons (Fukuda *et al.*, 1998).

S100 is a family of CaBPs which are localized mainly to glial cells in the nervous system. They have a wide range of effects, which are still not completely understood (Rothermundt *et al.*, 2003). It is possible that under conditions of stress, astrocytes utilize a similar defense tool as neurons, i.e. they overexpress their available (naturally occurring) CaBPs to attenuate the effect of the calcium overload. Accordingly, upregulation of S100 β was documented in astrocytes in the spinal cord of ALS patients (Migheli *et al.*, 1999). Furthermore, in parallel studies on ALS patients and SOD1 transgenic mice S100A overexpression was also documented (Hoyaux *et al.*, 2000, 2002). In wobbler mice, another model of motor neuron degeneration, the distribution of S100 β overexpressing astrocytes paralleled the presence of neurons showing oxidative damage (Corvino *et al.*, 2003).

Although the contribution of elevated glial Ca^{2+} in the degenerative process has not been proven definitely, these findings highlight the potential contribution of calcium-mediated damage of astrocytes in the pathogenesis of motor neuron injury in ALS. Such data also highlights the protective effects of astrocytes, and the need to guard the guardians. The combination of interventions aiming to improve the defense mechanisms against calcium-mediated injury in astrocytes as well as in motor neurons might yield more effective overall neuroprotection.

Neuroprotective role of CaBPs in other systems

Diverse studies have suggested that CaBPs may exert a general neuroprotective effect in neurodegenerative diseases. The concept was supported by the observation of age-dependent decline of expression of calcium binding proteins, particularly calbindin- $\text{D}_{28\text{k}}$ (Iacopino & Christakos, 1990; Potier *et al.*, 1994; Villa *et al.*, 1994; Amenta *et al.*, 1994; Kishimoto *et al.*, 1998), and by recognizing that calbindin- $\text{D}_{28\text{k}}$ could protect cells from excitotoxicity in a wide variety of in vitro systems (Mattson *et al.*, 1991; Lledo *et al.*, 1992; Clementi *et al.*, 1996; McMahon *et al.*, 1998). Other supportive in vivo studies demonstrated increased survival

Fig. 6.3 Calcium-dependent mechanisms of motoneuronal degeneration integrating different models of ALS. If intracellular calcium is increased, several direct (proteases, phospholipases, endonucleases) and indirect destructive mechanisms (production of free radicals) are initiated. Normally, free radicals are neutralized by appropriate components of the cellular defense system. However, the presence of mutant SOD1 results in a series of toxic reactions, which damage cytoskeletal components, as well as pumps/transport molecules (e.g. glutamate transporters) on neighboring glia. Impaired glutamate glial uptake could lead to increased glutamate available to stimulate AMPA/kainate receptors, and further increase intracellular calcium. The mechanism might be amplified by calcium influx through voltage-gated calcium channels due to IgG, and release of calcium from intracellular stores as a consequence of activation of metabotropic receptors. If the calcium increase endures, it might overwhelm extrusion pumps and intracellular organelles, particularly mitochondria. Such increased calcium might impair mitochondrial function, leading to overproduction of free radicals, and depletion of ATP. Finally, if not interrupted, the process may culminate in the opening of the mitochondrial megachannel leading to apoptotic or necrotic cell death, depending on the energy actually available.

of neurons containing calbindin-D_{28k} (Rami *et al.*, 1992), or parvalbumin (Tortosa & Ferrer, 1993) after ischemia, or deafferentation (Beck *et al.*, 1994).

Studies aiming to correlate calcium binding protein content of neurons in affected brain regions and the degree of degeneration revealed positive correlations in Parkinson's and Alzheimer's disease. Calretinin-containing neurons were resistant to intrastriatal 6-hydroxydopamine

lesions (Tsuboi *et al.*, 2000), and calbindin-D_{28k} containing substantia nigra dopamine neurons are relatively spared in Parkinson's disease (Yamada *et al.*, 1990). Similarly, parvalbumin immunoreactive neurons in the neocortex of patients with Alzheimer's disease were relatively resistant to degeneration (Ferrer *et al.*, 1991; Hof *et al.*, 1991). Further indirect evidence for the protective role of PV or calbindin-D_{28k} is derived from studies on transgenic animals

expressing the spinocerebellar ataxia-1 gene, which demonstrate that the reduced immunoreactivity to CaBPs in Purkinje cells precedes the onset of ataxia and loss of Purkinje cells (Vig *et al.*, 1998). Not all studies support the protective role of CaBPs. For example, it was claimed that the presence of calbindin-D_{28k} may not be relevant to the pathogenesis of Parkinson's disease (McRitchie & Halliday, 1995). Freund *et al.* (1990) reported the lack of a consistent and systematic relationship between neuronal calbindin-D_{28k} or parvalbumin content and ischemic vulnerability in different brain regions. Hartley *et al.* (1996) reported that increased expression of parvalbumin in cultured cortical neurons using a HSV-1 vector system actually enhanced NMDA neurotoxicity. Furthermore, Klapstein *et al.* (1998) demonstrated that hippocampal neurons in calbindin-D_{28k} knockout mice with reduced calcium buffering capacity were relatively protected against calcium-mediated damage. Thus, the relative protective role of calbindin-D_{28k} and parvalbumin in motor neurons does not necessarily extend to other neuronal systems. The neuroprotective effects of CaBP may depend on the nature of the insult, and the unique intrinsic, e.g. particular CaBP compositions/content (Parvizi *et al.*, 2003) or network properties of the affected neurons. To clarify these discrepancies, the specific modulatory effects of CaBP must be defined in each class of neurons, and determinations made as to whether CaBP specifically modify voltage-gated channels, ligand-gated channels (such as the AMPA/kainate receptor), Ca ATPases, or other structural and functional properties.

Conclusions: calcium-mediated degeneration of motor neurons

Increased intracellular calcium appears to be the key factor in coupling different pathways to cell destruction in models of ALS. Thus, stabilization of motoneuronal calcium homeostasis could be a potential tool to increase motor neuron resistance to stress. The summary of our present concept is illustrated in Fig. 6.3.

The proposed model addresses an increasing number of literature data documenting the interplay of some of the individual mechanisms, assuming a calcium-dependent link (see e.g. La Bella *et al.*, 1997; Roy *et al.*, 1998). Furthermore, the data suggest that degeneration of motor neurons could be attenuated by increasing the levels of calcium binding proteins in vulnerable motor neurons. It is important, however, that these neurons could not be ultimately rescued, which is in accord with the observation that certain motor functions such as eye muscles and voluntary

sphincter functions are only relatively spared (Bergmann *et al.*, 1995). This failure to completely prevent ultimate motor neuron injury could be the consequence of failing to address all of the cellular participants of the destructive process during the in vivo attempts of neuroprotection, or it could be the consequence of the role of the calcium binding proteins as calcium buffers. By definition, all buffers would be saturated sooner or later, if the stress signal endures. Nevertheless, CaBPs, considered as "buffers," could minimize the calcium-mediated pathological mechanisms and slow progression, but the loop could not be broken, or the mechanism halted. To be effective, therapy must be initiated at early stages prior to the start of irreversible changes in the cells and organelles. The goal then would be to delay injury in spinal motor neurons and provide the same relative neuroprotection that is present in relatively resistant motor neurons. Even achieving that goal would be worthwhile.

Apoptosis in neurodegenerative diseases

Jörg B. Schulz

Department of Neurodegeneration and Restorative Research, University of Göttingen, Germany

Introduction

Although reports on the morphological characteristics of apoptosis in neurodegenerative diseases remain controversial, accumulating evidence suggests that the molecular and biochemical pathways of apoptosis are involved in neuronal death of various neurodegenerative disorders and in related cellular and animal models. This includes stroke, head trauma, Huntington's (HD), Parkinson's (PD), Alzheimer's disease (AD and amyotrophic lateral sclerosis (ALS)). This evidence includes the activation of the mitogen activated protein (MAP) kinase pathway, the induction of Bax, prostate apoptosis response-4 (Par-4) and glyceraldehyde-3-phosphate dehydrogenase (GAPDH), evidence of aberrant activation of the cell cycle machinery, and the activation of caspases. Caspases are the mammalian cell-death-effector proteins. They may have an important role in acute and chronic neurodegenerative diseases. They execute cell death but may also be linked to the initiation of chronic neurodegenerative diseases. Peptide or protein inhibitors of caspases protect neurons *in vitro* or in animal models of neurological disorders. Although preclinical results are promising, clinical studies have not been performed because of the lack of synthetic caspase inhibitors that cross the blood-brain barrier. Such agents are a major focus in current programs of drug development and will hopefully become available soon. However, in some cell culture and animal models caspase inhibitors block cell death but may result in survival of a dysfunctional neuron. In contrast, therapeutic interference with the signaling phase of apoptosis, e.g. inhibition of the MAP kinase pathway, or the combination of caspase inhibitors with neurotrophins may provide morphological and functional protection.

Apoptosis

Apoptosis is an important form of cell death characterized by a series of distinct morphological and biochemical alterations, suggesting the presence of a common execution machinery in different cells. Condensation and fragmentation of nuclear chromatin, compaction of cytoplasmic organelles, a decrease in cell volume and alterations to the plasma membrane are classically observed resulting in the recognition and phagocytosis of apoptotic cells. The nuclear alterations are often associated with internucleosomal cleavage of DNA, recognized as DNA laddering on conventional agarose gel electrophoresis. Internucleosomal cleavage of DNA is a relatively late event in the apoptotic process, which in some models of neuronal cell death may be dissociated from early critical steps (Yakovlev *et al.*, 1997; Namura *et al.*, 1998; Springer *et al.*, 1999). Apoptosis is not restricted to nucleated cells (Kroemer, 1997). Nevertheless, detecting DNA fragmentation is simple and often used as a criterion to determine whether or not a cell is dying by apoptosis. Unfortunately, it is often overinterpreted and not without shortcomings. In addition, it has become clear that there is no clear-cut difference between necrosis and apoptosis. In addition, several forms of non-caspase-mediated forms of programmed cell death have been reported. Based on morphological grounds, one may differentiate (Leist & Jaattela, 2001) among

- (i) classical apoptosis,
- (ii) apoptosis-like programmed cell death, in which the chromatin condensation characteristically is less compact and complete than in apoptosis (the typical feature found in non-caspase mediated forms of programmed cell death),

- (iii) necrosis-like programmed cell death, in which chromatin condensation is lacking (the initiation of this cell death may be dependent on caspase activation; however the execution is independent of caspases and
- (iv) accidental necrosis and cell lysis.

Caspases

Caspases are the major executioners of apoptosis but some caspases are also involved in cytokine processing and inflammation. A family of at least 14 related cysteine proteases are known, named caspase-1 to caspase-14, depending upon their sequence of discovery. The family includes two murine homologues (caspase-11 and -12) that have no known human counterparts yet. Caspases are synthesized and stored as inactive proenzymes. They contain an N-terminal prodomain together with one large (p17 to p20) and one small (p10 to p12) subunit. The activation of caspases requires cleavage (usually by other caspases) to liberate one large and one small subunit, which associate into a heterotetramer, containing two small and two large subunits (Nicholson, 1999). Owing to their differential substrate specificities, they may be divided into three major groups, which also provides insight into their biological roles in inflammation and apoptosis (Rano *et al.*, 1997; Thornberry *et al.*, 1997). The three groups can be largely distinguished by their P4 preferences, a crucial determinant in caspase specificity. Group-I enzymes (caspases-1, -4, -5 and -13) prefer hydrophobic residues at P4 and are involved in the maturation of multiple pro-inflammatory cytokines. Group II enzymes (caspases-2, -3, and -7) have a strict requirement for Asp at P4 and will cleave DxxD apoptotic substrates. The cleaved substrates will disable cellular repair, halt cell cycle progression, inactivate inhibitors of DNA fragmentation, dismantle structural elements and mark dying cells for engulfment (Fischer *et al.*, 2003). Group III enzymes (caspases-6, -8, -9, -10) prefer branched-chain aliphatic amino acids in the position P4 and will activate group II caspases and other group III caspases.

Death receptor, exogenous pathway of apoptosis

The exogenous pathway of apoptosis is recruited following the activation of cell-surface death receptors such as Fas/CD95 and the tumour necrosis factor receptor 1 (TNFR1). These receptors are activated by specific ligands like Fas/CD95 and TNF α . On binding, the intracellular death domains (DD) of these receptors associate with adaptor proteins that contain the death effector domains,

e.g. FADD (Fig. 7.1). Adaptor proteins recruit procaspase-8, leading to its activation. Activated caspase-8 then activates other caspases, either directly or indirectly, by cleaving Bid. The exogenous pathway plays a major role in cancer cells and in immunity. However, its role in neuronal death is discussed controversially. Although caspase-8 is activated in several pathological conditions, including stroke, Huntington's disease and Parkinson's disease (Sanchez *et al.*, 1999; Velier *et al.*, 1999; Hartmann *et al.*, 2001b) and caspase-8 is activated in neurons in experimental paradigms of apoptosis, neurons in many models appear to be resistant to the activation of the cell death receptors that trigger the exogenous cell death pathway even in the presence of these receptors at the cell surface (Gerhardt *et al.*, 2001; Putcha *et al.*, 2002). Certain inhibitory mechanisms that interfere with Fas/CD95-mediated signaling including the expression of inhibitory proteins like c-Flip (Raoul *et al.*, 1999) and Lifeguard (Somia *et al.*, 1999), appear to silence the death receptors.

Mitochondrial, endogenous pathway of apoptosis

In mature, postmitotic and differentiated neurons apoptosis in most instances is induced through the mitochondrial, endogenous cell death pathway (Gerhardt *et al.*, 2001; Putcha *et al.*, 2002). Mitochondria are life-essential organelles for the production of metabolic energy in the form of ATP. Paradoxically mitochondria also play a key role in pathways leading to cell death (van Loo *et al.*, 2002). This role of mitochondria is not just a loss of function resulting in an energy deficit but is an active process involving different mitochondrial proteins. Cytochrome c was the first characterized mitochondrial factor shown to be released from the mitochondrial intermembrane space and to be actively implicated in apoptotic cell death. Since then, other mitochondrial proteins, such as the apoptosis-inducing factor (AIF), the second mitochondria-derived activator of caspase (Smac)/direct inhibitor of Apoptosis (AIT)-binding protein with low pI (DIABLO), endonuclease G and Omi/high temperature requirement A2 (HtrA2), were found to undergo release during apoptosis and have been implicated in various aspects of the cell death process. Pro- (Bid, Bax, Bak, Bok, Bik, Bnip3, Bad, Bim, Bmf, Noxa, Puma) and antiapoptotic (Bcl-2, Bcl-x_L, Bcl-w, Mcl-1, Boo, Bcl-B) members of the Bcl-2 protein family control the integrity and response of mitochondria to apoptotic signals. The precise molecular mechanisms by which Bcl-2 family proteins protect from or induce mitochondrial damage are still controversial (Martinou & Green, 2001).

Fig. 7.1 Cascade of apoptotic events in acute and chronic neurodegenerative diseases. The panel depicts our current understanding of intracellular events leading to the activation of effector caspases, e.g. caspase-3. Different apoptosis-triggering pathways employ distinct signal transduction pathways that culminate in the release of cytochrome c from mitochondria. Alternatively, caspase-8 which contains two death effector domain-like molecules (DED), reacts with FADD (Fas-associated protein with death domain), and is recruited for activation at either the CD95 death-inducing signaling complex (DISC) or the tumor necrosis factor- α receptor-1 (TNF-R). However this mechanism has not clearly been shown to occur in mature, differentiated neurons (**Induction phase**). Two general mechanisms for release of cytochrome c (or other caspase-activating proteins) have been proposed: one involves osmotic disequilibrium leading to an expansion of the matrix space, organellar swelling, and subsequent rupture of the outer membrane; the other envisions opening of channels in the outer membrane, thus releasing cytochrome c from the intermembrane space of mitochondria into the cytosol. Members of the Bcl-2 family may perform double duty, controlling cytochrome c release from mitochondria and also possibly binding Apaf-1. Cytochrome c activates caspases by binding to Apaf-1 causing it to associate with initiator procaspases (e.g. procaspase-9). Apaf-1 shares sequence similarity with the prodomain of Ced-3 and other initiator caspases with long prodomains including caspase-1, -2, -8, -9 and -10. This domain may serve as a caspase recruitment domain (CARD complex) by binding to caspases that have similar CARDS at their NH₂ termini. Upon reception of a death stimulus, the complex might dissociate, freeing Apaf-1 and thereby triggering the activation of initiator caspases (**Propagation phase**). Active initiator caspases may activate effector caspases (e.g. caspase-3), initiating the proteolytic cascade that culminates in apoptosis (**Execution phase**). Potential sites for peptide (zIETD-fmk, caspase-8 inhibitor; zLEHD-fmk, caspase-9 inhibitor; DEVD-fmk, caspase-3 inhibitor) and protein inhibitors (IAP, p35) of caspases to interfere with this pathway are noted.

Following release from mitochondria, cytochrome c, together with the apoptosis protease-activating factor (Apaf-1), dATP and the cytosolic procaspase-9, forms a high molecular weight caspase-activating complex, termed apoptosome (Fig. 7.1). Once assembled, the apoptosome activates procaspase-9 as the initiator caspase, which in turn proteolytically activates the executioner procaspase-3 (Fig. 7.1) (Li *et al.*, 1997). A proteolytic cascade is then initiated in which caspase-3 activates procaspase-2, -6, -8 and -10, resulting in a feedback amplification of the apoptotic signal (Slee *et al.*, 1999).

AIF was originally discovered as a mitochondrial protein that, like cytochrome c, is released into the cytoplasm during cell death. Following an apoptotic stimulus AIF translocates to the nucleus in response to apoptogenic stimuli to induce apoptosis characterized by large-scale (~50 kb) DNA fragmentation instead of oligonucleosomal DNA laddering. The molecular mechanisms of cell death induced by AIF are only poorly understood; they are independent of caspases (Cande *et al.*, 2002). Overexpression of the heat shock protein (HSP)70 antagonizes AIF (Ravagnan *et al.*, 2001). New evidence suggests, however, that a redox-active enzymatic region of AIF may be antiapoptotic while the DNA binding region is proapoptotic (Klein *et al.*, 2002; Lipton & Bossy-Wetzel, 2002).

The Apaf-1/cytochrome c apoptosome complex contains the X-chromosome-linked IAP (XIAP), which binds and inhibits caspase-3 and caspase-9 (Bratton *et al.*, 2001; Srinivasula *et al.*, 2001). Smac/DIABLO, a 29 kDa mitochondrial protein, is a mitochondrial XIAP antagonist. It is processed to a 23 kDa mature protein and translocates to the cytosol after an apoptotic trigger. Besides its interaction with XIAP, Smac/DIABLO also binds other IAP proteins including c-IAP1, c-IAP2, surviving and baculoviral OpIAP. Whether Smac/DIABLO is an essential factor in the apoptotic process is still unclear. Smac/DIABLO-deficient mice are completely viable and do not show any abnormality. Further, all types of Smac/DIABLO-deficient primary cells respond normally to a broad range of apoptotic stimuli (Okada *et al.*, 2002). These observations suggest the existence of redundant factors compensating for the loss of Smac/DIABLO, e.g. Omi/HtrA2, or that Smac/DIABLO has no essential and general role in apoptosis during development.

The serine protease Omi/HtrA2 shares functional properties with Smac/DIABLO. Upon induction of apoptosis, the protease is released from the mitochondrial intermembrane space and interacts with cytosolic IAP proteins with an IAP binding motif. In contrast to Smac/DIABLO, which shows a differential expression pattern with abundant expression in skeletal muscle, lung,

thymus and brain, Omi/HtrA is expressed ubiquitously. Besides its IAP-interacting property, Omi/HtrA is also an inducer/accelerator of cell death through its serine protease catalytic domain. When the mature protein, without its mitochondrial presequence, is overexpressed in the cytoplasm, it induces cell death independent of caspase activation or IAP interaction. The catalytic domain is essential for its cytotoxic, caspase-independent activity, whereas the IAP binding domain is necessary for caspase-dependent mechanisms (Hegde *et al.*, 2002). Mutations in Omi/HtrA have been linked to the mouse mutant *motor neuron degeneration 2* (mnd 2) (Jones *et al.*, 2003). This mutant mouse does not only show a neuromuscular disorder but also striatal damage and a Parkinsonian phenotype (Rathke-Hartlieb *et al.*, 2002).

Evidence for apoptosis and caspase activation in human diseases

The development of therapeutic targets for acute and chronic neurodegenerative diseases depends in part upon identifying specific mechanisms of cell death in humans and animal models. In sporadic and inherited neurodegenerative disorders like Huntington's disease (Portera-Cailliau *et al.*, 1995), Alzheimer's disease (Anderson *et al.*, 1996) and ALS (Martin, 1999), the presence of chromatin condensation and DNA fragmentation suggests that cells are dying by an apoptotic-like mechanism. The results are more controversial for Parkinson's disease: two studies reported that 5–8% of neurons in the *substantia nigra pars compacta* (SNpc) of Parkinson's disease patients show DNA-end labeling, a third study reported 6% of the melanin-containing neurons with chromatin changes upon electron microscopy (Mochizuki *et al.*, 1996; Anglade *et al.*, 1997; Tompkins *et al.*, 1997). On the other hand, others have failed to detect apoptotic changes in the SNpc (Kosel *et al.*, 1997; Banati *et al.*, 1998; Wüllner *et al.*, 1999), possibly because apoptotic DNA fragments have a relatively short half-life. While the significance of morphologic features suggestive of apoptosis remains controversial in human postmortem tissue, the detection of molecular apoptotic markers in human brain tissue and in animal models supports the pathological evidence. In Parkinson's disease (Hartmann *et al.*, 2000; 2001b), Huntington's disease (Ona *et al.*, 1999; Sanchez *et al.*, 1999), Alzheimer's disease (Gervais *et al.*, 1999), and ALS (Guegan *et al.*, 2001) translocation of cytochrome c from mitochondria to cytosol, activation of caspases, or appearance of substrate cleavage products support the hypothesis that apoptosis and

processed caspases are important mediators of neuronal cell death in neurodegenerative diseases.

In brain tissue taken during surgical decompression for acute intracranial hypertension following trauma, cleavage of caspase-1, upregulation and cleavage of caspase-3 were found along with DNA fragmentation with both apoptotic and necrotic morphologies (Clark *et al.*, 1999).

Evidence for apoptotic cell death in human stroke is scant at the present time. In two autopsy cases, a significant number of TUNEL-positive granule cells were found in the cerebellum after global ischemia (Hara *et al.*, 1995); the importance of such changes to postmortem interval was not clarified. Unlike rodents, human cerebral neurons reportedly exhibit little or no caspase-3 immunoreactivity under normal conditions (Krajewska *et al.*, 1997). However, during ischemic degeneration, caspase-3 protein expression increases.

T-cell mediated inflammation may play a key role in the pathogenic mechanism sustaining multiple sclerosis. At nearly all stages of multiple sclerosis, apoptotic cells bearing myelin markers, presumably oligodendrocytes, are present in brain (Ozawa *et al.*, 1994; Dowling *et al.*, 1996). Multiple sclerosis plaques show a pronounced expression of Fas/Apo-1/CD95 and Fas ligand death signaling molecules on glia cells, including oligodendrocytes, suggesting that the Fas signaling pathway may be pathogenetically relevant to multiple sclerosis (D'Souza *et al.*, 1996; Dowling *et al.*, 1996).

Studies in animal models

Because postmortem brains often contain artifacts due to autopsy delay, and typically show end stage disease rather than an evolving disease process, the best clues to mechanisms underlying neurodegenerative diseases come from animal studies.

Stroke

Morphological and biochemical characterization of central neurons following global or focal ischemia suggest that apoptosis contributes to ischemic death of neurons (MacManus *et al.*, 1993; MacManus *et al.*, 1994). Two lines of evidence indicate that caspase-3 activation plays a key role following transient forebrain ischemia. First, immunohistochemical and biochemical studies show that caspase-3 activation occurs in susceptible cortical and hippocampal neurons following temporary (2 h) middle cerebral artery occlusion produced by filament insertion into the carotid artery or four vessel occlusion for 12 min and global ischemia, respectively (Namura *et al.*, 1998; Xu *et al.*, 1999).

Second, intracerebral administration of selective caspase peptide inhibitors reduce cellular and behavioral deficits following transient focal (30 min to 2 h filament insertion into the carotid artery) or global ischemia (bilateral carotid artery occlusion for 5 min) (Hara *et al.*, 1997b; Endres *et al.*, 1998; Himi *et al.*, 1998). Moreover, neuroprotection can still be achieved when intracerebral administration of a caspase-3-specific (DEVD-cmk) or a pan-specific (zVAD-fmk)-caspase inhibitor was delayed by 6–9 h after mild transient (30 min) focal ischemia (Endres *et al.*, 1998; Fink *et al.*, 1998) or after chemically induced hypoxia (Schulz *et al.*, 1998). In both models the *N*-methyl-D-aspartic acid receptor antagonist dizolcipine (MK-801) is only efficacious when administered less than 1 hour after the initial insult. The prolonged therapeutic window makes caspase inhibitors particularly attractive for the treatment of stroke.

The observation that distinct mechanisms of cell protection reduce neuronal injury in ischemia suggests the possibility that, when combined, these treatments may act in synergy. Pretreatment with subthreshold doses of MK-801, and delayed treatment with subthreshold doses of zVAD-fmk, provide synergistic protection compared with either treatment alone. Moreover, both treatments extend the therapeutic window for caspase inhibition for an additional 2 to 3 hours (Ma *et al.*, 1998; Schulz *et al.*, 1998). The data suggest the potential value of combining treatment strategies to reduce potential side effects and to extend the treatment window in cerebral ischemia.

Inhibitors of apoptosis proteins (IAPs) are a family of proteins which confer resistance to neuronal apoptosis (Simons *et al.*, 1999) by caspase inhibition (Deveraux *et al.*, 1998; Robertson *et al.*, 2000). Adenovirally mediated overexpression of neuronal apoptosis inhibitory protein (NAIP) and of X-chromosomal IAP (XIAP) attenuates ischemic damage in the hippocampus after global ischemia induced by four vessel occlusion for 12 min and behavioral deficits (Xu *et al.*, 1997, 1999).

Spinal cord ischemia activates caspases-8 and -3, which colocalize in neurons with cells showing DNA fragmentation. The Fas receptor expressed in neurons coexpressing caspase-8, may provide one upstream mechanism for caspase activation (Matsushita *et al.*, 2000).

Trauma

The inhibition of caspases may offer therapeutic potential in the treatment of traumatic brain or spinal cord injury. Caspases-1 and -3 are cleaved and activated after fluid percussion-, impact- or cold injury-induced brain trauma (Yakovlev *et al.*, 1997; Fink *et al.*, 1999; Morita-Fujimura

et al., 1999) and impact spinal trauma (Springer *et al.*, 1999) in neurons and oligodendrocytes. Intracerebroventricular injection of zVAD-fmk, a panspecific caspase inhibitor, zDEVD-fmk, a caspase-3 specific inhibitor, or YVAD-fmk, a caspase-1 specific inhibitor, markedly reduces posttraumatic apoptotic cell death and significantly enhances neurological recovery (Yakovlev *et al.*, 1997; Fink *et al.*, 1999; Morita-Fujimura *et al.*, 1999). Intraocular application of caspase inhibitors reduces delayed cell death of retinal ganglion cells caused by transection of the optical nerve (Kermer *et al.*, 1998).

Multiple sclerosis

Inhibition of oligodendrocyte apoptosis in autoimmune demyelinating diseases may block or attenuate the neurological manifestations of the disorder. Experimental autoimmune encephalomyelitis (EAE) is a rodent model of multiple sclerosis. Oligodendrocytes from transgenic mice that express the baculovirus anti-apoptotic protein p35 (inhibits multiple caspases), were resistant to cell death induced by TNF- α , agonistic anti-Fas antibody and INF- γ . Further, cre/p35 transgenic mice were resistant to EAE induction by immunization with the myelin oligodendrocyte glycoprotein. The numbers of infiltrating T cells and macrophages/microglia in the EAE lesions were significantly reduced, as were the numbers of apoptotic oligodendrocytes expressing the activated form of caspase-3 (Hisahara *et al.*, 2000).

Huntington's disease

This disease is characterized by the presence of mutated Huntingtin protein containing extended repeats of the amino acid glutamine; this mutated protein appears to be neurotoxic, but proteolytic cleavage may be needed to generate a neurotoxic fragment from the full-length, mutated huntingtin protein. Caspase-3 cleaves huntingtin in vitro and in apoptotic cells (Goldberg *et al.*, 1996; Wellington *et al.*, 1998). Recently, caspase-cleaved huntingtin fragments were identified in postmortem brains of Parkinson's disease patients, but also in controls, indicating that caspase-mediated cleavage of huntingtin may occur as a normal physiological event (Wellington *et al.*, 2002). However it was thought that the cleavage of mutant huntingtin would release fragments with the potential for increased toxicity and accumulation, due to the presence of the expanded polyglutamine tract (Wellington *et al.*, 2002). According to conventional theories, procaspases are not active; recently, however, several groups have shown that procaspases may also have catalytic activity, albeit at a level

much lower than that of active caspases (Stennicke *et al.*, 1999). Mutant, full-length huntingtin with extended polyglutamine tracts may provide a suitable substrate for basal procaspase activity in the absence of apoptosis generating neurotoxic huntingtin fragments.

Ona and colleagues have shown that a dominant-negative mutant of interleukin-1 β -converting enzyme (caspase-1), delays the onset and progression of pathology in a transgenic model of Huntington's disease expressing a mutant human Huntingtin exon 1 encoding an expanded polyglutamine repeat (Ona *et al.*, 1999). Further, intracerebroventricular administration of the panspecific caspase inhibitor zVAD-fmk (Ona *et al.*, 1999) and minocycline (Chen *et al.*, 2000), which indirectly inhibits caspase-1 and -3, delays mortality in this model.

Caspase-8 is another caspase that might be involved in the pathogenesis of Huntington's disease. More evidence points to an endogenous activation of caspase-8 than an activation through death receptors. The caspase is recruited to intracellular aggregates and is subsequently activated in neuronal cells that express an expanded polyglutamine repeat (Sanchez *et al.*, 1999). In a cellular system, caspase inhibition prevents cell death but not inclusion formation (Saudou *et al.*, 1998). Activated caspase-8 has been detected in the insoluble fraction of brains of Huntington's disease patients but not of controls (Sanchez *et al.*, 1999). Caspase-8 may also be activated by the formation of proapoptotic heterodimers consisting of huntingtin interacting protein 1 (Hip1) and Hip1 protein interactor (Hippi), which is favored by the disease-associated polyglutamine expansion (Gervais *et al.*, 2002).

Parkinson's disease

1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) produces clinical, biochemical and neuropathologic changes reminiscent of those occurring in idiopathic Parkinson's disease (PD). The toxicity of its active metabolite MPP⁺ involves the activation of caspases in vitro (Dodel *et al.*, 1998; von Coelln *et al.*, 2001) and in vivo (Yang *et al.*, 1998; Eberhardt *et al.*, 2000; Hartmann *et al.*, 2000). In mice chronic administration of MPTP induces apoptotic cell death in dopaminergic *substantia nigra* neurons. Transgenic mice expressing a dominant-negative mutant of interleukin-1 β converting enzyme are relatively resistant to MPTP toxicity (Klevenyi *et al.*, 1999). Further, the overexpression of the antiapoptotic protein, Bcl-2, prevents activation of caspases and provides protection against MPTP toxicity (Yang *et al.*, 1998).

The mitochondrial activation pathway requires the release of cytochrome c from mitochondria in connection

with the opening of the mitochondrial transition pore. Cytochrome c then forms a ternary complex with Apaf-1 and caspase-9 in the cytosol. MPP⁺ has been reported to be able to induce the opening of the mitochondrial transition pore (Cassarino *et al.*, 1999). Adeno-associated virus mediated expression of a dominant negative form of Apaf-1, consisting of the wild-type caspase recruitment domain, provides protection against dopaminergic cell loss and striatal catecholamine depletion in the mouse MPTP model (Mochizuki *et al.*, 2001). Consequently, nigral neurons showing activated caspase-3 were only found on the non-injected side.

Neurons expressing non-activated caspase-3 seem to be particularly prone to early degeneration as their number is low in parkinsonian SNpc compared with controls, whereas a higher number of cells with activated caspase-3 (6.5% vs. 3.9%) than in non-affected controls was observed (Hartmann *et al.*, 2000); and, as MPP⁺-induced cell loss proceeds in culture, the number of neurons expressing activated caspase-3 declines rapidly.

Caspase inhibition is achieved by tri- or tetrapeptide inhibitors or viral proteins and their mammalian homologues (IAPs) with different substrate specificity (Deveraux & Reed, 1999; Robertson *et al.*, 2000). Some of the peptide inhibitors are not entirely specific in that they also block cathepsins. Peptide caspase inhibitors (zVAD-fmk or selective caspase-3 inhibitors) protect primary mesencephalic cultures against MPP⁺ (Dodel *et al.*, 1998; Eberhardt *et al.*, 2000; Bilslund *et al.*, 2002). However, the loss of [³H]dopamine uptake as a marker for dendritic function is not reversed (Eberhardt *et al.*, 2000). Recently, more detailed analysis provided evidence that, although caspase inhibitors are protective against MPP⁺ toxicity in primary dopaminergic neurons or dopaminergic cell lines in culture, this rescue may be temporary, may cause a switch from apoptosis to necrosis or may not result in functional benefit (Choi *et al.*, 1999; Eberhardt *et al.*, 2000; Hartmann *et al.*, 2001b). An inhibitor of caspase-1 like enzymes was not effective against MPP⁺ in primary mesencephalic or cerebellar granule cells (Du *et al.*, 1997; Bilslund *et al.*, 2002).

Inhibitors of apoptosis proteins (IAP) were first discovered as viral proteins and were shown to suppress the defensive apoptotic host response to viral infection. Ectopic expression in mammalian cells blocks apoptosis (Deveraux & Reed, 1999). They share one or several baculoviral IAP repeat (BIR) domains. Many of them also have a RING domain (dispensable for antiapoptotic effect) and some of them possess a caspase recruitment domain (CARD). They block caspase activity by direct binding to specific pro-caspases or active caspases (Deveraux *et al.*, 1998). The baculoviral protein p35, for example, is a broad inhibitor

of caspase function, while cowpox virus product CrmA inhibits primarily caspase-1 and -8. In humans, at least six homologous proteins were discovered: NAIP, cIAP1/HIAP-2, cIAP2/HIAP-1, Survivin, Bruce and X-linked inhibitor of apoptosis protein (XIAP).

In cellular models we compared the efficacy of different adenoviral constructs (AdV-XIAP, AdV-HIAP1, AdV-HIAP2, AdV-NAIP, AdV-p35, AdV-crmA) against apoptotic stimuli and found XIAP expression to be most effective (Simons *et al.*, 1999; Kugler *et al.*, 2000; Gerhardt *et al.*, 2001). XIAP preferably blocks activation of pro-caspase-3, -6 and -7 by inhibiting the processing of procaspase-9. The XIAP protein contains a RING finger domain and three BIR domains, of which BIR-3 assumed to associate with caspase-9, and BIR-1/2 with caspase-3 and -7 (Robertson *et al.*, 2000). It is expressed ubiquitously in human tissues, but is sequestered from caspases by the Smac/Diablo protein under normal circumstances. In some instances, an intact JNK1 signalling pathway seems to be required for its antiapoptotic function (Sanna *et al.*, 1998, 2002). Interestingly, XIAP has been identified as a ubiquitin ligase, providing possible cross-talk to the ubiquitin-proteasome system.

Transfection of the nigrostriatal pathway with an Ad-XIAP led to a strong expression of XIAP protein in the striatum and in dopaminergic neurons of the SNpc (Eberhardt *et al.*, 2000). Expression of XIAP provided protection against the MPTP-induced loss of tyrosine hydroxylase-positive neurons but not against the reduction of striatal catecholamine concentrations, suggesting a dissociation between neuronal survival and the loss of neuritic function. Additional studies in primary mesencephalic cultures provided evidence that caspase inhibition by zVAD-fmk rescued the tyrosine hydroxylase-positive somata, but not their neurites and synapses from MPP⁺- and 6-hydroxydopamine-induced toxicity (Eberhardt *et al.*, 2000; von Coelln *et al.*, 2001). In contrast, the adenovirus-mediated expression of GDNF resulted in higher striatal catecholamine concentrations but did not protect against the MPTP-induced loss of dopaminergic neurons. The combination of adenoviral gene transfer of XIAP and GDNF provided synergistic effects: the MPTP-induced loss of tyrosine hydroxylase-positive neurons was almost completely blocked and the dopamine concentrations in the striatum were fully restored (Eberhardt *et al.*, 2000).

In transgenic mice expressing p35, a broad-spectrum viral caspase inhibitor, cell loss after MPTP treatment was reduced and striatal catecholamines were preserved partially (Viswanath *et al.*, 2000). In these mice, activation of caspase-3, -8 and -9, release of cytochrome c and cleavage of Bid (a proapoptotic Bcl-2 family member) after MPTP injections was reduced compared with wild-type

mice (Viswanath *et al.*, 2001). Studying the effects of MPP⁺ in PC12 cells and primary mesencephalic culture, a temporal sequence of activation after cytochrome c release from caspase-9 to caspase-3 and finally caspase-8 was established, all of which could be abrogated by a caspase-9 inhibitor (LEHD-CHO). A caspase-8 inhibitor (IETD-CHO) decreased caspase-3 or -9 activation only slightly (Viswanath *et al.*, 2001). Bid was cleaved by caspase-8 and promoted cytochrome c release, providing integration between the mitochondrial and the death-receptor pathway of caspase activation (Hengartner, 2000). The activation of caspase-8 occurs in a minority of neurons and glial cells in parkinsonian SNpc and in nigral neurons after MPTP treatment of mice (Hartmann *et al.*, 2001b). These data would be compatible with a model of cytochrome c-induced caspase-9 activation leading to caspase-3 activation that mediates the effector phase of apoptosis, and with an amplification loop involving caspase-8 (Fig. 7.1). The induction of CD 95 Fas could provide another source of caspase-8 activation, but has been denied at least in cell culture experiments with MPP⁺ (Gomez *et al.*, 2001). Minocycline, a clinically approved tetracycline derivative that inhibits microglial activation and presumably also inhibits caspase-1 and caspase-3, mitigates MPTP-induced neurodegeneration (Du *et al.*, 2001; Wu *et al.*, 2002). However, these protective effects of minocycline in MPP⁺/MPTP toxicity have been disputed by others (Yang *et al.*, 2003, Cornet *et al.*, 2004, Diguet *et al.*, 2004). Taken together, this would suggest that caspase inhibition is effective in preventing MPTP-induced death of dopaminergic neurons; however, an additional neurorestorative treatment may be required to fully restore their functional activity.

Mitochondrial dysfunction plays a central role in the pathogenesis of Parkinson's disease and MPTP toxicity. Several mechanisms have been proposed in models of neuronal apoptosis and MPTP/MPP⁺ toxicity, by which pro-apoptotic factors may be released from mitochondria to activate the caspase cascade. Prostate apoptosis response-4 (Par-4) was identified as being upregulated in prostate tumour cells undergoing apoptosis, but is now known to be essential in developmental and pathological neuronal death (Guo *et al.*, 1997; Mattson, 2000). Levels of Par-4 increase rapidly in response to various apoptotic stimuli through enhanced translation of Par-4 mRNA. A leucine zipper domain in the carboxy-terminus of Par-4 is essential for its pro-apoptotic function, and interactions of Par-4 with other proteins, including protein kinase C γ and Bcl-2, through this zipper may be central to the mechanisms by which Par-4 induces mitochondrial dysfunction. Levels of Par-4 are increased selectively before death in dopaminergic neurons of SNpc in

Parkinson's disease brain and in mice and monkeys following MPTP treatment (Duan *et al.*, 1999). In culture a block of Par-4 induction by antisense treatment provides protection.

Bax may have a central role in mediating mitochondria-dependent apoptosis in neurons (Deckwerth *et al.*, 1996). Models of Bax activation indicate that its oligomerization may result in a homomultimeric pore (Saito *et al.*, 2000), a VDAC-containing pore (Shimizu *et al.*, 1999), or a permeabilization of mitochondrial outer membrane (Kluck *et al.*, 1999) to release cytochrome c. Following MPTP treatment there is an upregulation of Bax in the SNpc (Hartmann *et al.*, 2001a). Bax upregulation appears to be of functional relevance since mutant mice lacking Bax are significantly more resistant to MPTP toxicity than their wild-type littermates (Vila *et al.*, 2001). Collectively, the results indicate that Bax plays a pivotal role in SNpc dopaminergic neuronal death in the MPTP mouse model likely by acting in injured neurons before the onset of irreversible cell death events.

One way by which the new transcription of death inducing genes, including Bax, Par-4, or Bim (Putcha *et al.*, 2001; Whitfield *et al.*, 2001) that lead to the translocation of cytochrome c from mitochondria may occur is activation of the mitogen activated protein (MAP) kinase pathway. Saporito and colleagues were the first to show that in the MPTP model the JNK pathway is activated and that the pharmacological inhibition of this pathway with CEP1347 leads to neuroprotection (Saporito *et al.*, 1999, 2000). Recently we investigated the role of the pro-apoptotic c-Jun NH₂-terminal kinase (JNK) signaling cascade in SH-SY5Y human neuroblastoma cells in vitro and in mice in vivo (Xia *et al.*, 2001). MPTP/MPP⁺ led to the sequential phosphorylation and activation of JNK kinase (MKK4), JNK and c-Jun, the activation of caspases and apoptosis. In mice, adenoviral gene transfer of the JNK binding domain of JNK-interacting protein-1 (a scaffold protein and inhibitor of JNK) inhibited this cascade downstream of MKK4 phosphorylation, blocked JNK, c-Jun and caspase activation, death of dopaminergic neurons and the loss of catecholamines in the striatum. Furthermore, the gene transfer resulted in behavioral benefit. Therefore, inhibition of the JNK pathway offers a new treatment strategy for Parkinson's disease which blocks the death signaling pathway upstream of the execution of apoptosis in dopaminergic neurons, providing a therapeutic advantage over the direct inhibition of caspases.

Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) has been shown to play a role in apoptosis in some cellular models. Age- and cytosine arabinoside-induced apoptosis in cerebellar granule cells and age-induced

apoptosis in cerebral cortical cultures are associated with an increased expression of GAPDH and prevented by treatment with GAPDH antisense oligonucleotides (Ishitani & Chuang, 1996; Ishitani *et al.*, 1996a, b). Cell death associated with nuclear translocation of GAPDH and antisense protection occurs in several neuronal and non-neuronal systems (Ishitani *et al.*, 1997; Saunders *et al.*, 1999; Shashidharan *et al.*, 1999). Downregulation of GAPDH expression by antisense oligonucleotides protected mesencephalic dopaminergic neurons from MPP⁺ toxicity (Fukuhara *et al.*, 2001). CGP 3466 (dibenzo[b,f]oxepin-10-ylmethyl-methyl-prop-2-ynyl-amine) is structurally related to R-(–)-deprenyl and shares its ability to bind to GAPDH and rescue neurons in several in vitro and in vivo paradigms (Kragten *et al.*, 1998; Carlile *et al.*, 2000). CGP3466 was shown to protect against MPTP- and 6-hydroxydopamine-induced toxicity and behavioral deficits in vivo without affecting monoamine oxidase B activity (Andringa & Cools, 2000; Andringa *et al.*, 2000; Waldmeier *et al.*, 2000). However, crucial experiments including the proof of GAPDH upregulation and nuclear translocation and the effects of CGP 3446 on these changes have not been done yet in dopaminergic neurons. A phase II clinical trial for Parkinson's disease was initiated.

Amyotrophic lateral sclerosis

Whereas 90% of human cases with ALS are sporadic, about 10% are inherited. Of these, about 10 to 20% carry a dominant mutation in the superoxide dismutase 1 (SOD1) gene. Expression of these mutations in mice replicate the clinical and pathological hallmarks of ALS. In mice transgenic for mutant SOD1, there are clear apoptotic cells in the spinal cord, though they are rare (Vukosavic *et al.*, 2000). In the spinal cord of human ALS patients and in affected transgenic SOD1 mice, Bax is not only upregulated but it is also expressed mainly in its deleterious homodimeric conformation. In mice, Bax is translocated from the cytosol to the mitochondria (Vukosavic *et al.*, 1999). Overexpression of Bcl-2 prolongs survival of transgenic SOD1 mice (Kostic *et al.*, 1997). Evidence for a prominent recruitment of the mitochondrial pathways of apoptosis has been found in the spinal cord of patients and transgenic SOD1 mice (Guegan *et al.*, 2001). Pharmacological inhibition of cytochrome c release delays disease onset and extends the survival of transgenic SOD1 mice (Zhu *et al.*, 2002). A functional role for caspases has been implicated by studies showing that the panspecific caspase inhibitor, zVAD-fmk, attenuates mutant SOD1-mediated cell death in transfected PC12 cells and in transgenic SOD1 mice (Ghadge *et al.*, 1997; Li *et al.*, 2000). Motor neurons isolated from transgenic mice that overexpress different ALS-

linked SOD1 mutants showed increased susceptibility to activation of the Fas-triggered death pathway (Raoul *et al.*, 2002). However, in general differentiated motor neurons are more resistant to FasL/CD95L than immature motor neurons, This resistance that has been linked to an increased expression of c-Flip (Raoul *et al.*, 1999). In mice transgenic of mutant SOD1 activation of caspase-8, like induction of TNF α (Nguyen *et al.*, 2001), occurs in the spinal cord only near end-stages of the cell death process (Guegan *et al.*, 2002). This observation indicates that the extrinsic pathway of apoptosis in this model – if at all – only makes a late contribution to cell death.

Caspase inhibition and inflammation

Until recently, the brain was considered immunologically privileged and unable to develop inflammation unless the blood–brain barrier was disrupted. We now know that the brain is capable of sustaining its own endogenous inflammatory reaction, and the evidence in Alzheimer's disease is particularly strong (McGeer *et al.*, 1988), but information occurs in other neurodegenerative diseases as well. It has been hypothesized that this reaction contributes heavily to progressive neuronal death.

Non-specific caspase inhibitors block group II and III caspases involved in apoptosis, and caspase-1, the enzyme that cleaves pro-interleukin-1 β to mature interleukin-1 β . Since interleukin-1 receptor antagonists prevent damage after focal ischemia induced by permanent middle cerebral artery occlusion (Loddick & Rothwell, 1996), the first study using pan-caspase inhibitors was intended to show that blocking ICE activity prevents ischemic damage in the same model (Loddick *et al.*, 1996). Transgenic mice expressing a dominant negative caspase-1 are protected in animal models of stroke induced by 3 h of cerebral artery occlusion followed by 24 h of reperfusion (Hara *et al.*, 1997a), impact-induced head trauma (Fink *et al.*, 1999), Parkinson's disease (Klevenyi *et al.*, 1999), amyotrophic lateral sclerosis (Friedlander *et al.*, 1997) and Huntington's disease (Ona *et al.*, 1999). It remains to be elucidated whether both inhibition of inflammation and inhibition of caspase-mediated neuronal apoptosis contribute to the protective effects of caspase inhibitors. Of note, murine caspase-11, with homology to human caspase-4, promotes both caspase-1 and caspase-3 processing, thereby enhancing both apoptosis and cytokine maturation (Kang *et al.*, 2000).

Limitations and cautions

Caspases and related proteins are emerging as important therapeutic targets in a variety of acute and chronic CNS

diseases. Preclinical evidence in stroke supports the need to investigate anti-apoptotic treatment strategies, particularly because caspase inhibitors reduce tissue injury when administered many hours after mild ischemia. In the clinical setting, anti-apoptotic strategies might become useful to treat brief episodes of brain ischemia or be given in advance of risky surgical procedures (e.g. cardiopulmonary by-pass) or combined with thrombolytics or agents in which synergy has been documented (e.g. glutamate receptor antagonists). Furthermore, caspase inhibitors may provide promising opportunities for other neurological conditions in which cell death is prominent. Although the results of treatment in animals with caspase inhibitors are promising, clinical studies have not yet been performed because of the lack of synthetic caspase inhibitors that cross the blood-brain barrier. Such agents are a major focus in current programs of drug development and hopefully will become available soon. In addition, therapies that lead to the increased expression of IAPs are a potential avenue for treatment of chronic neurodegenerative disorders.

Neurotrophic factors

Michael Sendtner

Institute for Clinical Neurobiology, Würzburg, Germany

Introduction

During development of higher vertebrates, many types of neurons including spinal and bulbar motoneurons are generated in excess. When developing motoneurons become postmitotic, they grow out axons and make contact with their target tissue, the skeletal muscle. Subsequently, about 50% of the motoneurons are lost during a critical process, which is called physiological motoneuron cell death. This phenomenon has been the focus of research for about a century and has led to the identification of neurotrophic factors that regulate survival of motoneurons during this developmental period. Motoneuron cell death is also observed *in vitro* when these neurons are isolated from the embryonic avian or rodent spinal cord. These cultured motoneurons have been a useful tool for studying basic mechanisms underlying neuronal degeneration. Such studies have revealed insights into signaling pathways that modulate survival during development and that might be disturbed under pathophysiological conditions in neurodegenerative disorders such as amyotrophic lateral sclerosis (ALS). However, specific differences in mechanisms that regulate survival of developing and postnatal motoneurons have also been identified. These findings could help to develop new therapeutic strategies that could counteract the pathophysiological processes underlying ALS.

Developmental motoneuron cell death

Viktor Hamburger and other pioneer researchers have shown during the first part of the twentieth century that the developmental cell death of motoneurons is guided by influences provided from the target tissue (Hamburger, 1934, 1958). Removal of limb buds in developing chick

embryos enhances massively developmental motoneuron death, and transplantation of an additional limb reduces the number of dying motoneurons. This kind of plasticity allows the individual organism to react to deviations from genetically determined developmental programs, and thus might have contributed during evolution to the generation of a highly complex nervous system in higher vertebrates. On the other hand, this high complexity also implies possibilities for disturbances by gene mutations and dysregulation of gene expression, which then could lead to specific diseases.

The concept that factors from skeletal muscle play a major role in regulating motoneuron survival during development has been challenged recently by the observation that mice deficient for erb-B3, the receptor for glial growth factor (GGF), show a severe deficit of developing Schwann cells, and then, as a consequence, a significant reduction (79%) in motoneurons (Riethmacher *et al.*, 1997). Thus, developing Schwann cells appear to be at least as important for motoneurons as skeletal muscle. However, these findings are not necessarily contradictory. These data could also indicate that motoneurons first become dependent on muscle-derived neurotrophic support and then, subsequently, on Schwann cell-derived factors. When skeletal muscle is destroyed (Grieshammer *et al.*, 1998), motoneuron survival in the lumbar spinal cord is reduced highly during embryonic development, thus confirming earlier data obtained from experiments in chick when limb buds are removed (Oppenheim, 1985). In conclusion, neurotrophic factors provided from various cell types apparently play together in regulating survival and functional integrity of motoneurons both during development and in the adult.

This scenario appears even more complex with respect to early findings that motoneuron cell death in vertebrates can also occur in a target-independent manner. Rita Levi-Montalcini and others have shown (Levi-Montalcini,

1950; O'Connor & Wyttenbach, 1974; Oppenheim *et al.*, 1989) that, during early development of the chick embryo around day 4, massive cell death can be observed in a specific population of motoneurons in the ventral cervical spinal cord. This type of cell death is highly synchronized, in contrast to motoneuron cell death observed in this and other regions of the developing chick spinal cord between embryonic day 6 and 10, which roughly corresponds to embryonic day 14 and postnatal day 3 in the mouse or rat. A recent study (Yaginuma *et al.*, 1996) has shown that this type of early motoneuron cell death occurs in a target-independent manner and may be determined by a cell-autonomous program. Taken together, these data suggest that cell death programs in motoneurons probably change during development, and at least some of the motoneurons pass through an early phase when cell-autonomous and/or target-independent processes regulate cell death and then undergo a phase when signals from skeletal muscle play a major role. Subsequently, signals from Schwann cells such as CNTF and other survival factors acting through signaling pathways that involve Stat-3 contribute to the maintenance of motoneurons, and evidence from experiments with various mouse mutants suggests that postnatal survival of motoneurons becomes increasingly dependent again on cell autonomous processes such as sufficient expression of the "survival of motoneuron" (SMN) protein (Jablonka *et al.*, 2000; Monani *et al.*, 2000) and protection from glutamate-mediated toxicity (Rothstein, 1995). Further research has to show how these signals and the intracellular signaling pathways play together and how the motoneurons react to disturbances of individual signals. The availability of mouse mutants, in which individual signals are disrupted either by classical homologous recombination or in a cell type-specific or otherwise inducible manner by use of the Cre/loxP and other recombination techniques, will help to understand such processes and thus could provide a basis for rational design of therapeutic strategies for treatment of various forms of motoneuron disease.

Neurotrophic factors for motoneurons

Nerve growth factor (NGF) was the first neurotrophic factor to be discovered. It is a prototypic target-derived neurotrophic molecule that regulates survival of subpopulations of sensory and sympathetic neurons. Since 1989, more than ten neurotrophic factors have been identified and characterized on a molecular level. This list includes factors called neurotrophins, which are related to NGF. At least three neurotrophins, brain-derived neurotrophic

Table 8.1. Neurotrophic factors for motoneurons and their receptors

	Receptor on motoneurons
1. Neurotrophins	
Brain-derived neurotrophic factor (BDNF)	p75 ^{NTR} , trk-B
Neurotrophin-3 (NT-3)	p75 ^{NTR} , trk-C
Neurotrophin-4/5 (NT-4/5)	p75 ^{NTR} , trk-B
2. CNTF/LIF family	
Ciliary neurotrophic factor (CNTF)	CNTFR α , LIFR β , gp130
Leukemia inhibitory factor (LIF)	LIFR β , gp130
Cardiotrophin-1 (CT-1)	?, LIFR β , gp130
Cardiotrophin-1 like cytokine (CLC)	CNTFR α , LIFR β , gp130
3. Hepatocyte growth factor/scatter factor (HGF/SF)	
	c-met
4. Insulin-like growth factors	
IGF-I	IGFR-1
IGF-II	IGFR-1, Mannose-6P receptor
5. Glial-derived neurotrophic factor and related factors	
Glial-derived neurotrophic factor (GDNF)	GFR α 1, c-ret
Neurturin (NTR)	GFR α 2, c-ret
Persephin	GFR α 4, c-ret
Artemin	GFR α 3, c-ret

factor, neurotrophin-4 and neurotrophin-3, but not NGF, support motoneuron survival (Henderson *et al.*, 1993; Hughes *et al.*, 1993; Sendtner *et al.*, 1992a). Motoneurons are also supported by other neurotrophic molecules, indicating that motoneuron survival and function is a highly complex process, which is influenced by a cooperative function of these molecules so far not fully understood. Some of these molecules are expressed only postnatally. Thus the requirement for neurotrophic factors seems to change from developmental periods to postnatal life. Moreover, neurotrophic factors do not only act on motoneuron survival but also on functional parameters such as the regulation of transmitter synthesis and release, axon outgrowth and synaptic stability (for review, see Sendtner, 1998).

The CNTF family supports motoneuron survival through the activation of complex membrane receptors involving gp130 and LIFR- β (Nakashima & Taga, 1998). Factors that bind to such complexes are the ciliary neurotrophic factor (Arakawa *et al.*, 1990), the leukemia-inhibitory factor (Hughes *et al.*, 1993), cardiotrophin-1 (Pennica *et al.*, 1995)

and the recently identified cardiotrophin-like cytokine (CLC) (Pennica *et al.*, 1995; Senaldi *et al.*, 1999; Shi *et al.*, 1999), which also can bind to the CNTF receptor complex (Elson *et al.*, 2000).

Survival of cultured motoneurons is also supported by members of the glial-derived neurotrophic factor (GDNF) gene family of transforming growth factor- β -related survival factors (Henderson *et al.*, 1994; Zurn *et al.*, 1994). Factors that support motoneuron survival include GDNF (Henderson *et al.*, 1994), neurturin (Klein *et al.*, 1997), persephin (Milbrandt *et al.*, 1998), and artemin (Baloh *et al.*, 1998). These molecules act through receptors involving the c-ret tyrosine kinase, and specific α -receptors (Baloh *et al.*, 1997).

HGF is a heterodimeric protein with similarities to plasminogen. However, it lacks enzymatic activity (Weidner *et al.*, 1991). Only lumbar motoneurons from 5-day old chick embryos survive with HGF, but not motoneurons from thoracic or cervical spinal cord (Novak *et al.*, 2000). In chick embryos, the c-met tyrosine kinase is expressed in lumbar but not in thoracic motoneurons between embryonic day 5 and 10 during the period of physiological motoneuron cell death. However, the expression of c-met in lumbar motoneurons seems to be regulated by target tissue-derived factors other than HGF. This conclusion is based on the observation that the massive cell death of motoneurons that occurs in the lumbar spinal cord after limb-bud removal cannot be reduced by treatment with HGF, probably because the c-met receptor is down-regulated by limb-bud removal and signals that lead to expression of this receptor are thus removed. Thus, HGF is another example of a neurotrophic factor (Wong *et al.*, 1997) that influences survival of specific subpopulations of motoneurons, and needs cooperation with other signals in order to exert its survival-promoting effect. The list of molecules that support motoneuron survival is still growing, and it is expected that it will become even longer in the future.

Motoneurons are also supported by insulin-like growth factor-1 and IGF-2 (Arakawa *et al.*, 1990; Ebens *et al.*, 1996; Yamamoto *et al.*, 1997). In cultures of isolated embryonic chick spinal motoneurons, the survival-promoting effects of IGFs are relatively low, in contrast to cultures of embryonic rat motoneurons, which can be maintained in serum-free medium (Hughes *et al.*, 1993). However, when IGFs are combined with other neurotrophic factors such as CNTF, this leads to supraadditive survival effects (Arakawa *et al.*, 1990). Thus neurotrophic factors potentate each other, suggesting that survival of motoneurons *in vivo* depends on a complex cooperation of more than one factor. Similarly, when BDNF was administered for prolonged

periods to lesioned facial motoneurons via a gene therapeutic approach, it supported survival but could not prevent atrophy of the motoneuron cell bodies (Gravel *et al.*, 1997). Only when BDNF and CNTF were added together was a significant anti-atrophic effect observed.

This observation is important for designing therapies with neurotrophic factors. The administration of a single factor does not meet the physiological requirements of motoneurons, in particular when these cells suffer from a chronic degenerative process, and combinations of factors might be necessary to influence the course of the disease in ALS.

Identification of cellular signaling pathways responsible for neurotrophic factor mediated survival of motoneurons

A major focus of molecular neurobiology is signaling pathways, which mediate the various functions of neurotrophic factors. These pathways could serve as targets for rational drug design and thus for development of therapeutics to treat symptoms such as axon degeneration and cell death of motoneurons, the hallmarks of ALS (Chou, 1992). Neurotrophins have served as a prototypic gene family for investigation of such signaling pathways in primary neurons (Segal & Greenberg, 1996). Signaling through high affinity neurotrophin receptors that include members of the trk gene family involves several pathways. Initiation of these pathways depends on the cytosolic adapter protein Shc, the activation of PLC- γ and the activation of the PI-3-kinase/AKT-pathways directly at the level of the trk transmembrane tyrosine kinases.

The Shc adapter proteins have been the focus of research, as they can couple trk-signaling to the Ras/MAP-kinase pathway. This pathway is involved in promoting neuronal survival and neurite outgrowth. Experiments with PC-12 cells (Bar-Sagi & Feramisco, 1985), with primary sympathetic neurons (Borasio *et al.*, 1993) and with mice in which the Shc binding site in trk receptors is altered demonstrate that activated Ras supports differentiation and survival of neuronal cells. At least in PC-12 cells, sustained activation of the MAPK pathway (Aletta, 1994; Traverse *et al.*, 1992; Wixler *et al.*, 1996) supports differentiation vs mitogenic effects of NGF in comparison to epidermal growth factor (EGF), and sustained activation of the MAPK pathway also appears necessary for neurotrophin-mediated survival of motoneurons. Moreover, a second Ras-independent pathway for activation of the MAPK pathway has been found to be involved in mediating the differentiation effects of NGF (York *et al.*, 1998). This redirects the focus of interest

on activation mechanisms upstream from Ras and other small GTP-binding proteins, which transduce the signal from receptor molecules to the MAPK and other intracellular signaling pathways.

In neurons, several forms of Shc exist, which are named ShcA, ShcB, and ShcC/N-shc (Cattaneo & Pelicci, 1998). The expression of these Shc isoforms is under strict control during development. The ratio of ShcA and ShcC/N-Shc expression deserves particular attention. ShcC/N-Shc has been detected as a neuron-specific Shc isoform (Nakamura *et al.*, 1996), which mediates the coupling of trk signaling to Ras activation. Whereas ShcA is expressed ubiquitously, ShcC expression is only found in the nervous system. The upregulation of ShcC corresponds to downregulation of ShcA expression in the brain at a developmental stage when neuronal cells become postmitotic (Conti *et al.*, 1997) and at least some populations of neurons including the motoneurons become dependent on neurotrophic factors for their survival. It is tempting to speculate that this switch from ShcA to ShcC expression is responsible for a switch in response to neurotrophic factors from a differentiation signal to a survival signal (Segal & Greenberg, 1996). This could be of importance for understanding how developing motoneurons become responsive to neurotrophic factors for their survival.

Recent evidence from mice in which the Shc binding site in trkB was mutated (Minichiello *et al.*, 1998) suggests that differences between various neurotrophic factors exist in the utilization of this pathway for survival and neurite outgrowth. Mice in which the Shc binding site of trkB is mutated show that NT-4-mediated survival effects were reduced more dramatically than BDNF-dependent differentiation or survival. These mice display a complete loss of the NT-4-dependent D-hair sensory cells but no change in BDNF-dependent, slowly adapting mechanotransducing sensory neurons. However, survival of motoneurons has not been investigated in such mice so far, and it remains to be demonstrated whether survival or functional properties in subpopulations of motoneurons are altered when the Shc binding site is mutated in the trkB receptor. Nevertheless, this report showed that significant differences exist between various ligands in the activation of downstream pathways, even if shared receptor components such as trkB in the case of BDNF and NT-4 are involved.

Besides the Ras/MAPK pathway, a second pathway involving activation of PI-3K is highly important for neuronal survival (Dudek *et al.*, 1997). PI-3K can associate directly with trk receptors under various experimental conditions (Obermeier *et al.*, 1993). However, it is now accepted widely that Shc signaling plays a major role for activation of PI-3K downstream of trks in neuronal cells (Baxter

et al., 1995; Datta *et al.*, 1997; Greene & Kaplan, 1995). The PI-3-kinase in turn activates Akt, a serine/threonine kinase with a broad spectrum of substrates including the proapoptotic Bad (Datta *et al.*, 1997), caspase-9 (Cardone *et al.*, 1998), the forkhead transcription factor FKHRL1 (Brunet *et al.*, 1999) and IKK α kinase (Ozes *et al.*, 1999; Romashkova & Makarov, 1999). Future studies will show which of these downstream pathways could modulate motoneuron survival under pathophysiological conditions such as ALS.

A third important pathway, which could be of importance in particular for motoneurons is the activation of PLC γ 1 (Obermeier *et al.*, 1994; Segal & Greenberg, 1996; Tinhofer *et al.*, 1996). Activation of PLC γ 1 leads to increased release of free Ca²⁺ from intracellular stores, which in turn activates cyclic AMP response-element-binding protein (CREB) (Finkbeiner *et al.*, 1997). In addition, elevated intracellular Ca²⁺ levels have also been described to activate the small GTP-binding protein Rap1 but not Ras (Grewal *et al.*, 2000). Rap1 activates B-Raf but not Raf-1. In developing motoneurons, B-Raf is expressed at relatively high levels during the period of physiological cell death (Wiese *et al.*, 2001). Thus increased levels of Ca²⁺ could contribute to activation of Rafs, which seem to play a central role both in activation of the MAPK pathway and also as effector kinases for bcl-2, which phosphorylates BAD and thus inhibits its proapoptotic activity (Wang *et al.*, 1994, 1996).

Dysregulation of these processes might also contribute to the pathophysiology of motoneuron disease, and future studies have to show which members of the Shc family are expressed in motoneurons in ALS patients, and whether changes in expression levels could alter signals from target tissues, glial cells and possibly also from pharmacologically applied neurotrophic factors.

The role of neuronal activity and glutamate for motoneuron survival

Removal of afferent synapse activity leads to increased cell death *in vivo* (Okado & Oppenheim, 1984) in various neuronal cell types. This finding corresponds to observations in cell culture that neurons can be maintained under conditions that mimic depolarization, such as elevated potassium concentration (Wakade *et al.*, 1983) or even addition of glutamate receptor agonists at optimal concentrations (Meyer Franke *et al.*, 1995). However, various types of neurons differ in their capacity to survive in culture in the presence of increased levels of potassium or glutamate. Whereas 35 mM K⁺ in the culture medium supports survival of sympathetic neurons from 10-day-old chick

embryos (Wakade *et al.*, 1983), motoneurons from 5- or 6-day old chick embryos cannot survive for periods longer than 3 days under the same conditions. In this respect, motoneurons resemble retinal ganglion cells, which cannot survive for prolonged periods with elevated potassium concentration in the culture medium (Meyer Franke *et al.*, 1995). On the other side, BDNF-mediated survival was enhanced strongly in isolated retinal ganglion cells when the cells were depolarized or when NMDA or kainic acid were added to these cultures. The effect appears to be mediated by elevation of cAMP, as inhibitors of protein kinase A inhibit the potentiation of the BDNF survival effect by increased potassium or glutamate agonists. These data also suggest that intracellular Ca^{2+} elevation is involved in potentiating survival effects of neurotrophic factors.

Glutamate toxicity is considered as a major pathomechanism in amyotrophic lateral sclerosis (Choi, 1992). Although first clinical trials with specific glutamate receptor inhibitors failed (Gredal *et al.*, 1997), Riluzole is thought to delay progression of the disease by interfering with excitotoxic mechanisms (Bensimon *et al.*, 1994). However, it is not clear whether the effect occurs at the presynaptic or postsynaptic site, or even by interference with pathogenic mechanisms other than glutamatergic signaling such as presynaptic potassium channels.

Embryonic motoneurons express NMDA receptors (Kalb *et al.*, 1992) and AMPA receptors including subtypes of AMPA receptors that mediate Ca^{2+} influx in response to glutamate (Metzger *et al.*, 2000). When these motoneurons are exposed to enhanced concentrations of glutamate or NMDA in vitro, motoneuron cell death is not enhanced (Metzger *et al.*, 1998). This seems surprising with respect to the observation that massive cell death occurs under the same conditions in other types of neurons, for example in cultures of cortical neurons (M.S., unpublished observations). Even when the motoneurons are depolarized in order to remove the Mg^{2+} -block in NMDA receptors, this does not influence the survival of motoneurons in cell culture. On the other hand, NMDA or glutamate exposure does not potentiate the survival effect of BDNF or other neurotrophic factors, as observed with isolated retinal ganglion cells (Meyer Franke *et al.*, 1995). Despite this negative effect, motoneurons show specific responses to enhanced glutamate levels in the culture medium. Glutamate treatment leads to specific inhibition of dendrite growth in a fully reversible manner. Axon outgrowth was not affected under the same culture conditions by glutamate exposure, suggesting that glutamate could play an important role in plasticity of dendrite growth and synapse formation between motoneurons and other types of neurons within the spinal cord.

An active role of NGF signaling in motoneuron cell death?

Genetic determination of cell death plays an important role during development of non-vertebrates such as *Caenorhabditis elegans*. The *ces-2* gene apparently acts cell-autonomously to trigger programmed cell death (Metzstein *et al.*, 1996). *Ces-2* is expressed specifically in two distinct pharyngeal motoneurons in the worm and initiates death in these specific cells. Such cell-autonomous cell death genes have not been identified so far in motoneurons from higher vertebrates, although it is likely that they could play a role, for example during an early phase of development when motoneuron cell death apparently occurs in a target-independent manner. The cell death receptor Fas and the corresponding Fas ligand are expressed in early motoneurons, and Fas has been found to transmit a cell death signal in cultured motoneurons from 12.5-day-old mouse embryos (Raoul *et al.*, 1999). Fas and Fas-ligand are expressed early during development in motoneurons, and coexpression of these two molecules is expected to confer cell-autonomous cell death programs. When embryonic motoneurons are cultured for 3 days with neurotrophic factors, they become resistant to Fas-induced cell death, either by interference with downstream-effectors such as activated caspase-8 and caspase-3, or by promoting motoneuron maturation to a stage when they are resistant to other mediators of cell-autonomous cell death programs, or by both mechanisms. Thus, Fas and Fas-ligand could play a role during early stages of motoneuron cell death when these cells do not yet depend, or even cannot react, to neurotrophic factors, and further studies for example involving Bid-deficient mice, which are resistant to Fas-induced cell death, could be of great help in understanding the physiological role of Fas-mediated cell death for motoneurons.

The p75 neurotrophin receptor (p75^{NTR}) shares structural and functional similarities with other transmembrane molecules of the Fas/Apo-1/CD95 and tumor necrosis factor receptor – 1 family (for review see Nagata, 1997). In a variety of cellular contexts in vitro and in vivo, p75^{NTR} mediates cell death after the binding of NGF, in particular when *trkA* is not expressed (Chao *et al.*, 1998; Friedman & Greene, 1999). Injection of neutralizing antibodies into the eye of early chick embryos has shown that NGF and p75^{NTR} are involved in early developmental cell death of retinal ganglion cells that have just been formed and are starting to grow axons (Frade *et al.*, 1996; Frades Barde, 1998). This early phase of cell death is not regulated by the target tissue. In the specific case, the source of NGF were microglial cells that had invaded the retina

during these early developmental stages (Frade *et al.*, 1996).

The role of p75^{NTR} as a mediator of cell death has also been shown in basal forebrain cholinergic neurons (Yeo *et al.*, 1997). Overexpression of the cytoplasmic part of the p75^{NTR} in mice (Majdan *et al.*, 1997) leads to significant loss of several populations of neurons, including motoneurons in the facial nucleus. Thus, it appears intriguing that p75^{NTR} could have similar functions in motoneurons, in particular when this receptor is expressed at high levels after axotomy. When the expression of this receptor was abolished in adult p75^{NTR} $-/-$ mice, survival and regeneration of axotomized motoneurons were improved in comparison to control animals (Ferri *et al.*, 1998), and overexpression of the cytoplasmic part of p75^{NTR} enhances lesion-induced cell death of facial motoneurons in adult mice (Majdan *et al.*, 1997). Moreover, application of NGF to axotomized sciatic (Miyata *et al.*, 1986) or facial (Sendtner *et al.*, 1992a) motoneurons significantly increases the rate of cell death (Wiese *et al.*, 1999b). These results are compatible with the assumption that p75^{NTR} is a cell death receptor in developing motoneurons. On the other side, and in contrast to other neuronal populations (Bamji *et al.*, 1998; Van der Zee *et al.*, 1996, 1998; Yeo *et al.*, 1997), the number of motoneurons in 6–9 week old p75^{NTR} $-/-$ mice is reduced in comparison to wild-type mice, as revealed by quantification of facial motoneuron numbers and axon profiles in brainstem and peripheral nerves (Ferri *et al.*, 1998; Wiese *et al.*, 1999b). However, in the case of basal forebrain cholinergic neurons, contradictory results have been obtained in the meantime so that at least one of the originally published reports apparently is not reproducible, and the findings thus do not support a proapoptotic function through the p75 neurotrophin receptor as has been reported originally for postnatal basal forebrain cholinergic neurons (Van der Zee *et al.*, 1996).

Motoneurons do not only express high levels of p75^{NTR} in neurodegenerative disease including ALS (Kerckhoff *et al.*, 1991) or after axotomy, but also under physiological conditions during early development. Expression of this receptor molecule occurs before the motoneurons contact skeletal muscle and before they become responsive to neurotrophins for their survival. In order to test the possibility that NGF and p75^{NTR} are mediators of the early phase of motoneuron cell death in brachial spinal cord, cell death in the spinal cord of p75^{NTR} $-/-$ and NGF $-/-$ mice has been investigated. Between E10.5 and 12.5, before the period of classical target-dependent cell death starts (Frade & Barde, 1999), an increase in the thickness of the mantel zone was observed. However, the number of ISLET-1 positive motoneurons was not increased

in the ventral portion of the spinal cord of these mutant mice.

The role of p75^{NTR} in motoneuron cell death is different at later developmental stages (Wiese *et al.*, 1999b). NGF reduces the survival effects of BDNF and NT-3 in wild-type but not in p75^{NTR} $-/-$ motoneurons. These data thus favor a model of p75^{NTR} functioning as a cell death receptor in motoneurons. However, the quantities of NGF that interfere with the survival responses of BDNF and NT-3 are very low (7×10^{-13} M) (Fig. 8.1). They do not reach the levels necessary for saturating those low-affinity binding sites on primary neurons that are thought to correspond to p75^{NTR} receptors (Meakin & Shooter, 1992; Rodriguez-Tébar *et al.*, 1990). It has been described that p75^{NTR} can be expressed in neuronal cells in a conformation conferring high-affinity binding of NT-3 (Dechant *et al.*, 1997). However, under the same experimental conditions, NGF did not bind to p75^{NTR} when added at 10^{-12} M.

Observations that very low quantities of NGF interfere with BDNF and NT-3 effects in neurons could be explained by a model in which the p75^{NTR} is part of the high-affinity receptors for BDNF and NT-3. Previous observations that NGF enhances motoneuron survival at later developmental stages in chick (Qin-Wei *et al.*, 1994) when p75^{NTR} expression is low (Ernfors *et al.*, 1988) suggest that the presence of p75^{NTR} increases the specificity of BDNF and NT-3 binding to their receptors. Reduction of NT-3- and BDNF-mediated survival by NGF is not seen in p75^{NTR} $-/-$ motoneurons. This observation supports the model that p75^{NTR} receptors are components of the high-affinity binding sites for NT-3 and BDNF on E14 lumbar motoneurons and do not constitute separate NGF receptors. The BDNF dose necessary for half-maximal survival is shifted from 1.2×10^{-12} M in wild-type motoneurons to 5.4×10^{-12} M in p75^{NTR} $-/-$ motoneurons. This supports previous data that trk homodimers are not equivalent to high-affinity neurotrophin receptors in primary neurons (Mahadeo *et al.*, 1994; Wolf *et al.*, 1995). Thus p75^{NTR} appears as part of the high-affinity receptor complex for BDNF and possibly also NT-3 on motoneurons. Only part, if any, of the p75^{NTR} transmembrane molecule receptors should exist separately and function independently as cell death receptors on these cells. In the latter case, one would expect that NGF signaling through p75^{NTR} should also reduce the survival response mediated through CNTF or GDNF receptors. However, even high quantities of NGF (20 ng/ml) known to saturate low-affinity receptors on neuronal cells (Rodriguez-Tébar *et al.*, 1990) did not reduce CNTF- and GDNF-mediated survival of motoneurons. This was surprising insofar as the CNTF-mediated survival response of embryonic chick mesencephalic trigeminal neurons was

Fig. 8.1 NGF antagonizes BDNF-mediated survival of mouse motoneurons in culture. Motoneurons were isolated from lumbar spinal cord of 14-day-old mouse embryos (Wiese *et al.*, 1999b). Survival of motoneurons was determined by counting surviving motoneurons after 3 days in culture. Values shown are a percentage of initially plated neurons in the culture dish. BDNF and NGF were added at concentrations indicated at 10 or 100 pg/ml. The survival effect of BDNF is significantly reduced in the presence of NGF at equimolar concentrations, and completely abolished when NGF is given at doses 10 times higher than BDNF. Note that maximal concentration of NGF in this experiment was 100 pg/ml, which is below the concentration thought to saturate low-affinity neurotrophin receptors. NGF could not reduce the survival response initiated by GDNF, even when the concentration was increased to a level of 1000 pg/ml, thus suggesting that NGF acts as a specific antagonist, probably at the receptor level, rather than acting as an independent cell death effector on these cultured motoneurons.

reduced by NGF (Davey & Davies, 1998). Thus, the role of p75^{NTR} differs depending on cell type and developmental stage. Whether such differences are caused by the presence or absence of downstream-effectors of trk and p75^{NTR} signaling, or simply by the fact that apoptosis through p75^{NTR} requires higher expression levels than those found in motoneurons from E14 mouse spinal cord, remains to be seen.

Downstream signals which mediate the neuronal survival response to neurotrophins and CNTF: the role of members of the IAP family

Not very much is known about the downstream signals involved in execution of motoneuron cell death and neurotrophic factor-mediated survival. Research on the role of bcl-2 has guided the way to our present knowledge. Overexpression of bcl-2 significantly reduces the extent of motoneuron cell death during development (Dubois-Dauphin *et al.*, 1994; Martinou *et al.*, 1994). However, mice in which bcl-2 expression is abolished by homologous recombination show only a small reduction of motoneuron numbers at birth (Michaelidis *et al.*, 1996), indicating either that bcl-2-related molecules can substitute for this deficiency or that bcl-2 and related molecules are not necessary physiologically for motoneuron survival during development. Motoneuron cell death in bcl-2 $-/-$ mice is enhanced only during the postnatal period, leading to loss of 40% of facial motoneurons in 6-week-old mice. This suggests that bcl-2 becomes important for postnatal survival at least of subpopulations of motoneurons. However, bcl-2 deficient motoneurons do not lose their responsiveness to neurotrophic factors. BDNF and CNTF are still capable of rescuing motoneurons from lesion-induced cell death after facial nerve transection in newborn animals. Nevertheless, survival in response to these neurotrophic factors was lower in bcl-2 deficient mice, indicating that subpopulations depend on bcl-2 for survival after nerve lesion, and/or that compensation by other antiapoptotic members of the bcl-2 family is only incomplete in these cells.

Observations that neurons from BAX-deficient mice (Deckwerth *et al.*, 1998; Knudson *et al.*, 1995) are resistant against cell death after neurotrophic factor deprivation provide a second indication that members of the bcl-2 family are involved, and that mitochondria play a role in motoneuron cell death. Recently, it has been shown that BAX-dependent release of cytochrome c from mitochondria plays an essential role in the initiation of cell death in NGF-deprived sympathetic neurons (Deshmukh & Johnson, Jr., 1998). However, microinjection of cytochrome c into the cytoplasm could not initiate cell death when the primary sympathetic neurons were grown in the presence of NGF. Based on these observations, it was speculated that NGF leads to a rapid production of an intracellular protein, which protects cells from proapoptotic actions of cytochrome c (Newmeyer & Green, 1998). Furthermore, it was concluded that such protective molecules are expressed at low basal levels and upregulated within a short time after NGF exposure.

Members of the IAP/ITA family are candidates for such protective proteins. They inhibit the activation of procaspase-9 (Deveraux *et al.*, 1998), which is initiated by cytochrome c and Apaf-1 (Slee *et al.*, 1999; Stennicke *et al.*, 1999). Furthermore, they inhibit the function of activated caspase-3, -6 and -7, and thus interfere at at least two levels with cellular programs for apoptosis (Deveraux *et al.*, 1997; Roy *et al.*, 1997). The identification and cloning of the chick *ita* gene (Digby *et al.*, 1996), which encodes a protein of 611 amino acids with highest homology to human cIAP-2, allowed investigation on the role of this protein in NGF-mediated survival of developing chick neurons. ITA expression is induced rapidly by neurotrophic factors (Fig. 8.2). This upregulation of ITA mRNA and protein levels involves the PI-3K pathway. Overexpression of ITA in primary sensory and sympathetic neurons can promote neuronal survival in the absence of NGF, and antisense expression of ITA abolishes NGF-mediated survival in sensory and sympathetic neurons. These actions involve the baculovirus IAP repeat (BIR) domains of the ITA protein, as expression of a BIR-deleted form of ITA was without any effect on neuronal survival.

These data suggest that members of the IAP family, which include the mammalian IAP-2 and XIAP, are key regulators in the signaling machinery for neurotrophic factor-mediated neuronal survival. The expression of inhibitors for caspases could be an essential mechanism, which contributes to motoneuron survival once these caspases are activated (Fig. 8.3), and they probably could be of high importance in protecting motoneurons against any kind of proapoptotic signaling that occurs during postnatal life.

Animal models for human motoneuron disease

Despite significant progress in the understanding of survival and cell death signaling for developing motoneurons, little is known about how these mechanisms relate to pathological cell death in human motoneuron disease. A subtype of autosomal dominant familial amyotrophic lateral sclerosis is caused by mutations of the superoxide-dismutase gene (Rosen *et al.*, 1993; Deng *et al.*, 1993). Overexpression of mutated SOD-1 in motoneurons causes cytoplasmic aggregation of the enzyme, and neurons with such aggregates subsequently undergo apoptotic cell death (Durham *et al.*, 1997). Mice in which mutated SOD-1 (G93A) is overexpressed exhibit postnatal degeneration of motoneurons (Gurney *et al.*, 1994). When these mice are crossbred with *bcl-2* overexpressing mice, onset of disease is delayed (Kostic *et al.*, 1997), suggesting that

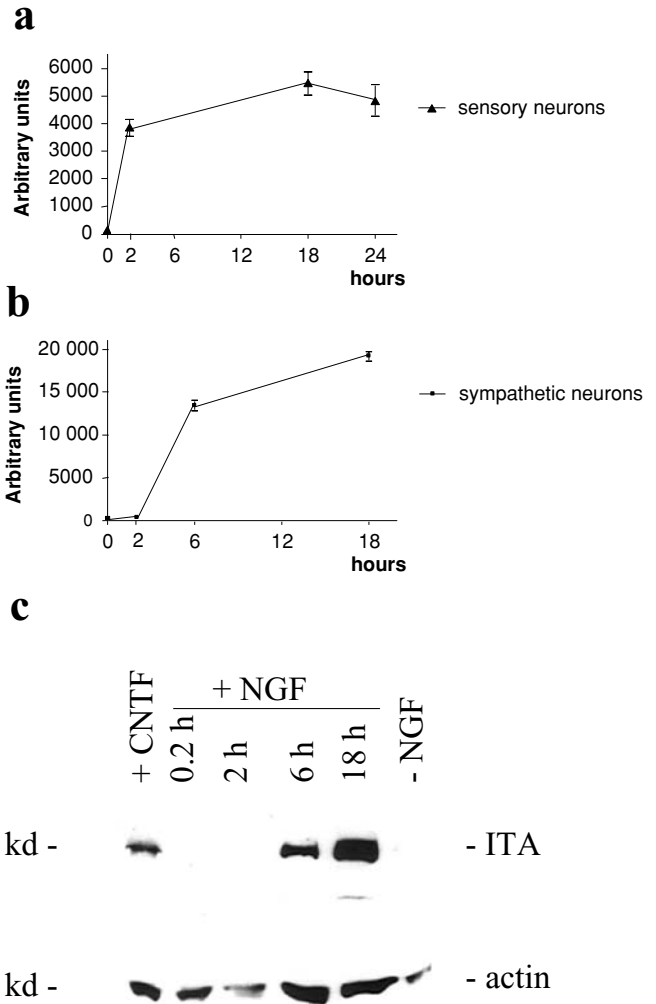

Fig. 8.2 NGF and CNTF promote rapid upregulation of the IAPs in cultured neurons. IAPs are potent inhibitors of caspases, and thus could participate in the survival response of neurons to neurotrophic factors. See Wiese *et al.* (1999a) for details. Reproduced with permission from this publication.

bcl-2 protects the motoneurons from pathogenic processes caused by mutated SOD-1. Therefore, whatever the pathogenic process in patients with mutations of SOD-1 or in transgenic mice overexpressing mutated SOD-1 is, it seems to interfere with classical cell death programs.

Similar findings have also been made with other mutant mice in which the underlying gene mutation is not known so far. Treatment with neurotrophic factors can interfere with motoneuron degeneration in mouse mutants, such as progressive motoneuronopathy (pmn) (Sendtner *et al.*, 1992b) and wobbler (Mitsumoto *et al.*, 1994) mice, and it is not clear whether the underlying gene defects are involved

Fig. 8.3 Signaling pathways for neurotrophic factor-mediated survival of motoneurons. Recent studies (Deshmukh & Johnson, Jr., 1998) have shown that injection of cytochrome-C into the cytoplasm of cultured neurons can induce apoptosis only when nerve growth factor is absent or added after the injection of cytochrome-C. This has led to the conclusion that nerve growth factor and other neurotrophic factors lead to upregulation of an activity, which directly interferes with the activation of apoptosome activity and downstream caspases. In the absence of neurotrophic factors, cytochrome-C is released from mitochondria by a process in which Bax is involved. This leads to the formation of apoptosomes by a process also requiring Apaf-1 and ATP. By this means, procaspase-9 is cleaved and activated. Caspase-9 in turn can cleave procaspase-3, -6 and/or -7, which then activate downstream substrates, among them ICAD (inhibitor of caspase-activated Dnase (CAD)) and finally leads to apoptosis of the neuron. Members of the IAP-family (inhibitor of apoptosis protein) can block activated caspases and inhibit these regulatory steps in the execution of apoptosis. In cultured sensory and sympathetic neurons, NGF and CNTF upregulate ITA expression at least 20-fold. This upregulation takes place within less than 6 hours. Thus, ITA and mammalian homologues of this protein could be essential mediators in the downstream signaling machinery for neurotrophic factor-mediated survival of primary neurons.

in cell death or survival signaling pathways. Overexpression of bcl-2 in pmn mice does not delay the onset of the disease or prolong survival of pmn mice, although it inhibits the degeneration and cell death of motoneurons cell bodies in these mutant mice (Ikeda *et al.*, 1995). Similar observations have also been made when pmn mice were treated with GDNF (Sagot *et al.*, 1996). However, in contrast to CNTF, GDNF treatment does not lead to prolonged survival of the pmn mice. Although this neurotrophic factor reduces the extent of degeneration of motoneuron cell bodies, the degeneration of axons was not prevented, indicating that various families of neurotrophic factors differ in their potential to influence specific parameters of motoneurons such as axon maintenance or axon regeneration, at least in pmn mice.

During recent years accumulating evidence suggests that nitric oxide (NO) also plays a role in motoneuron cell death (Estevez *et al.*, 1998b; Estevez *et al.*, 1998a). Deprivation of embryonic motoneurons in culture from neurotrophic factors leads to enhanced production of neuronal nitric acid synthetase. Moreover, enhanced nitrotyrosine immunoreactivity could be observed in these motoneurons. NOS inhibitors could prevent apoptosis of cultured motoneurons, at least for short periods up to 3 days. Similar findings were made when a cell-permeable scavenger of superoxide was added to neurotrophic factor deprived motoneurons in culture. Thus enhanced superoxide and NO production, possibly also the production of peroxynitrite, could play a role as proapoptotic signals, which represent a first step in the execution of cell death in motoneurons. Recently, it was

demonstrated that NO mediates the cell death of motoneurons when the superoxide-dismutase protein lacks a zinc ion, a scenario which could underlie familial ALS (Estevez *et al.*, 1999). Nevertheless, very little is known so far about how these pathways are connected with activation of caspases in motoneurons, or whether these mechanisms represent an independent proapoptotic stimulus, which acts in a caspase-independent fashion.

First evidence for interaction between these proapoptotic stimuli was shown by crossbreeding mice carrying the G93A mutation in the SOD gene with mice overexpressing a dominant-negative ICE isoform, which prevents caspases from activation of cell death pathways (Friedlander *et al.*, 1997). Thus, it will be interesting to know how neurotrophic factors interfere with such proapoptotic pathways. This could be at the transcriptional level, preventing the upregulation of proapoptotic genes such as NOS, or by upregulation of members of the IAP family, which block caspase activity. Future research has to show how pro- and antiapoptotic signaling in motoneurons is regulated in individual motoneurons, and how individual cell-specific genetic programmes at specific developmental stages, and signals from contacting cells such as muscle, glial cells and neurons, play together in these regulatory processes.

Protein misfolding and cellular defense mechanisms in neurodegenerative diseases

Michael Y. Sherman¹ and Alfred L. Goldberg²

¹Department of Biochemistry, Boston University Medical School, MA, USA

²Department of Cell Biology, Harvard Medical School, Boston, MA, USA

Introduction

In many major neurodegenerative diseases, including amyotrophic lateral sclerosis (ALS), Alzheimer's disease, Parkinson's disease, and several hereditary diseases caused by expansions of polyglutamine (PolyQ) tracts (e.g. Huntington's disease and the spinocerebellar ataxias) (Table 9.1), the pathology and the eventual death of specific neuronal populations occur due to the accumulation of specific abnormal polypeptides, which form insoluble intracellular inclusions. Many observations suggest that these various types of inclusions arise through common mechanisms and elicit similar host responses. For example, all these inclusions contain components of the ubiquitin-proteasome degradation pathway and also molecular chaperones, which represent the two main systems that eukaryotic cells use to protect themselves against the buildup of unfolded polypeptides. The accumulation of abnormal polypeptides in the form of inclusions in various neurological disorders must result from an inability of neurons to either refold or degrade these abnormal species. Because these neurological diseases are of late onset, and the very same mutant proteins are expressed without causing obvious pathology in younger individuals, it seems likely that the failure to adequately deal with these abnormal molecules progresses with aging.

Because the continued accumulation of unfolded, non-functional polypeptides is likely to cause cell toxicity, it is not surprising that defense mechanisms emerged early in evolution that enable cells to withstand the appearance of large amounts of unfolded proteins, as may result from mutations, errors in protein synthesis, or inefficient folding of nascent polypeptides. These mechanisms are activated upon various experimental conditions that cause widespread damage to cell proteins and massive accumulation of abnormal polypeptides, such as exposure to

high temperatures, oxygen radicals, heavy metals, certain antibiotics that reduce the fidelity of translation, or genetic diseases. It seems very likely that these defense mechanisms also function during the slower accumulation of mutant or damaged proteins in neurodegenerative disease. The major adaptation is the induction of a set of highly conserved heat-shock proteins (Hsps), which function as the major cellular defense against the buildup of unfolded proteins. Among the Hsps in eukaryotic cells are molecular chaperones (Feldman & Frydman, 2000; Frydman, 2001), which reduce protein denaturation and aggregation and promote refolding of denatured polypeptides, several antioxidant enzymes (Hass & Massaro, 1988; Xi *et al.*, 2001; Yamashita *et al.*, 1998), which reduce oxidative damage to cell proteins, and components of the ubiquitin-proteasome pathway (Seufert & Jentsch, 1990; Sommer & Seufert, 1992; Watt & Piper, 1997), which catalyse the selective degradation of unfolded polypeptides (Glickman & Ciechanover, 2002; Hershko & Ciechanover, 1998; Schwartz & Ciechanover, 1999) (Table 9.2).

The trigger for induction of the heat shock proteins is the accumulation of unfolded polypeptides in the cytosol or nucleus (Ananthan *et al.*, 1986; Goff & Goldberg, 1985). For example, the heat-shock response can be induced by treatments that cause the production of large amounts of abnormal polypeptides, such as incorporation of amino acid analogs (which prevent normal folding) or puromycin (which leads to premature termination of nascent polypeptides) (Goff & Goldberg, 1985). Furthermore, direct microinjection into cells of unfolded polypeptides or the expression of recombinant abnormal polypeptides, but not the corresponding native proteins, induces this response (Ananthan *et al.*, 1986; Goff & Goldberg, 1985). Presumably, the ability of unfolded proteins to stimulate the expression of heat-shock genes may play an important role in protection from

Table 9.1. Neurodegenerative diseases with inclusion bodies associated with ubiquitin and proteasome

Disease	Inclusion	Major Constituent
Alzheimer's	Neurofibrillary tangles	Tau
Parkinson's	Lewy body	α -synuclein, crystallins
Lewy body dementia	Lewy body	α -synuclein
Amyotrophic lateral Sclerosis	Skein, Bunina bodies	SOD, neurofilaments
<i>Polyglutamine extension disorders</i>		
Huntington's	Nuclear, cytosolic	huntingtin
Spinocerebellar Ataxias 1, 2 and 3	Nuclear, cytosolic	ataxins 1, 2 and 3
Spinobulbar muscular Atrophy (Kennedy's)	Nuclear, cytosolic	Androgen receptor

Table 9.2. Functions of cytosolic and ER chaperones probably important for protection against neurodegenerative diseases

- Prevent aggregation of mutant and damaged proteins
- Catalyze protein folding and multimer assembly
- Solubilize aggregated proteins in cells
- Promote ubiquitination and degradation of abnormal proteins
- In ER, promote proper folding and glycosylation of membrane and secreted proteins
- Suppress protein kinases (e.g. JNK) and thus inhibit apoptotic program
- Regulate their own expression in cytosol (heat shock response) and ER ("unfolded protein response")

neuronal loss in neurological disorders associated with accumulation of damaged and mutant proteins and their aggregation.

Cells also contain efficient mechanisms to prevent accumulation of mutant or misfolded proteins in the endoplasmic reticulum (ER). Such abnormal secreted or membrane molecules are transported from the ER back into the cytosol where they are rapidly degraded (da Costa *et al.*, 1999; Fewell *et al.*, 2001; Honda *et al.*, 1999; Kopito, 1999; Steiner *et al.*, 1998; Tsai *et al.*, 2002; Xiong *et al.*, 1999). This degradative process is important in various inherited diseases (e.g. cystic fibrosis), but the retrograde transport system may also account for the generation of the self-perpetuating forms of prion protein in neurons (Ma *et al.*, 2002). If this degradative mechanism is insufficient to prevent the accumulation of the abnormal proteins in the ER, cells

Ubiquitin conjugation to protein substrates

THE UBIQUITIN - PROTEASOME PATHWAY

**Fig. 9.1** Ubiquitin-proteasome pathway.

respond by activation of the "unfolded protein response". This transcriptional program is analogous to the heat shock response in the cytosol and is triggered by the buildup of unfolded proteins within the ER. This adaptive response increases production of a group of molecular chaperones in the ER (often termed Grps), many of which are homologous to the cytosolic Hsps (Chapman *et al.*, 1998; Welihinda *et al.*, 1999). This adaptation further enhances the ER's capacity to generate properly folded membrane and secreted proteins and to translocate such unfolded molecules back into the cytosol for degradation by the ubiquitin-proteasome pathway (Fig. 9.1). Interestingly, defects in the "unfolded protein response" have been observed in cells that express the mutant Presenilin 1 (Imaizumi *et al.*, 2001; Katayama *et al.*, 2001; Katayama *et al.*, 1999), which predisposes to Alzheimer's disease (see below).

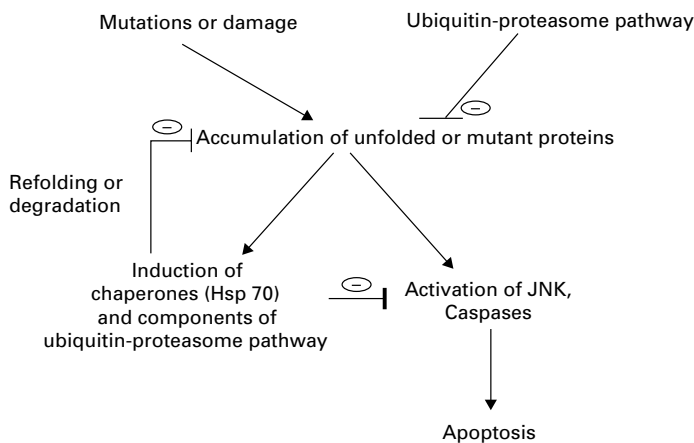

Fig. 9.2 Induction of protective and apoptotic programs by abnormal proteins.

Protective functions of heat shock proteins

Molecular chaperones, i.e. members of the Hsp70, Hsp90, Hsp104, Hsp40, and small Hsp (Hsp27, α -crystallins) families, bind selectively to denatured or partially unfolded domains in polypeptides (Feder & Hofmann, 1999; Johnson & Craig, 1997; Samali & Orrenius, 1998). Most of these chaperones are major cell constituents under normal conditions, where they are essential to ensure the proper folding and intracellular localization of newly synthesized polypeptides (Table 9.2). Surprisingly, in spite of the function of molecular chaperones, a significant fraction (perhaps up to 30%) of newly synthesized polypeptides normally fails to achieve the correct conformation and is rapidly digested (Schubert *et al.*, 2000). Under conditions that cause protein damage (e.g. heat shock) or upon accumulation of mutant proteins (e.g. huntingtin with expanded polyQ sequences), the cell's need for the chaperones increases, and their expression is stimulated (Fig. 9.2). Cells also utilize the capacity of chaperones to bind selectively unfolded polypeptides to monitor the intracellular levels of such abnormal, potentially toxic molecules. In unstressed cells, the expression of heat shock genes normally is inhibited by the presence of molecular chaperones (Baler *et al.*, 1996; Liberek *et al.*, 1992; Voellmy, 1996). Increased transcription of the heat shock genes is triggered when the abnormal proteins accumulate and bind preferentially to Hsp 90 (Zou *et al.*, 1998) and Hsp70 (Shi *et al.*, 1998), thus preventing these chaperones from inhibiting the expression of heat shock genes.

Damage from oxygen radicals has been associated with several neurodegenerative diseases and accompanies acti-

vation of inflammatory responses. A specific group of heat shock proteins serves to protect cells against oxygen free radicals. For example, superoxide dismutase, heme oxygenase, and catalase can all be induced as part of the heat shock response and help protect against oxidative damage to cell proteins, DNA, and lipids (Amrani *et al.*, 1993; Massa *et al.*, 1996). If any of these enzymes is overproduced in transgenic animals or in cultured cells, it can protect cells from ischemia-reperfusion injury (Chan, 1996), which is associated with extensive production of reactive oxygen species (ROS) and oxidative protein damage. Another enzyme that appears to play an important role in maintaining the proper redox potential in the cytosol is gamma-glutamylcysteine synthetase, a rate-limiting enzyme in the synthesis of glutathione (Soltaninassab *et al.*, 2000). Gamma-glutamylcysteine synthetase is strongly induced in response to oxidative stress and other stressful treatments that lead to protein damage, and this enzyme therefore is likely to be important for cell protection (Sekhar *et al.*, 2000; Soltaninassab *et al.*, 2000). The amino acid in proteins most susceptible to oxidative damage is methionine, and many tissues, especially the brain and retina, contain the enzyme methionine sulfoxide reductase (Kuschel *et al.*, 1999); (Moskovitz *et al.*, 1996), which specifically repairs this type of damage to proteins. Decreased levels of this enzyme have been reported in brains of Alzheimer's disease patients (Gabbita *et al.*, 1999), while overexpression of this enzyme helps protect cells from oxidative stress (Moskovitz *et al.*, 1998). Enzymes that protect from oxidative damage may be particularly important in defense against Parkinson's and perhaps Alzheimer's diseases, where oxidative stress seems to be a critical aspect of the disease process.

Selective degradation of abnormal proteins

The ubiquitin-proteasome degradation system rapidly eliminates certain proteins, including mutant and damaged polypeptides, without causing non-specific destruction of other cell proteins. To achieve this selectivity, proteins to be degraded are first marked by covalent linkage to the small polypeptide cofactor ubiquitin (Fig. 9.1). The linkage of a chain of four or more ubiquitins to a lysine on the substrate marks it for rapid breakdown by the very large proteolytic complex, the 26S proteasome (Coux *et al.*, 1996; Glickman & Ciechanover, 2002; Hershko & Ciechanover, 1998; Rock *et al.*, 1994). The 26S proteasome consists of two 19S regulatory complexes situated at either end of the 20S core proteasome, a hollow, barrel-shaped structure, within

which proteins are degraded. Substrates first bind via their ubiquitin chains to the 19S regulatory complex (Fig. 9.1). This structure contains a ring of six homologous ATPase molecules, which have many of the properties of molecular chaperones; for example, they can unfold globular proteins and translocate them into the 20S proteasome for degradation (Benaroudj & Goldberg, 2000; Navon & Goldberg, 2001). Concomitantly, the regulatory complex releases the chain of ubiquitin molecules, which are then recycled for use in the degradation of other proteins.

The ubiquitin requirement for degradation and the isolation of proteolysis within a microcompartment of the cell, to which substrate entry is highly restricted, all help ensure that degradation occurs in a highly selective and efficient manner. Proteolysis occurs within the central chamber of the 20S proteasome, which contains six proteolytic sites, two of which preferentially cleave after hydrophobic residues, two after basic ones, and two after acidic residues (Coux *et al.*, 1996; Kisselev *et al.*, 1999a). Thus the proteasome, unlike typical proteases, does not simply cut a protein into two pieces, but instead these six sites function together to degrade proteins processively to small peptides ranging from three to 25 residues long (Kisselev *et al.*, 1999b). These products once released from the proteasome are hydrolyzed rapidly to amino acids by cytosolic peptidases. Thus, the proteasome has the capacity to cleave a large variety of peptide bonds within proteins, but it lacks the capacity to hydrolyze within repeated sequences of glutamine, which may be an important factor in the ability of extended polyglutamine sequences to cause neurodegenerative diseases (Ventrakaman & Goldberg, unpublished data).

The exquisite specificity of the degradative process results from the properties of enzymes for ubiquitin conjugation (Fig. 9.1). In this process, the ubiquitin molecule is activated first by the enzyme, E1, which transfers the ubiquitin to one of the cell's approximately 20 distinct ubiquitin-carrier proteins (E2s), which then, together with a specific ubiquitin-protein ligase (E3), transfers the activated ubiquitin molecule to lysine residues on the protein substrate. The selectivity in this pathway comes primarily from the E3. Mammalian cells typically contain hundreds of different E3s, which function with a specific E2 in the ubiquitination of different types of protein. Although much has been learned recently about E3 function (Fig. 9.1), it is still unclear exactly how most unfolded or damaged proteins are recognized and degraded selectively. Amongst the genes induced as part of the heat-shock response are certain ubiquitin-carrier proteins (E2s) and the polyubiquitin gene, which encodes multiple ubiquitin molecules in

a linear polymer (Glickman & Ciechanover, 2002; Hershko & Ciechanover, 1998; Watt & Piper, 1997). Its expression and subsequent cleavage represent a special mechanism that enables the cell to generate large amounts of ubiquitin quickly when the overall rate of proteolysis rises (Mitch & Goldberg, 1996) (Finley *et al.*, 1987).

The two main protective strategies, the repair of damaged proteins and their selective degradation, are complementary mechanisms to eliminate unfolded polypeptides, which may perturb cell function and initiate cell death programs (see below). However, refolding and degradation are not independent processes involving distinct cellular components, but rather appear to be linked at several levels. The ATPases within the 26S proteasome, in addition to promoting proteolysis, have chaperone-like activities and can block protein aggregation and even promote the refolding of denatured proteins (Braun *et al.*, 1999; Strickland *et al.*, 2000), at least in model experiments. In addition, the chaperones Hsp70 and Hsp40, not only play an important role in preventing aggregation and refolding, but are also essential for the ubiquitination and rapid degradation of many abnormal species (Bercovich *et al.*, 1997; Lee *et al.*, 1996a; Meacham *et al.*, 2001; Ohba, 1997; Sherman & Goldberg, 1996; Zhang *et al.*, 2001). Apparently, the capacity of these chaperones to associate selectively with unfolded polypeptides facilitates substrate recognition by E3s and perhaps degradation by proteasomes. One such E3, termed CHIP, seems to function together with Hsp70 and Hsp40 or with Hsp90 in the ubiquitination of various unfolded proteins (Meacham *et al.*, 2001; Murata *et al.*, 2001). It remains to be seen whether this system is important in degrading the abnormal proteins that cause these various neurodegenerative disorders. An interesting finding was that CHIP enhances the activity of Parkin, another E3 ligase, mutations which cause the majority of familial Parkinson's disease cases (Imai *et al.*, 2002).

The dual roles of the chaperones in refolding and degradation of unfolded proteins appear highly advantageous to the organism in dealing with damaged polypeptides (Table 9.2). Since it must be impossible for the chaperones to refold many types of abnormal proteins (e.g. certain mutant proteins or ones covalently damaged by oxygen radicals), the ability of the chaperones to also facilitate the destruction of these proteins appears quite important, since it should reduce the concentration of these toxic species in a cell. In many neurodegenerative disorders and upon aging, the capacity of both chaperone and degradation systems appear to be reduced (see below), which may result in the inability of certain populations of neurons to cope with mutant or damaged proteins, leading to neuronal toxicity.

Protein inclusions and aggresome formation

If a eukaryotic or prokaryotic cell's ability to degrade or refold abnormal polypeptides is exceeded, as occurs experimentally when a mutant protein is expressed at high levels or when the proteasome is inhibited, the denatured or partially unfolded molecules accumulate and tend to aggregate (Cotner & Pious, 1995; Dubois *et al.*, 1991; Gragerov *et al.*, 1991; Johnston *et al.*, 1998; Kampinga *et al.*, 1995; Klemes *et al.*, 1981; Prouty *et al.*, 1975; Wigley *et al.*, 1999) eventually forming large inclusion bodies. Because these structures have not been isolated and characterized rigorously biochemically in the various human diseases or animal models, their precise composition and the forces holding them together in these various conditions are largely unknown.

It had been assumed initially that the formation of inclusion bodies results solely from the inherent tendency of denatured protein molecules to associate with one other to form insoluble aggregates. However, recent findings indicate that inclusion body formation in mammalian cells is a more complex process, in which cellular machinery appears to be actively involved. Generally, these structures are found in the cytoplasm at the microtubular organization center (MTOC or centrosome) (Anton *et al.*, 1999; Fabunmi *et al.*, 2000; Garcia-Mata *et al.*, 1999; Vidair *et al.*, 1999; Wigley *et al.*, 1999; Wojcik *et al.*, 1996), while in the nucleus, these bodies tend to be found in discrete structures that had been termed "promyelocytic leukemia oncogenic domains" (PODS) (Anton *et al.*, 1999). Several recent publications indicate that the formation of these inclusions is a multistep process, which involves transport of smaller aggregates from the cell's periphery towards the MTOC along the microtubuli (Garcia-Mata *et al.*, 1999; Johnston *et al.*, 1998, 2002). Hsps, ubiquitinated proteins, ubiquitin-conjugating enzymes, and 26S proteasomes associate with the inclusion bodies (Anton *et al.*, 1999; Fabunmi *et al.*, 2000; Garcia-Mata *et al.*, 1999; Vidair *et al.*, 1999; Wigley *et al.*, 1999) and form a large structure, recently termed the aggresome (Johnston *et al.*, 1998). Aggregates of mutated membrane proteins, such as the CFTR variants in cystic fibrosis and the presenilin-1 mutant associated with Alzheimer's disease (Johnston *et al.*, 1998; Wigley *et al.*, 1999), as well as cytosolic abnormal proteins (Garcia-Mata *et al.*, 1999), can all be found in aggresomes. It is noteworthy that aggresome formation is accelerated when proteasome inhibitors are added to block the degradation of the abnormal polypeptides (Garcia-Mata *et al.*, 1999; Johnston *et al.*, 1998). The process of aggresome formation is very rapid, and the first indications of this process (e.g. the

relocalization of Hsp25 to the centrosome) can be seen 10 min after addition of a proteasome inhibitor (M. Borrelli, personal communication). It appears likely that reducing proteolysis generally exposes a process that occurs in patients during the slow progression of many neurodegenerative diseases.

In the neurodegenerative diseases associated with polyQ repeats, such as Huntington's disease and the spinocerebellar ataxias, as well as in Alzheimer's disease, and the prion disorders, the inclusions appear to involve protein-protein interaction that are especially stable due to extensive formation of β -sheet structures, which are held together by multiple hydrogen bonds (Bates *et al.*, 1998; Lathrop *et al.*, 1998). In addition, in the polyQ disorders some aggregated polypeptides may be covalently crosslinked by transglutaminase (Cooper *et al.*, 1997; Igarashi *et al.*, 1998; Kahlem *et al.*, 1998). Inclusion bodies formed by the polyQ-containing proteins are strikingly similar to aggresomes. When expressed in cultured cells, the polyQ-containing proteins form several inclusion bodies in the nucleus or one per cell in the cytosol. Results from several groups indicate that huntingtin fragments with an expanded polyQ tract form inclusions at the centrosome in the cytosol (Hoffner *et al.*, 2002; Meriin *et al.*, 2001; Sathasivam *et al.*, 2001; Waelter *et al.*, 2001), while ataxin 1-containing inclusions colocalize with promyelocytic leukemia bodies in the nucleus (Chai *et al.*, 1999b; Takahashi *et al.*, 2002). Like the formation of aggresomes, the generation of inclusion bodies requires transport of small aggregates to the centrosome along microtubuli, at least in some models of polyQ-expansion diseases (Muchowski *et al.*, 2002; Shimohata *et al.*, 2002).

Despite their chemical stability, protein aggregates composed of β -sheets, once formed are not necessarily permanent cellular components, and can disappear with time, due to protein refolding or degradation. In experimental models, the proteins in the inclusions appear to be in a dynamic state, continually turning over and being replaced by other unfolded molecules. For example, in transgenic mice, induction of huntingtin with an expanded polyQ repeat leads to the formation of inclusion bodies and neurodegeneration, but, if subsequently huntingtin expression is prevented, the inclusion bodies can disappear (Yamamoto *et al.*, 2000), apparently via a proteasome-dependent mechanism, since this process is blocked by proteasome inhibitors (Martin-Aparicio *et al.*, 2001). Moreover, the behavioral symptoms associated with the disease are reversed. Even when a large fraction of the cytosol of bacteria (Prouty *et al.*, 1975) or reticulocytes (Klemes

POSSIBLE INTERRELATION BETWEEN SOLUBLE ABNORMAL
PROTEINS AND LARGE INCLUSIONS

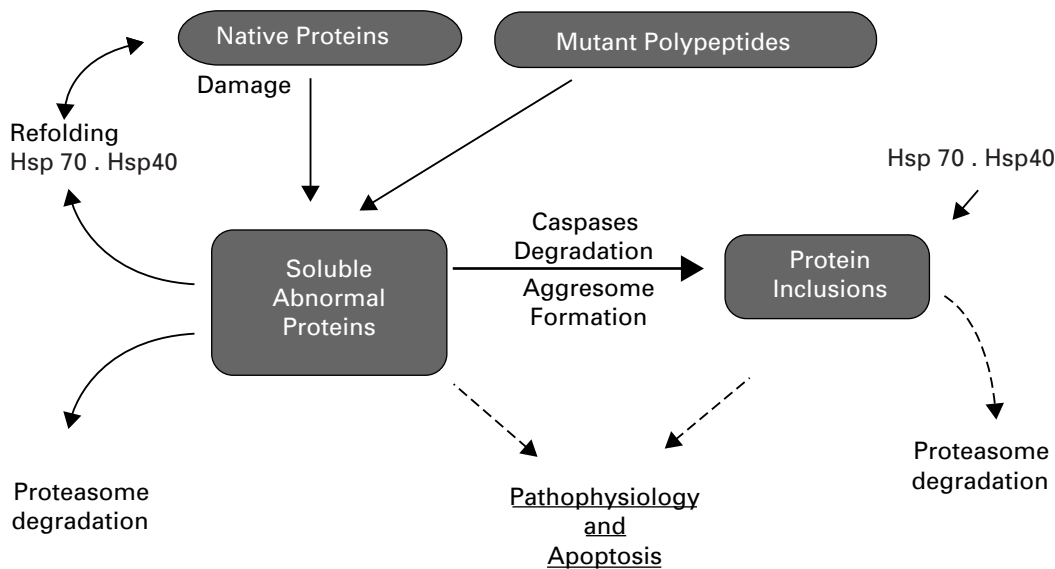

Fig. 9.3 Possible interrelation between soluble abnormal proteins and aggregated proteins. This model summarizes the different possible fates of a mutant or damaged protein in neurons and the factors that can influence these alternative paths. Once synthesized, the abnormal protein may be partially or completely unfolded and tend to form microaggregates with itself and with other cell constituents. Eventually, these structures can be transported into microscopically visible inclusions (resembling “aggresomes”). Opposing these developments are the molecular chaperones, which functioning in teams may refold or solubilize the abnormal polypeptides, and the Ub-proteasome pathway, which may degrade them. On the other hand, ubiquitin-conjugation or cleavage by caspases may also reduce the protein’s solubility, thus favoring formation of large inclusion bodies. There is also clear evidence that even after inclusion formation, the mutant polypeptides within these bodies can be degraded or solubilized. In addition, the soluble abnormal proteins, by interacting with other cell components may disturb neuronal function or by soaking up proteasomes or chaperones (especially Hsp70) can and trigger neurodegeneration and apoptosis. It remains unclear whether the insoluble inclusions also contribute to the neurodegeneration or if by sequestering the potentially damaging polypeptides, their formation may help reduce the cytotoxic effects. This summary also emphasizes how the apparent failure of abnormal proteins in aged organisms to activate the heat-shock response may reduce these protective mechanisms that help defend against these deleterious consequences.

et al., 1981) is occupied by such inclusions, the cells can completely eliminate these inclusions by proteolysis, if the production of the denatured proteins ceases. Similarly, in cells treated with a proteasome inhibitor, short-lived forms of the influenza virus nucleoprotein accumulated in the aggresome but then were lost rapidly from these structures after the inhibitor was removed (Anton *et al.*, 1999). Either the insoluble ubiquitinated proteins are digested directly by proteasomes (e.g. those present in the inclusions), or they undergo chaperone-mediated solubilization followed by proteasome-dependent hydrolysis. In either case, the aggresome may function as a storage compartment that protects the cell by temporarily isolating the denatured, potentially damaging polypeptides until they can be refolded or digested (Fig. 9.3).

The formation of inclusion bodies by mutant proteins in polyQ expansion diseases, like the formation of aggresomes in general, appears to be a highly regulated process. For example, treatment of cells with glucocorticoids was found to strongly suppress the aggregation and nuclear localization of both the androgen receptor and huntingtin fragments containing expanded polyQ sequences (Diamond *et al.*, 2000). This steroid hormone appears to be acting through its receptor to cause the transcription of a still-unidentified factor that inhibits the aggregation of these mutant proteins. Other components of cellular signaling pathways were also found to regulate the formation of inclusion bodies. When the protein kinase MEKK1, which catalyzes an early step in the JNK signaling pathway, is activated, it stimulates the formation of the inclusion

bodies (Meriin *et al.*, 2001). A similar enhancement of inclusion formation was seen upon expression of arfaptin 2, a guanine nucleotide exchange factor for small GTP-binding proteins (Peters *et al.*, 2002). Moreover, both MEKK1 and arfaptin 2 were found to be colocalized with the inclusion bodies. Since small GTP-binding proteins can regulate MEKK1, it is possible that both components are acting through the same signaling pathway, and may even be related to the glucocorticoid effect. Importantly, MEKK1 appears to promote an early nucleation step(s) in the formation of small seeds of polyQ aggregates, and it was hypothesized that this kinase activates a putative cellular factor that catalyzes the nucleation of polyQ aggregates (Meriin *et al.*, 2001).

In a *C. elegans* model of human Spinocerebellar Ataxia type 1, formation of inclusion bodies was regulated by the PI3-kinase pathway, which also involves AKT kinase and the transcription factor Forkhead (encoded by *daf-16* gene of *C. elegans*) (Morley *et al.*, 2002). This signalling pathway controls aging of the worms. Mutations in any of these signaling proteins reduced the formation of inclusion bodies and delayed the age of onset of cell abnormalities (Morley *et al.*, 2002). At present, it is not clear whether these effects are associated directly with alterations in this signaling pathway or related to a general delay in aging in the mutant worms. In any case, this finding is especially intriguing, since it establishes a link between signaling pathways that regulate formation of inclusion bodies and aging. Taken together, these observations further indicate that inclusion body formation represents a complex, regulated cellular response, even though the inherent tendency of unfolded proteins to aggregate and leave solution must play a key role. Further understanding of this process is of importance, since such information could have therapeutic implications.

The finding that a large fraction of the cell's chaperones and proteasomes are found in aggresomes (Fabunmi *et al.*, 2000), indicates that either inclusion bodies are sites specialized for protein refolding and proteolysis or, alternatively, that the aggregated polypeptides in the inclusion bodies resist degradation and may even trap proteasomes in nonfunctional degradative complexes. The trapping of proteasomes in inclusion bodies may contribute to a reduction in the total capacity of the cells for protein breakdown in neurological diseases (Bence *et al.*, 2001; Helmuth, 2001). Therefore, when the cell's protective machinery is overwhelmed with abnormal proteins, the stressed cells appear to localize them, together with the chaperones and degradative apparatus, in a special compartment in which the potentially toxic polypeptides can be resolubilized or refolded or undergo degradation. By

contrast, in non-stressed cells, where chaperones and the proteasome are dispersed throughout the cytosol and the nucleus, degradation of the majority of proteins appears to take place outside the aggresome. This segregation of the unfolded molecules within the aggresome probably also helps reduce the threat to cell homeostasis by limiting the capacity of these unfolded proteins to associate with other cell constituents (e.g. nascent polypeptides, cell membranes, etc.), which potentially could disrupt various cellular functions. On the other hand, in many models of neurodegenerative diseases inclusion bodies certainly cause toxicity, although the mechanisms of the toxicity associated with formation of inclusion bodies have not been dissected yet.

Like aggresomes, inclusion bodies containing proteins with polyQ domains (Chai *et al.*, 1999a; Cummings *et al.*, 1998; Wyttenbach *et al.*, 2000) and other abnormal polypeptides involved in neurological pathology associate in the cytosol with molecular chaperones, in this instance Hsc70 and Hsp40 (Fig. 9.3). Overexpression of these chaperones leads to an inhibition of the inclusion body formation in various disease models (Carmichael *et al.*, 2000; Chan *et al.*, 2000; Jana *et al.*, 2000; Zhou *et al.*, 2001), which is consistent with the well-established role of molecular chaperones in prevention of protein aggregation. Furthermore, reduction of Hsps levels by downregulation of the transcription factor HSF1 in *C. elegans* expressing ataxin-1 led to an increase in the formation of inclusion bodies and increased toxicity (Morley *et al.*, 2002). On the other hand, experiments with yeast models of polyQ expansion disease showed that the relationship between chaperones and inclusion body formation is more complex. There are two steps that can be distinguished genetically in inclusion body formation – seeding and growth of small aggregates. Mutations in chaperones Hsp104 and the Hsp40 homolog, Sis1, prevented seeding of the polyQ aggregates, while mutations in Hsp70 and another Hsp40 homolog, Ydj1, slowed down the growth of aggregates (Meriin *et al.*, 2002). Overexpression of either Hsp104 or Hsp70 also suppressed polyQ aggregation in these models (Muchowski *et al.*, 2000). Although the mechanisms of these effects are not understood, it appears that some optimal levels of chaperones are necessary for inclusion body formation, and over- or underexpression of various chaperones reduces the efficiency of aggregation.

Recent study in yeast models of polyQ expansion disease demonstrated that another factor that controls aggregation and toxicity of polyQ-containing polypeptides is the yeast prion Rnq1. Like other prions, this glutamine- and asparagine-rich protein (Sondheimer & Lindquist, 2000; Sondheimer *et al.*, 2001; Wickner *et al.*, 2001) can be present in cells in either a normal (soluble) or prion (insoluble)

conformation. The presence of molecules in the prion conformation forces soluble Rnq1 molecules to change their conformation and to join the aggregates. These aggregates can somehow propagate and be transferred into daughter cells. In a *rnq1* deletion strain, in spite of very high expression levels of polyQ, its aggregation was suppressed, and there was no toxicity. Furthermore, Rnq1 could promote aggregation of polyQ-containing polypeptides only when present in the prion conformation (Meriin *et al.*, 2002). The dependence on Rnq1 was specific for polyQ aggregation and was not seen with other polypeptides that form inclusions (e.g. a mutant form of SOD that can cause Amyotrophic Lateral Sclerosis) (Meriin *et al.*, 2002). The obvious question raised by these findings is whether the aggregation of proteins with expanded polyQ domains in neurons also requires an unknown prion-like protein.

Proteasomal hydrolysis of polyQ-containing proteins

It is unclear whether the presence within the inclusions of a high concentration of ubiquitinated proteins and proteasomes indicates that proteolysis is occurring at high rates in such structures or that there has been an unsuccessful attempt of the proteasomal apparatus to efficiently eliminate the abnormal insoluble molecules. The β -sheets formed by extended polyQ sequences and other fibril-forming polypeptides present in various types of inclusion bodies are likely to represent a major challenge for the proteasomal ATPases, which unfold and translocate substrates into the 20S particle (Navon & Goldberg, 2001). It is presently unknown how the proteasome digests a ubiquitinated polypeptide containing an extended polyQ domain, but it must do so successfully most of the time. For example, in Huntington's disease patients, the abnormal form of huntingtin accumulates in inclusions only in specific regions of the brain, even though this gene is also expressed in other neurons and non-neuronal cells. In these cells, the mutant huntingtin must be continually degraded without the formation of toxic aggregates or large inclusion bodies. Indeed, recent data indicate that in non-neuronal cells in culture, huntingtin with extended polyQ is degraded with a half-life of several hours by a proteasomal mechanism (Martin-Aparicio *et al.*, 2001). Recent data indicate that in none of the 20S proteasome's peptidase sites, which are trypsin-like, chymotrypsin-like, or caspase-like in their substrate specificity, can cleave within a polyQ stretch (Venkatraman & Goldberg, unpublished data). Therefore, when the proteasome digests a protein containing a normal or extended polyQ tract, it probably

releases long polyQ sequences, and one or more of the cytosolic peptidases that complete the hydrolysis of proteasome products must be able to digest peptides containing only glutamine residues. Otherwise, these relatively insoluble polyQ sequences would aggregate and form inclusion bodies.

In principle, each of these steps in the degradative pathway could on occasion fail, leading to the accumulation of the abnormal polypeptides. There is evidence that the mutant form of ataxin-1 with an extended polyQ sequence is degraded by proteasomes inefficiently, despite normal rates of ubiquitination (Cummings *et al.*, 1999). Perhaps the extended polyQ sequence interferes with complete degradation by the 26S proteasome by causing tight associations with other molecules and preventing protein entry into the 20S particle. In such a case, either the 26S proteasome may release a polyQ-containing fragment, which could be more toxic than huntingtin itself, or the aggregated polyQ sequence may stay attached to the 19S particle and prevent degradation of other proteins (Navon & Goldberg, 2001). In cultured cell models, caspase 3 seems to serve such a pathogenic role by cleaving the extended forms of huntingtin, ataxin, and the androgen receptor to smaller fragments that contain the deleterious polyQ domains (Ellerby *et al.*, 1999; Martindale *et al.*, 1998; Wellington *et al.*, 1997, 1998). However, it remains uncertain what step actually fails in the affected neurons of patients, leading to an accumulation of these abnormal species.

There is growing evidence that the failure of proteasomes to degrade efficiently polyQ-containing polypeptides and other abnormal proteins (e.g., alpha-synuclein, mutant SOD) and their accumulation can result in an inhibition of proteasome function and a general reduction in protein degradation by the ubiquitin-proteasome pathway (Bence *et al.*, 2001; Helmuth, 2001; Jana *et al.*, 2001). An inhibition of this pathway has been observed in various cellular and animal models of Huntington's and Parkinson's diseases and amyotrophic lateral sclerosis (Chung *et al.*, 2001a; McNaught & Jenner, 2001; McNaught *et al.*, 2002; McNaught *et al.*, 2001; Tanaka *et al.*, 2001; Urushitani *et al.*, 2002). The proteasome-associated peptidase activities were suppressed in these conditions, suggesting a general defect in proteasome function in these diseases. In addition, the ubiquitination step of this pathway is also affected in at least some disorders, most clearly in inherited Parkinson's disease (see below) (Chung *et al.*, 2001b; Shimura *et al.*, 2000, 2001). In cell culture, only neurons with inclusion bodies have general defects in protein degradation, while cells that express the same abnormal proteins in soluble form do not demonstrate the defect (Bence *et al.*, 2001). These data argue that inhibition of protein degradation in

these neurodegenerative disorders is associated with the emergence of inclusion bodies. One potential mechanism of such an inhibition is the trapping of the proteasomes in the inclusions, which may make these particles inaccessible to their normal substrates. Another possibility is that mutations that retard the degradation of certain domains in normally unstable proteins (e.g. expanded polyglutamine domains) may lead to a tight association of the mutant polypeptide within the proteasome and an inhibition of its activity towards other substrates. Model experiments with a protein substrate which was chemically linked to a large globular protein so that it could not be translocated through the ATPase ring to the 20S core particle showed that such a modified polypeptide can become tightly associated with the ATPase and acts like a dominant inhibitor of protein breakdown (Navon & Goldberg, 2001). Independently of the specific mechanism, the non-translocated protein complex causes failure of proteasomes to remove abnormal proteins, which in vivo would cause their further accumulation in an autocatalytic process (Table 9.2).

One of the great mysteries concerning these neurodegenerative diseases is their tendency to specifically affect only certain neuronal populations (e.g. basal ganglia in Huntington's disease or motor neurons in ALS). In these susceptible cell populations, the defenses against these specific abnormal proteins must be different or defective. When the abnormal genes responsible for Huntington's (Saudou *et al.*, 1998) or Parkinson's (Masliah *et al.*, 2000) diseases are expressed in cultured neurons or in the brain, the neuropathology is evident in those cell types affected by the human disease. An alternative possibility, for which there is some evidence in Huntington's disease, is that these susceptible neurons are the sites of somatic mutations, such that their DNA contains a huntingtin with exceptionally long polyQ sequences. In other words, these neurons may be expressing an even more abnormal gene product than the rest of the brain (Aronin *et al.*, 1995; Telenius *et al.*, 1994).

Protein damage can induce apoptosis

If a cell's protective systems are unable to handle the buildup of abnormal polypeptides, and if the induction of Hsps is insufficient to prevent their continued accumulation, a program for cell suicide (apoptosis) is initiated (Gabai *et al.*, 1998). In other words, when the cell's mechanisms for repair, segregation, and digestion of the unfolded proteins are inadequate, this situation is sufficiently threatening to the organism to trigger programmed cell death.

For example, apoptosis occurs in response to a variety of highly stressful treatments that are damaging to cell proteins (e.g. exposure to high temperatures). Cell death apparently occurs before the cells have sufficient time to induce the Hsps to achieve enhanced protection (Gabai *et al.*, 1997; Mosser *et al.*, 1997; Mosser & Martin, 1992). Similarly, apoptosis can be triggered by incubation with amino acid analogues or low doses of puromycin (Sugita *et al.*, 1995), which causes the production of improperly folded or incomplete proteins. If shorter fragments of proteins are generated, they appear less toxic than longer ones, perhaps because they are more readily degraded or less likely to associate with other cell components (Chow *et al.*, 1995).

Recently, important insights have been obtained as to how abnormal proteins can trigger apoptosis. When mammalian cells are subjected to a variety of stressful conditions, a number of protein kinases are activated. One of these stress-activated kinases, called JNK, plays a key role in the activation of apoptosis triggered by unfolded proteins (for review, see Gabai *et al.*, 1998). Inhibition of the JNK signaling pathway reduces the ability of protein-damaging conditions, such as high temperatures, to induce programmed cell death. JNK activates apoptosis by multiple mechanisms. It increases the phosphorylation of the major anti-apoptotic proteins Bcl-2 and Bcl-x, thus reducing their anti-apoptotic activity (Kharbanda *et al.*, 2000; Srivastava *et al.*, 1999). JNK can also somehow promote cleavage and activation of the pro-apoptotic protein Bid (Gabai *et al.*, 2002). These effects of JNK control the major mitochondria-dependent apoptotic pathway (Gabai *et al.*, 2002). The two major isoforms, JNK1 and JNK2, play an essential role in apoptosis induced by DNA damage (Tournier *et al.*, 2000) and in neuronal apoptosis during brain development (Kuan *et al.*, 1999). JNK can also activate apoptosis through the induction of the FAS ligand (Faris *et al.*, 1998a; Faris *et al.*, 1998b). In the brain, there is a specific JNK isoform, JNK3, which is essential for the neuronal apoptosis induced by excitotoxic agents (e.g. kainic acid), and perhaps other stimuli (Yang *et al.*, 1997). It remains unclear which of the JNK isoforms is critical in cell death caused by the accumulation of mutant polypeptides in neuronal cells. Inhibition of proteasomes by lactacystin or other specific inhibitors activates JNK, and this activation leads to induction of apoptosis in both neuronal and non-neuronal cell lines (Hideshima *et al.*, 2002; Masaki *et al.*, 2000; Meriin *et al.*, 1998). This activation of the JNK-dependent apoptotic pathway by the proteasome inhibitors is likely to lead to a stabilization and accumulation of pro-apoptotic proteins (e.g. p53 or Bax). A similar accumulation of the pro-apoptotic proteins was seen in cellular models of Huntington's disease (Jana *et al.*, 2001). These findings

are also consistent with results from proposed models in which neuronal loss in these neurodegenerative disorders results from an inhibition of the ubiquitin-proteasome pathway.

It is noteworthy that the expression of proteins with extended polyQ sequences can activate signaling pathways and induce apoptosis in similar ways as other types of unfolded polypeptides. Cell death induced by overexpression of mutant huntingtin has been reported to depend on the activation of JNK (Liu, 1998; Yasuda *et al.*, 1999). However, other apoptotic pathways, perhaps independent of JNK, may also be involved in Huntington's disease. For example, there is evidence that caspase 8 can be activated by association with inclusion bodies, and this activation may also contribute to huntingtin-induced dysfunction and apoptosis (Sanchez *et al.*, 1999; Urushitani *et al.*, 2001).

The major heat shock protein Hsp70 plays a key role in the regulation of JNK. Specific inhibition of Hsp72 induction with anti-sense RNA enhances JNK activation by protein-damaging insults (Gabai *et al.*, 2000), while increased expression of Hsp72 dramatically reduces the capacity of protein damage to activate JNK (Gabai *et al.*, 1997) (Fig. 9.2). This crosstalk between the chaperone machinery and the apoptotic signaling pathway may play an important role in reducing the toxicity of abnormal polypeptides in neurological disorders. Direct inhibition of the apoptotic pathway by Hsp70 can explain the findings in *Drosophila* and in certain cellular models of polyQ-expansion diseases that overexpression of Hsp70 did not reduce the number of inclusion bodies but dramatically suppressed apoptosis (Warrick *et al.*, 1999; Zhou *et al.*, 2001). These data indicate that Hsp70 probably also protects cells at a step that follows inclusion body formation.

Key unresolved issues

There are several closely related fundamental questions that have to be resolved if we are fully to understand the pathogenesis of the polyQ-expansion disorders: (a) Is neuronal death critical in the disease process? (b) Is it a soluble form of the abnormal proteins or the inclusion bodies that cause cell toxicity? (c) What are the molecular pathways that lead to neuronal dysfunction and/or death in these disorders?

(a) In Huntington's disease patients, there is extensive neuronal loss in the striatum and cerebral cortex, leading to a marked reduction in brain size at later stages of the disease. On the other hand, in transgenic mouse models that express fragments of huntingtin containing the expanded

polyQ, there are behavioral abnormalities similar to those in Huntington's disease, but massive neuronal death was not found (Davies *et al.*, 1997; Yamamoto *et al.*, 2000). Neurons that express the mutant huntingtin differ from ones expressing the normal forms in several respects, including a reduced number of dendrites and reduced transport of dyes along the neuron (Young, 1998). Furthermore, an altered expression of NMDA receptors, which led to enhanced sensitivity of neurons to excitotoxic stimuli, was seen in animal models of Huntington's disease (Cepeda *et al.*, 2001; Zeron *et al.*, 2001, 2002). At present, it is not clear which of these alterations (if any) causes the neurological symptoms, cellular loss, and eventually disease progression. In *C. elegans* transfected with the mutant huntingtin, the expressing neurons do not undergo apoptosis, but show symptoms of neurodegeneration that could be suppressed by inhibitors of caspases, the key proteolytic enzymes in the apoptotic pathway (Faber *et al.*, 1999). Thus, activation of certain components of the cell death program seems to play a role in the neurodegeneration, even without causing classic apoptosis. In case of huntingtin-caused cell death, caspases may be involved not in the execution step of the apoptosis, but rather in production of toxic huntingtin fragments. Several observations on transfected cells in culture suggest that the truncated forms of huntingtin and ataxins that are found in inclusions may be generated by caspase-mediated cleavages (Ellerby *et al.*, 1999; Kobayashi *et al.*, 1998; Martindale *et al.*, 1998; Wellington *et al.*, 1998). The inclusions themselves may also bind and further activate caspase, thus perhaps inducing programmed cell death or promoting neurodegeneration (Miyashita *et al.*, 1999; Ona *et al.*, 1999; Sanchez *et al.*, 1999; Wang *et al.*, 1999). In striatal cells transfected with huntingtin, there is a dramatic enhancement of autophagy, i.e. the incorporation of large regions of the cytoplasm into vacuoles followed by their digestion in lysosomes (Kegel *et al.*, 2000; Petersen *et al.*, 2001). A similar activation of autophagy was seen with PC-12 cells expressing the mutant form of alpha-synuclein, which is responsible for an inherited form of Parkinson's disease (Anglade *et al.*, 1997; Stefanis *et al.*, 2001). Autophagy is activated in most cell types deprived of essential growth factors. In several cell types, including neurons, enhanced autophagy may lead to cell dysfunction and eventually death and may thus represent an alternative to the classical apoptotic mechanism of programmed cell death (Stefanis *et al.*, 2001). It is possible that the enhanced autophagy may contribute to neurodegeneration in polyQ expansion disorders. On the other hand, autophagy may also contribute to the elimination of the mutant huntingtin molecules (Ravikumar *et al.*, 2002).

Table 9.3. Consequences of accumulation of unfolded proteins demonstrated in model systems

1. Proteasomes form aggresome-like inclusions
2. Non-translocatable aggregated proteins may bind to ATPases in 26S proteasome, block its function, and cause further accumulation of abnormal proteins
3. Trapping of proteasomes and chaperones in inclusions may cause further accumulation of abnormal proteins
4. Binding of normal polyQ-containing proteins to aggregates of mutant polyQ proteins may interfere with normal cell function (e.g. trapping of histone acetylase in inclusions may block transcription of many genes)

(b) The formation of inclusion bodies generally precedes neurodegeneration in all models, and in instances where cell death has been documented, the formation of large inclusions precedes it as well. Such observations initially led to the widely held assumption that aggregate formation is the critical event triggering neuropathology in Huntington's disease and related diseases. On the other hand, there is appreciable evidence that soluble polyQ-containing polypeptides cause neuronal toxicity. This apparent contradiction probably indicates that there are multiple mechanisms of neuronal toxicity, which may be initiated by either soluble or aggregated abnormal polypeptides.

There are several hypotheses on the mechanisms of toxicity of polypeptides with expanded polyQ domains related to inclusion body formation (Table 9.3). All these hypotheses consider that various types of essential proteins are recruited into inclusion bodies, leading to the cessation of critical cellular functions. Toxicity due to the trapping of proteasomes in inclusion bodies and related inhibition of the ubiquitin-proteasome degradation pathway is discussed above. Another hypothesis stipulates that the trapping of Hsp70 and Hsp40 in inclusion bodies may deplete the pool of free chaperones, thus leading to cessation of protein-folding activity and eventually to neurodegeneration. This idea is consistent with the fact that overexpression of Hsp70 or Hsp40 strongly suppresses the polyQ-induced toxicity in *Drosophila* and in cellular models (Warrick *et al.*, 1999; Zhou *et al.*, 2001) (although there are other explanations of these data, as discussed above). Furthermore, inhibition of Hsp70 function by expression of a dominant-negative Hsp70 mutant in *Drosophila* led to neurodegeneration similar to that seen upon expression of ataxin-1 with an expanded polyQ domain (Chan *et al.*, 2000).

Another hypothesized pathogenic mechanism is that the mutant polypeptides with expanded polyQ domains co-aggregate with normal essential proteins with polyQ or glutamine/asparagine-rich domains, leading to neuronal

dysfunction (Table 9.3). Although the human genome has not been analyzed extensively for the presence of such proteins, in *Drosophila* and yeast, there are hundreds of such polypeptides, and some of them are essential for cell growth and survival. In model experiments, a polypeptide with short polyQ (25Q) co-aggregated with a polypeptide with long polyQ (103Q) (Kazantsev *et al.*, 1999; Preisinger *et al.*, 1999). Furthermore, some of the normal critical polyQ-containing proteins were found to be present in inclusion bodies, including CBP, a transcription co-activator CREB-binding protein (Nucifora *et al.*, 2001; Steffan *et al.*, 2000), and nucleolin (Preisinger *et al.*, 1999). Recruitment to inclusion bodies of CBP also leads to the inhibition of its histone acetyltransferase activity and a reduction of histone acetylation in a cellular model of Huntington's disease (Nucifora *et al.*, 2001). Accordingly, inhibition of histone deacetylase, which leads to a net increase in the level of acetylated histones and thus opposes the inhibition of histone acetyltransferase, increased cell survival and partially suppressed neurodegeneration in the *Drosophila* model (Steffan *et al.*, 2001). Therefore, recruitment of CBP, and perhaps other transcriptional regulators, to inclusion bodies represents at least one of the mechanisms of neurodegeneration in the polyQ expansion diseases.

(c) Although apoptosis is often associated with the formation of inclusion bodies in cells expressing proteins with extended polyQ, soluble forms of the polypeptides may also cause cell death. For example, deletion of the C-terminal portion of huntingtin enhances formation of inclusions but does not increase the fraction of apoptotic cells (Saudou *et al.*, 1998). Furthermore, deletion of the self-association regions of ataxin 1 blocks aggregation but does not suppress apoptosis (Klement *et al.*, 1998). Moreover, in transgenic mice lacking the ubiquitin-protein ligase E6-AP, formation of ataxin-1 inclusion bodies is reduced, while toxicity is more prominent (Cummings *et al.*, 1999). In another example, when the dominant negative form of the ubiquitin-conjugating enzyme Cdc34 was transfected into such cells, it suppressed the formation of inclusions, but actually led to increased apoptosis (Saudou *et al.*, 1998). These observations all suggest that a soluble form of these abnormal molecules could be the primary trigger of apoptosis in these systems. Among potential mechanisms of induction of cell death by soluble polyQ-containing proteins are direct interaction of these proteins with various pro- or anti-apoptotic factors. One of these putative mechanisms is the interaction of soluble huntingtin with normal polyQ with a pro-apoptotic protein Hip1 (Kalchman *et al.*, 1997), leading to its inhibition and cell survival. Huntingtin with an expanded polyQ domain cannot interact with Hip1 and can no longer inhibit it, leading to interaction of Hip1 with another pro-apoptotic protein

Hippi, which can activate caspase 8 and cause cell death (Gervais *et al.*, 2002).

It should be emphasized that activation of cell malfunction and death by polyQ polypeptides need not involve a single molecular mechanism; in fact, as discussed above, strong evidence has been obtained for multiple mechanisms, all of which may function synergistically in causing cell damage and death. Moreover, additional mechanisms of toxicity may also be discovered as these models are studied in further depth. In any case, as discussed above, the activation of JNK, cytochrome C release, and the activation of caspases are probably the downstream events initiated independently of the particular mechanism triggering apoptosis. Finally, while many aspects of neuronal function are clearly altered in these neurodegenerative diseases (e.g. the number of dendrites, transport of molecules along the neuron, expression of receptors for excitotoxic transmitters), it is quite unclear whether the inclusions or the soluble species may cause such changes, since only their relationship to apoptosis has been studied.

Neuronal protection by molecular chaperones

Based on findings in non-neuronal cells expressing various mutant proteins, it seems very likely that chaperones, especially Hsp70 and Hsp40, also serve important protective roles in neurons that express mutant proteins, including those with polyQ expansions. As mentioned above, in *Drosophila* models of human polyQ diseases, overproduction of Hsp70 and Hsp40 strongly protected neurons that expressed mutant forms of human huntingtin (Fernandez-Funez *et al.*, 2000; Kazemi-Esfarjani & Benzer, 2000; Warrick *et al.*, 1999). In neuronal cultures, expression of Hsp70 and Hsp40 protected cells from apoptosis induced by the mutant androgen receptor (Kobayashi *et al.*, 2000). Similarly, overexpression of the inducible isoform of Hsp70 reduced neuronal degeneration in mice caused by an extended form of ataxin-1 (Cummings *et al.*, 2001). Also, overproduction of another chaperone Hsp104 in *C. elegans* dramatically reduced neurotoxicity of the mutant huntingtin (Satyal *et al.*, 2000).

There are several possible mechanisms by which these chaperones might help protect the neurons. (a) The Hsps may help combat the tendencies of huntingtin and ataxin to unfold and aggregate. In yeast cells, these chaperones can reduce the formation of inclusion bodies by a huntingtin fragment with expanded polyQ, and *in vitro* decrease aggregation of this fragment (Muchowski *et al.*, 2000). The huntingtin fragment tends to form two types of aggregates, either amyloid-like fibrils that are unusual in resisting solubilization by the ionic detergent SDS, or

amorphous structures that can be solubilized with detergents. Hsp70 and its cofactor Hsp40 can bind to the soluble molecules, and facilitate the formation of the amorphous aggregates, while suppressing formation of the fibrillar structures (Muchowski *et al.*, 2000). It seems very likely, although it remains to be proven, that chaperones have similar effects in neurons. (b) The abnormal species, whether soluble or aggregated, probably serve as seeds to which other partially unfolded proteins associate, and thus may inhibit the successful folding of newly synthesized polypeptides. By binding to the abnormal species, the Hsps may reduce the harmful consequences of this accumulation. (c) In addition to associating with aggregated species and perhaps promoting their resolubilization, the chaperones may bind preferentially to the soluble polyQ-extended molecules and reduce their toxicity by preventing them from interacting with proteins that trigger apoptosis and neurodegeneration. (d) The Hsps may also facilitate the ubiquitination and degradation of huntingtin and ataxins, as Hsp70 and Hsp40 do for certain other abnormal proteins (Bercovich *et al.*, 1997; Lee *et al.*, 1996a; Sherman & Goldberg, 1996). Other chaperones may also contribute to these effects; for example, in yeast a distinct chaperone, Hsp104 (but not Hsp70 or Hsp40), is essential for the degradation of ataxin-1 (Lee *et al.*, in press).

(e) Finally, Hsp72, by inhibiting the activation of JNK, should directly inhibit the ability of these mutant polypeptides to cause apoptosis. It therefore appears likely that at some stages of the disease, the heat shock response is activated as part of the standard cellular response to a buildup of abnormal proteins. However, reliable information on the levels of Hsp expression in neurons during progression of these diseases is unfortunately not available (see below). This question is of appreciable importance, since, in principle, treatments that cause induction of Hsps could be a very useful approach for therapy of these neurodegenerative diseases.

Abnormal protein inclusions in Parkinson's disease

In addition to the polyQ diseases, several other major neurodegenerative diseases are also associated with an accumulation of proteinaceous inclusions and neuronal apoptosis (Table 9.1, Fig. 9.2). For example, in the substantia nigra of patients with Parkinson's disease, α -synuclein, a very abundant pre-synaptic protein of unknown function, accumulates in inclusions, termed Lewy bodies, in cell bodies and neurites (Mezey *et al.*, 1998) of dopaminergic neurons. α -Synuclein was first implicated in the pathogenesis of Parkinson's disease through the identification

of mutated forms of this protein in families having the rare inherited forms of this disease (Polymeropoulos *et al.*, 1997). In more recent studies, Lewy bodies, the characteristic inclusions in non-inherited forms of these and other neurodegenerative diseases (e.g. multiple systems atrophy) have been shown to contain an abnormal form of α -synuclein, which contains nitrated tyrosine residues (Giasson *et al.*, 2000). This covalent modification results from oxidative damage to the protein, and there had been appreciable evidence implicating oxidative injury in the pathogenesis of this disease (Giasson *et al.*, 2000). By reacting with nitric oxide, oxygen free radicals (especially superoxide) generate the highly reactive species, peroxynitrite, which modifies tyrosines in proteins, and presumably the resulting abnormal form of α -synuclein is particularly prone to aggregate in cells. Nitrative insult of cells that caused generation of peroxynitrite led to aggregation of α -synuclein (Paxinou *et al.*, 2001). A similar aggregation of α -synuclein was seen upon exposure of cells to mitochondrial inhibitors (Lee *et al.*, 2002) that cause oxidative stress and produce Parkinson's-like symptoms in an animal model. Similar inclusions containing ubiquitin and α -synuclein are also seen in patients with Dementia with Lewy Bodies (DLB) (Baba *et al.*, 1998; Spillantini *et al.*, 1998; Takeda *et al.*, 1998).

Like the inclusions containing huntingtin and the ataxins, the α -synuclein inclusions contain large amounts of ubiquitin and proteasomes (Bennett *et al.*, 1999; Ii *et al.*, 1997). Importantly, the major hereditary form of Parkinson's disease results from mutations in the protein parkin (Kitada *et al.*, 1998; Tanaka *et al.*, 1998), which was shown to be a ubiquitin-protein ligase (E3). In the patients with this form of the disease, this enzymatic activity is lost. The question of what the natural substrates for parkin are is presently highly controversial. It appears that normal α -synuclein cannot bind to parkin and cannot be ubiquitinated by parkin (Shimura *et al.*, 2001). However, parkin can associate with an α -synuclein-interacting protein, synphilin-1, and ubiquitinate it (Chung *et al.*, 2001b). Importantly, in transfected cells the presence of all three components, α -synuclein, synphilin-1, and parkin, was essential for the appearance of Lewy body-like inclusions (Chung *et al.*, 2001b), and all three components are found in these inclusions. Furthermore, mutations in parkin that inactivate the E3 ubiquitin ligase activity and cause familial forms of Parkinson's disease prevented the interaction of parkin with synphilin-1 and prevented inclusion body formation (Chung *et al.*, 2001b). Accordingly, in cases of familial Parkinson's disease associated with mutations in parkin (Mizuno *et al.*, 2001), there is a lack of Lewy bodies, which are characteristic of other forms of this disease. These data

suggest that ubiquitination of synphilin-1, or other proteins, is essential for formation of inclusion bodies. This idea is in accord with observations that formation of inclusion bodies in models of polyQ expansion diseases was suppressed upon inactivation of the ubiquitin-conjugating enzymes Cdc34 and E6-AP (Cummings *et al.*, 1999; Saudou *et al.*, 1998).

Other hereditary forms of Parkinson's disease are also associated with distinct mutations affecting the ubiquitination system. In one form, the mutation inactivates the ubiquitin carboxy-terminal hydrolase L1 (Leroy *et al.*, 1998). This enzyme is one of the cell's many isopeptidases, or enzymes capable of removing ubiquitin from peptide conjugates, but recent findings indicate that under certain in vitro, and possibly in vivo, conditions, it can also promote ubiquitin conjugation (Liu *et al.*, 2002). For unknown reasons, this enzyme is one of the most abundant proteins in the brain, and it is rapidly induced in aplysia during post-synaptic facilitation (Hegde *et al.*, 1997). Curiously, mutations in a distinct deubiquitinating enzyme are associated with a distinct neurodegenerative disease, gracile axonal dystrophy (Saigoh *et al.*, 1999). However, the precise role of these deubiquitinating enzymes in overall ubiquitin metabolism and in protein degradation is uncertain. Most likely, such mutations lead to a general disorder in ubiquitin recycling, but it is quite unclear why such a defect would lead in Parkinson's disease to a specific accumulation of α -synuclein and not other abnormal brain proteins. If ubiquitination is, in fact, critical for Lewy body formation, one would expect that mutations in ubiquitin carboxy-terminal hydrolase L1 would increase the levels of ubiquitin-conjugated proteins, thus increasing the formation of inclusion bodies. In any case, it is conceivable that the α -synuclein mutation, free radical damage to this protein, or a failure to ubiquitinate α -synuclein leads to an accumulation of abnormal species, which interfere with normal cell function and eventually trigger apoptosis of the dopaminergic neurons. If so, Hsps would be anticipated to play a role in retarding the development of Parkinson's disease, by reducing α -synuclein aggregation, promoting its solubilization or degradation, or inhibiting the events leading to apoptosis.

Apoptosis and inclusions in other neurodegenerative diseases

Another late-onset neurodegenerative disease that appears to involve some similar cellular mechanisms is amyotrophic lateral sclerosis (ALS), a rapidly progressive disease characterized by death of motor neurons (Brown,

1998). Some of the hereditary forms of ALS are due to mutations in superoxide dismutase, including ones that cause a loss-of-function or a gain-of-function (Brown, 1998; Cleveland, 1999). Initially, oxidative stress associated with dysfunction of SOD was suggested to be the primary cause of ALS (Cleveland & Rothstein, 2001), but subsequent experiments have ruled out this possibility and indicated instead that accumulation of misfolded SOD is the cause of the disease. Briefly, it was shown that the progression of the disease does not correlate with SOD activity and production of reactive oxygen species, and symptoms develop even in individuals with mutations in SOD that completely lack enzyme activity (Brown, 1998; Cleveland, 1999). Furthermore, a specific “copper chaperone” is necessary for loading of Cu^{2+} onto SOD, and deletion of this gene, while dramatically reducing SOD activity, did not change the course of the disease in animal models (Subramaniam *et al.*, 2002). Thus, ALS appears to represent another “abnormal protein disorder”. In transgenic animals expressing the mutant SODs, apoptosis is evident and can be retarded by central administration of caspase inhibitors (Li *et al.*, 2000) or by mutations affecting certain caspases (Friedlander & Yuan, 1998). ALS, in both its hereditary and acquired versions, is associated with the presence in affected motor neurons of proteinaceous inclusions that contain mutant forms of SOD, stain with anti-ubiquitin antibodies (Ii *et al.*, 1997; Kawashima *et al.*, 1998; Mayer *et al.*, 1996; Shibata *et al.*, 1999; Tu *et al.*, 1997), and contain excess neurofilaments. The development of these inclusions containing SOD closely resembles the formation of aggresomes (Johnston *et al.*, 2000). Although rigorous demonstration of abnormal polypeptides is lacking in the common non-hereditary form of ALS, there is evidence for oxidative or heavy-metal-mediated damage to neuronal proteins. Importantly, in culture the viability of neurons expressing the mutant SOD can be improved by increasing the content of Hsp72 (Bruening *et al.*, 1999).

Alzheimer's disease, the most common cause of senile dementia, appears (at least) superficially to be very different from these other diseases. This condition is associated with extracellular amyloid plaques, but Alzheimer's-affected brains are also characterized by intracellular accumulation of ubiquitin conjugate of the cytoskeletal protein tau, which also accumulates in neurons in the much rarer disease, progressive supranuclear palsy. The molecular basis for these inclusions and their relationship to the extracellular amyloid-related damage is quite unclear, especially since in transgenic mouse models of Alzheimer's disease, extracellular plaques are seen without the intracellular inclusions. One intriguing observation is the finding in the brains of some Alzheimer's disease patients

an anomalous form of ubiquitin (UBB^+) (van Leeuwen *et al.*, 1998), resulting from transcriptional misreading of the stress-induced polyubiquitin gene (see below). As a result, some ubiquitin molecules are generated with aberrant C-terminal extensions and therefore cannot be conjugated to substrates. Such an extended version, however, can become linked to other ubiquitin molecules and, in principle, such ubiquitin chains might competitively inhibit proteasomal function. Recent experiments demonstrated that UBB^+ can be incorporated in ubiquitin trees, and overexpression of UBB^+ in cells can dramatically inhibit protein degradation by the ubiquitin-proteasome pathway (Lindsten *et al.*, 2002; van Leeuwen *et al.*, 2002). Such an inhibition could significantly contribute to the toxicity of various types of abnormal polypeptides involved in neurodegenerative disorders, especially since production of UBB^+ increases in aged organisms (van Leeuwen *et al.*, 1998, 2002).

Because of these striking similarities, it is attractive to hypothesize that diverse neurodegenerative diseases develop through a common mechanism, in which the accumulation of abnormal proteins in the affected neurons is recognized as evidence of massive and probably irreparable damage to cell constituents, leading to neuronal dysfunction and the activation of the apoptotic program. Although such a unifying mechanism remains unproven and largely untested, these various observations emphasize that, in very long-lived non-dividing cells, such as neurons, any rare event favoring production of an aberrant protein (e.g. free radical damage) can lead to its slow accumulation, with toxic consequences. Because structural defects in any of a variety of neuronal proteins can generate pathology, the proper functioning of the molecular chaperones and the ubiquitin-proteasome pathway must be particularly important in host defenses against neuronal degeneration.

Ageing, Hsps, and susceptibility to neurodegenerative diseases

An important common feature of many of these neurological diseases that has long puzzled investigators is their late onset. In most cases, the marked neurodegeneration (e.g. in Huntington's disease or ALS) occurs in middle age or later (Brown, 1998; Young, 1998). The mechanisms proposed here for cell protection and pathology in these various conditions also suggest a possible explanation for their late onset. The onset of an inherited disease in middle age or later implies that the affected neurons can deal successfully with the mutant proteins for many years. During this

time the potentially toxic polypeptides must be continually synthesized and degraded without causing disease symptoms or cell death, until, with aging, abnormal molecules accumulate in certain neurons and eventually reach toxic levels. In other words, with aging, the cell's capacity to handle the aberrant polypeptides becomes insufficient to prevent their accumulation and toxic consequences. It is noteworthy that earlier onset of disease is seen in Huntington's disease and related polyQ disease as the extent of the abnormality in protein structure becomes greater (i.e. as the length of the polyQ repeat increases) (Young, 1998). Similarly, in transgenic mouse models of ALS, earlier onset occurs if the extent of the expression of the abnormal gene product is increased (i.e. they show a gene dosage effect) (Cleveland, 1999).

We suggest that one important factor contributing to the enhanced sensitivity of aged organisms to these disorders is a reduced capacity of cells from older individuals to cope with abnormal proteins. Of particular interest in this regard are various observations indicating that aged organisms and senescent cultures of mammalian cells are less able to induce Hsps in response to protein-damaging conditions (Heydari *et al.*, 1994; Rattan & Derwentzi, 1991), due to the defect in activation of transcription factor HSF1 (Heydari *et al.*, 2000; Lee *et al.*, 1996b). For example, in rodents, the magnitude of the increase in Hsp expression in various tissues, including brain, after a mild heat shock is much smaller in aged animals than in young ones (Heydari *et al.*, 1994). A similar reduction with aging in the ability of rat and human tissues to induce Hsps has been observed upon exposure to oxidative stress and amino acid analogs (Locke & Tanguay, 1996; Muramatsu *et al.*, 1996). In agreement with this suggestion, inhibition of HSF1 in the *C. elegans* model of polyQ expansion disease leads to significantly earlier onset of the disease (Morley *et al.*, 2002).

Since these Hsps can promote refolding, solubilization and degradation of damaged polypeptides, the loss of this protective response should seriously compromise the cell's capacity to cope with the mutant or damaged proteins, which could have been handled successfully at younger ages. These considerations predict that neurons from aged humans should be defective in inducing Hsps when mutant huntingtin, ataxins, α -synuclein, and other abnormal proteins tend to accumulate. As a consequence of decreased Hsp inducibility, the mutant polypeptides should build up in cells of aged individuals to higher levels and result in a greater tendency to form inclusions, to cause neurodegeneration, and to trigger apoptosis. Decreased expression or inducibility of chaperones may account for the large number of observations suggesting the presence in

aged organisms and senescent cultures of various types of abnormal polypeptides (Grune *et al.*, 1997; Sastre *et al.*, 1996), including oxidatively damaged polypeptides, ones containing isomerized residues and inactive proteins due to altered conformations (Chiu & Liu, 1997; Mrak *et al.*, 1997; Sastre *et al.*, 1996; Tarcsa *et al.*, 2000). It is also interesting that cells infected with the mutant prion protein (Tatzelt *et al.*, 1995) also show diminished capacity to induce Hsps, which may increase their vulnerability to prion-induced apoptosis. Furthermore, mutations in Presenilin 1, which cause early onset of Alzheimer's disease, reduce the neuron's capacity to induce chaperones in the ER (Katayama *et al.*, 1999). This defect could contribute to the enhanced production of A β peptide in these cells and to the greater susceptibility of such cells to apoptosis and neurodegeneration. Also, it was recently reported that brains of aged individuals have a specific mechanism that causes frame-shift mutations at the RNA level and thus generation of nonsense polypeptides (van Leewen *et al.*, 1998).

With aging, cells also seem to have a reduced capacity for protein degradation, although this issue has not been rigorously examined. One proteolytic pathway affected by aging is the lysosomal pathway (Cuervo & Dice, 1998b), which catalyzes the breakdown of endocytosed components, including most surface membrane proteins. The breakdown of proteins that are specifically targeted to lysosomes for degradation is dramatically reduced in senescent cultures and in cells isolated from aged organisms (Cuervo & Dice, 1998a; Dice, 1993). This defect seems to be due to a reduced capacity to translocate polypeptides into lysosomes for degradation (Cuervo & Dice, 1996, 1998a; Hayes and Dice, 1996). These observations would also suggest a reduced capacity for proteolysis by autophagic vacuole formation, which has been reported in certain cellular models of polyQ disease. The capacity of the ubiquitin-proteasome pathway also seems to be reduced with aging, although the data on age-dependent alteration of the pathway are sometimes contradictory (Carrard *et al.*, 2002; Shringarpure & Davies, 2002; Szweda *et al.*, 2002). It should be noted, however, that in some tissues and cell types, a clear decline of the ubiquitin-proteasome-dependent degradation of certain proteins and of proteasome activity was demonstrated (Shang *et al.*, 1997). Also, in aged mouse muscles, expression of mRNA for multiple components of this pathway is reduced (Shang *et al.*, 1997). Another potentially important age-related alteration is the recently described mutant form of ubiquitin, UBB⁺, resulting from a frame shift at the RNA level (van Leewen *et al.*, 1998), which, as noted above, may reduce the cell's capacity to degrade aberrant molecules. Production of UBB⁺ has been seen not only

in aging, but especially in several neurological disorders (Bardag-Gorce *et al.*, 2002; De Vrij *et al.*, 2001; van Leeuwen *et al.*, 2000), and was suggested to play a major role in reducing the capability of neurons to degrade abnormal polypeptides (van Leeuwen *et al.*, 2002).

Whatever the molecular basis for these intriguing observations, such changes in the cell's proteolytic capacity, and the general increase in unfolded molecules, should further limit the capacity of the aged organism to cope with a mutant protein or other abnormal polypeptides and may thus indirectly contribute to the development of neurodegenerative diseases.

Neurodegenerative disease and the repair of oxidatively damaged DNA

Marcus S. Cooke

Departments of Cancer Studies and Genetics
University of Leicester, Leicester Royal Infirmary, UK

Free radicals and oxidative damage to DNA

In addition to endogenous sources of free radicals, such as those derived from normal metabolism (see Chapter 1), pathophysiological or environmental events may also generate free radicals. Cellular biomolecules, including nucleic acids, proteins and lipids are all targets for these damaging species. Reactive oxygen species (ROS) are of particular interest. Enzymic and non-enzymic antioxidants (discussed in Chapter 2) contribute to the limit on the extent to which ROS are produced, and hence their interaction with cellular components. If the balance between the anti- and pro-oxidant factors is altered in favour of the latter, a condition of oxidative stress arises, with a concomitant increase in biomolecule modification. Given its central role in cellular events, modification of DNA, for example 8-hydroxyguanine (8-OH-Gua), and thymine glycol (Tg), has been the subject of intense study. Such lesions may have a plethora of effects, most notably mutation, but also replicative block, deletions, microsatellite instability and loss of heterozygosity, as well as various epigenetic effects (for review see Cooke *et al.*, 2003). Furthermore, a great deal of literature exists that describes elevated levels of lesions in a variety of diseases, suggesting that the induction of damage is an important event in pathogenesis (for review, see Cooke *et al.*, 2003). Unlike oxidatively modified lipids and proteins, which may be removed and replaced as part of normal turnover, DNA needs to be repaired, and intense study has revealed much about the processes that maintain genome integrity.

Maintenance of genome integrity

In terms of repair, it may be viewed that genome integrity is maintained via two approaches: (i) the prevention of

incorporation of oxidatively modified deoxynucleotide triphosphates into nuclear and mitochondrial genomes, and (ii) removal of oxidative lesions, formed *in situ*, from nuclear and mitochondrial DNA. By far the most studied oxidative DNA lesion is 8-OH-Gua, and consequently the remainder of the chapter will focus principally upon this lesion. It may be implied, although not taken for granted, that similar principles apply for other lesions.

Prevention of incorporation

Free deoxynucleotides have a greater propensity for oxidation compared with base-paired deoxynucleotides in DNA (Mo *et al.*, 1992). Furthermore, mitochondrial sources of deoxynucleotides are larger than nuclear sources (*mitochondria*: 18.0 pmol dGTP/ μ g DNA vs *nuclear*: 8.0 pmol dGTP/ μ g DNA; Bestwick *et al.*, 1982). Taken together, these would suggest an imperative for preventing modified DNA precursors being incorporated into the genome. The best characterized enzyme which performs such a role is 8-hydroxy-2'-deoxyguanosine triphosphatase (8-oxodGTPase; Bialkowski & Kasprzak, 1998), hydrolysing 8-oxodGTP to 8-oxodGMP (Fig. 10.1). Further processing, perhaps by 5'(3')-nucleotidases, may give rise to the deoxynucleoside form of this lesion, 8-hydroxy-2'-deoxyguanosine (8-OH-dG), which can be excreted (Cooke *et al.*, 2000).

Removal of oxidative lesions from DNA

Numerous repair systems, with overlapping substrate specificities, ensure that a failure in one enzyme does not render a lesion irreparable. Broadly speaking, these multiple pathways can be divided into base excision repair (BER) and nucleotide excision repair (NER) and are targeted towards global genome repair (GGR) and repair

Fig. 10.1 Pathways to prevent the persistence of oxidatively damaged DNA, using 8-hydroxyguanine (8-OH-Gua) as a representative lesion. CS, coding strand; NS, nascent strand.

of actively transcribed regions (via transcription-coupled repair, TCR).

Base excision repair

The prevailing understanding is that, quantitatively, BER is by far the most important route for the removal of the majority of oxidative lesions. At its simplest, this process involves a specific enzyme, with a defined repertoire of substrate, removing the modified base, leaving an apurinic-apyrimidinic (AP) site. The subsequent fate of this AP site is proposed to be dependent upon whether the glycosylase also possesses an AP lyase activity, and may involve simply the removal of one nucleotide (short patch repair), or 2–6 nucleotides (long patch repair; Fortini *et al.*, 1999), followed by gap filling and ligation.

The glycosylase considered to have the primary responsibility for the removal of 8-OH-Gua in human cells, is the human 8-OH-Gua glycosylase (hOGG1; Arai *et al.*, 1997, Rosenquist *et al.*, 1997). This enzyme acts via short

patch repair, and has a specificity for 8-OH-Gua: C pairs present in double-stranded DNA, i.e. formed *in situ* (Fig. 10.1). The hOGG1 characterisation studies revealed two isoforms, designated α - and β -hOGG1, which exhibited specificity for subcellular localization to the nucleus and mitochondrial inner membrane, respectively (Croteau *et al.*, 1997, Nishioka *et al.*, 1999). The activity of hOGG1 is complemented by another enzyme, denoted hOGG2, which removes the 8-OH-Gua from the nascent strand in 8-OH-Gua: A or 8-OH-Gua: G pairs, arising from misincorporation of 8-OH-dGTP (Nishioka *et al.*, 1999; Fig. 10.1). Similarly, 8-OH-Gua: A and 8-OH-Gua: G mismatches may arise from misincorporation of A or G opposite 8-OH-Gua in the coding strand. In this case, the unmodified base in the nascent strand is removed by mismatch repair, involving the human homologue of *Escherichia coli* MutY protein, hMYH (McGoldrick *et al.*, 1995, Slupska *et al.*, 1996; Fig. 10.1). Repair synthesis, after removal of the mismatched native base is more likely to insert a C opposite 8-OH-Gua, and hence become a target for hOGG1.

Nucleotide excision repair

Despite appearing to be directed principally towards bulky lesions, such as cyclobutane thymine dimers (T<>T), there is evidence that NER (Figs. 10.1 and 10.2) may act upon non-bulky lesions such as 8-OH-Gua and Tg (Cooper *et al.*, 1997, Reardon *et al.*, 1997). The rate of 8-OH-Gua removal appears comparable to that for T<>T, generating a lesion-containing oligomer, approximately 24–32 nucleotides long (Reardon *et al.*, 1997). In the case of T<>T, at least, these oligomers are then subject to 5'–3' exonucleolytic attack (Galloway *et al.*, 1994), whether this is the case for 8-oxoGua, and ultimately generates the 8-OH-dG moiety so often measured extracellularly (for review, see Cooke *et al.*, 2002), remains uninvestigated.

NER of oxidative DNA damage may be a backup for BER, being dependent upon cell type, and under specific conditions, e.g. when BER is compromised. Despite this, evidence from studies examining the significance of oxidative DNA damage in xeroderma pigmentosum (XP), implies that the NER of such damage, although not necessarily 8-OH-Gua specifically, has some functional significance.

Transcription coupled repair

The purpose of TCR is to remove lesions from actively transcribed genes. In general, lesions that block the processivity of RNA polymerase (RNAP) are subject to TCR (Tornaletti & Hanawalt, 1999). Whilst some proteins of the NER pathway are also involved in TCR, this does not necessarily make TCR a sub-pathway of NER, as the function of these proteins can be clearly separated between the two pathways (Evans *et al.*, 2004). Some studies exist which suggest that non-bulky lesions, such as 8-OH-Gua and Tg, may also be substrates for TCR (Le Page *et al.*, 2000, Cooper *et al.*, 1997), implying the recruitment of glycosylases to this role. TCR is vital to cell metabolism as it removes the stalled RNAP, allowing the recruited repair proteins to act upon the lesion.

DNA repair abnormalities and neurological symptoms

Oxidative stress, and concomitant elevated levels of oxidative DNA damage, has been proposed to be important in a number of neurodegenerative conditions, such as Alzheimer's disease (for review, see Evans *et al.*, 2004), a role supported by promising results from antioxidant supplementation studies (Mattson *et al.*, 2002). Whilst numerous factors may affect levels of damage, it is becoming increasingly clear that DNA repair, in particular, may have a crucial role.

The association between DNA repair and the neurological deficits in neurodegenerative diseases is perhaps most evident in the (rare) human hereditary diseases caused by mutations in DNA repair genes, as discussed below.

Xeroderma pigmentosum

Xeroderma pigmentosum is a rare, autosomal recessive condition, displaying acute photosensitivity and an associated strong predisposition to skin cancer. The condition arises from mutations in the key genes (complementation groups) associated with NER (Sancar, 1995). Of the seven complementation groups with NER defects (A–G), A, B, D and G display varying degrees of neurological deficiency (Table 10.1). This deficiency manifests in early infancy, arising from the progressive loss of neurones from the cerebral cortex (Sarasin, 1991), reportedly due to the failure to repair DNA damage (Robbins, 1988, Robbins *et al.*, 1991, 1993). More specifically, it is the failure of NER to remove a class of oxidative DNA damage, which appears associated with neurological symptoms in the affected complementation groups (Chopp *et al.*, 1996). Exactly which lesions are responsible is not clear. XPA has received perhaps the most attention, due to the most severe symptoms, and almost total loss of NER activity (2%; Table 10.1). Indeed, XPA cells have been shown to be deficient in the removal of 8-OH-Gua, Tg (Reardon *et al.*, 1997), 5-hydroxycytosine, 2,6-diamino-4-hydroxy-5-formamidopyrimidine, 4,6-diamino-5-formamidopyrimidine (Lipinski *et al.*, 1999), and 8,5'-cyclo-2'-deoxyadenosine (Brooks *et al.*, 2000). In contrast XPD, for example, demonstrates efficient 8-OH-Gua repair (Cappelli *et al.*, 2000). Whilst further work is still required, these findings strongly implicate ROS, and the resulting oxidative DNA damage, in the pathogenesis of the neurological symptoms in XP, with implications for other neurodegenerative diseases.

Cockayne's syndrome

Unlike XP, this recessive, progeroid disease is not associated with an increased cancer incidence, although patients are photosensitive. Patients have short stature, progressive neurological degeneration and mental retardation. Whilst levels of global genome NER are normal, accounting for the absence of cancer predisposition, TCR is defective (van Hoffen *et al.*, 1993, Leadon & Cooper, 1993). This condition can be divided into two complementation groups (CS–A and CS–B), and again the defective repair of oxidative DNA damage has been proposed to contribute to the CS phenotype (Hanawalt, 1994, Dianov *et al.*, 1997), and neurological abnormalities, specifically. CSB cells have been shown to possess downregulated *hOGG1* expression, resulting in a deficiency in GGR of 8-OH-Gua specifically, uracil and

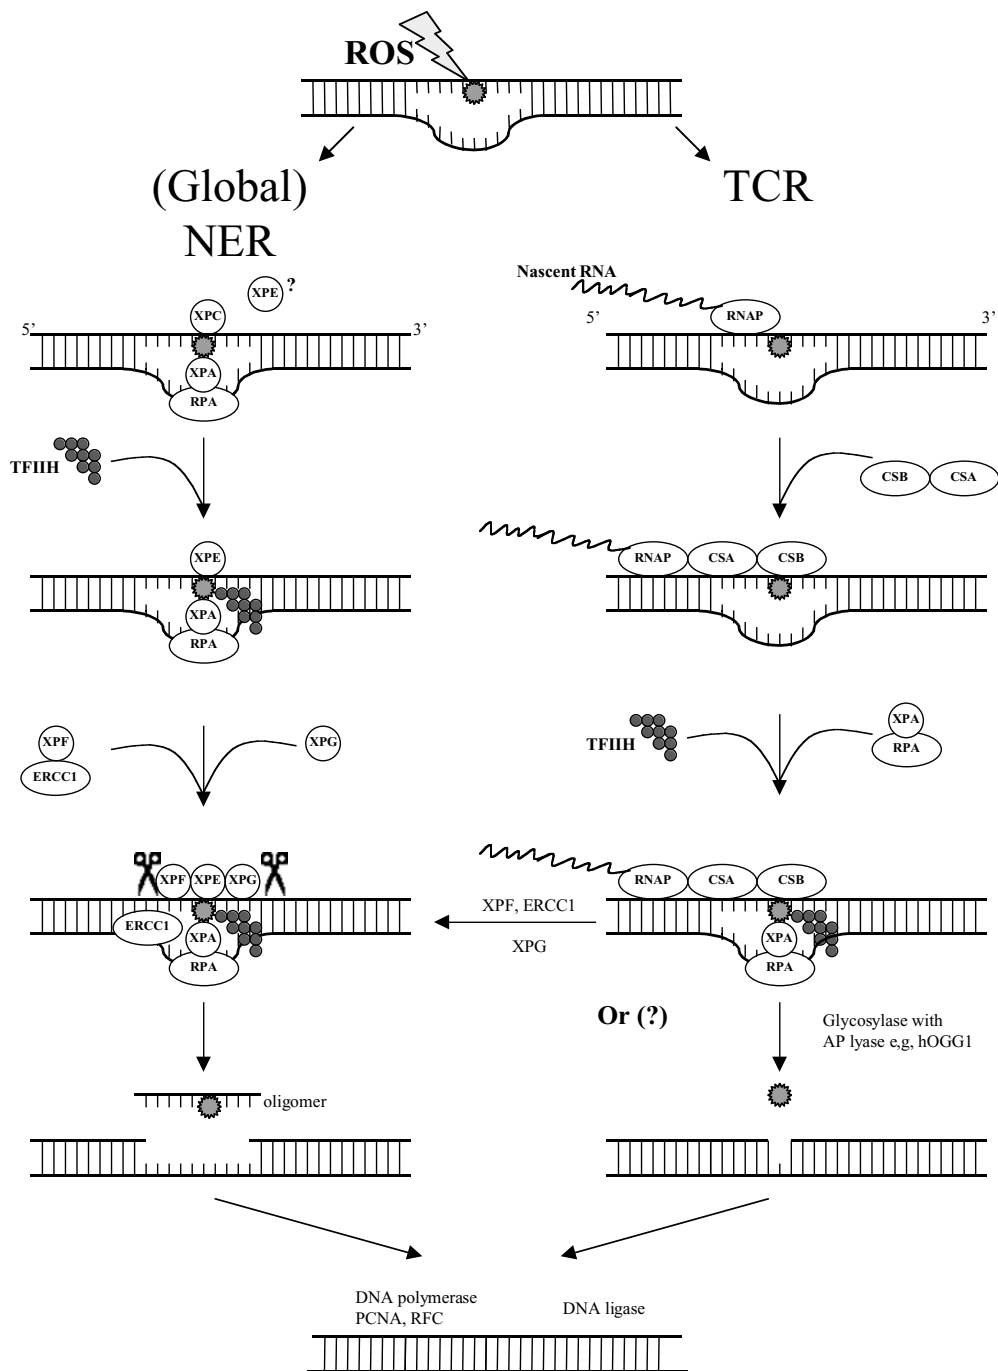

Fig. 10.2 Representation of the nucleotide excision repair (NER) and transcription-coupled repair pathways. (i) NER: lesion recognition by XPC and possibly XPE, perhaps aided XPA in conjunction with replication protein A (RPA, a.k.a human single strand binding protein). Recruitment of other proteins; TFIIH (containing the helicase sub-units XPB and XPD), and the XPF/ERCC1 complex. The 5' incision is made by the XPF/ERCC1 complex and 3' by XPG. The oligomer is removed, and the gap filled and sealed by DNA polymerases δ or ϵ , proliferating cell nuclear antigen (PCNA), replication factor C (RFC) and DNA ligase. (ii) TCR: RNA polymerase II (RNAPII) stalls at the lesion, at which point CSA and CSB proteins are recruited. The following steps are as for NER, although there is a suggestion that glycosylases may also be recruited to perform a TCR function at the lesion excision stage.

Table 10.1. Summary of major disorders associated with nucleotide excision repair/transcription-coupled repair deficiency¹.

Mutated gene	Gene function in NER/TCR	Residual NER activity (% of wild type)	Neurological symptoms	Clinical symptoms				
				XP	CS	XP + CS	TTD	UV-sensitive COFS syndrome
<i>XPA</i>	DNA damage recognition	< 2	Severe	X				
<i>XPB</i>	DNA unwinding, subunit (helicase) of TFIIH	< 10	Severe			X	X	
<i>XPC</i>	Repair of non-transcribed DNA	+/- 20	Absent	X				
<i>XPD</i>	DNA unwinding, subunit (helicase) of TFIIH	+/- 30	Variable		X		X	X
<i>XPE</i>	DNA damage recognition?	+/- 45	Absent	X				
<i>XPF</i>	Incision 5' to DNA damage	+/- 20	Absent	X				
<i>XPG</i>	Incision 3' to DNA damage	+/- 10	Variable	X		X		X
<i>CSA</i>	TCR	100	Severe		X			X
<i>CSB</i>	Transcription-coupling factor	100	Severe		X			
<i>TTD-A</i>	Unidentified subunit of TFIIH	+/- 10	Severe				X	

¹ Table derived from de Vries and van Steeg (1996), and Graham *et al.* (2001).

Tg being unaffected (Dianov *et al.*, 1997). For other oxidative lesions, the impact of mutated *CSB* in TCR may jeopardize their removal from actively transcribed genes, even their GGR is unaffected. It appears to be defects in TCR that are responsible for the CS phenotype. For example, the rare mutations in *XPB*, *XPD* and *XPG* all give rise to a combined XP/CS phenotype, at least in part due to the impact they have on TCR (Cooper *et al.*, 1997, Le Page *et al.*, 2000) and, as noted above, are all associated with severe neurological abnormalities (de Vries & van Steeg, 1996). The basis for this relationship has been proposed. Given the brain's high requirement for oxygen, the generation of ROS, and hence DNA damage, is likely to be equally high. Therefore, to maintain cell activity and neurological function, repair of actively transcribed genes is of great importance. As long as TCR is present, cells can function when global levels of lesions would normally be lethal. However, in the case of CS, not only is TCR absent, but lesions in transcribed strands are inaccessible to GGR due to the stalled RNAP, leading to an accumulation of lesions which block transcription. Protein synthesis ceases as mRNA levels decline, postulated to account for the symptoms of neurological deterioration and wasting (Le Page *et al.*, 2000).

Trichothiodystrophy

Patients with TTD have sulfur-deficient, brittle hair and nails, are of short stature, and are mentally retarded. Of the TTD patients, only those who are photosensitive have a repair defect, associated with the *XPB* or *XPD* genes.

Another class of TTD exists that cannot be associated with XP. Neurological symptoms are present, as well as defective DNA repair, seemingly associated with the transcription initiation complex, TFIIH, designated TTD-A (Vermeulen *et al.*, 1994; Table 10.1; Fig. 10.2).

Repair of mitochondrial DNA damage and neurodegenerative disease

Increasingly, mitochondria are being proposed an important role in neurodegenerative diseases, such as Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis and multiple sclerosis (Calabrese *et al.*, 2001). There is evidence that oxidative damage to mitochondrial DNA (mtDNA), and its repair, may be important, not only for neurodegenerative disease, but also other conditions, as a small number of mtDNA mutations have been associated with a significant number of mitochondrial myopathy disorders and aging (Wallace, 1992, 1994).

Certainly, mtDNA contains more damage than its nuclear counterpart (Yakes & Van Houten, 1997), not least because mitochondria produce 90% of the free radicals in a cell (Berdanier & Everts, 2001), but also mtDNA possesses little of the structural features that serve to protect nuclear DNA. Another factor is repair. As mentioned above, β -hOGG1 is targeted towards mitochondria, as are other repair proteins, such as hMTH1 (Kang *et al.*, 1995), hMYH, and hNTH1 (Takao *et al.*, 1998).

Table 10.2. Evidence for elevated levels of oxidatively damaged DNA in human neurodegenerative disease.

Disease	Damage increased?	Observations
Parkinson's disease (PD)	↑	• DNA levels of 8-OH-dG significantly elevated ($P=0.0002$) in substantia nigra of PD brains (Alam <i>et al.</i> , 1997)
	↑	• Levels of 8-OH-dG and 8-OH-Gua in cytoplasmic DNA and RNA, respectively, are elevated in substantia nigra neurons of Parkinson's disease patients and, although to a lesser extent, in multiple system atrophy-Parkinsonian type and dementia with Lewy bodies (Zhang <i>et al.</i> , 1999).
	↑	• Serum and CSF levels of 8-OH-dG significantly higher in PD and multiple system atrophy, compared to matched controls (Kikuchi <i>et al.</i> , 2002).
Alzheimer's disease (AD)	→	• DNA levels of 8-OH-dG in Alzheimer's disease brain, not associated with disease (Koppele <i>et al.</i> , 1996).
	↑	• Higher levels of 8-OH-dG in cortex and cerebellum of AD patients vs. controls (Lezza <i>et al.</i> , 1999).
	↑	• Ventricular cerebrospinal fluid (CSF) DNA levels of 8-OH-dG significantly ($P<0.05$) elevated and CSF levels of free 8-OH-dG significantly reduced ($P<0.05$) compared to controls (Lovell <i>et al.</i> , 1999).
	↑	• Significantly higher levels ($P<0.001$) of 8-OH-dG in lymphocytes from AD patients compared to controls (Mecocci <i>et al.</i> , 1998).
	↑	• Significant increase in 8-OH-Guo ² levels in CSF of AD patients, compared to controls, which decreased with duration of illness, and progression of cognitive dysfunction (Abe <i>et al.</i> , 2002). Consistent with the observation that oxidative damage to nucleic acids is an early event in pathogenesis of AD (Nunomura <i>et al.</i> , 2001).
	↑	• Significant increase in nuclear DNA 8-OH-dG levels and highly significant, threefold increase in mitochondrial DNA levels of 8-OH-dG in parietal cortex of AD patients compared with controls (Mecocci <i>et al.</i> , 1994).
Huntington's disease (HD)	→	• No difference between the levels of 8-OH-Gua, FapyAde ³ , 8-OH-Ade, FapyGua, 2-OH-Ade, xanthine and hypoxanthine in caudate, putamen and frontal cortex from HD brains, compared to controls (Alam <i>et al.</i> , 2000).
	↑	• Nuclear levels of 8-OH-dG significantly elevated in HD caudate (Browne <i>et al.</i> , 1997)
	↑	• Significantly increased mitochondrial 8-OH-dG levels in parietal cortex of HD patients, compared to controls. No significant differences in lesion levels in frontal cortex or cerebellum of HD patients, compared to controls (Polidori <i>et al.</i> , 1999).
Dementia with Lewy Bodies (DLB)	↑	• Increased levels of 8-OH-Gua, FapyGua, 5-OHCyt, 5-OHUr, 5-OHMUr and xanthine in cortical region of brain in DLB patients compared to control tissue (Lyras <i>et al.</i> , 1998).
Multiple sclerosis	↑	Significantly elevated levels of 8-OH-dG in plaques, compared to normal-appearing white matter in multiple sclerosis-affected cerebella (Vladimirova <i>et al.</i> , 1998).
Amyotrophic lateral sclerosis (ALS)	↑	• Levels of 8-OH-dG significantly increased in plasma, urine and CSF, compared to controls; levels of urinary 8-OH-dG increased over a nine month period and correlated with disease severity (Bogdanov <i>et al.</i> , 2000)
Down syndrome (DS) and AD	→	No difference in levels of 8-OH-dG in either cerebral cortex, or cerebellum in DS or AD brains, compared to controls Seidl <i>et al.</i> , 1997).

¹ 8-OH-Guo; 8-hydroxyguanosine.² FapyAde (4,6-diamino-5-formamidopyrimidine); 8-OH-Ade (8-hydroxyadenine); FapyGua (2,6-diamino-4-hydroxy-5-formamidopyrimidine); 2-OH-Ade (2-hydroxyadenine); 5-OHCyt (5-hydroxycytosine); 5-OHUr (5-hydroxyuracil); 5-OHMUr (5-hydroxymethyluracil).

It appears that mtDNA is only subject to GGR (Anson *et al.*, 1998). This situation is exacerbated in CSB where hOGG1 activity is deficient, eliminating 8-OH-Gua repair, although other lesions (uracil, hypoxanthine and Tg) do not appear affected (Stevnsner *et al.*, 2002). Whilst there are suggestions that NER might be involved in the repair of damage to mtDNA (for review see Croteau *et al.*, 1999), the inability to remove T<>T casts doubt upon this (Clayton *et al.*, 1974), emphasizing the importance of BER.

Inefficient repair of damage to mtDNA has a potential involvement in neurodegenerative disease, and yet, apart from the diseases arising from hereditary repair defects, there appear to be few studies directly linking repair deficiency and major neurodegenerative diseases. However, given the central role of repair in damage limitation, the numerous reports of elevated lesion levels in a variety of neurodegenerative diseases (see Table 10.2), and in corresponding mouse models (Bogdanov *et al.*, 2001; Aguirre *et al.*, unpublished data, 2004), might suggest defective DNA repair to be a common factor. Supportive of this hypothesis are a number of emerging reports which have considered repair. Of these, there are indications of impaired repair of oxidatively damaged mtDNA in Down syndrome (Druzhyňa *et al.*, 1998), although repair of nuclear DNA was not considered. In contrast, an increased expression of poly(ADP)-ribose polymerase, involved in the repair of strand breaks, has been reported in the brains of ALS patients, albeit suggested to be simply response to widespread oxidative stress (Kim *et al.*, 2004).

Marginally, more appears to be known about DNA repair and AD, with the suggestion that a repair defect may be present (Parshad *et al.*, 1996), although this does not appear to be TCR, given findings with T \leftrightarrow T (Link *et al.*, 1995). A more recent report notes that hOGG1 activity and helicase activity is significantly reduced in specific regions of AD brain (Lovell *et al.*, 2000). Consistent with this is the finding that lymphocytes from AD patients have a diminished repair of hydrogen peroxide-induced oxidized purines (Morocz *et al.*, 2002), which also implies that the repair defect is not restricted to neuronal tissue. A study with amyloid precursor protein mutant mice demonstrated that folic acid deficiency reduced the repair of amyloid β -peptide induced oxidative modification of DNA bases (Kruman *et al.*, 2002). This would suggest that environmental conditions, e.g. diet, may be responsible for the reduction in DNA repair capacity, rather than a genetic defect, perhaps explaining the reduced repair capacity in both neuronal cells and lymphocytes, described above.

Defects in the DNA damage response and neurological symptoms

The BRCA1-associated genome surveillance complex (BASC) is a large multiprotein complex, which comprises many proteins involved in the maintenance of genome stability, including: ATM (ataxia telangiectasia, AT), BLM (Bloom's syndrome, BS), and FANCD2 (Fanconi anemia, FA; (Watters, 2003) proteins. Whilst not involved in the repair of DNA *per se*, these proteins are worth mentioning, for when defective, they give rise to clinical symptoms with some similarity to those arising from DNA repair defects. For example, amongst the symptoms of AT is sensitivity to ionizing radiation, susceptibility to cancer, progressive neurodegeneration and premature aging (Watters, 2003). Similarly, symptoms of BS include cancer predisposition and mental retardation; FA, cancer predisposition, ventricular defects and microphthalmia (Rolig & McKinnon, 2000). Like XPB and XPD, FA and BLM are helicases, as are RECQL4 and WRN. Whilst not part of BASC, patients with defects in RECQL4 and WRN develop the cancer prone syndromes, Rothmund–Thomson syndrome and Werner syndrome (premature aging), with progressive neurodegeneration and mental retardation, respectively (Rolig & McKinnon, 2000).

Concluding remarks

Evidence for elevated levels of oxidative DNA damage has been reported in many of the major neurodegenerative diseases. Whether this arises from an overwhelming oxidative production, defects in repair, or a combination of the two, appears unclear. More certain is that, in general, diseases associated with DNA repair deficiencies, and TCR specifically, do exhibit neurological problems. In a broader context, defects in the response to DNA damage, may also result in neurological symptoms, particularly where helicases are involved. Therefore, a link between DNA repair deficiencies and neurological impairment does exist. Whilst there is some tantalizing evidence that this same mechanism may contribute to the pathogenesis of at least one of the major neurodegenerative diseases, further studies need to be performed, with the subsequent potential for intervention.

Compounds acting on ion channels

Holger Lerche and Frank Lehmann-Horn

Departments of Neurology and Applied Physiology, University of Ulm, Germany

Important factors of neuronal death in various diseases ranging from acute illness such as head trauma or stroke to rapidly or slowly progressive disorders such as amyotrophic lateral sclerosis or idiopathic parkinsonism are energy deficit and membrane depolarization. The communication of nerve cells via action potentials and synaptic transmission needs a highly negative resting membrane potential as well as strong transmembrane ionic gradients, which guarantee a regulated ion flow across the membrane. A large part of the energy demand of neurons is therefore required for active ionic pumps such as the Na/KATPase. A reduction of membrane excitability preventing membrane depolarization and decreasing the transmembrane ionic flow therefore diminishes the energy demand of neurons considerably. The pharmacological modification of the gating of voltage- or ligand-activated ion channels thus provides potentially powerful strategies for neuroprotection. The block of voltage-gated sodium or calcium channels directly reduces the influx of respective ions and decreases excitability, whereas the activation of potassium channels leads to a membrane hyperpolarization reducing excitability and secondarily influx of sodium and calcium through voltage-gated channels and other mechanisms. These neuroprotective strategies, the targets and compounds used for pharmacotherapy and available studies in animal models and humans are discussed in this chapter. The concept of excitotoxicity and neuroprotection by its antagonism by a block of glutamate receptors belonging to the group of ligand-gated ion channels is discussed in Chapter 4 of this book.

Sodium channel blockers

Voltage-gated sodium channels provide the basis for the generation and conduction of action potentials in nerve

and muscle cells. They open briefly upon depolarization and then close to a fast inactivated state, which limits the duration of an action potential and initiates its repolarizing phase. Upon repolarization they recover from inactivation and will be available for another action potential after a certain refractory period. Brain sodium channels consist of a main α - and two auxiliary β -subunits. The α -subunit is built of four homologous repeats with six transmembrane segments each. It constitutes both the gating and permeation machinery of the sodium channel as well as all known drug binding sites (Catterall, 2000a).

Sodium channel blockers can be divided into several different groups. The two most important categories are blockers of the outer pore such as Tetrodotoxin (TTX), and so-called use-dependent blockers binding to the inner pore, which are in clinical use as local anesthetics, antiarrhythmics or anticonvulsants. Whereas TTX is not suited for clinical use because of its toxicity due to a high-affinity block even in the resting state of the channel, use-dependent blockers bind predominantly to the inactivated state of the channel, which occurs only upon depolarization. These agents suppress series of action potentials increasingly with their frequency (therefore called “use dependence”) but do not considerably disturb activation, thus excitation, from the resting state (Urenjak & Obrenovitch, 1996).

The influx of sodium into neurons seems to have an intrinsic neurotoxicity as could be shown by experiments using the sodium channel opener veratridine or ischemia models in brain preparations or cell cultures. Whereas removing extracellular calcium had relatively small beneficial effects in these models and did not prevent cell death, replacing extracellular sodium in various of such experiments prevented neuronal death presumably due to failure of depolarization and subsequent influx of NaCl with excessive osmotic load, cell swelling and bleb formation.

Moreover, excessive sodium influx leads to an increase of calcium influx via a reversal of the Na/Ca exchanger, which under resting conditions extrudes calcium driven by the large transmembrane sodium gradient. Sodium channel blockers thus should have several different potentially neuroprotective mechanisms such as (i) a direct reduction of sodium influx, (ii) an indirect reduction of calcium entry, (iii) a direct reduction of membrane excitability and (iv) an indirect reduction of transmitter release via a decrease of presynaptic membrane excitability. The latter two mechanisms reduce the energy demand of nerve cells as well as the excitotoxicity by glutamate. Therefore, the block of sodium channels should be a very effective neuroprotective strategy, which has been demonstrated in a large number of animal studies (for review see Urenjak & Obrenovitch, 1996; Taylor & Meldrum, 1995).

The high affinity pore blocker tetrodotoxin as well as local anesthetics (e.g. lidocaine), anticonvulsants (e.g. phenytoin) and more unspecific drugs with action on sodium channels like flunarizine or vinpocetine showed neuroprotective effects in numerous anoxic *in vitro* and *in vivo* animal models such as cell cultures, the optic nerve, hippocampal and neocortical slice preparations or transient global and focal ischemia. Measurable effects were an improved recovery of population spikes in the hippocampus or of compound action potentials in the optic nerve, as well as a reduction of infarct volume and the extent of cell death. Cellular and molecular mechanisms, which might have been involved in these neuroprotective effects, included a delay of extracellular acidosis and anoxic depolarization, block of sodium and calcium entry as well as potassium efflux, reduction of ATP depletion and of the brain metabolic rate (comprehensive overview: Urenjak & Obrenovitch, 1996). Clinical trials with different sodium channel blockers in early therapy of ischemic stroke are under way or planned, but results have not been published until now. Since most of the described neuroprotective effects in animal studies were observed with early application of the drugs, sometimes before the injury, it might be difficult to obtain a measurable benefit in clinical trials of acute stroke therapy.

Riluzole is the only drug that has been shown to have a neuroprotective effect in a chronic neurodegenerative disease, amyotrophic lateral sclerosis (Bensimon *et al.*, 1994), besides its well-documented effect in numerous animal models ranging from brain ischemia to spinal cord injury (Obrenovitch & Urenjak, 1997). The drug also blocks sodium channels in a use-dependent manner with a high affinity for the inactivated state similar to local anesthetics and anticonvulsants. This might be one of the main mechanisms of action in neuroprotection of riluzole as

derived from *in vitro* investigations (Doble, 1997). However, other pharmacological properties of this drug might be even more important for its neuroprotective effects as will be outlined further below (see potassium channel activators).

Potassium channel openers

There is a huge variety of potassium channels expressed in excitable and non-excitable tissues (comprehensive and detailed overview: Hille, 2001). Voltage-gated potassium channels (K_v) activate upon membrane depolarization and contribute to the repolarizing phase of the action potential. They can be inactivating or not. The inactivating channels yield the transient A current, whereas the non-inactivating ones the so-called delayed rectifier potassium current characterized by sustained activation increasing with depolarization. K_v channels are structurally similar to sodium and calcium channels with six transmembrane regions but are built of four identical domains. Large-conductance calcium-activated potassium channels (BK_{Ca}) have a similar structure but a much weaker voltage dependence and are opened by elevated intracellular calcium concentrations. Inward rectifier potassium channels (K_{ir}) may be important for the resting membrane potential since they open at negative potentials and close with depolarization. They are tetramers of only two transmembrane domains, which are structurally conserved among potassium channels and form the pore region with the selectivity filter as was first demonstrated for the crystallized bacterial potassium channel KcsA (Doyle *et al.*, 1998). ATP-dependent potassium channels (K_{ATP}) are derived from K_{ir} and have an octameric structure with another subunit yielding the ADP/ATP-sensitivity, the sulfonyleurea receptor. K_{ATP} channels are closed when enough ATP is present intracellularly. They open with falling ATP and increasing ADP levels, thus when cells are energetically exhausted. Recently, a different class of potassium channels with four transmembrane segments has been identified, called 'two P domain potassium channels' (K_{2P}), due to their two pore regions. They are responsible for background or 'leak' potassium currents and are regulated by several different mechanisms such as membrane stretching, pH, lipids, second messengers and drugs (for review see Patel & Honore, 2001).

As a potassium outward current hyperpolarizes the cell membrane until the potassium equilibrium potential of about -85 mV is reached, an activation of potassium channels is needed for a neuroprotective effect based on a reduction of membrane excitability and secondarily of the neuronal energy demand. However, a lot of potassium channels

for which activators have been developed are more or less expressed ubiquitously in mammalian cells which makes their use as therapeutic targets for a neuroprotective therapy difficult, due to systemic, mainly cardiovascular side effects.

The first potassium channel activators were available for K_{ATP} channels and a neuroprotective effect, for example, in ischemic models of rat hippocampus could be shown for several different types of these drugs (Heurteaux *et al.*, 1993). The neuroprotective mechanism seems to be related to an endogenous form of neuroprotection. During neuronal hypoxia, an initial hyperpolarization is followed by the final and lethal depolarization (Hansen, 1985). The hyperpolarization is caused by an activation of K_{ATP} channels (Riepe *et al.*, 1992). Activation of K_{ATP} channels might play an important role in ischemic and chemical preconditioning as the neuroprotective effect of chemical preconditioning could be partly antagonized by glibenclamide, a classical blocker of K_{ATP} channels (Riepe *et al.*, 1997). An endogenous neuroprotective role of these channels is also suggested by experiments showing that differential expression of the sulfonylurea receptor correlates to the expression of functional K_{ATP} channels and might contribute to the selective vulnerability in dopaminergic midbrain neurons (Liss *et al.*, 1999). Owing to cardiovascular side effects, K_{ATP} channel openers have not been used in clinical trials. New compounds with direct or indirect action on these channels dissociating vasorelaxation from protective effects in the heart and/or the brain might be key to a clinical use of these drugs (Yoo *et al.*, 2001).

Another newly developed potassium channel opener, BMS-204352, with neuroprotective effects acts on BK_{Ca} channels and a type of slow delayed rectifier potassium channels, so-called KCNQ channels. This compound was effective in rodent stroke models (Gribkoff *et al.*, 2001). It was well tolerated in patients but failed to be efficient in therapy of acute stroke in a Phase III trial (Jensen, 2002).

As already mentioned above, the neuroprotective mechanism of action of riluzole in amyotrophic lateral sclerosis as well as in various models of ischemia and trauma is not completely understood. Recently, it was demonstrated that two types of K_{2P} channels (TREK-1 and TRAAK), both activated by arachidonic acid and stretching, are activated directly by riluzole (Duprat *et al.*, 2000). Similar to the block of sodium channels by riluzole, this different mechanism of action would stabilize the resting membrane potential and decrease membrane excitability which first has a direct neuroprotective effect and second could also explain the known reduction of glutamate release. While TREK-1 is expressed in many tissues, TRAAK is found only in brain, spinal cord and retina. Therefore, in particular, TRAAK may

be a very attractive target for future selective neuroprotective agents.

Calcium channel antagonists

Voltage-gated calcium channels were first divided physiologically in low-voltage activated, fast inactivating ("transient," T-type) channels and high-voltage activated, slowly inactivating ("long-lasting," L-type) channels. Both channel types are mainly found in muscle and nerve cells. L-type channels are key players of electromechanical coupling transferring an action potential into a muscle contraction. They are blocked by three classes of drugs, dihydropyridines (e.g. nifedipine), phenylalkylamines (e.g. verapamil) and benzothiazepines (e.g. diltiazem). In neurons, several additional types of calcium channels were found, which are similar in their electrophysiological properties with activation by large depolarizations (high-voltage activated) and a slow inactivation. They could be differentiated by their response to peptide toxins from cone snails and spiders. N-type channels (neuronal) are sensitive to ω -conotoxin GVIA and P/Q-type channels (purkinje) to ω -Aga IVA, whereas R-type channels are resistant to these toxins. These neuronal channels are dominant at presynaptic nerve terminals and important for transferring an action potential into the secretion of neurotransmitters into the synaptic cleft. Calcium channels are all structurally very similar to sodium channels and built of several subunits, a main α_1 -subunit containing the pore, gating machinery and drug binding sites, and different auxiliary subunits called β , $\alpha_2\delta$ and γ (Hille, 2001; Catterall, 2000b).

Since a calcium overload is thought to be one of the crucial steps in neurodegeneration (see Chapters 4 and 6) and since calcium enters the cell upon depolarization through ion channels, a block of voltage-gated calcium channels should be a promising strategy for neuroprotection. Various L-type calcium channel antagonists are in clinical use as antihypertensive and antiarrhythmic drugs. They have been investigated for many years for their neuroprotective effects in *in vitro* and *in vivo* models of ischemia and many clinical trials have been performed with acute stroke patients. While beneficial effects in animal models seemed first to be convincing, the clinical trials could only partly reveal positive effects. In two recent meta-analyses, Horn and colleagues evaluated both animal studies and clinical trials with L-type calcium channel antagonists designed for the treatment of stroke (Horn *et al.*, 2001; Horn & Limburg, 2001). The overall results were not promoting a neuroprotective effect of these drugs (mainly nifedipine or flunarizine, isradipine or nicardipine in one trial each) in stroke

patients. The authors even concluded that the animal studies did not reveal a clear neuroprotective effect of nifedipine and discussed whether clinical trials should have been performed at all with regard to these poor experimental results. Furthermore, there are also reports that L-type calcium channel antagonists or low extracellular calcium or potassium concentrations may induce apoptotic cell death via a permanently reduced calcium influx or a reduced intracellular calcium concentration (Koh & Cotman, 1992; Galli *et al.*, 1995). Altogether, the hints for a possible neuroprotective effect of L-type calcium channel antagonists are weak and these drugs seem not to be suited for clinical use, at least in acute stroke therapy.

However, compounds blocking neuronal calcium channels (N-type, P/Q-type) might be more effective (Kobayashi & Mori, 1998), but they have yet not been investigated in clinical trials. For example, the imidazoline compound, antazoline, which protects against hypoxia and NMDA toxicity in neuronal cell cultures, was shown to block P/Q- and N-type calcium channels (Milhaud *et al.*, 2002). The N-type calcium channel antagonist, SNX-111, a synthetic product of the naturally occurring ω -conotoxin MVIIA, also seems to have a neuroprotective potential (Perez-Pinzon *et al.*, 1997; Bowersox & Luther, 1998).

Concluding remarks

In summary, many different drugs acting on ion channels have proved to be neuroprotective in various animal and cell culture models. The clinical benefit of such drugs, however, remains questionable as long as only for a single compound – riluzole, for which the mechanism of action is still not fully understood – a neuroprotective effect could be shown in a single disease, amyotrophic lateral sclerosis. A major problem of all clinical trials, in particular those for acute stroke therapy, might be that therapy starts always too late. We can only hope that earlier diagnosis and treatment in both stroke and neurodegenerative disorders will be possible in the future and that trials starting therapy as early as possible will be able to transfer the positive laboratory results into a clinical benefit for our patients.

The role of nitric oxide and PARP in neuronal cell death

Mika Shimoji, Valina L. Dawson and Ted M. Dawson

Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Nitric oxide

Nitric oxide (NO) is a novel neuronal messenger molecule that is not confined to the synaptic cleft and can mediate rapid signaling by diffusing freely in three dimensions to act throughout local regions of neural tissue (Dawson & Dawson, 1998). NO can be generated in most tissues in the body and was first identified as endothelium-derived relaxing factor (EDRF) in blood vessels where it is the major regulator of vascular tone (Furchgott & Zawadzki, 1980; Palmer *et al.*, 1987; Kilbourn & Belloni, 1990; Ignarro, 1991). NO is produced by the enzymatic conversion of L-arginine to L-citrulline by nitric oxide synthase (NOS). In the NO biosynthetic scheme, L-arginine is first oxygenated to the intermediate N^G-hydroxy-L-arginine, which is then oxygenated to produce NO and L-citrulline. NO has a short half-life due to the pervasive action of superoxide (Palmer *et al.*, 1987). There are three isoforms of NOS. Two isoforms are expressed constitutively (neuronal; nNOS, endothelial; eNOS) and one that expressed only after induction (inducible; iNOS) (Fujisawa *et al.*, 1994; Chartrain *et al.*, 1994; Marsden *et al.*, 1993). Both the constitutive and inducible forms are tetrahydrobiopterin (BH₄) dependent (Tayeh & Marletta, 1989; Kwon *et al.*, 1989). The constitutive isoforms, nNOS and eNOS are Ca²⁺/calmodulin regulated and thus NO generation is dependent on calcium signaling events. However, iNOS is Ca²⁺/calmodulin independent and therefore NO is generated from iNOS upon protein expression. NO generation from iNOS is regulated by the duration of mRNA expression for iNOS (Dawson & Dawson, 1998). Regulation of iNOS occurs primarily at the transcriptional and translational level, once the transcriptional signal has been eliminated, iNOS message and protein are rapidly degraded (Lowenstein *et al.*, 1993).

NO can elicit such diverse cellular signaling due to a wide variety of molecular targets including soluble

guanylylate cyclase, other heme-containing enzymes including cyclooxygenase, thiol moieties and tyrosine residues on proteins, iron-sulfur-containing proteins and superoxide anion. Although NO is a free radical, it is not widely reactive and has a limited chemistry restricting the potential target molecules it can modify. Signaling is thought to occur largely through nitrosylation and nitration reactions (Stamler *et al.*, 2001; Marshall *et al.*, 2000). While NO is important in normal neuronal signaling, when NO production is unregulated or excessive, NO can mediate neuronal degeneration. Many of the toxic actions of NO have been linked to the generation of peroxynitrite following the reaction with superoxide anion. NO has been implicated in the neuropathology of stroke, trauma, AIDS dementia, Alzheimer's disease, Parkinson's disease, multiple sclerosis, as well as bacterial and viral encephalitis (Dawson & Dawson, 1998).

Poly(ADP-ribose) polymerase-1

Poly(ADP-ribose) polymerase-1 (PARP-1; EC 2.4.2.30) is a nuclear zinc-finger DNA binding enzyme that facilitates DNA repair upon activation by DNA damage (Shall & de Murcia, 2000; Lautier *et al.*, 1993). DNA strand breaks, generated either directly by endogenous free radicals (i.e. oxygen radicals), exogenous DNA damaging agents (i.e. ionizing radiation, mono-functional alkylating agents) or indirectly following enzymatic incision of DNA, can trigger an acute cellular response accompanied by the synthesis of poly(ADP-ribose) by PARP-1. At the site of DNA breakage, PARP-1 catalyzes the successive transfer of ADP-ribose moiety units from its substrate, β -nicotinamide adenine dinucleotide (NAD⁺), to a variety of proteins (Chambon *et al.*, 1963) including PARP-1 itself. Poly(ADP-ribose) polymers are negatively charged, therefore proteins that are

poly(ADP-ribose)ylated such as those involved in chromatin structure including histones H1, H2B, high mobility group (HMG) proteins and lamin B or proteins involved in DNA metabolism lose their affinity for DNA. PARP enzyme activity has been documented in many different classes of organisms from lower eukaryotes such as *Dictyostelium discoideum* and *Cryptosporidium parvum* (Rickwood & Osman, 1979; Werner *et al.*, 1984), to higher eukaryotes from snail, *Helix pomatia* to man (Burtscher *et al.*, 1986, 1987; Ushiro *et al.*, 1987). The nucleotide and amino acid sequence comparison among different organisms reveals 61 to 88% homology and structural conservation of functional elements (two zinc fingers, nuclear localization signal, leucine-zipper motif and NAD-binding structure) among *Drosophila melanogaster*, *Xenopus laevis*, chick, mouse, bovine and human PARP-1 (Uchida & Miwa, 1994).

PARP-1 is a very abundant enzyme with up to one PARP-1 molecule for each 1000 bp of DNA (Lautier *et al.*, 1993) or one million molecules per cell (Ludwig *et al.*, 1988; Yamanaka *et al.*, 1988) and it has a long half-life. PARP-1 is the isoform of PARP family that produces the large, branched chain polymers. It is a 113 kDa protein localized to the nucleus of all cells. PARP-1 is composed of three major domains: the NH₂-terminal region, the central auto-modification domain, and COOH-terminal region. The 42 kDa NH₂ terminal is the DNA binding domain containing two zinc fingers for DNA strand break recognition (Cherney *et al.*, 1987; Mazen *et al.*, 1989) and it contains the nuclear localization signal for targeting PARP-1 to the cell nucleus (Uchida *et al.*, 1987). The 16 kDa internal region of PARP-1 includes the auto-modification domain (Alkhatib *et al.*, 1987; Kurosaki *et al.*, 1987) containing 15 conserved glutamic acids that are presumed targets for poly(ADP-ribose) (Cherney *et al.*, 1987; Uchida *et al.*, 1987) and a BRCT (BRCA1 C terminus) domain at amino acids 384–479 (Zhang *et al.*, 1998). BRCT domains are suggested to be protein–protein interaction modules, allowing strong and specific associations with other BRCT-motif containing proteins. The 55 kDa COOH-terminal region of PARP-1 contains the NAD⁺ binding site and catalytic domain, which synthesizes the poly(ADP-ribose), and is the most conserved region of the protein in all species (Ruf *et al.*, 1996; Uchida & Miwa, 1994).

PARP-1 is inactive in the absence of DNA damage or fragmentation; however, its enzymatic activity can increase 500-fold on binding to DNA fragments. PARP-1 ribosylates histones (Krupitza & Cerutti, 1989), topoisomerase I and II (Krupitza & Cerutti, 1989; Scovassi *et al.*, 1993), DNA-dependent protein kinase (Ruscetti *et al.*, 1998), DNA polymerase α and β (Ohashi *et al.*, 1986; Yoshihara *et al.*,

1985), DNA ligase I and II (Yoshihara *et al.*, 1985), HMG proteins (Tanuma *et al.*, 1985; Tsai *et al.*, 1992), p53 (Wesierska-Gadek *et al.*, 1996a; Wesierska-Gadek *et al.*, 1996b), and PARP-1 itself (Lautier *et al.*, 1993). PARP-1 activation following DNA damage/fragmentation is an early event and is elicited by very small amounts of DNA damage. Poly(ADP-ribose)ylation of histones results in chromatin relaxation (Frechette *et al.*, 1985; Niedergang *et al.*, 1985). The chromatin de-condensation is restored when poly(ADP-ribose) is degraded (de Murcia *et al.*, 1986). The de-condensation of chromatin is believed to facilitate the DNA repair at sites of DNA damage and affects DNA transcription at transcription initiation sites. Autopoly(ADP-ribose)ylation inhibits PARP-1 activity by separating PARP-1 from DNA. The release of PARP-1 from DNA permits DNA repair enzymes access to the break points (de Murcia & Menissier de Murcia, 1994). The timing of PARP-1 attachment to and release from DNA helps to synchronize the repair process. Binding of PARP-1 to DNA may also prevent inappropriate DNA recombination by repelling other DNA molecules (Chatterjee *et al.*, 1999, de Murcia *et al.*, 1997; Morrison *et al.*, 1997; Wang *et al.*, 1997).

Activation of PARP-1 is energetically expensive, for every mole of ADP-ribose transferred from NAD⁺, one mole of NAD⁺ is consumed and four free energy equivalents of ATP are required to regenerate NAD⁺ to normal cellular levels (Shall & de Murcia, 2000; Lautier *et al.*, 1993). Intense activation of PARP-1 can result in a rapid depletion of cellular NAD⁺ and ATP (Berger, 1985; Carson *et al.*, 1986). During PARP-1 activation, it consumes up to 200 molecules of NAD⁺ at each catalytic step and leads to cellular depletion of NAD⁺ and ATP, decreased DNA, RNA, and protein synthesis (Berger, 1985; Carson *et al.*, 1986; Oleinick & Evans, 1985). Additionally, excessive PARP-1 activation often occurs in a setting of impaired cellular respiration and metabolism, which combined with the loss of NAD⁺ and ATP may contribute to eventual cell death. This process, however, can be prevented by chemical inhibition of PARP-1 activity or PARP-1 gene deletion in mice (Pieper *et al.*, 1999b; Szabo & Dawson, 1998; Pieper *et al.*, 1999a).

PARP-1 mediated neurotoxicity is executed by apoptosis inducing factor

Studies from different laboratories link production of NO and other free radical species to PARP-1 activation and to the cell death and tissue damage after excitotoxic or immunologic insults (Smith, 2001). However, it is still uncertain how activation of PARP triggers the cell death

cascade. Recent investigations indicate that excitotoxicity followed by PARP-1 activation is likely mediated via apoptosis inducing factor (AIF) and its translocation from mitochondria to the nucleus (Yu *et al.*, 2002).

AIF is a mitochondrial flavoprotein that mediates caspase-independent cell death (Ferri & Kroemer, 2001). In response to toxic stimuli, AIF initiates cell death by translocation from mitochondria to the nucleus to induce nuclear condensation and DNA fragmentation (Susin *et al.*, 1999; Joza *et al.*, 2001; Daugas *et al.*, 2000). Excitotoxic concentrations of NMDA triggers neurotoxicity that is caspase independent and PARP-1 dependent (Yu *et al.*, 2002). Following PARP-1 activation AIF translocates from mitochondria to the nucleus, preceding cytochrome c release and activation of the major execution caspase, caspase 3. The time course of AIF translocation is coincident with changes in nuclear morphology (nuclear condensation) and DNA damage (Yu *et al.*, 2002). Accompanying AIF translocation is mitochondrial membrane depolarization and phosphatidylserine exposure on the cell surface. Overexpression of Bcl-2, an anti-apoptotic protein, can delay or prevent AIF translocation and protect against PARP-1 dependent cell death (Yu *et al.*, 2002). Furthermore, neutralizing antibodies to AIF provides substantial cytoprotection against PARP-1 dependent cell death (Yu *et al.*, 2002). Taken together, these data suggest a key role for AIF in affecting caspase-independent forms of cell death in the nervous system.

Excitotoxicity and experimental stroke

NO is an important signaling molecule; however, in the presence of superoxide anion the potent neurotoxin, peroxynitrite is produced (Dawson *et al.*, 1993a). The reaction of NO with superoxide anion results in peroxynitrite that can oxidize proteins, lipids, RNA, and DNA (Beckman *et al.*, 1994a, b; Koppenol *et al.*, 1992). In particular, peroxynitrite oxidizes DNA leading to single strand breaks that trigger PARP-1 activation. There is an important link between NO formation and neurotoxic PARP-1 activation (Zhang *et al.*, 1994). Brain extracts treated with NO results in ADP-ribosylation of PARP-1 (Zhang *et al.*, 1994).

In cerebral cortical cultures and primary brain cultures excess stimulation of glutamate receptors results in excitotoxicity. NO-mediated excitotoxicity occurs primarily through activation of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors. nNOS is physically coupled to the NMDA receptor via postsynaptic density 95 protein (PSD95) (Christopherson *et al.*, 1999). Disruption of this interaction results in loss of NO production and

rescue from excitotoxic and ischemic cell death (Sattler *et al.*, 1999; Aarts *et al.*, 2002). Pharmacological inhibition of nNOS or genetic deletion of nNOS provides neuroprotection. Exposure of cerebral cortical cultures to chemical donors of NO also results in neurotoxicity (Dawson *et al.*, 1991, 1993a). Exposure to superoxide dismutase (SOD) reduced NMDA and NO neurotoxicity implicating superoxide anion and peroxynitrite formation in excitotoxicity. These findings in cell culture have been extended into whole animals. In the nNOS knockout mice experimental stroke damage is diminished in male mice (Huang *et al.*, 1994), and NOS inhibitors reduce stroke damage to a similar extent as glutamate antagonists (Samdani *et al.*, 1997). Although nNOS knockout mice are very resistant to focal and global ischemia (Hara *et al.*, 1996; Panahian *et al.*, 1996), the resistance to ischemia diminishes with non-specific NOS inhibitors treatment (Dalkara & Moskowitz, 1997). In part this is due to non-specific inhibition of eNOS. Regulation of cerebral blood flow is critically dependent on NO generated by eNOS. Infarct volume is increased in eNOS knockout mice, and this injury is reduced following treatment with NOS inhibitors (Huang *et al.*, 1996). Thus, NO derived from nNOS mediates neurotoxicity following focal ischemia, while NO derived from eNOS is important in maintaining cerebral blood flow and has a protective role in focal ischemia (Moskowitz & Dalkara, 1996).

Although peroxynitrite can oxidize most cellular constituents including proteins, lipids, RNA and DNA, it is its actions on damaging DNA and activating PARP-1 that appears to be the primary mechanism of triggering neurotoxicity. Primary cortical cultures treated with pharmacologic antagonists of PARP are resistant to exposure to neurotoxic concentrations of NMDA, NO or oxygen-glucose deprivation (Eliasson *et al.*, 1997; Zhang *et al.*, 1994). Similarly, cultures generated from PARP-1 null mice are also resistant to these toxic insults (Eliasson *et al.*, 1997). In the transient middle cerebral artery occlusion experimental mouse model of stroke, PARP-1 knockout mice show 78% decrease and PARP-1 heterozygous mice show 65% decrease in ischemic tissue damage as compared to wild-type mice (Eliasson *et al.*, 1997). Similarly, the potent PARP inhibitor, 3,4-dihydro-5-[4-(1-piperidinyl)butox]-1(2H)-isoquinolinone (DPQ), protects against experimental stroke damage in rats (Takahashi *et al.*, 1999). A role for PARP activation in human stroke is suggested by the observation of elevated levels of poly(ADP-ribose) in patients who suffered global cerebral ischemia after cardiac arrest when compared with matched controls (Love *et al.*, 1999b).

Parkinson's disease

Some of the neuropathology of Parkinson's disease can be elicited by selective destruction of dopamine (DA) neurons of substantia nigra (SN) following administration of the neurotoxin, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) in primates and rodent animal models (Burns *et al.*, 1983; Lau *et al.*, 1990; Petroske *et al.*, 2001). The neurotoxic effect of MPTP that results in the parkinsonian syndrome was first discovered in the intravenous drug user community in early 1980s (Langston *et al.*, 1983). MPTP is a highly lipophilic chemical that can easily cross the blood–brain barrier; however, MPTP itself is not toxic in the brain. Once MPTP is inside the brain, it is taken up by astrocytes and metabolized to MPDP⁺ by monoamine oxidase B (MAO-B) (Chiba *et al.*, 1984; Markey *et al.*, 1984) then oxidized to MPP⁺. MPP⁺ is then released to the extracellular space and taken up selectively and actively by the high affinity DA transporter and accumulated in DA neurons (Chiba *et al.*, 1985; Javitch *et al.*, 1985). In DA neurons MPP⁺ accumulates in mitochondria via energy driven uptake (Singer *et al.*, 1987), where it binds to complex I (Nicklas *et al.*, 1985; Ramsay *et al.*, 1991) and disrupts the NAD-linked mitochondrial respiratory chain. This disturbance in mitochondrial respiration results in a decrease in ATP production and an increase in superoxide anion formation in DA neurons (Ramsay & Singer, 1992). The increase in superoxide anion formation can lead to formation of peroxynitrite, further inhibition of mitochondrial function by damaging MnSOD activity (MacMillan-Crow *et al.*, 1996), and more superoxide formation, starting a self-destructive cycle of events. Peroxynitrite can also damage DNA leading to PARP activation (Zhang *et al.*, 1994, 1995), loss of energy and possibly AIF translocation. Preliminary data suggest that AIF translocates following MPTP intoxication. Consistent with the hypothesis that DA neurons dies via this pathway following MPTP intoxication are the findings that nNOS, iNOS and PARP-1 knockout mice are resistant to MPTP neurotoxicity (Przedborski *et al.*, 1996; Liberatore *et al.*, 1999; Mandir *et al.*, 1999).

Aggregated alpha-synuclein is a major component of Lewy bodies, which are the histochemical hallmarks of Parkinson's disease. In vitro, exposure of human recombinant alpha-synuclein to peroxynitrite induces formation of highly stable nitrated alpha-synuclein oligomers and nitrated pre-assembled alpha-synuclein filaments leads to the formation of high molecular mass aggregates (Souza *et al.*, 2000). Nitration of alpha-synuclein also occurs in the mouse striatum and ventral midbrain following intoxication with MPTP (Przedborski *et al.*, 2001). In human post-mortem tissue nitrated alpha-synuclein is present in Lewy

bodies from patients with Parkinson's disease (Giasson *et al.*, 2000). Taken together, these findings support the hypothesis that NO plays a major role in the neurodegeneration and neurotoxicity of Parkinson's disease.

Inflammatory neurodegenerative diseases

Acquired immunodeficiency syndrome patients often present with neurological symptoms and cognitive impairment that is sometimes associated with pronounced cortical atrophy (Navia *et al.*, 1986; Atwood *et al.*, 1993; Power & Johnson, 1995). However, the localization of the HIV virus in the CNS is almost exclusively in macrophages, microglia and multi-nucleated giant cells (Takahashi *et al.*, 1996; Wiley *et al.*, 1986). First, it was suggested that this atrophy was caused indirectly by toxic effects of HIV coat protein, gp120 (Lipton, 1992) activating glutamate excitotoxicity through a NMDA receptor/nNOS pathway (Dawson *et al.*, 1993b). However, local inflammatory responses including expression of cytokines and iNOS are a consistent observation in human tissue. In HIV-associated dementia, the HIV coat protein gp41 may be the molecule that significantly contributes to the induction of iNOS and other inflammatory molecules leading to the production of NO and subsequent neuronal cell death/tissue atrophy (Adamson *et al.*, 1996). There is evidence of increased iNOS mRNA expression and protein level in cortical brain tissues of HIV patients with severe HIV-1 dementia that correlates with the levels of HIV-1 coat protein gp41, but not gp120 (Adamson *et al.*, 1996). Gp41 can induce iNOS in mixed neural cultures to trigger neuronal cell death in a NO-dependent manner. Neuronal cultures from iNOS knockout mice are resistant to gp41 neurotoxicity (Adamson *et al.*, 1999). The actions of gp41 are specific to the N-terminal region of gp41, which induces iNOS protein activity and iNOS-dependent neurotoxicity at picomolar concentrations in a manner similar to recombinant gp41 (Adamson *et al.*, 1999).

Alzheimer's disease is a progressive dementing neurologic disorder, and the most frequent cause of dementia in the elderly. Pathologically, Alzheimer's disease is characterized by excessive deposition of the protein beta-amyloid and the formation of neuritic plaques and tangles. A striking feature of neuritic plaques is the presence of activated microglia, cytokines, and complement components, suggestive of "inflammatory foci" within Alzheimer's disease brain (Butterfield *et al.*, 2002). Included in these inflammatory foci is the expression of iNOS and markers of increased oxidation (Luth *et al.*, 2001; Heneka *et al.*, 2001; Floyd, 1999) implicating expression of iNOS and NO as a contributory factor in the pathogenesis of Alzheimer's disease. Although

it is not clear by which mechanism PARP-1 might play a role in Alzheimer's disease, study of postmortem tissue reveals increased poly(ADP-ribose) levels in brains of Alzheimer's disease patients implicating PARP activation in neuronal cell loss in this disorder (Love *et al.*, 1999a).

Nitric oxide (NO) has been implicated as a pathogenic mediator in central nervous system demyelinating disease states, including multiple sclerosis and the animal model of experimental allergic encephalomyelitis. Induction of iNOS occurs in active demyelinating regions in brains of patients with multiple sclerosis (Liu *et al.*, 2001; Bo *et al.*, 1994; Bagasra *et al.*, 1995; De Groot *et al.*, 1997). Induction of iNOS is observed in experimental allergic encephalomyelitis (Lin *et al.*, 1993; Parkinson *et al.*, 1997; Gold *et al.*, 1997; Cross *et al.*, 1997; Sun *et al.*, 1998). Experimental induction of iNOS is toxic to neurons (Dawson *et al.*, 1994) and to the myelin producing oligodendrocytes (Merrill *et al.*, 1993). NO generated from iNOS may contribute significantly to the cytotoxicity of oligodendrocytes and destruction of myelin in brain and spinal cord in patients suffering from multiple sclerosis.

Inhibitors of nitric oxide synthase

Although there are three structurally distinct isoforms of NOS: neuronal (nNOS), endothelial (eNOS) and inducible (iNOS), the catalytic domains of these proteins are similar which has hampered development of selective agents. Since overactivation of nNOS and iNOS are injurious to the nervous system but eNOS is critical for the maintenance of cerebral blood flow, the development of selective agents is critical for the successful therapeutic use of NOS inhibitors for the treatment of neurologic disease. However, information on the enzyme structure at all levels from the primary to quaternary structure may facilitate the development of selective therapeutic tools (Alderton *et al.*, 2001). The NOS enzymes are dimers in their active form, although they require calmodulin at each subunit and therefore could be considered tetramers (two NOS monomers associated with two calmodulins). They contain tightly bound cofactors including: (6R)-5,6,7,8-tetrahydrobiopterin, FAD, FMN and iron protoporphyrin IX (heme). *In situ*, NOSs are regulated by cofactor binding or expression, phosphorylation, localization, protein-protein interactions, myristoylation, and palmitoylation. Most pharmacologic development, however, has focused on generating agents active towards the catalytic domain. Unfortunately, a comparison of human eNOS and iNOS oxygenase structures reveals them to be very similar in overall molecular shape, relative orientation of cofactors

and stereochemistry within the catalytic center and so it is not obvious from a structural starting point how selective inhibitors may be designed. There are numerous NOS inhibitors described in the literature and used as pharmacological tools. The most widely used have been L-NMMA, L-NNA, NG-nitro-L-arginine methyl ester (L-NAME) and aminoguanidine. These agents are commercially available and have good tissue penetration, however, they are generally non-specific and so experimental data must be interpreted with caution. There is currently no consideration for the use of these agents in the clinic. The general classes of inhibitors are arginine analogs, thiocitrullines, indazoles, substituted guanidamines, thioureas and noncompetitive agents. Specificity has been assigned by small differences in potency for inhibiting one isoform over another, apparent *in vivo* selectivity due to bioavailability (such as the case for 7-nitroindazol), or differences in the time course to inhibit the difference enzymes. Unfortunately, most inhibitors are relatively non-selective to NOS isoform. The identification of selective inhibitors of iNOS and nNOS has been a goal of both academic and pharmaceutical scientists. The observation of very high structural homology between the catalytic and regulatory domains of the three isoforms has led to concern about whether selective inhibition is feasible. Recently, there have been reports of agents that are selective for iNOS/nNOS over eNOS and some agents that are highly selective for iNOS. These sulfur-substituted acetamidine amino acids (GW273629 and GW274150) are an advance over previously reported iNOS selective inhibitors in that they have tissue penetration and are not acutely toxic (Alderton *et al.*, 2001). There are still many questions regarding the biology of NOS isoforms that may shed light on the development of selective agents. Are there post-translational modifications that are significantly different in the regulation of the three isoforms that can be capitalized on? What is the significance and basis of the subcellular localization of the NOSs? Where are splice variants of the NOS isoforms expressed and do they have biologic significance in disease states? What is the molecular and structural basis of the high isoform selectivity of some NOS inhibitors? If selective iNOS, nNOS or dual iNOS/nNOS inhibitors can be identified, it is expected that they will prove to be of value in the treatment of human diseases.

PARP inhibitors

Development of neuroprotective PARP inhibitors faces additional challenges because activation of PARP has dual effects on the survival or death of cells. Comprehending the

complex role of PARP in the cell death process is important to understanding how PARP inhibition can protect from or enhance cytotoxicity depending on the nature and severity of DNA damage. The exact mechanism of how PARP activation promotes cell death in certain systems or protects from cytotoxicity in others requires further investigation. The nature of genotoxic stimuli (oxidative stress, alkylating agents, ionizing radiation, etc.) and cellular metabolism are usually considered to be key factors in determining the role of poly(ADP-ribosylation) in the cell death process. Depending on the intensity of the stimulus, genotoxic agents can trigger three different pathways. In the case of mild DNA damage, poly(ADP-ribosylation) facilitates DNA repair and thus survival. Increasing DNA damage may activate the p53-dependent (or possibly independent) apoptotic pathway(s). The most severe DNA damage may cause excessive PARP activation, depleting cellular NAD^+ /ATP stores and resulting in necrotic-like cell death. Inhibiting PARP in cells that are attempting DNA repair will send the cells into apoptosis however, inhibiting PARP in cells that are undergoing cell death may facilitate their survival.

The prototype PARP inhibitors include nicotinamide, benzamide and 3-aminobenzamide that have long served as experimental agents suitable for laboratory investigations. These compounds inhibit the enzyme with a low potency, have limited cell uptake and have a short half-life. Additionally, these agents are non-specific to PARP isoform as well as exhibiting other non-specific effects, including acting as antioxidants. Recently, several other classes of more potent and selective PARP inhibitors have been synthesized. Most PARP inhibitors fall into the categories of monoaryl amides and bi-, tri-, or tetracyclic lactams. Most PARP inhibitors are designed as competitive inhibitors blocking the NAD^+ binding site in the catalytic domain. 3,4-dihydro-5-methyl-isoquinolin-1(2H)-one, benzoxazole-4-carboxamide, dihydroisoquinolin-1(2H)-ones, 1,6-naphthyridine-5(6H)-ones, quinazolin-4(3H)-ones, thieno[3,4-c]pyridin-4(5H)ones and thieno[3,4-d]pyrimidin-4(3H)ones, 1,5-dihydroxyisoquinoline, and 2-methyl-quinazolin-4[3H]-one are potent and relatively selective inhibitors of PARP. Their isoform selectivity is not yet known. 1,8-Naphthalimide derivatives and (5H)-phenanthridin-6-ones are new PARP inhibitors represented by PJ34 and GPI 6150. These agents have been shown to be effective in limiting injury in experimental rodent models of focal cerebral ischemia, traumatic brain injury, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced damage to dopaminergic neurons, regional myocardial ischemia, streptozotocin-induced

diabetes, septic shock, and arthritis. PARP inhibitors have been shown not only to block early neuronal injury elicited in large part by excitotoxic cascades but to also limit inflammatory reactions. This secondary effect of PARP inhibitors may prevent the secondary injury seen in many neurological diseases due to activation of local inflammation around the site of injury. Inhibition of PARP will be most important in disease states where inflammatory activation is augmented in systems by MAP kinase activation and NF- κ B translocation resulting from free-radical and oxidant formation. In the nervous system PARP inhibitors have the potential to protect against two different types of insult triggered by a single disease trigger thus eliciting a greater overall protection than anti-excitotoxic or anti-inflammatory approaches alone. The marked protection achieved with various PARP inhibitors in animal models of many different diseases suggests that PARP inhibitors can be developed to treat human diseases. However, before PARP inhibitors can be used in humans, certain safety issues should be addressed to determine under what conditions PARP inhibition should be advised. Because PARP has been implicated in DNA repair and maintenance of genomic integrity, one possible risk associated with long-term PARP inhibition might be increased mutation rate and cancer formation. While this will not be a concern for the treatment of acute neurological injuries such as stroke, for chronic neurodegenerative disorders such as Parkinson's disease, this might be a serious consideration. The risk-benefit ratios associated with the development of PARP inhibitors for therapeutic purposes is not yet known, yet this class of therapeutic agents holds promise for the treatment of neurological diseases.

In the initiation phase of neurotoxicity, activation of NMDA glutamate receptors leads to increased intracellular calcium that activates neuronal nitric oxide synthase (nNOS) producing nitric oxide (NO) (Fig. 12.1). Neuronal activation will also result in increased oxidative phosphorylation and subsequently increased superoxide anion production. Superoxide anion production can also be elevated by complex 1 inhibition with chemicals such as MPTP, rotenone or paraquat and decrements in complex 1 are observed in Parkinson's patients. Superoxide is not membrane permeable and resides largely in the mitochondria where it is generated. NO and superoxide anion react to form the potent oxidant, peroxynitrite. Peroxynitrite generation can trigger an amplification phase of neurotoxicity by attacking mitochondrial proteins in the electron transport chain including complex I and IV as well as the superoxide scavenging enzyme, manganese superoxide

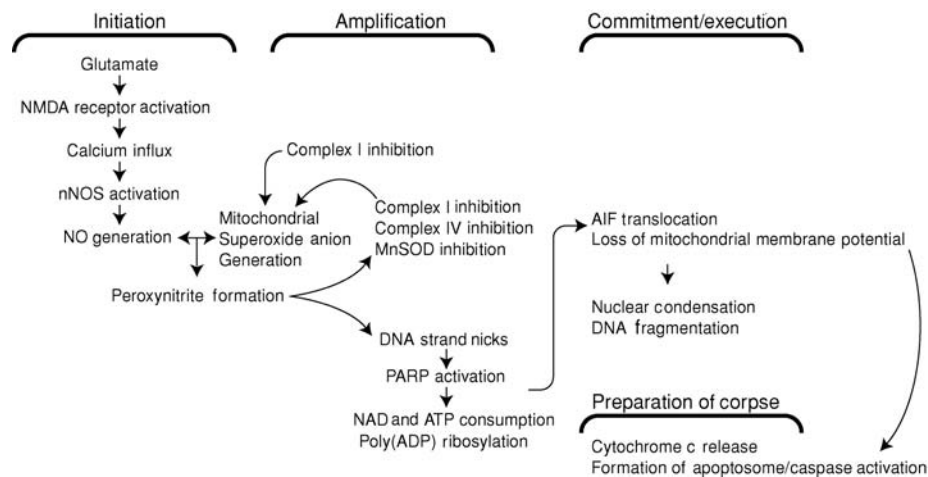

Fig. 12.1 Model of nitric oxide, poly (ADP-ribose) polymerase mediated neuronal cell death.

dismutase (MnSOD). This initiates a vicious cycle of peroxynitrite generation through sustained superoxide anion generation. Peroxynitrite is membrane permeable and can move to the nucleus triggering DNA strand breaks. Damaged DNA activates poly (ADP-Ribose) polymerase (PARP) resulting in the synthesis of PAR polymers, ribosylation of proteins and consumption of NAD and ATP. These PARP dependent events signal to the mitochondria to release apoptosis inducing factor (AIF) that translocate to the nucleus. In the nucleus AIF triggers large-scale DNA fragmentation and nuclear condensation. These nuclear changes in neurons are likely to be the final commitment and execution point in the neurotoxic cascade. Subsequent to these events Cytochrome c is released and caspases are activated. Blocking these events does not prevent NO/PARP dependent neurotoxicity but may be important in preparation of the corpse and the degradation of the cell.

Copper and zinc in Alzheimer's disease and amyotrophic lateral sclerosis

Avi L. Friedlich¹ and Ashley I. Bush²

^{1,2}Laboratory for Oxidation Biology, Genetics and Aging Research Unit, Massachusetts General Hospital, Charlestown, MA, USA and Mental Health Research Institute of Victoria, and Department of Pathology, University of Melbourne, Australia

Introduction

The non-infectious neurodegenerative disorders, Alzheimer's disease, and amyotrophic lateral sclerosis are heterogeneous with respect to etiology, neuropathology and clinical presentation. Yet, these disorders share a number of features in common to suggest some common pathogenic events. Each disorder is age related and is characterized by progressive and symmetric degeneration of discrete populations of neurons. Each disorder is associated with biochemical markers of oxidative attack, and each is associated with deposition of a CuZn metalloprotein in affected tissue.

Molecular genetic analysis has linked autosomal dominant forms of AD, PD, and amyotrophic lateral sclerosis, respectively, to mutations in β -amyloid precursor protein, α -synuclein, and superoxide dismutase 1. Each of these proteins or its proteolytic products may aggregate in affected tissue during the course of disease.

In this chapter we summarize current knowledge of CNS Cu and Zn metabolism in normal physiology. Then, focusing on AD and ALS, we review evidence for pathophysiologic Cu and Zn metabolism and evidence linking Cu and Zn to the physiologic and toxic activities of β -amyloid protein and superoxide dismutase 1.

Protein interactions in brain copper and zinc metabolism

At the active site of many enzymes, Cu participates in one-electron transfer reactions. Zn, which is electrochemically inert, maintains structural stability of many proteins. In addition to these essential and ubiquitous roles for Cu and Zn, brain-specific functions exist for these metals. The brain contains high concentrations of Cu and Zn in the

neocortex and spinal cord (reviewed in Bush, 2000), the functions of which are poorly understood but may relate to the specialized metabolism of neurotransmission.

Zn²⁺ is sequestered into pre-synaptic vesicles in a subset of corticofugal glutamatergic fibers by the zinc transporter 3 protein (Palmiter *et al.*, 1996; Frederickson *et al.*, 2000). Its release on depolarization may raise the concentration of Zn²⁺ in the synaptic cleft to 300 μ M (Assaf & Chung, 1984; Howell *et al.*, 1984). Cu²⁺ may also have a role in neurotransmission, as extracellular Cu²⁺ concentrations have been observed to rise transiently to 15 μ M during neuronal depolarization (Hartter & Barnea, 1988a,b).

Because free Cu and Zn are potentially neurotoxic (for review see Atwood *et al.*, 1999) stringent homeostatic mechanisms exist to regulate extracellular and intracellular concentrations, and the blood-brain barrier is relatively impermeable to transient changes in plasma Cu and Zn levels, such as those which occur prandially and postprandially. The concentrations of Cu and Zn in neocortex are >1 order of magnitude higher than that in plasma, and the concentrations in plasma are 10 to 20 orders of magnitude higher than those in cerebrospinal fluid (CSF). These large metal concentration gradients suggest that energy-dependent pathways exist to transport Cu and Zn from plasma or CSF to neocortex and that passive transport mechanisms may exist for their clearance into CSF or plasma. Zn²⁺ in some regions of the brain is in rapid exchange with the plasma, but these are still poorly understood (Pullen *et al.*, 1990).

Zn²⁺ released during neurotransmission is in an ionic, dissociable form. Less is known about the chemical form of Cu²⁺ that is released during neurotransmission into the synapse. The mechanisms for transport, storage, and release of Cu and Zn are currently being elaborated. Knowledge of Cu transport mechanisms has been augmented by elucidating the mechanisms of Mendelian genetic diseases

of Cu and Zn metabolism associated with neurodegeneration. Wilson's disease and Menkes disease, two disorders of systemic Cu metabolism associated with pronounced neurodegeneration, are associated with different genes from the same family. These genes encode cation transporting P-type ATPases localizing to the trans-Golgi network (Chelly *et al.*, 1993; Tanzi *et al.*, 1993; Mercer, 2001). The major Cu binding protein in serum is ceruloplasmin, and aceruloplasminemia is associated with basal ganglia degeneration (Morita *et al.*, 1995). Other Cu transport and loading proteins have also been identified. Ctr1 is a transmembrane protein involved in Cu uptake at the plasma membrane (Zhou & Thiele, 2001; Lee *et al.*, 2001). Ctr1 knockout mice have decreased Cu levels in brain (Kuo *et al.*, 2001; Lee *et al.*, 2001).

For Zn²⁺ sequestration and transport, several families of proteins are now known. Intestinal absorption of Zn and cellular zinc uptake are largely mediated by the zip family of transport proteins (Wang *et al.*, 2002). Transendothelial zinc transport at the blood-brain barrier is probably mediated by receptors for Zn-histidine or Zn-albumin. Intracellular sequestration and transport of Zn²⁺ is largely mediated by the metallothionein (MT) family of proteins (Vallee, 1995; Jacob *et al.*, 1998), with MTII and MTIII being the most significant in brain. The zinc transporter (ZnT) family is involved in sub-cellular zinc compartmentation. ZnT3 mediates the vesicular sequestration of synaptic zinc (Masters *et al.*, 1994; Palmiter & Findley, 1995; Palmiter *et al.*, 1996). ZnT3 seems generally to stimulate zinc migration through the blood-brain cerebral spinal fluid system, as targeted disruption of ZnT3 decreases cerebral zinc levels (Cole *et al.*, 1999). Even with elaborate mechanism for Cu and Zn homeostasis, a steady rise in brain Cu and Fe levels is observed as a function of age in post-reproductive life (Maynard *et al.*, 2002). The reasons for this are unclear. Elevated levels of Cu or Fe may increase oxidative stress and render the brain more susceptible to neurodegenerative disorders such as AD and ALS.

Alzheimer's disease

A consensus has yet to emerge about the levels of total Zn and Cu in plasma and CSF in AD. Zn and Cu are largely bound in an ionic form to ligands such as proteins and amino acids in these fluids. Fasting serum Zn 1 year prior to death has been reported to correlate negatively with amyloid plaque density in seven brain regions (Tully *et al.*, 1995). Two reports have indicated that that serum Cu is elevated in Alzheimer compared to age-matched control patients (Kapaki *et al.*, 1993; Squitti *et al.*, 2002). It remains to be

determined whether there are specific biochemical fractions associated with Zn²⁺ and Cu²⁺ within the blood that are altered in AD.

In AD CSF, one study has reported an increase in Cu (Basun *et al.*, 1991), two studies have reported an increase in Zn (Hershey *et al.*, 1983; Rulon *et al.*, 2000), and two studies have reported a decrease in Zn (Kapaki *et al.*, 1993; Molina *et al.*, 1998). Other reports have found no differences between AD and control CSF, with respect to Cu and Zn (Hershey *et al.*, 1983; Sahu *et al.*, 1988).

While a consensus has emerged that Cu and Zn are elevated in amyloid, reports of alterations in bulk metal levels in AD have not shown consistency. Cu and Zn accumulation in AD amyloid deposits has been demonstrated by micro particle X-ray emission (PIXE; Lovell *et al.*, 1998). Cu was localized predominantly to the senile plaque rim, while Zn was elevated in the senile plaque rim and core. Additionally, Zn was elevated in the AD neuropil, compared to age-matched control. Histochemically reactive Zn has also been localized to amyloid plaques and amyloid angiopathy in AD tissue (Suh *et al.*, 2000), and APP2576 transgenic mouse brain (Lee *et al.*, 1999). Another PIXE study demonstrated increased Zn levels in the Alzheimer hippocampus and amygdala in unstained cryostat sections, though no correlation with plaques was made (Danscher *et al.*, 1997). Raman microscopy from purified plaque cores suggests that Cu and Zn present in senile plaques are coordinated to histidine residues and the only metals ion coordinating A β (Dong *et al.*, 2003).

Numerous studies have quantified metal levels in gross brain specimens or homogenates using instrumental neutron activating analysis (INAA) and inductively coupled plasma mass spectroscopy (ICP-MS), with conflicting results. The ICP-MS studies have demonstrated decreased Zn in the AD hippocampus, thalamus and gyri (Panayi *et al.*, 2002) and also in the frontal, occipital and temporal cortices (Corrigan *et al.*, 1993). An INAA study found decreased Cu and increased Zn in AD hippocampus and amygdala (Deibel *et al.*, 1996). An INAA sub-cellular fractionation study found decreased nuclear Zn in the temporal lobe (Wenstrup *et al.*, 1990).

Investigations of the expression and distribution of Cu and Zn transport and sequestration proteins in AD provide additional evidence for disrupted Cu and Zn metabolism in AD. Expression of ceruloplasmin (Castellani *et al.*, 1999), MT-III (Yu *et al.*, 2001), MMP-1 (Leake *et al.*, 2000), MMP2 (Backstrom *et al.*, 1992), and MMP-9 (Asahina *et al.*, 2001) have all been reported to be altered in the Alzheimer brain.

MTIII is deficient in AD brain tissue (Uchida *et al.*, 1988; Uchida *et al.*, 1991; Yu *et al.*, 2001), which may impair the buffering capacity of the cortical tissue, and contribute

to the extracellular pooling of Zn and Cu that occurs in AD.

Whereas abnormal Cu^{2+} elevation may drive the toxicity of A β (Huang *et al.*, 1999b), interstitial Zn^{2+} elevation may reflect a homeostatic antioxidant response. Mechanistically, this could be due to Zn^{2+} release from the metallothionein (MT) pool upon glial activation (Penkowa *et al.*, 1999) or due to MT thiols being oxidized by H_2O_2 (Maret & Vallee, 1998), perhaps produced by A β (Huang *et al.*, 1999a,b; Opazo *et al.*, 2002). The hypothesis that Zn^{2+} elevation forms amyloid is supported by the distribution of exchangeable Zn^{2+} in the synaptic vesicles of the glutamatergic corticofugal system (Frederickson, 1989), paralleling the anatomical sites most prone to amyloid deposition.

Other A β -associated proteins may also modulate the precipitation of A β in the presence of Zn^{2+} , and so play a role in amyloid formation. The Zn^{2+} binding properties of alpha-2-macroglobulin, a genetic risk factor for AD (Blacker *et al.*, 1998) modulate its binding to A β (Du *et al.*, 1997). Also, apolipoprotein E preserves A β solubility in the presence of Zn^{2+} , and the ApoE4 isoform, a risk factor for amyloid deposition and AD, is the poorest solubility chaperone under these conditions (Moir *et al.*, 1999). Therefore, in ApoE4 carriers, A β is more likely to be precipitated by Zn^{2+} .

Beta amyloid protein

The ~4 kDa β amyloid protein (A β) deposits as amyloid in the neuropil and cerebrovasculature in Alzheimer disease. Strong genetic evidence links A β and its precursor the β -amyloid precursor protein (APP) to Alzheimer's disease pathogenesis. Although much progress has been made over the past few years towards understanding the biology and pathobiology of A β and APP, consensus on the biologic and pathogenic functions of each protein has not been reached. The β -amyloid protein (A β) possesses high and low affinity binding sites for Cu and Zn (Bush *et al.*, 1994; Atwood *et al.*, 1998; Miura *et al.*, 2000). The affinity of the Zn^{2+} binding sites on A β 1-40 are 100 nM and 5 μM (Table 13.1), indicating that they might be occupied under physiological conditions (Atwood *et al.*, 1998, 2000). The highest affinity Cu^{2+} binding site on A β 1-42 has a measured $K_a \approx 10^{-18}$ M, much greater than the highest affinity Cu^{2+} binding site on A β 1-40 ($K_a \approx 10^{-10}$ M) (Atwood *et al.*, 1998, 2000).

The differential affinity of A β ₄₂ and A β ₄₀ for Cu^{2+} (Atwood *et al.*, 2000) may account for the differential redox behaviour and toxicity of these two species (Huang *et al.*, 1999). The Cu^{2+} -A β 1-42 complex has a strong reduction

Table 13.1. Copper and zinc binding affinities of the 40 and 42 residue beta amyloid protein. Data are from Atwood *et al.* (2000).

K_d (M)	High affinity	Low affinity
A β 1-40/Zn	1.0×10^{-7}	1.3×10^{-6}
A β 1-42/Zn	1.0×10^{-7}	1.3×10^{-6}
A β 1-40/Cu	4.6×10^{-11}	1.3×10^{-6}
A β 1-42/Cu	7.0×10^{-18}	5.0×10^{-9}

potential (+550 mV vs Ag/AgCl) compared with the blue copper proteins. Such strong electrochemical potential probably denotes a biological significance, and because A β binds Cu^{2+} and Zn^{2+} to form a superoxide dismutase like structure (Curtain *et al.*, 2001), we hypothesized that metal binding to A β in health may subserve a physiological function, such as metal clearance. A role for A β or the A β precursor protein (A β PP) in metal ion homeostasis is consistent with the observed reduction of brain Cu and Fe levels in mutant A β PP expressing (Tg2576 and C100-V717F) transgenic mice (Maynard *et al.*, 2002). The presence of an iron responsive element on the 5' untranslated region of the A β PP mRNA is also consistent with a role for A β or A β PP in metal ion homeostasis (Rogers *et al.*, 2002). The oxidative damage induced by A β may be mechanistically related to the oxidative stress induced by mutant SOD1 (Atwood *et al.*, 1998, 2000). Hydrogen peroxide (H_2O_2), implicated in AD pathogenesis, is produced by Cu A β (Huang *et al.*, 1999b). Among A β species, Cu A β ₄₂ produces H_2O_2 at a faster rate than Cu A β ₄₀, while mouse Cu A β produces much less H_2O_2 (Huang *et al.*, 1999a). The redox activities of these Cu A β species correlate with their respective neurotoxicity in culture, which is largely mediated by H_2O_2 formed by Cu A β (Huang *et al.*, 1999b). H_2O_2 formation by Cu A β and CuZn A β can also be inhibited by chelation (Huang *et al.*, 1999b), and the H_2O_2 mediated toxicity of A β in culture can be exaggerated by Cu^{2+} and ameliorated by Zn^{2+} (Cuajungco *et al.*, 2000).

It is now well established that A β is rapidly precipitated by physiological concentrations of Zn^{2+} , a redox inert cation. Under mildly acidic conditions (pH 6.8 to 7.0), the redox-active metals Cu^{2+} and Fe^{3+} induce greater A β aggregation than does Zn (Atwood *et al.*, 1998). Significantly, the turbidity of rodent A β 1-40 (with substitutions of Arg→Gly, Tyr→Phe and His→Arg at positions 5, 10 and 13, respectively) is unaffected by Zn^{2+} or Cu^{2+} at low micromolar concentrations (Atwood *et al.*, 1998).

CuZn selective chelators markedly enhance the resolubilization of A β deposits from post-mortem AD brain samples (Cherny *et al.*, 1999) supporting the possibility that

Cu and Zn ions play a significant role in assembling these deposits. The metallochemistry of A β links oxidative damage and amyloidosis in AD. In vitro precipitation of A β by Cu²⁺ or Zn²⁺ can be completely reversed by chelation (Huang *et al.*, 1997). In postmortem AD brain, selective Cu or Zn chelators can induce the resolubilization of A β from plaques (Cherny *et al.*, 1999). Oxidative damage may be the earliest pathological event in AD (Nunomura *et al.*, 2001), and a negative correlation exists between amyloid burden and levels of 8-hydroxyguanosine, a marker of hydroxyl radical activity (Cuajungco *et al.*, 2000). This is possibly because Zn suppresses H₂O₂ formation from A β . Thus, the mature plaque in AD may form through a compensatory mechanism where Zn²⁺ is sequestered into accumulations of A β .

Pre-clinical and clinical data now support Cu and Zn metabolism as a valid therapeutic target in AD. Clioquinol (CQ), a retired antibiotic with a 0.5 billion patient day history, was evaluated by Cherny *et al.* (2001) for efficacy in 21 month old APP2576 transgenic mice. Administration by gavage of 30 mg/kg for 9 weeks resulted in a 49% decrease in brain A β load, a decrease in serum A β , with no evidence of drug-induced toxicity or systemic loss of metals. General health and body weight parameters were significantly improved in the treated animals after only 16 days of treatment. Treatment of APP2576 mice with CQ induced a \approx 15% increase in brain Cu and Zn, indicating that the therapeutic mechanism of CQ is not simply chelation and clearance. A phase II double-blinded clinical trial of CQ in Alzheimer patients has recently been completed. CQ decreased plasma A β levels and, in more advanced AD patients, slowed the rate of cognitive decline (Colin L. Masters *et al.*, personal communication). Continued investigation into Cu and Zn metabolism, the metallobiology of A β and APP, and the mechanism of action of CQ seems likely to increase understanding of AD pathogenesis and lead to new treatments for the millions of patients suffering from the disorder.

Amyotrophic lateral sclerosis

In frontal and occipital gray matter, Zn levels have been reported to be decreased by INAA (Yasui *et al.*, 1993). Decreased serum and CSF Cu but not Zn has been reported in ALS (Kapaki *et al.*, 1997). Metallothionein immunoreactivity is increased in the spinal cord in ALS, and liver and kidney metallothionein levels are also elevated in ALS (Sillevis-Smitt *et al.*, 1992; Sillevis-Smitt *et al.*, 1994). The same pattern of elevated metallothionein immunoreactivity occurs in a transgenic model of ALS. SOD1-G93A

transgenic mice demonstrate increased MTI and MTII, and MTIII expression in astrocytes in both white and gray matter. Neuronal MT-III expression is also elevated (Gong & Elliott, 2000). Metallothionein elevation is likely compensatory and protective. In the G93A mutant SOD1 transgenic model of ALS, deficiency of MTI, MTII or MTIII exacerbates the ALS phenotype (Nagano *et al.*, 2001; Puttaparthi *et al.*, 2002). Total body and cerebral Cu and Zn metabolism in ALS may be altered, though the pathophysiological metabolism remains to be characterized.

Superoxide dismutase 1

Over 100 mutations in CuZn superoxide dismutase (SOD1) are associated with autosomal dominant ALS (Rosen, 1993; Brown & Robberecht, 2001). SOD1 represents a major biochemical pool of Cu²⁺ and Zn²⁺ in all tissues. That toxicity of mutant SOD1 (mSOD1) is independent of wild type activity has been established. The ALS associated mSOD1 species possess varying amounts of wild-type enzymatic activity, ranging from 0% (e.g. H46R and G85R) to 100% (e.g. G37R) of wild-type activity. SOD1 knockout mice do not develop the ALS phenotype (Reaume *et al.*, 1996), and the age of onset and duration of disease in ALS transgenic mice is unaffected by levels of wild-type SOD1 activity (Bruijn *et al.*, 1998). Thus, the toxicity of mSOD1 is a gain-of-function.

Several gain-of-function redox reactions have been proposed for mSOD1, and at least two currently appear plausible. Increased peroxidase activity has been reported in vitro (Wiedau-Pazos *et al.*, 1996; Liochev *et al.*, 1997) in the H48Q, A4V, and G93A variants, although not consistently (Singh *et al.*, 1998). Increased peroxidase activity in vivo has been reported in the A4V and G93A (Roe *et al.*, 2002) species.

Also, peroxynitrite formation from nitric oxide and dioxygen has been proposed as a toxic gain-of function for mSOD1:

Cu replete, Zn deficient SOD1 has been reported to confer toxicity by producing peroxynitrite according to these reactions (Estevez *et al.*, 1999), and loss of Zn from mSOD1 has been proposed as a primary pathogenic event (Crow *et al.*, 1997).

Pathological findings in mSOD1-associated ALS and in transgenic models are consistent with the redox hypotheses for mSOD1 pathogenicity. Elevated levels of nitrotyrosine and its major metabolite 3-nitro-4-hydroxyphenylacetic

acid have been demonstrated in the lumbar and thoracic spinal cord in familial ALS (Beal *et al.*, 1997). Motor neuron immunopositivity for 3-nitrotyrosine, malondialdehyde, and heme oxygenase have been reported as well (Beal *et al.*, 1997). Similar patterns of immunoreactive oxidative adducts have been reported in the G93A and G37R transgenic mice (Ferrante *et al.*, 1997; Bruijn *et al.*, 1997), and protein carbonyl levels have been found to be elevated in the G93A mice as early as 30 days of age (Andrus *et al.*, 1998). Further, mitochondrial vacuolation is a prominent feature in the ALS transgenic mice (Wong *et al.*, 1995; Gurney *et al.*, 1998), and impairment of respiratory transport chain function has been confirmed in the G93A model (Mattiuzzi *et al.*, 2002). The copper chelators trientine (Nagano *et al.*, 1999) and D-penicillamine (Hottinger *et al.*, 1997) have shown efficacy in the transgenic models.

The possibility of copper involvement in mSOD1 pathogenicity must now be carefully reassessed in light of work by Subramaniam *et al.* (2002) demonstrating that CCS dependent Cu transport does not contribute to mSOD1 toxicity. Those authors crossed the G37R, G85R, and G93A transgenic mice with CCS-knockouts and found no modification of disease phenotype with the CCS-/- background. They confirmed in the CCS knockouts that wild type SOD1 activity was reduced by 80% and that ⁶⁴Cu incorporation into SOD1 was markedly decreased 24 hours after intraperitoneal ⁶⁴Cu injections.

A pathogenic role for Cu properly inserted into the mSOD1 active site cannot be ruled out on the basis of data reported by Subramaniam *et al.* (2002). The CCS knockout mice do retain 20% of wild-type SOD1 activity, and the results of Subramaniam *et al.* (2002) would still be consistent with toxic Cu reactivity at the mSOD1 catalytic site if (a) the pathogenic mSOD1 species were compartmentalized (e.g. localized to mitochondria or other subcellular compartment) throughout the course of disease and (b) the compartmentalized SOD1 pool conferring pathogenicity were activated with copper loading through a mechanism independent of CCS.

In addition, Cu mediated mSOD1 pathogenicity from Cu coordinated at sites other than the catalytic site (Bush, 2002) cannot be ruled out on the basis of data reported by Subramaniam *et al.* (2002). Cu can be coordinated by mSOD1 at several locations, including the wild type Zn binding site (Goto *et al.*, 2000) and the surface residue C111 (Liu *et al.*, 2000). Such metallated species would not be expected to possess significant wild type SOD1 activity. The ⁶⁴Cu experiments of Subramaniam *et al.* (2002) demonstrate a decrease in the rate of Cu incorporation into SOD1 but do not demonstrate a decrease in the amount of Cu incorporated at all metal binding sites: SOD1 : Zn : Cu

stoichiometry was not measured in that report. Total Cu levels in brain are elevated in the CCS knockouts (Subramaniam *et al.*, 2002). The evidence favoring a Cu mediated pathogenic mechanism for mSOD1 therefore remains fundamentally unchallenged.

Future prospects

Growing evidence exists to support pathophysiological Cu and Zn metabolism in AD and ALS. Moreover, pre-clinical data in ALS and pre-clinical and clinical trials data in AD now support a pathogenic role for Cu and Zn. Increased understanding of the pathogenic mechanism of Cu and Zn in AD and ALS will identify new targets for drug discovery, which can then be tested for efficacy in transgenic animal models of AD and ALS, as well as other neurodegenerative disorders such as Parkinson's disease. Thus, for AD, ALS and other neurodegenerative disorders, clinical trials with agents that interdict pathogenic Cu and Zn metabolism may be rapidly approaching. Demonstrating therapeutic efficacy of drugs attenuating pathogenic Cu and Zn metabolism will be required to establish a role for these metals in the non-infectious degenerative disorders of the central nervous system.

The role of inflammation in Alzheimer's disease neuropathology and clinical dementia. From epidemiology to treatment

Giulio Maria Pasinetti

Neuroinflammation Research Laboratories, Mount Sinai, School of Medicine, New York, USA

Several epidemiological studies have demonstrated a significantly lower incidence of Alzheimer's disease in individuals who regularly consume non-steroidal anti-inflammatory drugs (NSAIDs) compared with the general population. Despite this evidence, therapeutic studies investigating NSAIDs, including inhibitors of cyclooxygenase (COX)-1 and COX-2 and steroids, do not support this hypothesis. This discrepancy might be due to the fact that the bulk of epidemiological evidence has examined the likely incidence of AD prior to the onset of clinical symptoms of the disease. This inconsistency has led to the hypothesis that NSAIDs may be optimally effective as a preventive therapy prior to the onset of clinical symptoms or in individuals at high risk for AD, such as cases with mild cognitive impairment. This review will discuss recent findings from experimental models of AD neuropathology describing novel mechanisms involved in the potential beneficial role of NSAIDs. It will then examine the importance of evidence for the potential role of inflammation in amyloidosis in the AD brain. The implications of this evidence will be considered in the context of the potential negative role of inflammation in the brain during amyloid vaccination therapy in AD trials. On the basis of this information, this review will attempt to formulate a possible scenario in which optimal NSAIDs might be tested in the most favorable clinical therapeutic conditions in order to determine whether NSAIDs can provide beneficial treatment for the clinical progression of AD dementia. Alzheimer's disease is a chronic, progressive, irreversible neurodegenerative disorder associated with the process of ageing (McGeer *et al.*, 1996; In't Veld *et al.*, 2001; Stewart *et al.*, 1997). Presently, there are four million patients afflicted with AD in the USA, and the incidence is expected to increase exponentially over the next

10 years (Hebert *et al.*, 2003). Neuropathologically, AD is characterized by abnormal deposition of amyloid plaques in the brain parenchyma. The abnormal deposition appears to be the consequence of an elevation in amyloid peptides caused by altered processing of the amyloid precursor protein (APP) (Selkoe 2001). Abnormal phosphorylation of the microtubule-binding protein, tau (τ), also appears to play an important role in AD neuropathology and leads to neurofibrillary degeneration (Mandelkew & Mandelkew, 1998).

At present, there is no cure for AD. However, in the past year, research on AD has brought us closer to realizing the fundamental goal of sparing future generations the ravages of AD. A large body of evidence indicates progress in understanding the biological mechanisms of the disease, improving treatment options, and providing quality care. In the realm of therapeutics, we have gained new insights into the promising class of drugs known as non-steroidal anti-inflammatory drugs. Although it is not presently known whether inflammatory mechanisms (e.g. elevation of amyloid content and neurodegeneration) are responsible for AD neuropathology, or whether neurodegenerative events actually lead to inflammation (Pasinetti 1998), much of the epidemiological data support a protective effect for NSAIDs against AD (McGeer *et al.*, 1996; In't Veld *et al.*, 2001; Stewart *et al.*, 1997). Recent studies have further reinforced this evidence by suggesting that, in addition to beneficial anti-inflammatory actions, NSAIDs might also target AD amyloid pathology and possibly mediate neuroprotection. Ongoing investigations on the role of NSAIDs in AD dementia presently focus on preventive initiatives to slow the progression and possibly onset of AD dementia rather than exploring NSAIDs as a potential therapeutic agent in AD.

Fig. 14.1 Hippocampal COX-2 protein content correlates linearly with clinical progression of Early AD dementia.

Inflammation as a function of clinical progression of AD dementia

Recent studies suggest that select segments of inflammatory cascades are elevated in the AD brain as a function of the progression of clinical dementia in AD. The Clinical Dementia Rating (CDR) (Morris, 1993; Luterman *et al.*, 2000; Haroutunian *et al.*, 1998) measures stages of AD from early to late onset. The CDR scale ranges from mild cognitive impairment (MCI; CDR 0.5) through mild (CDR 1), moderate (CDR 2) and severe dementia (CDR 5). Pro-inflammatory activities have been found as early as the CDR 1 stage and become increasingly evident as the disease progresses. For example, as will be discussed below, recent evidence indicates that cyclooxygenase (COX)-2, an enzyme responsible for converting arachidonic acid to prostaglandin, is upregulated in the brain of AD cases, and increases between cases of CDR 0.5 to CDR 1.0 (Ho *et al.*, 2001) (Fig. 14.1). Other classical markers of inflammation such as cytokine expression and major histocompatibility complex (MHC) HLA-DR immunoreactive microglia are also apparent in AD, but occur in later, more-severe phases of the disease, such as in cases with CDR 5 (Fig. 14.1). Extensive oxidative damage and widespread activation of caspase pathways involved in apoptotic brain cell death are also found but, again, predominantly in severe cases of AD dementia (CDR 5) (Pompl *et al.*, 2003). Consequently, anti-inflammatory treatments designed to target inflammatory cascades specific to each stage of AD might optimize efficacy.

Implications for the potential beneficial role of NSAIDs in cases with MCI

As mentioned earlier, several epidemiological studies support the hypothesis that anti-inflammatory drugs delay the onset and possibly the progression of AD (McGeer *et al.*, 1996). In a meta-analysis review of 17 epidemiological studies (McGeer *et al.*, 1996), it was suggested that anti-inflammatory treatment such as NSAIDs and steroids might decrease the risk for AD by as much as 50%. Moreover, a prospective study found that relative risk (RR) for AD fell with increasing duration of NSAID use (In't Veld *et al.*, 2001). The same study showed that two or more years of NSAID treatment resulted in a 40% decrease in RR (In't Veld *et al.*, 2001).

However, epidemiological and therapeutic studies are inconsistent. For example, in a 6-month study of the NSAID Indomethacin (100–150 mg day⁻¹), patients showed some improvement on a battery of cognitive tests (Rogers *et al.*, 1993), yet this finding could not be reproduced in a study using other NSAID compounds such as Diclofenac-Misoprostol (although a high drop-out rate prevented statistically significant results) (Scharf *et al.*, 1999) or Prednisone (Aisen *et al.*, 2000) (among others). Although these data appear discouraging, it is likely that subclasses of NSAIDs have varying levels of efficacy for AD treatment. Furthermore, the epidemiological evidence was based on studies of patients prior to the apparent clinical manifestation of AD, in contrast with therapeutic studies conducted on patients with illnesses severe enough to exceed the clinical detection threshold (e.g. \geq CDR 1). Thus, patients at high

risk for AD, such as cases affected by MCI, might represent a better population for testing the potential preventive role of anti-inflammatory activities in AD.

MCI is a term used to describe memory decline or other specific cognitive impairment in individuals who do not yet have AD dementia or significant impairment of other cognitive functions beyond that expected for their age or education (Petersen *et al.*, 1999). However, despite the high conversion rate to early AD dementia, MCI cannot be used synonymously with early or mild AD, as patients with AD are impaired not only in memory performance but in other cognitive domains as well, and meet diagnostic criteria for dementia (Shah *et al.*, 2000; Sramek *et al.*, 2001). Furthermore, there is heterogeneity among MCI cases with regard to the likelihood of conversion to early AD. Thus, it might be expected that inflammatory activities in the brain may ultimately affect the progression from MCI to early AD. We hypothesize that anti-inflammatory therapeutic approaches administered in cases with CDR exceeding MCI (CDR 0.5), such as CDR 1, might not be optimally effective, possibly explaining the discrepancy between epidemiological and therapeutic evidence for the role of NSAIDs in AD.

AD anti-inflammatory prevention trial (ADAPT)

A large body of epidemiological evidence supports a protective role for NSAIDs in AD; however, several attempts to translate these findings into successful treatment strategies for AD have largely failed. NSAIDs may impart neuroprotective effects that slow the progression of AD pathology, but we need to keep in mind that, most probably, these compounds will not yield short-term improvement in clinical symptoms. A further consideration is that the trials with NSAIDs have been conducted in diagnosed (clinically progressed) AD patients, and it may be the case that these drugs prove effective only when administered prior to the development of significant AD pathology. Thus, traditional clinical trial designs and clinical outcome measures (e.g. as have been employed in clinical efficacy trials of the classic cholinesterase inhibitors and other symptomatic drugs) are unlikely to be useful for testing anti-inflammatory compounds. For example, the ongoing AD Anti-inflammatory Prevention Trial (ADAPT) may prove that the “penultimate” test of NSAID efficacy may be primary prevention trials, wherein thousands of subjects at high risk for AD are treated for a number of years prior to clinical symptoms of AD. The significant sample size and high cost necessitated by such trials is a significant barrier to the effective demonstrating of primary prevention. For these reasons, current research

is focusing on developing more efficient assessment methods for use in AD primary prevention trials, and focusing on the development of biomarkers to help steer future prevention measures.

In part because of these considerations, the Alzheimer's Disease Anti-Inflammatory Prevention Trial (ADAPT) currently in progress was designed to test the hypothesis that NSAIDs might delay or prevent the onset of AD and age-related cognitive decline (Breitner, personal communication, 2003, Pompl *et al.*, 2003). This ongoing 5–7-year randomized clinical study at Johns Hopkins (sponsored by the National Institute of Aging) is testing the NSAID medications Naproxen and Celecoxib (a non-selective and a selective COX-2 inhibitor, respectively, see below) in patients who have not been diagnosed with AD. Adapting more-refined criteria for stages of AD in clinical trials should increase our understanding of NSAID treatment efficacy, and hopefully should resolve the inconsistency between epidemiological and therapeutic studies.

COX: a target for NSAIDs in AD

While the mechanism of action of NSAIDs is not entirely clear, it is generally believed that their effects are attributable to a competitive inhibition of COX catalytic activity, and a subsequent reduction of inflammatory PG production. COX exists in two isoforms, COX-1 and COX-2, that are encoded by distinct genes on different chromosomes (Kujubu *et al.*, 1991; Cao *et al.*, 1995; O'Banion *et al.*, 1992). There is an approximate 50% homology between these enzymes, as well as similar catalytic activity (Kujubu *et al.*, 1991; Cao *et al.*, 1995; O'Banion *et al.*, 1992). However, the isoforms are physiologically distinct. COX-2 is inducible in response to inflammatory signals such as cytokines and lipopolysaccharide, and is downregulated by glucocorticoids. By contrast, COX-1 is generally constitutive. Thus, it would appear that the COX-2 isoform is responsible for the normal mediation of inflammatory activity, while COX-1 maintains housekeeping functions (including gastric cytoprotection and platelet aggregation).

Traditional NSAIDs are non-selective COX inhibitors, effecting both COX-1 and COX-2 at varying levels. However, the effects of these compounds on inflammation are believed to derive from inhibition of COX-2 activity. COX-1 inhibition, on the other hand, has previously been implicated in gastrointestinal, renal and platelet toxicity associated with some non-selective COX inhibitors. Thus, the use of newly developed highly selective COX-2 inhibitors in AD treatment hold promise for anti-inflammatory action and reduced toxicity (Vane & Botting, 1995; Warner *et al.*, 1999).

Fig. 14.2 Hypothetical mechanism through which COX-2 may influence amyloidosis.

As discussed, major efforts are under way to determine whether COX inhibitors can help control the progression of AD dementia. However, given the growing number of candidate NSAIDs and their widely divergent activities, it is vital that drug selection and study design are optimized. As discussed, proper characterization of NSAID activities, and administration of these compounds in a fashion that is specific to the phase of the disease, is essential. Better understanding of the influence of inflammatory activity in AD, and identification of specific mechanisms that play an early role in the progression of the disease, will vastly improve the likelihood of assessing the potential value of NSAID treatment strategies.

Novel evidence for the beneficial role of NSAIDs in AD neuropathology

Though the preponderance of research on NSAIDs in AD supports the theory that the anti-inflammatory "COX-inhibiting" properties of these drugs are responsible for

their prophylaxis (Aisen 1997), recent in vitro studies offer alternative/additional explanations (Weggen *et al.*, 2001; Lim *et al.*, 2000). For example, there is evidence that non-selective COX inhibitors, rather than selective COX-2 (the inducible form of COX) inhibitors may inhibit the production of the fibril forming β -amyloid ($A\beta$)₁₋₄₂ (the major component of $A\beta$ plaques) at mM concentrations; and in some instances, in cellular systems devoid of COX activity. While this new evidence is of extreme interest, it is unclear these data will impact clinical studies in humans due the toxic doses studied. For example, it has been calculated that the in vitro efficacious dose for $A\beta$ inhibition would be the equivalent of approximately 10 g a day of NSAIDs (e.g. ibuprofen). However, it is without question that these mechanisms deserve continued exploration, so that we can eventually define the mechanisms by which certain NSAIDs, and other compounds, preferentially reduce $A\beta$ ₁₋₄₂ production. Addressing these questions will help determine the utility of this approach in reducing $A\beta$ deposition and other AD-associated pathology in vivo. Future studies in AD-like disease mice should prove to be useful tools for determining the relative merits of NSAIDs on selective $A\beta$ lowering activities and for altering $A\beta$ deposition and other AD like pathology in transgenic mice. Moreover, it is extremely important to consider that although certain NSAIDs may prevent $A\beta$ production in COX deficient cells in vitro systems, this evidence does not preclude involvement of COX in the onset/propagation of AD neuropathology in the brain. Indeed these studies do in no way disprove the relevance of COX to AD neuropathology, nor indicate that the COX inhibiting actions of NSAIDs are dispensable. For example, COX-2 and also COX-1 is significantly elevated in AD (Ho *et al.*, 1999; Pasinetti & Aisen, 1998; Oka & Takashima, 1997; Yasojima *et al.*, 1999), and the predominance of epidemiological evidence supporting a protective role for NSAIDs, exclusively find COX inhibitors to be effective. Thus, although alternative/additional mechanisms for NSAIDs are being explored (e.g. anti-amyloidogenic, peroxisome proliferator activated receptor- γ activation), it remains possible that the COX inhibiting properties of these drugs are what imparts their protection against AD. This hypothesis is further supported by the fact that previous studies (including Weggen) show that ibuprofen potently diminishes amyloid pathology as does that potently inhibiting COX activity in the brain, and recent findings from our laboratory demonstrate that COX overexpression in a mouse model of AD type neuropathology significantly exacerbates amyloid pathology (Xiang *et al.*, 2002), possibly through a mechanism involving prostaglandin mediated induction of γ -secretase activity (Qin *et al.*, 2003). This is schematized in Fig. 14.2.

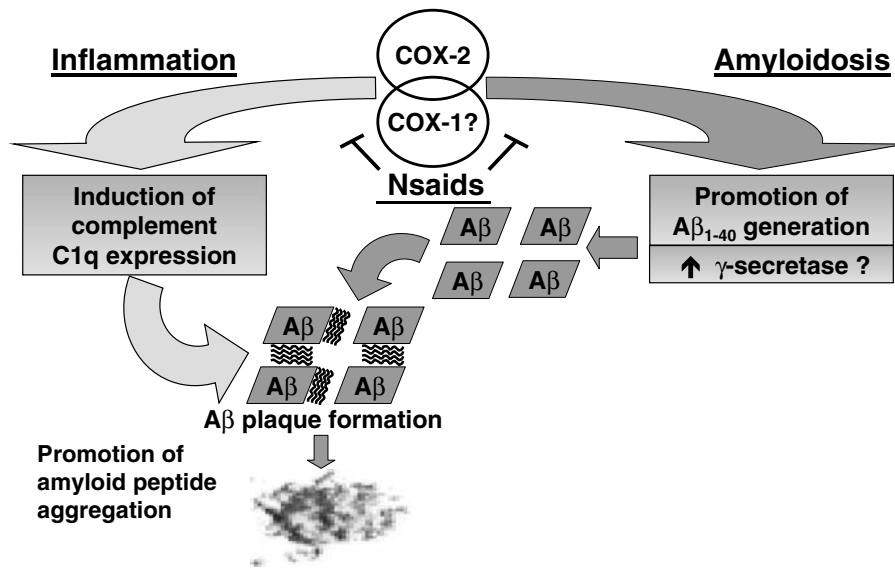

Fig. 14.3 Hypothesized roles of COX's in the creation of Aβ plaques and NSAIDs' blocking roles.

Hypothesis for the role of COX-2 in Aβ-amyloid plaques

On the basis of the above findings, we hypothesize that an additional factor that might promote Aβ fibril formation in AD is through COX-2-mediated pro-inflammatory activities in the brain (e.g. the induction of pro-inflammatory complement components) (Fig. 14.3). Evidence has recently been found that COX-2 might promote the expression of the complement component C1qB (Spielman *et al.*, 2002), which is known for its role in promoting Aβ aggregation (Webster *et al.*, 1994). In the light of the Weggen *et al.*, 2001 study showing that non-selective COX inhibitors, rather than selective COX-2-specific inhibitors, prevent Aβ peptide production and our data showing that COX-2 expression in the brain may potentiate AD-type amyloidogenesis and Aβ peptide generation in the brain (Xiang *et al.*, 2002), add a new layer of complexity to understanding the relationship between inflammation and AD neuropathology. For example, while COX-2 may be an important promoter of amyloidogenic activities in the AD brain, non-selective, rather than selective, COX inhibitors could preferentially influence APP processing and result in decreased Aβ production in vitro (Lim *et al.*, 2000).

Thus, a preferential COX-2 inhibitor with tolerable (i.e. minimal) COX-1 inhibitory activity (e.g. without gastrointestinal toxicity) may be an "ideal" NSAID with respect to anti-amyloidogenic activity for chronic treatment in cases at high risk of developing AD (MCI 0.5) (Fig. 14.1).

Future studies investigating the pharmacological relevance of NSAIDs in amyloidosis, and the role of COX, will help clarify the potential efficacy of COX-inhibiting drugs as therapeutic treatment in AD. The following sections will discuss recent evidence suggesting that COX-2 might also influence cell-cycle activities implicated in AD neuropathology.

Paradoxical role of inflammatory mediators in the brain. Implications for AD dementia

Although current data indicate that inflammation is closely correlated with AD neuropathology, the role of inflammatory mediators in the brain and AD may demand more complex measures than mere suppression of inflammation. For example, there is evidence that the complement derived pro-inflammatory anaphylatoxin C5a may exert neuroprotective properties in the brain (as demonstrated in C5 knock-out mice), possibly through activation of MAP kinase pathways (Mukherjee & Pasinetti, 2001). This evidence is consistent with the demonstration that activation of the complement system in the brain can protect against Aβ-induced neurotoxicity, and reduces amyloidosis (either by blocking deposition or promoting the clearance of amyloid) in mouse models of AD neuropathology. These results indicate that complement activation products can protect against brain injury, including Aβ, and possibly influence amyloidosis. Collectively, these findings support the concept that certain inflammatory defense mechanisms in the brain may be beneficial in neurodegenerative disease.

Thus, therapeutic designs aimed at non-specifically suppressing segments of inflammatory cascades may inhibit select neuroprotective actions of the complement system (among others), and possibly exacerbate neurodegenerative mechanisms. It is certain that future elucidation of the role of target inflammatory mediators will lead to the development of more successful therapeutic strategies that are specific for each (progressive) stage of AD dementia/neuropathology.

The role of COX derived prostaglandin in the cell cycle

Four phases comprise the cell division cycle: G1 (growth), S (DNA synthesis and replication), G2 (growth for cell division) and M (mitosis). The main regulators of the progression of the cell cycle are the cyclin/cyclin-dependent kinase (CDK) complexes. The sequential expression/activation of these proteins not only orchestrates the transition from one phase to the next, but can also serve as markers of different stages of the cell cycle (Grana & Reddy, 1995). The transition of resting cells from the G0 to G1 phase is controlled by the cyclinD-CDK4/6 complexes. Activation of these complexes is triggered by mitogenic growth factors and inhibited by the CDK4/6 inhibitor protein (p)18 (see below).

Little is known about the role of CDK4/6 inhibitors in the brain, including p18. Using a high-throughput microarray DNA technique, it was found that overexpression of hCOX-2 in neurons coincided with decreased mRNA expression of CDK4/6 inhibitor p18 in the brains of hCOX-2 transgenic mice (Mirjany *et al.*, 2002). Conversely, the hCOX-2-mediated inhibition of p18 expression was reversed by treatment of mice with the preferential COX-2 inhibitor Nimesulide. Similarly, hippocampal expression of CDK4 and COX-2 in hippocampal neurons appears to be coregulated during the clinical progression of AD dementia, which is consistent with evidence that COX-2 may facilitate the re-entry of neurons into the cell cycle (G. M. Pasinetti, unpublished observations). Generally, it is thought that the CDK4/6 and cyclinD complex regulate the G0 to G1 transition.

One important target substrate for this complex is the retinoblastoma protein (Rb), a tumour suppressor that is phosphorylated by activated cyclinD-CDK4/6. Recent evidence shows that RB can also be phosphorylated during the cell response to A β -mediated neurotoxicity (Giovanni *et al.*, 2000). Hyperphosphorylated Rb is released from the transcription factor complex E2F, which then activates genes required for S phase transition. COX-2 is induced in neurons following glutamate excitotoxic injury (Kelley

et al., 1999), and aggregated A β peptides (Pasinetti & Aisen, 1998) may promote cell-cycle activities by decreasing the expression of the CDK4/6 inhibitor p18 (Mirjany *et al.*, 2002). Thus, it might be possible that COX leads neurons to attempt (prostaglandin mediated) unsuccessfully to re-enter the cell cycle, and eventually to die. We suggest that prostaglandin-responsive cell-cycle activities could facilitate transition of resting neurons from the G0 into G1 phase, representing an important target for neuroprotection by NSAIDs.

Cell cycle, COX-2 and AD neuropathology

The search for factors responsible for the formation of neurofibrillary and neuritic plaque pathology has yielded several clues to the hypothesis that the cell cycle may play an important role in AD neurodegeneration. For example, the accumulation of potentially mitogenic growth factors (e.g. epidermal growth factor) in AD amyloid plaques could represent a trigger that initiates the re-entry of neurons into the cell cycle. COX-2, whose expression is also regulated by growth factors and tumour promoters (Fletcher *et al.*, 1991), might represent an important link between amyloid pathology and the cell cycle. Another factor associated with amyloid pathology, also known to influence cell-cycle pathways is oxidative stress (Raina *et al.*, 2000). Thus, it is possible that, if neuronal COX-2 expression leads to increased oxidative stress in brain (for review, see Pasinetti 1998), this might influence susceptibility of neurons to injury through control of cell-cycle activities. This hypothesis is consistent with evidence showing that COX inhibitors can also arrest the progression of cell division (Shiff *et al.*, 1996).

An important step towards understanding AD-related neuritic pathology was the identification of protein kinases involved in τ phosphorylation. For example, there is evidence showing that, in vitro, CDK5 can phosphorylate τ into AD-type NFTs (Baumann *et al.*, 1993). The importance of this finding is that it might explain intracellular changes and increased phosphorylation of cytoskeletal proteins, such as τ neurofilaments, seen in AD. While destabilization of microtubules and coincidental activation of different kinases that are able to phosphorylate τ are features of the cell division cycle, COX-2 expression is preferentially elevated in NFT⁺ neurons of the hippocampal formation (Oka & Takashima, 1997).

Thus, inappropriate re-entry into the cell cycle and interrupted mitotic processes might be significant factors not only in the neuronal degeneration but also in the cytoskeleton that characterizes the pathology of AD. In addition to its potential role on amyloidosis, it could still be possible that

COX-2, by promoting cell-cycle activities, might also participate in abnormal τ phosphorylation, further influencing AD neuropathology and possibly the clinical progression of AD dementia.

Inflammation and A β vaccination therapy in AD

Recent studies have found that highly specific immune responses may yield clinical benefits for AD. Investigators at Elan Pharmaceuticals studying neuropathological changes in a murine model of AD found that immunization with A β peptides can evoke an antibody response that is capable of preventing amyloidosis in pre-treated animals, and can significantly mitigate existing pathology in already affected subjects. These results have been replicated in numerous laboratories (Bard *et al.*, 2000; Janus *et al.*, 2000; Morgan *et al.*, 2000; Schenk *et al.*, 1999), and preliminary studies have already begun with human AD patients. On the basis of observations from animal models, investigators have found that either passive (intraperitoneal (IP) injection of pre-derived A β antibodies) or active (IP injection of A β peptides) immunization with A β can activate pro-inflammatory microglial cells through immunoglobulin receptor signaling, which facilitates clearance and degradation of A β plaques (Bard *et al.*, 2000; Schenk *et al.*, 1999); this presents a potentially beneficial role for features of inflammation in AD. These studies are undoubtedly the most significant leap in understanding the role of A β in AD neuropathology in the past decade.

However, the induction of pro-inflammatory cascades, such as inducing microglial cytokine synthesis and generation of free radicals (Levi *et al.*, 1998), are little understood and have been implicated in neuronal injury (Ulvestad *et al.*, 1994). As already discussed in this chapter, these underlying phenomenon are characteristic of AD, and raise significant concern about potential pro-inflammatory consequences of A β immunization (Mukherjee & Pasinetti, 2001; Pasinetti *et al.*, 2002). Furthermore, these data offer new challenges for the development of anti-inflammatory strategies to be used as therapeutic treatment in conjunction with vaccination therapy. For example, if the induction of specific cytokines or other unknown microglial pro-inflammatory factors are integral to microglial scavenging of A β plaques, the use of anti-inflammatory drugs that interfere with microglial cytokine activity may aberrantly affect immunization-based A β plaque clearance. If A β immunization induces/intensifies inflammation in patients with early-stage AD dementia, this treatment could potentially promote neurodegeneration and lead to acceleration of dementia.

Thus, it is early to speculate on the outcome of this therapy, either in conjunction with NSAIDs or alone, particularly as the trials have been discontinued owing to cerebral inflammation in a small subset of cases. Without question, vaccination is the most promising therapeutic treatment known so far. However, I believe this therapy is in the very early stages of development and requires much more investigation before it can safely be used for AD.

Research in progress and outstanding research questions: is there a "better" NSAID for AD?

Toxicity remains a major roadblock for studying dosages of traditional NSAIDs. One way to reduce NSAID toxicity is to add a cytoprotective agent to the treatment regimen. However, it is unlikely that a study of a treatment regimen that is tolerated (over the course of a year) by a minority of subjects will yield definitive results. The Alzheimer's Disease Cooperative Study (ADCS; <http://antimony.ucsd.edu/>) has opted to study two NSAID-type regimens that are expected to have substantially less toxicity than the Indomethacin and Diclofenac regimens reported (see above).

The first drug chosen by the ADCS is a new selective COX-2 inhibitor called Rofecoxib. As discussed, COX-2 may be the target of action of NSAIDs in the AD brain, and since COX-2 inhibitors appear to carry much reduced risk of serious gastrointestinal toxicity, Rofecoxib may be effective in preventive but not therapeutic trials.

The second active drug regimen in the new ADCS trial is low-dose Naproxen. Naproxen is a non-selective COX inhibitor, and therefore carries the risk of toxicity at full dose, similar to Indomethacin and Diclofenac. However, if in fact COX-1 is an important target for NSAID action in AD amyloidosis, Naproxen could be more effective than a selective COX-2 inhibitor. It is important to note that 200 mg is the over-the-counter analgesic dose, which is substantially less than a full anti-inflammatory dose. Nevertheless, studies suggest that this regimen is reasonably well tolerated in the elderly (DeArmond *et al.*, 1995; Geczy *et al.*, 1987), although there is little data on long-term treatment. In rodents, it has been found that systemic administration of Naproxen suppresses COX activity in the brain (Abdel-Halim *et al.*, 1978; Ferrari *et al.*, 1990), indicating effective brain penetration. But will the low dose tested in the ADCS trial be sufficient to alter the AD process? The epidemiological studies suggest that casual use of NSAIDs obtained over-the-counter may be neuroprotective, supporting further study of a low-dose regimen.

Collectively, the studies discussed above demonstrate significant support for the use of NSAIDs in the treatment

of cases at high risk of developing AD dementia such as those with MCI. Specifically, studies on the role of COX inhibitors in amyloidogenesis indicate that non-selective COX inhibitors might be more favorable candidates for such therapies. These compounds should be proven highly tolerable both in experimental and in clinical studies, and demonstrate beneficial effects on AD-type neuropathology at lower concentration, possibly through their potential high penetrability of the blood-brain barrier. Thus, the optimal COX inhibitor needs superior tolerability relative to other COX inhibitors and should promote (directly or indirectly) anti-amyloidogenic activities, and possibly exert neuroprotective functions (as previously demonstrated for some categories of COX inhibitors) (Mirjany *et al.*, 2002).

In conclusion, elucidating the role of inflammatory processes provides an impetus for further development of anti-inflammatory therapies for AD. However, it remains critical that diagnosis of patients in the very earliest stages of AD is improved. Continued research is necessary to identify very early neurobiological inflammatory abnormalities clearly so that effective treatments can be developed.

Introduction

This review on selected neurodegenerative diseases, including Alzheimer's disease, amyotrophic lateral sclerosis (ALS), and Parkinson's disease, and frontotemporal dementia with Parkinsonism (FTD-P), focuses on the ways by which genetically engineered models have clarified the mechanisms of these disorders and have identified new targets for therapy, and been used to test new treatment strategies. These neurodegenerative diseases are some of the most challenging diseases in medicine because of their general prevalence, cost, lack of mechanism-based treatments, and impact on individuals and caregivers (Lipp & Wolfer, 1998; Wong *et al.*, 2002). The classical clinical phenotypes are, for the most part, quite distinct and reflect the dysfunction and death of specific populations of neurons. These brain lesions are characterized by the presence of intracellular or extracellular peptides/aggregates, which appear to be critical contributors to neurotoxicity, partially damaging to synapses. Genetic risk factors influence these age-associated, chronic illnesses. In rare instances, cases are inherited in Mendelian fashion (usually as autosomal dominants). Susceptibility genes, environmental risk factors, or other influences remain to be defined. Information from genetics has allowed investigators to express or to target genes in efforts to model these diseases and to study the (Armstrong *et al.*, 1996) molecular participants critical in pathogenic pathways. This body of research is the principal topic of this review.

In this review, we emphasize the value of genetically engineered mouse models for studies of mechanisms and for experimental therapeutics, but we also briefly describe the extraordinary utility of non-mammalian genetic models. The identification of mutations in specific genes causing each of these illnesses has provided new opportunities

for scientists to investigate the molecular participants in pathological processes and to explore disease mechanisms using transgenic approaches. In these autosomal dominant disorders, the mutant proteins often do not exhibit reductions in normal functions, but instead, malformed mutant peptides acquire toxic properties that directly or indirectly impact on the structures, functions and viabilities of neural cells. Introducing mutant genes into mice reproduces some features of these diseases. Moreover, targeting of the genes that influence pathogenic pathways has provided new insights into disease mechanisms and has led to identification of potential therapeutic targets. Over the next several years, we anticipate that additional targets will be identified and novel treatments will be tested in these model systems and eventually will be examined in clinical trials. Because of limitations on citations, our references are predominantly reviews (Cleveland & Rothstein, 2001; Dawson *et al.*, 2002; Dunnett & Bjorklund, 1999; Goedert, 2001a,b; Julien, 2001; Kopan & Goate, 2002; Lee-Price, 2001; Lee & Trojanowski, 1999; Lin *et al.*, 1999; Lipp & Wolfer, 1998; Olanow & Tatton, 1999; Price *et al.*, 1998; Selkoe, 2001; Sherman & Goldberg, 2001; Sisodia & George-Hyslop, 2002; Tanzi & Bertram, 2001; Vassar & Citron, 2000; Wichmann & DeLong, 1996; Wong *et al.*, 2002; Wong *et al.*, 1998; Cleveland & Rothstein, 2001).

Alzheimer's disease

Clinical features, pathology and genetics

Affected individuals usually develop clinical manifestations (difficulty in memory and cognitive functions followed by progressive dementia) during the seventh decade (earlier in familial cases) (Lipp & Wolfer, 1998; Price *et al.*, 1998; Selkoe, 2001; Sisodia & George-Hyslop, 2002; Wong

et al., 2002). Alzheimer's disease is the most common cause of senile dementia, a term that refers to a syndrome, occurring in elderly people, resulting in memory loss and cognitive impairments of sufficient severity to interfere with social, occupational, and personal functions. This type of dementia affects more than 4 million people. Because of increased life expectancy and the postwar baby boom, the elderly are the fastest growing segment of our society. During the next 25 years, the number of people with Alzheimer's disease in the United States will triple, as will the cost. Thus, Alzheimer's disease is one of society's major public health problems.

Most individuals with sporadic Alzheimer's disease exhibit the first clinical signs during their seventh decade. However, some cases develop in mid-life; in these cases, it is more likely that there is a family history of the disease. In both the sporadic and familial forms of Alzheimer's disease, affected individuals show abnormalities of memory, problem solving, language, calculation, visuospatial perceptions, judgment, and behavior. Some patients develop psychotic symptoms, such as hallucinations and delusions. In these patients, mental functions and activities of daily living are increasingly impaired. In the late stages, these individuals are mute, incontinent, and bedridden and usually die of intercurrent medical illnesses. To make a diagnosis, clinicians rely on histories from patients and informants as well as physical, neurological, and psychiatric examinations, neuropsychological testing, laboratory studies, and a variety of diagnostic tests including neuroimaging studies. The clinical profile, in concert with a variety of laboratory assessments, allows the clinician to make a diagnosis of possible or probable Alzheimer's disease. Alterations in levels of specific proteins in the serum or cerebrospinal fluid, such as the A β peptide and tau, may eventually prove useful in diagnosis, but values may vary between individuals, and single measures are not of great diagnostic value. The presence of the ApoE-4 allele confers risk in late-onset disease (see below) and ApoE genotyping is a useful research tool but is not helpful for routine diagnostic purposes. Computerized tomography (CT) or magnetic resonance imaging (MRI), performed on the majority of patients with this syndrome, can identify other potentially treatable diseases and may detect abnormalities, particularly in the medial temporal lobe (atrophy of hippocampus and entorhinal cortex), that may have predictive value for establishing a diagnosis of Alzheimer's disease. In Alzheimer's disease, positron emission tomography (PET) and single photon emission computerized tomography (SPECT) usually show decreased regional blood flow in the parietal and temporal lobes with involvement of other cortical areas at later stages. At present, except for brain biopsy,

there are no tests that definitively establish the diagnosis of Alzheimer's disease in living subjects. It is extremely important for the physician to exclude other causes of dementia because some other types of dementia respond to specific treatments. However, Alzheimer's disease is a disorder for which there are no mechanism-based therapies. Only symptomatic treatments are available at present.

There are five principal risk factors for Alzheimer's disease: age; mutations in the *presenilin 1* (*PS1*) gene on chromosome 14; mutations in the *presenilin 2* (*PS2*) gene on chromosome 1; mutations in the *APP* gene on chromosome 21; and *ApoE* alleles positioned on the proximal long arm of chromosome 19. The presence of any of the mutations in the genes encoding *APP*, *PS1*, or *PS2* causes the disorder to occur earlier in the third through sixth decades. Specific *ApoE* alleles appear to predispose to later onset Alzheimer's disease and some cases of late-onset familial Alzheimer's disease. Thus approximately 10% of cases of Alzheimer's disease exhibit clinical syndromes in mid life (early onset) and are inherited in an autosomal dominant manner.

In a small fraction of early-onset families, missense mutations have been identified in the *APP* gene on chromosome 21. In all cases, mutations invariably occur within, or immediately proximal to, the A β region. In several families, the normally occurring valine residue at position 717 (of APP-770) is replaced with Ile, Gly, or Phe. Cells that express *APP* with mutations at position 717 secrete increased levels of A β 1-42,43. These longer A β forms have a propensity to nucleate rapidly into amyloid fibrils. In two large, related, early-onset Alzheimer's disease families from Sweden, a double mutation at codons 670 and 671 results in a substitution of the normal Lys-Met dipeptide to Asn-Leu; cells that express this mutant polypeptide secrete approximately 6-8-fold higher levels of A β . In a hereditary disease associated with A β deposition around blood vessels and cerebral hemorrhage, an *APP* mutation at position 693 leads to a Glu-Gln substitution (corresponding to amino acid 22 of A β). This mutation is associated with the A β peptide species that are more prone to aggregate into fibrils. Thus, some of the mutations linked to Alzheimer's disease can change the processing of *APP* and influence the biology of A β by increasing the production of A β peptides or the amounts of the longer, more toxic A β 42, or by promoting fibril formation. In those pedigrees in which missense mutations in either *APP* or *PS* genes promote the formation of the more toxic form of A β , it is highly likely that A β is central to the pathogenesis of disease.

Nearly 50% of cases of early-onset familial Alzheimer's disease are linked to the *PS1* gene (chromosome 14), which encodes a 467-amino acid polypeptide containing between

seven and nine transmembrane domains. Two mutations in the *PS2* gene, which encodes a protein homologous to PS1, cause autosomal dominant Alzheimer's disease in two familial Alzheimer's disease pedigrees. Approximately 50% of *PS1* mutations occur within, or immediately adjacent to, predicted transmembrane domains. Mutant PS1 and PS2 influence APP processing in a fashion that results in the elevated production of A β 1–42/43. In cultured cells and brains (human, monkey, and mouse), PS1 accumulates as an N-terminal ~28 kDa fragment, and a C-terminal ~18 kDa fragment, providing strong support for the idea that PS1 is subject to endoproteolytic processing *in vivo*. In view of the paucity of accumulated full-length PS, it has been suggested that PS fragments may be functional units. As indicated above, it is believed that PS are critical components of the γ -secretase complex. PS are highly homologous to sel-12, a gene product that plays a role in the determination of cell fates during development, suggesting roles for PS in these processes. Recent work indicates that γ -secretase cleaves APP and Notch-1, generating intracellular domains that traffic to the nucleus where they are involved in transcriptional activation. The results of studies of PS1 and Nct studies are consistent with the concept that they are components of γ -secretase and the phenotype of knockout mouse embryos are the result of failed Notch1 signaling. Mutant PS1 and PS2 influence APP processing in a fashion that results in the elevated production of A β 1–42/43.

An allele of ApoE, a glycoprotein that carries cholesterol and other lipids in the blood, has been implicated as a risk factor for the disease in Alzheimer's disease. At the single ApoE locus, three alleles are expressed: apoE2, apoE3, and apoE4. The apoE3 allele is most common in the general population (frequency of 0.78), whereas the allelic frequency of apoE4 is 0.14. However, in clinic-based studies, patients with late-onset disease (>65 years of age) have an apoE4 allelic frequency of 0.50; thus, the risk for Alzheimer's disease is increased by the presence of apoE4. The mechanisms whereby the apoE allele type elevates the risk for late-onset disease are not known but may reflect differences in the abilities of apoE isoforms to bind A β and possibly influence aggregation, deposition and/or clearance.

In some individuals with autosomal dominant Alzheimer's disease, mutations have been identified in three different genes: *Amyloid Precursor Protein (APP)*; *Presenilin1 (PS1)*; and *Presenilin2 (PS2)*. APP, a type I transmembrane protein existing as several isoforms, is expressed in many different cell types. Significantly, APP is particularly abundant in neurons, is synthesized in cell bodies, and is transported rapidly anterograde in axons, by interacting with a kinesin motor, possibly serving as a cargo

receptor (Goldstein & Yang, 2000). Cleavages of APP generates A β peptides via the activities of BACE1 (β -site APP cleaving enzyme 1) and the γ -secretase complex (Cai *et al.*, 2001; Sisodia & George-Hyslop, 2002; Vassar *et al.*, 1999; Vassar & Citron, 2000), which generate the N- and C-termini of A β peptides, respectively. The γ -secretase cleavage liberates the APP intracellular domain (AICD), which, upon translocation to the nucleus, appears to play a role in transcription. (Cao & Südhof, 2001; Sisodia & George-Hyslop, 2002). The levels and distributions of APP and the neuronal pro-amyloidogenic cleavage enzymes, particularly BACE1, are hypothesized to be the principal determinants of high levels of A β in the brain (Cai *et al.*, 2001; Wong *et al.*, 2001). In contrast, formation of A β is precluded by cleavage of APP within the A β domain by α -secretase and by BACE2, which are either expressed at low or non-detectable levels, respectively, in the brain, but at variably higher levels in other organs (Lipp & Wolfer, 1998).

Several FAD linked *APP* mutations are located in proximity to the pro-amyloidogenic cleavage sites (Sisodia & George-Hyslop, 2002; Tanzi & Bertram, 2001). For example, the *APP^{swe}* mutation, a double mutation at the N-terminus of A β , enhances BACE1 cleavage many-fold and is associated with elevated levels of all A β peptides, including A β 42, the *APP 717* mutation, located near the C-terminus of A β , promotes γ -secretase activity, leading to increased secretion of A β 42, the longer and more toxic A β peptide.

PS1 and *PS2*, which encode two highly homologous 43 to 50 kD multipass transmembrane proteins that are processed to stable N-terminal and C-terminal fragments, are conserved from invertebrates to humans and are involved in Notch 1 signaling critical for cell fate decisions (Kopan & Goate, 2002; Sisodia & George-Hyslop, 2002). They are widely expressed at low abundance in the CNS. PS influence APP processing and are recognized as components of the γ -secretase complex along with Nicastrin, a type I transmembrane glycoprotein (Kopan & Goate, 2002; Sisodia & George-Hyslop, 2002), as well as Aph1 and Pen2, two multipass transmembrane proteins (Francis *et al.*, 2002). The *PS1* gene has been reported to harbor more than 80 different FAD mutations, whereas only a small number of mutations have been found in *PS2*-linked families (Sherington *et al.*, 1995; Sisodia & George-Hyslop, 2002; Tanzi & Bertram, 2001). The majority of abnormalities in *PS* genes are missense mutations that result in single amino acid substitutions, which enhance γ -secretase activity and increase the levels of the A β 42 peptides. See below for discussion of the results of gene targeting studies, which have begun to clarify some of the properties of APP, BACE1, and components of γ -secretase complex.

BACE1 and BACE2, encoded by genes on chromosomes 11 and 21, respectively, have been shown to be transmembrane aspartyl proteases that are directly involved in the cleavage of APP. BACE1 mRNA is present in a variety of tissues, and BACE1 mRNA levels are high in many regions of brain. Intriguingly, BACE1 protein is only abundant in the brain while it is undetectable in other non-neural tissues, such as the pancreas, where the mRNA is alternatively spliced to a smaller protein incapable of cleaving APP. BACE2 mRNA is very low in neural tissues, except for scattered nuclei in the hypothalamus and brainstem. The functions of BACE1 processed peptides generated from APP are unknown, but it has been suggested that A β may influence synaptic activity. Interestingly, BACE1, along with APP and components of γ -secretase complex, is transported in axons and enriched at some synapses in several highly plastic structures of brain (i.e. the mossy fiber pathway originating from hippocampal granule cells and the glomeruli of olfactory bulb, observations consistent with the idea that A β released in synaptic fields may influence synaptic plasticity.

BACE1 preferentially cleaves APP at the +1 and +11 sites of A β in APP and is critical for the generation of A β . *BACE1* deficient mice show no overt developmental phenotype. In cultures of *BACE1*^{-/-} neurons, the secretion of A β _{1-40/42} as well as A β _{11-40/42} is abolished. Thus, BACE1 is the principal neuronal β -secretase and makes proamyloidogenic cleavages. In contrast, BACE2 makes antiamyloidogenic cleavages at +19/+20 of A β . Thus, BACE2 acts more like a α -secretase. While BACE1 is critical for amyloidogenesis in brain, BACE2 does not appear to play a significant role in APP processing in neurons. In contrast to the ubiquitous expression of BACE1 mRNA in a variety of tissues, BACE1 protein is abundantly expressed in the brain while it is undetectable in other non-neural tissues, such as the pancreas. Although BACE1 protein is expressed at comparable levels in most brain regions, BACE1-specific immunoreactivities are particularly localized in the hippocampus.

γ -Secretase activity is essential for the regulated intramembraneous proteolysis of a variety of transmembrane proteins dependent upon a multiprotein catalytic complex, including PS and several other transmembrane proteins. It is not clear whether PS1 itself acts as an aspartyl protease, functions as a co-factor critical for the activity of γ -secretase, or exerts its influence by playing a role in trafficking of APP or other essential protein critical for enzyme activity, to the proper compartment for γ -secretase cleavage. The concept that PS1 may act as an aspartyl protease or may be a critical co-factor essential for the activity of γ -secretase is suggested by several observations: PS1 is

isolated with γ -secretase under specific detergent soluble conditions; PS1 is selectively cross-linked or photoaffinity labeled by transition state inhibitors; substitutions of aspartate residues at D257 in TM6 (although controversial) and at D385 in TM7 have been reported to reduce secretion of A β and ultimately cleavage of Notch1 in vitro; cells in which *PS1* has been targeted show decreased levels of secretion of A β . Recent work is focused on roles of different proteins in the multiprotein catalytic complex, including Nicastrin (NCT), Aph-1, and Pen-2 domain. *NCT* null (*NCT*^{-/-}) mice and *NCT*^{-/-} fibroblasts have shown that *NCT* is an integral member of the γ -secretase complex. Partial decreases in the level of NCT significantly reduce the secretion of A β and NCT may be a valuable therapeutic target for Alzheimer's disease. Aph-1 and Pen-2 are novel transmembrane proteins: Aph1 has seven predicted transmembrane domain; while Pen-2 has two predicted transmembrane regions. These proteins interact with sel-12/PS and aph-1/nicastrin and their inactivation with RNAi methods in *Drosophila* cells decreases γ -secretase of APP and Notch and reduces levels of processed PS. For these reasons, Aph-1 and Pen-2 are now believed to be critical components of γ -secretase complex.

Models of A β amyloidosis

Both spontaneously occurring and genetically produced diseases in animals have now been used to model features of Alzheimer's disease. Rhesus monkeys, *Macaca mulatta*, with an estimated lifespan of >35 years, show cognitive and memory deficits that appear at the end of the second and the beginning of the third decades of life. These animals develop virtually all of the brain abnormalities observed in older humans and, to a lesser degree, patients with Alzheimer's disease.

In mice, expression of APP^{swe} or APP717 minigenes encoding FAD-linked mutations (with or without mutant *PS1*) leads to an A β amyloidosis in the CNS. Levels of A β are elevated, and diffuse A β deposits and neuritic plaques appear in the hippocampus and cortex (Benoist & Mathis, 1997; Lipp & Wolfer, 1998; Price *et al.*, 1998; Wong *et al.*, 2002). Classical neurofibrillary tangles are not present in a region of the brain. The pathology evolves in stages: elevated levels of A β ; synaptic alterations; formation of neurites, axon degeneration; and diffuse amyloid evolving to plaques. The nature and levels of the expressed transgene and the specific mutation influence the severity of the pathology. Mice expressing both mutant *PS1* and mutant *APP* develop accelerated disease (Benoist & Mathis, 1997). Learning deficits, problems in object recognition memory, and difficulties performing tasks assessing spatial

reference and working memory have been identified in some of the lines of mutant mice (Chen *et al.*, 2000). Thus, these animals have an A β amyloidosis in the CNS, although the mutant mice do not fully recapitulate the full phenotypes of Alzheimer's disease; they are very useful subjects for research designed to examine mechanisms and to test therapies for this type of disease.

In attempts to obtain mice with both plaques and tangles, mutant *APP* transgenic mice have been mated to mice expressing the *P301L tau* mutant, a mutation linked to familial frontotemporal dementia with parkinsonism (FTDP). These mice appear to have a greater number of tangles and an apparent shift in distribution of NFT (Lewis *et al.*, 2001). Moreover, tau pathology appears to be induced by introducing A β fibrils into the brains of *P301L tau* mutant mice. However, mice bearing both mutant *tau* and *APP* or mutant *tau* mice injected with A β are problematic as models of FAD because the FTDP mutation alone is associated with the presence of tangles. A more appropriate model of Alzheimer's disease might be achieved by co-expression of mutant *FAD* linked genes and all six isoforms of wild type human *tau*.

Gene targeting relevant to Alzheimer's disease

In an effort to understand the functions of some of the genes thought to play roles in Alzheimer's disease, investigators have targeted a variety of genes including: *APP*; *APLPs*; *BACE1*; and *PS1*.

Homozygous *APP*^{-/-} mice are viable and fertile, but appear to have subtle decreases in locomotor activity and forelimb grip strength (Zheng *et al.*, 1995). The absence of substantial phenotypes in *APP*^{-/-} mice is thought to be related to functional redundancy of two amyloid precursor-like proteins, *APLP1* and *APLP2*, homologous to *APP*. Consistent with this idea, *APLP2*^{-/-} mice appear normal, but *APP* and *APLP2* null mice and *APLP1* and *APLP2* null mice do not survive the perinatal period (Heber *et al.*, 2000).

BACE1, a type 1 transmembrane aspartyl protease, is relatively abundant in brain, and is transported by axons to terminals. *BACE1* null mice are viable and healthy, have no obvious phenotype or pathology, and can mate successfully (Cai *et al.*, 2001; Luo *et al.*, 2001; Vassar & Citron, 2000). Importantly, cortical neurons cultured from *BACE1*^{-/-} embryos, do not show cleavages at the +1 and +11 sites of A β , and the secretion of A β peptides is abolished even in the presence of elevated levels of exogenous weight or mutant *APP* (Cai *et al.*, 2001). In brains of *BACE1* null mice, A β peptides are not produced. These results establish that *BACE1* is the neuronal β -secretase required to cleave *APP* to generate the N-termini of A β (Cai *et al.*, 2001). At present, there

is no consensus on other substrates cleaved by *BACE1*. Behavioral studies of the null mice, in vitro and in vivo challenges of *BACE1* neural cells, and two-dimensional gels of organs from *BACE1* +/+, +/-, -/- mice will be critical in determining the consequences of the absence of *BACE1* on behavior, susceptibility to challenge, and other substrates that may be cleaved by the enzyme. Results thus far indicate that *BACE1* is an excellent therapeutic target for development of an anti-amyloidogenic drug.

In contrast to *BACE1* null mice, *PS1*^{-/-} mice do not survive beyond the early postnatal period and show severe developmental abnormalities of the axial skeleton, ribs and spinal ganglia, features resembling a partial *Notch 1*^{-/-} phenotype (Wong *et al.*, 1997). These abnormalities occur because *PS1* along with Nicastrin, *APH1* and *PEN2* and perhaps other proteins are components of the γ -secretase complex that carries out the S3 intramembranous cleavage of *Notch1*, a receptor protein involved in critical cell-fate decisions during development. Without this cleavage, the *Notch1* intracellular domain (NICD) is not released from the plasma membrane and does not reach the nucleus to initiate transcriptional processes essential for cell fate decisions. In cell culture, absence of *PS1* or substitution of particular aspartate residues leads to reduced levels of γ -secretase cleavage products and levels of A β . *PS2* null mice are viable and fertile, though they develop age-associated mild pulmonary fibrosis and hemorrhage. Mice lacking *PS1* and heterozygous for *PS2* die midway through gestation with full *Notch1* null-like phenotype. To study the role of *PS1* in vivo in adult mice, two groups generated conditional *PS1*-targeted mice lacking *PS1* expression in the forebrain after embryonic development. As expected, the absence of *PS1* resulted in decreased generation of A β ; further establishing that *PS1* is critical for γ -secretase activity in the brain. As indicated above, more recent work has established that Nicastrin, *APH1* and *PEN2* are also components of the γ -secretase complex and are critical for stabilizing *PS* and for generation of A β (Francis *et al.*, 2002). In concert, these findings suggest that γ -secretase inhibitors may be useful as therapeutic agents for A β amyloidosis.

Alzheimer's disease, a neuronal disease

The source of *APP* giving rise to A β has been debated (Wong *et al.*, 2001). Significantly, key participants in A β amyloidosis (*APP*, *PS1* and *BACE1*) are synthesized by neurons, transported to terminals, and are colocalized with neurites in immediate proximity to sites of A β deposition in brain, providing circumstantial evidence consistent with a neuronal origin for A β . Moreover, *APP* is cleaved by *BACE1* in

distal axon terminal to generate C-terminal amyloidogenic peptides. More compelling is the demonstration that lesions of specific neuronal populations or their axonal projections (i.e. entorhinal cortex or perforant pathway) reduces the levels of A β and the numbers of plaques in terminal fields of these neurons (Sheng *et al.*, 2002).

Because BACE1 is the principal β -secretase in neurons and BACE2 and α -secretase may serve to limit the secretion of A β peptides in other organs, we have hypothesized that the relative levels of BACE1 and BACE2 activities, in conjunction with high levels of APP in neurons, are major determinants of A β amyloidosis in the CNS (Cai *et al.*, 2001; Wong *et al.*, 2001). This hypothesis predicts that the secretion of A β peptides will be the highest in neurons and brain as compared to other cell types or tissues because neurons express high levels of APP and BACE1 coupled with low level expression of BACE2 and α -secretase. Seemingly inconsistent with this hypothesis is a study showing high levels of BACE1 mRNA in the pancreas. BACE1 is critical for A β amyloidosis and both BACE1 and APP are expressed in β cells of the pancreas. Why do Alzheimer's disease and diabetes mellitus not occur together? It now appears that BACE1 mRNAs in the pancreas are alternatively spliced to generate a BACE1 isoform that is incapable of cleaving APP. Taken together with the observations that pancreas possesses low levels of normal BACE1 protein and activity, these results are consistent with the view that a high ratio of BACE1 to BACE2 activity leads to the selective vulnerability of neurons to A β amyloidosis, whereas the cells of the pancreas are spared.

One important member of the γ -secretase complex is nicastrin (NCT), a type I transmembrane glycoprotein, which forms high molecular weight complexes with presenilins (Yu *et al.*, 2000) and binds to the membrane-tethered form of Notch1 (Chen *et al.*, 2001). Recent studies have indicated that nicastrin is required for Notch signaling and APP processing (Chung & Struhl, 2001; Edbauer *et al.*, 2002; Hu *et al.*, 2002; Lopez-Schier & St Johnston, 2002; Yu *et al.*, 2000). Studies in *Drosophila* have shown that nicastrin may function to stabilize PSs and appears to be critical for the trafficking of PSs to the cell surface. Likewise, PS is required for the maturation and cell surface accumulation of nicastrin (Edbauer *et al.*, 2002; Kaether *et al.*, 2002; Leem *et al.*, 2002). These results have suggested that nicastrin and PSs form functional components of a multimeric complex required for the intramembraneous proteolysis of both Notch and APP.

To determine whether nicastrin is required for proteolytic processing of Notch and APP in mammals and the role of nicastrin in presenilin/ γ -secretase complex assembly, we generated nicastrin-deficient (*NCT*^{-/-}) mice and

derived fibroblasts from *NCT*^{-/-} embryos. Nicastrin-null embryos died by embryonic day 10.5 and exhibited several patterning defects, including abnormal somite segmentation, phenotypes that are reminiscent of embryos lacking Notch1 or both presenilins. Importantly, secretion of A β peptides is abolished in *NCT*^{-/-} fibroblasts, whereas it is reduced by ~50% in *NCT*^{+/-} cells; the failure to generate A β peptides in *NCT*^{-/-} cells is accompanied by destabilization of the presenilin/ γ -secretase complex and accumulation of APP-C-terminal fragments. Moreover, APP trafficking analysis in *NCT*^{-/-} fibroblasts revealed a significant delay in the rate of APP reinternalization compared with that of control cells. Together, these results establish that nicastrin is an essential component of the multimeric γ -secretase complex in mammals required for both γ -secretase activity and APP trafficking and suggest that nicastrin may be a valuable therapeutic target for Alzheimer's disease.

Among the most challenging mysteries of Alzheimer's disease is the identification of factors that render the brain particularly susceptible to the extracellular deposition of b-amyloid (A β). A β peptides are thought to be toxic and are the central component of neuritic plaques, which are preferentially localized to brain regions that are critical for memory, cognition, emotional state, and personality.

Recent research has begun to provide new clues concerning the biological basis for the vulnerability of the brain to these abnormalities, and this information has relevance to developing therapies for Alzheimer's. A β is generated from cleavages of the b-amyloid precursor protein (APP) by b site APP-cleaving enzyme 1 (BACE1) and by an enzyme activity termed g-secretase. In vivo, BACE1 has been found to be the principal b-secretase necessary to cleave APP to generate A β . In contrast, APP can also be cleaved within the A β sequence by putative " α -secretases" or by BACE2 to release the ectodomain (the amino-terminal soluble fragment) of APP; these cleavages within the A β domain of APP preclude the formation of A β . In Alzheimer's, why is the brain but not any other organ (such as the pancreas, for example) particularly vulnerable to A β deposition?

BACE1 and BACE2 are expressed ubiquitously, but levels of BACE1 messenger RNA (mRNA) are particularly high in brain and pancreas, whereas the levels of BACE2 mRNA are relatively low in all tissues, except in the brain, where it is nearly undetectable. Because BACE1 is the principal b-secretase in neurons and BACE2 limits the secretion of A β peptides, we propose that BACE1 is a pro-amyloidogenic enzyme, whereas BACE2 is an anti-amyloidogenic enzyme.

In this scenario, the relative levels of BACE1 and BACE2, in concert with the abundance of APP in neurons, are major determinants of A β formation. Under this model, the secretion of A β peptides would be expected to be highest in

neurons and brain, as compared with other cell types or organs, because neurons express high levels of BACE1 coupled with low expression of BACE2. If the ratio of the level of BACE1 to BACE2 is a critical factor that selectively predisposes the brain to the formation of A β , Alzheimer's disease would be predicted to involve the brain rather than heart or pancreas.

Seemingly inconsistent with this hypothesis is the observation that there are very high levels of BACE1 mRNA in the pancreas. It appears that some of this mRNA is alternatively spliced to generate a BACE1 isoform that is incapable of cleaving APP; thus, A β is not deposited in the pancreas. Taken together with the observations that the pancreas has low levels of BACE1 protein, as well as low BACE1 enzymatic activity, these results are consistent with the view that a high ratio of BACE1 to BACE2 activity is a major determinant of selective vulnerability of the brain to formation of A β plaques.

Potential therapeutics for Alzheimer's disease

Although these mutant transgenic mice do not recapitulate the full phenotype of Alzheimer's disease, they represent excellent models of A β amyloidosis and are highly suitable for identification of therapeutic targets and for testing new treatments. Although both β - and γ -secretase activities represent therapeutic targets for the development of novel protease inhibitors for Alzheimer's disease, the demonstration that BACE1 is the principal β -secretase in cultured neurons and that, in contrast to *PS1*^{-/-} mice, the *BACE1*^{-/-} mice seem to be normal, provides an excellent rationale for focusing on the design of novel therapeutics to inhibit BACE1 activity in brain. Significantly, BACE1-deficient neurons fail to secrete A β even when co-expressing the *APP*^{*swe*} and mutant *PS1* genes, and these *BACE-1* coexpressing mutant *APP/PS* gene mice lacking BACE1 do not exhibit A β plaques in the brain (H.Cai, D.L.P. and P.C.W., unpublished data). PS, Nicastrin, APH1, and PEN2 are necessary for γ -secretase activity. With the latter, these proteins stabilize PS. Recent work suggests that PS1 is essential for activity, but it is not the protease performing γ cleavage (at least for Notch1) (Taniguchi *et al.*, 2002). Because of the role of the γ -secretase complex in Notch processing, it may be valuable to try to design therapeutics that inhibit selectively the γ -secretase activity, with regard to APP, without allowing the activity involved in Notch1 processing. This approach is being pursued because several populations of cells, hematopoietic stem cells in particular, use Notch 1 signaling for cell-fate decisions even in adults.

A variety of other treatments have been tested in mouse models, but space constraints limit discussion. However, to illustrate the challenges of extrapolating outcomes in mice to trials with humans, it is useful to briefly discuss recent problems with A β immunotherapy. In both prevention and treatment trials, both A β immunization (with Freund's adjuvant) and passive transfer of A β antibodies reduce levels of A β and plaque burden in mutant APP transgenic mice. Efficacy seems to be related to antibody titer. The mechanisms of enhanced clearance are not certain, but two not mutually exclusive hypotheses have been suggested: (i) a small amount of A β antibody reaches the brain, binds to A β peptides, promotes the disassembly of fibrils, and via the Fc antibody domain, attracts activated microglia that remove A β (Schenk *et al.*, 1999); and (ii) serum antibodies serve as a sink to draw the amyloid peptides from the brain into the circulation, thus changing the equilibrium of A β in different compartments and promoting removal from the brain (DeMattos *et al.*, 2001). Immunotherapy in transgenic mice was successful in clearing A β and attenuates learning and behavioral deficits in at least two cohorts of mutant *APP* mice. Although phase 1 trials with A β peptide and adjuvant were not associated with any adverse events, phase 2 trials of this strategy have been suspended because of severe adverse reactions (encephalomyelitis) in a subset of patients.

One of these patients arrived in autopsy in comparison with unimmunized cases of Alzheimer's disease, several unusual features were identified in the immunized case. Specifically, there were areas of cortex with very few plaques, yet they contained a relatively high density of tangles in neuropil and vascular amyloid deposits but lack plaque associated dystrophic neurites and astrocytic clusters; A β immunoreactivity was associated with microglia; and a T-cell predominant meningoencephalitis was identified (Nicoll *et al.*, 2003). Investigators have continued to pursue the passive immunization approach, experimental systems using passive immunization and attempting to make antigens that do not stimulate T-cell mediated immunologic attacks.

It is clear that amyloid burden can be significantly reduced by a variety of approaches. As indicated above, lesions of the entorhinal cortex or the perforant pathway reduced the levels of A β and the number of plaques in the terminal fields (molecular dentate gyrus). This work clearly shows that APP is a major source of the A β peptide in the brain (Lazarov *et al.*, 2002; Sheng *et al.*, 2002).

Another approach to reduce the amyloid burden is to use the Lentiviral vector system to express human neprilysin, a putative A β degrading enzyme, into the brain of transgenic mice with amyloid deposits. Unilateral

intercerebral injections of lentivirus expressing neprilysin reduce A β deposits and may attenuate neurodegenerative processes. Another strategy is the use of non-steroidal anti-inflammatory drugs (NSAIDs) as a therapeutic approach. Retrospective studies had suggested that the prevalence of Alzheimer's disease was reduced in individuals who had used NSAIDs. Lim *et al.* (2000) demonstrated that Ibuprofen suppresses plaque pathology and inflammation in a transgenic model of A β amyloidosis. Initially, this outcome was thought to be attributable to the impact of NSAIDs on CNS inflammation. However, more recent results suggest that ibuprofen (Weggen *et al.*, 2001) may lower A β 42 independent of inhibition of cyclo oxygenase activity. Experiments by Weggen *et al.* (2001) show that several, but not all, NSAIDs decrease the levels of A β 42 and increase the levels of A β 1–38, a less toxic isoform. These studies suggest that NSAIDs can impact on the pathology in the brain by reducing levels of A β 42 independent of COX activity and lead to the suggestion that other types of NSAIDs may do this with a greater degree of specificity. Another approach has been to target copper and zinc, which are enriched in A β deposits in the brains of individuals with Alzheimer's disease. It has been suggested that these metals play a role in aggregation of A β and local H₂O₂ production and thus, their removal might attenuate the deposition of A β and its consequences. In one study (Cherny *et al.*, 2001) they used clioquinol, a brain penetrate antibiotic that binds zinc and copper to reduce the levels of these metals in the brain. Nine-week therapy was associated with a modest increase in soluble A β and a reduction in A β deposition in the brain.

Amyotrophic lateral sclerosis

Clinical features, pathology and genetics

Individuals with this motor neuron disease have muscle weakness and atrophy, as well as spastic paralysis (Cleveland & Rothstein, 2001; Julien, 2001; Wong *et al.*, 1998). These signs result from selective degeneration of spinal and corticospinal motor neurons, respectively. In motor neurons, proximal axonal segments are swollen with accumulations of neurofilaments and cell bodies show ubiquitin-positive protein aggregates. Distal motor axons degenerate and terminals become disconnected from the denervated muscles, and, presumably, as trophic support is compromised, cell bodies shrink and then dendrites are attenuated. Clinical signs appear to be most closely linked to the disconnection of the motor terminals from their targets. Ultimately, neurons degenerate, exhibiting several features

consistent with oxidative damage, and programmed cell death. Ultimately, the numbers of motor neurons in the spinal cord and brainstem nuclei are reduced.

Approximately 10% of cases of ALS are familial, and, in most of these individuals, the disease is inherited in an autosomal dominant pattern. Approximately 15–20% of patients with autosomal dominant FALS (up to 2% of all ALS cases) have mutations in the gene that encodes cytosolic Cu/Zn superoxide dismutase (SOD1), a widely expressed and abundant antioxidant enzyme that catalyzes the conversion of $\cdot\text{O}_2^-$ to O₂ and H₂O₂. To date, at least 90 different missense mutations have been identified in the *SOD1* gene. Although some FALS *SOD1* mutants show reduced enzymatic activities, many variants retain full activity as occurs with the G37R *SOD1* mutation (Borchelt *et al.*, 1995). These mutations are scattered throughout the protein and are not preferentially localized near the active site or the dimer interface. It is puzzling how these mutations lead to a common phenotype. Thus, it is hypothesized that the mutant enzyme causes selective neuronal degeneration through a gain of toxic property, a concept consistent with autosomal dominant inheritance (Wong *et al.*, 1995). It has been suggested that the misfolded mutant SOD1 could catalyze aberrant reactions, including enhanced peroxidase activity, increased reactions with peroxynitrite, and mutation-induced conformational changes that result in aberrant activity catalyzed by Cu bound to mutant SOD1 (see below for discussion of potential aberrant copper chemistry in mutant SOD mediated disease) (Wong *et al.*, 1995). The presence of ubiquitin aggregates containing mutant SOD1 protein raises the possibility that aggregated mutant proteins, which may exhibit conformational changes, are toxic, that the protein aggregates sequester molecules which are critical for cell viability, or the malformed mutant proteins damage proteosomal degradative machinery (Cleveland & Rothstein, 2001).

Several chronic experimental and clinical axonopathies are associated with the accumulation of cytoskeletal pathology, particularly accumulation of NF. The experimental toxin β,β' -iminodipropionitrile (IDPN), the prototype for this type of disorder, selectively blocks NF transport, perhaps by altering interactions of NF with microtubules or with anterograde motors. The transport of other cytoskeletal proteins, including actin and tubulin, is relatively unaffected, and fast anterograde and retrograde transport appear to be relatively normal. NF synthesis is unaltered, and newly synthesized NF proteins continue to enter the axon normally after systemic intoxication with IDPN. However, the transport of these proteins along the axon is markedly impaired, resulting in the accumulation of NF and distension of the proximal axon. Similar kinds

of NF axonal pathology occur in other experimental models: aluminum intoxication; the overexpression of a species of wild-type NF proteins (altering their stoichiometry); and the expression of mutant NF proteins, which fail to interact properly for accurate assembly; a dominant disorder that occurs in Brittany spaniels (hereditary canine spinal muscular atrophy); *PMN* mice; and mutant *SOD1* mice. Similar pathology occurs in human amyotrophic lateral sclerosis (Lou Gehrig's disease). These diseases are characterized by the abnormal accumulation of NF in the neuronal cell bodies and proximal axons. This form of pathology, which is a distinct form of pathology seen in ALS and several other models, appears to reflect the impaired transfer of newly synthesized NF proteins from the cell body to the axon, is associated with axonal degeneration and neuronal death, which raises the possibility that the accumulation of NF in the cell body may reflect a more general derangement of the entire axonal transport mechanism, including the transport of membranous organelles. As mentioned above, NF pathology also occurs in the distal portions of axons in a number of clinical and experimental disorders, including giant axonal neuropathy and intoxication with n-hexane, and acrylamide, and BPAU. The mechanisms that lead to distal NF swellings have not been clarified, but these changes may also reflect a general impairment of both the fast and slow transport systems because they are also associated with the distal accumulation of membranous organelles and distal axonal degeneration. The distal accumulation of membranous organelles in these settings occurs in axons devoid of NF (i.e. in the quiverer quail, where NF assembly is prevented by a mutation that blocks the transcription of NF-L) (Brown, 2000; Bruijn *et al.*, 1998; Terada & Hirokawa, 2000).

Pathology indicative of altered transport occurs in several genetic diseases in rodents and humans, including: Charcot Marie Tooth type 2A (*KIF1B* β mutations); in a form of autosomal recessive motor neuron disease (mutant *dynactin*); and in a mouse model of *dynamitin* overexpression (a situation where there is interference with the dynein/dynactin complex). Moreover, it is likely that disorders associated with tau abnormalities (i.e. Alzheimer's disease and tauopathies, including Frontotemporal Dementia) are associated with alterations of transport. In these disorders, pathological filaments (comprised of tau) accumulate in cells.

Although distal axons show Wallerian degeneration after transection (and following other insults), the degeneration of these axons and nerve terminals can be prevented by the presence of an unusual gene. In the slow Wallerian degeneration mutant mouse (C57BL/WLd^s), transected distal axons survive several weeks after transac-

tion. The protective gene encodes an N-terminal fragment of ubiquitination factor E4B (*Ube4b*) fused to a nicotinamide mononucleotide adenylyl transferase. The mechanism of this autosomal semi-dominant protection is unknown, but is suspected to be related to altered ubiquitination or changed purine nucleotide metabolism. This unique genetic model provides an opportunity to discover new pathways of degeneration and protection.

Other forms of motor neuron degeneration or motor axonopathies have been linked to mutations

Als 2 is associated with mutations in the *alsin* gene. Charcot Marie Tooth disease is associated with microtubule motor Kif 1B β , a mutation associated with dynactin. Although motor neuron disease has been linked to a mutation in dynactin, this single base pair change results in a substitution that is predicted to alter the folding of dynactin's microtubule binding domain leading to motor neuron disease in humans (Puls *et al.*, 2003).

A disruption of dynein/dynactin inhibits transported motor neurons and causes a late onset progressive neurodegeneration in transgenic mice. In this study, mice overexpressing dynamitin demonstrate a late onset slowly progressive motor neuron disease associated with muscle weakness, trembling, altered posture and gait, and weakness. Neurofilament accumulations and evidence of degeneration of motor neurons and denervation atrophy of muscle described in this mouse model with disrupted axonal transport (LaMonte *et al.*, 2002).

Other disease models of motor neuron disease are in progress. In addition to models of spinal muscular atrophy created by manipulations of the survivor motor neuron disease, mutations in *din* result in progressive motor neuron degeneration in heterozygous mice (Jan *et al.*, 2003; Kriz *et al.*, 2003; Rothstein, 2003).

SOD1 mutant mice

Although there are a variety of other extraordinarily interesting models of motor neuron disease (Cleveland & Rothstein, 2001; Julien, 2001), this review focuses on mice expressing FALS-linked mutant *SOD1*. The mice harboring mutations develop progressive weakness and muscle atrophy, and cellular pathology closely resembling that occurring in ALS. For example, the *G37R SOD1* mice accumulate to 3–12 times the endogenous levels in the spinal cord, and the levels of the mutant protein influence the age of onset (Wong *et al.*, 1995). High molecular weight complexes of mutant *SOD1* accumulate in neural tissues but not in non-nervous system organs (Bruijn *et al.*, 1997). Some

neuronal cell bodies show SOD1, ubiquitin, and phosphorylated NF-H immunoreactive inclusions (Wang *et al.*, 2002); in some lines of mutant mice, vacuolization and swelling of mitochondria appear early in some motor neurons. Toxic SOD1 is transported anterograde in axons, and early on, SOD1 accumulates in axons, where it is associated with structural pathology, occurring approximately 2–3 months before the appearance of clinical signs. Thus, SOD1, neurofilaments and degenerating mitochondria appear in irregular, swollen, intraparenchymal portions of motor axons, and axonal transport is abnormal. Wallerian degeneration of axons occurs, and the mice become weak (Bruijn *et al.*, 1997; Li *et al.*, 2000; Lipp & Wolfer, 1998; Wong *et al.*, 1995). In mutant mice (and in cases of ALS), it has been reported that caspase 1 and 3 activities increase (early and late, respectively), followed by evidence of action of caspase 9 (Bruijn *et al.*, 1998; Cleveland & Rothstein, 2001). Eventually, the number of motor neurons is decreased and glial proliferation is present in the anterior horns.

Potential therapies for ALS

Mutant *SOD1* mice have been used to test pharmacological and gene-based therapies (Cleveland & Rothstein, 2001). Several potential treatments, including administration of vitamin E, selenium, riluzole, gabapentin, and d-penicillamine (a copper chelator), have been tested with unencouraging results. Treatments with creatine, caspase inhibitors, minocycline (which inhibits release of cytochrome C from mitochondria) have had modest influences on onset of disease and survival.

Treatment strategies would be more effectively targeted if the molecular mechanisms whereby mutant *SOD1* causes selective degeneration of motor neurons were better understood. Although it was initially speculated that loss of enzyme activity might be a factor in disease, this idea is not compatible with the following observations: some mutants show full activity; *SOD1* null mice do not develop motor neuron phenotypes; and elevations or reductions in mutant *SOD1* by mating to *SOD1* overexpressors of *SOD1* null mice, respectively to animals with mutations, does not influence phenotype (Cleveland & Rothstein, 2001; Subramaniam *et al.*, 2002). It has been proposed that the toxic property of mutant *SOD1* involves mutation-induced conformational changes in *SOD1* that result in aberrant oxidative activities. In this scenario, cell dysfunction and death could be initiated by chemistries catalyzed by Cu bound in the active site of mutant *SOD1* (Wong *et al.*, 2000). To test this hypothesis, we took advantage of the discovery in yeast of Lys7 and its mammalian homologue Cu chaperone

for *SOD1* (CCS), and generated mice lacking *CCS*. Inactivation of the *CCS* gene in mice demonstrates that *CCS* is required for efficient Cu incorporation into *SOD1* in mammals, and the phenotypes of the *CCS* null mice resemble those of the *SOD1* null mice. These mice were crossed with multiple lines of mutant *SOD1* mice. Metabolic Cu labeling studies in mutant *SOD1* mice lacking *CCS* show that copper incorporation into wild-type and mutant *SOD1* is significantly diminished. Thus, *CCS* is necessary for efficient copper incorporation into *SOD1* of motor neurons. However, although the absence of the *CCS* results in a significant reduction in the level of Cu-loaded mutant *SOD1*, the *CCS*−/− genotype has no effect on the onset, progression or pathology of the motor neuron disease occurring in mutant *SOD1* mice (Wong *et al.*, 2000), a result which is inconsistent with the concept that aberrant, Cu-dependent activity of mutant *SOD1* is involved in the pathogenesis of FALS (Finney & O'Halloran, 2003; Subramaniam *et al.*, 2002).

A pathological hallmark of ALS is the accumulation of neurofilaments in swollen proximal axons (and cell bodies) of motor neurons, whether primary or secondary, these abnormalities are associated with axonal transport, a process important for the long-term viability of neurons (Cleveland & Rothstein, 2001; Julien, 2001; Wong *et al.*, 1998). To test the role of neurofilaments in mutant *SOD1*-induced motor neuron disease, mutant *SOD1* mice were cross-bred to several lines of mice with altered levels/distributions of neurofilament proteins. When mice expressing an *NF-H-β-galactosidase* fusion protein (*NF-H-lacZ*), which cross-links neurofilaments and prevents their export into axons, are crossed with mutant *SOD1* mice, the progeny show no changes in progression of disease. Mutant *SOD1* mice lacking *NF-L* (neurofilament light chain) have a moderate increase in lifespan, while mutant *SOD1* mice overexpressing wild-type *NF-L* exhibit attenuation of disease progression and an increased lifespan. A more significant protection of motor neurons was achieved by introducing the *NF-H gene* into lines of mutant *SOD1* mice. However, it is possible that some of the influences on phenotype described with genetic mutations may be related to the introduction of new strain backgrounds into mutant mice rather than the presence or absence of specific genes.

Although the molecular mechanisms underlying mutant *SOD1*-linked familial ALS remain unclear, several pathogenic mechanisms (Cleveland & Rothstein, 2001; Higuchi *et al.*, 1998; Wong *et al.*, 2002) other than the copper hypothesis have been proposed, including roles for: toxicity or sequestration of mutant *SOD1*-containing aggregates; excitotoxicity related to reduction in levels

of GLT1 or activity of this glial transporter important in glutamate uptake in the spinal cord; reduced chaperone activity; damage to the proteosomal degradative machinery by malformed or aggregated mutant SOD1 and activation of caspases. These hypotheses are being explored. For example, overexpression of *Bcl2* in mutant *SOD1* mice has a modest impact on onset and survival.

At present, Riluzole is the only drug approved for therapy in human ALS, but the benefits are modest. Investigators are examining other ways to ameliorate excitotoxicity, possibly by influencing the levels or activity of the glial glutamate transporter. Trials with growth factors were stopped because of complications. To date, there have been no trials of inhibitors of apoptosis nor have engineered cells or stem cells been implanted, although these areas of research are promising for the future.

A variety of therapies have utilized mouse models. Minocycline inhibits the activity of caspase-1, caspase-3, inducible nitric oxide synthase (iNOS), and p38 mytogen activated protein kinase (MAPK). Several of these enzymes have been implicated in motor neuron disease; Zhu *et al.* (2002) have shown that minocycline delays disease onset; and extends survival in mutant *SOD1* mice. Perhaps by inhibiting mitochondrial permeability transition mediated cytochrome release (Zhu *et al.*, 2002).

In another study, creatine was administered orally to G93A *SOD* mice. The disease onset was delayed and the survival of the mice was prolonged, though the effects were very modest. Recent clinical trials of creatine in patients with ALS did not find beneficial evidence of survival or disease progression (Growlenvelt, page 437 *Annals of Neurology*). Combination of creatine and minocycline showed enhanced survival, which extended beyond the effects of creatine. More recently, a combination of minocycline, creatine, and riluzole showed an additive effect on survival (Rothstein paper, *Annals of Neurology* and Criz paper, *Annals of Neurology* – same as Growlenvelt).

Parkinson's disease

Clinical features, pathology and genetics

Usually appearing in the sixth or seventh decade, classical parkinsonism, is characterized by resting tremor, rigidity, slowness of voluntary movement (bradykinesia), stooped posture, impaired postural stability, and shuffling gate (Baron *et al.*, 1996; Dunnett & Bjorklund, 1999; Edbauer *et al.*, 2002; Foix, 1921; Goedert, 2001b; Lozano *et al.*, 1998; Markham & Diamond, 1993; Olanow & Tatton, 1999; Vazques *et al.*, 1996; Wichmann & DeLong, 1996). PD

is the second most common neurodegenerative disease (to Alzheimer's disease) and affects ~1% of individuals >65 years of age, both sexes are equally affected. The motor deficits are related to degeneration of pigmented dopaminergic neurons in the substantia nigra, pars compacta (SNpc) (Forno, 1966; Forno *et al.*, 1986; Greenfield & Bosanquet, 1953; Hassler, 1938; Oppenheimer & Esiri, 1992; Sima *et al.*, 1996). These neurons often exhibit: Lewy bodies (LB), spherical, intracytoplasmic, usually ubiquitin-immunoreactive inclusions with a filamentous core often surrounded by clear halo; and Lewy neurites (LN), which are LB-like, smaller inclusions in processes of nigral neurons and several other affected neuronal populations (Braak *et al.*, 1999, 2000; Forno, 1966; Oppenheimer & Esiri, 1992; Spillantini *et al.*, 1997). A major fibrillar component of these two types of inclusions is α -synuclein (α -syn) (Chung *et al.*, 2001) (see Genetics Section below), but other proteins, including synphilin (Lozano *et al.*, 1998) are associated with these inclusions. The abnormalities in the nigral neurons are associated with reductions (80–95%) in dopaminergic markers are the number of dopamine receptors in striatum (Lozano *et al.*, 1998). In the basal ganglia, the loss of dopaminergic influences on striatal cells (Lee *et al.*, 2001; Lozano *et al.*, 1998; Wichmann & DeLong, 1996) leads to overactivity of the indirect pathway and decreased activity of the direct pathway. Because of different actions of D1 and D2 receptors in these two pathways, the result of dopaminergic deafferentation of the striatum leads to increased activity of nerve cells in the globus pallidus interna, leading to enhanced inhibition of thalamocortical neurons; the clinical outcome is bradykinesia.

The disease may be familial in ~10% of cases, and mutations have been identified in α -syn, *Ubiquitin Carboxy Terminal Hydrolase L1 (UCH-L1)* and *Parkin* (Armstrong *et al.*, 1996; Dawson *et al.*, 2002; Goedert, 2001b; Kitada *et al.*, 1998; Kruger *et al.*, 1998). The first disease-specific mutation (A53T α) was located within the exon 4 of γ -syn (chromosome 4q21–q23) (Polymeropoulos, 1998; Polymeropoulos *et al.*, 1997) a sequence is normally present in α -syn (of rodents) and in synelfin, an avian α -syn homologue (zebra finch) (Ueda *et al.*, 1993). The same mutation was found in several Greek kindreds. More recently, a second α -syn mutation (i.e. A30P) was discovered in two affected members of a small German pedigree (Kruger *et al.*, 1998; Polymeropoulos, 1998; Polymeropoulos *et al.*, 1997). α -syn, comprised 140 amino acids, is highly conserved protein found in mammals, fish, and birds (95% to 86% identity) (George *et al.*, 1995; Irizarry *et al.*, 1996; Maroteaux *et al.*, 1988; Südhof, 1995). In mammals, α -syn is a member of a multigene family consisting of at least two other *synuclein* genes (β -Syn and γ -Syn) (Goedert, 1997;

Lucking *et al.*, 2000). The synucleins, small cytosolic proteins of unknown function enriched at the synaptic terminals of neurons, show a conserved N-terminal repeat region (100 amino acids) consisting of seven imperfect repeats of 11 amino acid residues (KTKEGV), a hydrophobic sequence in the middle of the protein, and a less well conserved, negatively charged C-terminal domain.

Mutations (I93M) in the *UCH-L1* gene have been identified in two members of kindred with autosomal dominant PD. However, it is not certain that this mutation is truly causative of disease.

An autosomal recessive form of juvenile Parkinsonism (AR-JP) has been linked to truncations, frame shifts, and missense/nonsense mutations in *parkin* (chromosome 6q27) (Armstrong *et al.*, 1996; Kitada *et al.*, 1998; Kruger *et al.*, 1998; Zhang *et al.*, 2000). Parkin, a protein that shows some features common with ubiquitin at the amino terminus and has a cysteine ring finger motive at the carboxy-terminus, acts as (Zhang *et al.*, 2000) an E3-ubiquitin ligase, and, as such, provides for substrate specificity of ubiquitination (Dawson *et al.*, 2002; Imai *et al.*, 2000; Laptook *et al.*, 1994; Zhang *et al.*, 2000). Parkin may participate in ubiquitination and metabolism of α -syn and synphilin, α -syn-interacting protein implicated in α -syn aggregation. It is generally believed that *parkin* mutations lead to Parkinson's disease without LBs and that other substrates of parkin, such as Pae 1 receptor, may be toxic to neurons if not degraded. It has been suggested that reduced parkin activity may result in the accumulation of proteins/peptides (α -syn and Pae 1 receptor) that are toxic to dopaminergic neurons leading to parkinsonian phenotype in vivo (Dawson *et al.*, 2002).

α -syn transgenic mice

To understand the mechanisms whereby mutant α -syn leads to motoric abnormalities and neurodegeneration, investigators have produced multiple lines of transgenic mice (Abediovich *et al.*, 2000; Giasson *et al.*, 2002; Masliah *et al.*, 2000; Van der Putten *et al.*, 2000). For example, we expressed high levels of either wild-type or FPD-linked A30P or A53T human α -syn in mice (Masliah *et al.*, 2000). To achieve high levels of transgene expression in mice, the transgene expression (cDNAs encoding human *wild type*, A30P, or A53T α -syn) was controlled by the murine prion promoter (MoPrP-*Hu* α -syn). Analysis of transgene-derived mRNA and protein shows high levels of *Hu* α -syn expression in the brains of these mice. The levels of total α -syn protein (human and mouse combined) in the brains of MoPrP-*Hu* α -syn mice are 4–15 times higher than in the non-transgenic mice. *In situ* hybridization discloses

widespread expression of transgene-derived *Hu* α -syn mRNA in all brain regions, particularly the brainstem. The A53T *Hu* α -syn mice, but not mice with wild-type or the A30P variants, develop adult-onset, progressive motoric dysfunction leading to death. Affected mice accumulate α -syn and ubiquitin in neuronal perikarya and neurites, and brain regions with pathology show detergent-insoluble α -syn and α -syn aggregates. Immunoblot analyses of total SDS-soluble proteins disclose three α -syn polypeptides and peptide fragments corresponding to the full-length α -syn polypeptide (α -syn 16) and two truncated α -syn polypeptides (α -syn 12 and α -syn 10). The majority of α -syn fractionates with the S1 fraction, an observation consistent with α -syn being a cytosolic protein. However, α -syn in the P2 fractions from the brainstems of clinically affected A53T *Hu* α -syn mice is different quantitatively and qualitatively from α -syn polypeptides in the other P2 fractions. Specifically, the brainstem P2 fraction from the affected A53T *Hu* α -syn mice contains significantly more detergent-insoluble full-length (\approx 16-kDa) α -syn. Moreover, the P2 fraction is also enriched for α -syn species with a lower molecular mass α -syn (α -syn 10 and 12) and a series of higher molecular mass aggregates of α -syn. Parallel analysis of (wt) *Hu* α -syn and A30P *Hu* α -syn mice shows that the α -syn species enriched in the P2 fraction is specific of A53T *Hu* α -syn or the expression. These results suggest that mutant α -syn can be cleaved (by "synucleinases") in both the N- and C-terminal regions, generating peptides that aggregate, gain a toxic property, and track with the disease. Moreover, the A53T α -syn and derived peptides are associated with significantly greater in vivo neurotoxicity as compared with other α -syn variants, and α -syn-dependent neurodegeneration is associated with abnormal accumulation of detergent-insoluble α -syn. In a similar study (Van der Putten *et al.*, 2000), mice were generated expressing either wild-type or A53T *Hu* α -syn; only the mice expressing the mutant protein developed motor impairments, paralysis, premature death, and age-dependent intracytoplasmic α -syn fibrillary inclusions in neurons. α -Syn was present in the detergent insoluble fraction, but α -syn peptide fragments were not commented upon. A major research question in this field is whether these α -syn fragments are present in FPD and in sporadic Parkinson's disease. If such is the case, it will be critical to identify the enzymes carrying out these cleavages, which may be targets for therapy.

Thus, although the expression of wild-type or mutant α -syn has been associated with neuropathology in several lines of transgenic mice and in flies, these studies of A53T α -syn document that the expression of this mutant gene leads to formation of truncated α -syn peptide high molecular aggregates in vivo neurotoxicity compared with

either the A30P or WT Hu α -*syn* variants associated with progressive neurodegeneration and death (but not classical PD). Although increase in vivo toxicity of the A53T mutation is consistent with this mutation being associated with a more aggressive disease course in humans than the A30P mutation, the lack of significant neuropathology in mice expressing A30P Hu α -*Syn* is unexpected. Although the A30P mutation is found in a small pedigree with only two affected members, the potential for toxicity was assumed to be greater than with A53T mutation because A30P is a highly non-conservative substitution, whereas the A53T mutation is actually a normal sequence in rodents. It remains possible that the two mutations in Hu α -*syn* initiate disease in different ways, or that the A30P variant could be a rare polymorphism.

α -Syn gene targeted mice

Initial studies of α -syn^{-/-} mice indicate that α -syn is not essential for the viability of the mice. Knockout mice are viable and fertile; neural development appears normal; the complement of dopaminergic cell bodies, fibers, and synapses is normal; and the pattern of dopamine discharge and reuptake in response to electric stimulation is unremarkable. However, dopaminergic terminals in α -syn^{-/-} mice exhibit faster recovery from paired pulse stimuli (Feany, 2000). Shortened recovery from the prepulse can be mimicked in the wild-type mice by elevations of extracellular calcium. Significantly, α -syn^{-/-} mice exhibit reductions in total striatal dopamine levels and in the dopamine-dependent locomotor response to amphetamines. These results are consistent with the concept that α -syn is a presynaptic, activity-dependent, negative regulator of dopaminergic neurotransmission. It is possible that both β - and γ -syn can compensate for the loss of α -synuclein expression, and it will be useful to study mice that display other syn isoforms to determine the importance of various syn proteins with regards to normal synaptic activity.

The tauopathies

Clinical features, pathology and genetics

The tauopathies are a group of disorders that include frontotemporal dementia with parkinsonism linked to chromosome 17 (FTD-P 17) (Edbauer *et al.*, 2002; Hutton *et al.*, 1998; Lee *et al.*, 2001; Lee & Trojanowski, 1999; Munoz *et al.*, 2003), progressive supranuclear palsy (PSP), and corticobasal degeneration (CBD). The clinical phenotypes reflect the involvement of populations of neurons that

exhibit fibrillar tau immunoreactive inclusions (Edbauer *et al.*, 2002; Lee *et al.*, 2001; Lee & Trojanowski, 1999; Munoz *et al.*, 2003) and degeneration of subsets of neural cells. These diseases are less common than classical Alzheimer's disease and Parkinson's disease. Alzheimer's disease is also a tauopathy, in that the neurofibrillary tangles, neuropil threads, and swollen neurites in plaques are enriched in filamentous aggregates of hyperphosphorylated tau (Lee *et al.*, 2001) (See section on Alzheimer's disease).

In this section, we focus principally on FTD-P 17, usually occurring in mid to late life, manifest as two principal phenotypes: an illness in which dementia is conspicuous; and a less common phenotype in which the movement disorder is a major feature (Edbauer *et al.*, 2002). In addition to dementia and parkinsonism, affected individuals may show other clinical signs reflecting abnormalities of the cortico-spinal pathways, and of circuits controlling eye movements and speech. Magnetic resonance imaging (MRI) (Pasquier *et al.*, 2003) discloses frontotemporal atrophy, and [¹⁸F]-deoxy-glucose positron emission tomography (PET) shows hypometabolism, usually marked in the frontal and temporal regions (Pasquier *et al.*, 2003).

Neuropathological exams confirm that atrophy of the frontal and temporal lobes is accompanied by dilation of the third ventricles. Evidence of neuronal degeneration exists in the substantia nigra, hippocampus, and neocortex. Surviving neurons in these areas often contain intracellular aggregates of phosphorylated tau; similar inclusions may also be seen in oligodendroglial cells, and there may be evidence of white matter pathology.

Several other tauopathies manifest somewhat different clinical and pathological phenotypes. For example, PSP is characterized by progressive axial rigidity, slowed movements, vertical gaze palsy, IPS, dysarthria, and dementia. In PSP, globose neurofibrillary tangles, reactive astrocytosis, and evidence of neuronal loss are observed particularly in brainstem nuclei (Edbauer *et al.*, 2002). CBD also manifests as a movement disorder (rigidity and apraxia) with frontal type dementia. PET scans of these patients show alterations in glucose metabolism in parts of the cortex and thalamus regions; neuropathological analyses disclose regional atrophy (usually frontal), ballooned tau immunoreactive neurons, and glial pathology (Edbauer *et al.*, 2002).

As indicated above, the tauopathies share a disease-defining neuropathological feature: affected cells contain inclusions enriched in tau, a low molecular weight microtubule-associated protein (MAP) (Cleveland *et al.*, 1997a,b; Johnson & Hartigan, 1999). Normally, tau, a protein transported anterograde in axons (Mercken *et al.*, 1995), acts to stabilize tubulin polymers critical for microtubule assembly and stability (Caceres & Kosik, 1990). In

mature human brains, the six isoforms of tau are derived by alternative splicing from a single gene on chromosome 17, and all six isoforms contain repeat regions, which interact with tubulin (Bird *et al.*, 2003; Edbauer *et al.*, 2002; Lee *et al.*, 2001; Munoz *et al.*, 2003). The isoforms consist of three isoforms of three repeat tau (3-R tau) and three isoforms of four repeat (4-R) tau encoded by exon 10 (Bird *et al.*, 2003; Lee *et al.*, 2001; Munoz *et al.*, 2003). The poorly soluble post-translationally modified tau underlying the cellular pathology differs somewhat in the different tauopathies: the six isoforms of tau are present in Alzheimer's disease; 4-R tau characterize the inclusions of PSP and CBD; 3-R tau is enriched in PiD (Munoz *et al.*, 2003). In contrast, in Alzheimer's disease, paired helical filaments of tangles are composed primarily of six isoforms of tau.

In FTD-P 17, *tau* mutations can be divided into three classes: mutations in exons; mutations in alternatively spliced exon 10; and mutations at the exon 10 5' splice site (Bird *et al.*, 2003; Dumanchin *et al.*, 1998; Hong *et al.*, 1998; Hutton *et al.*, 1998; Kitada *et al.*, 1998; Lee *et al.*, 2001; Spillantini *et al.*, 1998). The most commonly encountered *tau* mutation is P301L. The effects of some of the intronic mutations have come from knowledge of the importance of a stem-loop structure that begins with the final codons of exon 10 and continues into intron 10. The stem-loop decreases the efficiency inclusion of exon 10; when the mutations destabilize this loop, there is increased inclusion of exon 10 in sequences in the protein leading to an increase in 4-R tau in the soluble and insoluble pools of tau. The P301L *tau* mutation is absorbed predominantly with aggregates of 4-R tau. Mutations that influence tau mRNA splicing, 4-R, are enriched in filamentous lesions. In contrast, mutations that alter the 4-R/3-R tau ratios result in twisted ribbons essentially composed of 4-R tau; these filaments accumulate in both neurons and glia. Individuals with PSP or CSB share the H1 tau haplotype, which appears to be a risk factor linked to the accumulation of 4-R tau in aggregates.

Gene targeting of *tau*

Tau was isolated initially as a stabilizer of microtubules (Hong *et al.*, 1998). In cultures, antisense strategies showed that downregulation of tau adversely influenced neurite outgrowth (Caceres & Kosik, 1990). However, when the *tau* gene was targeted, the only phenotype was mild differences in the organization of microtubules in small caliber axons (Harada *et al.*, 1994). MAPs exist and the lack of phenotype in tau $-/-$ mice presumably reflects some redundancy in MAPs. Consistent with this idea is the observation that

mating of tau $-/-$ and MAP1B $-/-$ mice leads to a lethal postnatal phenotype (Takai *et al.*, 1999, 2000).

Models of tauopathies

In examining the outcomes of a variety of transgenic approaches in mice, it is important to remember that mice express three copies of the murine variant of 4-R tau, while humans express three copies of both 3-R tau and 4-R tau. The early efforts to produce mice expressing mutant *tau* transgenes did not lead to striking clinical phenotypes or pathology (Duff *et al.*, 2000). However, subsequent studies were more successful in producing disease (Probst *et al.*, 2000; Spittaels *et al.*, 1999). Thus overexpression of human tau can lead to weakness and hypophosphorylated insoluble tau immunoreactivity in neurons in the spinal cord, brainstem, and cortex; motor axons showed degeneration (Ishihara *et al.*, 1999; Lee *et al.*, 2001; Lee & Trojanowski, 1991). Tau immunoreactive lesions occur in some human *tau* mice (Hinguchi *et al.*, 2002).

Efforts have been made to overexpress wild-type tau to produce NFT of the Alzheimer's disease type (Lee *et al.*, 1999). More striking are the mice overexpressing *tau P301L* (Lewis *et al.*, 2000). When the prion or Thy1 promoter was used to drive *P301L tau*, neurofibrillary tangles occurred in neurons of the brain and spinal cord (Gotz *et al.*, 2001; Ishihara *et al.*, 1999; Lewis *et al.*, 2000). Moreover, when A β 42 fibrils were injected into P301L mice, there was an increase in the number of tangles at injection sites.

Mice expressing wt human *tau* transgene do not develop pathology. However, when similar strategies are used to introduce human *tau* into tau $-/-$ mice, the animals show accumulations of tau immunoreactivity in neurons, including the presence of certain phosphorylated and conformational epitopes seen in human disease (Peter Davies, personal communication). These observations have been interpreted to suggest that, in mice, endogenous mouse tau may interfere with the formation of tangles by human tau.

Investigators have created genetic models of tau-related neurodegeneration in invertebrates (Feany, 2000). For example, when wild-type or mutant *tau* are expressed in *Drosophila melanogaster*, transgenic flies develop a variety of clinical abnormalities; adult onset progressive disease; early lethality; greater toxicity with mutant tau; and accumulation of abnormal tau in nerve cells (Feany, 2000; Wittmann *et al.*, 2001).

Experimental therapeutics

The human tauopathies and genetically engineered animal models of these disorders are under active investigation,

but it is clear that introduction of mutant *tau* and changes in the ratios of 3-R and 4-R tau lead to clinical disease and to accumulation of hypophosphorylated tau filamentous inclusions. It is likely that these biochemical abnormalities impact on the stability of tubulin and on microtubules, and thus might be expected to perturb axonal transport. It seems likely that the nature of tau isoforms, their ratios, and the balance of protein kinases/phosphatases activities acting on tau play roles in the pathogenesis of tauopathies. Understanding these issues is very important in that selected inhibitors of the appropriate kinases or phosphatases could be the basis for design of novel strategies to ameliorate abnormalities associated with alterations in this disease. Moreover, it is increasingly apparent that tau pathology can be associated with other abnormalities of protein aggregation. For example, in cases of Alzheimer's disease, the accumulation of A β 42 peptide is in some way, as yet uncertain, linked to the appearance of tau pathology manifest by tangles, threads, and neuritis (in plaques). Similarly, the presence of α -synuclein, possibly specific peptide fragments of α -synuclein (Lee *et al.*, 2002) as occurs in Parkinson's disease and mouse models of synucleinopathies, is often associated with tau pathology in some of the neurodegenerative diseases (Giasson *et al.*, 2003; Trojanowski, 2002). The interactions of these conformationally altered pathological peptides are very active exciting areas of research, and understanding the abnormalities of biology of their proteins is critical for developing new mechanism-based therapies for these disorders.

Conclusions

The identification of genes mutated or deleted in the inherited forms of many neurodegenerative diseases has allowed investigators to create *in vivo* and *in vitro* model systems relevant to a wide variety of human neurological disorders.

In this review, we emphasized the value of transgenic and gene targeted models and the lessons they provided for understanding mechanisms of their neurodegenerative diseases. For example, the study of *BACE1*^{-/-} mice and mutant *APP/PS1* transgenic models has provided extraordinary new insights into the mechanisms of A β amyloidogenesis, the reasons why Alzheimer's disease is a brain amyloidosis, and into potential therapeutic targets. In contrast, our studies of mutant *SOD1* mice lacking *CCS* demonstrate that aberrant activities dependent on copper-loaded *SOD1* are unlikely to be involved with pathogenic mechanisms, and that other mechanisms/targets should be explored. Finally, with regard to mutant α -syn linked FPD, results from studies of mouse models suggest that α -syn may

undergo C- and N-terminal cleavages, generating toxic peptides. Strategies designed to delineate the participants in these cleavage processes, discover separate synucleinases, the consequence of deleting or inhibiting these enzymes will need to be explored. If these cleavages occur in humans with Parkinson's disease, it will be essential to understand the mechanisms of cell injury and to design inhibitors that block cleavages of α -syn.

Invertebrate organisms, like *C. elegans* or *Drosophila melanogaster*, provide excellent genetically manipulatable model systems for examining many aspects of neurodegenerative diseases (Kamal *et al.*, 2001; Lin *et al.*, 1999; Warrick *et al.*, 1998, 1999; Wittmann *et al.*, 2001). Invertebrates harboring mutant transgenes can be generated rapidly and their nervous systems are relatively simple. Moreover, behavior can be scored, with flies having the ability to carry out more complex behaviors and having a longer lifespan than worms. Significant new information has come from transgenic technologies, which have allowed mutant genes to be introduced into, or ablated in, flies and worms. For example, when wild-type or mutant human α -syn is expressed in the nervous system of flies, dopaminergic neurons degenerate in adult life, nerve cells show accumulations of γ -syn and filamentous inclusions, and animals develop progressive motor dysfunction (Warrick *et al.*, 1999). Similar experiments have been carried out in models of the CAG repeat diseases that encode expansions of polyglutamine (Kamal *et al.*, 2001; Warrick *et al.*, 1998; Wittmann *et al.*, 2001). When expanded *ataxin-3* is expressed in the retina of *Drosophila*, the retina degenerates, but the disease can be attenuated by manipulations of p35 or Hsp70. Similarly, introductions of wild-type or mutant human *tau* into flies, models tau-related neurodegenerative disease. Flies carrying these transgenes exhibit adult onset progressive neurodegeneration, evidence of enhanced toxicity of mutant tau, accumulations of abnormal tau in cells (but without neurofibrillary tangles), and early lethality (Kamal *et al.*, 2001). Because these invertebrate models reproduce aspects of pathologies occurring in human neurodegenerative diseases, studies of these systems should prove very useful in delineating disease pathways, identifying suppressors and enhancers of these processes, and in testing the influences of drugs on phenotypes in flies and worms.

These new models allow investigators to examine the molecular mechanisms by which mutant proteins cause selective dysfunction and death of neurons and to determine possible pathogenic pathways that can be tested by crossing animals with either mutated or deleted alleles of other molecular players in the pathogenic process. The use of RNA methods will accelerate the validation of

molecules involved in pathogenic pathways. The results of these approaches will provide us with a better understanding of the mechanisms leading to diseases.

In summary, investigations of genetically engineered (transgenic or gene targeted) mice have disclosed participants in pathogenic pathways, have reproduced some of the features of human neurodegenerative disorders, have provided important new information about the disease mechanisms, and allow identification of new therapeutic targets. Moreover, the models can be used for testing novel treatments. These lines of research have made spectacular progress over the past few years, and we anticipate that discoveries will lead to the design of more promising therapies that can be tested in models of these devastating diseases.

²Department of Environmental Medicine and Center for Aging and Developmental Biology, University of Rochester, NY, USA

Introduction

As discussed elsewhere (Przedborski *et al.*, 2003), the term “neurodegenerative disease” refers to a group of neurological disorders with heterogeneous clinical and pathological expressions. These diseases are all characterized by a loss of specific subpopulations of neurons confined to functional anatomic systems, arising in most cases for unknown reasons and progressing in a relentless manner. Among the variety of neurodegenerative disorders, the lion’s share of attention has been given only to a handful, including Alzheimer’s disease, Parkinson’s disease, Huntington’s disease, and amyotrophic lateral sclerosis (ALS). So far, the most consistent risk factor for developing a neurodegenerative disorder, especially AD and PD, is increasing age. Over the past century the growth rate of the population age 65 and beyond in the industrialized countries has far exceeded that of the population as a whole. Thus it can be anticipated that, over the next generations, the proportion of elderly citizens will double and, with this, the number of individuals suffering from a neurodegenerative disorder. This prediction is at the centre of the growing concerns from the medical community and from legislators, as one can easily foresee a dramatic increase in the emotional, physical, and financial burden on patients, caregivers, and society related to these disabling illnesses. The problem is made worse by the fact that, although to date several approved drugs do, to some extent, alleviate symptoms of several neurodegenerative diseases, their chronic use is often associated with debilitating side effects, and none seems to stop the progression of the degenerative processes. It is now clear that the development of effective preventive or protective therapies has been thus far impeded by our limited knowledge of the causes and mechanisms by which neurons die in neurodegenerative diseases. Thanks to the development of experimental models, several neurobiological

breakthroughs have brought closer than ever the day that the secrets of several neurodegenerative disorders will be unlocked and effective therapeutic strategies will become available. So far, among the various accepted experimental models, neurotoxins have been the most popular means employed to produce selective neuronal death in both in vitro and in vivo systems. In this chapter, we will thus review the key neurotoxic models of neurodegeneration, which will be categorized based on their main molecular targets as we currently know them. For each of the selected neurotoxins, attention will be paid to providing the reader with information regarding their respective mechanisms of action and the kinds of diseases that they model. Although in vitro data will be mentioned whenever necessary, this chapter will focus on in vivo studies.

1-Methy-4-phenyl-1,2,3,6-tetrahydropyridine

1-Methy-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is a byproduct of the chemical synthesis of a meperidine analogue with potent heroin-like effects. MPTP can induce a parkinsonian syndrome in humans almost indistinguishable from PD (Langston & Irwin, 1986). Recognition of MPTP as a neurotoxin occurred early in 1982, when several young drug addicts mysteriously developed a profound parkinsonian syndrome after the intravenous use of street preparations of meperidine analogs which, unknown to anyone, were contaminated with MPTP (Langston *et al.*, 1983). In humans and non-human primates, depending on the regimen used, MPTP can produce an irreversible and severe parkinsonian syndrome that replicates almost all of the features of PD; in non-human primates, a resting tremor characteristic of PD has only been demonstrated convincingly in the African green monkey (Tetrud *et al.*, 1986). It is believed that, in PD, the neurodegenerative process

occurs over several years, while the most active phase of neurodegeneration is completed within a few days following MPTP administration (Langston, 1987; Jackson-Lewis *et al.*, 1995). However, recent data suggest that, following the main phase of neuronal death, MPTP-induced neurodegeneration may continue to progress “silently” over several decades, at least in humans intoxicated with MPTP (Vingerhoets *et al.*, 1994; Langston *et al.*, 1999). Except for four cases (Davis *et al.*, 1979; Langston *et al.*, 1999), no human pathological material has been available for study, and thus the comparison between PD and the MPTP model is mainly based on non-human primates (Forno *et al.*, 1993). Neuropathological data show that MPTP administration causes damage to the nigrostriatal dopaminergic pathway identical to that seen in PD (Dauer & Przedborski, 2003), yet there is a resemblance that goes beyond the loss of SNpc dopaminergic neurons. Like PD, MPTP causes a greater loss of dopaminergic neurons in the SNpc than in the ventral tegmental area (Seniuk *et al.*, 1990; Muthane *et al.*, 1994) and, in monkeys treated with low doses of MPTP (but not in humans), a greater degeneration of dopaminergic nerve terminals in the putamen than in the caudate nucleus (Moratalla *et al.*, 1992; Snow *et al.*, 2000). However, two typical neuropathologic features of PD have, until now, been lacking in the MPTP model. First, except for the SNpc, pigmented nuclei such as the locus coeruleus have been inconsistently affected, according to most published reports. Second, the eosinophilic intraneuronal inclusions, called “Lewy bodies,” so characteristic of PD, thus far, have not been convincingly observed in MPTP-induced parkinsonism (Forno *et al.*, 1993); although, in MPTP-injected monkeys, intraneuronal inclusions reminiscent of Lewy bodies have been described (Forno *et al.*, 1986). Despite these imperfections, MPTP continues to be regarded as the best animal model of PD, and it is believed that studying MPTP toxic mechanisms will shed light on the molecular basis of PD.

Over the years, MPTP has been used in a large variety of animal species, ranging from worms to mammals. To date, the most frequently used animals for MPTP studies are monkeys, mice and rats. The administration of MPTP through a number of different routes using different dosing regimens has led to the development of several distinct models, each characterized by some unique behavioral and biochemical features. The manner in which these models were developed is based on the concept of delivering MPTP in a fashion that creates the most severe and stable form of nigrostriatal damage with the least number of undesirable side effects such as acute death, dehydration and malnutrition. Although MPTP can be given by a number of different routes, including gavage and stereotaxic

injection into the brain, the most common, reliable, and reproducible lesion is provided by its systemic administration (i.e. subcutaneous, intravenous, intraperitoneal or intramuscular). The most commonly used regimens in monkeys are the multiple intraperitoneal or intramuscular injections and the intracarotid infusion of MPTP (Petzinger & Langston, 1998). The former is easy to perform and produces a bilateral parkinsonian syndrome. However, often the monkey exhibits a generalized parkinsonian syndrome so severe that chronic administration of drugs such as L-DOPA is required to enable the animal to eat and drink adequately (Petzinger & Langston, 1998). Although unilateral intracarotid infusion is technically more difficult, this regimen causes symptoms mainly on one side (Bankiewicz *et al.*, 1986; Przedborski *et al.*, 1991), so it has the advantage of allowing the monkey to maintain normal nutrition and hydration without the use of L-DOPA. For many years monkeys were mainly, if not exclusively, treated with harsh regimens of MPTP to produce an acute and severe dopaminergic neurodegeneration (Petzinger and Langston, 1998). More recently, several investigators have treated monkeys with low doses of MPTP (e.g. 0.05 mg/kg 2–3 times per week) for a prolonged period of time (i.e. weeks to months) in an attempt to better model the slow neurodegenerative process of PD (Schneider & Roeltgen, 1993; Bezard *et al.*, 1997; Schneider *et al.*, 1999). While both the acute and the chronic MPTP-monkey models are appropriate for the testing of experimental therapies aimed at alleviating PD symptoms, the chronic model is presumably the most suitable for testing neuroprotective strategies. Among the numerous mammalian species susceptible to MPTP (Kopin & Markey, 1988; Heikkila *et al.*, 1989; Przedborski *et al.*, 2000), in addition to monkeys, mice have become the animals most commonly used. However, several problems need to be emphasized. First, mice are much less sensitive to MPTP than monkeys; thus, much higher doses are required to produce significant SNpc damage in this animal species. Higher doses present a far greater hazard, requiring tighter safety precautions (Przedborski *et al.*, 2001b). Second, unlike monkeys, mice treated with MPTP do not develop parkinsonism. Third, the magnitude of striatal dopamine nigrostriatal damage depends on the dose and dosing schedule (Sonsalla & Heikkila, 1986). The use of MPTP in rats presents an interesting situation (Kopin & Markey, 1988). For instance, rats injected with mg/kg doses of MPTP comparable to those used in mice do not exhibit any significant dopaminergic neurodegeneration (Giovanni *et al.*, 1994a,b). Conversely, rats injected with much higher doses of MPTP do exhibit significant dopaminergic neurodegeneration (Giovanni *et al.*, 1994a,b) although, at these high doses, rats have

Fig. 16.1 Schematic representation of MPTP metabolism. After its systemic administration, MPTP crosses the blood-brain barrier. Once in the brain, MPTP is converted to MPDP⁺ by MAO-B within non-dopaminergic cells, and then to MPP⁺ by an unknown mechanism (?). Thereafter, MPP⁺ is released, again by an unknown mechanism (?), into the extracellular space. From there, MPP⁺ is taken up by the DAT and thus enters dopaminergic neurons. Inside dopaminergic neurons, MPP⁺ can (i) bind to the vesicular monoamine transporters (VMAT) and translocate into synaptosomal vesicles, (ii) accumulate into the mitochondria by an active process, and (iii) remain in the cytosol and interact with different cytosolic enzymes.

to be pretreated with guanethidine to prevent dramatic peripheral catecholamine release and extensive mortality (Giovanni *et al.*, 1994a). These findings indicate that rats are relatively insensitive to MPTP, but regardless of this drawback, rats continue to be used quite often in MPTP studies (Storey *et al.*, 1992; Giovanni *et al.*, 1994a,b; Staal & Sonsalla, 2000; Staal *et al.*, 2000). In rats, however, the systemic administration of MPTP is rarely

used and the vast majority of studies involve the stereotaxic infusion of 1-methyl-4-phenylpyridinium (MPP⁺), a toxic metabolite of MPTP (Storey *et al.*, 1992; Giovanni *et al.*, 1994a,b; Staal & Sonsalla, 2000; Staal *et al.*, 2000).

Prior to using the MPTP model it is crucial to remember that several factors influence the reproducibility of the lesion in monkeys, rats and mice. However, to our knowledge, an extensive and systematic assessment of these factors has only been done in mice (Heikkila *et al.*, 1989; Giovanni *et al.*, 1991, 1994a,b; Miller *et al.*, 1998; Hamre *et al.*, 1999; Staal & Sonsalla, 2000) and the results can be summarized as follows: different strains of mice (and even within a given strain, mice from different vendors) can exhibit strikingly distinct sensitivity to MPTP. This differential seems to be inherited as an autosomal dominant trait (Hamre *et al.*, 1999). As discussed in greater detail in (Przedborski & Vila, 2001), gender, age and body weight are also factors that modulate MPTP sensitivity and reproducibility of the lesion.

MPTP mode of action

As illustrated in Fig. 16.1, the metabolism of MPTP is a complex, multistep process (Przedborski & Vila, 2003; Dauer & Przedborski, 2003). After its systemic administration, MPTP, which is highly lipophilic, rapidly crosses the blood–brain barrier (BBB). Once in the brain, the pro-toxin MPTP is metabolized to 1-methyl-4-phenyl-2,3-dihydropyridinium (MPDP⁺) by the enzyme monoamine oxidase B (MAO-B) within non-dopaminergic cells such as glial cells, and then (probably by spontaneous oxidation) to 1-methyl-4-phenylpyridinium (MPP⁺), the active toxic compound. Thereafter, MPP⁺ is released (by an unknown mechanism) into the extracellular space. Since MPP⁺ is a polar molecule, unlike its precursor MPTP, it cannot freely exit cells within which it has been produced or enter cells within which it will cause toxicity. It is thus likely that the translocation of MPP⁺ from its site of production to its site of cytotoxicity depends on the plasma membrane carriers. Consistent with this view is the fact that MPP⁺ has a high affinity for plasma membrane dopamine transporter (DAT) (Mayer *et al.*, 1986), as well as for norepinephrine and serotonin transporters, enabling it to gain access to monoaminergic neurons and more particularly dopaminergic neurons. The obligatory character of this step in the MPTP neurotoxic process is demonstrated by the fact that blockade of DAT by specific antagonists such as mazindol (Javitch *et al.*, 1985) or ablation of the DAT gene in mutant mice (Bezard *et al.*, 1999) completely prevents

MPTP-induced toxicity. Conversely, transgenic mice with increased brain DAT expression are more sensitive to MPTP (Donovan *et al.*, 1999).

Once inside dopaminergic neurons, MPP⁺ can follow at least three routes (Fig. 16.1): (i) it can bind to the vesicular monoamine transporters (VMAT) which will translocate MPP⁺ into synaptosomal vesicles (Liu *et al.*, 1992), (ii) it can be concentrated within the mitochondria (Ramsay & Singer, 1986), and (iii) it can remain in the cytosol and interact with different cytosolic enzymes (Klaidman *et al.*, 1993). The fraction of MPP⁺ destined to each of these routes is probably a function of MPP⁺ intracellular concentration and affinity for VMAT, mitochondrial membrane potential, and cytosolic enzymes. The importance of the vesicular sequestration of MPP⁺ is demonstrated by the fact that cells transfected to express greater density of VMAT are converted from MPP⁺-sensitive to MPP⁺-resistant cells (Liu *et al.*, 1992). Conversely, we demonstrated that mutant mice with 50% lower VMAT expression are significantly more sensitive to MPTP-induced dopaminergic neurotoxicity compared to their wild-type littermates (Takahashi *et al.*, 1997). These findings indicate that there is a clear inverse relationship between the capacity of MPP⁺ sequestration (i.e. VMAT density) and the magnitude of MPTP neurotoxicity. Inside dopaminergic neurons, MPP⁺ can also be concentrated within the mitochondria (Fig. 16.1) (Ramsay & Singer, 1986), where it impairs mitochondrial respiration by inhibiting complex I of the electron transport chain (Nicklas *et al.*, 1985; Mizuno *et al.*, 1987) through its binding at or near the site of the mitochondrial poison rotenone (Ramsay *et al.*, 1991; Higgins, Jr. & Greenamyre, 1996; Schuler & Casida, 2001).

MPTP mechanism of action

Currently, it is believed that the neurotoxic process of MPTP is made up of a cascade of multiple deleterious events, which can be divided into early and late neuronal perturbations and secondary non-neuronal alterations. All of these, to a variable degree and at different stages of the degenerative process, participate in the ultimate demise of dopaminergic neurons.

Early events

Soon after its entry into dopaminergic neurons, MPP⁺ binds to complex I and, by interrupting the flow of electrons, leads to an acute deficit in ATP formation (Chan *et al.*, 1992). It appears, however, that complex I activity should be reduced >70% to cause severe ATP depletion in non-synaptic mitochondria (Davey & Clark, 1996) and that, in contrast to *in vitro*, *in vivo* MPTP causes only a

transient 20% reduction in mouse striatal and midbrain ATP levels (Chan *et al.*, 1991), raising the question as to whether MPP⁺-related ATP deficit can be the sole factor underlying MPTP-induced dopaminergic neuronal death.

Another consequence of complex I inhibition by MPP⁺ is an increased production of reactive oxygen species (ROS), especially of superoxide (Rossetti *et al.*, 1988; Hasegawa *et al.*, 1990; Cleeter *et al.*, 1992). Early ROS production can also occur in this model from the auto-oxidation of dopamine resulting from an MPP⁺-induced massive release of vesicular dopamine to the cytosol (Lotharius & O'Malley, 2000). Dopamine can also be oxidized to the highly reactive dopamine-quinone by cyclooxygenase-2, an enzyme which is upregulated in SNpc dopaminergic neurons in MPTP-intoxicated mice and PD postmortem samples (Teismann *et al.*, 2003). The importance of MPP⁺-related ROS production in the dopaminergic toxicity process *in vivo* is demonstrated by the fact that transgenic mice with increased brain activity of copper/zinc superoxide dismutase (SOD1), a key ROS scavenging enzyme, are significantly more resistant to MPTP-induced dopaminergic toxicity than their non-transgenic littermates (Przedborski *et al.*, 1992). However, several lines of evidence support the concept that ROS exert many or most of their toxic effects in the MPTP model in conjunction with other reactive species such as nitric oxide (NO) (Schulz *et al.*, 1995b; Ara *et al.*, 1998; Pennathur *et al.*, 1999; Przedborski *et al.*, 2001a) produced in the brain by both the neuronal and the inducible isoforms of the enzyme NO synthase (Przedborski *et al.*, 1996; Liberatore *et al.*, 1999). A comprehensive review of the source and the role of NO in the MPTP model can be found in the following references (Przedborski & Vila, 2001; Przedborski & Dawson, 2001; Tieu *et al.*, 2003).

Late events

In response to the variety of functional perturbations caused by the depletion in ATP and the production of ROS, death signals, which can activate the molecular pathways of apoptosis, arise within intoxicated dopaminergic neurons. Although at this time we cannot exclude with certainty the possibility that apoptotic factors are not consistently recruited regardless of MPTP regimen, only prolonged administration of low to moderate doses of MPTP is associated with definite morphologically defined apoptotic neurons (Jackson-Lewis *et al.*, 1995; Tatton & Kish, 1997). Supporting the implication of apoptotic molecular factors in the demise of dopaminergic neurons after MPTP administration is the demonstration that the pro-apoptotic protein Bax is instrumental in this toxic model (Vila *et al.*, 2001a). Overexpression of the anti-apoptotic Bcl-2 also protects dopaminergic cells against MPTP-induced

neurodegeneration (Offen *et al.*, 1998; Yang *et al.*, 1998). Similarly, adenovirus-mediated transgene expression of the X-chromosome-linked inhibitor of apoptosis protein (XIAP), an inhibitor of executioner caspases such as caspase-3, also blocks the death of dopaminergic neurons in the SNpc following the administration of MPTP (Eberhardt *et al.*, 2000). Other caspases are also activated in MPTP-intoxicated mice such as caspase-8, which is a proximal effector of the tumor necrosis factor receptor family death pathway (Hartmann *et al.*, 2001). Other observations supporting a role of apoptosis in the MPTP neurotoxic process include the demonstration of the resistance to MPTP of mutant mice deficient in p53 (Trimmer *et al.*, 1996), a cell cycle control gene involved in programmed cell death, or the resistance of mice treated with inhibitors of c-Jun N-terminal kinases (Saporito *et al.*, 1999, 2000). Collectively, these data show that, during the degenerative process, the apoptotic pathways are activated and contribute to the actual death of intoxicated neurons in the MPTP model.

Secondary events

The loss of dopaminergic neurons in the MPTP mouse model is associated with a glial response composed mainly of activated microglial cells and, to a lesser extent, of reactive astrocytes (Vila *et al.*, 2001b). From a neuropathological standpoint, microglial activation is indicative of an active, ongoing process of cell death. The presence of activated microglia in postmortem samples from MPTP-intoxicated individuals who came to autopsy several decades after being exposed to the toxin (Langston *et al.*, 1999) suggests an ongoing degenerative process and thus challenges the notion that MPTP produces a “hit-and-run” kind of damage. Therefore, this important observation (Langston *et al.*, 1999) suggests that a single acute insult to the SNpc by MPTP could set in motion a self-sustained cascade of events with long-lasting deleterious effects. Looking at mice injected with MPTP and killed at different time points thereafter, it appears that the time course of reactive astrocyte formation parallels that of dopaminergic structure destruction in both the striatum and the SNpc, and that GFAP expression remains upregulated even after the main wave of neuronal death has passed (Czlonkowska *et al.*, 1996; Kohutnicka *et al.*, 1998; Liberatore *et al.*, 1999). These findings suggest that, in the MPTP mouse model (Przedborski *et al.*, 2000), the astrocytic reaction is secondary to the death of neurons and not the reverse. This conclusion is supported by the demonstration that blockade of MPP⁺ uptake into dopaminergic neurons completely prevents not only SNpc dopaminergic neuronal death but also GFAP up-regulation (O’Callaghan *et al.*, 1990). Remarkably, activation of microglial cells, which is also quite strong

in the MPTP mouse model (Czlonkowska *et al.*, 1996; Kohutnicka *et al.*, 1998; Liberatore *et al.*, 1999; Dehmer *et al.*, 2000), occurs much earlier than that of astrocytes and, more importantly, reaches a maximum before the peak of dopaminergic neurodegeneration (Liberatore *et al.*, 1999). In the light of the MPTP data presented above, it can be surmised that the response of both astrocytes and microglial cells in the SNpc occurs within a timeframe allowing these glial cells to participate in the demise of dopaminergic neurons in the MPTP mouse model and possibly in PD. Activated microglial cells can produce a variety of noxious compounds including ROS and reactive nitrogen species (RNS) via NADPH-oxidase (Wu *et al.*, 2003) and inducible NOS (Liberatore *et al.*, 1999) as well as pro-inflammatory cytokines and prostaglandins. Observations showing that blockade of microglial activation mitigates nigrostriatal damage caused by MPTP supports the notion that microglia participate in MPTP-induced neurodegeneration (Wu *et al.*, 2002).

Reactive oxygen species-producing neurotoxins

Reactive oxygen species, such as superoxide radicals, are produced constantly during normal cellular metabolism, primarily as byproducts of the mitochondrial respiratory chain and, when it applies, catecholamine metabolism. Defense mechanisms, however, exist to limit the levels of ROS and the damage they inflict on cellular components such as lipids, proteins, and DNA. It has been hypothesized that the finely tuned balance between the production and destruction of ROS is skewed in a number of pathological conditions including neurodegenerative disorders such as Parkinson’s disease, resulting in oxidative stress that leads to severe cellular dysfunction and, ultimately, to cell death. For this reason, ROS-generating neurotoxins such as 6-hydroxydopamine (6-OHDA) and paraquat have been extensively used to model neurodegeneration.

6-Hydroxydopamine and related compounds

Since the introduction of 6-OHDA more than 30 years ago, several related compounds have been synthesized and tested both *in vitro* and *in vivo*. So far, however, none of them have been found to be superior to 6-OHDA as a monoamine neurotoxin. Among the 6-OHDA analogues, only 6-OH-DOPA and 6-aminodopamine have been used to a certain extent, especially to damage noradrenergic pathways. Yet, the much greater body of information available on the use of 6-OHDA over any other of its derivatives (Jonsson, 1980) may also explain why 6-OHDA is the

preferred compound of its group for producing catecholaminergic lesions. With respect to the mode and mechanism of action, it is well established that 6-OHDA accumulates specifically in catecholaminergic neurons, causes depletion of norepinephrine and dopamine and, ultimately, inflicts structural damage to these neurons (Jonsson, 1983). The specificity of 6-OHDA's action on catecholaminergic neurons is explained by the high affinity of the toxin for the plasma membrane catecholamine transporter, allowing 6-OHDA to be rapidly and efficiently taken up by norepinephrine and dopamine neurons. Given this fact, it is not surprising that pre-treatment of animals with a norepinephrine uptake (Herve *et al.*, 1986; Luthman *et al.*, 1989) or dopamine uptake blocker (Luthman *et al.*, 1987, 1989), by preventing the entry of the toxin in these neurons, mitigates 6-OHDA cytotoxicity. Once inside of the neurons, 6-OHDA accumulates in the cytosol where it produces quinones, which inactivate some biological macromolecules by binding to their nucleophilic groups (Saner & Thoenen, 1971), as well as a variety of ROS (Cohen & Werner, 1994). Although quinone-based and ROS-based mechanisms are probably both operative in 6-OHDA cytotoxicity, available evidence favors the notion that ROS play the dominant neurotoxic role (Graham, 1978; Cohen & Werner, 1994). Of note, since 6-OHDA forms the *para*-quinone it does not react as well with external nucleophiles as the dopamine *ortho*-quinone does. ROS generated by the metabolism of 6-OHDA emanate from its autooxidation and from its oxidative deamination mediated by the MAO. However, the finding that pretreatment with MAO inhibitor such as pargyline, rather than mitigating 6-OHDA toxicity, instead enhances it (Jonsson, 1980), suggests that auto-oxidation and not oxidative deamination is instrumental in 6-OHDA-induced neuronal death. Because auto-oxidation of 6-OHDA can occur both intra- and extraneuronally, this neurotoxin is prone to causing specific and nonspecific effects. Consistent with this view is the demonstration that, in mesencephalic cultures, 6-OHDA toxicity is not restricted to dopaminergic neurons (Lotharius *et al.*, 1999), and that several cell types devoid of catecholaminergic transporters including C6 glioma, NIH-3T3, and CHO cells can be damaged by the toxin (Blum *et al.*, 2001). It is thus important to use as low a dose of 6-OHDA as possible and to prevent auto-oxidation of 6-OHDA from occurring extraneuronally by, for example, administering a reducing agent such as ascorbic acid with 6-OHDA. Under experimental conditions devoid of non-specific toxicity, 6-OHDA affects primarily dopaminergic and noradrenergic neurons, much less peripheral adrenergic neurons, and, according to most reports, not at all central adrenergic and serotonergic neurons (at least in rodents). Among

the various central catecholaminergic pathways, the locus coeruleus noradrenergic system (nerve terminals) appears to be the one most sensitive to 6-OHDA, whereas the adrenergic neuron systems are most resistant (Jonsson *et al.*, 1976). The dopaminergic systems range from being relatively sensitive (e.g. the nigrostriatal pathway) to almost completely resistant (e.g. the tubero-infundibular pathway) to 6-OHDA (Jonsson, 1980). In general, it has been observed that the nerve terminals appear to be the most sensitive, that the axons are less so, and that the cell body structures are least sensitive to the neurotoxic action of 6-OHDA (Jonsson, 1983). These differences can at least partly be related to differences in surface-volume relationships. Since the 6-OHDA dose, injection volume, time and route of administration, and the injection technique are the crucial factors, one may find it worthwhile to refer to Jonsson (1980) to optimize lesioning conditions.

In adult animals, 6-OHDA has been used most commonly in rats and to a lesser extent in mice, cats, dogs, and monkeys (Jonsson, 1983), but no one species has a real scientific advantage over the other. Since 6-OHDA does not easily cross the BBB it has to be injected intravenicularly, intracisternally, or intracerebrally to damage the central catecholaminergic systems (Jonsson, 1983). Intraventricular and intracisternal administration of 6-OHDA calls for high doses (500–1000 µg/kg in 25–50 µl) and produces a bilateral catecholaminergic lesion, observed within a few hours of the injection of the toxin, with generally limited regrowth of affected nerve fibers (Jonsson, 1983). Unexpectedly, these routes of administration produce a very heterogenous pattern of denervation with profound reductions in norepinephrine in the cerebral cortex and cerebellum and only mild reductions in the hypothalamus and brainstem (Jonsson, 1983). Similarly, reductions in dopamine are maximal at the level of the nigrostriatal pathway and minimal at the level of other dopaminergic pathways (Jonsson, 1983). Within the ventral midbrain dopaminergic neuronal groups, the highest loss is found in the substantia nigra, followed by the retrorubral field, and ventral tegmental area (Rodriguez *et al.*, 2001). When a bilateral 6-OHDA lesion is severe, rats will often die primarily due to the occurrence of marked aphagia, adipisia, and seizures (Ungerstedt, 1971a; Bourn *et al.*, 1972). However, the few rats which survive and recover normal ingestion and weight show interesting behavioral abnormalities including hypokinesia, purposeless chewing, and catalepsia which can, at least partially, be reversed by the administration of dopaminergic agonists (Rodriguez *et al.*, 2001). In contrast to this widespread mode of lesioning, local intracerebral injection of 6-OHDA is often used to target a specific catecholaminergic pathway of the brain (Ungerstedt,

1968, 1971c). This kind of lesion is achieved by stereotaxic administration usually of 1–10 µg of toxin infused in 1–10 µl at a rate of 1 to 5 µl/min. To avoid non-specific damage the solution injected should not contain more than 2.5 µg/µl of 6-OHDA (Przedborski *et al.*, 1995). Also it is important to keep in mind the fact that the size of the lesioned areas and the magnitude of the lesion (specific and non-specific) are dependent on the volume of 6-OHDA solution infused as well as its concentration and the rate at which it is infused (Agid *et al.*, 1973). To specifically target the nigrostriatal dopaminergic pathway, 6-OHDA must be injected stereotaxically into the substantia nigra, the nigrostriatal tract or the striatum (Javoy *et al.*, 1976; Jonsson, 1983). Following 6-OHDA injections into substantia nigra or the nigrostriatal tract, dopaminergic neurons start degenerating within 24 hours and die by non-apoptotic morphology (Jeon *et al.*, 1995). Maximal reduction of striatal dopamine is reached within 3 to 4 days post-lesion (Faulk & Laverty, 1969) and, in most studies, residual striatal dopamine content is less than 20% of controls. When injected into the striatum, 6-OHDA produces a more protracted retrograde degeneration of the nigrostriatal system which can last from 1 to 3 weeks post-lesion (Sauer & Oertel, 1994; Przedborski *et al.*, 1995). Here, the death of nigral dopaminergic neurons occurs by retrograde degeneration and dying neurons exhibit a mixed morphology (Marti *et al.*, 1997), which is quite distinct from that seen following the injection of the toxin directly into the nigra (Jeon *et al.*, 1995). Regardless of the site of 6-OHDA injection along the nigrostriatal pathway, a number of pre- and postsynaptic changes occur, even with only moderate damage (Joyce *et al.*, 1996). These include increased dopaminergic turnover within the remaining dopaminergic terminals (Zigmond *et al.*, 1990) and upregulation of striatal dopamine D2 receptors (Ungerstedt, 1971b); the latter is only seen for a dopamine depletion greater than 90% and is maximal within 2–3 weeks postlesion (Marshall *et al.*, 1989). Usually, 6-OHDA is injected into one hemisphere while the other hemisphere serves as an internal control. Unilateral injections lead to asymmetric circling motor behavior whose magnitude depends on the degree of nigrostriatal lesion (Ungerstedt & Arbuthnott, 1970; Hefti *et al.*, 1980; Przedborski *et al.*, 1995) and is best observed after administration of direct (rotation away from the lesion) or indirect (rotation toward the lesion) dopamine agonists, due to physiological imbalance between the lesioned and the unlesioned striatum. Over the years, this turning behavior, which can be quantified, has been widely used to assess the antiparkinsonian properties of new drugs, as illustrated in (Jiang *et al.*, 1993), or the success of transplantation and gene therapies in repairing the

lesioned pathways (Kirik *et al.*, 2002; Bjorklund *et al.*, 2002). The 6-OHDA model does not mimic all the clinical and pathological features characteristic of PD nor does it result in formation of the cytoplasmic inclusions (Lewy bodies) so typical of PD. Furthermore, the acute nature of the nigrostriatal neurodegeneration seen after the injection of 6-OHDA differs from the more progressive time course of PD.

Studies in rodents have demonstrated that developing monoaminergic neurons respond differently to 6-OHDA than their mature counterparts (Jonsson, 1983). In neonatal rats 6-OHDA has been mainly administered systemically, which can only be done during the first postnatal week, due to the development of the BBB around 7–10 days of life, and intracisternally to produce widespread lesion of the nervous system. Both routes of administration induce profound alterations of the norepinephrine systems, particularly in the nucleus ceruleus and cerebral cortex as well as of the dopaminergic systems (Jonsson, 1983; Breese *et al.*, 1984). Upon reaching adulthood, in contrast to the noradrenergic denervation in the nucleus ceruleus and cerebral cortex, neonatally lesioned rats exhibit noradrenergic and serotonergic hyperinnervation in other brain regions, such as the brainstem (Jonsson, 1983; Joyce *et al.*, 1996). Of note, some serotonergic sprouting in the striatum also occurs after 6-OHDA in adult animals, too. They also show increased serotonin receptor density and functional dopamine D1 receptor supersensitivity (Joyce *et al.*, 1996). The latter can be elicited by challenging neonatally lesioned rats with dopamine D1 receptor agonists, which results in behavioral abnormalities such as increased locomotion and self-mutilation (Breese *et al.*, 1990). The association of the aforementioned biochemical and behavioral alterations has led experts to propose neonatal 6-OHDA-lesioned rats as an experimental model of Lesch–Nyhan syndrome, a rare genetic disorder characterized by chorea, spasticity, and compulsive auto-mutilation (Moy *et al.*, 1997). Neonatal rats have also been lesioned with 6-OHDA by intra-striatal infusion to study the mode of cell death of injured developing nigrostriatal dopaminergic neurons (Marti *et al.*, 1997). In this study the authors demonstrate that the lesion results in an induction of apoptotic cell death in phenotypically defined dopaminergic neurons; this appears on the third postlesion day and persists until the tenth and is most marked when the lesion is performed before postnatal day 14 (Marti *et al.*, 1997).

Finally, 6-OHDA can be utilized to produce a chemical sympathectomy, which is preferentially achieved by intravenous injection of the toxin at a dose of 50 to 500 mg/kg either once or twice at 16-hour intervals (Jonsson, 1983). Of note, while 50 mg/kg, which is well

tolerated, reduces norepinephrine content by 90% in most peripheral organs such as the iris and heart, higher doses (e.g. 250–500 mg/kg), which cause high lethality, are needed to damage cell bodies in the sympathetic ganglia (Jonsson, 1983). Although 6-OHDA-induced sympathectomy is permanent in neonatal animals, it is transient in adults and, with time, there is regeneration of noradrenergic fibers (Jonsson, 1983). Over the years, 6-OHDA-induced sympathectomy has proved to be a useful model for studying the role of sympathetic innervation in a large variety of symptoms such as pain, and in physiologic functions such as immune, cardiovascular, bone, and glucose metabolisms (Khalil & Helme, 1989; Kaul, 1999; Sherman & Chole, 2000; Cao *et al.*, 2002).

Paraquat

The potent herbicide paraquat (*N,N'*-dimethyl-4,4'-bipyridinium) is another prototypic toxin known to exert deleterious effects through oxidative stress. It is now well established that paraquat toxicity is mediated by redox cycling with cellular diaphorase such as nitric oxide synthase (Day *et al.*, 1999), thereby elevating intracellular levels of the ROS superoxide. Since its introduction in agriculture, there have been several cases of lethal poisoning resulting from ingestion or even from dermal exposure (Smith, 1988). Until recently, most experimental studies of paraquat were related to its effects on lung, liver and kidney probably because the toxicity induced by this herbicide in these organs is responsible for death after acute exposure. However, the structural similarity of paraquat to the neurotoxin MPP⁺ (Fig. 16.2) has sparked major interest in this herbicide as a potential environmental parkinsonian toxin. In support of this view are the published observations that significant damage to the brain is seen in individuals who died from paraquat intoxication (Grant *et al.*, 1980; Hughes, 1988) despite the fact that paraquat poorly crosses the BBB (Shimizu *et al.*, 2001). Furthermore, epidemiological studies have suggested an increased risk for PD due to paraquat exposure (Liou *et al.*, 1997). Yet, paraquat accumulation in the brain appears not to follow any known enzymatic or neurotransmitter distribution (Widdowson *et al.*, 1996a,b). While oral administration of paraquat to rats appears ineffective in lesioning the central nervous system (Widdowson *et al.*, 1996b), its intraventricular or intracerebral injection produces unequivocal neurodegeneration which, however, does not seem restricted to any specific neuronal groups (De Gori *et al.*, 1988; Liou *et al.*, 1996). When injected systemically into mice, conflicting results are obtained. Some authors have reported reduced motor activity and dose-dependent losses of striatal dopaminergic nerve fibers and

Fig. 16.2 Structural similarity between paraquat and MPP⁺. The only difference between these two compounds is the second *N*-methyl-pyridium group that paraquat has instead of the phenyl group as seen in MPP⁺.

substantia nigra neuronal cell bodies in paraquat-treated mice (Brooks *et al.*, 1999). Conversely, others have failed to see any behavioral abnormality or nigrostriatal dopaminergic pathway damage in similarly treated mice (Thiruchelvam *et al.*, 2000a,b). This discrepancy may be explained by the fact that the propensity of paraquat to damage the nigrostriatal pathway in mice is not only dose-, but also age-dependent (McCormack *et al.*, 2002; Thiruchelvam *et al.*, 2003). The use of Stereology to assess cell loss in some, but not all, studies may also be a reason for the previous inconsistent results. Aside from killing dopaminergic neurons, paraquat induces α -synuclein upregulation and aggregation (Manning-Bog *et al.*, 2002). This suggests that the paraquat model could be quite valuable to recapitulate some of the key neuropathological features of PD such as SNpc neuronal loss and α -synuclein-positive inclusions.

It is worth mentioning that manganese ethylenebis-dithiocarbamate, or “Maneb,” which is used in overlapping geographical areas with paraquat, has been shown to decrease locomotor activity and potentiate paraquat effects on the nigrostriatal pathway in mice (Thiruchelvam *et al.*, 2000a,b). In these studies, combined paraquat and Maneb exposures produce greater loss of dopaminergic neurons than either of the chemicals alone (Thiruchelvam *et al.*, 2000a,b). However, none of these studies has found meaningful reductions in striatal dopamine levels after paraquat injection, even when combined with Maneb. This paradoxical finding may be due to some kind of compensation mechanism that makes up for the modest loss of neurons caused by these toxins. In light of this, the biochemical basis for the reported behavioural abnormalities found in these animals cannot be attributed to a deficit in brain dopamine as in PD; thus, based on our current knowledge of this model, those motoric perturbations cannot be used to mimic PD symptoms.

In contrast to SNpc dopaminergic neurons, GABAergic elements in the substantia nigra and the striatum are not

Fig. 16.3 Inhibitors of electron transport chain (ETC). Under normal physiological conditions, electrons donated from NADH to Complex I (NADH: ubiquinone oxidoreductase) or from succinate to Complex II (succinate: ubiquinone oxidoreductase) are passed to coenzyme Q (ubiquinone), ubisemiquinone, ubiquinol, Complex III (ubiquinol: cytochrome c oxidoreductase), cytochrome c, Complex IV (cytochrome c oxidase) and finally to O_2 to produce H_2O . The energy released from this ETC is used to pump the protons out of the inner mitochondrial membrane into intermembrane space creating a membrane potential gradient. This potential energy then drives the flow of protons back into the mitochondrial matrix via Complex V (ATP synthase) and thereby producing ATP. The specific sites of action of various inhibitors are illustrated here.

affected by paraquat as evidenced by Western blot and immunohistochemical studies of glutamic acid decarboxylase (GAD) (McCormack *et al.*, 2002; Thiruchelvam *et al.*, 2003). Beyond these two neuronal populations, none of the studies cited above has systematically assessed the status of other neuronal types such as cholinergic, serotonergic or adrenergic in the brain. At this point, therefore, it remains unclear whether the observed paraquat/Maneb cytotoxicity is really specific to the dopaminergic systems and could thus be regarded as a reliable experimental model of PD.

Mitochondrial neurotoxins

Mitochondrion is a small organelle, which assures by itself a large number of vital cellular metabolic pathways such as the tricarboxylic acid cycle, the fatty acid beta-oxidation, and the electron transport chain (ETC), to cite only a few. Despite the multiplicity of potential mitochondrial metabolic targets, so far, investigators interested in producing toxic experimental models of neurodegeneration essentially have used natural or synthetic compounds capable of inhibiting various enzymatic components of the

ETC to achieve their goals (Fig. 16.3). Presumably the main reason for this intense research effort is that defects in mitochondrial ETC function have been identified in several prominent neurodegenerative disorders in which they are believed to play a pathogenic role. Although a long list of ETC inhibitors has been tested, especially in rodents, only a handful, which include rotenone, malonate, and 3-nitropropionic acid (3-NP) have been used more than anecdotally and will be discussed here. Although these toxins will also be discussed by Timothy Greenamyre elsewhere in this book, here we will focus our review on the use of rotenone, malonate, and 3-NP in the production of experimental models of neurological diseases. Of note, MPTP and isoquinoline, which are known to affect the ETC, but whose cytotoxic mechanisms may involve additional cellular targets, will not be discussed in this section.

Rotenone

Rotenone is the most potent member of the rotenoids, a family of natural cytotoxic compounds extracted from *Leguminosa* plants, used as insect and fish poison and more recently also regarded as a potential parkinsonian

environmental toxin. Rotenone is highly lipophilic and can thus readily gain access to all organs with an apparent fast pharmacokinetic. For instance, after a single intravenous injection, rotenone reaches maximal concentration in the brain within 15 min and decays to about half of this level in approximately 100 min (Talpadé *et al.*, 2000). Although it accumulates throughout the CNS, the distribution of rotenone in the brain is heterogeneous (Talpadé *et al.*, 2000), apparently not because of regional variations in cerebral blood flow (Kilbourn *et al.*, 1997), but rather regional differences in oxidative metabolism (Talpadé *et al.*, 2000). By virtue of its lipophilicity, rotenone freely enters all cells and, once inside, it probably diffuses into all organelles including mitochondria, where it blocks complex I of the ETC. The effect of rotenone on mitochondrial respiration is time and dose dependent and results from its insertion in a large binding pocket in the hydrophobic part of complex I (Okun *et al.*, 1999), probably made of the ND1 subunit. While rotenone has been used extensively as a prototypic mitochondrial poison *in vitro*, only a limited number of studies used rotenone to specifically kill dopaminergic neurons or to model PD. Treatment of embryonic ventral midbrain cultures with rotenone has been shown to cause major neurotoxicity (Marey-Semper *et al.*, 1995), especially in the presence of glial cells (Gao *et al.*, 2002). In both studies dopamine uptake was significantly more affected than GABA uptake, thus supporting the hypothesis of selective vulnerability of dopaminergic cells. *In vivo*, rotenone has been administered to animals by different routes. Oral administration of rotenone appears to cause little neurotoxicity (Betarbet *et al.*, 2000). By contrast, stereotaxic injection of rotenone into the median forebrain bundle causes substantial depletion of striatal dopamine and serotonin (Heikkilä *et al.*, 1985), findings consistent with the notion that rotenone lesions the median forebrain bundle, which carries dopaminergic and serotonergic fibers into the striatum. In rats treated for 7–9 days with high doses of rotenone (10–18 mg/kg/d) as a continuous intravenous infusion, there were major lesions in both the striatum and the globus pallidus, characterized by neuronal loss and gliosis (Ferrante *et al.*, 1997). The nigrostriatal pathway, however, appeared intact (Ferrante *et al.*, 1997). This latter finding is consistent with the demonstration that the systemic acute administration of high doses of rotenone (15 mg/kg), while causing high lethality, failed to affect striatal dopamine contents (Thiffault *et al.*, 2000). The possibility that nigrostriatal injury may be induced by rotenone under less severe experimental conditions and different paradigms of administration has also been evaluated. In one such study (Thiffault *et al.*, 2000), the effect of multiple subcutaneous injections of rotenone (1.5 mg/kg three times per week for 3 weeks) failed to

cause any significant neurochemical signs of dopaminergic damage in rats. However, when rotenone was intravenously infused (2–3 mg/kg/day) for 1–3 weeks, treated rats developed no apparent striatal lesion, but exhibited the specific nigrostriatal pathway neurodegeneration associated with nigral intraneuronal proteinaceous inclusions (Betarbet *et al.*, 2000) reminiscent of Lewy bodies, a neuropathological hallmark of PD. However, in this study only 50% of the treated rats exhibited clear nigrostriatal damage and only Lewis rats showed a consistent lesion (Betarbet *et al.*, 2000), indicative of a significant inter-individual and inter-strain variability in the observed effect of rotenone. Although this toxic model of PD appears quite promising, it is also quite challenging. A review of the current problems and limitations that surround this model can be found in Perier *et al.* (2003). Moreover, subsequent studies have challenged the notion that rotenone infusion would cause a selective lesion of the nigrostriatal pathway (Lapointe *et al.*, 2004; Hoglinger *et al.*, 2003).

Malonate and 3-nitropropionic acid

Malonate and 3-NP share similar mechanisms of action and both have been used to model the same type of neurological disorder; therefore, these two toxins will be discussed together. Although malonate and 3-NP can be readily synthesized, both are natural molecules in that the former is a product of animal fatty acid metabolism and the latter is a secondary metabolite of the fungus *Arthrinium*, considered to cause a form of acute food poisoning called “moldy sugarcane poisoning.” It is now well established that malonate and 3-NP inhibit, in a competitive reversible and irreversible manner respectively, the binding of succinate to the enzyme succinate dehydrogenase (SDH) (Alston *et al.*, 1977; Cooper & Clark, 1994). Because SDH is a main enzymatic component of both the tricarboxylic acid cycle and the ETC complex II, its blockade impairs tricarboxylic acid metabolism and mitochondrial respiration. Not surprisingly, therefore, the administration of malonate and 3-NP is associated with impaired ATP synthesis (Beal *et al.*, 1993b; Zeevalk *et al.*, 1995; Kaal *et al.*, 2000) and increased local lactate production (Beal *et al.*, 1993a), metabolic alterations which, upon equimolar intra-striatal injections, are less pronounced and short lasting with the reversible inhibitor malonate than with the irreversible inhibitor 3-NP. It is believed that the interference of electron flow in ETC by 3-NP and malonate leads to membrane depolarization which, in turn, activates the voltage-dependent NMDA receptors (Greene & Greenamyre, 1996). According to this scenario, once NMDA receptors are activated, a massive influx of calcium occurs, thus triggering numerous cell death pathways and stimulating ROS production which ultimately

cause cell demise (Albin & Greenamyre, 1992; Dugan & Choi, 1994). Consistent with a role for NMDA receptors in this deleterious cascade are the autoradiographic and electrophysiologic demonstrations that malonate- and 3-NP-induced SDH inhibition does activate NMDA receptors (Wullner *et al.*, 1994; Calabresi *et al.*, 2001) and that NMDA antagonists such as MK-801 can attenuate malonate- and 3-NP-induced neurotoxicity (Greene & Greenamyre, 1996; Massieu *et al.*, 2001). In addition, after exposure to these toxins, NMDA-dependent increased intracellular calcium (Calabresi *et al.*, 2001; Lee *et al.*, 2002), activation of proteases such as caspases (Schulz *et al.*, 1998; Lee *et al.*, 2002), and rise in ROS (Schulz *et al.*, 1996; Ferger *et al.*, 1999) were all documented. While most steps of the outlined sequence of events have been studied in great detail, there is a surprising lack of information about the process by which 3-NP and malonate actually enter the central nervous system and subsequently the neurons and mitochondria. Because these two toxins share structural similarity with succinate it may be surmised that malonate and 3-NP entry into the mitochondria may be facilitated by one of the succinate carriers (Kakhniashvili *et al.*, 1997). It should be mentioned that several variants of the mitochondrial succinate carriers are expressed at the level of the BBB and the plasma membrane of neurons (Pajor *et al.*, 2001). It is thus possible that these transporter variants participate in the translocation of 3-NP and malonate into the brain and neurons. If correct, it would appear that 3-NP benefits more from this mechanism than malonate since only 3-NP, and not malonate, can cause neurodegenerative changes after systemic administration. It would also suggest that the reported protective effects of large doses of succinate against malonate may be due, not to a rescue of SDH function as speculated by the authors (Greene *et al.*, 1993), but simply to the excess of succinate impeding malonate cellular and mitochondrial entry.

From the very beginning, the rat has emerged as the preferred species to study malonate and 3-NP neurotoxicity, although occasionally mice and monkeys have also been used (Brouillet *et al.*, 1999). Thus, most available data regarding the use of these toxins emanates primarily from investigations in rats and, as far as 3-NP is concerned, this toxin has been effectively administered systemically or intracerebrally to rats using very different regimens to cause very different behavioral and neuropathological alterations and death rates (Brouillet *et al.*, 1999). Higher doses of 3-NP have also been used in mice (Klivenyi *et al.*, 2000; Fernagut *et al.*, 2002) to induce striatal lesions; however, under these harsh regimens, death rate is as high as 50% in these animals. Surprisingly, while 3-NP is known to cause neurotoxicity following its ingestion, we did not come

across any studies in which this toxin was administered orally. Among the different regimens used, it appears that conspicuous brain neuropathology with low lethality can be obtained in rats by intraperitoneal injections or subcutaneous infusion of 10 to 20 mg/kg/day of 3-NP for 5 to 30 days (Brouillet *et al.*, 1999). As depicted in (Brouillet *et al.*, 1999), after a prolonged low dose regimen, lesions are small and restricted consistently to the dorsolateral part of the anterior striatum, whereas after a brief high dose regimen, lesions are larger, invading the entire lateral striatum and involving, in several cases, the most caudal part of the striatum. In addition, while chronic 3-NP-treatment is not associated with extrastriatal lesions, acute and subacute 3-NP treatment is frequently associated with significant pallidal and hippocampal damage. These data indicate that the consistency and extent of the damage to the brain produced by 3-NP depends on the dose and rate of administration. In keeping with this, it should be emphasized that the chronic delivery of a low dose of 3-NP (e.g. 12 mg/kg/day) induces motor abnormalities and selective neuropathology in less than half of the treated animals (Beal *et al.*, 1993b). Other factors known to influence 3-NP neurotoxicity are the age and the genetic background of the rats (Brouillet *et al.*, 1993; Ouary *et al.*, 2000). As for malonate, because of its inability to cross the BBB, 2 to 4 μmol of the toxin is usually injected stereotaxically into the striatum. As with 3-NP, malonate neurotoxicity is age dependent as, after intrastriatal injections, 4- and 12-month-old rats show greater extent of striatal lesions than do 1-month-old animals (Beal *et al.*, 1993a). However, there is no difference in the extent of neuronal loss between 6- and 27-month-old rats (Meldrum *et al.*, 2000).

Microscopically, 3-NP injected systemically or intrastriatally produces tissue damage similar to that produced by stereotaxic injection of malonate in the striatum, consisting of a necrotic core at the centre of the lesion surrounded by an intermediate zone between the core and the normal striatal tissue in which there is gliosis and a loss of only certain subtypes of neurons. However, in the case of 3-NP, only with chronic low dosage are the size of the intermediate zone substantial and the pattern of neuronal loss similar to that produced by malonate. For instance, harsh 3-NP treatment appears to affect all striatal subpopulations of neurons (Beal *et al.*, 1993b), whereas more gentle 3-NP treatment, like intrastriatal injection of 2 μmol of malonate, affects medium-sized GABAergic spiny neurons and spares the medium-sized aspiny NADPH-diaphorase in rodents and monkeys (Beal *et al.*, 1993a,b; Brouillet *et al.*, 1995). In addition, malonate, but apparently not 3-NP, also affects striatal dopaminergic structures and causes some degree of nigral dopaminergic loss through a retrograde degeneration

process (Sonsalla *et al.*, 1997; Zeevalk *et al.*, 1997); why there should be no retrograde degeneration after 3-NP treatment is an enigma. Although not identical (Borlongan *et al.*, 1995; Sun *et al.*, 2002), this pattern of neuronal loss is reminiscent of that seen in Huntington's disease, thus supporting the usefulness of both 3-NP and malonate in modeling HD. However, while malonate and 3-NP recapitulate rather faithfully HD's chemical neuropathology, neither in rats nor in monkeys do they reproduce well HD's motor abnormalities. From the 3-NP perspective, both in rats and monkeys a harsh treatment produces mostly hypokinesia and limb weakness, and occasionally dystonia, uncoordination, and even somnolence (Brouillet *et al.*, 1995; Borlongan *et al.*, 1997; Sun *et al.*, 2002). In rats, the more chronic regimen was associated with hyperkinesia initially, followed by hypokinesia (Borlongan *et al.*, 1997) or subtle motor abnormalities only observable using sophisticated motor testing (Guyot *et al.*, 1997). In monkeys, the situation appears even more deceiving in that no spontaneous motor abnormalities were detected in three animals treated for 3–6 weeks with 8 mg/kg/day of 3-NP, and only foot dyskinesia and dystonia were seen in two others treated for an even longer period with a slightly higher dose (Brouillet *et al.*, 1995). Although the significance of this is unclear, these authors also show that a variety of abnormal movements, including chorea, could be induced in otherwise asymptomatic 3-NP-treated monkeys by the administration of a dopamine agonist such as apomorphine. Regardless of the type of abnormal movements observed in these animals, it was found that the degree of neurological impairment correlates with the severity of striatal lesions, consistent with the view that most of the observed motor symptoms directly result from striatal cell loss (Guyot *et al.*, 1997).

The reason that 3-NP and possibly malonate cause preferential damage to the striatum despite widespread brain SDH inhibition (Brouillet *et al.*, 1998) is unknown. To date, two hypotheses, which are not mutually exclusive, prevail. First, as discussed above, several *in vitro* and *in vivo* studies have demonstrated the importance of excitotoxicity in 3-NP's and malonate's deleterious effects (Brouillet *et al.*, 1999). Therefore, since the striatum receives prominent glutamatergic input from the cerebral cortex and the thalamus, it may be hypothesized that the rich striatal glutamatergic innervation is a key factor in 3-NP striatal selectivity. In favor of this view is the finding that the ablation of the cortical glutamatergic afferences to the striatum mitigates 3-NP striatal neurotoxicity (Beal *et al.*, 1993b). However, the fact that there is no evidence of increased striatal extracellular glutamate concentrations after systemic administration of 3-NP and that several brain areas not affected by 3-NP possess even greater glutamatergic

innervation than the striatum represent strong arguments against this idea. Second, mounting evidence indicates that dopamine is instrumental in 3-NP and malonate's deleterious actions (Reynolds *et al.*, 1998; Maragos *et al.*, 1998; Moy *et al.*, 2000; Calabresi *et al.*, 2001; Xia *et al.*, 2001), which fits well with the fact that the striatum contains a conspicuous dopaminergic innervation and that virtually all striatal neurons are dopaminergic. It has been found consistently that striatal dopamine depletion, produced either by 6-OHDA lesion or by pharmacological inhibition of dopamine synthesis, attenuates the effects of malonate and 3-NP (Reynolds *et al.*, 1998; Maragos *et al.*, 1998; Moy *et al.*, 2000; Calabresi *et al.*, 2001; Xia *et al.*, 2001). So far, however, the molecular basis of the role of dopamine in the malonate and 3-NP models may be mediated by oxidative stress (mainly due to autooxidation of dopamine), dopamine receptor activation, or both. Relevant to both mechanisms are the demonstrations that antioxidant strategies protect from malonate- and 3-NP-induced toxicity (Schulz *et al.*, 1995a; Schulz *et al.*, 1996) and that dopamine D2 receptor agonists can restore the effect of malonate or of 3-NP in 6-OHDA-lesioned animals, whereas D2 receptor antagonists attenuate the effects of both neurotoxins (Calabresi *et al.*, 2001; Xia *et al.*, 2001). In conclusion, from all of the above evidence it appears quite obvious that, except for moldy sugarcane poisoning, both 3-NP and malonate do not represent perfect models of HD or any other neurodegenerative disorder of the basal ganglia. This fact should not undermine, however, the critical importance of these two neurotoxins as tools to further dissect the functional chemical neuroanatomy of the basal ganglia and the role of excitotoxicity and dopamine in the striatal neurodegenerative process.

Other ETC mitochondrial toxins

For each mitochondrial enzymatic complex of the ETC, numerous reasonably specific inhibitors are available (Cooper & Clark, 1994). Some of these, namely MPP⁺, rotenone, malonate, and 3-NP, have already been discussed. Others such as piericidin (complex I), antimycin A (complex III), and cyanide and azide (complex IV), while extensively used *in vitro*, have rarely been used *in vivo* to model neurological disorders. Because the rare surviving victims from cyanide suicide or homicidal attempts may develop parkinsonism and dementia or delayed onset dystonia combined with a severe parkinsonism (Sanchez-Ramos, 1993), animals have been treated with cyanide to elucidate the chemical neuroanatomy underlying the emergence of the movement disorders. In keeping with this, it has been reported that a third of the mice injected

subcutaneously with potassium cyanide (6 mg/kg) twice daily for 7 days exhibited reduced locomotor activity, which could be reversed by L-DOPA, as well as catalepsy, which could not be reversed by L-DOPA (Kanthasamy *et al.*, 1994). Although behavioral abnormalities were only seen in a fraction of the treated mice, all had significant dopaminergic loss at the level of the basal ganglia (Kanthasamy *et al.*, 1994); since the authors only studied the dopaminergic system in these mice, it is unknown whether or not cyanide affects these neurons preferentially. While there is no *in vivo* evidence that any specific neurotransmitter pathway would be more sensitive to cyanide than any other, note that, following infusion of cyanide to cats, severe lesions were only seen in the corpus callosum, pallidus and substantia nigra (Funata *et al.*, 1984). More surprisingly and in contrast to neuropathological reports from human autopsy, the treated cats did not show significant lesions in the cerebral cortex and the hippocampus (Funata *et al.*, 1984). Except for the lack of the cortical and hippocampal damage, the topography of neuropathological changes resembles that reported in carbon monoxide intoxication, thus suggesting that cyanide may be a useful model of chemical brain hypoxia. Alternatively, given the prominent pallidal lesion, the administration of cyanide to animals may produce a unique means to explore the pathophysiology of akinetic-rigid syndromes.

Neurotoxic amphetamines

Amphetamines are potent, highly addictive and widely abused psychostimulants. Among the amphetamine derivatives, four have been shown to have neurotoxic effects on the nervous system, namely *p*-chloroamphetamine (PCA), methamphetamine (METH), 3,4-methylenedioxymethamphetamine (MDMA) and fenfluramine. These four compounds have been extensively used in various mammals to study the basis and the lasting consequences of amphetamine addiction on the brain. The neurotoxic profile of these four analogues, however, is not identical in that PCA and fenfluramine, when used in moderate doses, tend to affect serotonergic neurons specifically, while methamphetamine and MDMA are toxic to both dopaminergic and serotonergic neurons.

While neurotoxic amphetamines can be administered effectively to animals through a variety of routes, systemic injection is by far the most popular. From these animal studies we learned that, almost immediately after amphetamine administration, there is a massive release of monoamines from their storage sites in the nerve terminals from both the central and peripheral

nervous system (Segal & Kuczenski, 1994); compared with the other amphetamines' analogues, methamphetamine causes more pronounced central effects and fewer peripheral ones. In the brain, the release of dopamine begins soon after the injection of amphetamines and peaks within 1 hour (Clausing & Bowyer, 1999; Kita *et al.*, 2000). This time course coincides with the brain levels of amphetamine following its systemic injection (Clausing & Bowyer, 1999). As in humans, during this early phase, animals such as rats and monkeys injected with low doses of amphetamines exhibit a range of acute behavioral changes such as increased locomotor activity (Segal & Kuczenski, 1994). However, as the doses increase, the motor activity becomes more stereotyped (e.g. sniffing) (Segal & Kuczenski, 1994), and increased salivation and self-injurious behaviors occur (Kita *et al.*, 2000). In addition, animals develop a dose-dependent hyperthermia (potentially exceeding 41°C) whose magnitude correlates with the levels of brain amphetamine and released dopamine and whose time course is delayed by about 30 minutes compared to that of brain amphetamine and released dopamine (Clausing & Bowyer, 1999). Although our knowledge of the pathophysiology underlying amphetamine-induced hyperthermia remains incomplete, it is well known that it correlates with lethality and neurotoxicity (Ali *et al.*, 1994; Albers & Sonsalla, 1995; Malberg & Seiden, 1998).

Following the acute phase, it is now well accepted that neurotoxic amphetamine analogues not only cause functional deficits, such as profound monoamine depletion, but also structural alterations. Amphetamine-induced neurotoxicity depends on the regimen used since only high dosage and repeated injections will produce significant and consistent neurodegeneration (Davidson *et al.*, 2001). As reviewed in Axt *et al.* (1994), neurotoxic regimens of amphetamine and analogs cause selective loss of dopaminergic and serotonergic nerve terminals with relatively little effects on the corresponding cell bodies. Furthermore, data obtained from rats and non-human primates show that the destruction of the serotonergic and dopaminergic nerve terminal is not even throughout the various regions of the brains. Amphetamines consistently destroy the fine serotonergic terminals that originate from the dorsal raphe nucleus but spare the beaded ones that originate from the median raphe nucleus (Axt *et al.*, 1994). Similarly, amphetamines selectively destroy dopaminergic nerve terminals in the striatum, nucleus accumbens and frontal cortex but spare dopaminergic cell bodies in the ventral tegmental area and substantia nigra (Axt *et al.*, 1994). Although this represents the prevalent view, some studies have reported significant neuronal loss especially in the substantia nigra of rodents following very high levels

of methamphetamine administration (Trulson *et al.*, 1985; Sonsalla *et al.*, 1996). Among the affected dopaminergic brain areas, the dorsal aspect of the striatum appears to be the most susceptible to the neurotoxic amphetamines, whereas the ventral aspect of the striatum and the shell of the nucleus accumbens are much less sensitive, and the olfactory tubercle and the septum are rather resistant (Axt *et al.*, 1994). Moreover, within the striatum it would appear that dopaminergic projections to the matrix are affected, while those to the patches are resistant (Axt *et al.*, 1994). Surprisingly, despite these dramatic biochemical and structural changes, there is still no consensus regarding the nature of their spontaneous behavioral correlates, neither in monkeys nor in rodents (Ricaurte *et al.*, 1994). However, several studies have reported strikingly abnormal responses to pharmacological challenges in amphetamine-treated animals (Ricaurte *et al.*, 1994), thus suggesting that such an approach may represent an effective and reliable means to reveal lasting behavioral alterations in these lesioned animals.

Several studies have shown that, after the administration of neurotoxic amphetamines to monkeys and rodents, monoaminergic innervation, especially in the forebrain, exhibits signs of recovery (Axt *et al.*, 1994). It appears that the milder the lesion the more extensive the re-innervation, but with the current regimens, recovery is moderate at best. Because this process is slow by nature, it is important to remember that it may take anywhere from several months to several years before re-innervation is completed and conclusions about the extent of the recovery can be drawn. For example, in non-human primates injected with MDMA (5mg/kg twice daily for 4 days, SC), the recovery of serotonin axon density in frontal cortex is only about 60% after 7 years (Hatzidimitriou *et al.*, 1999). Rostral neocortex and ventral forebrain are reinnervated sooner and more completely than the caudal neocortex and dorsal forebrain, which is a pattern of axonal re-growth reminiscent of that of axonal growth during development.

Major disagreements still persist about the mechanisms by which neurotoxic amphetamines destroy nerve terminals. All neurotoxic amphetamines cited above are quite lipophilic and can thus readily gain access to all organs including the brain. While amphetamine analogs may, to a certain extent, enter cells such as neurons by diffusion, their accumulation within dopaminergic neurons, for example, is facilitated by DAT (Zacsek *et al.*, 1991a,b). It is thus not surprising that mutant mice deficient in DAT are more resistant to methamphetamine (Fumagalli *et al.*, 1998). Once inside monoaminergic neurons, amphetamines inhibit MAO (Scorza *et al.*, 1997), promote flux reversal by plasma membrane monoamine trans-

porters (Sulzer *et al.*, 1993), and induce monoamine efflux from vesicles (Sulzer *et al.*, 1995). The latter redistribution of monoamines from vesicles to cytosol is believed to be a pivotal event in amphetamine analog neurotoxicity as it gives rise to massive intracellular production of ROS (Cubells *et al.*, 1994; Fumagalli *et al.*, 1999). Although the evidence summarized above suggests that endogenous monoamines and monoamine-derived ROS play a critical role in amphetamine analog neurotoxicity, recent *in vivo* data indicate that at least some of the results implicating monoamines such as dopamine in the neurotoxic process may have been confounded by secondary drug effects on core temperature. The neuroprotective effects of several pharmacologic agents on MDMA and methamphetamine neurotoxicity appear to be related to their thermoregulatory actions, rather than to their primary pharmacologic actions (Miller & O'Callaghan, 1994; Albers & Sonsalla, 1995; Callahan & Ricaurte, 1998). One of the most damaging findings against the actual role of dopamine in the neurotoxic process is the demonstration that hypothermia rather than catecholamine depletion contributes to the neuroprotective effects of reserpine and α -methyl-*p*-tyrosine in MDMA and methamphetamine-treated animals, since prevention of drug-induced hypothermia abolishes the neuroprotection of reserpine and α -methyl-*p*-tyrosine, alone or in combination (Yuan *et al.*, 2001, 2002). In contrast to the above findings in animals, however, *in vitro* data obtained from cell cultures question whether change in body temperature is related to methamphetamine toxicity. Using postnatally derived ventral midbrain mouse cultures, it is shown that the specific loss of neurites in dopaminergic neurons induced by methamphetamine is a consequence of its upregulation of TH activity, leading to elevated levels of cytosolic dopamine and consequently increased production of toxic cytosolic ROS (Larsen *et al.*, 2002). This study also demonstrates that, in the absence of vesicular sequestration of dopamine as seen in cultures derived from VMAT-deficient mice, the toxicity of methamphetamine is exacerbated, further supporting the deleterious role of dopamine. Since all cultures are maintained at constant temperature, the authors argue that, in their system, temperature is not involved in the toxicity of methamphetamine. From all these studies, the issue of core temperature and toxicity of amphetamine and its analogs warrants further investigation. At the moment, at least in the animal models, hyperthermia is likely involved but itself *per se* may not be solely responsible for toxicity (Albers & Sonsalla, 1995). Caution should be exercised especially when these compounds are to be used in animals. The above discussion shows that administration of neurotoxic amphetamines to animals provides a powerful model to explore the molecular basis

of acute and chronic amphetamine exposure on the brain. Aside from this, it also provides a unique model to elucidate the mechanisms governing regeneration in the adult brain, which is a topic of major importance in the field of neurorepair.

Isoquinolines derivatives

As reviewed in McNaught *et al.* (1998), isoquinoline derivatives refer to isoquinoline itself, substituted congeners such as 6-methoxyisoquinoline, and the various reduced species 1,2- or 3,4-dihydroisoquinolines, and 1,2,3,4-tetrahydroisoquinolines (TIQ), all of which may occur in their neutral or charged form, i.e. the isoquinolinium ion. These compounds are heterocycles in which a benzene ring and a pyridine ring are fused through carbon, and are formed from Pictet-Spengler non-enzymatic condensation of catecholamines (e.g. dopamine and L-DOPA) with aldehydes (Deitrich & Erwin, 1980). Among the isoquinoline derivatives, TIQ, 1-benzyl-TIQ and (R)-1,2-dimethyl-5,6-dihydroxy-TIQ ((R)-*N*-methyl-salsolinol) have the most potent toxicity (Nagatsu, 1997); of note, contrary to the other derivatives mentioned above, (R)salsolinol is formed enzymatically from dopamine and acetaldehyde by (R)salsolinol synthase (Naoi *et al.*, 1996). Many isoquinoline derivatives are found naturally in the environment and in foodstuffs as well as in human body fluids and brain tissues (McNaught *et al.*, 1998).

All available data support the notion that the mode and mechanism of action of isoquinolines is very close to that of MPTP and will thus not be discussed here. However, readers may find a comprehensive review on these topics in (Nagatsu, 1997; McNaught *et al.*, 1998). Isoquinolines have been used as neurotoxins both *in vitro* and *in vivo*, but, so far, they have produced much more consistent cytotoxicity in cell cultures than in animals (McNaught *et al.*, 1998). For instance, the administration of both TIQ and 1-benzyl-TIQ to monkeys produced behavioral and neuroanatomical abnormalities consistent with a lesion of the nigrostriatal dopaminergic pathway (Nagatsu & Yoshida, 1988; Yoshida *et al.*, 1990; Kotake *et al.*, 1996). In contrast, administration of *N*-methyl-TIQ, *N*-methylisoquinolinium, or *N*-methyl-norsalsolinol to monkeys failed to produce any pathological change in the substantia nigra (Yoshida *et al.*, 1993). A similar confusing situation exists in rodents where both lesion (Yoshida *et al.*, 1993; Antkiewicz-Michaluk *et al.*, 2000; Lorenc-Koci *et al.*, 2000; Abe *et al.*, 2001) and no lesion of the nigrostriatal pathway has been reported following the systemic administration of various TIQ analogues (Perry *et al.*, 1988). More disturbing is the lack of dopaminergic

neurotoxicity found following the stereotaxic injection of *N*-methyl-norsalsolinol into the medial forebrain bundle of rats (Yoshida *et al.*, 1993; Moser *et al.*, 1996). These discrepancies may relate to technical differences among the cited studies or to distinct physicochemical properties among the various analogues used, such as lipophilicity, making the particular isoquinoline derivatives differ in the degree to which they enter the brain. Regardless of the reason for this inconsistency, at this point the available data raise serious doubts about the ability of this group of toxins to produce a reliable experimental model of PD.

Glutamate and analogues

As discussed by Ikonomidou and Turski in this book, the amino acid glutamate is the main excitatory neurotransmitter in the brain implicated in a large array of physiological actions mediated through the activation of the glutamate receptors. These authors also remind us that, aside from its role in numerous normal functions of the brain, glutamate and its analogues have emerged as potent neurotoxins. The concept of glutamate and analogues as neurotoxins is quite interesting and emanates primarily from the demonstration that excitatory properties of various glutamate analogues correlate with their ability to cause neurotoxic damage (Olney *et al.*, 1971). Yet, while the list of identified neurotoxic excitatory amino acids, or "excitotoxins," is long, up to now only glutamate and a few of its analogues have been extensively utilized to lesion the nervous system, especially *in vivo*. By far the most popular excitotoxins include kainic acid (KA) and ibotenic acid (IA), which are isolated from the marine algae *Digenea simplex* off the coast of Japan and the mushroom *Amanita muscaria*, respectively, and quinolinic acid (QA) which is formed endogenously from tryptophan through kynurenine pathways. Like other amino acids, neither glutamate nor KA, IA or QA efficiently cross the BBB, thus requiring their stereotaxic injection in the brain or CSF to produce significant excitotoxic lesions of the central nervous system. So far, excitotoxins have been regarded as unique chemical tools for killing intrinsic neurons while sparing passing axons, nerve terminals and glial cells in discrete regions of the brain. Although this mode of lesioning may appear straightforward at first, accurate injury often requires laborious pilot studies to determine the appropriate coordinates, toxin concentrations, and injection volumes to produce a specific axon-sparing neuronal lesion with minimal necrosis confined within the boundary of the nucleus of interest. However, once those conditions are set, the lesion is quite reproducible, whether it is performed in rodents

or in monkeys, in adult or immature animals, or to target large or small brain areas. Although all of the different excitotoxins mentioned above are effective in producing axon-sparing lesions, it may be important for certain investigators to remember that the actual morphology of the degenerating neurons (e.g. apoptosis or necrosis) is quite different depending on the excitotoxin used and the age of the animals (Portera-Cailliau *et al.*, 1997a,b). Beyond these technical considerations, it must be emphasized that, over the past decades excitotoxins, through their ability to produce axon-sparing lesions, have contributed tremendously in our understanding of the role of specific neuronal systems in both normal and pathological situations. This fact is particularly well illustrated in the context of the MPTP monkey, where the use of IA stereotaxic injection has led to the demonstration of the pivotal role of the subthalamic nucleus in the pathophysiology of parkinsonism (Bergman *et al.*, 1990).

In addition, excitotoxins are thought to be implicated in the pathogenesis of a variety of acute and chronic neurological diseases and have thus been tested with more or less success in various animal species in attempts to model these pathological conditions. For instance, it has been well established that the systemic, intracerebroventricular, or intraparenchymal injection of KA produces an excellent experimental model of epilepsy (Ben Ari & Cosart, 2000). KA, IA and QA have also been proposed as suitable neurotoxins to generate an animal model of HD given the fact that their intrastriatal injections replicate many of the biochemical, neuropathological and even behavioral hallmarks of this neurodegenerative disorder. Using choline acetyltransferase (CAT), GAD and TH as markers, intrastriatal injections of glutamate, KA and IA produce significant reduction in cholinergic and GABAergic markers with normal or even increased dopaminergic markers on the site of injection (McGeer & McGeer, 1976; Coyle & Schwarcz, 1976; Schwarcz *et al.*, 1978, 1979). These alterations occur as early as 6 h after injection, with maximal effect observed at 48 h and lasting up to 21 days after KA injection (Schwarcz & Coyle, 1977). Consistent with the known chemical neuroanatomy of the striatal projections, the excitotoxic lesion of the striatum is accompanied with a reduction of GAD activity (McGeer & McGeer, 1976) and substance P content (Hong *et al.*, 1977) in the ipsilateral substantia nigra. KA has also been demonstrated to induce other biochemical changes that parallel those found in HD such as reduced levels of the angiotensin converting enzyme as well as receptors for serotonin, dopamine, acetylcholine, and GABA (McGeer & McGeer, 1982). Despite these striking similarities to HD, the enthusiasm for the intrastriatal KA model was dampened after it became clear

that KA fails to spare striatal somatostatin-containing neurons (Araki *et al.*, 1985) as seen in HD, and, even more troublesome, that KA causes remote neurodegeneration in, for example, the hippocampus, following its intrastriatal injection (Zaczek *et al.*, 1980). Unfortunately, intrastriatal injection of IA has not been proven to be more selective than KA in killing neurons and has thus been usually regarded as not particularly suitable to model HD either (Kohler & Schwarcz, 1983; Beal *et al.*, 1986). In contrast to KA and IB, QA has been proposed as a more suitable agent to model HD, since intrastriatal injections of QA (240 nmol), unlike the other two, result in marked depletions of both GABA and substance P, with selective sparing of somatostatin and neuropeptide Y neurons (Beal *et al.*, 1986, 1991). Likewise, quantitative assessment of QA-induced striatal lesion in rats using radioligand binding assays has also shown the selectivity of the damage (Levivier *et al.*, 1994). However, other laboratories have failed to observe similar selective effects from QA (Davies & Roberts, 1987; Boegman *et al.*, 1987). Although technical differences may underlie the discrepancy, to date, the actual reason remains obscure.

From a behavioral point of view, rats receiving bilateral striatal injection of KA (1 µg) exhibit locomotor changes such as increased swing time and decreased stance time (Hruska & Silbergeld, 1979). These animals spend more time swinging their feet in the air than on the ground, movements that are somewhat reminiscent of chorea (Hruska & Silbergeld, 1979). Rats with this kind of lesion also show enhanced locomotor response to amphetamine but not to apomorphine (Mason *et al.*, 1978), a type of dissociate response that has been reported in HD patients. In addition to motor abnormalities, KA-lesioned rats also show impairments in learning (Dunnett & Iversen, 1981). Although, as with other animal models, the behavioral changes induced by KA are difficult to extrapolate to the abnormalities seen in humans, KA appears to mimic at least some behavioral features of HD. The abnormal behavioral profiles of IA and QA have not been as well characterized as those of KA. In one study different doses of QA ranging from 75 to 300 nmol were injected in to rats and behavioral testings were performed 2 and 4 weeks afterward (Sanberg *et al.*, 1989). The animals receiving 150 and 225 nmol were hyperactive and lost weight, whereas those that received 75 nmol behaved similar to controls and those that received 300 nmol died. Abnormal movements closer to HD have been induced in monkeys with excitotoxic lesion of the striatum (Kanazawa *et al.*, 1986, 1990; Hantraye *et al.*, 1990; Burns *et al.*, 1995). However, as seen with 3-NP, typical chorea in these animals was only elicited after administration of dopaminergic agonists (Kanazawa *et al.*, 1986, 1990; Hantraye *et al.*,

1990; Burns *et al.*, 1995) and, more importantly, only in animals with lesions encompassing the posterior putamen (Kanazawa *et al.*, 1986; Burns *et al.*, 1995).

When using KA, IA and QA as a model for HD, there are several variables to consider (McGeer & McGeer, 1978; Coyle & Schwarcz, 1983). Dose-response studies (0.5–5 µg) of KA show a steep curve and toxicity is not linear with increasing doses (Coyle & Schwarcz, 1976; Coyle *et al.*, 1978). For example, an injection of 0.5 µg reduces by 20% the activity of GAD but 2 µg causes a near maximal GAD loss (80%) (Coyle & Schwarcz, 1976). Similarly, a histological study from Nissl-stained sections shows that at a dose of 0.5 µg, KA produces a discrete spherical lesion with a radius of 0.3 mm, but at 1 µg, the lesion increases to 1.4 mm (Coyle *et al.*, 1978). Also, due to differing sensitivity to excitotoxins among cell types, the dose of glutamate or analogues selected is dependent on the type of targeted cells and the desired magnitude of lesion. However, as a rule of thumb, to avoid non-specific damage due to pressure, excitotoxins should be delivered in the smallest possible volume slowly over a prolonged period of time. Furthermore, variation in response to excitotoxins has been linked to differences in strains (Sanberg *et al.*, 1979) and age of animals (Gaddy *et al.*, 1979). When given unilateral intrastriatal injections of either 2.5 or 5 nmol of KA, Wistar are more sensitive than Sprague–Dawley rats (Sanberg *et al.*, 1979). Similar types of injections produce a greater magnitude of damage in older (69–172 days) than in younger (48–49 days) Sprague–Dawley rats (Gaddy *et al.*, 1979). Sex and hormones have also been shown to influence the effect of excitotoxins. Bilateral striatal injections of QA produces higher locomotor activity (Emerich *et al.*, 1991) but less weight loss (Zubrycki *et al.*, 1990) in female than in male or ovariectomized female rats. Since KA induces seizures, if the animals were to be pretreated with anticonvulsants one should bear in mind that pharmacological agents such as diazepam and carbamazepine attenuate the excitotoxic effect of KA (Zaczek *et al.*, 1978). The type of anesthetics used has also been shown to influence the effect of excitotoxins. Anesthetics with a short half-life such as ether or hexobarbital potentiate the action of KA whereas those with a long half-life such as chloral hydrate or pentobarbital attenuate it (Zaczek *et al.*, 1978). When IA is used, one should be aware that the injected animals may sleep for a long time (up to 8h) even at a low dose (5 µg) (Coyle & Schwarcz, 1983). This might present a drawback for the behavioral assessment of the animals. Finally, care should also be taken to avoid non-enzymatic decomposition of IA since this chemical is thermolabile and photosensitive.

Acknowledgements

The authors wish to thank Drs Donato A. Di Monte, Jim Greene, J Timothy Greenamyre, Theresa Hasting, Jörg Schultz, and David Sulzer for their insightful comments on the manuscript, and Ms Pat White, Mr Brian Jones, and Mr Matthew Lucas for their help in its preparation. A genetic outline of the pathways to cell death in Alzheimer's disease, Parkinson's disease, frontal dementias and related disorders

John Hardy

Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, MD, USA

Over the last 10 years, genetic and pathological analysis has allowed the dissection of the major pathways to cell death in Alzheimer's disease, Pick's disease and Lewy body disease. The central findings are these.

First, the pathology of Alzheimer's disease consists of plaques, made of the A β peptide, derived from the APP protein, and neurofibrillary tangles made of the tau protein: Lewy bodies, made of the synuclein protein, are a frequent, but not invariant pathology of Alzheimer's disease (Hansen & Samuel, 1997).

Second, all pathogenic mutations in the APP and presenilin genes alter APP metabolism such that more of the peptide, A β 42, is produced (Hardy & Selkoe, 2002). These data suggest that A β is the primary molecule in the pathogenic cascade for Alzheimer's disease and that tau dysfunction and tangle formation are a necessary downstream event in disease pathogenesis and that α -synuclein dysfunction and Lewy body formation are an occasional downstream event in disease pathogenesis.

Third, mutations in the tau gene causes some frontal temporal dementias and other entities in which tau is deposited (Hutton *et al.*, 1998). In some sporadic tangle disorders, the tau haplotype is a risk factor for disease (Baker *et al.*, 1999). These data suggest that cell death and dementia are a consequence of tau dysfunction and tangle formation (Hardy *et al.*, 1998).

Fourth, mutations in the α -synuclein gene cause Parkinson's disease and other entities in which α -synuclein is deposited (Polymeropoulos *et al.*, 1997). In sporadic Lewy body disorders, the α -synuclein haplotype is a risk factor for disease (Farrer *et al.*, 2001a). These data suggest that cell death and dementia are a consequence of synuclein dysfunction and Lewy body formation.

Fifth, transgenic mice in which only A β levels are manipulated show plaque deposition, but only marginal cell loss (Irizarry *et al.*, 1997) and a subtle behavioral phenotype

(Morgan *et al.*, 2000): however, mice which have been primed for either tangle formation through a mutant tau transgene (Lewis *et al.*, 2000), or primed for α -synuclein pathology with an α -synuclein transgene (Masliah *et al.*, 2000), show much more fulminant pathology and cell loss (Lewis *et al.*, 2001; Masliah *et al.*, 2001), which, certainly in the case of the tau transgene, closely resembles the full pathology of Alzheimer's disease including the cell loss.

All of these genetic data, pathological data and data derived from mouse models can be incorporated into a remarkably simple scheme shown in Fig. 17.1, or represented by two alternate pathways for cell death shown in Figs. 17.2 and 17.3.

These skeletal pathways of pathogenesis are useful because they suggest points at which therapy might be aimed; however, they also provide a framework within which to discuss the many gaps in our knowledge.

Gaps in our knowledge

There are many gaps in our knowledge. It is most convenient to organize these gaps in a hierarchical fashion.

First, to what extent do the entities represent single pathogenic processes?

For Alzheimer's disease, the answer seems clear; the disease process seems to be similar in all cases since, with few exceptions, the final pathology is the same. For frontal dementias, the relationship between clinical phenotypes and pathogenesis is much less clear: some frontal dementias appear to have different pathologies and may therefore have either completely different, or may have overlapping pathogeneses. Conversely, some tangle disorders show no tau association or mutations suggesting that there are other

Fig. 17.1 Diagram showing the hierarchical relationship between APP/A β /plaques, tau/tangles and cell death based on observations in families with hereditary disease and on transgenic mouse models.

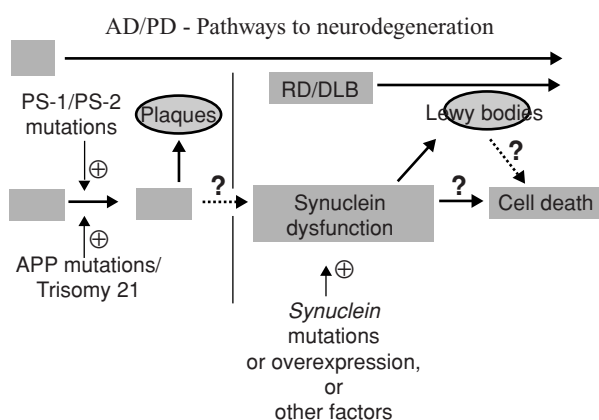

Fig. 17.2 Diagram showing the hierarchical relationship between APP/A β /plaques, α -synuclein/Lewy bodies and cell death based on observations in families with hereditary disease and on transgenic mouse models.

routes to this final pathway. Finally, for Parkinson's disease, the answer is extremely unclear: while some mutations in the parkin gene lead to disease with Lewy body pathology (suggesting a common pathogenesis: Farrer *et al.*, 2001b), the majority do not: thus, determining whether all cases of Parkinson's disease share a single pathogenic process is not yet possible.

Second: what other genes are involved in disease pathogenesis?

The answer to this question is dependent on the answers to the issues of whether the entities are single pathogenic entities, or multiple entities. Since the evidence is that Alzheimer's disease is indeed a single pathogenic entity, the strong suggestion is that any genetic loci which contribute to the familial clustering of late onset Alzheimer's

disease should be involved in A β production or clearance, as apolipoprotein E appears to be (Bales *et al.*, 1999). For frontal dementias, there are at least two extant linkages to chromosomes 9 and 3 (Hosler *et al.*, 2000; Brown *et al.*, 1995) but the pathology does not seem to involve tau, and thus the question as to whether identification of this gene will directly aid in developing an understanding of the tau pathway to cell death remains open. For Parkinson's disease, there are seven extant genetic linkages (Gwinn-Hardy *et al.*, 2002): in the absence of detailed neuropathological descriptions of the characteristics of these forms of Parkinson's disease, the pathogenesis of these forms of disease, relative to the synuclein pathway outlined above, remains uncertain.

Third, what are the relationships between the molecules involved in these pathogenic processes?

The outlined pathogenic pathways shown in Figs. 17.1 and 17.2 show clearly the deficits in our knowledge: perhaps most clearly, we do not know the nature of the interaction between A β or either tau or α -synuclein. However, at least we now have animal models in which these important issues can be probed.

Fourth, what are the toxic species of these pathogenic molecules?

The plaque, the tangle, and the Lewy body are the pathological hallmarks of these prevalent diseases and these lesions certainly mark damaged and dying neurons. It is not clear, however, whether these lesions are themselves damaging or merely relatively harmless space filling accumulations of material. While most recent data suggests that A β oligomers, rather than plaques, may be the primary pathogenic species, it is difficult to believe that the disruption to neuronal circuitry evident in a neuritic plaque is benign: perhaps, the A β deposited within the plaque acts as a reservoir for the toxic species. Similarly, it is not clear the extent to which tangles and Lewy bodies are damaging species or whether they too are "just" space-filling inert lesions and reflect dysfunction of the cognate protein. However, when one sees electron micrographs of neurons with tangles in them, it is difficult to imagine that they are benign since they can fill up one-third of the cells volume and apparently block off the axon hillock (Sumpter *et al.*, 1986). With respect to Lewy bodies, while one might previously have hypothesized that their formation reflects a disruption of normal α -synuclein function, the fact that individuals with a triplication of the α -synuclein locus develop severe Parkinson's disease with extensive Lewy body

formation (Singleton *et al.*, 2003) does not easily fit with the notion that the problem is caused by a lack of normal α -synuclein function. In both these cases it would seem likely that the visible pathological lesions contribute to the problem, although the possibility that pathologic oligomers contribute to the cellular dysfunction cannot be ruled out.

Experimental therapies based on the amyloid cascade hypothesis

The disease schemes outlined in Figs. 17.1 and 17.2 lead directly to suggestions concerning potential points of intervention. For Alzheimer's disease, if disease initiation represents the effects of a chronic imbalance between A β production and A β clearance, there are several ways in which the disease may be treated. Five broad strategies have been proposed with this idea in mind.

First, one could attempt to partially inhibit either of the two proteases, β - and γ -secretase, that generate A β from APP. In the case of the former enzyme, compound screening and medicinal chemistry are being vigorously pursued to identify potent small molecule inhibitors that can fit the large active site of this aspartyl protease and still penetrate the blood brain barrier. In the case of the latter, potent membrane-permeable inhibitors are already in hand, but their testing in humans has barely been attempted, in light of the theoretical concern that most such compounds might interfere importantly with signaling by Notch proteins and other cell surface receptors which would likely lead to serious disorders in turn (Haass & DeStrooper, 1999).

Second, one could attempt to prevent the oligomerization of A β or enhance its clearance from the cortex. This approach is exemplified by the use of active or passive A β immunization, in which antibodies to A β decrease cerebral levels of the peptide by promoting microglial clearance (Schenk *et al.*, 1999; Bard *et al.*, 2000) and/or by redistributing the peptide from the brain to the systemic circulation (DeMattos *et al.*, 2002). Although active immunization with synthetic A β 1–42 peptide produces robust benefits in APP transgenic mice without detectable toxicity, the recent extension of this approach to AD patients resulted in a small but unacceptable fraction of the study subjects developing a usually transient CNS inflammatory reaction which, in a few cases, was fatal (Nicoll *et al.*, 2003), precluding further testing with this preparation. Of note, those who were enrolled in the clinical trial surely had a significant plaque and tangle burden: it is possible that if this treatment were possible very early, even presymptomatically in the course, this unacceptable adverse effect could be

avoidable. Analysis of a subset of A β immunized patients suggested that the treatment may have slowed disease progression (Hock *et al.*, 2003) although definitive conclusions on this await the report of the analysis of the whole trial (Winblad & Blum, 2003). Several alternative preparations intended to provide A β antibodies by either active or passive routes have been formulated (e.g. Weiner *et al.*, 2000), and one or more of these is likely to reach clinical testing before long.

The third broad approach to the treatment of Alzheimer's disease is anti-inflammatory. This strategy was initiated based on evidence that a cellular inflammatory response in the cortex is elicited by the progressive accumulation of A β (Rogers *et al.*, 2002). Additionally, it has recently been shown that some anti-inflammatory drugs may have direct effects on the cleavage of APP by γ -secretase, independent of their inhibition of cyclo-oxygenase 2 and other inflammatory mediators (Weggen *et al.*, 2003). Some such drugs have been shown to reduce cytopathology in APP transgenic mice (Lim *et al.*, 2001; Jantzen *et al.*, 2002).

The fourth approach is based on modulating cholesterol homeostasis (Burns & Duff, 2003). Chronic use of cholesterol-lowering drugs has recently been associated with a lower incidence of AD (Wolozin *et al.*, 2000; Jick *et al.*, 2000). Concurrently, high cholesterol diets have been shown to increase A β pathology in animals (Sparks *et al.*, 2000; Refolo *et al.*, 2001), and cholesterol-lowering drugs have been shown to reduce pathology in APP transgenic mice (Refolo *et al.*, 2000). These effects seem to be caused by a direct (though poorly understood) effect of cholesterol on APP processing (Fassbender *et al.*, 2001; Wahrle *et al.*, 2002). A particular advantage of this approach is that statin drugs are generally well tolerated and have already been widely prescribed. Again, clinical trials are under way.

The fifth approach is based on the surprising observation that A β aggregation is, in part, dependent on Cu²⁺ and Zn²⁺ ions (Bush *et al.*, 1994). This has led to the suggestion that chelation of these ions may have therapeutic potential and clinical trials of such a chelating agent, clioquinol, which has been used "successfully" in the transgenic model (Cherny *et al.*, 2001), are currently under way.

Another approach would be to try and break the link between A β and tangle formation: this approach has only been amenable to experimental attack since the development of mice in which both pathologies occur (Lewis *et al.*, 2001). One approach which may have merit is to inhibit glycogen synthase kinase-3 β as this seems to be one of the key enzymes involved in tau phosphorylation and this seems to be a key initiator of tangle formation (Takashima *et al.*, 1998). While inhibiting tangle formation would have

the potential merit of being a useful therapeutic approach for other diseases such as progressive supranuclear palsy as well as for Alzheimer's disease, it has the potential drawback of allowing other routes to cell death, such as the α -synuclein pathway, come into operation.

Conclusions

We are at a pivotal point in research into neurodegenerative diseases: currently, all the therapies for these diseases are based on transmitter replacement approaches and not on dealing with underlying pathogenic mechanisms. Now, especially for Alzheimer's disease, but increasingly for the other diseases reviewed above, we are beginning to understand the mechanisms underlying cell death and to believe that we can alter these underlying mechanisms: over the next few years, it is to be hoped that this apparent understanding does indeed lead to a radically different, and more mechanistic approach to therapy for these devastating and prevalent disorders.

Neurophysiology of Parkinson's disease, levodopa-induced dyskinesias, dystonia, Huntington's disease and myoclonus

Antonio Currà, Rocco Agostino and Alfredo Berardelli

Department of Neurological Sciences and I.N.M. Neuromed IRCCS, University of Rome "La Sapienza", Italy

Introduction

Movement disorders are a disease group related to functional or structural abnormalities of the basal ganglia.

The term "basal ganglia" refers to the following structures: the striatum (caudate and putamen), globus pallidus (internal and external segments, GPi and GPe), subthalamic nucleus, and substantia nigra (SN) (SN pars compacta, SNpc, and SN pars reticulata, SNpr). The striatum receives connections from specific cortical areas and from the SNpc; the basal ganglia output nuclei, the GPi and SNpr, exert an inhibitory effect on the thalamus. Diminished phasic activity in the GPi/SNpr disinhibits the thalamus thus facilitating cortical motor areas, whereas increased phasic activity in the GPi/SNpr causes the opposite effect. The GPi–SNpr inhibition of the thalamus is modulated through two parallel pathways. According to the classical model of basal ganglia functioning (Albin *et al.*, 1989; Alexander & Crutcher, 1990; Alexander *et al.*, 1990; De Long, 1990; Parent & Hazarati, 1995; Wichmann & De Long, 1996) the first is an inhibitory "direct" pathway that originates in the striatum and projects directly onto the GPi/SNpr; the second is an "indirect" inhibitory pathway that crosses the GPe and subthalamic nucleus to project indirectly onto the GPi/SNpr. Activation of the direct pathway tends to disinhibit the thalamus. Activation of the indirect pathway disinhibits the subthalamic nucleus thereby increasing GPi/SNpr excitation thus resulting in increased thalamic inhibition: the two parallel circuits have an opposing action on the GPi/SNpr and hence on the thalamus. The direct pathway plays a positive feedback role on central motor areas and facilitates movement; the indirect pathway plays a negative feedback role and suppresses unwanted motor activity (Fig. 18.1).

Because movement disorders present with distinct clinical features, they can usually be differentiated on clinical grounds alone. The role of neurophysiological techniques in the clinical setting is chiefly to provide supplementary information in atypical cases and in patients in whom clinical features alone fail to specify the precise movement disorder.

The most prominent role of neurophysiological techniques is to increase our understanding of the mechanisms and pathophysiology underlying these diseases. A review of all neurophysiological studies in neurodegenerative diseases is beyond the scope of a single chapter, and certain specifics are covered in chapters discussing individual diseases in detail. In this chapter we therefore chose to review the neurophysiological findings and the results obtained from neurosurgical interventions in patients with Parkinson's disease (and levodopa-induced dyskinesias), dystonia, Huntington's disease, and myoclonus. Readers will find additional information in the tables summarizing the currently available neurophysiological tests (Table 18.1) and their use in neurodegenerative disorders (Table 18.2).

We based our selection of the topics to review on the two criteria. First, the importance and the greater understanding of the disease; second, the conditions we have chosen serve as examples of the use of some electrophysiological techniques and the insights that they provide.

Parkinson's disease (PD)

Parkinson's disease is a neurodegenerative disease primarily due to the progressive loss of neurons in the pars compacta of the substantia nigra. The main motor symptoms of PD are bradykinesia, rigidity and tremor.

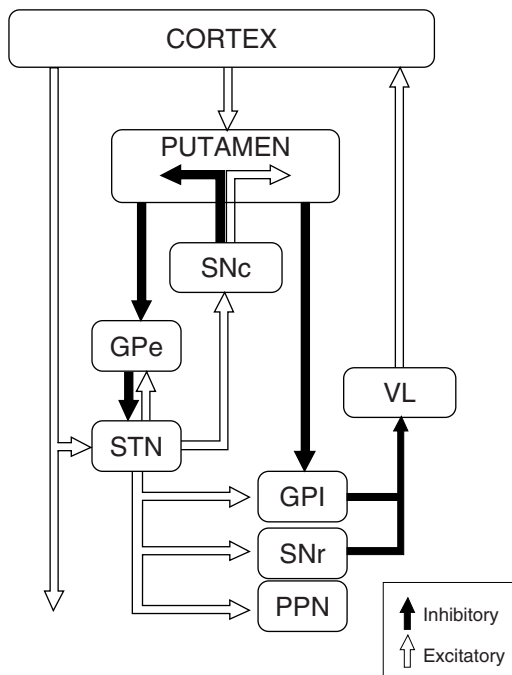

Fig. 18.1 Physiological model of the basal ganglia thalamo-cortical motor circuit under normal conditions. Indirect and direct pathways from the striatum are labeled. GPe and GPI, external and internal segments, respectively, of the globus pallidus; PPN pedunculopontine nucleus; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulata; STN, subthalamic nucleus; VL ventrolateral thalamus.

Neurophysiological findings obtained in experimental parkinsonism and in patients undergoing surgery

In patients with PD an abnormal output from the basal ganglia generates error signals. Recordings from GPI and STN cells show hyperactivity in patients off-medication and reduced rates after dopaminergic activation by apomorphine injection. Conversely, GPe cells fire at low rates in the off-medication period, and the rates increase when patients are on-medication (Hutchison *et al.*, 1997, 1998; Stephani *et al.*, 1997). Increased output from the GPI neurons modifies the activity in the thalamo-cortical neurons and consequently in the cortical motor areas (Berardelli *et al.*, 2001; Marsden & Obeso, 1994).

Important physiological measures of basal ganglia function include not only the absolute level of discharges but also the temporal and spatial pattern of output from GPI and SNpr (Berardelli *et al.*, 1998). A normal discharge pattern might help focus cortical activation so that appropriate muscles are activated and others suppressed during performance of a task. In Parkinson's disease, the

temporal variability of pallidal discharges increases, and discharges tend to be more synchronized between distant cells in parkinsonian patients than in the healthy state.

Bradykinesia: EMG, movement studies, sensorimotor integration studies, movement-related potentials, transcranial magnetic stimulation

To investigate the causes of bradykinesia, EMG and kinematic recording techniques (trajectories, velocity, and acceleration) have been used to study patients with PD during voluntary movement tasks (Berardelli & Currà, 2002; Berardelli *et al.*, 2001). The movements studied are classically of two types: simple movements (performed under isometric or isotonic conditions and by activating a single joint) and complex movements (combination of several simple movements executed sequentially or simultaneously).

In normal subjects performing rapid simple voluntary movements, EMG recordings from agonist and antagonist muscles show three successive phases of activity forming a "triphasic pattern": the first "burst" of activity in the agonist muscles (AG1) produces the force required to move the limb, the second antagonist (ANT) muscle burst stops the movement at the desired point, and the third antagonist muscle burst (AG2) serves mainly to stabilize the limb when it approaches the target point. This triphasic pattern originates in the central nervous system and is modulated by inputs of various origins. Parkinsonian patients perform "simple" rapid movements with cycles of multiple EMG "bursts" and are slower than normal subjects in initiating and performing movements (Berardelli *et al.*, 2001; Hallett & Khoshbin, 1980). The AG1 "burst" is insufficient not because the production mechanism saturates but because patients are unable to adapt activation to movement amplitude ("scaling" defect) (Berardelli *et al.*, 1986b). Patients with PD tend to compensate the defective activation of AG1 with multiple EMG activations (Fig. 18.2).

Simple clinical observation of parkinsonian patients suggests as a key feature of their motor disorder abnormal performance of "complex" movements (Agostino *et al.*, 1998). Defects have been reported in simultaneous isotonic elbow flexion and isometric thumb and finger oppositions. Unlike normal subjects, patients with PD accomplish single movements executed separately faster than the same single movements executed simultaneously (Benecke *et al.*, 1986, 1987). Baseline hypometria also worsens when patients are distracted by a second simultaneous non-motor task (for example a lexical decision). Hence the difficulty in executing simultaneous movements is not simply due to

Table 18.1. Neurophysiological investigations for neurodegenerative disorders

Neurophysiological test	Description
Accelerometry and EMG analysis of tremor	Frequency and amplitude recordings of tremor by devices applied to the trembling body parts; surface EMG recording of the activity evoked in at least two antagonistic muscles involved in the tremor
Resetting of tremor rhythm	Resetting of tremor rhythm at accelerometry and EMG following various perturbing events (muscle stretch, mechanical perturbation, electrical stimulation of peripheral nerves, transcranial electric or magnetic stimulation)
EMG analysis of fast single joint movements	Surface recording of agonist and antagonist muscles acting at the joint
EMG analysis of involuntary movements	Surface EMG recording of the activity evoked in the muscle involved in the involuntary movement
EMG analysis of external anal sphincter	Needle recording of motor unit potentials in the external anal sphincter
Blink reflex excitability	Surface recording of the R2 component of the blink reflex from the orbicularis oculi muscles following paired electrical stimuli at various interstimulus intervals (ISI) or electrical repetitive single stimuli delivered at fixed rate
Facial reflexes to upper limb stimulation	Simultaneous EMG recording in upper and lower facial muscles of the activity evoked by electrical stimulation of the median nerve at the wrist
Auditory startle responses	Surface EMG recording in various cranial and limb muscles of the responses evoked by high-intensity auditory stimuli which differ randomly in tonal frequency and intensity, and delivered at very long ISIs (minutes)
Reciprocal inhibition	EMG recording of the H reflex in forearm flexor muscles conditioned by a radial nerve stimulus delivered at various ISIs
Stretch reflexes and long-latency reflexes	EMG recording in limb muscle of the activity evoked by muscle stretching or electrical stimulation of a mixed/cutaneous nerve
Motor potential (MEP) evoked by transcranial magnetic stimulation (TMS)	EMG recording of the compound motor action potential evoked by TMS of the motor cortex
TMS-induced silent period	Period of inactivity in the EMG recordings during voluntary contraction induced by single pulse TMS of the motor cortex
Intracortical inhibition to paired-pulse TMS	MEP size reduction following paired pulse TMS at short (1–5 ms) or long (100–150 ms) ISIs
Premotor potentials	Slow rising negative EEG waves recorded from the scalp before the onset of a self-paced voluntary movement (Bereitshaftpotential), or between the warning and the go signal in a reaction time paradigm (Contingent Negative Variation)
EEG analysis of myoclonus with or without back-averaging	Scalp recording of the EEG activity simultaneous or preceding the myoclonus detected by polygraphic EMG
Somatosensory, visual and auditory evoked potentials	Averaged scalp recordings of cortical and subcortical activity evoked by peripheral multimodal sensory stimuli
Autonomic nervous system testing	Specific tests designed to investigate the autonomic function in the cardiovascular, genito-urinary, gastrointestinal, cutaneous, and ocular districts

altered planning of two simultaneous movements. Similar abnormalities are seen for sequential movements (Benecke *et al.*, 1987; Berardelli *et al.*, 1986a). When patients with PD perform short motor sequences of various types, movement times are longer for each movement in the sequence than for the same movement performed separately. An abnormally long interval also elapses between the end of one movement and the beginning of the next, showing a defect in assembling two sequential motor programs. The

difficulty in producing sequential movements (improved by dopaminergic treatment) becomes increasingly evident as the motor sequence progresses (sequence effect) and involves passing from one movement to the next (Agostino *et al.*, 1992, 1994).

Studies of sequential finger oppositions in patients with PD show that bradykinesia impairs individual more than non-individual finger movements (Agostino *et al.*, 2003). Patients perform these movements slowly and with

Table 18.2. Neurophysiological investigations in neurodegenerative movement disorders

Disease	Neurophysiological test	Expected finding
Parkinson's disease	Tremor accelerometry	Measure of tremor frequency
	EMG analysis of tremor	Alternating, co-contracting pattern
	Postural tremor resetting	By mechanical, peripheral electric, transcranial electric and magnetic stimulation
	EMG analysis of fast single joint movement	Defective scaling of the first agonist burst
	EMG analysis of external anal sphincter	May be neurogenic in longstanding patients
	Blink reflex excitability	Enhanced
	Auditory startle responses	Delayed
	Reciprocal inhibition	Abnormally modulated before movement
	Long-latency and stretch reflexes	Enhanced amplitude
	Premotor potentials	Reduced amplitude
	Central motor conduction time to TMS	Normal
	TMS-induced silent period	Shortened
	Intracortical inhibition to paired-pulse TMS	
Autonomic nervous system testing	Abnormal	
Corticobasal degeneration	EMG analysis of external anal sphincter	Neurogenic
	Blink reflex excitability	Normal
	Somatosensory evoked potentials	Abnormal or absent frontal component
	Central motor conduction time to TMS	May be prolonged
	MEP to TMS	May be increased
	Paired-pulse TMS (inhibition, facilitation)	Increased size of conditioned MEP
Progressive supranuclear palsy	EMG analysis of external anal sphincter	Neurogenic
	Facial reflexes to median nerve stimulation	Absent responses in upper facial muscles
	Blink reflex excitability	Enhanced
	Auditory startle responses	Strongly delayed or absent
	Central motor conduction time to TMS	May be prolonged
MEP to TMS	May be abnormal	
Multiple system atrophy	EMG analysis of external anal sphincter	Neurogenic in almost all patients
	Blink reflex excitability	Enhanced
	Auditory startle responses	Enhanced and exaggerated
	Central motor conduction time to TMS	May be prolonged
		May be abnormal
	Multimodal sensory evoked potentials	May be abnormal
Autonomic nervous system testing	Abnormal	
Dystonia	EMG analysis of fast single joint movement	Increased duration of EMG bursts; co-contraction; overflow
	EMG analysis of involuntary movements	Very long bursts; co-contraction; exacerbation during voluntary movement
	Blink reflex excitability	Enhanced
	Reciprocal inhibition	Abnormal early and late phase
	Long latency reflexes	LLR-1 amplitude may be enhanced; LLR2 may be decreased in amplitude or absent
	Premotor potentials	Reduced amplitude
	Central motor conduction time to TMS	Normal
	TMS-induced silent period	Shortened
	Intracortical inhibition to paired-pulse TMS	Reduced
	Somatosensory evoked potentials	Abnormal spatial and temporal summation; abnormal premovement gating

Table 18.2. (cont.)

Disease	Neurophysiological test	Expected finding
Huntington's disease	EMG analysis of fast single joint movement	Disorganised triphasic pattern, variable duration of EMG bursts
	EMG analysis of involuntary movements	Variable and random patterns of muscle activation
	Blink reflex excitability	Reduced
	Long-latency and stretch reflexes	Reduced or absent M2; delayed LLRs in leg muscles
	Central motor conduction time to TMS	Normal
	TMS-induced silent period	Often prolonged; may be reduced in rigid patients
	Premotor potentials	Absent before choreic movement
Myoclonus	Somatosensory evoked potentials	Reduced amplitude of early cortical components
	EMG analysis of involuntary movements	Short-duration EMG bursts in cortical jerks
	Long latency reflexes	Increased amplitude
	EEG analysis (back-averaging technique)	Positive EEG transient before muscle jerk in cortical myoclonus
	Somatosensory evoked potentials	Often giant potentials in cortical myoclonus
	Central motor conduction time to TMS	Normal
	TMS-induced silent period	May be shortened
Essential tremor	Intracortical inhibition to paired-pulse TMS	Reduced
	Accelerometry	Frequency, amplitude and power spectrum
	EMG analysis of two antagonist muscles	Co-contracting, alternating pattern
	Tremor resetting	By mechanical, peripheral electric, transcranial electric and magnetic stimulation
	Long latency reflexes	LLR1 may be increased

reduced amplitude, but their slowness worsens as finger oppositions progress predominantly when patients have to move fingers individually. This finding suggests that finer cortical control is needed to promote and sustain the highly fractionated motor output responsible for individual finger movements.

Kinematic defects in producing sequential movements have been described also in motor tasks requiring bimanual simultaneous movements or reaching a target in space, normal activities of daily life such as drinking from a cup, or grasping a small object and placing it on top of a larger one (Bennett *et al.*, 1995). The conclusions of these studies is that bradykinesia originates mainly from abnormalities in movement execution.

Patients with PD are abnormally dependent on sensory information for motor performance, especially on visual information available during the task. Various studies have shown that the difficulty in executing movements diminishes when patients are allowed visual control (Georgiou *et al.*, 1993, 1994). In a series of experiments involving the sequential pressing of ten illuminated or non-illuminated buttons, the PD group's slow motor

performance in sequential motor tasks worsened without illumination and improved when they received acoustic stimuli. In various motor tasks, such as walking, writing and daily activities, patients with PD can at least partly reduce their bradykinesia by using external visual and non-visual stimuli to improve their degree of attention.

Sensorimotor integration refers to those cerebral processes that link sensory input to motor output to produce appropriate voluntary movements (Abbruzzese & Berardelli, 2003). Many studies have been designed to investigate whether, and to what extent, abnormal sensorimotor integration is responsible for bradykinesia in parkinsonian patients. Among tasks studied is precision gripping of an object between the thumb and index finger and raising the index finger, or maintaining the index finger at a fixed height above a table, applying various load perturbations under the two conditions (Fellows *et al.*, 1998). Another study investigating discrimination between two points and the positional sense of patients with PD reported diminished precision (Demirci *et al.*, 1997). A study of limb movements that tested the effects of visual and kinesthetic information reported altered peripheral feedback (Klockgether

Fig. 18.2 Rapid movements performed at a single joint (15° and 60° of movement amplitude) in a normal subject and a patient with Parkinson's disease (off and on therapy). The normal subject performed the movement with a single triphasic pattern in the agonist and antagonist muscles, whereas the patient performed the movement with multiple EMG bursts. EMG activity was recorded from forearm flexors (FF) and extensors (FE) muscles. (From Berardelli *et al.*, 1986, with permission.)

et al., 1995). Last, when parkinsonian patients use kinesthetic information to approach a visual target they perceive distances as shorter than they really are. All these observations imply that altered sensorimotor integration is among the causes of hypometria or bradykinesia and that kinesthesia may have a role in the pathophysiology of PD. What remains unclear is whether the motor deficit originates from changes in peripheral cutaneous receptors or from abnormal central processing of this afferent input due to basal ganglia dysfunction.

Bradykinesia: cortical function (reaction times, movement-related potentials, magnetic stimulation)

Studies of reaction times (RT) and premotor potentials have provided information on abnormal motor

programming in PD (Evarts *et al.*, 1981; Jahanshahi *et al.*, 1992, 1993, 1995). The term RT refers to the interval elapsing between the stimulus to move and movement initiation. In simple RT (sRT) experiments subjects receive a complete advance description of the required movement so that they can preprogram it. In choice RT (cRT) experiments they receive only a partial description of the movement so that the movement can be only partially preprogrammed. Numerous studies have provided evidence of increased RTs in parkinsonian patients whereas the results for cRTs are controversial. Among the various mechanisms held responsible for increased RTs are difficulty in incorporating advance information into the motor plan, in retaining the appropriate motor programs in memory and in enacting them. Regardless of the precise mechanisms responsible, increased RT implies that preparation for voluntary movement is in some way abnormal in PD.

In normal subjects, preparation for movement can also be studied by recording the slow-rising negative EEG potentials generated before the onset of a voluntary movement (premotor potentials). The premotor potential (bereitschaftspotential, BP) begins during the 2 seconds that precede the onset of self-initiated movements and can be recorded from the scalp. The BP comprises two components: the early component (BP1) is a bilateral, symmetric negative potential that precedes the onset of movement by 1–2 seconds and increases to reach maximum amplitude at the vertex. The late component (BP2) precedes the onset of movement-related EEG activity by 650–50 ms. Recordings from subdural electrodes have shown that the BP1 component predominantly reflects the activation of the primary motor area and supplementary motor area (SMA), whereas BP2 originates exclusively from the primary motor area (Ikeda *et al.*, 1992). In patients with PD in the “off” condition the amplitude of the BP1 is reduced whereas the amplitude of BP2 is increased. The reduction of the early BP component has been attributed to reduced SMA activation, compensated during the preparation for movement by hyperactivity in the lateral motor areas (Cunnington *et al.*, 1995; Dick *et al.*, 1989).

In normal subjects, transcranial magnetic stimulation (TMS) primarily activates the motor cortex and elicits recordable EMG responses in limb muscles contralateral to the stimulated hemisphere (motor evoked potentials, MEP), due to activation of the corticospinal system (Hallett, 2000). Most investigators also report that these patients have normal motor threshold, defined as the minimum stimulation intensity required to evoke a MEP (Dick *et al.*, 1984). Experiments investigating changes in MEP amplitudes as a function of stimulus intensity and degree of voluntary contraction have shown that stimuli of

equal intensity delivered at rest induce abnormally large-amplitude MEPs in patients with PD. Conversely, stimuli of similar intensity delivered during a muscle contraction elicit abnormally small-amplitude MEPs (Valls-Solè *et al.*, 1994).

As well as inducing an MEP, magnetic stimuli delivered during a voluntary contraction induce a period of EMG inactivity termed the silent period (SP) that lasts about 200 ms. Consensus is that the interruption of voluntary EMG activity originates from the cortex possibly through the activation of inhibitory interneurons that project onto pyramidal cells in the motor cortex. Patients with PD have an abnormally short-lasting SP (Cantello *et al.*, 1991; Priori *et al.*, 1994a). This reduction may depend on a loss of striatal dopamine that, by increasing GPi/SNr inhibition on the thalamus in turn, results in reduced cortical facilitation. Besides improving patients' clinical conditions, dopaminergic therapy lengthens the SP (Priori *et al.*, 1994a), whereas surgical therapy lengthens or shortens the SP duration according to the lesion/stimulation site and the pre-surgery clinical condition (Chen *et al.*, 2001; Cunic *et al.*, 2002; Strafella *et al.*, 1997; Young *et al.*, 1997).

Another application of TMS consists of delivering paired pulse in a conditioning–test paradigm at various interstimulus intervals (ISIs). This experimental technique is used to study the intracortical inhibitory and excitatory circuits. Patients with PD tested at rest with short ISIs have reduced intracortical inhibition, thought to reflect altered basal ganglia input (Ridding *et al.*, 1995a). When suprathreshold conditioning-test stimuli are delivered at long ISIs, inhibition increases at ISIs of 100 and 150 ms. The reduced thalamic excitatory action on cortical motor areas could therefore flatten the excitability curve of the motoneuronal pool thereby facilitating tonic activity thus inhibiting the final increase in excitability needed for rapid motor tasks (Berardelli *et al.*, 1996b).

This interpretation is in line with findings reported in studies using repetitive TMS. Modern magnetic stimulating devices allow stimuli to be delivered in trains (rTMS) at various frequencies and intensities. In normal subjects, during rTMS trains at 5 Hz the MEP to each stimulus progressively increases in size. This effect is absent in parkinsonian patients in the “off” state and is partially restored with dopaminergic medications. Reduced MEP facilitation together with normal SP lengthening during rTMS in patients with PD reflects a decreased facilitation of the excitatory cells in the cortical motor areas (Gilio *et al.*, 2002).

A recent application of TMS techniques is to investigate how cortical excitability changes during the

transition from rest to voluntary movement, by delivering single or paired-pulse during the reaction time. In patients with PD, the period of increasing excitability before EMG onset is prolonged and the rate of rise slower than normal (Pascual-Leone *et al.*, 1994; Chen *et al.*, 2001b). The period of increased excitability following EMG offset is also prolonged (Chen *et al.*, 2001b). Thus, both activation and deactivation of the corticospinal system associated with simple movements is slower in PD.

Conclusions on bradykinesia

The data reviewed suggest that the main deficit underlying bradykinesia is an insufficient recruitment of muscle force during the initiation of movement. Important features are the underscaling of muscle force and increased dependence on external cues. Bradykinesia seems to result primarily from the underscaling of movement commands in internally generated movements (Currà *et al.*, 1997; Klockgether *et al.*, 1995). This defect reflects the role of the basal ganglia in selecting and reinforcing the pattern of cortical activity during movement preparation and performance. Finally, other regions of the CNS can adapt to the primary basal ganglia deficit of PD (Berardelli & Currà, 2002; Berardelli *et al.*, 2001).

Tremor: neuroimaging and TMS studies

In patients with PD, tremor typically has a frequency of 4–5 Hz and manifests on the EMG with the alternating activation of agonist and antagonist muscles. Some patients also have action tremor (postural and kinetic), at a frequency ranging from 6 to 12 Hz. Tremor at rest can be reproduced in experimental animals with lesions of the ventromedial tegment of the mesencephalon that involve the nigro-striatal, cerebello-rubral, cerebellar-thalamic and rubro-olivary pathways. To produce tremor, the association between lesions of the nigrostriatal dopaminergic pathways and the cerebellar pathways seems to be important. Recent experimental observations in monkeys with MPTP-induced parkinsonisms have shown periodic discharges in the pallidal cells of the pars interna (GPi) and subthalamic nucleus at frequencies similar to those of tremor. An important role in producing tremor is played also by the thalamus and cerebral cortex. Accordingly, tremor can be reduced or abolished by lesions of these structures. The thalamic lesioning site that yields the greatest reduction in limb oscillations is the ventral intermediate nucleus (VIM). This small area contains large cells, is well developed in superior primates and humans and lies between the pars oralis of the posterior lateroventral nucleus (VPLo) and the

Fig. 18.3 Shortening reaction in Parkinson's disease. Electromyographic responses in tibialis anterior (shortening reaction) and lateral gastrocnemius (stretch reflex) produced by dorsiflexion stretch at three different acceleration levels (a,b,c) in a patient who was exerting a slight voluntary plantar flexion background force. (From Berardelli & Hallett, 1984, with permission.)

ventrolateral nucleus. Investigating the role of the motor cortex in tremor, Britton *et al.* (1992) noted that the tremor phase in patients with PD can be modulated by TMS most probably through the activation of cortical motor areas. Imaging studies using positron emission tomography (PET) have indicated a cerebellar role in tremor related to PD (Deiber *et al.*, 1993). In patients undergoing thalamic stimulation a reduction in tremor was associated with reduced regional blood flow to the median and paramedian rostral cerebellar areas. This reduction, mediated by the rubro-olivo-cerebellar circuit and activated by the cerebellar nuclei, is thought to represent the final inhibitory outcome of a central oscillator that passes through the VIM nucleus of the thalamus.

Cross-spectral analysis (including coherence and phase) of the electromyographic tremor activity in the arm, leg and neck muscles showed that multiple oscillators are responsible for the tremor in the different extremities (Raethyen *et al.*, 2000).

Rigidity: spinal and long loop reflexes, spinal inhibitory mechanisms

Although the increased muscle tone is thought to reflect patients' difficulty in maintaining muscles completely at rest, it is also secondary to the increased stretch reflex.

Numerous studies have shown that the monosynaptic spinal component of the stretch reflex is normal whereas the long-latency stretch reflex has an abnormally increased amplitude. Rigidity may therefore be caused by an increased long-latency stretch reflex (Rothwell *et al.*, 1983; Tatton & Lee, 1975). Long-latency reflexes (LLRs)

may be elicited also by electrical stimulation of the median nerve and recorded from thenar muscles under isometric contraction. These responses are thought to be mediated by transcortical anatomic circuits (thalamus, sensorimotor cortex, and spinal cord) and by functional changes in basal ganglia caused by hyperactivity in these circuits. In particular, the reduced SMA activation (present in parkinsonian patients) could reduce tonic inhibition of the long-latency reflexes. An alternative explanation is that the increased LLR depends on the increased activity in group II fibers (owing to their low conduction velocity these fibers result in long-latency muscle responses) (Berardelli *et al.*, 1983).

A recent study investigating the early and late facilitation of the quadriceps H reflex deriving from non-monosynaptic group I and group II excitations showed that group II facilitation was enhanced in the rigid lower limb of unilaterally affected PD patients (Simonetta Moreau *et al.*, 2002). Facilitation of the transmission in the interneuronal pathway activated by group II afferents in rigid lower limb is thought to result from a change in their descending monoaminergic inhibitory control.

Another possibility is that rigidity is caused by an increased shortening reaction to passive movements generated by joint and tendon organ afferents (Fig. 18.3) (Berardelli & Hallett, 1984).

Last, other possible pathophysiological mechanisms to explain rigidity in patients with PD are increased reciprocal inhibition between agonist and antagonist muscles, and reduced Ib tendon inhibition (Delwaide *et al.*, 1991). Reciprocal inhibition (RI) between agonist and antagonist muscles in the forearm consists of an initial short-lasting disynaptic Ia inhibitory phase followed

by a long-lasting, presynaptic, phase of inhibition of the large proprioceptive afferent fibers. Disynaptic Ia reciprocal inhibition acts, at the spinal level, by actively inhibiting antagonist motor neurons and reducing the inhibition of agonist motor neurons. Changes in these spinal circuits probably reflect the increased activity in the dorsal reticulospinal system. A recent study investigated the short-lasting inhibitory phase of RI at rest and at the onset of a voluntary wrist flexion (Meunier *et al.*, 2000). At rest, patients had normal RI. In contrast, before voluntary movements patients lacked the descending supraspinal modulation seen in normal subjects. On the less affected side, the descending modulation was present but less intense than in controls; on the more affected side, the modulation was almost absent. Recent studies also suggest that changes in the activity of the pedunculopontine nucleus – partly involving the ventral tegmental segment – contribute to changes in muscular tone.

EMG of the external anal sphincter for the differential diagnosis of parkinsonism

External and sphincter electromyography (Sph-EMG) is a helpful test to disclose Onuf's nucleus degeneration. Quantitative Sph-EMG in normal controls showed a trend for increased motor unit potential (MUP) amplitude, duration, area, and polyphasicity with advancing age (Giladi *et al.*, 2001). Pathological studies show that various neurodegenerative disorders including PD, multiple system atrophy (MSA), progressive supranuclear palsy (PSP), may reduce the neuronal population of this spinal nucleus far more than normal aging.

Multiple system atrophy (MSA) is a degenerative disease manifesting a combination of parkinsonism, cerebellar, pyramidal, and autonomic (including urinary, sexual, and anorectal) dysfunction. Compared with normal subjects patients with MSA almost invariably exhibit neurogenic abnormalities (Pramstaller *et al.*, 1995). A more recent study also showed MUP size and fiber density similar to normal subjects, but a reduced recruitment pattern and number of active MUPs at rest (Giladi *et al.*, 2001). Abnormal Sph-EMG has been found also in patients with MSA without clinical urological or anorectal problems (Giladi *et al.*, 2001), and may reflect either the decreased number of motor cells in Onuf's nucleus without significant consequential reinnervation, or upper motor neuron involvement affecting the anal sphincter in MSA.

In a recent study investigating Sph-EMG in patients with PD, patients with probable MSA of parkinsonian type (MSA-p), and patients with probable MSA of cerebellar type (MSA-c) abnormal, denervated Sph-EMG was observed in 95.7% of patients with MSA-p, 86.4% of those with MSA-c,

and 33.3% of those with PD. These results did not correlate with the severity of parkinsonism (Lee *et al.*, 2002). Previous papers showed that abnormalities in Sph-EMG were present early in patients with MSA, whereas similar abnormalities appeared only later (after 5 years or more) in patients with PD (Stocchi *et al.*, 1997). Because patients with early PD do not show severe Sph-EMG abnormalities (Pramstaller *et al.*, 1995) Sph-EMG helps to distinguish patients with PD from patients with other forms of parkinsonism in the first 5 years after the onset of symptoms and signs. Sph-EMG also distinguishes MSA from pure autonomic failure, as well as from cerebellar ataxias (if other causes of sphincter denervation have been ruled out) but not from progressive supranuclear palsy and corticobasal degeneration (Vodusek, 2001).

Levodopa-induced dyskinesias (LIDs)

Dyskinesias are one of the major problems in the long-term management of patients with PD. Patients manifest an array of motor symptoms that differ also in their time of onset after levodopa intake (Fahn, 2000).

Neurophysiological findings in experimental dyskinesias and during surgery

Early studies suggested that dyskinesias were due to reduced firing of neurons in the GPI, resulting in the loss of its inhibitory function on the thalamus and consequently in increased thalamo-cortical drive (Merello *et al.*, 1999; Wichmann & De Long, 1996). Evidence that lesions in the GPe did alleviate LIDs (Blanchet *et al.*, 1994), however, suggested that changes in the indirect pathway alone were not enough to generate LIDs. A recent neurophysiological study suggested that stimulation of the ventral pallidum controls dyskinesias by activating the large GPe axons responsible for inhibiting GPi neurons (Wu *et al.*, 2001). Not only abnormal firing rates but also changes in the quality of signaling, i.e. the pattern, synchronization, and somatosensory responsiveness, are responsible for the emergence of dyskinesias. Changes in the quality of signaling in the GPi neurons provoke corresponding changes in the activity of the thalamus that interfere with thalamo-cortical signal transmission. Disruption of the normal spatio-temporal pattern of cortical neuronal activity leads to disordered cortical output and altered motor control (Berardelli *et al.*, 2001). In patients with LIDs, most STN neurons have a high mean firing rate and an irregular firing pattern (Hutchinson *et al.*, 1998). Krack *et al.* (1999) found that off-period dystonia was associated with cellular hyperactivity, that diphasic dystonia reflected an altered pattern of STN

activity with alternating periods of hyperactivity, and that decreased activity in cells responsible for specific dyskinetic muscles and peak-dose dyskinesias were accompanied by STN hypoactivity.

EMG recordings

On surface EMG studies LIDs typically consist of synchronous or asynchronous irregular antagonist muscle bursts that last up to 500–800 ms (Hallett, 2000; Yanagisawa & Nezu, 1987). The most typical LID pattern is that of chorea associated with synchronous EMG activity. When LIDs manifest as repetitive alternating movements, the EMG pattern consists of asynchronous, alternating and pseudo-rhythmic bursts at about 1 Hz (Luquin *et al.*, 1992).

Blinking and brainstem function in patients with LIDs

Blinking is a function subserved by the brainstem trigeminal-facial circuitry that is sensitive to changes in brain dopamine concentrations. Spontaneous blinking is reduced in patients with PD and increases with dopamine replacement (Agostino *et al.*, 1987; Karson, 1983). The blink rate is faster in patients with LIDs (Karson, 1983).

The function of trigeminal–facial pathways in the brainstem may be studied by testing the blink reflex and masseter inhibitory reflex. In normal subjects, the blink reflex consists of an early unilateral response (R1), followed by a late bilateral response (R2). Excitability of the brainstem circuitry is commonly studied by investigating the blink reflex recovery curve. In parkinsonian patients the inhibition of the R2 component is reduced during the off state and increases during the on state (Agostino *et al.*, 1987). R2 inhibition is more intense in dyskinetic than in non-dyskinetic patients (Iriarte *et al.*, 1989). In conclusion, in off-therapy parkinsonian patients the deficiency of dopamine leads to decreased spontaneous blinking but increased blink reflex excitability. Excessively high dopamine plasma levels are necessary to reverse these abnormalities, because they disappear during peak-dose dyskinesias, but do not disappear with optimal treatment.

Primary dystonia

Dystonia is defined as a syndrome of sustained muscle contractions frequently causing twisting or repetitive movements or abnormal postures. Primary dystonia is the commonest form of dystonia and the term refers to patients who have no signs of structural abnormality in the CNS. Primary dystonia can be manifested as focal (writer's cramp,

torticollis or blepharospasm), segmental or generalized dystonia. Segmental dystonia affects two contiguous body parts, whereas generalized dystonia is more widespread and involves at least one lower limb plus another body segment. Focal dystonias affect only a single part of the body. These forms of dystonia include blepharospasm, cervical dystonia, and writer's cramp. An important feature in focal dystonia is that it is often task specific.

Neurophysiological findings in experimental dystonia and during surgery

The pathogenesis of dystonia depends partly on changes in the activity of the basal ganglia (GPi and STN) and thalamus (VOP/VIM). Animal studies suggested a lowered GPi output. Numerous studies in patients with dystonia have described a decreased mean discharge rate with a change in the pattern and somatosensory responsiveness of neurons in the internal and external pallidum (Krack *et al.*, 1999; Lenz *et al.*, 1998; Lozano *et al.*, 1999; Vitek *et al.*, 1998, 1999).

These findings suggest that hyperkinetic disorders result from underactive basal ganglia output (Krack *et al.*, 1999; Lenz *et al.*, 1998; Lozano *et al.*, 1999; Vitek *et al.*, 1998, 1999). Recent microelectrode exploration of the GPi in patients with segmental and generalized dystonia undergoing stereotactic surgery under local or generalized anesthesia showed that GPi firing rates and pattern change according to the type of anesthesia used. In patients who underwent surgery under local anesthesia, the mean GPi firing rate was similar to that observed in patients with PD, whereas in dystonic patients under propofol anesthesia, the mean GPi firing rate was substantially reduced, and the firing pattern characterized by long pauses in activity. These findings indicate that pathophysiology of dystonia does not rely on abnormally low basal ganglia output, and suggest that the widely accepted pathophysiological models of dystonia need to be reconsidered (Hutchison *et al.*, 2003).

EMG recordings

Dystonic movements are characterized by prolonged EMG bursts in agonist and antagonist muscles and by overflow activity in other distant muscles.

Brainstem reflexes

In patients with cranial dystonia, the recovery cycle of the late bilateral R2 component of the blink reflex, conditioned by electrical and photic stimuli, is enhanced (Berardelli *et al.*, 1985; Katayama *et al.*, 1996) (Fig. 18.4). The recovery cycle of the R2 component is abnormal also in patients

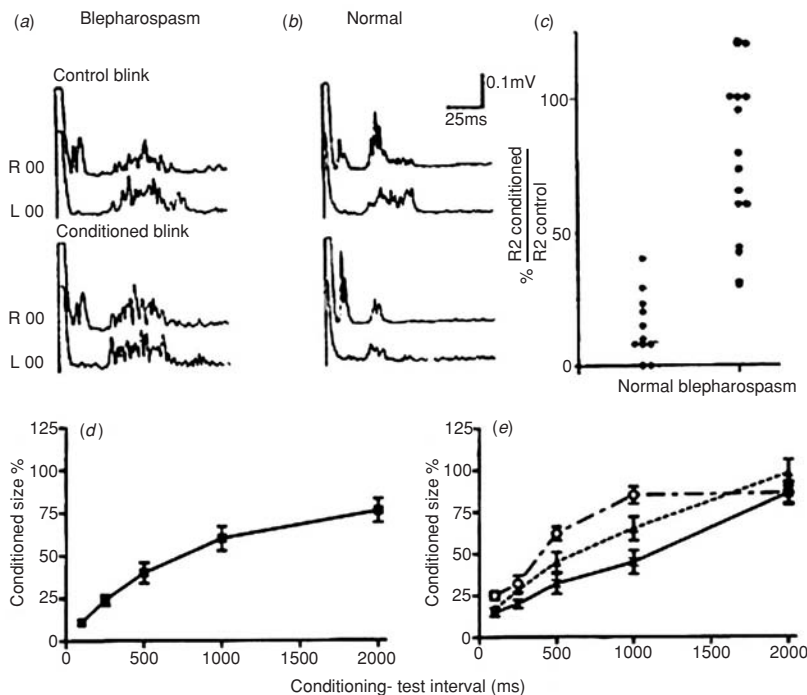

Fig. 18.4 Averaged data of the blink reflex from a representative patient with blepharospasm (a) and (b) a normal subject. Please note the increased duration and amplitude of the control and conditioned (interstimulus interval, ISI 500 ms) R2 responses. (c) Ratio between the amplitude of the conditioned and control R2 response in patients and controls at ISI 500 ms. (d), (e) The blink reflex recovery curve, i.e. the curve relating the amplitude of R2 response to the ISI. (d) controls; (e) crosses represent patients with arm dystonia; triangles represent patients with torticollis; circles represent patients with segmental dystonia. (Modified from Berardelli *et al.*, 1985, with permission.)

with dystonia without blepharospasm (Pauletti *et al.*, 1993). Prepulse inhibition was found to be abnormal in patients with blepharospasm: the R2 response of the blink reflex was abnormally gated by sensory stimulation, particularly in those patients who did not use a sensory trick (Gomez-Wong *et al.*, 1998).

Another way to investigate the function of trigeminal-facial pathways in the brainstem is to test the masseter inhibitory reflex. This response consists of an early phase (SP1), followed by a late phase (SP2) of inhibition in the ongoing EMG activity. The recovery cycle of the late phase of the masseter inhibitory reflex is enhanced in patients with cranial dystonia, even in those without jaw closing dystonia (Cruccu *et al.*, 1991).

Spinal reflexes and spinal inhibitory circuits

Vibration over the muscle tendon is an effective means for stimulating muscle spindle afferents (group Ia). After a short latency, in normal subjects vibration evokes a tonic contraction of the stimulated muscle, known as the tonic

vibration reflex. This response is mediated by spinal and supraspinal circuitry, and is abnormal in patients with hand dystonia. In patients with dystonia, after a short delay, vibration evokes dystonic contractions also in other muscles (Kaji *et al.*, 1995a). Despite having normal positional sense, patients with hand dystonia have severely impaired vibration-induced kinesthetic sense (Grunewald *et al.*, 1997), a finding that strengthens the notion of an abnormal sensory-motor link in dystonia.

In patients with writer's cramp, the late phase of reciprocal inhibition (RI), and sometimes both the early and late phases, are reduced (Nakashima *et al.*, 1989). Abnormalities in the presynaptic phase usually return to normal after botulinum toxin injection (Priori *et al.*, 1995). RI is also abnormal in the unaffected arms of patients with writer's cramp as well as in patients with cervical dystonia. Abnormal RI reflects altered processing of Ia input to the spinal cord in dystonia. The normalization of presynaptic inhibition after botulinum toxin is thought to be mediated by changes in the activity of intrafusal fibers that decrease the muscle spindle input to the spinal cord.

The technique of tendon stimulation allows one to study group III-elicited presynaptic inhibition of group I afferents (Priori *et al.*, 1998). In patients with dystonia, group III fibers exert an abnormal presynaptic inhibition on Ia fibers (Lorenzano *et al.*, 2000). Abnormalities in presynaptic inhibition could originate from abnormal supraspinal control of the interneurons that mediate presynaptic inhibition or from altered spinal input.

Movement studies

Besides abnormal movements, clinical observation also shows that patients with dystonia produce abnormal voluntary movement (Berardelli & Currà, 2002). In patients with dystonia the RT is normal during simple arm reaching movements (Inzelberg *et al.*, 1995), head rotation and finger extension (Kaji *et al.*, 1995b), and single pointing movements (Currà *et al.*, 2000b). Conversely, during tasks requiring consecutive motor responses, patients with generalized dystonia have slow RTs whereas patients with focal dystonia do not (Currà *et al.*, 2000b).

Patients with dystonia perform rapid elbow movements slowly and with variable amplitude, and the EMG activity shows longer agonist muscle bursts, co-contraction activity between agonist and antagonist muscles, and activity in remote muscles (van der Kamp *et al.*, 1989). EMG recordings during distal movements of isolated fingers in patients with hand cramps show a spread of EMG activity in muscles not directly involved in the desired movement (Cohen & Hallett, 1988).

Studies of arm reaching movements have also shown slowness, increased variability of movement, and a prolonged deceleration phase (Inzelberg *et al.*, 1995). During sequential movements patients with dystonia are slower than controls and take longer than controls to switch from one sub-movement to the next (Agostino *et al.*, 1992). In addition to this general impairment in the execution of sequential movements patients with generalized dystonia (but not patients with focal dystonia) are slower in executing self-initiated than externally triggered movements (Currà *et al.*, 2000b).

Sensory function and sensorimotor integration

Several studies have reported clinically detectable sensory abnormalities in dystonia. Discomfort, pain or kinesthetic sensations are frequently reported at various times before dystonia develops (i.e. patients with blepharospasm often complain of irritation or dry eyes) (Defazio *et al.*, 1998). Risk factors for the development of focal dystonia include

preceding loco-regional traumas and overuse of muscle groups.

Even though patients with dystonia have no abnormality in a single-touch, gross localization task, they perform worse than healthy subjects on somatosensory discrimination tasks. The abnormality correlates with the severity of dystonia (Bara-Jimenez *et al.*, 2000). Patients with generalized dystonia not only present with difficulties in timing functions but they also fail in cross-modal processing of visual–tactile stimuli (Aglioti *et al.*, 2003). Patients with hand dystonia are substantially worse also on graphesthesia and manual form perception (Byl *et al.*, 1996a). Functional MRI studies investigating the response in the primary sensory cortex to simultaneous tactile stimulation of the index and middle finger, and stimulation of each finger alone disclosed a non-linear interaction between the sensory cortical response to individual finger stimulation in patients with dystonia (Sanger *et al.*, 2002). These findings can be easily explained by observations from electrophysiology studies in a monkey model of focal dystonia disclosing noteworthy de-differentiation of sensory maps and the existence of single cells in hand regions of area 3b with enlarged receptive fields that extend to the surfaces of more than one digit (Byl *et al.*, 1996a). These changes may lead to abnormal processing of simultaneous sensory inputs and would explain clinical sensory deficits in human dystonia.

An important clinical feature of focal dystonia is the sensory trick (*geste antagoniste*), namely a tactile or proprioceptive sensory input to a nearby body part. This sensory input dramatically improves abnormal posture or movement. For example, in patients with blepharospasm, wearing sunglasses to avoid bright light effectively reduces contractions in the orbicularis oculi muscles.

The effectiveness of sensory tricks in improving dystonia suggests an abnormal link between muscle afferents and efferents in dystonia. Although traditional opinion considered the “sensory trick” as a sort of psychogenic manoeuvre for distracting patients’ attention, later physiological studies showed that it can actually modify EMG recruitment (Wissel *et al.*, 1999), and selectively affect dystonic tremor but not other forms of tremor (Masuhr *et al.*, 2000). In patients with cervical dystonia, PET scans showed that sensory tricks induce a perceptual dysbalance reducing the activation of the supplementary motor area and of the primary sensorimotor cortex (Naumann *et al.*, 2000). The additional sensory stimulus represented by the trick apparently acts by re-adjusting the abnormal link between afferent sensory input and movement output. Overall, current findings from neurophysiological investigations suggest a

sensory-motor mismatch in motor control in focal dystonia (Abbruzzese & Berardelli, 2003).

Cortical function (LLR, somatosensory evoked potentials, movement-related potentials, magnetic stimulation)

Patients with various forms of dystonia have abnormal LLR components, probably reflecting altered thalamo-cortical outflow to the supplementary motor area (Naumann & Reiners, 1997).

The studies that examined the frontal N30 component of the somatosensory evoked potentials (SEPs) in patients with dystonia provided conflicting results: some reported it to be increased (Reilly *et al.*, 1992), others reduced (Grissom *et al.*, 1995; Mazzini *et al.*, 1994) or normal (Nardone *et al.*, 1992). In patients with cervical dystonia the head position influences the amplitude of median SEPs (Kanovsky *et al.*, 1998). The study of the attenuation of SEPs or gating before a movement allows investigation of the relationship between sensory input and motor output (Murase *et al.*, 2000). In contrast to normal subjects, who had a substantial central gating of frontal N30 components, patients with focal hand dystonia had practically no gating of these components. Analysis of spatial and temporal summations of dual SEP inputs showed that these summations were less inhibited in patients with dystonia than in normal subjects (Tinazzi *et al.*, 2000). These findings suggest an abnormal control of sensory input in dystonia (Hallett, 1995).

The amplitude of the premotor EEG potential is depressed in patients with primary (van der Kamp *et al.*, 1995), secondary (Féve *et al.*, 1984), and focal dystonia (Deuschl *et al.*, 1995). Another movement-related EEG potential is the contingent negative variation (CNV) that is recorded from the scalp between a warning and a go stimulus in an RT task. The amplitude of the late component of the CNV is reduced in patients with torticollis during tasks imposing head turning (Kaji *et al.*, 1995b), and in patients with writer's cramp during tasks involving hand movements (Ikeda *et al.*, 1996). Hence, basal ganglia may have an important role in sensory gating at various cortical and subcortical levels (Kaji & Murase, 2001).

Studies with electrical (Thompson *et al.*, 1986) and magnetic (Mavroudakis *et al.*, 1995) stimulation showed that patients with primary dystonia have normal conduction along the corticospinal tract. They also have a normal threshold intensity for magnetic stimuli to induce MEPs. Increasing the levels of background contraction or stimulus intensities, the size of responses (input-output curves) increases more steeply in patients with dystonia than in

normal subjects (Ikoma *et al.*, 1996; Mavroudakis *et al.*, 1995). This defect possibly contributes to the excessive motor output that is typically present during action in these patients.

Investigations of the cortical SP, i.e. the silence in the EMG activity induced by a TMS pulse in contracting muscles, in patients with focal dystonias disclose shortened SP in upper limb muscles (Filipovic *et al.*, 1997; Ikoma *et al.*, 1996; Mavroudakis *et al.*, 1995; Rona *et al.*, 1998). In patients with focal dystonia, the SP is more prominently reduced in the cranial muscles than in upper limb muscles (Currà *et al.*, 2000c). This is of particular interest because the SP recorded in the facial muscle originates solely from intracortical inhibitory mechanisms.

Investigating dystonic patients with the paired-pulse technique at short ISIs in muscles at rest showed a diminished inhibition of the test response, suggesting decreased cortical inhibition (Gilio *et al.*, 2000; Ridding *et al.*, 1995b) (Fig. 18.5). Paired stimuli at long ISIs also showed an abnormal suppression of the test response in patients with dystonia (Chen *et al.*, 1997; Rona *et al.*, 1998). In a study investigating the effects of peripheral stimulation on intracortical inhibition in patients with cranial dystonia, the investigators showed that the inhibitory effect induced by conditioning stimulation of the median nerve is preserved, whereas in patients with focal hand dystonia it is lost and substituted by a paradoxical facilitation (Abbruzzese *et al.*, 2001). By investigating the inhibitory effect on the MEP size induced by peripheral stimulation of the cutis contiguous or non contiguous to the recorded muscle, Tamburin *et al.* (2002) found that, in patients with dystonia, the somatotopical arrangement of sensorimotor input-output organization is deranged.

TMS is also applied to map the motor cortex projections to the upper limb muscles. In patients with writer's cramp this TMS method has provided evidence of an altered corticomotor representation (Byrnes *et al.*, 1998). The distortion of cortical maps is temporarily reversed by botulinum toxin injections. Similar findings have been reported in patients with cervical dystonia (Thickbroom *et al.*, 2003).

The excitability of cortical motor areas in the phase preceding the onset of a voluntary wrist extension has been studied in patients with dystonia involving the upper limb by testing the MEP size and degree of intracortical inhibition during the reaction time (Gilio *et al.*, 2003). In dystonic patients, the MEP size and intracortical inhibition tested before movement lack the changes observed in normal subjects. In particular, the MEP size increase is lower and delayed, whereas the decreased intracortical inhibition

Fig. 18.5 Amplitude of the control and conditioned motor evoked potential in a representative normal subject and in a patient with upper limb dystonia studied before (T0), one month (T1) and three months (T2) after botulinum toxin injection into the affected muscles. Note the significant inhibition of the conditioned MEP amplitude in the normal subject and in the patient at T1, but not at T0 and T2 condition. EMG activity was recorded from forearm flexors. Horizontal calibration is 15 ms and vertical calibration is 0.5 mV. (From Gilio *et al.*, 2000, with permission.)

normally seen up to 60 ms before movement onset is absent. These findings suggest that patients with dystonia lack the normal cortical activation needed to produce movement.

Conclusions

The abnormalities typically seen in dystonic patients during voluntary movements are bradykinesia, co-contraction, and overflow of muscle activity (Berardelli & Currà, 2002; Berardelli *et al.*, 1998). Movement slowness predominantly affects self-initiated movements. The physiological abnormalities described in patients with (mainly focal) dystonia demonstrate a common pathophysiological mechanism of reduced inhibition (i.e. increased facilitation) at various levels of the motor system, including the spinal cord, brainstem, and cortical motor areas, probably at the level of interneuron function. In addition, growing evidence points to disturbed central processing of sensory input in the generation, maintenance, or even suppression of dystonic movements. The multilevel involvement in dystonia suggests an abnormality of a control structure. The most suitable candidates to exert this complex modulatory activity are the basal ganglia because they indirectly influence the cortical motor areas via the thalamus; the sensory cortices via their connections to cortical projections; and the brainstem and spinal cord motor circuitry by direct descending pathways.

Huntington's disease (HD)

Huntington's disease is an autosomal-dominant disease characterized by movement disorders (mainly choreic but also dystonic and myoclonic) and cognitive and behavioral changes. The pathological feature of HD is the degeneration of neurons in the caudate, the putamen and the globus pallidus.

Findings from experimental chorea

The degeneration of spiny neurons in the neostriatum is the main pathological feature of HD. Selective loss of striatal GABA/enkephalin neurons projecting to the external segment of the globus pallidus (GPe) is present in the early phase of the disease. Choreic movements result from the interruption of the indirect pathway (involving the striatal-external pallidum, subthalamic nucleus and internal pallidum). With advancing disease a loss of striatal GPi efferents (direct pathway) is also present (Albin *et al.*, 1992; Berardelli *et al.*, 1999; Crossman *et al.*, 1988; Mitchell *et al.*, 1989; Storey & Beal, 1993).

EMG recordings

EMG recordings of involuntary movements in choreic patients show bursts of EMG activity of variable duration with a random pattern of muscle activation and variable combination including co-contraction (Thompson *et al.*,

1988). As well as choreic movements, patients with HD may also manifest dystonic and myoclonic jerks.

Brainstem function

Patients with HD may also have abnormalities of the blink reflex, chiefly a prolonged latency and a greater habituation of the R2 response than normal (Agostino *et al.*, 1988; Caraceni *et al.*, 1976). Some of these abnormalities correlate with the distribution and severity of choreic movements in the face (Agostino *et al.*, 1988). They reflect reduced excitability of polysynaptic networks within the brainstem and indicate a depression of the blink reflex in HD.

Spinal cord function

Reciprocal inhibition between agonist and antagonists muscles has been investigated in patients with HD. In the arm muscles the second presynaptic phase of inhibition has been found to be reduced (Priori *et al.*, 2000). The most likely explanation for this abnormality is an abnormal descending control exerted by the basal ganglia on the spinal cord, possibly through the brainstem reticular formation. In the same patients, the H reflex recovery cycle studied with paired electrical shocks also showed an abnormally prominent facilitation. This increased excitability could be induced by the decreased presynaptic inhibition of the large muscle afferents. An interpretation of the spinal cord abnormalities is that the motor cortex in HD partly loses its inhibitory control, thus disinhibiting spinal cord circuitry (Priori *et al.*, 2000).

Movement studies

Early evidence in patients with HD showed prolonged reaction times for simple and complex finger movements (Hefter *et al.*, 1987; Jahanshahi *et al.*, 1993). More recent evidence that patients with HD have the same delay in the RT during simple and sequential motor acts indicates that impaired motor preparation in HD probably depends on kinematic variables other than the number of sub-movements (Currà *et al.*, 2000).

Patients with HD also perform simple voluntary movements slowly (Thompson *et al.*, 1988). This bradykinetic dysfunction is present from the early stages of the disease. In patients performing wrist flexion movements the EMG recording shows an abnormal pattern with prolonged bursts from the agonist and antagonist muscles. The duration of EMG bursts is variable and the sequence of agonist-antagonist contraction is often absent. In addition, movements are more variable in velocity and accuracy

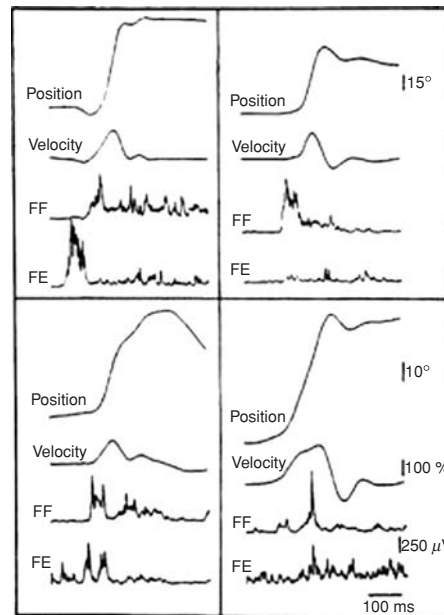

Fig. 18.6 Fast simple wrist flexion movements to 30° or 60° in patients with Huntington's disease. Please note that patients move slowly and with variable amplitude. Also the surface EMG is high variable. The first agonist burst (AG1) is poorly defined and the antagonist burst (ANT) starts either before or after the AG1 burst, and often these bursts coactivate. Plots of movement displacement, movement velocity, and EMG recordings from forearm flexors (FF) and extensors (FE) are shown. (From Thompson *et al.*, 1989, with permission.)

(Thompson *et al.*, 1988) (Fig. 18.6). Patients are also slow in executing repetitive finger movements (Hefter *et al.*, 1987).

Patients with HD are also bradykinetic in performing complex movements such as sequential hand squeezing-elbow flexing (Thompson *et al.*, 1988). In this task, patients are abnormally slow in executing each movement and in switching from one movement to the next. Both problems also affect their performance of sequential tracking arm movements. But unlike patients with Parkinson's disease, patients with HD do not have the accompanying progressive slowing with sequence completion (Agostino *et al.*, 1992). Patients with HD also have difficulty in adjusting movement execution to target size and movement length (Georgiou *et al.*, 1995, 1997). This applies also to free arm movements (Currà *et al.*, 2000a).

Sensorimotor integration

In patients with HD motor performance also depends crucially on how movements are cued. In two studies, Bradshaw *et al.* (1992) and Georgiou *et al.* (1995) showed that HD

patients are too reliant on external cues to sequence motor programs effectively. Investigating the kinematic variables of rapid sequential free arm movements executed with different types of submovement cueing, we studied how the same motor sequence was performed when subjects had to initiate movements in response to consecutive visual go signals (externally triggered condition) or when they could start the movement at will (self-initiated condition) (Currà *et al.*, 2000). Patients performed both tasks slowly. Although both groups executed externally triggered tasks slower than self-initiated tasks, the time needed to perform the two tasks differed less in patients than in controls, suggesting that HD impairs internal more than external cueing mechanisms. In contrast, two further studies showed that, in patients with HD, auditory cues improved neither the performance of bimanual coordination (Johnson *et al.*, 2000) nor gait (Churchyard *et al.*, 2001). A recent study showed that patients with HD were slow across all cue types especially in the absence of external visual cues. They also derived no benefit from an external auditory timing cue in unimanual upper limb movements.

Cortical function (LLR, SEPs, premotor potentials and TMS)

Some patients with Huntington's disease also have reduced or absent long-latency stretch reflexes in hand and arm muscles (Noth *et al.*, 1985; Thompson *et al.*, 1988). These abnormalities are not present in other choreic disorders, implying that they are related to the underlying pathology of HD rather than to the chorea itself.

A commonly reported abnormality in HD is a reduction in the size of the SEPs recorded at cortical level without changes at subcortical levels (Abbruzzese *et al.*, 1990; Noth *et al.*, 1984). This abnormality is also present in asymptomatic gene carriers and in rigid forms of the disease, suggesting that the SEP abnormalities result from the disease and not from the choreic movements. A possible explanation is that the hyperactivity of the reticular nucleus of the thalamus reduces the relay of somatosensory inputs from the ventral posterior thalamic nuclear complex to the cortex.

Recent research has shown significantly reduced amplitude of movement-related cortical potentials in patients with HD, regardless of whether the movement was internally or externally cued (Johnson *et al.*, 2001). External cues had no effects on the pre-movement cortical activity. These results have been interpreted as a problem in movement preparation in HD and reflect impaired activity in the SMA.

Corticospinal function in HD has been examined using transcranial electrical and TMS of the motor

cortex. All the studies confirmed that patients with HD have normal corticospinal conduction (Thompson *et al.*, 1986).

Studies investigating the SP found variable results. In an early study we found that the duration of the SP is increased in patients with HD (Priori *et al.*, 1994b). In addition, SP duration had greater variability in patients than in controls, a finding later confirmed by other investigators (Tegenthoff *et al.*, 1996), who also found an abnormally short SP in akinetic rigid HD patients, and a prolonged SP in patients with predominant chorea. Our group recently showed that abnormalities of the cortical SP are better disclosed by measuring the SP from unselected traces (Modugno *et al.*, 2001) (Fig. 18.7). Collecting consecutive trials therefore seems a useful method for detecting abnormalities in the duration of the SP that other methods of collection might leave undetected. The prolonged SP could originate from the pathophysiological mechanisms underlying HD. According to models of basal ganglia function (Wichmann & Long, 1996), the loss of striatal neurons in HD results in excessive thalamo-cortical facilitation and increased activity of cortical inhibitory interneurons (Priori *et al.*, 1994b). An alternative hypothesis is based on the assumption that the restart of voluntary EMG activity after the EMG inhibition evoked by a magnetic stimulus depends on the time needed by cortico-cortical pathways to resume their drive over corticospinal cells after the cortical shock (Modugno *et al.*, 2001). In normal subjects engaged in RT tasks, the voluntary response can be delayed by delivering a magnetic stimulus over the sensorimotor cortex just before the movement. The prolonged SPs in patients with HD could therefore indicate an excessive delay in restarting a motor task that has been interrupted. A delay in the process of restarting a voluntary movement after TMS also correlates with the finding of a delayed RT during simple and complex movements in HD (Currà *et al.*, 2000a; Thompson *et al.*, 1988) and with evidence of reduced activation of primary, non-primary motor areas, and parietal cortex (Weeks *et al.*, 1997).

One study conducted with the paired-pulse technique reported reduced cortico-cortical inhibition at short ISIs but an increased facilitation at longer intervals (Abbruzzese *et al.*, 1997). Conversely, others have reported normal cortico-cortical inhibition and facilitation in patients with HD (Hanajima *et al.*, 1996; Priori *et al.*, 2000). Studying cortico-cortical inhibition at short and long ISIs at rest and during muscle contraction, Priori *et al.* (2000) found that patients had practically normal cortical motor excitability under all conditions. Whether motor cortical excitability as tested with TMS is normal in patients with HD therefore remains unclear.

Fig. 18.7 On the left, raw data from consecutive unselected traces of the silent period evoked by suprathreshold transcranial magnetic stimuli in a normal subject. Note the constant duration of the silent period. On the right, raw data from consecutive unselected traces in a patient with Huntington's disease. Note the variable duration of the cortical silent period. Recordings are from the first dorsal interosseus muscle during slight voluntary contraction. Horizontal calibration = 200 ms, vertical calibration = 500 mV. (From Modugno *et al.*, 2001, with permission.)

Conclusions

Patients with HD have abnormalities of spinal inhibitory circuits probably due to a loss of supraspinal control on spinal mechanisms. In addition, neurophysiological findings show that the cortical motor areas are not globally hyperexcitable, implying that the model of hyperkinetic movement disorders need to be reappraised (Priori *et al.*, 2000). Besides chorea, bradykinesia is one of the cardinal manifestations of disordered movement in HD (Berardelli & Currà, 2002; Berardelli *et al.*, 1999). Patients with HD therefore have a generalized deficit in movement execution. HD disturbs external as well as internal cueing mechanisms. Yet, like other movement disorders originating from basal ganglia abnormalities, it predominantly affects the mechanisms controlling the internal cueing of sub-movements (Currà *et al.*, 2000a).

Myoclonus

Myoclonus refers to sudden shock-like muscular movements. These movements may be caused by the contraction of a group of muscles lasting less than 300 ms (positive

myoclonus) or they may be caused by the sudden relaxation of a group of muscles (negative myoclonus or asterixis).

Myoclonus may be observed in a variety of conditions including certain seizure disorders and hereditary, metabolic, infectious, vascular, neoplastic, mitochondrial, toxic, or neuro-degenerative disease processes. Myoclonus should be distinguished from other movement disorders such as tics, some forms of tremor, chorea, and dystonia, but – not rarely – myoclonus and other movement disorders coexist in the same patient. Indeed, myoclonus is observed in PD and Lewy body related disorders, MSA, cortical basal degeneration, progressive supranuclear palsy, HD, dentato-rubro-pallido-luysian atrophy, in frontotemporal dementia and parkinsonism linked to chromosome 17 (Berardelli *et al.*, 1998; Thompson *et al.*, 1994; Chen *et al.*, 1992).

Myoclonus may be classified according to anatomic distribution (focal, segmental, multifocal, generalized), triggering factors (spontaneous, reflex-, action-myoclonus), pattern of muscle contractions (rhythmic or irregular), etiology (physiological, essential, and secondary myoclonus), and finally pathophysiology. This classification best fits in with the scope of this chapter and therefore will be emphasized. It is based on the evidence that myoclonus results

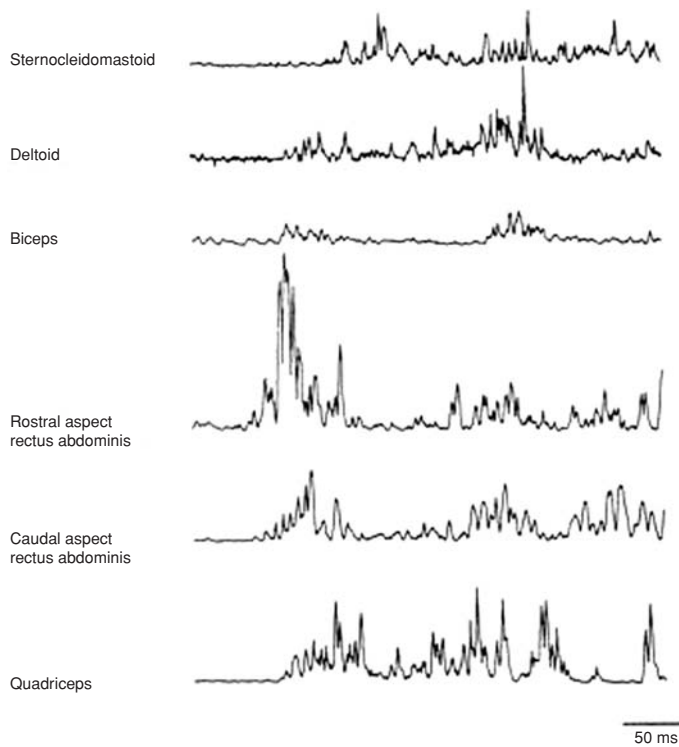

Fig. 18.8 EMG recordings of a single spontaneous jerk in different axial and limb muscles in a patient with propriospinal myoclonus. The leading muscle in the axial jerk is the rectus abdominis followed at various intervals by activation of the quadriceps and sternocleidomastoid muscles. This suggests propagation from a site within the thoracic spinal cord. Vertical calibration: top three channels 100 μ V, bottom three channels 200 μ V. (From Brown *et al.*, 1991, with permission.)

from abnormal electrical discharges originating in the nervous system.

According to the site of origin of the abnormal neuronal discharge myoclonus is categorized as cortical, subcortical, spinal, or peripheral (Marsden *et al.*, 1981). Cortical myoclonus arises from areas of the cerebral cortex, is considered “epileptic,” and is often associated with other types of seizures. Subcortical myoclonus arises within the brainstem, and spinal myoclonus arises within the spinal cord. Myoclonic jerks generated by nerve fibers are recognised as peripheral myoclonus (for example hemifacial spasm, stump myoclonus).

Cortical types of myoclonus appear spontaneously, or in response to voluntary movement or somatosensory stimulation. The EMG bursts of myoclonus are of short duration, 10 to 30 ms. The EEG recording may show simultaneous spike or spike-and-wave discharges. The technique of back-averaging shows that the jerks are preceded by a

positive EEG transient over the contralateral sensorimotor cortex, 20 ms before for the arm and 35 ms for the legs. Cortical somatosensory evoked potentials are enlarged in many of these patients (Shibasaki *et al.*, 1978).

Subcortical myoclonus is typically generalized and occurs in response to auditory stimulation or sensory stimulation to the head and neck area. It activates the sternocleidomastoid muscles first, then the facial, masseter, cranial and trunk and limb muscles. The order of activation is therefore up the brainstem and down the spinal cord (Marsden *et al.*, 1981). EMG recordings show bursts of muscle activity 100 ms in duration. The EEG may show generalized spike discharges though these are not time-locked to the myoclonus. Back-averaging the EEG activity before the jerks fails to demonstrate a preceding cortical event.

Spinal myoclonus arises from an abnormal discharge of spinal motoneurons. In spinal segmental myoclonus, muscle jerking is rhythmic and repetitive; it is confined to adjacent spinal segments and persists at a frequency of 0.5–2 Hz during sleep. In propriospinal myoclonus, an abnormal spinal generator recruits predominantly axial muscles over many segments of the spinal cord through a propriospinal network (Brown *et al.*, 1991). These result in brisk trunk flexion or less commonly extension movements. The order of muscle activation in each jerk spreads slowly from an axial focus upwards and down the spinal cord (Fig. 18.8). The accompanying EMG bursts often have long duration. These jerks are arrhythmic and stimulus sensitivity is uncommon and variable.

A widely accepted mechanism for myoclonus of peripheral nerve origin is ephaptic transmission from peripheral ectopically generated potentials (ectopic generator) as suggested by abolition of the abnormal movement by local nerve anesthesia (Assal *et al.*, 1998). Peripheral myoclonus is common in the facial district (hemifacial spasm), but has been also described in limb muscles (Evidente and Caviness, 1998). Central structures contribute to maintain or reinforce peripheral myoclonus, as supported by the evidence of secondary central reorganization after peripheral nerve lesion, and by the cases in which the innervation between the efferent motor activity responsible for myoclonus differs from that of the sensory afference able to modulate it (Assal *et al.*, 1998).

Diagnosis of myoclonus is centered on clinical assessment (careful patient and family history, and clinical examination). Neurophysiological testing (EEG, EMG, SEP, reflex studies) helps to evaluate the pathophysiological mechanism of the myoclonus, the possible factors able to induce the symptoms, and to determine the site of origin of the abnormal neuronal discharge within the nervous system.

Neuroimaging in neurodegeneration

Structural and functional magnetic resonance imaging in neurodegenerative diseases

Introduction

A full account of structural and functional MRI in neurodegenerative diseases would require an extensive volume. There are many neuroradiology texts which describe the common structural MRI abnormalities. MRI acquisition and processing techniques continue to develop apace and this chapter focuses on non-routine structural MRI and functional MRI (fMRI).

We define neurodegenerative diseases as having a distinct clinical picture, progressive natural history, focal or global pathology, and characteristic histopathology. This chapter describes diseases where neurodegeneration occurs intracranially, rather than in the spinal cord or peripheral nervous system. We do not include diseases where neurodegeneration occurs secondary to vascular or inflammatory processes, so we exclude diseases such as cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy, multiple sclerosis or complex biochemical disorders (e.g. leukodystrophies), but we do include some disorders of copper, iron and calcium metabolism as well as prion diseases. Accepting our limitations, we limit our discussion to five categories of neurodegenerative disorders: [i] dementias, [ii] extrapyramidal disorders, [iii] motor system disorders, [iv] ataxias and [v] prion diseases. Of these, the application of non-routine MRI and fMRI to dementia and movement disorders has seen the largest expansion so far.

Structural MRI in neurodegenerative disorders

Structural MRI acquisition and postprocessing techniques

Typical routine clinical sequences, such as T₁ and T₂-weighted, fluid attenuated inversion recovery (FLAIR) and

Short Tau Inversion Recovery (STIR) are effective at showing the location of pathological changes, but are seldom specific for the type of pathology. For this reason newer MRI techniques are being developed. A notable exception is the “eye of the tiger” appearance on T₂-weighted MRI in the pallidum in Neurodegeneration with Brain Iron Accumulation-1 (NBIA-1) (Hallervorden–Spatz syndrome) (Sethi *et al.*, 1988; Guillerman, 2000). The low signal on T₂, in the absence of calcification determined by CT, indicates deposition of iron compounds, while the non-specific high signal reflects vacuolation, gliosis, demyelinated fibers and swelling of axons (Savoirdo *et al.*, 1993) (Fig. 19.1). Although not specific to NBIA1 (Davie *et al.*, 1997; Molinuevo *et al.*, 1999; Guillerman, 2000), this sign in an appropriate clinical context is highly suggestive of this syndrome.

Very high spatial resolution can be achieved using small bore magnets having high magnetic field strengths of up to 7.1 tesla. This method, called “magnetic resonance microscopy,” has been applied to postmortem in vitro specimens (Huesgen *et al.*, 1993) and has recently been used to visualize neuritic plaques of Alzheimer's disease (Benveniste *et al.*, 1999) (Fig. ??). It is yet to be determined whether this method can be developed further for in vivo use to show other pathological structures, e.g. Lewy bodies in Parkinson's disease or glial intracytoplasmic inclusions in multiple systems atrophy (MSA).

Visual judgment of abnormalities of size, shape and intensity of structures is the basis of routine clinical approaches. More objective computer-assisted methods are being developed, in principle to provide more accurate and reproducible measures of abnormality, which may be important for understanding disease processes, improving diagnosis, evaluating therapy, recruiting patients for treatment and survival studies and reducing the time needed for manual measurements. Here we review some of the more important of these methods.

Fig. 19.1 The “eye of the tiger” sign of Neurodegeneration with Brain Iron Accumulation 1 (Hallervorden-Spatz syndrome). Transverse T_2 -weighted MR image depicts a low signal intensity ring (arrow) surrounding a central high signal intensity region (arrowhead) in the medial aspect of the globus pallidus. (Modified with permission Guillerman, 2000.)

Manual segmentation

The usual approach assumes that the user has made a prior decision about the location of the region or volume of interest (ROI or VOI), as opposed to methods where the goal is to identify regions as a result of computer processing. An interactive computer program is used to outline the relevant structures. Area, volume, shape and intensity measures are computed. Such methods have been particularly important in the quantification of atrophy (see section on dementias). An alternative to outlining boundaries is a tool where a matrix of regularly spaced points is superimposed on the image, so-called “stereology.” The user marks all points that are perceived to be inside the ROI. The spacing between the points is pre-determined, so an estimate of the area or volume is simply calculated from the number of points so marked.

Automated segmentation by analysis of image intensities

Methods for segmenting a large field of view using statistical analysis of the distribution of intensity values have been

widely used. It is assumed that gray matter, white matter and CSF can be separated into different intensity classes using one or more MRI sequences but in practice there is significant overlap between the tissue classes. One method of successful implementation depends on non-rigid coregistration of the subject’s MRI to a standard MRI from a probabilistic atlas in which gray and white matter and CSF voxels¹ have already been labeled (Van Leemput *et al.*, 1998). This labeling is copied to the subject’s MRI to initialize the processing. The intensity values from the subject are used to revise the initial labeling, to compute the probability of a voxel belonging to a particular tissue class. The likelihood of assigning a particular voxel to one class is increased if its neighbors have already been assigned to that class. A correction for inhomogeneities may be included (Wells *et al.*, 1996) and additional specific tissue classes may be allowed, e.g. for multiple sclerosis lesions (Van Leemput *et al.*, 2001). Similar methods may in future be particularly useful for segmentation of regions of altered signal in neurodegenerative diseases.

This approach has a number of difficulties but also advantages. The intensity classes overlap significantly and vary widely between scanners. Even on one scanner, repeat scan–scan variability is evident. However, the fact that each voxel is assigned a probability of being, for example gray matter has been used to advantage. Many voxels will only be partially occupied by gray matter (particularly at boundaries), and the probability of belonging to the gray matter tissue class is taken to represent the fractional occupancy of the voxel by gray matter, i.e. gray matter concentration (Ashburner & Friston, 1997). Statistical approaches to comparing group differences on a voxel-by-voxel basis can be directly applied to estimate volume. Measures of whole brain, total gray or white matter or subregional volumes – “volumetry” – are important outcome variables in many studies, and automated intensity-based segmentation is increasingly used in such studies. These are also the basis of voxel-based morphometry (VBM) (Ashburner & Friston, 2000). The advantage of these methods is that they can be applied to the whole brain and are not restricted to areas of pathology visible by inspection.

Automated measurement of volume differences using deformation analysis

An approach to measuring change is to quantify the shifts needed to bring a boundary from one image into alignment with another. This depends on prior coarse coregistration of the images to bring the majority of structures into

¹ A voxel is a 3-D volume element. A pixel is a 2-D picture element.

Fig. 19.2 (a) A silver stained pathological hippocampal section from a patient with Alzheimer's disease showing a row of plaques in parallel with the granule cell layer.

approximate correspondence, so that residual differences in position represent a biologically meaningful measure – such as the rate of atrophy. The term “deformation-based morphometry” tends to be applied to approaches which use a global non-rigid coregistration method. As with VBM, these methods allow identification of regions of significant change to be localized. For example, the boundary shift integral method of Freeborough and Fox (1997) has proved a sensitive method for detecting volume loss at the cortical surface in AD (Fox & Freeborough, 1997) (see below).

Diffusion-weighted imaging (DWI)

This method probes cerebral structures to provide clues to microscopic geometry (Bammer, 2003). The MR signal is sensitized to the diffusion of water molecules. Diffusion normally occurs randomly by Brownian motion and when unrestricted, water molecules move distances of around 10 μm in 50 ms. Their motion can be restricted by cell membranes, tortuous structures and other molecules (Pierpaoli *et al.*, 1996; Le Bihan *et al.*, 2001). Diffusion characteristics of separate components of the brain differ. Axons are notable because of the lack of restriction to diffusion along their length but their transverse restriction is highly consistent. Basic diffusion weighted images show signal intensity in a voxel when the diffusion-sensitizing gradient is applied in a single direction. Three images of the same slice are

typically displayed, each acquired with gradients in three directions, one orthogonal to the slice and the other two in the plane of the slice. Signal is attenuated (dark) in voxels where the diffusion gradient is aligned with fiber bundles running in the same direction. The images are influenced by the T_2 value of the tissue, so a limitation is that areas with increased T_2 cannot be distinguished from areas with impeded diffusion. By varying the strength (“b value”) of the diffusion gradient, an apparent diffusion coefficient (ADC) in the direction of the gradient can be calculated for each voxel. ADC maps are displayed so that voxels of high diffusion are bright, i.e. the opposite of basic diffusion weighted images. So far, the most practical use has been the early detection of areas of acute ischemia (Warach *et al.*, 1992), but since DWI can be performed on conventional scanners and scanning time is short, its use in neurodegenerative disorders is increasing.

Diffusion tensor imaging (DTI): quantitative analysis of DWI

Information provided by DWI and ADC maps is limited by the directions of the applied field gradients. A more general approach is to apply gradients in at least six directions and to fit a function (the tensor) that allows several quantities, independent of the directions of the applied gradients, to be derived (Pierpaoli *et al.*, 1996; Le Bihan *et al.*, 2001). Scalar

Fig. 19.2 (b) Corresponding T_2^* proton stain “magnetic resonance microscopy” with voxel size of $5.9 \times 10^{-5} \text{mm}^3$. A row of black rounded elements (arrowheads) can be located above the brighter band representing the granule layer. (Modified with permission from Benveniste *et al.*, 1999. Copyright 1999 National Academy of Sciences, USA.)

measures (non-directional) include mean diffusivity (MD) and fractional anisotropy (FA) (isotropy means equal in all directions). MD is the average of the ADCs estimated along any three orthogonal directions. This is also reported as the trace which is the sum rather than the average of the three values. FA expresses the extent to which diffusion varies in different directions and shows good contrast between gray and white matter. If disruption occurs in an organized fiber path, water will diffuse more along fiber tracts than across it and FA will decrease.

Directional measures provide information about the orientation of locally anisotropic structures. Many large fiber tracts form bundles several millimetres wide. Voxels within such bundles have a very clear direction of minimally restricted diffusion. However, other voxels may contain fibers running in more than one direction. The diffusion

tensor has six parameters which expresses the magnitude of the directional components in three orthogonal directions: (a) in the direction of the strongest component, (b) within the plane orthogonal to this in the direction with the strongest component, and (c) in the remaining direction orthogonal to these two. The function can be interpreted as an ellipsoid (Westin *et al.*, 1999). The width of the ellipsoid represents the strength of the component. Where there is only one predominant orientation of structures, the ellipsoid is needle-like. Where there are two strong components, the ellipsoid becomes like a two-dimensional disk. Where diffusion is equal in all directions, the ellipsoid is like a sphere (isotropy).

Fiber tracking (tractography) using DTI

Adjacent voxels within large fiber bundles have similar principal directions. The main direction of diffusivity can be mapped as a voxel-wise colour coded scale and superimposed on a structural MRI (Basser *et al.*, 2000; Jones *et al.*, 2002; Bammer *et al.*, 2003). The course of tracts can be followed by computing “streamlines,” that is chains of voxels in which one voxel is linked to its neighbor in the direction of principal diffusion (Conturo *et al.*, 1999; Jones *et al.*, 1999). For example, “streamlines” can be initiated in the optic radiation, which lead to the calcarine cortex. This method has an important potential application in interpreting functional imaging data to show how activated foci are anatomically connected.

However, away from major fiber bundles, little is known of human white matter anatomy. Many assumptions come from extrapolation from animal studies and small human tracts remain to be defined; some of these will be important for our understanding of neurodegenerative diseases. Tracking small bundles through areas of crossing fibers is difficult and several approaches are under investigation (Basser *et al.*, 2000; Poupon *et al.*, 2000; Parker *et al.*, 2001). For in vivo tractography in patients with neurodegenerative diseases, it will be important to validate methods by correlation with post-mortem studies on the same patient. Appropriate validation methods are under development (Bardinet *et al.*, 2001; Kenwright *et al.*, 2003).

Structural MRI in neurodegenerative diseases

Here, initially we give representative examples of some routine clinical structural MRI abnormalities seen in our five categories of neurodegenerative disorders (Fig. 19.3, parts 1–23). So far, non-routine structural MRI has been predominantly applied to normal subjects, stroke (Warach *et al.*, 1992; Chabriat *et al.*, 1999), disconnection syndromes (Molko *et al.*, 2002) and psychiatric disorders (Foong *et al.*,

2000). The newer applications have not been applied to the spectrum of neurodegenerative disorders. Below, we focus on specific examples where publications exist and, for clarity, we compare these to routine structural MRI. Figure 19.3 (parts 1–23) shows characteristic abnormalities of some common neurodegenerative diseases. For a more complete discussion on each disease, the reader is referred to relevant chapters in this volume.

Dementias

Alzheimer's disease

MRI in AD is used to exclude treatable disorders, to establish the extent of vascular white matter abnormalities and to assess focal atrophy. Medial temporal lobe atrophy (MTA) is an important feature of AD and is best seen on coronal sections orientated perpendicular to the inferior (temporal) horn of the lateral ventricle (Fig. 19.3(1)). Enlargement of the CSF spaces is seen early as an increased height of the choroid fissure superomedial to the hippocampus. Enlargement of the temporal horn of the lateral ventricle and reduction of the height of the hippocampus generally become visible later (Scheltens *et al.*, 1992), but the correlation with the degree of atrophy is poor. Visual impression of atrophy can be made more robust by grading specific features (Scheltens *et al.*, 1992). A series of studies have assessed the sensitivity and specificity of medial temporal atrophy using visual rating schemes in the diagnosis of AD (Scheltens *et al.*, 1992; Erkinjuntti *et al.*, 1993; Desmond *et al.*, 1994; de Leon *et al.*, 1996; Frisoni *et al.*, 1996; O'Brien *et al.*, 1997; Scheltens *et al.*, 1997; Pucci *et al.*, 1998; Barber *et al.*, 1999a; Wahlund *et al.*, 2000). The diagnosis of AD was based on clinical criteria in these studies, but the correlation between clinical and pathological classifications is known to be poor. Despite the limitations of using clinical diagnostic criteria as the standard by which to judge the accuracy of MR criteria, sensitivity was surprisingly high in most of the studies, ranging from 70–100% (Scheltens *et al.*, 1992; Desmond *et al.*, 1994; de Leon *et al.*, 1996; Frisoni *et al.*, 1996; O'Brien *et al.*, 1997; Scheltens *et al.*, 1997; Pucci *et al.*, 1998; Barber *et al.*, 1999a; Wahlund *et al.*, 2000), although one study showed only 41% sensitivity (Erkinjuntti *et al.*, 1993). Specificity ranged from 67–96%. The control groups were mostly normals, but similar high specificities were obtained against other dementias (O'Brien *et al.*, 1997; Pucci *et al.*, 1998) or patients with minimal cognitive impairment (de Leon *et al.*, 1996). The results of these small studies (mostly <50 patients) have been corroborated by two larger studies with 130 and 77 AD patients, respectively (de Leon *et al.*, 1996; O'Brien *et al.*, 1997). It is

Fig. 19.3(1) Alzheimer's disease. T_1 -weighted MR images orientated perpendicular to the long axis of the hippocampus showing progressive medial temporal lobe atrophy (MTA). (Modified with permission from Barber *et al.*, 1999a). Figure supplied by Drs Barber and O'Brian, Newcastle University, England, UK.)

now well established that assessing MTA by these methods is sensitive for AD and also specific within the context of the dementia subtypes included in the studies.

Most volumetry studies of medial temporal structures in dementia have used interactive segmentation methods. These allow volume measurement of the hippocampus, parahippocampal gyrus and other temporal substructures.

Comparing volumes of MTA with clinical diagnosis, sensitivity ranged from 0.80–0.94 for AD (Jack *et al.*, 1992, 1997; Ikeda *et al.*, 1994; Laakso *et al.*, 1995; Convit *et al.*, 1997; Pantel *et al.*, 1997, 1998; Krasuski *et al.*, 1998; Laakso *et al.*, 1998; Lehericy *et al.*, 1998; Frisoni *et al.*, 1999; Juottonen *et al.*, 1999), against normal controls specificities were 0.8–1.0 (Jack *et al.*, 1992, 1997; Ikeda *et al.*, 1994; Laakso *et al.*, 1995, 1998; Pantel *et al.*, 1997, 1998; Krasuski *et al.*, 1998; Lehericy *et al.*, 1998; Juottonen *et al.*, 1999). Against patients with minimal cognitive impairment or frontotemporal dementia (FTD), two small studies found similarly high specificity (Convit *et al.*, 1997; Frisoni *et al.*, 1999) of 0.86 and 0.90, respectively.

Limitations of volumetric quantification are evident even with structures which are primarily defined by their anatomy (Colchester *et al.*, 2001), e.g. the fusiform gyrus, inferior, medial and superior temporal gyri. The difficulties are compounded when assessing the perirhinal and entorhinal cortex, the definitions of which draw on animal data and cytoarchitectonic studies. Progress has been made in defining operational criteria for defining the boundaries of these structures (Insausti *et al.*, 1995; Insausti *et al.*, 1998) but substantial inter-subject variations cause significant difficulties. Juottonen (Juottonen *et al.*, 1999) estimated entorhinal cortex volumes and reported improved sensitivity and specificity (0.90 and 0.94). Patients with minimal cognitive impairment, as well as those with AD, have reduced entorhinal cortex volumes, but the hippocampus was significantly atrophied only in patients with AD (Dickerson *et al.*, 2001). Progression of minimal cognitive impairment to AD was best predicted by “partial entorhinal volume” (Killiany *et al.*, 2000). While such detailed subdivision of the temporal cortex is important for functional localization, subdivisions of the medial temporal lobe into hippocampus and parahippocampal gyrus is probably sufficient for diagnosis. The value of volumetry or semi-quantitative rating scales in the diagnosis of AD remains controversial, which is understandable noting the methodological difficulties described above. Some groups conclude that there is little or no value (Knopman *et al.*, 2001) while others suggest that the diagnostic value of hippocampal volumetry probably surpasses, and is at least equal to, clinical accuracy (Laakso, 2002).

For whole brain studies, Fox *et al.* used a technique in which the shift of boundaries was measured over time in a coregistered series of MR scans (Fox & Freeborough, 1997; Freeborough & Fox, 1997). By studying autosomal dominant AD, they followed the change in rate of atrophy associated with symptom onset and could predict the onset of clinical dementia (Fig. 19.4) (Fox *et al.*, 1997; Chan *et al.*, 2003). The use of voxel-based morphometry has

allowed the main areas of atrophy to be investigated without depending on prior definition of the region of interest (Baron *et al.*, 2001; Ohnishi *et al.*, 2001). As expected, these studies confirmed that the medial temporal lobe was the most severely affected region, but Baron *et al.* (2001) identified several other areas outside the medial temporal lobe which were also affected.

Dementia with Lewy bodies (DLB)

This is the second most common dementia in the elderly and importantly differs from AD in its good response to cholinesterase inhibitors and greater sensitivity to neuroleptics (Barber *et al.*, 2001b). Thus differentiation from AD has clear therapeutic goals. Early studies using volumetry showed that although patients with DLB have more MTA than controls (Barber *et al.*, 1999a), they have relative preservation of the hippocampus compared with AD (Fig. 19.3(2)) (Hashimoto *et al.*, 1998). These differences are present across the entire length of the hippocampus (Barber *et al.*, 2001a). There were no differences in amygdala (Hashimoto *et al.*, 1998), lateral temporal lobes (Barber *et al.*, 2001a), frontal lobes (Barber *et al.*, 2000a), occipital lobes (Middelkoop *et al.*, 2001) or whole brain volumes, and the rate of focal atrophy did not differ between AD and DLB (O'Brien *et al.*, 2001). The absence of MTA had a specificity of 100% and 88% for separating DLB from AD and vascular dementia respectively, and a sensitivity of 88% (Barber *et al.*, 1999a). Despite the fact that MTA correlated with memory decline in all dementia groups (Barber *et al.*, 1999a), these findings led some groups to suggest that the preservation of the medial temporal lobe on MRI volumetry should be incorporated into the consensus criteria for diagnosis of DLB (Barber *et al.*, 1999a).

White matter changes are common to normal aging, DLB, AD and vascular dementia. The relationship to cortical atrophy has been studied by semi-quantitative volumetric MRI and correlated to whole brain and ventricular volume. White matter changes are best visualized on T₂ or proton density images. Periventricular hyperintensity is positively correlated with age and ventricular dilatation and is more severe in all dementia groups than controls. Deep white matter hyperintensity correlates with a history of hypertension, does not correlate with age, atrophy or ventricular dilatation, is also significantly greater in all dementia groups but is highest in patients with vascular dementia (Barber *et al.*, 1999b, 2000b). These findings suggest that volumetric MRI can distinguish two pathological processes, which lead to periventricular or deep white matter changes and which may have a different impact on the clinical presentation of cognitive decline.

Fig. 19.3(2) Dementia with Lewy bodies. Selected T_1 -weighted MRI slice from a 71-year-old female patient with dementia with Lewy bodies illustrating boundaries of the hippocampal formation (H = hippocampal formation). In contrast to Alzheimer's disease, there is sparing of the hippocampus. (Modified with permission from Hashimoto *et al.*, 1998.)

Subcortical structures have also been investigated in DLB, AD and vascular dementia since they are implicated by the common presence of parkinsonism. Normalized volumetric measurements of the caudate from T_1 -weighted MR images showed no significant differences between the patient groups although the left caudate volume was reduced significantly in AD and DLB compared with controls (Barber *et al.*, 2002). This finding was not found in the first whole brain VBM study comparing AD, DLB and controls, although thalamic atrophy was found in AD (Burton *et al.*, 2002). The results of subcortical imaging are at an early stage and their significance is currently uncertain.

Fig. 19.3(3) Frontotemporal lobar degeneration. Striking frontal atrophy in a patient with frontotemporal dementia. T_1 -weighted MRI.

Fronto-temporal dementia (FTD)

The dementias associated with focal atrophy of the frontal and temporal lobes form a heterogeneous group for which nomenclature is evolving and often confusing (Fig. 19.3(3)). The term Pick's disease is best reserved as a neuropathological diagnosis, where marked frontal atrophy is associated with swollen tau- and ubiquitin-positive neurones with Pick body inclusions. "Dementia lacking distinctive histopathology" is another neuropathological category; cases show significant neuronal loss and gliosis and may have spongiform changes in the superficial layers, but (as the name implies) do not have Pick bodies or other distinctive features. No specific neuroimaging features have been identified to distinguish between these categories of FTD. The main emphasis is on distinction from cases of AD, with variable results. The rate of atrophy may be even higher than in AD (Chan *et al.*, 2001). In primary progressive

aphasia, atrophy is as expected most marked in the left temporal lobe (Radanovic *et al.*, 2001).

Extrapyramidal disorders

Huntington's disease

MRI is a sensitive marker for bi-caudate atrophy (Fig. 19.3(4)) and striatal high signal change (Oliva *et al.*, 1993). Striatal iron is increased in caudate, putamen and pallidum (Bartzokis & Tishler, 2000) and striatal atrophy is correlated with CAG repeat number (Rosas *et al.*, 2001). High-resolution MR and cortical surface reconstruction allows measurement of cortical thickness. Thinning of the cortex was detected early in HD, progressed from a posterior to anterior direction and correlated with disease progression (Rosas *et al.*, 2002). Affected regions included white matter, cerebral cortex, brainstem and cerebellum (Rosas *et al.*, 2003) suggesting that some of the clinical spectrum of HD may occur as a result of extra-striatal degeneration. In dentatorubropallidolusian atrophy, there are more extensive thalamic, midbrain and pontine high signal abnormalities (Fig. 19.3(5)) (Tomiyasu *et al.*, 1998).

Parkinson's Disease

High-resolution MRI is not normal and can show cortical atrophy. Subtle changes in the substantia nigra have been identified specifically by thin section T_2 -weighted images. Hutchinson and Raff used two inversion recovery sequences (white matter suppressed and grey matter suppressed) to calculate images of the ratio of these, which were color scaled. The ratio images show the width of the hyperintense substantia nigra band to decrease in PD, even in early cases (Fig. 19.5) (Hutchinson & Raff, 1999). This is not demonstrable on routine images (Adachi *et al.*, 1999; Oikawa *et al.*, 2002). It is possible that early (or even sub-clinical PD) might be detectable with refinement of this technique.

The subthalamic nucleus is of central importance in the pathophysiology and treatment of PD. High resolution MRI, specifically tailored with long TR, can visualize the subthalamic nucleus for neurosurgical interventions such as deep brain stimulation (Fig. 19.3(6)).

Atypical forms of parkinsonism and their differentiation from PD

The presence of high signal in white matter on T_2 -weighted MRI and the clinical presentation of is usually sufficient to diagnose vascular pseudoparkinsonism. Midbrain atrophy (Fig. 19.3(7)) and enlargement of the third ventricle on mid-sagittal MRI suggests progressive supranuclear palsy

(PSP), the so called "hummingbird sign" (Kato *et al.*, 2003) (Fig. 19.3(8)). Superior cerebellar peduncle signal dropout occurred in 4/9 patients with PSP on proton-density images and may represent focal gliosis or demyelination (Oka *et al.*, 2001).

Putaminal atrophy correlates with contralateral parkinsonism in the parkinsonian form of multiple system atrophy (MSA-P). On 0.5 tesla T_2 and proton density-weighted images, this is seen as a high signal in the posterolateral putamen. In contrast, using a higher field on 1.5 tesla images, the posterior putamen appears markedly hypointense on T_2 -weighted images because of the deposition of iron. Putaminal high signal intensity may be evident as a rim lateral to the low signal in the posterolateral putamen (Fig. 19.3(9)). Cerebellar, pontine and middle cerebellar peduncle high signal or atrophy suggests the cerebellar form of MSA (MSA-C) (Fig. 19.3(10)), although there is an overlap with other types of MSA (Naka *et al.*, 2002). Sparing of some pontine fibers and pyramidal tracts gives the "hot cross bun" sign in the pons but this is not specific to MSA and can also be seen in spinocerebellar ataxia. High signal changes around the dentate nuclei may be seen in the fragile X pre-mutation syndrome (Fig. 19.3(11)) (Brunberg *et al.*, 2002).

In corticobasal degeneration (CBD), MRI reveals asymmetrical frontal or parietal atrophy, especially affecting the perirolandic region and parasagittal regions (Fig. 19.3(12)). T_2 -weighted images show further low signal in putamen and globus pallidus and ventricular enlargement (Tokumaru *et al.*, 1996; Hauser *et al.*, 1996; Soliveri *et al.*, 1999; Kitagaki *et al.*, 2000). One patient is described with T_2 -weighted hyperintensity of white matter adjacent to bilateral frontal cortex atrophy (Doi *et al.*, 1999). These signal changes might reflect focal demyelination secondary to neuronal loss.

The degree of cortical grey matter volume loss has been studied in parkinsonian disorders. Whole brain 3D volumetry (Cordato *et al.*, 2002) with manually discerned cortical and ventricular ROIs was used to compare PD and PSP groups and showed an 8% whole brain volume loss in PSP with 77% increase in whole ventricular size. The frontal lobe (particularly the posterior frontal cortex) showed more atrophy in PSP (19% compared with PD) and this regional atrophy correlated with clinical measures of frontal behavioral changes (Fig. 19.6).

One early 3-D volumetry study of subcortical structures showed normal striatal, cerebellar, and brainstem volumes in PD, whereas brainstem and striatal atrophy were detected in atypical parkinsonism (MSA-C, MSA-P and PSP) (Schulz *et al.*, 1999). MSA patients showed additional cerebellar atrophy. With the exception of brainstem

atrophy in MSA-C, individuals and groups could not be differentiated on the basis of regional volumetry, unless a stepwise discriminant analysis was employed. The technique is, however, still considered insensitive in that typical PD could not be distinguished from controls, while MSA-P could not be distinguished from PSP. Another recent study showed similar patterns of midbrain volumes in both MSA-P and PD but that there was 50% greater putaminal atrophy in MSA-P (Ghaemi *et al.*, 2002).

A single study of subcortical structures using VBM found an increase in grey matter density in the nucleus ventralis intermedius (VIM) of thalamus contralateral to resting tremor in PD (Fig. 19.7) (Kassubek *et al.*, 2002). This is the first study to describe a structural difference in thalamus in PD. Whereas a loss of grey matter intensity might represent neuronal loss and could be straightforward to interpret, the nature of an *increase* in grey matter intensity is unclear, but could speculatively represent neuronal hypertrophy or a higher neuronal density secondary to reduced local inhibitory input.

Using DWI, Schocke *et al.* demonstrated that MSA-P could be differentiated from idiopathic PD (Schocke *et al.*,

2002) based on an increase in diffusion of water molecules in the putamen in atypical parkinsonism, implying disruption of striatal architecture. This study extended previous work on increased ADC in frontal and precentral white matter in patients with PSP compared with normals (Ohshita *et al.*, 2000). Most recently, regional ADC values in putamen and caudate were shown to be significantly increased in PSP and MSA-P compared with PD, reflecting neurodegeneration and gliosis (Seppi *et al.*, 2003). There was only one patient with PD whose putaminal ADC value was greater than the lowest value of the MSA-P group. No significant differences were found in thalamus, substantia nigra, pons, periventricular white matter or grey matter. This may reflect reduced sensitivity of DWI in these areas where a variable orientation of fiber tracts may hinder detection of differences. To date, only one DTI study has reported a significant finding in PD, that of a decrease of FA in the region between the substantia nigra and inferior basal ganglia when compared with controls (Yoshikawa *et al.*, 2004).

Disorders of copper, iron and calcium

(Figs. 19.3(16))

In these conditions, there is usually extensive but non-specific signal change in the basal ganglia. Examples of routine MRI abnormalities in Wilson's disease, acquired hepatolenticular degeneration (Ueki *et al.*, 2002), idiopathic calcification and neuroferritinopathy (Wills *et al.*, 2002) are shown in Figs. 19.3(13)–19.3(16).

Motor system disorders

MRI is undertaken in motor neuron disease (MND) to exclude differential diagnoses. The diagnosis of MND rests upon the clinical detection of predominantly lower motor neuron signs combined with upper motor neuron signs. The former are difficult to identify with MRI because of the small structure of the spinal cord and brainstem, and the latter are more variable (Leigh *et al.*, 2002). The use of MRI has focused on the detection and interpretation of upper motor neuron signs. Recently, high signal of the corticospinal tracts and low signal of the motor cortex have been described in T_2 -weighted images of amyotrophic lateral sclerosis (ALS) (Figs. 19.3(17) and 19.3(18)) (Carella *et al.*, 1995; Ellis *et al.*, 1999a).

MND is not solely a disorder of the motor system and imaging has been used to study both motor and non-motor cortical regions. Quantification of grey matter intensity by whole brain automated VBM has revealed deficits in grey

matter volume in Brodmann areas 8, 9, and 10 bilaterally (Ellis *et al.*, 2001). Patients with bulbar-onset ALS also have deficits in the white matter volume extending from the precentral gyrus to the internal capsule and brainstem, consistent with the course of the corticospinal tract, but without grey matter volume loss in the motor cortex. Combining these two findings suggests that ALS is a multisystem disease in which grey matter volume loss may occur at sites distinct from sites of white matter abnormalities (Ellis *et al.*, 2001).

Preliminary results on DTI in ALS (Ellis *et al.*, 1999b; Sach *et al.*, 2004) show increased mean diffusivity and decreased fractional anisotropy along the internal capsule in bulbar-onset disease, indicating disruption of water diffusion along the corticospinal tracts. Mapping such results to a whole brain volume may herald a new method to detect functional disruption. Although fractional anisotropy correlated with disease severity and mean diffusivity correlated with disease duration, the results overlapped con-

siderably with normals. A decrease in FA can also be detected despite the absence of clinical upper motor neuron signs (Sach *et al.*, 2004). It is possible that development of VBM and DTI will provide further *in vivo* evidence to corroborate the extensive nature of pathological changes of MND.

Ataxias

Ataxic disorders have not generally been studied with non-routine MRI. Routine T_1 -weighted MRI, may show non-specific cerebellar and brainstem atrophy (Fig. 19.3(19)). In the context of palatal tremor, this may be combined with hyperintensity and hypertrophy of the olivary nucleus (Fig. 19.3(20)) to suggest the diagnosis of the progressive ataxia and palatal tremor syndrome (Sperling & Herrmann, Jr., 1985; Phanthumchinda, 1999; Samuel *et al.*, 2004).

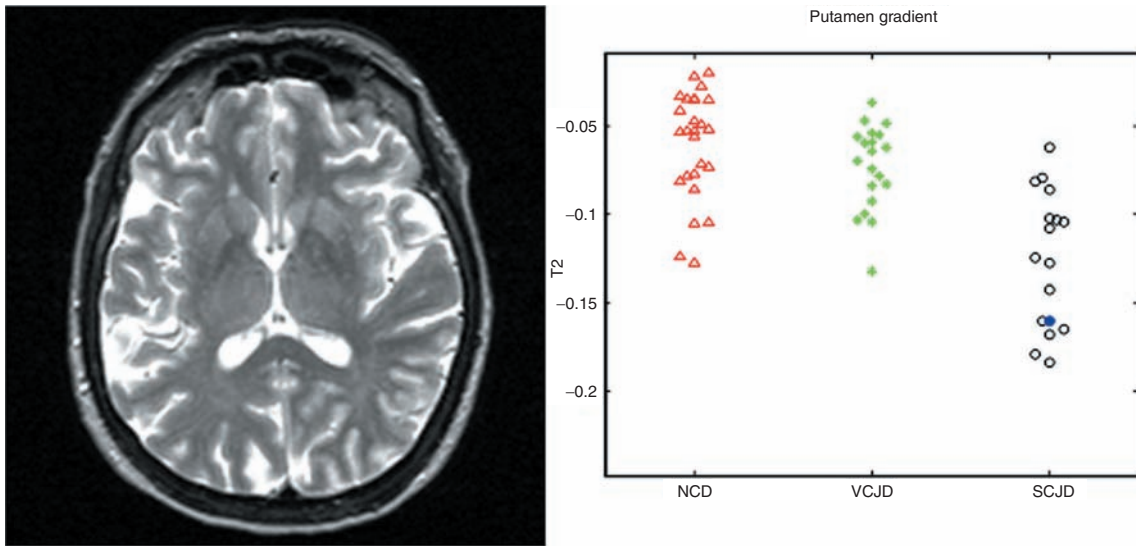

Fig. 19.3(21) Prion disease.

T_2 -weighted MRI in a patient with confirmed sporadic CJD showing hyperintensity of the head of the caudate and anterior part of the putamen, although this can be difficult to judge by eye. The graph shows quantitative data of the “putamen gradient” (rate of change of intensity from front to back along the putamen) in three groups of patients: non-CJD dementia NCD (left), confirmed vCJD (centre); and confirmed sCJD (right). The blue-filled circle in the sCJD group is from the patient whose MRI is shown, demonstrating that the “putamen gradient” for this patient falls outside the complete range of values for the two comparison groups ($p < 0.01$).

Prion diseases

Sporadic CJD (sCJD)

The earliest reports of MRI described only generalized atrophy (Kovanen *et al.*, 1985). Subsequently, there were reports of increased intensity, usually symmetrical, in the basal ganglia (Gertz *et al.*, 1988; Pearl & Anderson 1989; Kruger *et al.*, 1990; Milton *et al.*, 1991; Uchino *et al.*, 1991; Falcone *et al.*, 1992; Di Rocco *et al.*, 1993; Barboriak *et al.*, 1994; Garcia-Santos *et al.*, 1996) on T_2 and proton density MRI. In the first substantial series (Finkenstaedt *et al.*, 1996), high signal in the putamen and caudate head were observed in 79% of sCJD patients (14 definite and 15 probable), but this study lacked controls (Fig. 19.3(21)). The same patients were included in a review of a larger group of 157 sCJD patients (Poser *et al.*, 1999; Schroter *et al.*, 2000) where 67% of 29 sCJD patients had basal ganglia hyperintensity (sensitivity), while 52 of 56 non-CJD dementia controls did not show such changes (92% specificity). A less consistent finding is high signal in the cerebral cortex, which is often asymmetrical (Gertz *et al.*, 1988; Esmonde & Will, 1992; Falcone *et al.*, 1992, 1996; Garcia-Santos *et al.*, 1996; Tzeng *et al.*, 1997; Urbach *et al.*, 1998; Samman *et al.*, 1999; Collie *et al.*, 2001).

Signal changes have also been seen in periaqueductal grey matter (Collie *et al.*, 2001), thalamus (Gertz *et al.*, 1988), hippocampus (Sellar *et al.*, 2002), cerebellum (Tzeng *et al.*, 1997) and occasionally in the white matter of the hemispheres (Falcone *et al.*, 1992; Collie *et al.*, 2001) (Fig. 19.3(22)). Abnormal signal intensities in the deep grey matter are less conspicuous in sCJD than variant CJD. In a recent multi-centre quantitative study (Hojjat *et al.*, 2002), 34 digital MR scans were analyzed (12 sCJD, 11 variant CJD and 10 non-CJD dementia patients). Absolute intensities in the putamen and caudate head were generally increased but varied widely, and no simple reference structures for normalization could be identified that allowed confident discrimination of sCJD patients. However, intensity abnormalities of the caudate and putamen relative to frontal white matter were predictive of variant CJD (although with less sensitivity and specificity than the pulvinar), while sCJD could not be distinguished from non-CJD dementia controls. The most significant finding was that the normal gradient of intensity within the putamen (reducing signal from front to back on long TR MRI) was significantly greater in sCJD than either variant CJD or non-CJD dementia (Hojjat *et al.*, 2002). Using the optimum threshold, the sensitivity and specificity for

sCJD diagnosis using the “putamen gradient” were both 89%, comparable to any other non-invasive test for sCJD (Fig. 19.3(21)). Further evaluation of this test in a larger group is required.

FLAIR sequences improve the detection of grey and white matter hyperintensities and will almost certainly improve the sensitivity of visual analysis of MRI in sCJD (Fig. 19.3(22)). DWI has been described in sCJD in a number of case reports and small series (Demaerel *et al.*, 1997, 1999; Bahn *et al.*, 1997a; Bahn & Parchi, 1999; Na *et al.*, 1999; Samman *et al.*, 1999; Yee *et al.*, 1999; Kropp *et al.*, 2000; Oppenheim *et al.*, 2000; Kim, 2001; Matoba, 2001; Mao-Draayer *et al.*, 2002; Mittal *et al.*, 2002; Murata *et al.*, 2002; Rabinstein *et al.*, 2002; Martindale *et al.*, 2003; Mendez *et al.*, 2003) showing striking altered diffusion in the basal ganglia and cerebral cortex (Collie *et al.*, 2001; Mao-Draayer *et al.*, 2002; Murata *et al.*, 2002) (Fig. 19.8).

Variant CJD (vCJD)

MRI is very important for the diagnosis of vCJD. Following the first description of vCJD (Will *et al.*, 1996), two case

Fig. 19.3(23) Confirmed vCJD. Proton density axial MRI. There is striking hyperintensity of the posterior thalamus (“pulvinar sign”) with less hyperintensity of the medial thalamus. This combination has been referred to as the “hockey-stick” sign.

reports described high signal in the posterior thalamus (pulvinar) on proton density and T_2 -weighted MRI (Chazot *et al.*, 1996; Howard, 1996). In 12 of the first 14 cases, the initial MRI reports were unremarkable or showed non-specific atrophy (Zeidler *et al.*, 1997), but with re-examination, symmetrical high signal was seen in the posterior and medial thalamus in a majority of cases (Sellar *et al.*, 1997; Zeidler *et al.*, 2000). Zeidler *et al.* (2000) analysed scans from 36 patients with vCJD obtained between 1 and 23 months after symptom onset (ranging from 7 to 38 months from presentation to death) and compared them with two groups of patient controls: (a) 17 patients referred with suspected CJD but in whom CJD was subsequently ruled out, and (b) 40 patients with other types of CJD. Clear hyperintensity of the pulvinar was termed the ‘pulvinar sign’ (Fig. 19.3(23)) and was present in 78% of the vCJD cases (sensitivity). The sign was seen in 5–29% of the controls giving specificities of 71–95% (Zeidler *et al.*, 1997). Hyperintensity can be seen in vCJD in other grey matter areas: in about 2/3 of cases in dorsomedial thalamic nuclei (Sellar *et al.*, 2002), putamen (in 33%), head of caudate nucleus (in about 25%), and periaqueductal grey matter and /or tectal plate (Coulthard *et al.*, 1999; Oppenheim *et al.*, 2000; Zeidler *et al.*, 2000).

Fig. 19.4 Progression of atrophy in a 55-year-old subject with Alzheimer's disease. Enlarged regions show the left hippocampus. (a) Coronal slice taken from the baseline T_1 -weighted image. (b) Coronal slice taken from the repeat (approximately 1 year later) T_1 -weighted image. (c) Repeat image registered to the baseline image. Areas shaded red represent areas of change, based on voxels with significantly (greater than 20% of mean brain) lower intensity on the repeat image. (Courtesy of Dr N. Fox, Dementia Research Group, Institute of Neurology, London, UK.)

Hyperintensity may occasionally also be seen diffusely in the white matter of the centrum semiovale (Collie *et al.*, 2001).

Quantification of changes in three cases of vCJD (Coulthard *et al.*, 1999) confirmed the "pulvinar sign" when compared with a group of normal subjects. In a larger UK multi-centre study, 11 confirmed vCJD cases were compared with 28 controls (12 sCJD, 16 non-CJD dementia cases) (Colchester *et al.*, 2002). This study evaluated several different structures for normalizing intensities across subjects. The pulvinar-to-frontal white matter T_2 intensity ratio was an excellent discriminator between vCJD and non-CJD dementia and also between vCJD and sCJD (specificity 89% with sensitivity 100% when a T_2 intensity

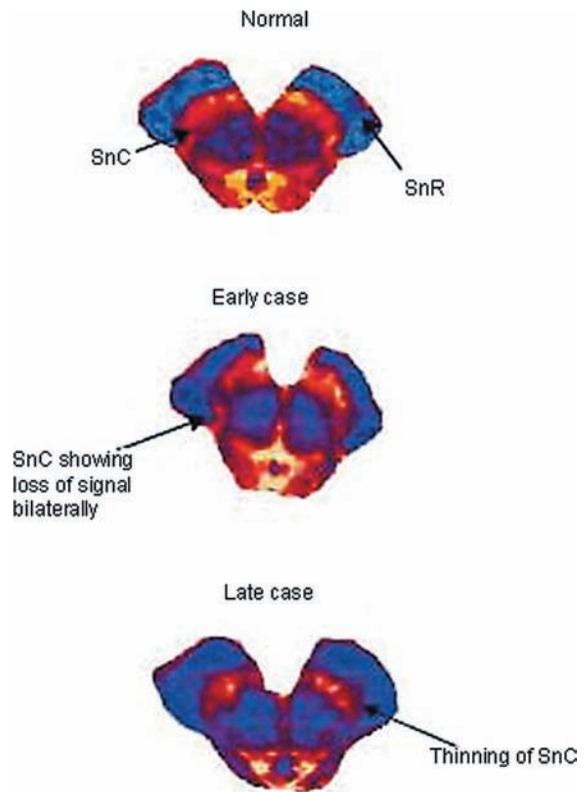

Fig. 19.5 Substantia nigra imaging in Parkinson's disease. Ratio images of normal, early and late PD (see text) presented as a coloured scaled figure (from 0–255). The substantia nigra compacta (SnC) reaches the cerebral peduncles in the normal but is thinner and smaller in the early and late cases. (Modified with permission from Hutchinson & Raff, 1999, and with permission BMJ Publishing Group.)

ratio of 1.51. was used). Such a ratio cannot be readily judged by eye. The pulvinar-to-putamen proton density ratio was also found to be a good discriminator (91% sensitivity and 89% specificity) (Colchester *et al.*, 2002) using a ratio of 1.0. This is more appropriate for visual reporting because the required discrimination is whether the pulvinar is brighter than the putamen. Confirmation of these findings is needed in a larger study but there is no doubt of the diagnostic importance of pulvinar hyperintensity in distinguishing vCJD from non-CJD dementias and sCJD.

With only small numbers of vCJD patients, there is a shortage of information about other MRI sequences. FLAIR shows changes in the deep nuclei clearly but the numbers of patients examined is very small, 3 of 36 patients in one study (Zeidler *et al.*, 2000). DWI was only carried out in 4/100 vCJD cases in the UK (Sellar *et al.*, 2002). Estimation

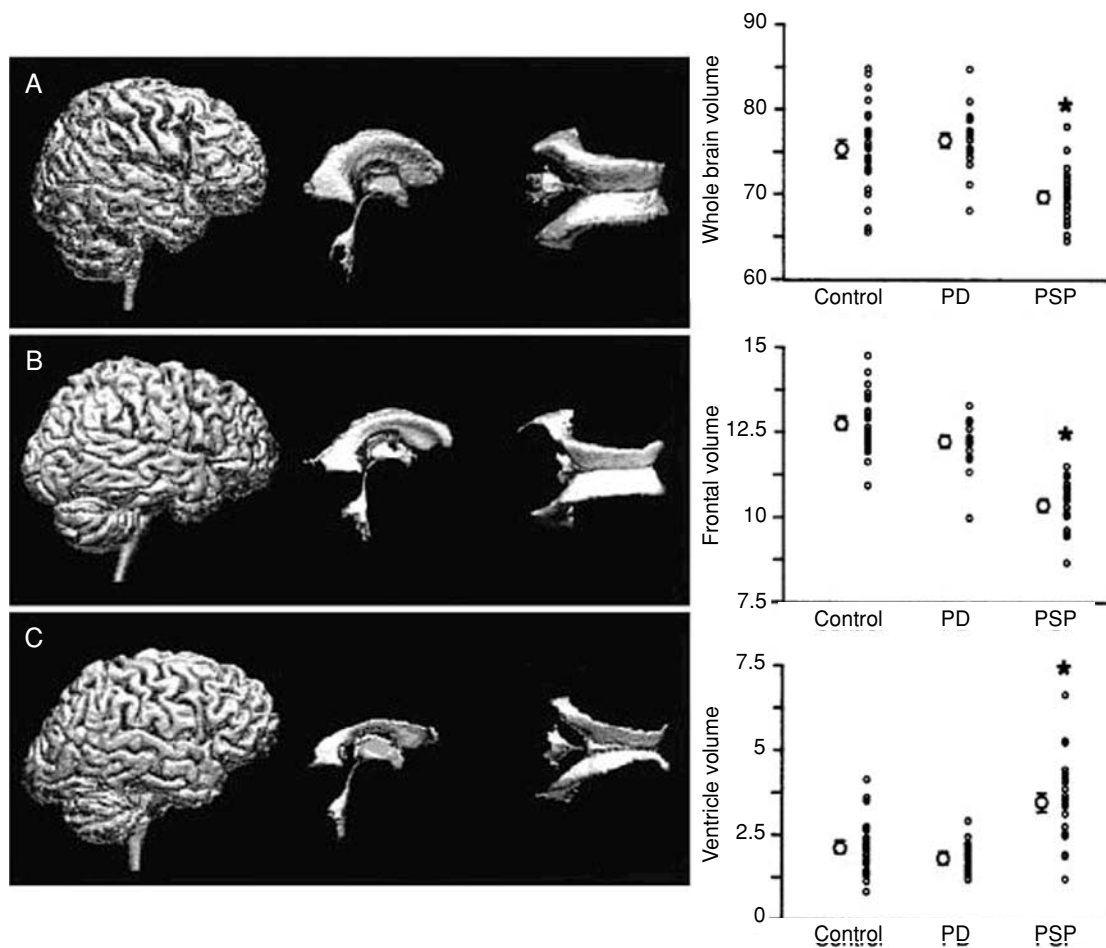

Fig. 19.6 Three-dimensional volumetry in extrapyramidal disorders. Volume rendered 3-D MRI reconstructions of the whole brain and ventricular system in PSP (A), PD (B), and a normal control (C). Left images: cortical atrophy, particularly is apparent in PSP. Middle images: lateral view of the ventricular system showing dilation in PSP compared with PD and controls. Right images: superior view of the ventricular images again shows dilation in PSP compared with PD and controls. The graphs on the right show the measured volumes as a percentage of the total intracranial volume. (Modified with permission from Cordato *et al.*, 2002. Also by permission of Oxford University Press.)

of the ADC was reported in one French vCJD case (Oppenheim *et al.*, 2000) where reduced striatal ADC was found in contrast to increased ADC in the pulvinar. These changes probably reflect different regional pathologies in vCJD: in the striatum, spongiosis predominates, while in the pulvinar, gliosis and neuronal loss are more prominent (Zeidler *et al.*, 2000).

Iatrogenic and familial CJD

There is much less information about the iatrogenic (iCJD) and familial (fCJD) forms. Iatrogenic CJD has arisen as a result of the use of contaminated neurosurgical instruments or EEG electrodes, grafts of dura mater or cornea,

and injection of human-derived pituitary growth hormone and gonadotrophin. It is notable that MRI signal abnormalities have not been observed in these cases (Thadani *et al.*, 1988; Pocchiari *et al.*, 1992; Lane *et al.*, 1994; Billette de Villemeur *et al.*, 1996; Rabinstein *et al.*, 2002). About 15% of all human CJD patients have a genetic basis, and more than 30 genotypes have been identified including various subtypes of the Gerstmann–Straussler–Scheinker syndrome and fatal familial insomnia. The phenotypes vary considerably. MRI findings of atrophy and basal ganglia signal hyperintensity in a small number of patients have been described (Windl *et al.*, 1996). In a time series study of 4 fCJD patients (Murata *et al.*, 2002), abnormalities

Fig. 19.7 Voxel-based morphometry in tremulous Parkinson's disease. Grouped analysis showing the areas of significantly increased grey matter density rendered on to three orthogonal slices of a stereotaxically normalized brain. Significance is denoted by the color code which represents Z scores. The cross hairs represent the thalamic area with the highest significance. on DWI appeared earlier in the caudate than in the putamen.

Functional MRI (fMRI) in neurodegenerative diseases

Introduction

Functional MRI is perhaps the most complex of the current MRI techniques. It is used as an index of regional cerebral blood flow (rCBF). fMRI measures a relative signal change between two states – active and baseline. This is a marker for a change in rCBF that is interpreted as a marker of neuronal metabolic activity. The result is correlated to performance of a specific task that was performed during scanning (Belliveau *et al.*, 1991; Rao *et al.*, 1993; Turner *et al.*, 1998). Advantages over radiotracer-based techniques (PET and SPECT) include the wider availability of imaging systems, independence of tracers, avoidance of ionizing radi-

ation and a relatively short scanning time. The use of fMRI in clinical practice is currently limited to case reports of planning of neurosurgical interventions, e.g. localizing the motor strip (Puce *et al.*, 1995; Atlas *et al.*, 1996) or language areas prior to resection of vascular malformations or tumours (Binder *et al.*, 1996; Bahn *et al.*, 1997b; Pouratian *et al.*, 2002; Baciú *et al.*, 2003) (Fig. 19.9). It is probable that its use in neurodegenerative disorders will increase in a similar manner.

For fMRI, the pattern of rCBF in an individual, or in a group of subjects, is compared with a control group who are scanned under identical conditions to make inferences concerning the activation. Questions which may be answered by fMRI can include the following.

Does a structurally abnormal area of cerebral tissue activate normally?

A structurally abnormal area would be hypothesized to have impaired activation. A structurally normal area may

Fig. 19.8 Diffusion-weighted image of confirmed sporadic CJD showing high signal in the anterior basal ganglia, and striking high signal in the right frontal lobe, with less marked cortical hyperintensity in the right insular and left frontal lobe.

however activate abnormally, providing pathophysiological information which is not detectable by routine structural imaging. Studies can also determine if activation is modulated by drugs (Loubinoux *et al.*, 1999; Pariente *et al.*, 2001).

Can fMRI detect subclinical or preclinical states?

One may be able to identify which members of an at-risk group have abnormal activation, e.g. the hippocampal activation in subjects with a family history of AD (Smith *et al.*, 1999). This could potentially lead to early enrolment of at-risk individuals in presymptomatic drug trials when neuroprotective therapies become available.

Does a cerebral region overactivate during task performance?

Regional overactivation may be a compensatory mechanism by which the diseased brain attempts to improve performance by recruiting cerebral regions which are less

affected by the disease. This method lends itself particularly to the study of developmental and learning disorders, e.g. dyslexia, but also applies to degenerative disorders, e.g. overactivation of lateral premotor cortex in PD during performance of sequential finger movements (Sabatini *et al.*, 2000). Over-activation should be cautiously interpreted since overactivation of an inhibitory nucleus may impair clinical function.

What is the time scale of the rCBF changes?

PET and SPECT have temporal resolutions of minutes, but changes in rCBF occur over seconds (Kleinschmidt *et al.*, 1996). The temporal resolution of fMRI allows for detection of haemodynamic changes which occur over approximately 1–3 seconds (Turner *et al.*, 1998; Samuel *et al.*, 1998).

Are discrete regions functionally related?

The spatial and temporal patterns of a set of activated regions allows inferences to be made on connectivity within a known neural network (Rowe *et al.*, 2002).

Method of fMRI

Basic principles

Some methods and pitfalls relevant to fMRI are similar to those of non-routine structural MRI, but others are specific to fMRI. To appreciate these, some knowledge of terminology is required and a brief account of fMRI will be given below.

Signal changes increase in proportion to the magnetic field strength: at 1.5 tesla, signal changes may be 2–4% (Kwong *et al.*, 1992), but at 4 tesla up to 28% signal change may be detected (Turner *et al.*, 1993). However, the safety of high field strength is not as well determined in humans, especially when combined with use of electrical equipment and most fMRI is currently performed on commercially available 1.5 tesla scanners. The abundance of hydrogen (^1H) nuclei and its large magnetic moment make it ideal for fMRI. As ^1H nuclei are excited by an applied radiofrequency (RF) pulse, some gain enough energy to flip (through a flip angle) to align anti-parallel to the magnetic field. A RF pulse sequence that involves application of a 90° followed by a 180° refocusing pulse is called a spin echo sequence. Relatively long TE (60 ms) and TR times (up to 2.5 s) are typically required². MRI data are encoded in a system called

² TE is the time from application of one RF pulse to the detection of the signal in the receiving coil (i.e. an echo) and determines the amount of decay. TR is the time from application of one RF pulse to the application of the next RF pulse (i.e. repetition) and determines the amount of recovery.

k -space (conceptually similar to a two-dimensional grid). Data are mathematically modelled along the rows of k -space, usually filling one row at a time. An image of voxels is generated after deconvolution. In conventional MRI, one line of k -space is filled every TR (i.e. during 1 echo, 1 line of voxels is filled). For a matrix of 256 voxels in one dimension and a TR of 0.5 s, filling 256 lines takes $256 \times 0.5 = 128$ seconds.

The two major advances which led to the development of fMRI from structural MRI were the ability to acquire MRI data very rapidly and the discovery of endogenous contrast.

Methods to acquire ultra-fast MRI

Involuntary head motion (even millimeters) from lengthy scanning protocols can seriously distort MR images (Weisskoff & Cohen, 1997). Cyclical motion artefact from heartbeat or respiration can be reduced by cardiorespiratory-gating but this adds to scanning time. Hemodynamic responses in vivo occur over 6–9 seconds (Frahm *et al.*, 1992) but can habituate over seconds (Samuel *et al.*, 1998). fMRI data are acquired in a slice-by-slice fashion and since the whole brain volume needs to be scanned in seconds, this means that each slice must be acquired in milliseconds.

A RF pulse sequence that varies as it is applied is called a gradient echo sequence. This requires additional coils within the bore of the magnet, leading to small inhomogeneities in the magnetic field. This causes additional loss of signal, called T_2^* decay. Gradient echo sequences are particularly susceptible to inhomogeneities and these were originally considered a nuisance in structural MRI, but it is the T_2^* signal which is used in fMRI. Hence, fMRI images are termed T_2^* weighted. By reducing flip angles and using gradient echo sequences, both TE and TR can be reduced (to about 5 and 50 milliseconds, respectively), enabling image acquisition in seconds. Fast MRI using gradient echo hardware has been achieved with different systems which have names depending on the manufacturer, e.g. FLASH (fast low angled shot) with Siemens. Using FLASH, visual cortex activation was detected during photic stimulation with a scanning time of 1.5 seconds (Frahm *et al.*, 1992). These conventional methods typically yield low signals and are sensitive to inflow phenomena and have now largely been superseded by the more advanced techniques described below.

Another method to reduce scanning time is to reduce encoding time. In the early 1980s, Mansfield's group were studying fast cardiac imaging and succeeded in acquiring whole body transverse human images in 57 ms (Chapman *et al.*, 1987) by filling k -space continually rather than sequentially. This encoding system fills a 2D plane of

k -space for each TR (i.e. during 1 echo, 1 plane was filled) and has become known as echo planar imaging (EPI). This approach generates more image distortion, especially near bony structures, such as sinuses. Technical advances have improved the signal/noise ratio and gradient echo EPI is now the basis for most fMRI studies (Kwong, 1995).

fMRI contrast

Exogenous contrast

This is analogous to the radiotracer method of PET. When Gadolinium diethylene triamine pentaacetic acid (Gd-DTPA) is injected during task performance, it accumulates in metabolically active areas. However, bolus injections render fMRI invasive and has now been replaced by methods relying on endogenous contrast.

Endogenous contrast

The BOLD (blood oxygenation level dependent) technique is the most commonly used method (Ogawa *et al.*, 1990). During activation, a mismatch occurs between the delivery of oxygenated blood and oxygen extraction (Fox & Raichle, 1986; Fox *et al.*, 1988; Frostig *et al.*, 1990), leading to a reduced concentration of deoxyhaemoglobin (dxHb) in venous capillaries of the activated region. Since dxHb is paramagnetic and decreases MR signal, a fall in the concentration of dxHb leads to an increase in T_2^* -weighted signal. In vivo, using 7 tesla gradient echo sequences, veins in rat cortex became brighter as blood flow through them increased (i.e. the veins received more oxygenated blood) (Ogawa *et al.*, 1990). Subsequently, in humans in vivo using a 1.5 tesla system, a 1.8% increase in signal was confirmed in primary visual cortex during photic stimulation (Kwong *et al.*, 1992). The decrease in dxHb concentration during activation has now been also shown by near infrared spectroscopy (NIRS). Motor cortex was identified by FLASH fMRI during finger movement and NIRS demonstrated a delay of <10 s from task performance to the fall in dxHb signal in the same region, demonstrating too the existence of the hemodynamic lag from neuronal activation to measured response (Kleinschmidt *et al.*, 1996).

Image pre-processing and analysis

This includes co-registration with emphasis on reduction of artefactual motion and removal of high and low frequency noise (Friston *et al.*, 1995a, c, 1996). For between-group comparisons in multi-subject studies, each individual's images can be spatially transformed into a standard stereotaxic space (Talairach & Tournoux, 1988). Spatial and temporal smoothing are applied to increase the signal to noise ratio. In the simplest form of analysis, each voxel

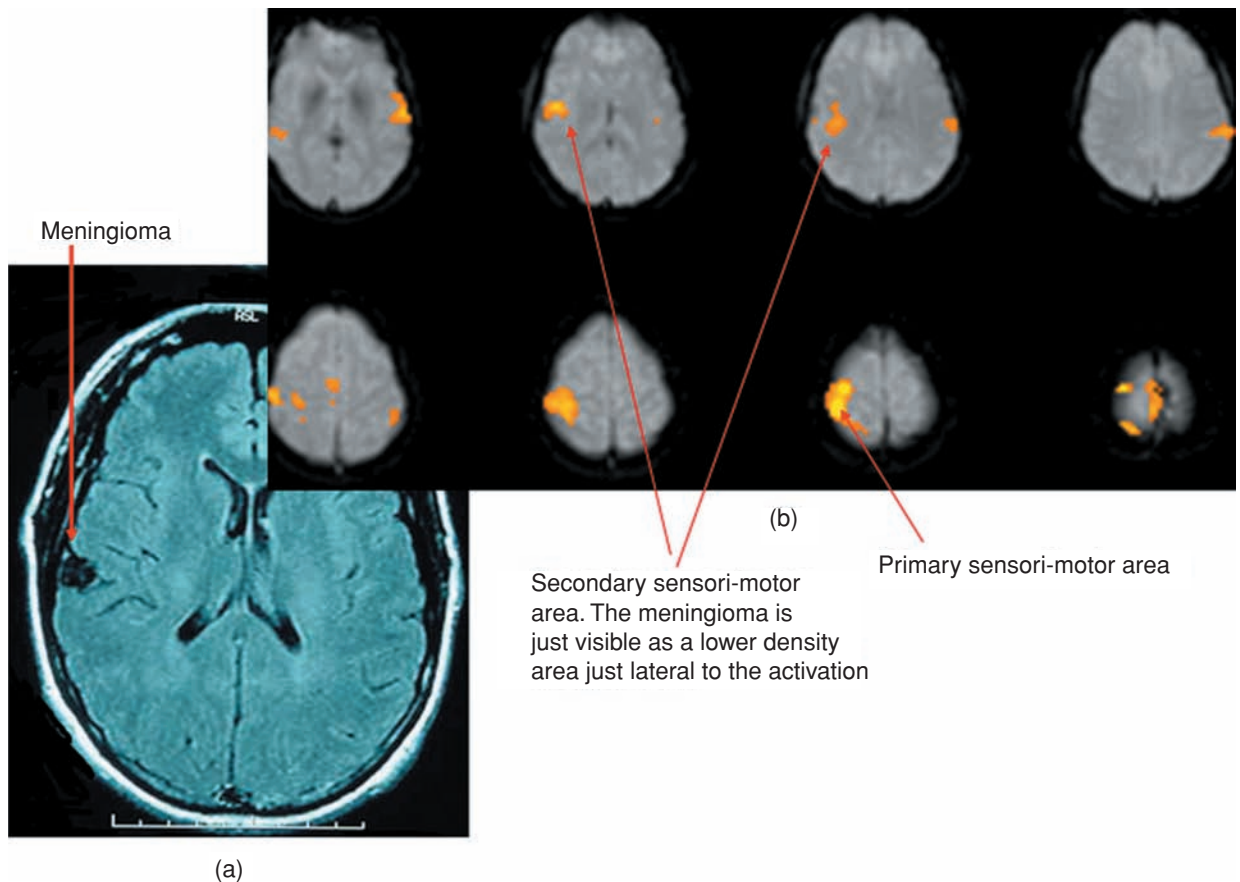

Fig. 19.9 The clinical application of fMRI in neurosurgical planning. (a) Structural axial FLAIR MRI of patient with a right superficial meningioma lying adjacent to the right secondary sensorimotor area. (b) FMRI activation associated with stimulation (using a brush) of the patient's left hand showing activation of right primary and secondary sensorimotor cortex. The activation is rendered directly on to T_2^* -weighted functional images in which the meningioma is visible as a low intensity area adjacent to the second sensorimotor area. The meningioma was successfully resected without sensorimotor compromise. (Personal communication, Courtesy of Mr R. Selway, King's College Hospital, London and Dr V. Ng, Maudsley Hospital, London.)

will display a time series, that is with a signal which alternates from lower intensity (during the baseline tasks) to a higher intensity (during the activated state). The task, hemodynamic response and BOLD effect can be modeled as a box-car function, i.e. alternating periods of "high" and "low" periods (e.g. see Fig. 19.10B), with the haemodynamic response typically lagged by 6–9 seconds after task performance. Alternatively, the hemodynamic response can be modelled as a sine wave or half-sine wave. Typically 60–100 T_2^* -weighted multi-slice data sets are acquired. Averaged "low" periods, (baseline state) are compared with averaged "high" periods (activated state) to determine activated voxels – so-called blocked-design subtraction studies.

Another method of fMRI analysis examines the hemodynamic responses but does not depend on prior assump-

tions of the shape or delay of the hemodynamic response, so called event-related fMRI. Voxels that are activated by a task are hypothesized to have a stereotyped hemodynamic response, irrespective of the shape of the response. Single cognitive or motor tasks are performed repeatedly every few seconds and fMRI signal is averaged in a manner similar to the back-averaging used in electrophysiological studies (Buckner *et al.*, 1996; Humberstone *et al.*, 1997b; Friston *et al.*, 1998; Clare *et al.*, 1999; Watanabe *et al.*, 2002). The variance of activated voxels would be expected to be lower than the variance of voxels depicting random noise. The magnitude of signal changes in event-related fMRI is generally smaller than in blocked-design subtraction studies and higher magnetic fields strengths (3 and 4 tesla) are usually required (Richter *et al.*, 1997; Humberstone

et al., 1997b; Clare *et al.*, 1999), although results have been reported using conventional scanners (Toma *et al.*, 1999).

Presentation of results

fMRI comparisons involve the analysis of tens of thousands of voxels by using automated statistical programs. Differences surviving a predetermined threshold are considered physiologically significant. Results are presented as color-coded maps rendered on to a structural MRI for gyral localization, giving a spatial resolution of 1–3 mm (Turner *et al.*, 1998) (e.g. Fig. 19.11). An alternative method is to present black and white 3-D maximum intensity projections (e.g. Fig. 19.12) with the spatially normalized stereotaxic coordinates of the voxel with peak statistical significance, representing the center of a cluster. One can determine the number of voxels in a cluster and the magnitude of the difference, usually 0.5–5% with conventional strength MRI scanners. The time course of the change can also be inspected (e.g. Fig. 19.10B).

Pitfalls in fMRI for neurodegenerative disorders

Experimental design

During fMRI, subjects are isolated from examiners and direct visual assessment is not possible. Claustrophobia can be a problem in normal subjects but more so in subjects with degenerative disorders. Cueing and stimulation equipment should be outside the scanner and signals delivered to the subjects via VDU projection systems or headphones. Assessment of task performance is by repetition of the task outside the scanner or by use of specifically designed, non-ferromagnetic equipment which can be safely introduced into the magnet. Long coiled cables can induce heating and can be dangerous if in contact with a subject.

Inter-subject variability

Early fMRI studies in normal humans reported results of several, single-subject analyses. Generally these were in agreement with PET results but some individual variability existed (Tyszka *et al.*, 1994; Richter *et al.*, 1997; Humberstone *et al.*, 1997a; Toma *et al.*, 1999). Possible explanations include motion artifact, task strategies, gyral anatomy and vessel architecture. These different activation patterns during performance of identical tasks in healthy controls will cause difficulty in the interpretation of patient studies, e.g. how should one interpret the results of a study in which a patient with PD, who fails to activate mesial frontal cortex, is compared with a control volunteer who also fails to

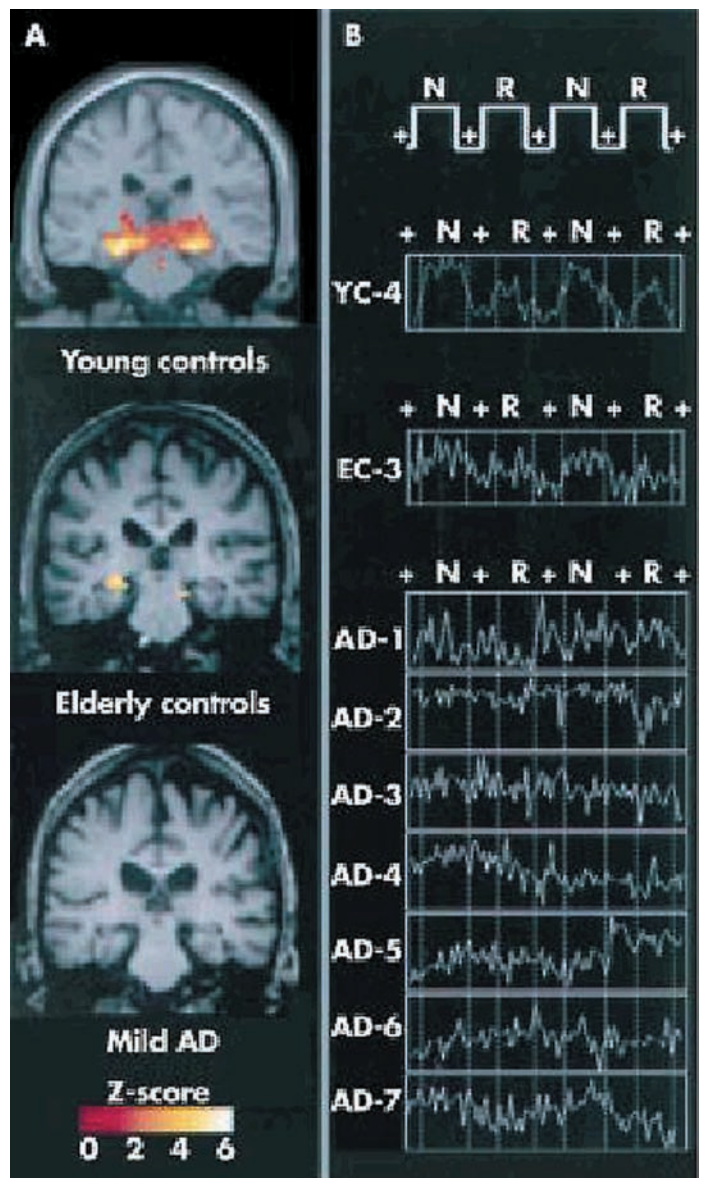

Fig. 19.10 Patterns of activation during visual memory testing in controls and AD. (A) Within-group activation in young controls, elderly controls and mild AD during presentation of novel and repeated face-name pairs. There is much less activation in the elderly controls and no activation in the AD group at the hippocampus. (B) The box car function of the paradigm of presentation of novel (N) and repeated (R) face-name pairs (upper tracing) shows a clear similarity to the fMRI signal in the hippocampal region from a young-control subject (YC-4), less similarity in an elderly control (EC-3) and little similarity in the seven AD subjects (AD-1 to 7). (Modified with permission from Sperling *et al.*, 2003 and with permission of BMJ Publishing Group.)

activate this region? It is anticipated that fMRI will evolve sufficiently to allow interpretation of individual studies.

Spatial normalization of brains with degenerative diseases

For multi-subject grouped studies, spatial normalization is required. This has the disadvantage of loss of spatial resolution but gives the advantage of less variability when making inferences about a disease process. While this may seem appropriate for normal scans, it may be less meaningful in studies of degenerative diseases with regional atrophy, because spatial normalization of an atrophic region may be inappropriate. Hence the stringency of spatial transformations should be considered.

Differing analytical software

The field of data analysis has seen an explosion of methods over the last decade (Gold *et al.*, 1998), each method developed by an institution with expertise in imaging (e.g. statistical parametric mapping (Friston *et al.*, 1995b), AFNI (Cox, 1996), STIMULATE (Strupp, 1996), Generic brain activation mapping (Brammer *et al.*, 1997)). One group showed that event-related fMRI detects activation which may not be detected by blocked-design subtraction methods (Mechelli *et al.*, 2003). Currently, there is no standard analysis method. This hinders the uniform interpretation of results from different centres. Also, high field strength scanners are more sensitive to small changes in signal and so the possibility of false negatives results on lower field scanners with high statistical thresholds should be recognized.

The brain-vein issue

In an early motor study of the precentral cortex, fMRI signal increased by 2–32% during finger–thumb oppositions. One individual who underwent a magnetic resonance angiogram (MRA) showed a correlation between the location of the activated fMRI focus and the location of a pial venule (<1 mm diameter), raising the possibility that BOLD signal might originate from draining venules (Lai *et al.*, 1993). Similarly, when primary visual cortex was directly viewed through cranial windows in lightly anesthetized monkeys during optical stimulation (Turner & Grinvald, 1994), the delayed decrease in dxHB concentration occurred 2–3 seconds following stimulus onset as expected but was predominantly detected in subpial venules up to 2 mm distant from the cortical parenchyma. These findings suggest that BOLD signal may have 2 components: one from parenchymal capillaries; the other from venules draining an area larger than the focus of activity. Flow components can be minimized by applying tailored RF pulses (Frahm *et al.*, 1987) and some groups

compare fMRI activations with MRA (Frahm *et al.*, 1992; Lai *et al.*, 1993). However, it would be surprising to see changes far downstream in a venule since effects of oxygenation and inflow in a small cortical domain are likely to be diluted rapidly. In multi-subject studies, it is unlikely that the location of individual venules is sufficiently similar to allow signal to persist after inter-subject averaging. Nonetheless, it should be remembered that BOLD signal may not originate solely from activated capillaries (Cannestra *et al.*, 2001).

Having described the methods and pitfalls of fMRI, we shall now review its current use in the investigation of neurodegenerative disorders.

Dementias

Alzheimer's disease

The majority of current literature relates to AD. Activation studies have interrogated the hippocampus and entorhinal cortex, where pathological studies, volumetric MRI and neuropsychological studies have demonstrated early changes in AD. Significant activation at these loci using auditory and visual encoding paradigms initially had to be demonstrated in young normal individuals (Kato *et al.*, 1998, 2000; Stark & Squire, 2000). In one study, no differences were found between younger and older nondemented individuals (Kato *et al.*, 2001) during visual encoding, whereas another study showed a decline of right hippocampal activation in the elderly during encoding of novel faces who also showed less prefrontal and greater bi-parietal activation than the younger individuals (Sperling *et al.*, 2003). Elderly individuals with age-related memory decline (Small *et al.*, 2002) showed a variable loss of entorhinal activation and less activation of the subiculum and dentate gyrus (Small *et al.*, 1999).

In contrast, patients with AD show a marked lack of activation in the entire hippocampal formation and the entorhinal cortex (Small *et al.*, 1999) (Fig. 19.10) (Small *et al.*, 2000; Kato *et al.*, 2001; Sperling *et al.*, 2003) and less activation in left temporal lobe, right prefrontal cortex and right supramarginal gyrus during visual encoding (Fig. 19.13). Another study employed a visuospatial angle estimation paradigm to specifically engage visual association cortex and showed less activity in superior parietal lobule but more activity in oculotemporal cortex in AD (Prvulovic *et al.*, 2002). A study of visually-guided saccadic tracking found impaired activation of the right intraparietal sulcus in 2/3 of patients, while the remaining 1/3 had normal patterns (Thulborn *et al.*, 2000). The reasons for these differences are currently unclear.

Fig. 19.11 Between-group fMRI differences in PD compared with controls during sequential finger movements ($P < 0.01$, $z =$ height in mm from commissural plane in spatially normalized images). (a) Areas of relative underactivity in PD compared with controls. (b) Areas of relative overactivity in PD compared with controls. (Modified with permission from Sabatini *et al.*, 2000. Also by permission of Oxford University Press.)

One multi-subject, between-group study showed no correlation between activation and atrophy in non-demented elderly individuals. In contrast, patients with AD showed a positive correlation between activation and atrophy in left inferior frontal gyrus, i.e. more activation in an area with more atrophy. This suggests a possible specific compensatory mechanism in left inferior frontal gyrus in AD (Johnson *et al.*, 2000). Additional regions of overactivation in AD have been described in bilateral frontal and cingulate cortex during match–mismatch verbal tasks requiring decision making (Saykin *et al.*, 1999). Treatment with rivastigmine enhances activation in fusiform and frontal cortex during visual encoding but simultaneously decreases activation in frontal cortex (Rombouts *et al.*, 2002), suggesting that the mechanism of action of anticholinesterases may not be uniform throughout the cortex.

In summary, the failure of activation of the entorhinal cortex appears to be a consistent feature of AD but the differences of activation of the other cortical sites is more variable and should always be interpreted in relation to the nature of the performed task. The variable results raise awareness that fMRI in neurodegenerative disorders should generally be considered preliminary and highlight the difficulties with interpretation as outlined earlier.

Individuals at risk of AD

Studies of subjects at risk of developing AD have attempted to detect early abnormalities which are undetectable by structural imaging or neuropsychological testing. In these studies, patients were considered at risk if they had a positive family history and the presence of at least one ApoEε4 allele. At risk individuals showed reduced activation in the mid- and posterior inferotemporal regions bilaterally during naming and letter fluency tasks despite identical performance to controls (Smith *et al.*, 1999). However, in other studies of at-risk individuals, hippocampal overactivation was detected along with a greater number of activated regions generally, including inferior frontal, prefrontal and temporal cortex, suggesting that at-risk individuals may need early recruitment of preserved cortical areas to maintain normal function (Bookheimer *et al.*, 2000; Burggren *et al.*, 2002). These studies require further corroboration as they hold a potential to identify at risk individuals who may benefit from disease-modifying therapies when these become available.

Other dementias

An early study on a single patient with DLB showed less primary visual cortex activation during a period with hallucinations compared with a period on treatment with

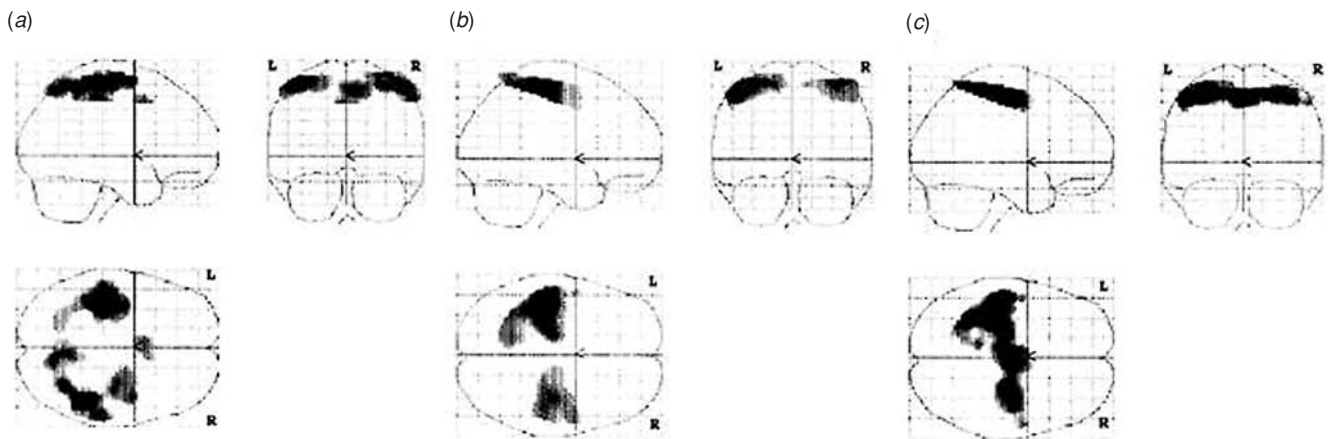

Fig. 19.12 Within-group maximum intensity projection maps of fMRI activation associated with joystick movements for controls, PD off and on treatment ($P < 0.01$ uncorrected, extent threshold 10 voxels). Fig. 19.13 Grouped differences between young controls, elderly non-demented controls and AD during visual stimulation. The area depicted in red is the right visual association area (1), where activation occurred in all three groups. The areas in blue are left anterior-inferior temporal lobe (2), the right entorhinal cortex (3), the right lateral prefrontal regions (4) and the right supramarginal gyrus (5), where there was activation in all non-demented subjects but no activation in AD subjects ($p < 0.0005$). (Modified with permission from Kato *et al.*, 2001.)

risperidone without hallucinations (Howard *et al.*, 1997). There have been no reported studies in other dementias. Undoubtedly, study of these will be rewarding since the presence of early associated features (e.g. aphasia, myoclonus, parkinsonism, hallucinations, apraxia, incontinence) offers new opportunities to study functional correlates of these less common symptoms and signs.

Extrapyramidal disorders

Parkinson's Disease

The majority of studies relate to PD. It is generally easier to study PD than other extrapyramidal syndromes because the MR images do not have discrete regions of altered signal,

which distorts MRI, (e.g. MSA Fig. 19.3(9), Wilson's disease Fig. 19.3(13)) and atrophy is usually not extensive early in the course of the illness. Many PET studies on PD also provide a standard with which to corroborate fMRI. One drawback of studying PD is motion artefact since most patients have tremor and those who do not may not represent typical idiopathic PD.

An early fMRI study comparing PD with controls confirmed that activation in dorsolateral prefrontal cortex (DLPFC) and rostral supplementary motor area (SMA) was reduced, while activation in caudal SMA, lateral premotor, primary motor and inferior parietal cortex was enhanced, during performance of complex finger movements (Sabatini *et al.*, 2000) (Fig. 19.11). These results

replicate previous PET studies (Playford *et al.*, 1992; Samuel *et al.*, 1997), although overactivation of primary motor cortex was not detected by PET. Similarly, primary motor cortex overactivation, associated with a diffuse hemispheric overactivation, has now also been demonstrated in vivo (Haslinger *et al.*, 2001) (Fig. 19.12) and in a rat model of parkinsonism during electrical stimulation of a forepaw (Pelled *et al.*, 2002). In contrast, primary motor cortex hypo-activation was detected in another recent study during finger movements and this hypo-activation reversed with levodopa treatment, in a manner analogous to the levodopa- and apomorphine-induced reversal of hypoactive SMA detected with PET (Jenkins *et al.*, 1992; Rascol *et al.*, 1994). Taken together, fMRI studies of PD are in broad agreement with PET studies, although the nature of primary motor cortex abnormality – or compensation – is more variable and needs clarification.

Studies of cognitive function using a sentence comprehension task in PD have shown a similar phenomenon (Grossman *et al.*, 2003). While a control group of seniors showed activation in temporal, ventral and inferior frontal regions of the left hemisphere and striatum, patients with PD showed under-activity of striatal, prefrontal, and right temporal regions but over-activity in right inferior frontal and left temporal-parietal areas. This study extends the concept of compensatory cortical overactivation for cognitive function in PD, in a manner similar to the proposed overactivation of premotor–parietal–cerebellar circuits to compensate for impaired motor performance (Samuel *et al.*, 1997; Sabatini *et al.*, 2000).

More complex analyses of cognitive processes in PD can be studied with fMRI. Rowe *et al.* studied effective connectivity (the influence of one brain region on another) by measuring fMRI signal during sequential finger movement tasks when subjects had either no additional cognitive load, or they were asked to “think about the next move” (i.e. attention to action), or during presentation of colored lights (a distractor task) (Rowe *et al.*, 2002). Comparing all motor tasks with rest, an atypical overactivation in SMA was detected in PD. This had previously been demonstrated only under specific conditions of additional cognitive load with PET (Catalan *et al.*, 1999; Samuel *et al.*, 2001). Normal subjects showed an increase in coupling between prefrontal cortex and SMA during attention to action, which did not occur with the distractor task. Patients with PD failed to show an increase in coupling during attention to action. This supports the view that in PD, there is a functional disconnection of SMA from prefrontal cortex during attention to action and implies that the typical underactivity of mesial frontal cortex is task dependent, rather than a fixed deficit.

Treatment of PD includes deep brain stimulation (DBS) of the thalamus, subthalamic nucleus, and globus pallidus. The safety of fMRI during DBS with external stimulation (i.e. before implantation of the pulse generator) was shown in patients with chronic pain and essential tremor (Rezai *et al.*, 1999). At the point of stimulation, the electrode tip causes an artefact which hinders analysis, but at sites distant to DBS, fMRI can assess metabolic responses. Patients with PD with DBS (of subthalamic nucleus or ventral intermedius nucleus of the thalamus) showed increased activation in subcortical nuclei ipsilateral to stimulation (thalamus, globus pallidus, substantia nigra, superior colliculus) and in prefrontal cortex and lateral premotor cortex (Jech *et al.*, 2001, 2003). There was, however, considerable individual variability and these results are considered preliminary.

In contrast to cortical signals, there is limited and variable information on subcortical activation. The subcortical nuclei, in particular dorsal striatum, are believed to be dysfunctional in PD and theoretically, fMRI would be an ideal tool with which to demonstrate abnormal metabolic activity here. Analysis methods may have to be tailored to specifically detect activation in the basal ganglia, for example the spatial smoothing applied to enhance cortical signal may be suboptimal for detection of a small number of voxels with low amplitude signal change. Some groups have detected basal ganglia activation in normal volunteers (Bucher *et al.*, 1995) and in patients with a variety of focal pallidal lesions, although results have been subtle and variable (Bucher *et al.*, 1996). In 15 normal volunteers studied by double slice (4 mm) FLASH fMRI, the mean number of activated voxels within pallidum was 7 ± 1 , contralateral to a limb during very rapid pronation-supination movements. Putaminal activation was more variable. Patients with pallidal lesions had generally less pallidal activation (mean = 5 ± 1 voxels). Only recently has striatal activation been detected in normal subjects with grouped studies (McClure *et al.*, 2003). Grouped studies may provide one manner with which to increase the signal/noise ratio in the basal ganglia. Detection of robust signals in basal ganglia is therefore at an early stage. fMRI of subcortical structures in neurodegenerative disorders is further hampered by the combination of atrophy, gliosis, and the local deposition of metallic compounds.

Other extra-pyramidal syndromes

There have been few studies of fMRI in Huntington's disease. During performance of a maze task, reduced fMRI signal was observed in caudate nucleus and sensorimotor, occipital, parietal cortex while increased activation was found in left postcentral and right middle frontal gyri (Clark

Fig. 19.14 Between-group fMRI differences in ALS compared with controls during right hand movements, showing the re-organization of the motor network in ALS. ALS (red) controls (blue). (Modified with permission from Springer-Verlag Journal; Konrad *et al.*, 2002.)

et al., 2002). The significance of these changes is undetermined and has not been correlated to focal regions of cortical atrophy. Cognitive and motor symptoms in HD have been suggested to result from a failure of central inhibitory mechanisms in basal ganglia-thalamo-cortical circuits. The presence of inhibitory central processing is postulated to prevent involuntary reactions from interfering with normal behavior. This phenomenon has been studied with fMRI with a “masked prime” task, in which visible left- or right-pointing arrows are presented, preceded by briefly presented and subsequently masked prime arrows (Aron *et al.*, 2003). Subjects performed key-presses to each target in either the same (a compatible response) or opposite direction (an incompatible response). Normally, there is a faster reaction time for incompatible responses. Chorea HD subjects showed an absence of this effect while non-chorea subjects showed an excessive inhibition compared with controls. These results suggest that dysfunction of basal ganglia-thalamo-cortical circuits can lead to either lack of motor inhibition or excessive inhibition but does not further distinguish the site of these mechanisms.

To date, there have been no reported fMRI studies of other extrapyramidal syndromes.

Motor system disorders

Currently available publications relate to upper motor neuron dysfunction in amyotrophic lateral sclerosis (ALS),

whereas the brunt of pathological change occurs in the anterior horn cells and in the giant Betz cells of the motor cortex. One early study investigated cortical reorganization in ALS by studying performance of simple finger flexions with a force generation of only 10% of the maximum in order to avoid the confounding effects of recruitment of additional muscles as patients attempt to overcome their motor impairment (Konrad *et al.*, 2002). This grouped study showed activation of primary motor, lateral premotor, mesial frontal and inferior parietal cortex, but in the ALS group the center of mass of activation of primary motor cortex was shifted anteriorly by 4–7 mm in stereotaxic space to encroach on the posterior aspect of lateral premotor cortex. This corroborates previous PET studies in ALS (Kew *et al.*, 1993). In addition, enhanced ipsilateral primary motor cortex activation was present. Premotor cortex has a direct projection to spinal cord (Dum & Strick, 1991) and the expansion of activation of motor areas in ALS may represent cortical reorganization in response to corticospinal tract disruption and Betz cell loss (Fig. 19.14).

It is, however, also possible that expansion of cortical motor areas during movement in ALS represents impaired cortico-cortical inhibition (Ziemann *et al.*, 1997) as a result of glutamate excitotoxicity. In direct contrast to motor studies, passively stroking the palm of ALS patients during a pure sensory paradigm consistently showed reduced

activation of sensorimotor cortex without significant differences in thalamic or cerebellar activation, indicating that the sensory system appears intact at least up to, but not including, the cortical level (Brooks *et al.*, 2000). The impaired cortical activation following passive sensory stimulation may simply be a result of loss of cortical neurons, detected subclinically. If reproducible, it raises the possibility that passive fMRI sensory studies can be performed in severely motorically impaired ALS patients for a potentially useful diagnostic test. Further studies of passive and cognitive tasks in motor neuron disease are eagerly awaited. There are no fMRI reports on the other forms of motor neuron diseases.

Ataxias

To date, there have been no reported studies of fMRI in degenerative sporadic or hereditary ataxias, such as SCA syndromes, Friedreich's ataxia, ataxia telangiectasia, ataxia with oculomotor apraxia or other idiopathic disorders. Cerebellar activation can, however, be studied with fMRI in cerebellar degeneration. One early study demonstrated cerebellar somatotopy (Wessel & Nitschke, 1997). It is likely that cerebellar studies will become more widespread in future.

Prion diseases

To date, there are no published reports of fMRI in prion diseases.

Introduction

Neurodegenerative diseases, particularly those affecting the basal ganglia and related pathways, are often associated with abnormal activity of nigrostriatal dopaminergic projections. The integrity of this system can be assessed by neuroimaging methods utilizing radioligands that bind to pre or postsynaptic components. By contrast, the functional organization of the basal ganglia and its projections can be assessed by imaging regional cerebral blood flow and metabolism as measures of neural activity. Single photon and positron emission tomographic imaging (SPECT and PET) have been applied in studies of network activity. While these studies have relied mainly upon PET imaging in the resting state and during brain activation, SPECT and magnetic resonance techniques have also been used for this purpose. In this chapter, we will review the development of PET and SPECT techniques as markers of neurodegenerative processes specifically to assess rates of disease progression and the effects of novel therapeutic interventions.

Presynaptic dopaminergic function

Dopamine transporter imaging

The dopamine transporter (DAT) enables the release and reabsorption of dopamine in the nigrostriatal intersynaptic cleft. Different radiotracers, mostly cocaine analogues, have been developed to quantify striatal DAT binding as an objective marker of the integrity of presynaptic nigrostriatal dopamine terminals (Wilson *et al.*, 1996; Ma *et al.*, 2002) (Fig. 20.1). DAT imaging can be implemented with a variety of radiotracers using either SPECT or PET techniques. The major SPECT compounds in current

use include [^{123}I]-2 β -carbomethyl-3 β -(4-iodophenyl) tropane (β CIT) and its fluoropropyl derivative [^{123}I] FPCIT, [^{123}I]-Altropane, [^{123}I]-(*N*)-(3-iodopropen-2-yl)-2 β -carbomethoxy-3 β -(4-chlorophenyl) tropane (IPT), and [$^{99\text{m}}\text{Tc}$]-2 β -((*N*, *N'*-bis(2-mercaptoethyl)ethylene diamino)methyl), 3 β -(4-chlorophenyl)tropane (TRO-DAT). DAT binding can be assessed with a variety of PET ligands including [^{18}F]-FPCIT, [^{76}Br]-fluorethylmethyl-2 β -carboxymethoxy-3 β -4-bromophenyl-tropane (FE-CBT), to name only a few (Dhawan & Eidelberg, 2001; Ribeiro *et al.*, 2002). Striatal DAT binding can be quantified by any of these methods, which differ primarily in the time of attained equilibrium and the duration of the scanning procedure.

The major application of DAT binding imaging procedures has been to assess the rate of decline in presynaptic dopaminergic function in patients with Parkinson's disease (Fig. 20.1). In SPECT studies with [^{123}I]- β CIT (Pirker *et al.*, 2002), striatal DAT binding declined by 7.1% per year in short duration PD, and 14.9% in short duration atypical parkinsonian syndromes. The rate of decline in PD appears to slow markedly with evolving disease (Pirker *et al.*, 2002). In another [^{123}I]- β CIT study, 32 PD patients and 24 healthy controls underwent longitudinal SPECT imaging over a 1–4 year period. PD subjects demonstrated a decline in striatal DAT binding of approximately 11.2% per year from baseline as compared to 0.8% per year in control subjects (Marek *et al.*, 2001).

Given that the rate of disease progression is likely to differ in typical and atypical parkinsonism, differential diagnosis may be an important attribute of imaging in the study of neuroprotective interventions for PD. A number of DAT binding studies have been performed to assess the use of this method in differentiating parkinsonian syndromes. Booij and colleagues (2001) used [^{123}I]-FPCIT to differentiate idiopathic PD patients

FPCIT/PET Images

Fig. 20.1 FPCIT PET images (see text) showing continued losses of dopamine transporters in the striatum of a patient with early stage Parkinson's disease scanned over a 3-year period. Annual declines in DAT binding of approximately 5% were present in the caudate and putamen of this subject. (Courtesy of Dr Yilong Ma.)

from those with other forms of parkinsonism (Booij *et al.*, 2001). [^{123}I]- βCIT has also been used to distinguish PD from vascular parkinsonism, in which striatal DAT binding was retained (Gerschlager *et al.*, 2002). In Wilson's disease, striatal DAT binding with [^{123}I]- βCIT was shown to be normal in asymptomatic patients and in patients with hepatic disease. By contrast, DAT binding was reduced in patients with neurological disease; the severity of neurological signs correlated with this measure (Barthel *et al.*, 2001). Another study revealed that patients with essential tremor do not exhibit abnormal reductions in striatal DAT binding (Antonini *et al.*, 2001). Striatal DAT binding is also normal in dopa responsive dystonia (DRD) (Jeon *et al.*, 1998), which differentiates these patients from those with young onset PD.

In a recent study, 157 PD and 26 multiple systems atrophy (MSA) patients were studied with [^{123}I]- βCIT /SPECT. Striatal uptake was markedly reduced in both the PD and MSA groups. However, the MSA subjects displayed more symmetric DAT loss compared with the PD patients, in accord with their clinical manifestations. Comparison of the relative loss of DAT binding in the caudate and putamen did not improve diagnostic accuracy in distinguishing between PD and MSA (Varrone *et al.*, 2001). SPECT can also detect decreased striatal DAT binding in asymptomatic relatives of PD patients, who are proposed to be at greater risk to develop PD (Maraganore *et al.*, 1999).

The assessment of striatal DAT binding with [^{123}I]- βCIT /SPECT has good test-retest reproducibility (Seibyl *et al.*, 1997); treatment with pergilide and L-selegiline has

no effect on imaging results (Ahlskog *et al.*, 1999; Innis *et al.*, 1999). Thus, patients may remain on these medications during scanning, although imaging parameters may be affected by concurrent levodopa administration (Guttman *et al.*, 2001). It has been shown that striatal DAT binding decreases with age in healthy volunteers and PD patients (Tissingh *et al.*, 1997; Kazumata *et al.*, 1998; Dhawan & Eidelberg, 2001). Therefore, age correction is generally needed when comparing subjects of different age groups or when conducting longitudinal progression studies (Sawle *et al.*, 1990; Eidelberg *et al.*, 1993; Kish *et al.*, 1995; van Dyck *et al.*, 1995; Ishikawa *et al.*, 1996; Volkow *et al.*, 1996; Kazumata *et al.*, 1998).

Dopa decarboxylase activity

Presynaptic nigrostriatal dopaminergic dysfunction has also been assessed extensively with [^{18}F]-FDOPA/PET. This imaging technique estimates the rate of decarboxylation of FDOPA to [^{18}F]-fluorodopamine, a function of dopa decarboxylase (DDC) activity, as well as its storage in dopaminergic nerve terminals. FDOPA/PET scans have routinely been analyzed by a multiple time graphical approach incorporating plasma or brain input functions (Brooks *et al.*, 1990; Ishikawa *et al.*, 1996; Eidelberg *et al.*, 2000), or by formal compartmental models to estimate specific kinetic rate constants for striatal DDC activity (Gjedde *et al.*, 1991; Dhawan *et al.*, 1996; Eidelberg *et al.*, 2000). The results of recent studies using this tracer suggest that the striato-occipital FDOPA uptake ratio

determined from a single 10 min 3-D PET scan can be as accurate as the more complex measures (Ishikawa *et al.*, 1996; Nakamura *et al.*, 2001; Dhawan *et al.*, 2002). Those PET approaches have been used to obtain objective correlates of disease severity and to discriminate early stage PD patients from normal volunteers (Eidelberg *et al.*, 2000; Dhawan & Eidelberg, 2001). Striatal FDOPA measurements were found to correlate with dopamine cell counts measured in postmortem specimens (Pate *et al.*, 1993; Snow *et al.*, 1993).

The progression of PD has also been widely studied with FDOPA/PET (Morrish *et al.*, 1996). In a 5-year follow-up study, it was estimated that the annual decline in FDOPA uptake is 10.3% in the posterior putamen, 8.3% in the anterior putamen, and 5.9% in the caudate (Nurmi *et al.*, 2001). According to these findings, the preclinical period was calculated to be 6.5 years for the posterior putamen, while caudate FDOPA uptake was likely to be normal at disease onset.

Additionally, FDOPA/PET has been used to differentiate among parkinsonian syndromes (Eidelberg *et al.*, 2000). For example, in early idiopathic PD, FDOPA uptake is diminished primarily in posterior putamen and relatively preserved in anterior putamen and caudate; this gradient is not present in MSA (Brooks *et al.*, 1990). Nonetheless, subsequent studies have shown that caudate/putamen differences are not always sufficiently precise to categorize individual cases (Eidelberg *et al.*, 1995, 2000). In a subsequent study, striatal FDOPA separated healthy subjects from patients with parkinsonism, but did not differentiate PD from MSA patients (Antonini *et al.*, 1997).

This method may, however, differentiate corticobasal ganglionic degeneration (CBGD) from PD (Laureys *et al.*, 1999). Mild nigrostriatal presynaptic dopaminergic hypofunction, with equally affected caudate and putamen, has also been described in periodic limb movements and restless legs syndrome (Ruottinen *et al.*, 2000), although FDOPA/PET was found to be normal in a prior study (Trenkwalder *et al.*, 1999).

The pathophysiology of hereditary PD has also been studied with FDOPA/PET. This technique was used to assess dopaminergic function in adult-onset parkinsonism of pseudo-dominant inheritance associated with parkin mutations (Hilker *et al.*, 2001, 2002). Striatal FDOPA uptake was reduced in patients with compound heterozygous parkin mutations, most prominently in the posterior putamen. In asymptomatic carriers of a single parkin mutation with an apparently normal allele, a mild but significant decrease in uptake was present in both caudate and putamen. The reduction in striatal FDOPA uptake increased in magnitude with the number of mutated alleles.

The dopaminergic innervation of extrastriatal brain regions has also been studied using FDOPA/PET. In one study, frontal mesocortical monoamine projections were imaged in unmedicated early PD patients and found to have increased activity (Rakshi *et al.*, 1999). A gender difference in this dopamine projection system has also been described in early stage disease (Kaasinen *et al.*, 2001).

Nigrostriatal dopaminergic function has been assessed in PD patients undergoing embryonic dopamine cell implantation. Transplant recipients rescanned one year following surgery demonstrated a 40.3% increase in putamen FDOPA uptake while placebo operated patients demonstrated a minimal decrement (Nakamura *et al.*, 2001). FDOPA/PET was also used to study the pathogenesis of the transplantation procedure. Caudate and putamen FDOPA uptake was compared between dyskinetic and non-dyskinetic transplant recipients. In the dyskinesia group, putamen FDOPA uptake was greater than in the non-dyskinetic group. The relative increases were localized to posterodorsal and ventral areas of the left putamen (Ma *et al.*, 2002) (Fig. 20.2).

Vesicular monoamine transporter

The presynaptic vesicular monoamine transporter (VMAT) is involved in the packaging and transport of monoamines to storage vesicles located in nerve terminals. Radioligands that bind to VMAT have been used to measure nerve terminal density (Frey *et al.*, 1996). These compounds may be especially valuable as markers of presynaptic dopaminergic function in PD patients because of the high level of VMAT2 in striatal terminals and the insensitivity of protein expression to antiparkinsonian therapeutic agents. Precise and specific *in vivo* measures of VMAT2 are possible with [¹¹C]-dihydrotetrabenazine (DTBZ) and PET imaging. This approach appears to be well suited to assess nigrostriatal dysfunction and disease progression (Frey *et al.*, 2001).

Postsynaptic dopaminergic function

In an earlier review, we summarized imaging studies of D1 and D2 neuroreceptor binding in PD (Eidelberg *et al.*, 2000). Subsequently, this approach has been used to differentiate between parkinsonian syndromes. A SPECT study was performed using [¹²³I]-(*S*)-5-iodo-7-N-[(1-ethyl-2-pyrrolidinyl)methyl] carboxamido-2,3-dihydrobenzofuran (IBF) to assess D2 receptor binding in patients with PD, MSA, and progressive supranuclear palsy (PSP) (Kim *et al.*, 2002). D2 binding in posterior putamen was abnormally elevated in the untreated PD cohort, and significantly reduced in the MSA group. The

Fig. 20.2 Striatal FDOPA uptake in dopamine cell transplant recipients with and without postoperative dyskinesia (DYS+ and DYS−, respectively). In the DYS+ group, post-transplantation FDOPA uptake was significantly elevated ($p < 0.001$, corrected) in a crescent-shaped cluster of voxels within the left putamen. Group differences in engraftment were greatest in the dorsal aspect of this structure ($Z_{\max} = 3.58$; $x = -32$, $y = -2$, $z = 6$ mm, red arrows). A second focal area of increased uptake in DYS+ subjects was localized ventrally and more anteriorly ($Z_{\max} = 3.39$; $x = -28$, $y = 2$, $z = -8$ mm, white arrows). No significant group differences were present in the right putamen. [The color stripe represents Z scores thresholded at 3.27 ($p = 0.001$). Representative sagittal (left) and coronal (right) MRI sections are displayed with reference to the anterior–posterior commissure line].

ratio of posterior putamen to caudate D2 binding revealed the caudate to be greater in 16 of 18 PD patients and in all PSP patients; the caudate was lower in 5 of 7 MSA patients. These findings suggest that SPECT quantification of striatal D2 receptor binding can be helpful in discriminating MSA from other forms of parkinsonism. Similarly, [^{123}I]-iodolisuride was used with SPECT to discriminate PD from parkinson-plus syndromes (PPS) (Prunier *et al.*, 2001). The striato-occipital ratio was different statistically between PD and PPS.

D2 receptor function in early stage PD has been assessed utilizing two PET ligands: [^{11}C]-raclopride (RAC) and [^{11}C]-N-methylspiperone (NMSP) (Kaasinen *et al.*, 2000). With both methods, receptor binding was increased in the putamen contralateral to the predominant symptoms as compared with the ipsilateral side. Because this increase was seen with both the reversible (RAC) and the irreversible ligand (NMSP), this phenomenon is not likely to be a consequence of altered endogenous dopamine levels.

RAC was used to measure synaptic dopamine release from embryonic nigral transplants in the striatum of a patient with advanced PD. In this patient, who had received a transplant in the right putamen 10 years previously, the grafts had restored both basal and drug-induced dopamine release to normal levels (Piccini *et al.*, 1999). PET scanning was also performed with the high-affinity D2/D3 receptor radioligand [^{11}C]-FLB 457 (Kaasinen *et al.*, 2000). The results suggest that extrastriatal (prefrontal, anterior cingulate, and thalamic) D2/D3 receptor binding is reduced in advanced PD but not in the early stages of the disease. The relationship of these findings to cognitive functioning in advanced PD is unknown.

The progressive loss of striatal D2 receptor binding was assessed in extrapyramidal movement disorders using [^{123}I]-(*S*)-2-hydroxy-3-iodo-6-methoxy-(1-ethyl-2-pyrrolidinyl)methyl benzamide (IBZM) and SPECT. Results from a 4-year follow-up study of nine PD patients showed constant D2 receptor binding. In contrast, patients with PPS revealed a decline of the binding of the D2 receptor (Hierholzer *et al.*, 1998). In another SPECT study with IBZM, decreased striatal D2 receptor densities in advanced PD reduced the “safety factor” for synaptic transmission and contributed to the development of motor fluctuation (Hwang *et al.*, 2002).

Functional brain imaging

Besides quantifying dopaminergic function in neurodegenerative disorders, functional brain imaging can also be used to measure regional cerebral perfusion and glucose utilization as indices of local synaptic activity. In PET, regional cerebral blood flow is routinely measured with [^{15}O]- H_2O . PET can also provide unique information on resting glucose metabolism with [^{18}F]-fluorodeoxyglucose (FDG). In SPECT, cerebral perfusion can be assessed with [^{133}Xe], [$^{99\text{m}}\text{Tc}$]-D,L-hexamethyl-propylene amine oxime (HMPAO), [^{123}I]-iodoamphetamine (IMP) and [$^{99\text{m}}\text{Tc}$]-ethylcysteinate dimer (ECD).

It is well appreciated that, although the primary pathology of PD lies in dopaminergic substantia nigra, the overall clinical picture reflects system-wide abnormalities of regional cerebral functioning involving the basal ganglia and cortico-striato-pallido-thalamo-cortical loops

Fig. 20.3 Typical axial ECD/SPECT images of cerebral perfusion from a normal volunteer, a PD subject, and an MSA subject. Lentiform hyperperfusion is evident in the PD subject; relative lentiform hypoperfusion is evident in the MSA subject. (Courtesy of Dr Angelo Antonini.)

(CSPTC) (Wichmann & DeLong, 1996). PET and other forms of functional brain imaging can be used to assess the impact of nigrostriatal degeneration on the functioning of these related motor pathways (Carbon & Eidelberg, 2002).

In this review, we will discuss the use of resting regional metabolism and blood flow as surrogate measures of neural function in movement disorders patients.

A recent FDG/PET study performed in 11 nondemented PD patients with advanced disease and 10 age-matched controls revealed significant regional reductions of glucose uptake in the parietal, frontal, temporal cortex, and in the caudate nucleus (Berding *et al.*, 2001). Local reductions in the frontal and temporal cortex correlated with parkinsonian disability.

Of particular clinical interest are studies employing this method to differentiate parkinsonian syndromes. In one such study, PD patients did not differ from controls in local glucose metabolism, whereas patients with striatonigral degeneration (SND) and PSP displayed relative hypometabolism in the basal ganglia (Arahata *et al.*, 1997). In a subsequent large retrospective study, 48 parkinsonian patients suspected as having possible atypical parkinsonism (APD) and a group of 56 patients with likely idiopathic PD were scanned with FDG/PET. A linear combination of caudate, lentiform, and thalamic values accurately discriminated APD from PD patients (Antonini *et al.*, 1998). A similar approach to differential diagnosis has been reported using ECD/SPECT for cerebral perfusion (Feigin *et al.*, 2002) (Fig. 20.3).

Statistical parametric mapping (SPM) analysis of FDG / PET data comparing CBGD to controls revealed metabolic decreases in premotor, primary motor, supplementary motor, primary sensory, prefrontal, and parietal associative cortices, as well as in the caudate and thalamus contralateral to the worse affected limbs (Laureys *et al.*, 1999). Except for the prefrontal regions, a similar metabolic pattern was observed when CBGD was compared to PD. In a similar

PET study, PD patients with autonomic failure displayed metabolic reductions in parietal and occipital regions, as compared to their counterparts without this manifestation (Arahata *et al.*, 1999).

In a recent study, FDG/PET was performed on 17 nondemented patients with uncomplicated PD undergoing a stable therapeutic regimen and correlational analysis was performed to determine the metabolic substrates of bradykinesia and tremor. Bradykinesia scores were positively correlated with putamen and globus pallidus metabolism, while tremor scores were correlated negatively with metabolism in the putamen and cerebellar vermis. There was a large overlap between areas of the putamen correlating with both extrapyramidal figures (Lozza *et al.*, 2002).

In order to identify specific metabolic brain networks associated with PD and other movement disorders, we have used PET imaging with FDG in conjunction with a multivariate analysis of regional data (Carbon & Eidelberg, 2002). This technique is based upon principal component analysis (PCA), which allows for the identification of disease-related patterns of regional metabolic covariation (i.e. brain networks) and the quantification of pattern expression (i.e. network activity) in individual subjects.

Utilizing this mathematical approach, we identified a specific regional metabolic network in PD patients scanned in the resting state (Eidelberg *et al.*, 1990, 1994). The PD-related covariance pattern (PDRP) is characterized by pallidal and thalamic hypermetabolism associated with metabolic decrements in the lateral premotor cortex (PMC), the supplementary motor area (SMA), the dorso-lateral prefrontal cortex (DLPFC) and the parieto-occipital association regions. This abnormal topography has since been validated in different ways: (i) PDRP activity reproducibility discriminates PD patients from controls in subsequent populations scanned with FDG/PET (Wichmann

& DeLong 1996), as well as ECD/SPECT perfusion methods (Feigin *et al.*, 2002); (ii) network activity correlates with nigrostriatal dopamine deficiency as determined by FDOPA/PET (Eidelberg *et al.*, 1990) and is modulated by exogenous dopamine (Feigin *et al.*, 2001); (iii) network activity in individual patients correlates consistently with motor disability (Eidelberg *et al.*, 1994, 1995); (iv) the PDRP is detectable early in the course of PD (Eidelberg *et al.*, 1995) and its expression increases with disease progression (Moeller & Eidelberg, 1997; Trošt *et al.*, 2002); (v) PDRP activity correlates with internal pallidal (GPi) single unit activity recorded during surgery (Eidelberg *et al.*, 1997). These data relate the PDRP network to the motoric features of parkinsonism. It is of interest that recent analyses of FDG/PET data have revealed additional metabolic topographies associated with the cognitive and affective manifestations of this disorder (Lozza *et al.*, 2001; Mentis *et al.*, 2002).

Interventional modulation of brain glucose metabolism in PD

Having established the PDRP as a functional imaging marker of parkinsonism, we examined the hypothesis that effective antiparkinsonian therapy is associated with modulation of abnormal network activity. We proposed that interventions at individual nodes of the motor CSPTC loop (Alexander *et al.*, 1990; Wichmann & DeLong, 1996) lead to significant reductions in PDRP expression. Additionally, we expected that the degree of network modulation would correlate with clinical improvement. To assess changes in network activity with therapy, we applied an automated computational procedure to quantify pattern expression in individual scans obtained in different treatment conditions (Eidelberg *et al.*, 1995; Moeller *et al.*, 1996). This algorithm is blind to intervention (drug, deep brain stimulation) and treatment status (ON, OFF).

In an FDG/PET study of GPi deep brain stimulation (DBS), we assessed seven patients off medication, comparing brain glucose metabolism ON and OFF stimulation (Fukuda *et al.*, 2001). GPi stimulation led to significant suppression of PDRP network activity. The degree to which the network was reduced by stimulation correlated with improvement in standardized motor ratings. Voxel analysis localized stimulation-induced increases within the network to the ipsilateral PMC and both cerebellar hemispheres. The metabolic increase in the PMC correlated significantly with clinical improvement, indicating the importance of functional modulation of neural activity at this CSPTC node for therapeutic efficacy.

Modulation of the PDRP is not unique to DBS, but is also present in other antiparkinsonian interventions in

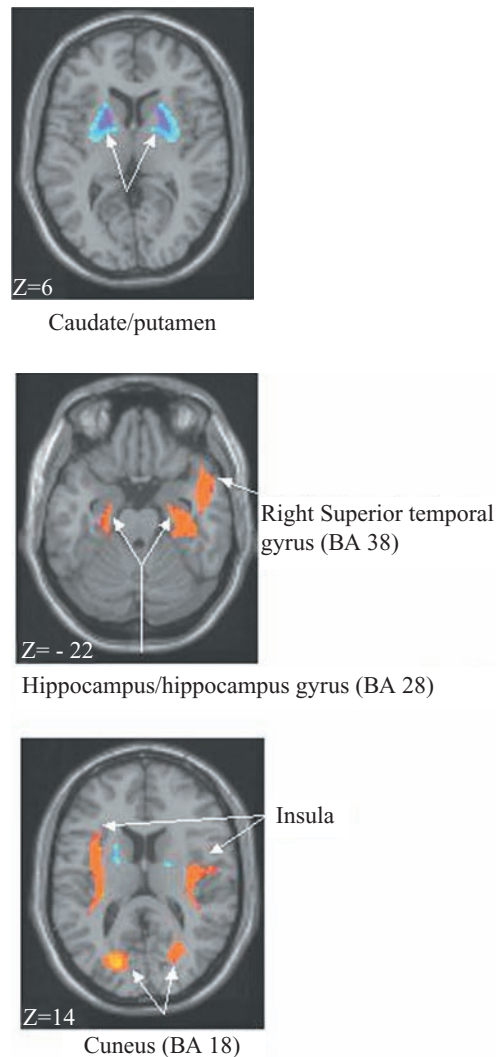

Fig. 20.4 Display of the regional metabolic covariance pattern associated with preclinical Huntington's disease overlaid on standardized MRI sections. This network topography was identified in a voxel analysis of FDG/PET scans from a combined group of 10 presymptomatic HD gene carriers and 20 gene negative controls. The HD-related pattern (HDRP) discriminated carriers from controls ($P < 0.0001$) and was characterized by relative metabolic decreases (*blue*) in the striatum associated with increases (*red*) in the temporal cortex, insula, and occipital association cortex. Region weights on this pattern correlated with those of the original HDRP that we identified in an independent population of preclinical HD gene carriers (Feigin *et al.*, 2001).

PD (Eidelberg *et al.*, 1996; Feigin *et al.*, 2001; Su *et al.*, 2001). In a cohort of eight patients undergoing unilateral pallidotomy, clinical outcome following surgery correlated with a reversal of the PDRP features, i.e. decreases in the glucose metabolism in the lentiform nucleus and the

thalamus, parallel to an increase in glucose metabolism in the SMA (Eidelberg *et al.*, 1996). Furthermore, in a cohort of six patients undergoing unilateral subthalamic nucleus ablation, a highly significant reduction in PDRP expression was present in all operated hemispheres, correlating with improvement in off-medication motor ratings (Su *et al.*, 2001). These subjects exhibited marked postoperative metabolic decrements within the network in the ipsilateral GPi, substantia nigra pars reticularis (SNr), and in the ventrolateral and anterior thalamic nuclei.

PDRP modulation is also a feature of dopamine replacement. We used FDG/PET to study seven patients during intravenous levodopa infusion titrated to maximal clinical benefit (Feigin *et al.*, 2001). PDRP expression declined with therapy in all subjects. This treatment-induced change correlated with the degree of motor improvement as measured by serial clinical ratings. Voxel analysis localized the treatment-mediated metabolic reductions within the network to the putamen, ventral thalamus, and cerebellar hemispheres.

In summary, these studies suggest a common mechanism of intervention in successful antiparkinsonian therapy. Both stereotaxic surgical and medical treatments reduce PDRP activity, although different nodes within the motor CSPTC loop and cerebellar pathways may be preferentially modulated by different interventions. Moreover, our findings suggest that despite comparable clinical benefit, the degree of metabolic network modulation during treatment can differ across interventions. Additionally, studies of novel therapeutic strategies such as gene therapy (During *et al.*, 2001) are being performed with network imaging to quantify the effects of treatment on neural systems as well as behavior.

Huntington's disease

Imaging markers of disease progression may be helpful in assessing the efficacy of potential neuroprotective interventions to retard the onset of symptoms in individuals at risk for Huntington's disease. PET has been used to identify functional abnormalities in the brains of HD gene carriers both preclinically and following the onset of symptoms. FDG/PET studies in symptomatic HD patients have consistently demonstrated reduced striatal metabolic rates (Kuhl *et al.*, 1982; Hayden *et al.*, 1986; Young *et al.*, 1986; Kuwert *et al.*, 1990). By contrast, regional metabolic data in presymptomatic individuals at risk have been inconsistent, with some studies demonstrating normal metabolic rates (Young *et al.*, 1987) and others demonstrating reduced levels of striatal glucose

metabolism (Hayden *et al.*, 1987; Mazziotta *et al.*, 1987; Kuwert *et al.*, 1992; Antonini *et al.*, 1996). Similarly, RAC/PET studies of postsynaptic D₂ dopamine neuroreceptor binding in HD have disclosed a reduction in striatal receptor binding in symptomatic patients (Turjanski *et al.*, 1995; Antonini *et al.*, 1996), but not consistently in the presymptomatic phase of the illness (Antonini *et al.*, 1996; Weeks *et al.*, 1996). In a recent PET investigation of preclinical and early stage HD, a brain metabolic pattern relating to gene carrier status and independent of symptoms was identified through the network analysis of FDG/PET data from preclinical gene carriers (with normal RAC binding) and gene-negative control subjects (Feigin *et al.*, 2001). This HD-related pattern (HDRP) of regional brain metabolism was characterized by relative hypometabolism in the caudate, putamen, and temporal cortex, that covaried with metabolic increases in the occipital lobe. In a cross-sectional study, HDRP expression was found to be elevated in presymptomatic subjects with abnormal reductions in RAC binding and further increased in symptomatic HD patients (Feigin *et al.*, 2001), suggesting that this may be a useful marker for following both presymptomatic and symptomatic HD. This study has now been reproduced and validated in a new cohort of presymptomatic HD gene carriers analyzed using a voxel-based network analytical approach (Feigin *et al.*, 2001) (Fig. 20.4).

Recently, the same investigators measured the change in expression of the HDRP over 18 months in seven presymptomatic HD gene carriers, and correlated these changes with declines in dopamine D₂ receptor binding (Feigin *et al.*, 2003). They found that RAC binding declined by 3.9% per year in caudate and by 4.1% per year in putamen, and that HDRP subject scores increased by a mean of 4.1 points over the period of follow-up. Baseline HDRP subject scores correlated with baseline striatal RAC binding. It remains unknown whether striatal atrophy is the primary determinant of these PET measures. In this regard, volumetric measures with magnetic resonance imaging also hold great promise for providing an objective measure of neurodegeneration in both presymptomatic and symptomatic HD (Aylward *et al.*, 2000; Rosas *et al.*, 2001).

Conclusions

Functional neuroimaging with both SPECT and PET can provide valuable information in assessing *in vivo* neurochemical abnormalities, especially involving the dopamine system. In Parkinson's disease, these methods are being used to quantify presynaptic nigrostriatal function at the

time of diagnosis as a means of assessing the integrity of dopaminergic projections from the substantia nigra. These imaging approaches may prove valuable in determining rates of neurodegeneration as part of the natural history of the disease and may facilitate the validation of potential neuroprotective agents. Similarly, postsynaptic measurements of dopamine neuroreceptors may be of great value in the study of hyperkinetic movement disorders such as Huntington's disease. Additional information concerning neurodegenerative processes can also be provided through network analytical strategies applied to images of brain blood flow and metabolism. This approach has recently yielded unique data concerning the modulation of neural systems during successful antiparkinsonian interventions. Multiregional network analysis has also been used to identify abnormal metabolic topographies in a variety of other neurological conditions and may be valuable in assessing rates of neurodegeneration, especially in the absence of other markers of disease progression.

Introduction

Since its introduction for human study in the early 1980s, magnetic resonance (MR) has proven itself an extremely versatile technique for evaluation of many different parameters of anatomic, physiologic, and metabolic interest. The number of phenomena amenable to analysis using magnetic resonance (MR) techniques is increasing every year. This versatility arises from the many different sources of magnetic contrast that can be generated using either endogenous or exogenous contrast, from the versatility of the techniques for manipulation of the nuclear spins that generate the observed signals, and from the extremely safe nature of MR that lends itself well to longitudinal studies and large patient populations.

MR techniques can now evaluate tissue parameters relevant to TCA cycle metabolism, anaerobic glycolysis, ATP levels, blood–brain barrier permeability, macrophage infiltration, cytotoxic edema, spreading depression, cerebral blood flow and volume, and neurotransmitter function. The paramagnetic nature of certain oxidation states of iron leads to the ability to map out brain function using deoxyhemoglobin as an endogenous contrast agent, and also allows for mapping of local tissue iron concentrations. In addition to these metabolic parameters, the number of ways to generate anatomic contrast using MR is also expanding, and in addition to conventional anatomic scans, mapping of axonal fiber tracts can also be performed using the anisotropy of water diffusion. A selective, non-exhaustive, summary of the various parameters of relevance to neurodegeneration (ND) that can be measured using MR techniques is presented in Table 21.1. A schematic representing the “phylogenetic tree” of MR techniques for chemical, physiological and structural purposes is shown in Fig. 21.1.

A competent review of all these various techniques would require more than just a chapter. Therefore, in what follows we will describe the use of magnetic resonance spectroscopy (MRS) for examination of neurodegeneration and potential therapeutic strategies. MRS techniques have much to offer for the evaluation of brain physiology, chemistry and function of neurodegenerative disorders. These types of studies can generally be divided into three main areas: studies of etiology, studies of the natural history and progression of the disease, and study of therapy. Our goal is not to provide an exhaustive review of MRS techniques and what has been done in prior work. Rather, we will discuss how a few select questions of interest to the study of neurodegeneration can be approached using various MRS techniques. We will provide examples of how best to integrate the potential of each MRS technique to answer specific questions related to a given question in both animal and human studies.

While a surprising convergence of evidence indicates that many neurodegenerative illnesses have a common etiologic origin in aberrant protein folding and aggregation (Schulz & Dichgans, 1999; Kopito, 2000), understanding the progression and finding potential therapies is still quite difficult. This is not surprising, as many of the pathways leading to neuronal death are common and progressive. Thus, for instance, the initial insult in focal ischemia is clear – an interruption of blood flow leading to cessation of ATP production. However, the cascade of events that results from this process is extremely complicated, and the ultimate neuronal destruction is a result of multiple interactive pathways. This fact is exemplified by the large number of different therapeutic approaches that prove efficacious in experimental ischemia. Aside from the obvious “clot busting” therapies such as TPA, effective reduction of final infarct size can be demonstrated using glutamate antagonism (e.g. MK-801) to ameliorate excitotoxicity, inhibition of

Table 21.1. Parameters of relevance to neurodegeneration amenable to MR analysis

Parameter and/or Chemical	Relevance to ND	MR Techniques and/or Parameters Used	MR References
ATP	ATP defects noted in mitochondrial disorders	³¹ P MRS	(Radda, 1992; Barbiroli <i>et al.</i> , 1993, 1998)
Lactate	Marker for impaired energy metabolism and/or reduced blood flow	¹ H MRS	(Matthews <i>et al.</i> , 1993; Dager <i>et al.</i> , 1995; De Stefano <i>et al.</i> , 1995a,b; Brownell <i>et al.</i> , 1998)
Glucose	Can be used in labeled form (¹³ C) to examine TCA cycle flux	¹³ C MRS; ¹ H MRS	(Gyngell <i>et al.</i> , 1991; Mason <i>et al.</i> , 1995; Gruetter <i>et al.</i> , 1994; Ross <i>et al.</i> , 2003)
Glutamate	Marker for potential excitotoxicity; in labeled form (¹³ C) marker for TCA cycle metabolism	¹³ C MRS; ¹ H MRS	(Mason <i>et al.</i> , 1995; Piore <i>et al.</i> , 1999; Rothman <i>et al.</i> , 1995)
Glutamine	Marker for determination of neuronal/glial glutamate/glutamine cycling or ammonia toxicity	¹³ C MRS; ¹ H MRS	(Yudkoff <i>et al.</i> , 1993; Ross <i>et al.</i> , 1996; Sibson <i>et al.</i> , 1997)
<i>N</i> -acetylaspartate	Marker for neuronal number, integrity and health	¹ H MRS	(Bates <i>et al.</i> , 1996; Kalra <i>et al.</i> , 1999; Jenkins <i>et al.</i> , 2000)
<i>myo</i> -Inositol	Marker for glial cells and cerebral osmolarity	¹ H MRS	(Thurston <i>et al.</i> , 1989; Brand <i>et al.</i> , 1993; Shonk <i>et al.</i> , 1995)
Phosphoesters	May be markers for neuronal membrane integrity	³¹ P MRS	(Pettegrew <i>et al.</i> , 1997)
Macromolecular/lipid resonances	Potential markers for macrophage/microglial activity	¹ H MRS	(Petroff <i>et al.</i> , 1992; Hwang <i>et al.</i> , 1996)
Apparent diffusion coefficient (ADC)	Markers for cytotoxic edema, cell swelling, and fiber tract mapping	Pulsed field gradient spin echoes	(Basser & Pierpaoli, 1996; Dijkhuizen <i>et al.</i> , 1996; Makris <i>et al.</i> , 1997; Pierpaoli <i>et al.</i> , 2001)
BBB permeability	Impairment during ischemia, tumors and possibly AD	Decreased T ₁ after injection of contrast agents	(Kermode <i>et al.</i> , 1990; Tofts & Kermode, 1991)
Iron content	Can be used to look for evidence of increased iron in PD or FA	Mapping of T ₂ [*] and T ₂ relaxivity changes	(Antonini <i>et al.</i> , 1993; Ordidge <i>et al.</i> , 1994; Ye <i>et al.</i> , 1996)
Blood oxygenation level dependent contrast (BOLD)	Marker for neuronal activity; can derive relative oxygen consumption	Fast gradient echo, or asymmetric spin echo imaging	(Kwong <i>et al.</i> , 1992; Ogawa <i>et al.</i> , 1992; Davis <i>et al.</i> , 1998)
Cerebral blood flow and volume (CBF, CBV)	Markers for tissue perfusion, neuronal and neurotransmitter activity	FAIR or arterial spin labelling (T ₁ -based), contrast injections (T ₂ [*] -based)	(Belliveau <i>et al.</i> , 1991; Detre <i>et al.</i> , 1992; Bartenstein <i>et al.</i> , 1997; Nguyen <i>et al.</i> , 2000)

References are non-exhaustive and weighted towards those of direct relevance to in vivo study of neurodegenerative disorders.

apoptosis using caspase inhibitors, trapping of free radicals using spin traps (e.g. α -SPBN) to block the negative consequences of excess free radical production, energy repletion, calcium channel blockers to inhibit intracellular calcium influx – and the list goes on (see the other chapters in this book as well as recent reviews in (Siesjo, 1992; Hossmann, 1994; Fisher, 1995; Kogure & Kogure, 1997; Endres *et al.*, 1998; Keller *et al.*, 1998). Each of these various approaches targets one component of an interactive mesh. Similar observations have been made with acute MPP⁺ toxicity, where the initial insult is impairment of ATP production via

blockade of complex I in the electron transport chain, yet multiple therapeutic strategies are effective in ameliorating the lesions (Beal *et al.*, 1994; Jenkins *et al.*, 1996, 1997).

It is easy to see why then, that many deleterious factors observed in a given neurodegenerative illness may be the result, rather than the cause of given disease. Once the initiation of the neurodegenerative process occurs, other negative factors, associated with natural aging, for instance, may accelerate the neurodegeneration. Thus, one needs to frame questions about etiology to address both the primary insult itself, as well as secondary consequences of the

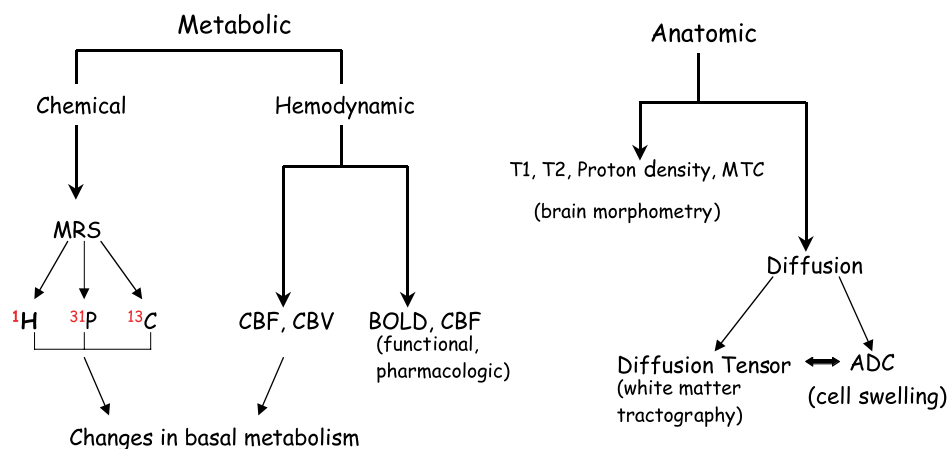

Fig. 21.1 Schematic for the “phylogenetic tree” of various MR techniques.

primary insult that may lead to further progressive degeneration. The secondary consequences can be considered part of the “natural history” of the disease. Such a parsing of primary, secondary and even tertiary effects with respect to energy metabolism has been proposed by Blass and colleagues previously (Blass *et al.*, 1988). Irrespective of questions related to etiology or natural history, the multiple factors involved in the “neurodegenerative cascade” provide many potentially efficacious therapeutic entry points for either preventing or slowing down the neurodegenerative process.

Thus, in this chapter we will cover the basics of *in vivo* MRS with an eye towards determining which parameters of relevance to the etiological and therapeutic questions can be addressed using *in vivo* MRS. In the interests of brevity, we will confine discussion to proton, carbon and phosphorus spectroscopy, with a focus on proton MRS as this is representative of the vast majority of *in vivo* studies.

Evaluation of neurochemistry

Magnetic Resonance Spectroscopy (MRS) is one of the few available techniques that can provide information on *in vivo* neurochemistry non-invasively. MRS is extremely versatile with respect to the different numbers of chemicals and brain processes that can be examined as can be seen in Tables 21.1 and 21.2. A number of different nuclei can be observed using MR, and those that are most commonly seen in brain disorders (in decreasing order of number of studies) are: ^1H , ^{31}P , ^{13}C , ^{19}F , ^{15}N , ^{23}Na , and ^7Li , with the first three nuclei accounting for approximately 99% of all studies. While only proton and phosphorous have been applied extensively to neurodegenerative conditions,

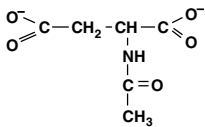

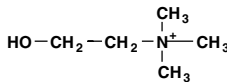

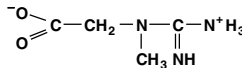

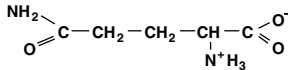

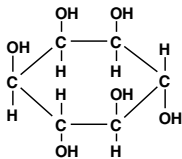

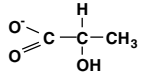

there are a number of potential studies of neurodegeneration that could be performed using both ^{13}C and ^{23}Na . In the former case one can assay TCA cycle dynamics and note the efficacy of a given neuroprotective compound in improving cellular energetics. In the latter case, it has been suggested that studies of ^{23}Na may be of use in studying stroke for examining changes in intracellular and extracellular sodium content (Hilal *et al.*, 1983; Kalyanapuram *et al.*, 1998; Thulborn *et al.*, 1999; Lin *et al.*, 2001).

Proton MRS is by far the most common application to the brain. The reason for this is that the gyromagnetic ratio of the proton is much larger than that of all other nuclei excluding tritium. Based upon three simple equations one readily predicts that the largest signal will arise from proton MRS. The three equations are:

- (i) The Larmor equation, which describes the frequency at which a given nucleus resonates – $\omega_0 = \gamma B_0$; where ω_0 is the resonant frequency (in radians per second), γ is the gyromagnetic ratio (a fixed constant for each nucleus) and B_0 is the applied magnetic field;
- (ii) The Planck–Einstein equation ($E = h\nu$), where E is the energy, h is Planck’s constant and ν is the resonant frequency;
- (iii) The Boltzmann distribution $N/N_0 = \exp(-\Delta E/kT)$ where N is the number of nuclei in the higher energy state, k is Boltzmann’s constant and T is the temperature.

Since the MR signal is linearly proportional to N , as the energy increases the population of spins that can be excited is larger. These three equations also predict that in addition to the gyromagnetic ratio, that the MR signal will increase with increasing magnetic field strength. This latter fact is the major impetus for the constantly increasing magnetic

Table 21.2. Most commonly observed neurochemicals and their relevance to neurodegeneration

Compound (Chemical shifts and approximate brain concentration)	Structure	Relevance to Neurodegeneration and neuroprotection
N-acetylaspartate (NAA) 2.023 ppm (CH ₃) 2.52 ppm (βCH) 2.70 ppm (β'CH) ~ 8–10 mM		Neuronal marker not present in glial cells. Synthesized in mitochondria, although role in the brain is not clear. Reflective of neuronal and mitochondrial health as well as neuronal loss.
Choline / phosphocholine (Cho) 3.23 ppm (CH ₃) ₃ ~ 1.5 mM		Can be composed of other trimethylamines, but is primarily glycerolphosphocholine. May represent lipid membrane breakdown or turnover products. Higher concentration in glial cells.
Creatine / phosphocreatine (Cr/PCr) 3.03 ppm (CH ₃) 3.95 ppm (CH ₂) ~7–10 mM		Peak represents sum of total creatine and remains constant in many pathologies. Hence, often used as denominator in ratio methods of quantification. Supplies phosphate for conversion of ADP to ATP in creatine kinase reaction.
γ-aminobutyrate (GABA) 1.91 ppm (βCH ₂) 2.31 ppm (αCH ₂) 3.02 ppm (γCH ₂) ~ 3 mM		Can be modulated using vigabatrin. Does not seem to be changed in neurodegenerative conditions where examined.
Glutamate (Glu) 2.06 ppm (βCH) 2.10 ppm (β'CH) 2.36 ppm (γCH ₂) 3.76 ppm (αCH) ~ 6–10 mM		Major excitatory neurotransmitter in brain. Potential excitotoxin. Separation of glutamate from glutamine is only possible at high fields (not at 1.5 T). Capable of being used in ¹³ C NMR to measure TCA cycle flux.
Glutamine (Gln) 2.14 ppm (βCH ₂) 2.46 ppm (γCH ₂) 3.78 ppm (αCH) ~ 3–5 mM		Source of glutamate for neurotransmission. Major endpoint for ammonia detoxification in the brain. Often elevated in hepatic encephalopathy. Capable of being used with ¹³ C labeling to measure neuronal-glial glutamate-glutamine cycling.
Myo-inositol (mi) 3.54 ppm ((1,3)CH) ~ 5 mM		Possible osmoregulator of brain glial volume. Increases in mi may reflect glial proliferation.
Lactate 1.33 ppm (CH ₃) ~ 0.5 mM		End product of anaerobic glycolysis. Barely detectable in normal brain but can be quite elevated in various mitochondrial encephalopathies.

field strengths pursued by the MR community, and is especially important in MRS where the signal to noise ratio is always at a premium.

Unfortunately, even though protons are the most sensitive nuclei, the inherent sensitivity of MR compared to, for instance, optical spectroscopy, is quite low (this is also why it is so safe – because the energies involved are so

small). Thus, while it is no problem imaging the 80M in water protons in the brain, imaging the other neurochemicals of interest is another matter entirely. The end result of this is that one must use much lower spatial resolution (much larger voxels) to acquire MRS images compared to conventional MRI imaging of water. Often, only one voxel, of about 4–8 cc, is acquired from a

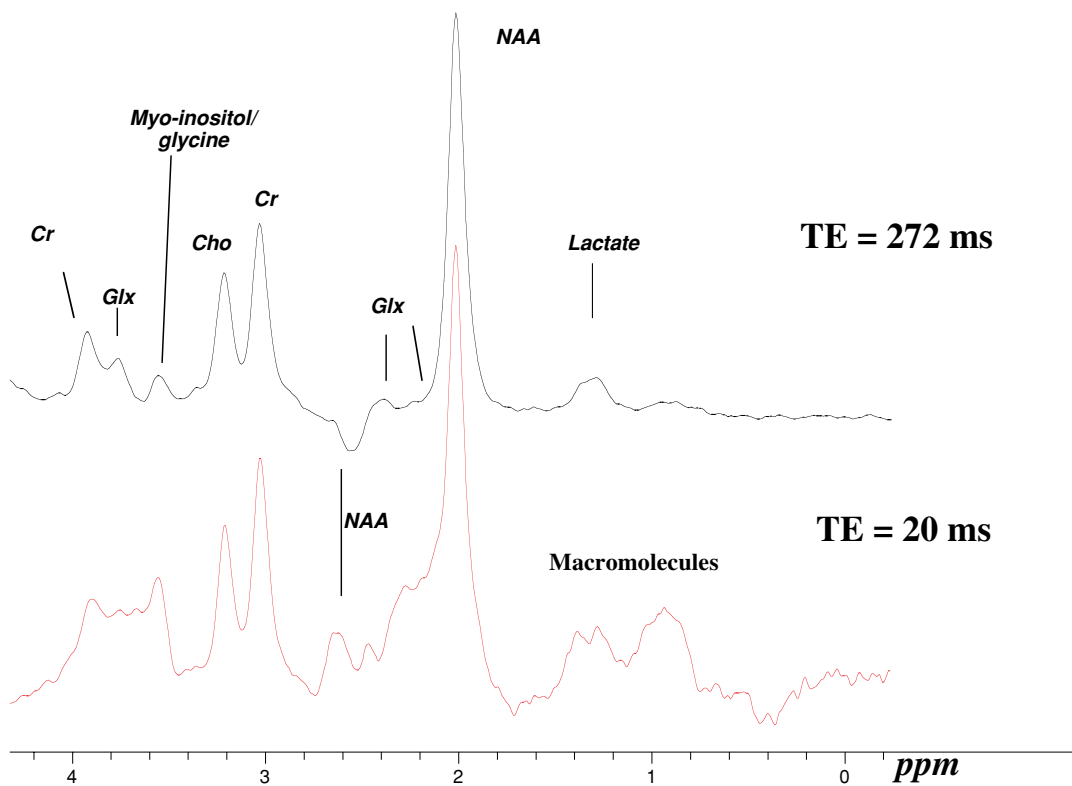

Fig. 21.2 Typical ^1H spectrum from cortex in Huntington's disease. The spectrum on top is an averaged spectrum from 38 patients. The spectra were acquired using a TR/TE of 2000/272 ms and an average voxel size of 5 cc. The only difference between the occipital cortex spectrum and that of a normal control is a slight, but significant, increase in the lactate peak at 1.33 ppm. On the bottom a spectrum is shown from an HD subject at an echo time of 20 ms. Note the spectrum on the bottom is from one subject showing the increased signal to noise available at a short echo time (20 ms). The major peaks are labeled.

brain region to avert the sensitivity problem. As shown in Table 21.2, there are a number of molecules of interest with concentrations between about 1–10 mM that can be observed using *in vivo* ^1H MRS. In order to orient the reader unfamiliar with MRS, typical brain spectra averaged from cortex are shown in Fig. 21.2 for patients with Huntington's disease at two different TE values. The most prominent peak in the spectrum is the methyl group from NAA at about 2 ppm. Also prominent are peaks at 3.0 and 3.2 ppm from the methyl groups of creatine and cholines. At the TE 20ms spectrum the myo-inositol/glycine peak is prominent and the peaks labeled "glx" (glutamate + glutamine) are also much larger. These effects are due to the fact that the observed signal will be proportional to $\exp(-TE/T_2)$ and the T_2 of glutamate/glutamine and myo-inositol are shorter than those of the methyl groups representing NAA, creatine and choline at 2, 3 and 3.2ppm, respectively. These spectra were acquired at 1.5 T. In addition to collection of data from a single voxel, one can collect data from multiple

voxels simultaneously. The latter data sets are referred to as spectroscopic imaging or chemical shift imaging. An example of a spectroscopic image is shown in Fig. 21.3. In this case a patient had a lesion in the anterior cingulate that led to a huge decrease in NAA and an increase in macromolecular resonances. The macromolecular resonances have been associated histologically with microglial infiltration in stroke patients (Hwang *et al.*, 1996). Collection of data using spectroscopic imaging is far more time efficient than conventional single voxel techniques; however, it comes at some price with regards to accurate spatial localization due to the increased point spread function associated with a limited number of phase encoding steps.

At much higher fields, such as 7 T in humans and 9.4 T in animals, it is possible to quantitate even more chemicals (Pfeuffer *et al.*, 1999; Tkac *et al.*, 2001). As an example, we show the ultimate in neurochemical detection – *in vitro* MRS spectra of brain extracts at high field. Shown in Fig. 21.4 is a spectrum coming from a mouse at 600 MHz

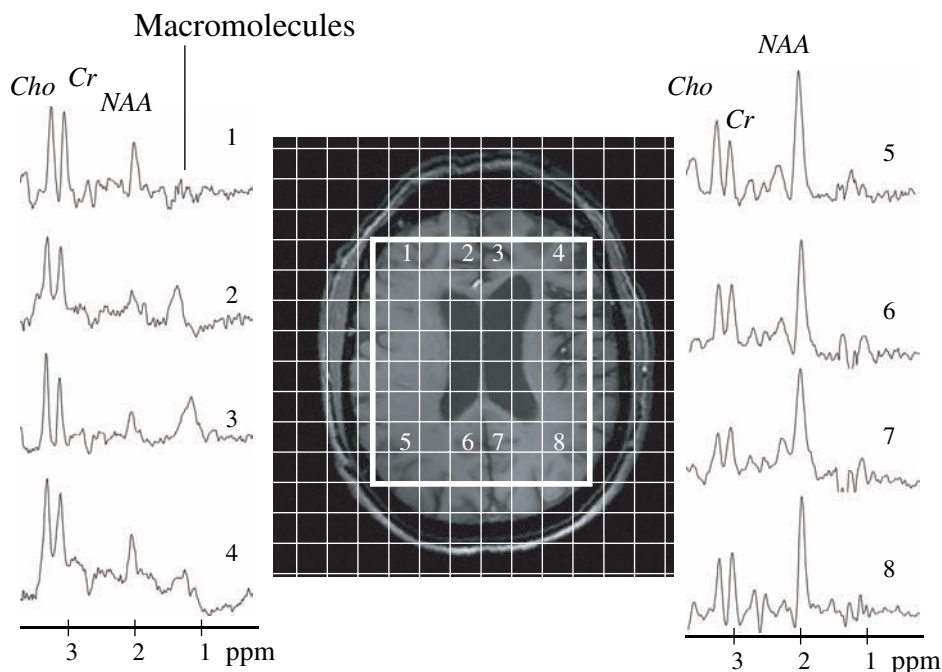

Fig. 21.3 Spectroscopic image from a patient after resolution of a lesion in the anterior cingulate. The water image is shown with a grid overlaid showing the spectroscopic voxels. The CSI data were collected with a TR/TE of 1500/135 ms. Spectra arising from the locations indicated are shown. Note that, in the frontal cortex there is a dramatic decrease in NAA and an increase in macromolecular intensities. The visibility of these resonances even at the long TE is indicative of macrophage/microglia infiltration (Hwang *et al.*, 1996).

Fig. 21.4 Spectra from a brain extract of a wild-type mouse taken at 600 MHz (14 T). The high field provides incredible spectral dispersion and discrimination of many different neurochemicals. The TR in this spectrum is 10 s, so the peak areas are proportional to concentration directly after correction for the number of protons giving rise to a particular resonance.

(14 T). It is clear that many chemicals can be detected. A brief synopsis of the relevance of the major neurochemicals, and their utility as markers for neuroprotection, is given below.

NAA

There seems to be little doubt that NAA is a marker for neurons because it is found almost exclusively in neurons but not glial cells (Birken & Oldendorf, 1989; Simmons *et al.*, 1991; Urenjak *et al.*, 1992, 1993). The concentration of NAA is fairly spatially uniform within either gray or white matter; with the major distinction in NAA concentrations being that those neurons with extensive axonal projections, like the substantia nigra, have higher concentrations than those with shorter projections, like the striatum. The NAA concentration seems to be relatively similar among the major neurotransmitter neuronal subtypes including cholinergic, noradrenergic, GABAergic and glutamatergic neurons (Simmons *et al.*, 1991). The biochemical literature indicates that the NAA concentration is higher in gray matter than in white matter (by a factor of about 2). The MRS literature in this regard is rather controversial. Some studies seem to find the NAA higher in white matter, while others find it higher in gray matter. The resolution of the controversy may come from more detailed study of the relaxation times of NAA in gray and white matter than has hitherto been performed. Accurate relaxation times are the *sine qua non* for accurate metabolite concentrations, but their acquisition is time consuming and few studies have attempted adequate measurements. NAA seems to have a longer T_2 in white than in gray matter (Frahm *et al.*, 1989), thereby leading to overestimates of its concentration when using Cr as a denominator since Cr seems to have a similar T_2 in white versus gray matter.

Given the neuronal localization of NAA it is reasonable to expect NAA to be a marker for neuronal loss in neurodegenerative conditions – and this is exactly what one finds. The association is borne out by the data for Alzheimer's disease where a number of studies indicate diffuse neuronal loss in various regions in the cortex. In addition, comparisons of AD with other dementias indicated NAA loss in the patients with dementia as well (Shonk *et al.*, 1995). There is less inter-laboratory consistency about NAA loss in Parkinson's disease in the brain areas examined, though the substantia nigra has not been examined due to its small size. In PD a number of studies found no change in NAA levels in the putamen or lentiform nucleus (Holshouser *et al.*, 1995; Cruz *et al.*, 1997). However, these findings are not universal, for a number of other authors have found decreases

in NAA in either putamen or temporoparietal cortex (Ellis *et al.*, 1997; Choe *et al.*, 1998). What was most intriguing in the latter study is that the NAA reductions were largest on the side contralateral to the side most affected by the motor symptoms. Part of the problem in these studies is the possible progression of the disease process leading to dynamic changes in NAA levels. We have found in a long-term chronic MPTP Parkinson's primate model that both pre-synaptic dopamine transporters measured using PET and NAA levels in putamen continue to decrease over a time course of 2 years after cessation of MPTP treatment (Brownell *et al.*, 1998).

In the case of HD there is NAA loss in the striatum, as might be expected, but no significant loss in the cortex in the patient populations that were examined (Jenkins *et al.*, 1993, 1998). It might be expected that, in patients with late stage HD, there would be NAA loss in the cortex, as MR imaging and histopathology indicate considerable neuronal loss at this time. However, examination of these patients is complicated by their severe chorea and fragile health. *Postmortem* spectroscopy of tissue extracts in HD patients revealed about 50% NAA loss in the putamen (Dunlop *et al.*, 1992), and studies of HD transgenic mice showed extensive NAA loss in striatum (Jenkins *et al.*, 2000). Huntington's disease is caused by an expanded CAG repeat on a gene that codes for a 364 kD protein (huntingtin) of unknown function. A number of different transgenic mouse models have been created with varying numbers of CAG repeats. A spectrum from striatum comparing an HD mouse with 141 CAG repeats to a wild-type mouse is shown in Fig. 21.5. Also shown are spectra from a wild-type and HD mouse brain extract. There is extensive loss of NAA, and increases in taurine, choline and glutamine detectable *in vivo*. In the *in vitro* spectra the greatly increased spectral resolution and sensitivity demonstrate changes in other peaks such as increases in scyllo-inositol. In the case of the mitochondrial encephalopathies, NAA loss is consistently found in most patients. Thus in almost every neurodegenerative condition examined to date, there is extensive NAA loss in the region of the brains affected by the pathology. This is also true in conditions like infarcts after stroke where NAA decreases dramatically and irreversibly (Fenstermacher & Narayana, 1990; Higuchi *et al.*, 1996; Saunders, 2000).

Thus large decreases in NAA levels are almost surely a result of some neuronal loss and/or axonal damage in most pathologies. At the same time it should be kept in mind that, in certain conditions, NAA levels can drop and then return. This phenomenon has been demonstrated in the plaques found in multiple sclerosis and demyelinating lesions (Davie *et al.*, 1994; De Stefano *et al.*, 1995a, 1997).

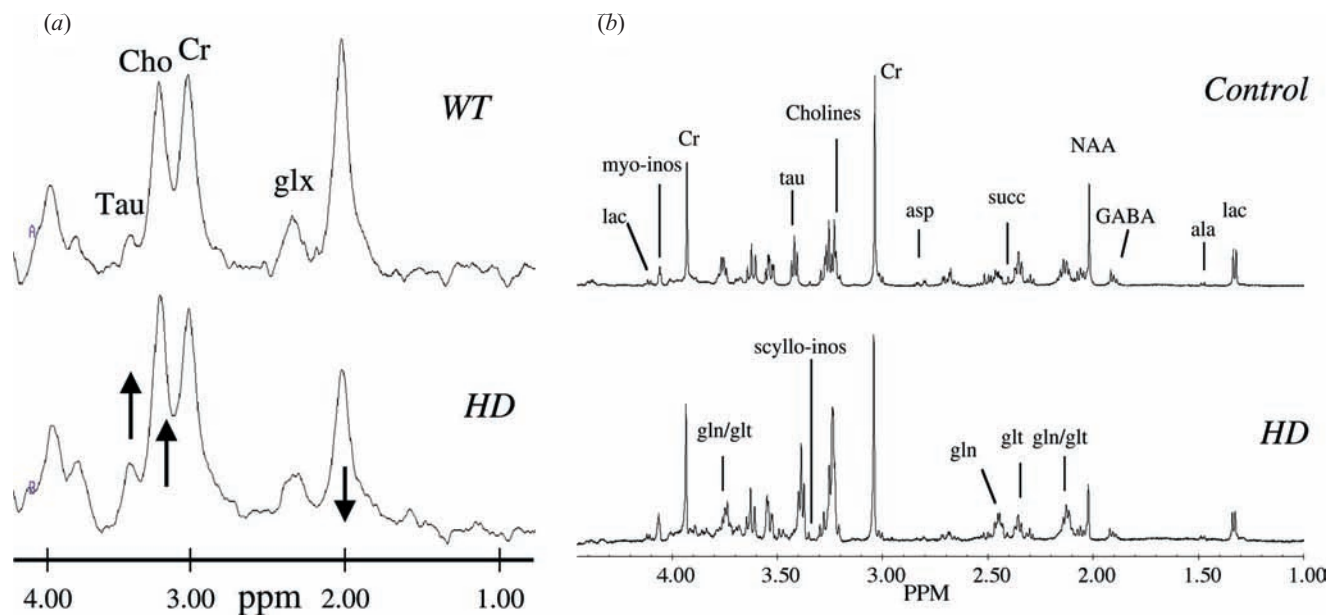

Fig. 21.5 (a) Typical ^1H spectrum from striata in a wild-type mouse and a transgenic HD mouse with 141 CAG repeats (TR/TE 2000/136 ms). Note the increases in taurine (tau) and choline and the decrease in NAA. (b) Comparison of ^1H spectra from striatal extracts of a wild-type and the same HD mouse model as in (a). The greatly increased spectral resolution and sensitivity lead to the ability to quantify many more resonances. The same pattern is detected as is found in vivo. Spectra were acquired at 500 MHz.

Furthermore, two recent comparisons of histopathological measurements of neuronal/gliar content and NAA loss from hippocampal tissue resected for surgical treatment of temporal lobe epilepsy, showed a surprising lack of correlation between NAA loss and neuronal loss (Kuzniecky *et al.*, 2001; Petroff *et al.*, 2002). We performed a study of NAA levels in transgenic HD mice that showed that although there is extensive NAA loss in the striatum this is accompanied by a decrease in neuronal area, but not number (Ferrante *et al.*, 2000; Jenkins *et al.*, 2000). These findings lead to the important conclusion that NAA decreases can reflect a decline in neuronal health as well as number.

As a last word about NAA we will mention the postulated roles for this molecule. Since most studies of neurodegeneration have assumed it to be a neuronal marker, it could be of value to understand its role in the brain as this may shed light on the neurodegenerative process itself. NAA seems to play no role as a neurotransmitter as it is neither excitatory nor inhibitory to other neurons. Postulated roles include involvement in lipid synthesis in myelin, both precursor and breakdown product of *N*-acetylaspartylglutamate (NAAG), and as a storage form of aspartate (Birken & Oldendorf, 1989). While these roles for NAA are reasonable, they remain speculative for the most part. A recent study has indicated that NAA may play a role in osmoregulation (Taylor *et al.*, 1995). This study, using microdialysis, determined that hypoosmolarity caused an increase of NAA

in the extracellular space. Because no other amino acids, except taurine, increased under these conditions this NAA increase was interpreted to be a specific response to hypoosmolarity. Taurine has already been shown to play a role in osmoregulation and it was reasoned that NAA may also serve this function to reduce osmotic stress and possibly prevent neuronal swelling. This hypothesis has been taken a step further with the proposal that NAA represents a “molecular water pump” to remove the metabolic water produced during both ordinary glucose oxidation as well as during pathological conditions (Baslow, 2002, 2003). Interestingly, the enzyme from which NAA is synthesized, *L*-*N*-acetylaspartyl transferase, seems to be localized in mitochondria. Thus, some of the postulated mitochondrial abnormalities in neurodegenerative disorders may also lead to changes in the concentration of NAA. Whatever the ultimate role of NAA in the brain, it seems fairly well established that, quantification problems notwithstanding, it will serve as a useful marker for neuronal loss in neurodegenerative illnesses.

Lactate

Lactate is the end product of anaerobic glycolysis. It is present in normal brain in barely detectable amounts by MRS (~ 0.5 mM). Therefore, when lactate is detected in

measurable amounts, the result is significant. The question is – significant of what? Lactate increases can be stimulated by neuronal activation (Prichard *et al.*, 1991), and lactate can be used as a fuel by the brain (Schurr *et al.*, 1988). Lactate is postulated to play a role as a metabolic fuel by means of coupling glutamate reuptake in glial cells after neuronal stimulation to increased glycolysis in glial cells (Magistretti & Pellerin, 1997). The increase in lactate concentration caused by neuronal stimulation is, however, rather small – being only about a factor of two – which makes it still barely, albeit reliably, above the noise level. The amount of lactate detected in mitochondrial disorders, or in some HD patients, is quite a bit higher than this, in some cases being four to tenfold over baseline in normal controls. The amount of lactate detected by MRS represents the net balance between production and efflux and/or consumption. Therefore, it is difficult to decide whether these increases represent increased production rates or decreased rates of efflux; either through the blood brain barrier or by reconversion to pyruvate via lactate dehydrogenase. In this regard, it is usually more important to know the lactate/pyruvate ratio because this quantity truly represents the cellular redox state through its relationship to NADH and NAD⁺ levels. Unfortunately, pyruvate concentrations are too low to be measured by in vivo MRS.

There are other sources of increased lactate in the brain that may not necessarily involve impaired oxidative phosphorylation. Increased macrophage activity in cerebral infarcts has been demonstrated to lead to elevated lactate levels as a result of the high glycolytic rates of the macrophages themselves (Petroff *et al.*, 1992). The lactate levels were highest, and NAA and Cr levels were lowest, in regions of high macrophage density. This type of process might be possible in late stage HD, but seems unlikely to occur in PD striatum or in other slowly progressing neurodegenerative conditions. Another possible source for elevated lactate levels is hyperventilation. It has recently been shown that hyperventilation can induce increases in lactate concentrations in normal subjects and even higher concentrations in subjects with panic disorders (Dager *et al.*, 1995). The mechanism by which this occurs is not yet clear; however, like neuronal stimulation, lactate concentrations only increase by about a factor of two. When the mechanism by which this increase occurs is found, it may prove to shed some light on the increases seen in the neurodegenerative disorders.

A final word about quantification of lactate is that increased lipids whose resonances are quite strong between 1 and 1.5 ppm may sometimes interfere with the lactate signal at 1.33 ppm – especially when the lactate concentrations are low. In addition, use of echo times of 136 ms

can often lead to gross underestimates of lactate concentrations in STEAM sequences (Sotak & Alger, 1991). There can often be underestimates even in PRESS sequences with brain movement and at higher fields (B. G. Jenkins, unpublished observations). Thus, it is usually better to use TEs of 272 ms rather than 136 ms when in doubt. However, the inversion of the lactate doublet at 136 ms is convincing evidence that the peak there has a ~ 7 Hz coupling constant which can aid in identification of lactate as opposed to lipid or macromolecular components.

Glutamate and Aspartate

Glutamate and aspartate are amino acids that are excitatory neurotransmitters in the brain. The role of glutamate as an excitotoxin is well documented elsewhere in this book and it will not be recapitulated here. Aspartate could also presumably function in such a role, although its concentration in the brain is about five times lower than that of glutamate. Due to their large concentrations, which for glutamate range from ~ 5 –10 mM at various locations within the brain, these neurotransmitters should be easy to detect using MRS. Detection, unfortunately, is not easy in vivo at the commonly used field strength of 1.5 T. The reasons for this have to do with the complicated spectral patterns induced by strong J-coupling at low fields and the severe overlap with other metabolites – especially glutamine, but including macromolecules as well. These reasons explain why one often sees glutamate and glutamine referred to in the MRS literature as Glx. Accurate quantification of glutamate and aspartate at these low field strengths is, in our opinion, nearly impossible. At 4 T, with an exceptionally good shim, it may be possible to separate glutamate from glutamine (Mason *et al.*, 1994). Almost nothing has been done with regards to quantification of aspartate, and this molecule will be a “very tough nut to crack” given its severe spectral overlap with the NAA methylene protons and its complicated coupling patterns.

Thus, elucidation of the role of glutamate and aspartate in neurodegenerative illness using MRS awaits higher field strengths. Because glutamate reuptake systems in the glial cells are so potent, it may be that elevations of neuronal glutamate will be difficult to detect, even in cases where there may actually be transient elevations. In a condition like amyotrophic lateral sclerosis (ALS) impaired glial uptake of glutamate is found via damage to the glutamate transporter EAAT2 (Rothstein *et al.*, 1995; Bristol & Rothstein, 1996). Thus, in ALS increases in glutamate might be postulated. This has been detected (as the sum of glutamate + glutamine) using MRS in both humans in medulla (Pioro *et al.*, 1999) and in transgenic mice with mutations in SOD1

(Andreassen *et al.*, 2001a). Certainly the presence of elevated glutamate, as a potential neurotoxin in early HD or PD would be amenable to testing using MRS techniques at high fields, presuming that increased iron concentrations found in the basal ganglia do not increase linewidths too much. We have detected elevations in glutamine in transgenic HD mice, possibly as a result of impaired glutamate/glutamine neuronal/glial cycling (Jenkins *et al.*, 2000); such a finding in humans remains to be seen. In addition, the elevations in ammonia seen in patients with hepatic encephalopathy lead to increased glutamine which is the end product of ammonia detoxification in the brain (for review, see Jenkins & Kraft (1999)).

Choline, creatine and myo-Inositol

For the sake of brevity we have lumped these chemicals together. As we have mentioned above, the peak labeled Cr at 3.03 ppm is composed of both Cr and PCr as well as smaller contributions from GABA and macromolecules. In conditions where there is impairment of energy metabolism, one expects hydrolysis of PCr to Cr. In this case the total resonance intensity would not change assuming that the relaxation times were the same for both molecules. Since most data indicate that the total PCr + Cr content is constant under a variety of conditions, it is reasonable to use this chemical as a denominator in ratio methods as long as it is realized that it may not really be constant.

Choline compounds are trimethylamines that may be chemically heterogeneous. What appears to be a singlet resonance at 1.5 T often appears more complicated at higher field strengths. The Cho observed in MRS may not be entirely water soluble because in vitro acid extracts of brain tissue often yield smaller intensities than in vivo measurements (Petroff *et al.*, 1995). Also, glial cells have a concentration of cholines that is 2–3 fold higher than that found in neurons (Urenjak *et al.*, 1993). Thus, the possibility of Cho serving as a marker for gliosis is reasonable; however this hypothesis will require histopathologic correlation. It is clear that many brain tumors derived from glial cells are highly enriched in choline as rapid membrane turnover leads to a high glycerolphosphocholine signal (Podo, 1999; Smith *et al.*, 2003).

Lastly, we discuss *myo*-inositol. We have examined our data from occipital cortex in 35 HD patients and found no significant change in this brain region compared to normal controls. The data in AD, however, seems to clearly indicate an increase in this compound in various cortical regions. By combining this increase with the decrease in NAA, Ross and

colleagues were able to distinguish AD from other dementias (Shonk *et al.*, 1995). Numerous other studies have confirmed the increase in *myo*-inositol and decrease in NAA in AD (Klunk *et al.*, 1996; Pettegrew *et al.*, 1997). The possible significance of this increase is not clear at this time, though these authors have speculated that it may be involved in osmoregulation. A potential problem with measurement of *myo*-inositol is that glycine has its CH₂ resonance at 3.55 ppm. Although *myo*-inositol has an approximately two-three fold higher concentration than glycine, it may have a shorter T₂. This should be kept in mind when analyzing purported changes in *myo*-inositol. *Myo*-inositol has a much higher concentration in glial cells than in neurons (Brand *et al.*, 1993), thus it may also serve as a good marker for gliosis. It also has a well-established role in osmoregulation as proposed by Thurston (Thurston *et al.*, 1989) and verified in many subsequent studies (Isaacs *et al.*, 1999).

Quantification of proton spectroscopy

Almost all proton spectra are acquired using some variation on what is known as a 'spin-echo' experiment. The spin-echo sequence starts with nutation of the magnetization vector from the *z*-axis to the *x,y* plane by use of a 90° pulse. This is followed by a time usually called TE/2 where the magnetization vector undergoes dephasing due to T₂ processes. If one then applies a 180° pulse, the direction of motion of the spins will be reversed (slower ω_{effs} appear to be faster and vice versa) and, if we wait another TE/2 interval, the magnetization will rephase and form what is aptly called an 'echo' (Hahn, 1950). One must then wait for the magnetization to reach close to thermal equilibrium (i.e. to realign along the *z*-axis) to repeat the process again – this time is generally called TR (TE being the time to echo and TR being the time of repetition). From these spin echo experiments one can collect either a spectroscopic image (MRSI or chemical shift image (CSI)) or just a single large voxel. The most common collection of data involves the use of what are known as the STEAM (stimulated echo acquisition mode (Granot, 1986; Frahm *et al.*, 1987) or PRESS (point resolved spectroscopy (Bottomley, 1987)) sequences. Both rely upon the use of three orthogonal slice selective pulses which make use of the fact that application of a linear magnetic field gradient causes a spreading of effective Larmor frequencies and a radiofrequency pulse applied at a narrow band of those frequencies will select a slice orthogonal to the gradient. By combining three of these pulses in a spin-echo sequence, selection of a volume is attained at the intersection of the three slices. The size can be adjusted

at will. Additional gradient encoding periods (called phase encoding) between the 90° and 180° pulses can be specified to create a spectroscopic image with N_x , N_y and N_z steps. A diagram of the spin echo sequence, along with the STEAM and PRESS sequences, is shown below

<i>Spin-echo</i>	TR – { 180° – TI} – 90° – TE/2 – 180° – TE/2 – Acquire
<i>STEAM</i>	TR – { 180° – TI} – 90° – TE/2 – 90° – TM – 90° – TE/2 – Acquire
<i>PRESS</i>	TR – { 180° – TI} – 90° – TE/4 – 180° – TE/2 – 180° – TE/4 – Acquire

The curly brackets indicate the option of including an inversion pulse before the sequence to start from the $-z$ -axis instead of the $+z$ -axis, followed by the inversion time TI. The differential equations which describe the return to equilibrium (T_1) and the dephasing (T_2^*) are called the Bloch equations. The solution to the simple case of the spin echo sequence described above is:

$$M(\text{TR}) = M_0 \cdot (1 - \exp(-\text{TR}/T_1)) \cdot \exp(-\text{TE}/T_2^*)$$

$$M(\text{TI}) = M_0 \cdot (1 - 2 \cdot \exp(-\text{TI}/T_1)) \cdot \exp(-\text{TE}/T_2^*)$$

where $M(T)$ is the magnetization at time T and M_0 is the equilibrium magnetization. The equations above indicates the solution to the case where one uses a preceding 180° pulse. Other pulse sequences will all have similar looking exponential solutions with slight differences depending upon the sequence of pulses in the acquisition scheme. An additional pulse, or set of pulses, must be added at the beginning of the sequence to perform water suppression or the small metabolite signals (~ 1 – 10 mM) will be buried under the large water peak (~ 80 M). This is usually performed by presaturating the water using a series of rf pulses followed by gradients to dephase the magnetization vector in the x, y plane.

Because the NMR signal is directly proportional to the number of nuclei absorbing the radiofrequency energy, the possibility exists for direct determination of molecular concentrations. However in order to do this, one must also know the T_1 and T_2 of each molecular species, and how the resonances of each species might overlap. This latter problem is especially important because most of the most highly concentrated neurochemicals have resonances between only 1–5 ppm, and some suffer from severe overlap. It turns out that the absolute concentration problem is quite difficult to solve in practice, though one can, in principle, come quite close. Thus, to avert these problems, one often sees brain spectra results reported as ratios of one compound to another.

Most often the denominator is chosen to be the creatine/phosphocreatine peak at 3.0 ppm due to its

supposed insensitivity to the state of the tissue. It has also become common practice to report “absolute” concentrations using water as an internal standard due to its relative molar invariance. This practice is also fraught with some difficulty, especially in neurodegenerative diseases. As much brain tissue in older subjects and subjects with neurodegenerative diseases will be somewhat atrophied, the possibility of CSF contamination is high. Since CSF has T_1 and T_2 properties quite different from tissue, water and neurochemicals, the degree to which it contaminates your voxel must be known. Further, metabolite relaxation times can vary between white and gray matter (Frahm *et al.*, 1989; Hetherington *et al.*, 1996), which means one must know how much each of the large spectroscopic voxels is composed of white and gray matter. In addition, due to severe overlap of metabolites with tissue macromolecules the unique determination of T_1 and T_2 for each neurochemical is quite difficult. Going to higher magnetic field strength helps in this regard as there are now more Hz per ppm. This means that our spectral resolution will increase leading to better discrimination of slightly overlapping chemicals.

A terse, but general, discussion of the quantification problem is described below. To convert the observed resonance intensity at a given frequency (here chosen to be NAA at 2.0 ppm) into a concentration using water (at 4.7 ppm) as an internal standard we would arrive at an equation which looks something like the following (for a simple spin echo sequence:

$$[2.0 \text{ ppm}] = \frac{A(2.0 \text{ ppm})}{A(4.7 \text{ ppm})} * 80 \text{ M}$$

$$\frac{A(2.0 \text{ ppm})}{A(4.7 \text{ ppm})} = \frac{\sum_{i=1}^n M_0^i \left(1 - \exp\left(-\frac{\text{TR}}{T_1^i}\right)\right) \exp\left(-\frac{\text{TR}}{T_2^i}\right)}{\sum_{j=1}^n M_0^j \left(1 - \exp\left(-\frac{\text{TR}}{T_1^j}\right)\right) \exp\left(-\frac{\text{TR}}{T_2^j}\right)}$$

where $A(\text{ppm})$ is the area at a given frequency, M_0^i is the magnetization of the i th resonance at that frequency (necessary because so many neurochemical resonances overlap – like NAA and glutamate at 2.0 ppm), and likewise the T_1^i and T_2^i are the longitudinal and transverse relaxation times of the i th components, M_0^j is the water magnetization of the j th compartment, with its longitudinal and transverse relaxation times (necessary because a given voxel may contain white matter, gray matter and CSF in differing amounts and these all have different relaxation times) and we have assumed that the molar proton concentration of water in the brain is ~ 80 M. It is apparent that this is a tricky problem, and this is notwithstanding the fact that a further complication relating to the splitting of resonances by “J-coupling” is ignored in the equation above.

Fig. 21.6 (a) Spectra from an HD subject in occipital cortex showing fits to the spectra. On the top is the modeled spectrum on the bottom is the original data. (b) STEAM spectra from occipital cortex in a normal control at a TE of 17 ms. On the top is the spectrum with a preceding inversion pulse of 210 ms to null the lipids. Note the macromolecules disappear. On the bottom is a normal spectrum without the preceding inversion pulse.

Currently, it is fair to say that these problems are often glossed over in the literature. For instance, one common approach to quantification fits linear combinations of metabolite sub-spectra to the observed spectra (the LCMoDel approach (Provencher, 1993)). This is an eminently reasonable approach, however it suffers from the problem that the relaxation times for both metabolites and water go undetermined (indeed they have to for a reasonable total acquisition time) and the macromolecule contributions are undetermined except as baseline noise. We discuss this problem extensively elsewhere (Jenkins *et al.*, 1997). It has been shown that without incorporation of prior knowledge of the macromolecules it is impossible to obtain concentrations of metabolites consistent with the biochemical literature (Bartha *et al.*, 1999). Since the macromolecular components are largely undetermined biochemically, and it is not known how they may change in disease, it is very difficult to remove them using a priori information from “template” spectra of controls. It is apparent that this is a major problem, and most “absolute” quantifications reported in the literature should be taken with a grain of salt. That this is true can be seen from “absolute” concentration determinations of NAA in cortex by MRS ranging from 7–11 mM in the literature.

On the other hand, if one wishes merely to compare control populations to patient populations or patient populations longitudinally then as long as one uses consistent methods, useful and statistically significant data can be obtained. Most often this problem is dealt with by taking ratios of peaks rather than absolute concentrations. Usually the peak called creatine (Cr) at 3.0 ppm, is used as

the denominator due to its relative invariance in multiple pathologies compared to the other major peaks. When comparing the ratios it is important to note that, due to the complexity of the equations above, the ratios will very likely change at different TE values. Thus, the NAA/Cr ratio, for instance, is greater at 272 ms than at 136 ms. This means direct conversion of a decrease in NAA/Cr ratios to percent neuronal loss is dangerous.

To illustrate these concepts shown in Fig. 21.6 are fits of spectra acquired from a voxel in occipital cortex in a Huntington’s disease patient at a long echo time where the macromolecular contamination is absent. The spectra fits well to combinations of individual resonance lines. Shown in Fig. 21.6(b) are spectra acquired from occipital cortex in a normal control before and after use of a preceding inversion pulse to suppress the macromolecular resonances (these have much shorter T_1 values than the metabolites). It is clear that significant macromolecular intensity lies under the methyl resonances of NAA and Cr at 2ppm, as well as under lactate and glutamate resonances.

³¹P spectroscopy

Using ³¹P spectroscopy, one can readily measure ATP, phosphocreatine (PCr), inorganic phosphate (Pi), and phosphomono- and di-esters. The difference in chemical shift between PCr and Pi allows one to measure tissue pH (Gadian & Radda, 1981). The ability to readily measure ATP levels makes this an attractive technique. Unfortunately, ATP levels are maintained at a near constancy under almost

Fig. 21.7 Left ^{31}P spectra (1.5 T) taken from occipital cortex in an HD patient and a normal control. Peaks corresponding to ATP, phosphocreatine, inorganic phosphate, and phosphomonoesters and diesters are visible. No major differences between the HD and control subject are seen in this brain region implying that any energetic defects seen are less severe than those found in ischemic regions or in patients with mitochondrial disorders. Right ^{31}P spectra (1.5 T) taken from muscle in an HD and control subject. In this case a decrease in the PCr/Pi ratio is detected that is significant. No change in pH was noted (Koroshetz *et al.*, 1997).

all but the most extreme metabolic conditions. Some workers attempt to calculate ADP levels (since ADP concentrations are usually too low to observe directly) based upon ATP and PCr and Pi concentrations using the equilibrium constant for the creatine kinase reaction below:

The ATP thus formed can then be used as a fuel:

Unfortunately, it is not clear that the creatine kinase reaction is always at equilibrium. It is certain that ATP levels are not held constant during ischemia or in the direct injection of a neurotoxin; however, it is more than likely that the neurodegenerative disorders manifest metabolic defects less severe than this. Most ^{31}P studies to date have examined muscle in mitochondrial disorders. These studies have long shown defects in many measures of high energy phosphate metabolism that in some cases are refractory to treatment with CoQ or vitamin therapy (Chance *et al.*, 1986; Argov & Bank, 1991; Bendahan *et al.*, 1992; Radda, 1992). Although we have shown defects in phosphocreatine levels in resting muscle using ^{31}P in HD (Koroshetz *et al.*, 1997) and these have also been found to a small degree in PD (Penn *et al.*, 1995) it is possible that use of exercise protocols could elicit

larger differences between controls and neurodegenerative disease patients (Argov & Bank, 1991; Bendahan *et al.*, 1992; Argov, 1998). Differences are seen in both resting PCr/Pi ratios and recovery of ATP in exercised muscle in HD (Lodi *et al.*, 2000).

In brain many studies have shown no decrease in ATP levels in AD or PD. We, and others (Hoang *et al.*, 1998), have found the same thing in HD brain as shown in Fig. 21.7, where no changes are observed in ATP or even PCr. Even in mitochondrial disorders, the primary observation is decreased PCr levels, not decreased ATP levels (Barbiroli *et al.*, 1993, 1997). However brain studies are complicated by the necessity of using large voxels due to the lower sensitivity of ^{31}P compared to ^1H . This means that there is quite a bit of partial volume averaging, which tends to decrease sensitivity for detection of focal changes. It would be of interest, for example, to examine the hippocampus in AD or the striatum in HD, however these studies will likely require higher fields such as 4 or 7 T in order to gain the increased sensitivity necessary for detection of focally specific changes. In any case even if small changes in ATP or PCr levels were to be detected, the low signal to noise ratios of ^{31}P compared to ^1H spectroscopy would render this technique to be less useful as a marker for possible therapeutic interventions. This is not true in the mitochondrial disorders where larger changes are noted.

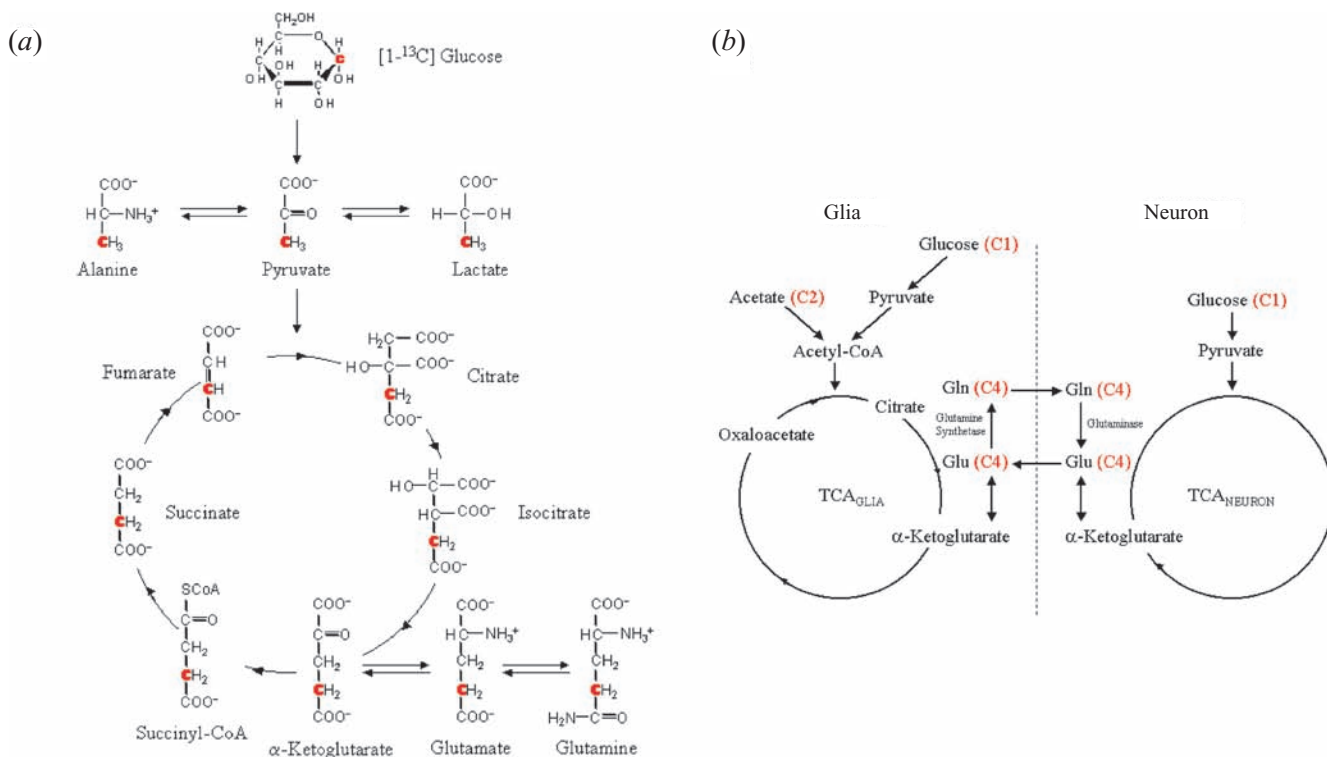

Fig. 21.8 (a) Schematic for the metabolism of glucose and its conversion to observable ¹³C-labeled compounds. The Cs in bold represent the carbon as it is passed through the TCA cycle. Note that, on the first pass, the glutamate and glutamine are labeled at the C-4 position. If the TCA cycle is blocked by, for instance, 3-nitropropionic acid, one will see an increase in lactate and alanine, as well as a buildup of succinate. (b) Schematic of neuronal/glia metabolism and glutamate/glutamine cycle. Neurotransmitter release of glutamate is taken up by the astrocyte where it is converted to glutamine and shuttled back to the neuron where it is reconverted to glutamate. Also shown is the metabolism of acetate which is only taken up by glial cells, and hence can provide a means to discriminate neuronal from glial metabolism using ¹³C MRS.

¹³C NMR spectroscopy

Although carbon is less sensitive than even phosphorus (the relative sensitivities of proton : phosphorus : carbon is 100 : 6.7 : 0.018) it makes a useful marker for a number of interesting biological pathways. Because the natural abundance of the carbon-13 isotope (the NMR active isotope with spin 1/2) is only 1.1%, one can label molecules and see them as they are metabolized. In such cases the background signal will be quite low as carbon-12 is NMR invisible. Such studies can be performed using glucose as a label to watch as it passes through the TCA cycle. Usually the C1 position of glucose is labeled using ¹³C, then the metabolism of the glucose molecule is followed as the glucose gets metabolized through the glycolytic pathway, and then through the TCA cycle. A schematic for this process is shown in Fig. 21.8. On the first pass through the TCA cycle the primary detectable molecule is ¹³C-labeled glutamate

in the C4 position, followed rather quickly by glutamine at the C4 position. Subsequent passes through the TCA cycle produce labeling at the C3 and C2 positions of glutamate and glutamine. One can also detect the absolute amount of ¹³C-labeled glucose in the brain at the same time. At later time points other metabolites start to appear, such as lactate, gaba and *N*-acetylaspartate (NAA).

In addition to labeling glucose, one can label acetate as well. This provides an interesting comparison with glucose labeling since acetate is only taken up by the glial cells and can be used to probe altered glial metabolism as shown in Fig. 21.8 (Badar-Goffer *et al.*, 1990; Hassel *et al.*, 1995; Bluml *et al.*, 2002; Lebon *et al.*, 2002).

Much work has gone into trying to model the kinetics of the reactions and determining, for instance, TCA cycle flux and glutamate-glutamine cycling from these numbers. Space precludes a full discussion here, however most researchers who study brain make the assumption that the

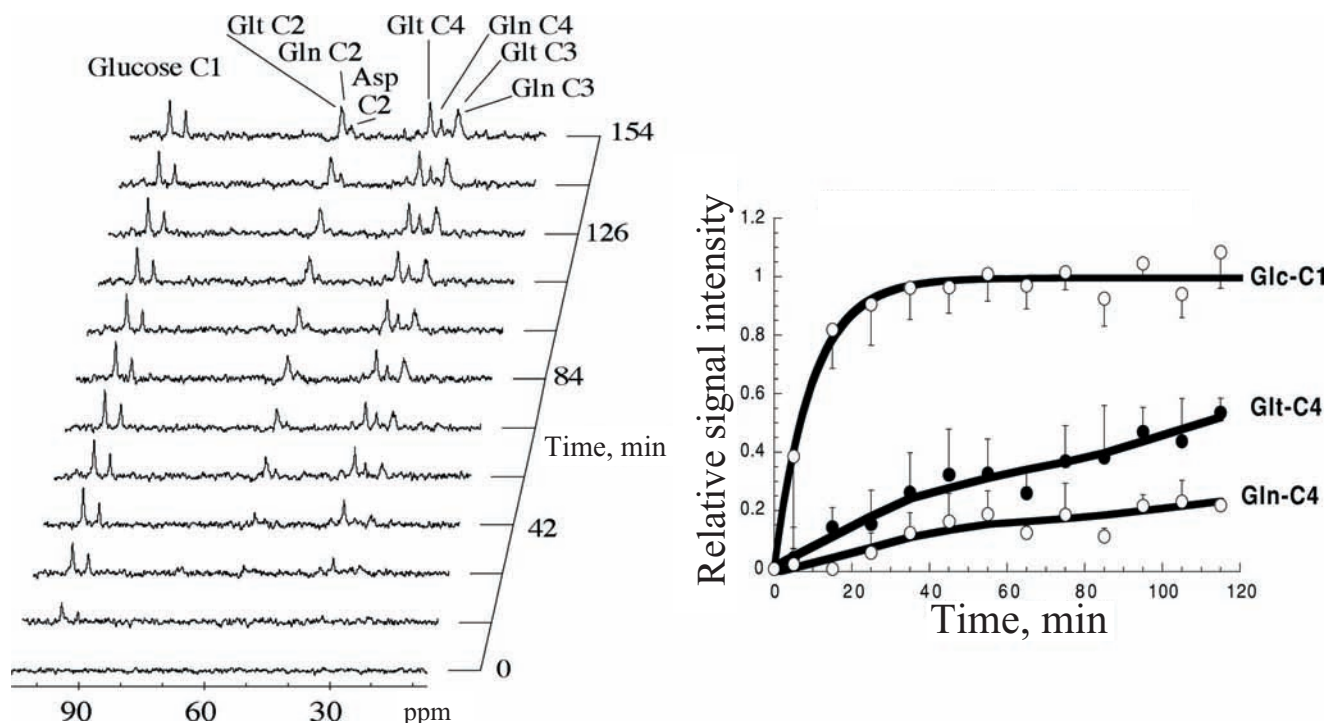

Fig. 21.9 Glucose metabolism using ^{13}C NMR. *Left:* Serial ^{13}C , ^1H -decoupled spectra acquired from a single rat from frontal cortex. Each spectrum is collected in 14 min and yields adequate SNR for temporal analysis of TCA cycle flux rates when combined with the metabolic modeling. *Right:* Average time courses for enrichment of glucose (C1), glut and gln (C4) carbons in seven halothane anesthetized rats.

reaction from oxo-glutarate to glutamate is much faster than the rate at which the substrate comes in (i.e. TCA cycle flux) and therefore the rate of C4 labeling is thus essentially the rate of TCA cycle flux. While this approach is somewhat controversial, its validity does not affect our qualitative understanding here. As an example of the type of information possible, we show data in Fig. 21.9 from a ^{13}C labeling experiment in a rat. The major metabolites observed, along with the corresponding time curves are shown. The rate at which the various TCA cycle intermediates gets labeled yields the desired information in the context of a metabolic model (Mason *et al.*, 1992; Gruetter *et al.*, 1994; Mason *et al.*, 1995; Sibson *et al.*, 1997; Van Zijl *et al.*, 1997)). Thus, administration of ^{13}C -labeled glucose to a patient with a suspected defect in glycolysis would yield a slower rate for labeling of glutamate compared to a control subject. At this point, such an observation would be indistinguishable from a defect in the TCA cycle. Preliminary data on such an experiment have been obtained for Alzheimer's disease, and the result was reduced glutamate labeling that correlated with measures of cognitive impairment obtained by NAA (Lin *et al.*, 2003). Large increases in lactate labeling, and decreased glutamate and NAA labeling were found ^{13}C spectra in two

patients with mitochondrial disorders (Bluml *et al.*, 2001). We have shown increased glutamate metabolism in mouse models of ALS and decreased glutamate and increased glutamine labeling in an HD mouse model (Choi *et al.*, 2003). These results are consistent with impaired neurons in HD and impaired glial function in ALS.

Although the biochemical specificity of carbon spectroscopy is tantalizing in its potential, it is unlikely to become anywhere nearly as well used as proton spectroscopy since the cost of ^{13}C -labeled glucose and the limited spatial resolution obtainable are likely to limit widespread application to humans. Nonetheless, it remains a very useful tool for investigation of etiological and symptomatic questions in neurodegenerative illness, especially when combined with proton MRS and other techniques such as PET.

Use of MRS in studies of therapeutics in humans

The use of MRS to study neuroprotection can only be defined as in its infancy for any number of reasons that are not worth digressing into here. Suffice it to say that, as the

end point in any human therapeutic trial, MR spectroscopy can be considered, at this point, only as complementary to other end points including clinical metrics. On the other hand, there are numerous animal studies where MR spectroscopic data can be considered as a major criterion for evaluation of the animal's neurochemistry. Instead of cataloguing the various studies that have been performed, let us examine what major end points may prove useful in future studies.

Because NAA is typically the largest peak in the MR spectrum, it remains an attractive target for assessment of therapeutic interventions. There are two reasons for this, first in any trial, reproducibility from one time point to the next is quite important. Due to the low sensitivity of MRS as well as the relatively low concentrations of the neurochemicals such as NAA, it is imperative to maximize the intrasubject reliability. This is best attained using those resonances that have the highest signal to noise ratios. This is a useful, but hardly compelling, reason. Second, since NAA is a marker for the health of neurons, it can be imagined to be a therapeutic marker in any pathology that anticipates the loss of neurons such as Alzheimer's disease, Huntington's disease or amyotrophic lateral sclerosis. Since the neuronal loss in these pathologies proceeds fairly rapidly, NAA makes for a reasonable choice to follow the neuronal loss. Among the complications that make such a study difficult is the need for reproducibility of the voxels (whether they are acquired as single voxels or as multiple voxels from a spectroscopic image). Because gray and white matter have different amounts of NAA it is important to collect a high resolution 3-D MRI image to assess the amount of gray and white matter in each voxel as well as to properly register the voxels (Hetherington *et al.*, 1996).

A number of studies have used NAA as a therapeutic marker in humans. A study in epilepsy showed re-normalization of NAA in epileptic patients rendered seizure-free after surgery (this re-normalization was significant compared both to before surgery as well as compared to patients who were not rendered seizure free) (Serles *et al.*, 2001). NAA has also been used as a marker for recovery in treatment of ALS with riluzole (Kalra *et al.*, 1998, 1999). In this case a small increase in NAA levels (6%) was recorded in motor cortex in those patients treated with riluzole. The untreated group showed a decline in NAA of about 4%. Studies of other brain regions more affected, such as the medulla where NAA is decreased by 17% compared to controls (Pioro *et al.*, 1999), may prove to provide better sensitivity for such types of studies. Further, large increases in NAA/Cr ratios correlated with improved recovery from traumatic head injury (Signoretti *et al.*, 2002).

An intriguing example of the use of MRS has been proposed in following therapy in Parkinson's disease in both primate models (Jenkins *et al.*, 1994) and in human patients (Ross *et al.*, 1999) after grafting of dopaminergic fetal cells in the striatum. Since fetal cells possess very little NAA it is possible to measure changes in NAA levels longitudinally after grafting. Presumably such increases in NAA levels indicates the graft is surviving and generating axonal sprouting (Ross *et al.*, 1999). Evaluation of NAA levels may prove complementary in this regard to study of dopamine transporter levels and binding using both PET and pharmacologic MRI (phMRI).

Use of NAA could thus be a powerful adjunct to other techniques to assess neuroprotective strategies such as NMDA antagonists in stroke, anti-epileptic medications in epilepsy, and potential therapies in ALS, AD and HD. One could study any neurodegenerative condition where progression of symptoms is rapid enough to assess neuroprotection in a reasonable time window. One important issue that must be settled in such a study is that of the neuronal loss vs. neuronal health. In the former case one would expect to find the rate of NAA loss slower than in the untreated controls, in the latter case one may actually see an increase in NAA levels if the neurons have not actually died.

Other molecules can be studied in addition to NAA and are usually collected in the same spectrum anyway. One chemical studied extensively has been lactate. MRS may be an attractive probe to monitor (experimental) treatment in patients with mitochondrial disorders. These disorders are progressive degenerative disorders, which affect multiple organs. Among the most common of these disorders is mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes (MELAS-syndrome). A hallmark of MELAS is elevated intracerebral lactate because of the dysfunctional oxidative metabolism. Therefore, monitoring lactate levels has potential as a therapeutic outcome measure. De Stefano *et al.* studied 11 patients with various mitochondrial disorders in a short term clinical treatment trial (De Stefano *et al.*, 1995b). The patients received sodium dichloroacetate in a placebo-controlled, double-blinded crossover study. Dichloroacetate can cause stimulation of pyruvate dehydrogenase activity and subsequent decreases in lactate. Seven of them showed a significant decrease of the Lac/Cr ratio after 1 week of treatment. However, their clinical disability remained unchanged, likely because a large fraction of the neuronal damage was not due to lactic acidosis (i.e. the lactate was a symptom not a cause of the encephalopathy). Pavlakis *et al.* studied one patient with MELAS over the course of several weeks of dichloroacetate therapy showing that the lactate levels decreased with time, and that NAA levels increased

(Pavlikis *et al.*, 1998). Unfortunately because of the variable clinical course of this disease the relapsing stroke-like episodes may resolve on their own and do not necessarily reflect responsiveness to treatment. Nonetheless, they did show that lactate levels were elevated even in tissue that showed no abnormalities in conventional MRI. In a similar disorder increased lactate has been observed in children with defects in pyruvate dehydrogenase complex (Harada *et al.*, 1996; Rubio-Gozalbo *et al.*, 1999). Rubio-Gozalbo *et al.*, 1999) determined that, in addition to increased lactate, there was increased alanine. Both these abnormalities correlated with changes in thiamine levels, lending support to the idea that MRS would be useful in following therapy. Harada *et al.* (1996) showed that the lactate levels renormalized in such patients upon treatment with dichloroacetate. One caveat to the dichloroacetate studies is that decreases in lactate may not be reflective of improved tissue metabolic status as it is the lactate/pyruvate ratio that truly reflects the cellular redox state, and lactate decreases induced via dichloroacetate are not always the result of stimulation of pyruvate dehydrogenase activity (Dimlich & Nielsen, 1992).

We also used treatment with coenzyme Q₁₀ to lower lactate levels in HD in occipital cortex. (Koroshetz *et al.*, 1997). In these subjects the small increase in lactate observed in occipital cortex (compared to controls) was lowered by about 28% in the HD subjects. As we discussed above, since the origins of the increased lactate in this population is not clear, the mechanism by which coenzyme Q₁₀ is working remains to be elucidated.

Neuroprotection in animal models

The non-invasive nature of MR makes studies of neuroprotection quite attractive. The ability to follow an animal longitudinally, and as its own control, allows evaluation of neuroprotection with smaller numbers of animals than might be attempted from histological methods. These types of MRS experiments have been performed in many of the animal models discussed above including models of neurodegeneration generated using mitochondrial poisons (injected both systemically as well as intracerebrally) as well as transgenic mice. Examples of the neuroprotective strategies evaluated using magnetic resonance techniques have included:

- (a) glutamate blockade by either antagonists such as MK-801 or by ablation of the cortical input of glutamate into the striatum via decortectomy (Storey *et al.*, 1992; Beal *et al.*, 1993; Henshaw *et al.*, 1994; Dijkhuizen *et al.*, 1996; Jenkins *et al.*, 1996; Lee *et al.*, 2000).
- (b) blockade of free radical production using blockers of neuronal nitric oxide synthase or trapping of free radicals after they are formed with compounds such as n-tert-butyl-alpha-(2-sulphophenyl)-nitron (S-PBN) (Schulz *et al.*, 1995a,b).
- (c) Administration of neuronal growth factors such as basic fibroblast growth factor (bFGF) (Kirschner *et al.*, 1996).
- (d) Energy repletion strategies whereby attempts are made to restore ATP levels with, for instance, mitochondrial electron transport chain substrates (e.g. coenzyme Q₁₀ or ubiquinone) or creatine supplementation (Beal *et al.*, 1994; Jenkins *et al.*, 1996; Matthews *et al.*, 1998; Ferrante *et al.*, 2000; Andreassen *et al.*, 2000a,b).

Many of these same strategies have proved useful in models of focal ischemia.

Magnetic resonance spectroscopy can play a role in assessing the efficacy of such potential therapies by monitoring their effects on: neuronal health and number using NAA; on oxidative phosphorylation using lactate or ATP; and on lesion size as measured by water imaging. Shown in Fig. 21.10 are data showing a focal increase in lactate and T₂ signal after acute intrastriatal injection with 3-NP (an inhibitor of succinate dehydrogenase or complex II). The lactate and NAA are shown in the form of spectroscopic images. (We also show as well, spectra demonstrating the identification of succinate at 2.40 ppm using comparisons with phantom spectra.) One week later, there is no lactate detectable at the lesion site, however, there is a large decrease in NAA as well as a decrease in the size of altered T₂ signal. The NAA would thus prove to be a good marker to follow long term neuroprotection, as we discuss below. On the other hand, lactate proves to be a useful marker for following the acute neuroprotection. As an example of this we present data, in Fig. 21.11, culled from more than 4 years' worth of neuroprotective experiments in the animal models discussed above using azide (a blocker of complex IV in the electron transport chain), malonate, 3-NP (another blocker of complex II) and MPP⁺ (a blocker of complex I in the electron transport chain). The protective agents that were used all have different mechanisms of action, and yet are all capable of producing neuroprotection to a varying degree. It is clear that MRS measurements of lactate correlate well with histological measures of neuroprotection in the majority of compounds studied. (One possible origin of this correlation is that the decrease in lactate measured in the striatum is actually due to the reduced size of the lesion while the actual concentration doesn't change (because the lactate measurements come from rather large voxels of greater than 2 × 2 mm)).

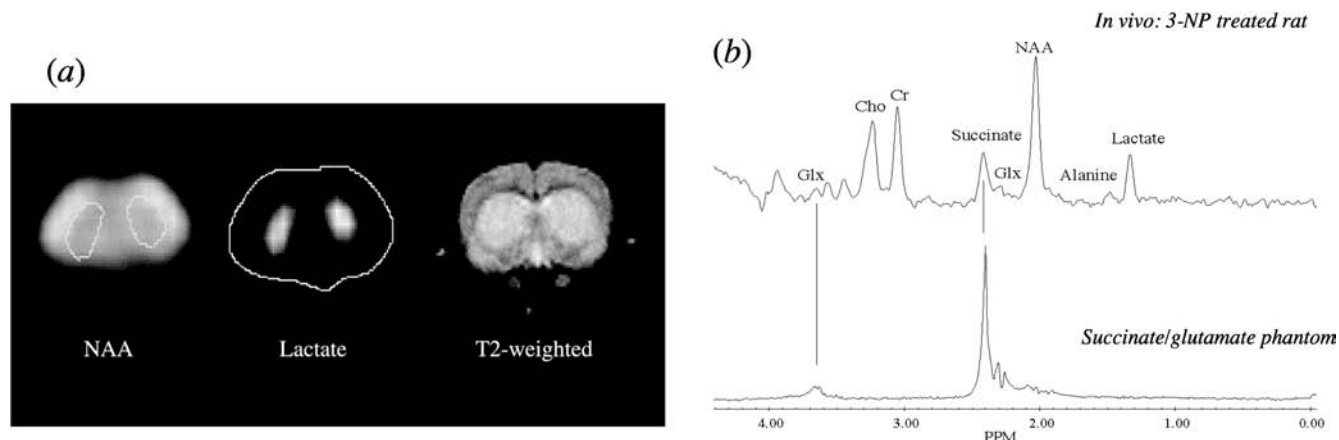

Fig. 21.10 MR images of focal energy impairment induced via systemic injections of 3-NP, an inhibitor of succinate dehydrogenase. (a) Spectroscopic images of decreased NAA, increased lactate and T_2 -weighted signal intensity taken 3–4 hours after i.v. injection of 33 mg/kg. The CSI images of lactate and NAA were acquired with a spatial resolution of approximately 2×2 mm with a 6 mm slice thickness. (b) Spectra from the striatum showing increased lactate and succinate after 3-NP. For comparison a phantom with glutamate and succinate is shown illustrating the singlet assignment of the succinate resonance at 2.40 ppm. Ordinarily, this peak is barely observable.

Fig. 21.11 Bar chart comparing measures of MRS lactate and lesion size determined histologically using either TTC or Nissl stain, as a function of neuroprotective strategies in the rat mitochondrial poison models of neurodegeneration. The MK-801 data are from intrastriatal MPP⁺ injections, the decortectomies were performed in systemically treated 3-NP rats, and the other results come from intrastriatal malonate injections.

NAA has been shown to be a useful marker for neuroprotection against MPP⁺ lesions using neuronal growth factors (Kirschner *et al.*, 1996). In this study, basic fibroblast growth factor (bFGF) was administered to neonatal rats (in whom the blood–brain barrier is not yet formed) and it was found that it could protect against neuronal loss as mea-

sured by NAA. A clear and marked protection was shown by measuring absolute NAA relative to water from proton density-weighted images (i.e. images in which the TR is long and the TE is short and in which CSF, edema and brain are nearly iso-intense) in the same animals. Using this method, it was shown that the NAA loss 2.5–3 months

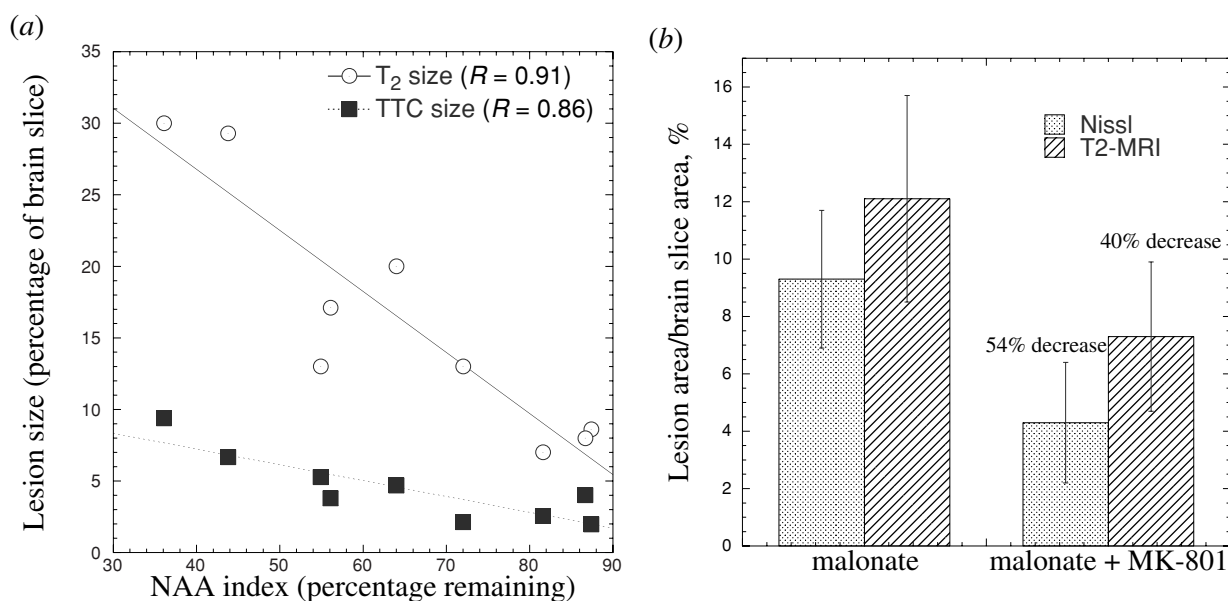

Fig. 21.12 Plots showing the relations between histology and T₂-weighted MRI measures of lesion sizes. (a) Plots of lesion areas/brain areas (percents) measured using either TTC or T₂-weighted MRI 2–3 months after lesioning with MPP⁺. The lesion areas are correlated quite well with an NAA measurement of absolute NAA loss. The animals with smaller lesions and less NAA loss have been treated with bFGF. (b) Plots of the relations between lesion size measured using Nissl staining 24 hours after intrastratial lesioning with malonate (either with or without MK-801 pre-treatment) or measured using T₂-weighted MRI 3–5 hours after lesioning. The T₂ measures lead to a larger lesion size, but the percentage reduction in lesion size between the two techniques is close.

after lesioning in the bFGF-treated animals was $85 \pm 3\%$ of the contralateral side compared to the untreated animals in which the loss in the lesioned side was $60 \pm 8\%$ (Kirschner *et al.*, 1996). These numbers also agreed with the histology and MRI measurements, and correlated with lactate measurements. These correlations are shown in Fig. 21.12(a). The lactate measurements also showed the protective effects of bFGF because the lactate concentration was lowered significantly. It is important to note that one can measure all the neurochemicals from one spectrum, and thus one can analyze neurodegeneration from a number of different perspectives with regards to neuronal loss and energy metabolism.

Numerous other animal studies have appeared using NAA as a marker for neuroprotective strategies. Our own studies have used NAA as a marker for neuroprotection in both neurotoxin models of neurodegenerative illness using blockade of mitochondrial complex II (succinate dehydrogenase) (Matthews *et al.*, 1998) or complex I (*N*-methyl-4-phenyl pyridinium (MPP⁺) (Kirschner *et al.*, 1996), as well as in transgenic mouse models of Huntington's disease (Ferrante *et al.*, 2000). In the latter study it was found that a dietary creatine supplementation (2% creatine in the food) leads to an increase in the life span of the R6/2 mice from about 15 weeks to about 17.5 weeks. Creatine

supplementation also led to a 30% increase in NAA in the striatum of these mice. These mice typically suffer loss of greater than 50% of the NAA in the striatum (Jenkins *et al.*, 2000). Typical spectra for HD and wild-type mice were shown in Fig. 21.5. MRS can simultaneously measure both the creatine increase in the brain, as well as the NAA and other neurochemicals by using, for instance, water as an internal reference standard. Thus, in this latter study we showed an increase in brain creatine levels of 21%. Most importantly, the increase in NAA levels correlated with the increase in creatine levels. The protection of NAA levels was also correlated with a protection of neuronal size (about 31%) by creatine supplementation. Since NAA has an exclusively neuronal localization, the decrease in neuronal size leads to a decrease in the total NAA signal detected. These results show that the time course of neuronal shrinkage is roughly parallel to that of the NAA loss in the absence of creatine treatment. Creatine supplementation delays the loss of both NAA and neuronal shrinkage to approximately the same degree. These are again reflective of the utility of NAA as a neuronal marker.

We also studied the ability of creatine to neuroprotect in a transgenic mouse model of ALS using a mutation in superoxide dismutase. In these mice lifespan was prolonged about 20% using 2% oral creatine supplementation

Fig. 21.13 ^{31}P spectra from occipital cortex in a Huntington's disease patient before and after treatment with oral creatine. Note that the spectra are quite similar with the exception of a decrease in the area of the peak labeled Pi. Spectra have been scaled to the PCr peak.

(Andreassen *et al.*, 2001). Further, the creatine lowered the elevated glutamate levels observed in these mice as measured by proton MRS. The peak labeled glx is smaller in the ALS mouse after creatine supplementation at about 80 days of age. Unfortunately, the effect wears off at 120 days in which the elevated glx reappears in spite of creatine supplementation (Andreassen *et al.*, 2001b).

Combined MRS and MRI of excitotoxicity

Use of MRI for examination of acute indirect excitotoxic insults using mitochondrial poisons was presented above. These studies are similar in nature to those used for the clinical aging of infarcts. In ischemia, as in the excitotoxic lesions, the first changes noted are decreases in the apparent diffusion coefficient (discussed below) that are consistent with redistribution of water from the extracellular to the intracellular space. At later time points (many hours to days) there is an increase in the T_2 relaxation time. The increased T_2 relaxation is believed to correlate with the cytotoxic edema, and more rapid rotational correlation times for the water. The lesion sizes determined using the T_2 -weighted MRI can be used to measure the effects of neuroprotective strategies. We made extensive comparisons between measurements of lesion size using T_2 -weighted

MRI and using TTC staining as well as Nissl staining postmortem. We found that the T_2 -weighted MRI generally yielded slightly larger sizes (by about 30%, although the percentage changes induced by the various neuroprotective strategies was similar in the postmortem and in vivo techniques. While the MRI may include tissue that eventually recovers (i.e. penumbral tissue), it is also true that the histological techniques suffer from some degree of tissue shrinkage. Examples of these experiments are shown in Fig. 21.12. On the left in Fig. 21.12(a) are data showing correlations between T_2 -weighted signal intensity, TTC staining lesion size and NAA decreases in a series of rats treated with MPP^+ and with or without bFGF (as discussed above). It is clear that there are good correlations between all three techniques. There is a larger increase in lesion area using T_2 -weighted imaging than with TTC, however there is very good correlation between T_2 area and TTC area ($R = 0.85$). Shown in Fig. 21.12(b) are data showing the neuroprotective effects of MK-801 in acute excitotoxic lesions induced using malonate (Henshaw *et al.*, 1994; Jenkins *et al.*, 1996) compared using T_2 -weighted MRI and Nissl staining. While again the T_2 -weighted MRI lesion sizes are larger than the histologically measured lesion areas, the overall correlation between the two techniques, as far as percent decrease in lesion size is good.

Unfortunately, the acute nature of the neurodegenerative models above are not directly applicable to the T_2 contrast

noted in the chronic neurodegenerative conditions. One possible exception to this is ALS. In this disease increased T_2 in the lateral cortical spinal tracts was measured in the cervical spine (Terao *et al.*, 1995). Other groups claimed there were no effects (Tanabe *et al.*, 1998). Our own studies indicate that the decreased volume of the cortical spinal tracts may lead to increased CSF signal in the region. Due to the exceptionally long T_2 of CSF this can be a potential confound.

³¹P spectroscopy

To conclude, we will briefly discuss phosphorus spectroscopy. Most ³¹P studies to date have examined muscle in mitochondrial disorders. These studies have long shown defects in many measures of high energy phosphate metabolism that in some cases are refractory to treatment with CoQ₁₀ or vitamin therapy (Chance *et al.*, 1986; Argov & Bank, 1991; Bendahan *et al.*, 1992; Radda, 1992). The efficacy of coenzyme Q₁₀ in improving abnormalities in high energy phosphates in patients with mitochondrial disorders has been claimed in both brain and muscle (Bendahan *et al.*, 1992; Barbiroli *et al.*, 1993, 1997, 1998); however other groups have claimed it is inefficacious (Matthews *et al.*, 1993). Due to the variable treatment times with coenzyme Q₁₀, variable clinical progression and courses in the various mitochondrial disorders, as well as the relative rarity of these diseases the question of efficacy remains open.

We have studied the ability of treatment with cyclocreatine and creatine to neuroprotect lesions induced by inhibitors of succinate dehydrogenase (electron transport chain complex II) using either systemic or intrastriatal injections (Matthews *et al.*, 1993). ³¹P spectroscopy showed increases in both PCr and phosphocyclocreatine in the brain. In addition, treatment with cyclocreatine increased ATP levels in control animals in brain (creatine treatment did not). The MRS proved invaluable in assessing the amount of creatine that made it into the brain, and how much an increase in high energy phosphates there were. These data would be even easier to collect in humans due to their larger brains. Shown in Fig. 21.13 are ³¹P spectra in an Huntington's disease patient before and after oral supplementation with 6 gms of creatine per day. Although the ³¹P spectra are not dramatically different there does appear to be a decrease in the inorganic phosphate peak (Pi) consistent with an increase in PCr. The spectra are scaled to the PCr peak. The spectra are consistent with an increase in PCr. Such studies, however, need to be performed over long periods of time, since the normal

variability of these chemicals in patient populations is not well characterized.

Acknowledgements

We would like to acknowledge the contributions of our many colleagues to the work presented here. In particular: Drs Diana Rosas, Alpaslan Dedeoglu, Ekkehardt Kuestermann, Iris Chen, Russell Matthews, Ole Andreassen, Jorg Schulz, and Bruce Rosen.

Therapeutic approaches in neurodegeneration

In the past 20 years, the development of molecular biology and genetic engineering has led to new horizons in therapy. Introducing therapeutic nucleic sequences into the organism for curing a disease is a very attractive approach for treating both inherited and acquired diseases for which classical drug therapy is not satisfactory. Although the idea is simple, many hurdles have to be overcome before clinical applications can be envisaged. The transfer vector and the therapeutic gene are the major determinants for successful therapy. An ideal vector would be easy to produce, and safe for the patient and the environment. Ideally, it must transduce only the target cells and do so efficiently. It should be possible to readminister the vector to the patients without triggering a deleterious immune reaction from the host, and the transgene has to be expressed at an appropriate level for the desired duration. The optimal characteristics of the gene depend on the disease. For a recessive monogenic disease, a wild-type allele of the mutated gene is generally required. For a dominant monogenic disease, sequences that inhibit the expression of the mutated allele, or that counter its physiological effect may be used. For many complex diseases, whether inherited or acquired, there are several potentially therapeutic genes. A therapeutic gene must be effective, but have minimal side effects. In particular, it should not lead to an immune response from the host organism, and this can be a major problem for recessive monogenic diseases, where the patient had never been in contact with the wild-type gene product.

In this chapter, we will address the development of the viral vectors most widely used for gene transfer into the nervous system. The principles of vector production will be described, with the advantages and limitations of the various vectors, with particular attention to gene transfer to the nervous system. We will also describe preclinical studies of gene transfer for treating two model diseases affecting the central nervous system (CNS): Parkinson's disease, a pro-

gressive neurodegeneration of a restricted area in the brain; and mucopolysaccharidosis type VII (MPS VII), a global enzymatic deficiency affecting all cells in the CNS.

Delivery vectors for gene transfer into the nervous system

The particular constraints on gene transfer into the nervous system have hampered its development. The complexity of the nervous system itself has been a psychological barrier inhibiting research in this field. There has also been a shortage of vectors for efficient transduction of quiescent cells, particularly neural cells. The first vectors were derived from the murine leukaemia virus (MLV) and they were unable to transduce non-dividing cells such as neurones. Vectors were then developed from a naturally neurotropic virus, the herpes simplex virus (HSV), but the complexity of its genome initially prevented the development of a transfer vector. A breakthrough came in 1993 with the idea of using a vector derived from a virus, adenovirus, that did not generally infect neural cells naturally, and the proof of principle of transferring genetic material in the CNS in this way (Le Gal La Salle *et al.*, 1993). Since then, HSV and adenovirus-derived vectors have been improved repeatedly and many other vectors have been developed, including the widely used adeno-associated-virus (AAV) and lentivirus. Another factor that limited the development of gene therapy for the nervous system was the high complexity of neurological affections, such as neurodegenerative diseases and trauma. Recent advances in the understanding of the pathophysiological mechanisms underlying these diseases have led to the identification of several endogenous factors that could be of therapeutic value. They include neurotrophic factors, enzymes involved in the clearing of free radicals and enzymes involved in the regulation of cell death or

apoptosis. Many of these factors have now been shown to protect neurones from decay or death and could be used as the basis for protective therapies.

There are various specific features that make gene therapy of CNS attractive. First, the CNS is isolated from the peripheral organs by physical barriers: a dense endothelial microvascular network known as the brain–blood barrier (BBB), the arachnoid epithelial membrane covering the surface of the brain, and the choroid plexus epithelium, which forms the blood–cerebrospinal fluid (CSF) barrier. These barriers block the entry of external factors including viruses and prevent the use of most vectors via the vascular route, unless special strategies are used involving penetrating or permeabilising them, or using retrograde transport of the vector. Nevertheless, this barrier confers a privileged immunological status on the CNS, helping prevent any immune reaction against either the vector or the therapeutic product of the transgene (Lowenstein, 2002). These barriers may also prevent side effects of the vector or the gene product in peripheral organs. A second advantage of the CNS for gene therapy is that many therapeutic products with potential clinical effects are diffusible and thus may be secreted from non-neuronal cells, such as astrocytes, and nevertheless act to prevent the pathological alteration of neuronal homeostasis and functions. The therapeutic molecules (or the vector) can also be captured by neurone terminals and transported to the neuronal soma by axonal retrograde transport. A third advantage is that the CNS is totally bathed in the cerebrospinal fluid (CSF) that can be used to deliver the vector or the gene product widely across the CNS. This can be done by intraventricular, intrathecal or intracisternal injection of the vector. Finally, the nervous system is structured and organized into many nuclei and layers that can be specifically targeted by locally, stereotactically, injecting the vector. Moreover, many neurological diseases affect a restricted area of the brain, such as the substantia nigra or the striatum, and such structures are relatively easy to target as compared to muscles and the intestine, for example. With all these characteristics, the nervous system is an organ particularly suited to experimental gene transfer.

Two approaches have been used to deliver genes to the nervous system. The first, called direct or *in vivo* gene delivery is the injection of the vector and thus the gene directly into the target organ. Although synthetic delivery systems may be appealing, the most efficient vectors currently available for this strategy are derived from viruses. The second approach is indirect or *ex vivo* gene delivery: the transplantation of genetically modified cells into the nervous system. These cells may be transplanted directly or may be encapsulated. The genetic

modification is performed using the same vectors as for *in vivo* delivery. In this chapter we will describe only the first delivery mode. Transplantation strategies are dealt with elsewhere.

Adenovirus derived vectors

Adenoviruses have a broad tropism, meaning that they can infect many species and cell types. They can infect both dividing and quiescent cells making them particularly useful for gene transfer to the nervous system. In 1993 we showed that adenovirus-derived vectors can transduce all cell types in the CNS after direct injection into the brain or the ventricles (Le Gal La Salle *et al.*, 1993). More than 100 adenoviruses have now been described, and about 50 different human serotypes have been found. They all contain a linear double-stranded DNA genome (30 to 38 kb long) encapsidated in an icosahedral protein shell measuring 60 to 100 nm in diameter. They enter cells via endocytosis following interaction with two distinct receptors. First, the protein fiber of the capsid interacts with CAR (coxsackievirus and adenovirus receptor), a cellular receptor (Bergelson *et al.*, 1997). Then, the base of the penton interacts with the cellular αv integrins (Wickham *et al.*, 1993). Two hours later, the DNA is transported to the nucleus and the first expression round starts with the immediate early genes (E1 to E4). The immediate early gene E1A is the first transcription unit to be expressed and it *trans*-activates a cascade of expression of other viral and cellular transcription units. The E1B products react with E1A products and transform the infected cell. E2 codes for proteins involved in viral replication, E3 products contribute to the inflammatory response by preventing the infected cells from being recognized by the host immune system and E4 products participate in viral DNA replication and the activation of late structural genes.

The first adenovirus-derived vectors were produced by deletion of the E1 region to prevent viral replication. A transcomplementing cell line (HEK 293 cells) was obtained by transforming embryonic human kidney cells with the E1 region of the Ad5 (Graham *et al.*, 1977). Recombinant adenovirus vectors are obtained by homologous recombination between a shuttle plasmid (containing the gene of interest) and the $\Delta E1$ adenoviral genome in HEK 293 cells. A recombinant genome in which the E1 region is replaced by the transgene is thereby obtained and can be propagated in HEK 293 cells. Clonal lysis plaques are selected, purified, analyzed and amplified in HEK 293 cells. This method of production is tedious and time consuming. Improved production techniques, avoiding lysis plaque selection have been developed based on homologous recombination in

yeast using YAC (Ketner *et al.*, 1994) or in *E. coli* (Chartier *et al.*, 1996; Crouzet *et al.*, 1997).

All these methods present a major inconvenience as they allow the production of replication competent adenovirus (RCA), due to the possible reinsertion of the E1 region of the HEK 293 cell into the vector genome during the amplification step. New transcomplementation cell lines have been produced by transformation with an E1 region that has no homology with the vector genome (Fallaux *et al.*, 1996, 1998). Nevertheless, all these first-generation Δ E1 vectors present several other limitations. First, their cloning capacity is limited to 7–8 kb as the total vector genome cannot exceed 105% of the wild type genome length. The E3 region was deleted to increase the cloning capacity, but this resulted in higher immune reaction from the host. Second, the direct injection of these vectors induces a local inflammation dependent on the dose because of a residual expression of viral genes, despite the E1 region being deleted. The expression of the viral genes induces cytotoxicity and specific cellular and humoral immune reactions, the consequence of which is the death of the transduced cells and therefore only short-term expression of the transgene.

Thus, second-generation adenovirus vectors were produced by introducing a thermosensitive mutation in the E2A gene. These vectors gave a smaller inflammatory reaction and greater transgene persistence, but the thermosensitive mutation was reversible and the improved efficacy did not seem to be consistently obtained (Fang *et al.*, 1996).

Third-generation adenovirus vectors were developed by deleting other regions of the viral genome: the E1 region, the E4 region and the E3 region. New transcomplementation cell lines derived from 293 and expressing a minimal E4 unit are used for their production. Although these vectors give reduced cytotoxicity and improved transgene stability, the persistence of transgene expression is not improved in all cases, production remains tedious and the generation of RCA is still possible.

The latest generation of adenovirus-derived vectors are called *helper-dependent* or *gutless* vectors. They are devoid of all viral coding sequences. They were first designed in 1995 (Mitani *et al.*, 1995), and several more or less complex systems of production have been developed since (Fisher *et al.*, 1996; Hardy *et al.*, 1997; Hillgenberg *et al.*, 2001; Kochanek *et al.*, 1996; Ng *et al.*, 2001). The process is based on the utilization of a helper virus providing in *trans* all the functions needed for production and amplification of defective recombinant vectors. The main difficulty is eliminating the helper virus from recombinant stocks. Currently, the best method consists in preventing encapsidation of helper genome by inducible recombination of the encapsidation signal (Ψ region) using Cre/Lox or FLP/FRT

systems. Although production is still laborious, the cytotoxicity of these vectors is much lower than that of earlier generation vectors. Inflammatory and immune responses in the host are lower, resulting in sustained high-level expression in many organs, including the brain (Thomas *et al.*, 2000; Zou *et al.*, 2000, 2001). Nevertheless, they retain a transient capsid-mediated inflammatory response (Thomas *et al.*, 2001). These latest vectors can be produced devoid of RCA and have an increased cloning capacity (up to 37 kb). The production process for this latest generation of adenoviral vectors will have to be scaled-up at low cost before clinical application can become routine.

The efficacy of adenovirus delivery to patients might be hampered because most people have been exposed to natural adenovirus infection. Classical vectors are derived from Ad2 and Ad5, for which most people have neutralizing antibodies. Several strategies have been proposed to overcome this problem. The simplest is to reduce the dose, as it has been shown that direct cellular toxicity increases linearly with vector dose (Thomas *et al.*, 2001). Another strategy consists of using adenoviral vectors derived from non-human serotypes or from rare serotypes in humans, or by using chimeric adenoviruses containing an ectopic fibre derived from rare serotype. Alternatively, the surface of vector particles could be coated with polymers such as PEG (Croyle *et al.*, 2002) or pHMPA (Fisher *et al.*, 2001). The use of different serotypes and the coating process also allow the repeated administration, an important factor for clinical applications.

Another important feature is the targeting of the vector to transduce specific cell types. Adenoviral vectors efficiently transduce most of the cells in the nervous system (Akli *et al.*, 1993; Bajocchi *et al.*, 1993; Davidson *et al.*, 1993; Le Gal La Salle *et al.*, 1993). Some serotypes are more efficient in certain cells and could thus be used to obtain relative specificity. For example, type D adenovirus (Ad17), and chimeric type C adenovirus (Ad2) containing a type D fiber, are more efficient for the infection of primary neurones (Chillon *et al.*, 1999). The re-routing of adenoviral vectors is also feasible by incorporating a ligand in the fiber (Krasnykh *et al.*, 2001; Magnusson *et al.*, 2001; Sosnowski *et al.*, 1999) or in a polymer used to coat the viral particles, thus combining both immune reaction prevention and specificity of interaction with a membrane receptor of the target cell (Fisher *et al.*, 2001). It is also possible to use a molecular adaptor (bi-allelic antibody) to create a specific interaction between the viral particle and the target cell (Goldman *et al.*, 1997; Wickham *et al.*, 1997). These techniques should permit very specific targeting of the vector, but they also make production more complex. Thus, it might be preferable to use the simpler approach

of restricting the expression of the transgene instead of restricting the entry of the particle. Transcriptional targeting can be obtained by using cellular or chimeric promoters specifically active in a certain type or subtype of cells of the nervous system (Hashimoto *et al.*, 1996; Kugler *et al.*, 2001; Lee *et al.*, 2000; Millecamps *et al.*, 1999; Navarro *et al.*, 1999; Robert *et al.*, 1997).

Another specific feature of adenovirus-derived vectors for gene transfer into the nervous system is that they can be transported via the axonal transport system of neurones. Thus, inoculation of the muscle with a vector targets the innervating motor neurones and sensory neurones (Finiels *et al.*, 1995; Ghadge *et al.*, 1995). Similarly, intranasal inoculation targets olfactory neurones (Zhao *et al.*, 1996) and administration may be possible in the area of projection of neurones for which the cell bodies are difficult or hazardous to reach in humans. An example is the dopaminergic neurones in the substantia nigra which can be accessed by injecting the vectors into the striatum (Kuo *et al.*, 1995). The efficacy of retrograde uptake of the vector particles is dependent on the synaptic sprouting of the innervating terminals and it can be enhanced by using botulinum toxin (Millecamps *et al.*, 2001, 2002). Another alternative route of inoculation of adenovirus-derived vectors is injection into the CSF, which leads to the transduction of meninges cells and vascular cells (Christenson *et al.*, 1998), ependymal cells (Ghodsi *et al.*, 1998) and motor neurones (Mannes *et al.*, 1998). Systemic hyperosmolality can be induced by mannitol before inoculation of the vector into the CSF (Ghodsi *et al.*, 1999) to enhance the spreading of the virus in the parenchyma.

In summary, the latest generations of adenoviral vectors are thus particularly promising for long-term gene transfer into both the CNS and the PNS for treating chronic diseases.

Herpes simplex virus (HSV)-derived vectors

The herpes simplex virus 1 has features making it attractive as the basis for gene therapy vectors, especially for applications in the nervous system. It is large and has a broad host range, high infectivity, and ability to infect quiescent cells. Most of all, it has a natural tropism for the CNS and PNS neuronal cells and can be transported retrogradely through axons. Moreover, it has a latent phase of its life cycle in neurones, which might be exploited for long-term expression of transgenes in these cells. The genome of this enveloped virus is 160 kb and has been sequenced. Following wild-type HSV primary cutaneous or mucosal inoculation, the virus replicates. Its replication is controlled by regulated temporal expression of its genes. The cycle

starts with the transcription of five immediate early genes (ICP0, ICP4, ICP22, ICP27 and ICP47), which initiate a cascade of transcription of the early and late genes. From the primary infection site, the virus may enter sensory neurones. The nucleocapsid and tegument are carried by retrograde axonal transport to the neuronal soma in the dorsal root ganglia or trigeminal ganglia where the viral genome enters the nucleus. At this point, lytic replication may occur. Alternatively, the virus can become latent and its genome persists as a stable episomal element, potentially for many years. During latency only the latency-associated transcripts (LATs) are expressed.

Two types of vectors can be obtained from this virus. First, recombinant HSV vectors deficient for replication can be constructed by the deletion of one or several immediate early genes and non-essential genes from wild-type HSV to prevent lytic viral replication. The production process is very similar to that of adenovirus-derived vectors. A transcomplementation cell line stably expressing the deleted immediate early genes is co-transfected with the deleted viral plasmid and a shuttle plasmid containing the transgene expression cassette flanked with viral sequences. An important advantage of these vectors is the cloning capacity, which is as high as 50 kb. When homologous recombination occurs, a recombinant defective HSV vector is obtained and packaged in empty virions. The next step consists of purification of vector stocks, as both deleted viral genome and recombinant vector are present. This requires selection of lysis plaques and further amplification on transcomplementation cells.

A major problem encountered with these vectors is their toxicity due to residual expression of viral genes. The toxicity can be greatly diminished by deletion of ICP0, ICP4, ICP22 and ICP47 (Samaniego *et al.*, 1998). Unfortunately, in the absence of ICP0, the vectors grow poorly and the transgene expression is low in most cells (Samaniego *et al.*, 1997). However, it seems that ICP0 retention is not deleterious in neurones, which simplifies the design and production of the vectors for many neurological gene therapy applications. Another important issue is the level and stability of the transgene expression in transduced cells. In many cases, expression is downregulated when ectopic promoters are used. As the latency potential of the HSV is potentially useful for sustained expression of the vector, latency promoters have been exploited to drive long-term expression of a transgene in neurones *in vivo*. Promoter elements of the LATs can be used at ectopic positions in the vector genome, combined with other strong viral immediate-early promoters or used in their original position by replacing a latency gene with the transgene. These approaches have been successfully used to obtain

long-term expression of transgenes in the PNS motor and sensory neurones (Goins *et al.*, 1994, 1999; Lachmann & Efstathiou, 1997; Palmer *et al.*, 2000), and in CNS neurones (Lachmann & Efstathiou, 1999; Scarpini *et al.*, 2001; Smith *et al.*, 2000).

The second type of vectors that can be obtained from HSV are called amplicons and were first generated by the transfection of an amplicon plasmid (containing the transgene expression cassette, the origin of replication of HSV (Ori_s) and a Ψ encapsidation signal), and the co-infection with an HSV helper virus (Geller & Breakefield, 1988). The amplicon plasmid replicates in a *rolling circle* mode forming a concatemer of about 150 kb containing several copies of the transgene (Leib & Olivo, 1993). Thus, amplicons can have a genome length up to 150 kb. However, the production technique for these forms gives stocks that are rich in wild-type helper virus, and thus are not adequate for safe gene transfer because of their toxicity. In 1996, Fraefel *et al.* proposed a method for producing amplicon stocks devoid of helper virus. The genome of HSV-1 has been deleted of the encapsidation signal and subcloned in several cosmids. The co-transfection of the cosmids and the amplicon plasmid give rise to amplicon vector stocks uncontaminated with helper virus (Fraefel *et al.*, 1996). Several teams have subsequently improved this method by using a bacterial artificial chromosome instead of cosmids (Saeki *et al.*, 1998; Stavropoulos & Strathdee, 1998). Recently, Logvinoff *et al.* designed a new process to ensure production of high titre stocks of helper-free amplicon vectors with a Cre/LoxP system excising the Ψ encapsidation signal from a helper virus (Logvinoff & Epstein, 2001). However, all these methods are limited by the fact that amplicon vectors cannot be amplified directly in a transcomplementation cell line.

Like adenoviruses, HSV vectors may be limited for use in human clinical applications because of the existence of wild-type virus in most patients. The injection of a HSV vector might reactivate endogenous virus, potentially causing encephalitis. Nevertheless, no reactivation was observed in two murine models of latent infection of HSV after intracerebral injection of HSV vectors (Wang *et al.*, 1997), or after intratumoral administration of HSV vectors in nine patients treated for gliomas in a gene therapy trial (Rampling *et al.*, 2000). Although pre-existing antibodies do not seem to impair HSV vector efficacy in murine models (Brockman & Knipe, 2002; Delman *et al.*, 2000), repeated administration of the vector might be problematic. To overcome this problem, HSV vectors have been delivered through liposome formulation, but efficiency was lower than that of non-formulated vectors (Fu & Zhang, 2001).

HSV vectors are able to infect many kinds of different cells, particularly in the nervous system. Virus entry

depends on the interactions of its numerous glycoproteins with cellular receptors which are still poorly characterised. Various strategies have been considered for modifying the tropism of the vectors. Engineered virions in which the viral gC glycoprotein is replaced by a gC-erythropoietin (EPO) fusion protein, and the viral gB partially deleted, have acquired specific binding properties to the EPO receptor (Laquerre *et al.*, 1998). An alternative strategy used consisted in pseudotyping the vectors with an ectopic glycoprotein (VSV-G) and deleting the gB or gD from the vector (Anderson *et al.*, 2000).

Applications in the nervous system for HSV-derived vectors are very similar to those for adenoviruses. Their ability to carry large DNA fragments and to be transported via the axonal retrograde pathway and their latency properties make them potentially valuable for chronic neurological diseases, particularly of the PNS. However, their toxicity must be reduced and their production facilitated for clinical applications.

Adeno-associated virus (AAV) derived vectors

The adeno-associated virus (AAV) is a dependovirus of the *Parvoviridae* family. It is one of the smallest and simplest of eucaryotic viruses. It is unique in the world of animal viruses in that it needs the co-infection with a helper virus (adenovirus or herpesvirus) for a productive cycle of infection (Atchison *et al.*, 1965; Buller *et al.*, 1981). This non-enveloped virus has an icosahedral structure of about 20 nm in diameter constituted only of proteins and DNA. Three proteins (VP1, VP2 and VP3) form a very stable capsid, resistant to pH inactivation, solvents and high temperatures (up to 50 °C). In the absence of helper virus, the AAV integrates specifically into a particular locus in humans (19q13.3-qter) (Kotin *et al.*, 1990). Its genome is a linear single-strand non-segmented DNA of 4.7 kb. Two terminal sequences (ITR) flank its two genes: *rep*, coding for the proteins controlling viral replication and integration into the host genome, and *cap* coding for the structural proteins. The wild-type AAV is not pathogenic for humans and is able to infect both dividing and quiescent cells making it particularly suitable for the development of transfer vectors for neurological applications.

The first method for producing AAV-derived vectors involved the co-transfection of a plasmid expressing *cap* and *rep* and a plasmid containing the transgene expression cassette flanked with the ITRs in cells infected with an adenovirus. After virus production, the adenovirus is heat-inactivated and the AAV vectors are purified on a CsCl gradient. This method gives only low-titre stocks and helper adenovirus contamination is frequent. Purification has been

improved by using HPLC (Drittanti *et al.*, 2001) or column purification (Auricchio *et al.*, 2001) to avoid contamination with helper virus. Several teams expressed *rep* and *cap* stably in transcomplementation cell lines and/or subcloned the AAV vector genome in a shuttle vector (adenovirus or baculovirus) to bypass the unreliable transfection step (Liu *et al.*, 1999; Sollerbrant *et al.*, 2001). The best approach however for preventing contamination with helper virus and by obtaining high titers stocks is to isolate the necessary adenoviral genes on a plasmid and to co-transfect this plasmid with the AAV vector plasmid and the *cap/rep* plasmid (Matsushita *et al.*, 1998; Xiao *et al.*, 1998). This protocol has been further improved by reducing the number of plasmids to two (Collaco *et al.*, 1999). AAV vectors are reliably and efficiently produced and purified in an increasing number of laboratories, making it one of the most popular vectors for in vivo applications. Indeed, with high titre stocks devoid of helper adenovirus, AAV vectors are very effective for the transduction of many cell types including neural cells. They drive stable and strong expression of the transgene with a very low toxicity and immune/inflammatory reaction (Chamberlin *et al.*, 1998; McCown *et al.*, 1996; Okada *et al.*, 2002; Peel & Klein, 2000). Another advantage of AAV vectors is their great stability, which allows the lyophilisation of stocks, which is useful for clinical applications (Croyle *et al.*, 2001). Finally, the harmlessness of wild-type AAV in humans makes it particularly suited for human applications.

However, AAV vectors have several drawbacks. First, their cloning capacity is very limited (about 4.5 kb), such that the use of several genes or long transgenes (for example a long cDNA or a long segment of a cellular promoter) cannot be used in AAV vectors. Some have bypassed the problem by using mini-genes (Wang *et al.*, 2000), or reconstituting a protein from different subunits expressed from several vectors (Burton *et al.*, 1999). A more generally applicable approach is to exploit the in vivo concatemerization of AAV genomes before their integration (episomal AAV genomes persist in a variety of molecular forms including concatemers (Duan *et al.*, 1999; Nakai *et al.*, 1999)). By splitting an expression cassette between two vectors, a functional cassette can be reconstituted after concatemerization in the cell nucleus (Duan *et al.*, 2001; Nakai *et al.*, 2000; Yan *et al.*, 2000).

Another issue for AAV vectors is their integration property. Although wild-type AAVs integrate into a specific locus due to the *rep* proteins, the recombinant vector integrates more or less randomly and the integration ratio depends on the cell type and cell cycle stage (Alexander *et al.*, 1994; Podsakoff *et al.*, 1994; Ponnazhagan *et al.*, 1997; Rutledge & Russell, 1997; Wu *et al.*, 1998). Integration of the vector

genome into the host genome may cause an insertional mutagenesis that could be tumorigenic. Moreover, recombinant AAV genome integration preferentially occurs in active genes and is usually associated with chromosomal rearrangements including deletions and translocations (Miller *et al.*, 2002; Nakai *et al.*, 2003). To make AAV vectors safer, several teams are developing new vectors which specifically integrate into the human chromosome 19 locus, using various approaches including chimeric vectors (Kogure *et al.*, 2001; Palombo *et al.*, 1998; Recchia *et al.*, 1999; Rinaudo *et al.*, 2000; Rizzuto *et al.*, 1999; Satoh *et al.*, 2000; Tsunoda *et al.*, 2000; Ueno *et al.*, 2000).

Another hurdle is the pre-existing immunity in the population. The immune reaction to AAV2 is very variable between individuals. Although anti-AAV2 immunoglobulins are common, most are not neutralizing antibodies (Chirmule *et al.*, 1999). The repeated administration of AAV vectors may be problematic, but switching capsid serotypes (Halbert *et al.*, 2000) or using vectors derived from non-human parvoviruses may avoid the potential impediments (Gao *et al.*, 2002).

The tropism of AAV vectors can be targeted by modification of the capsid. Not all serotypes have the same efficacy for a given cell type. For example, vectors derived from AAV4 and AAV5 are more efficient than AAV2-derived vectors for the transduction of ependymal cells after intraventricular injection. When injected into the striatal parenchyma of rodents, AAV4 has a selective tropism for ependymal cells, whereas AAV2 seems to transduce mainly parenchymal neurones and AAV5 transduces both neurones and astrocytes (Davidson *et al.*, 2000). Some serotypes diffuse more than others into the brain parenchyma (Mastakov *et al.*, 2002). Nevertheless, as for adenoviruses, diffusion can be enhanced by mannitol injection (Mastakov *et al.*, 2001), heparin co-infusion (Mastakov *et al.*, 2002) or by the use of *convection enhanced delivery* (Bankiewicz *et al.*, 2000; Nguyen *et al.*, 2001). Targeting can also be achieved by modifying the capsid with a ligand (Girod *et al.*, 1999; Grifman *et al.*, 2001; Nicklin *et al.*, 2001) or with a bispecific antibody (Bartlett *et al.*, 1999). The use of tissue-specific regulatory sequences (cellular promoters or chimeric promoters) can also direct expression to a given cell type or subtype (Peel & Klein, 2000). Unlike adenovirus and HSV-derived vectors, AAV-derived vectors are not transported retrogradely through axons. However, they can be administered via the CSF route to efficiently transduce neural cells (Elliger *et al.*, 1999).

All these properties give AAV-derived vectors great potential for chronic neurological affections although they cannot be used easily for applications needing a large transgene. The increasing number of gene therapy clinical

trials for various diseases reflects the potential of these vectors.

Retrovirus derived vectors

The retrovirus family is divided into seven genders of which two have been extensively used for gene transfer purposes: mammal type C retroviruses (such as the murine leukaemia virus, MLV) and lentiviruses (such as the human immunodeficiency virus, HIV). Retroviruses are enveloped particles of about 100nm in diameter presenting an internal conical core (capsid) protecting a genome of two molecules of RNA. The viral replication cycle involves the adsorption of the virions through specific receptor and fusion to the cell membrane, reverse transcription leading to the formation of a linear double stranded DNA (provirus) and integration of the provirus into the host genome. Two viral RNA molecules are packaged into an assembled capsid and the virion buds from the cell membrane which expresses the envelope protein at its surface. The RNA (+) genome of retroviruses is about 7–12 kb long, and is composed of two long terminal repeats (LTRs) flanking three coding genes and several *cis* acting elements involved in the genome replication, transportation and encapsidation. The *gag* gene codes for the matrix, the capsid and the nucleocapsid proteins. The *pol* gene codes for two enzymes necessary for the viral replication cycle: the retrotranscriptase and the integrase. The *env* gene codes for the glycoprotein present at the surface of the virions (envelope). A Ψ encapsidation signal ensures the specific packaging of the retroviral RNAs into the capsid. Some of the complex retroviruses such as lentiviruses contain additional accessory genes (for example, *Vpr*, *Vif*, *Nef*) important for viral infectivity and pathogenicity. They also contain regulatory proteins such as *Tat* and *Rev*, governing the expression of the viral gene at both transcriptional and post-transcriptional levels. The LTRs have many important functions involved in retrotranscription, integration and replication.

Retroviruses have potentially valuable properties for gene transfer. They are relatively easy to manipulate and they integrate stably into the host genome. The first retroviral vectors were derived from MLV, by a relatively simple method. A proviral genome is subcloned into a plasmid and the *gag*, *pol* and *env* genes are replaced by the transgene. Recombinant retroviral particles are obtained by co-transfection of this plasmid with a transcomplementing plasmid encoding all the structural proteins. To facilitate production, encapsidation cell lines have been generated by stable transformation of cells with *gag*, *pol* and *env* genes. To prevent the risk of creating replication competent retroviral vectors, the three genes can be introduced

at different loci into the transcomplementation cell's genome (Bosselman *et al.*, 1987; Cosset *et al.*, 1995; Danos & Mulligan, 1988; Miller *et al.*, 1991).

MLV-derived vectors cannot be used for most neurological applications because they are unable to cross the nuclear membrane to integrate, preventing them from transducing non-dividing cells in which the nuclear membrane is complete. However, lentiviruses can transduce quiescent cells including neurones, and thus have potential for developing transfer vectors. The development of efficient lentiviral vectors has been delayed by production problems. The first HIV1-derived vectors were generated in exactly the same way as MLV vectors, but the titers were low (Page *et al.*, 1990; Poznansky *et al.*, 1991; Richardson *et al.*, 1995). Replacing the HIV *env* gene with a VSV-G envelope, i.e. by pseudotyping the vector, was a substantial step forward. The VSV envelope is resistant to ultracentrifugation, allowing concentration of the virions to high titers (Akkina *et al.*, 1996; Naldini *et al.*, 1996a,b). It is also able to attach to the majority of the mammal cells, broadening the tropism of the vectors. Such vectors have proved very efficient for transducing many tissues, but are particularly efficient for the CNS.

Because of the high risk inherent to wild-type lentiviruses, the bio-safety of lentivirus-derived vectors has been optimized. Many non-human lentiviral vectors have been engineered from the simian SIV (Nakajima *et al.*, 2000), feline FIV (Poeschla *et al.*, 1998), equine EIAV (Mitrophanous *et al.*, 1999), bovine BIV (Berkowitz *et al.*, 2001), or ovin Visna virus (Berkowitz *et al.*, 2001) for this reason. However, it is still unclear whether non-primate lentiviruses are safer than primate lentivirus-derived vectors. The main risk is possible interactions between the vector and endogenous retrovirus in the patient leading to rescue of a vector RNA by wild-type virions. A vector RNA molecule and a wild-type RNA molecule could be recruited into the same particle, enhancing the risk of recombination and the generation of novel viruses. It has been shown that FIV RNA could be rescued by HIV viruses (Browning *et al.*, 2001) and the risk might be greater if HIV-derived vectors are used to transduce wild-type-HIV-infected cells. However, thanks to knowledge of MLV vectors, the development of lentiviral vectors has been extremely fast, and researchers have focused particularly on safety issues. In the latest production systems for HIV vectors, using transient transfections, the *trans* functions are supplied by three or four separate plasmids to reduce the risk of formation of replication competent vectors. Moreover, four accessory genes have been deleted from the packaging plasmids with no effect on transduction efficacy (Zufferey *et al.*, 1997), and several packaging cell lines have been generated to

facilitate production (Dull *et al.*, 1998; Kafri *et al.*, 1998, 1999; Xu *et al.*, 2001). Thus, with the latest generation of vectors, it is theoretically impossible to form wild-type lentivirus during the production process, because this would require at least three recombination events, and because some of the accessory genes, important for the pathogenicity of lentiviruses, are missing from the packaging plasmids. Nevertheless, it is also important to optimize the design of the vector genome, carrying the transgene between the LTRs, in terms of safety as well as efficiency. The basic vector genome comprises the LTRs flanking the packaging sequences, an intron, the RRE sequence (rev responsive element, important for the export of the RNA) and the expression cassette. Because LTRs contain enhancer and promoter functions that may possibly activate cellular genes or disturb the activity of the internal expression cassette, vectors with a deletion in the U3 regulatory region of the LTRs have been developed, and show improved expression in the brain (Iwakuma *et al.*, 1999; Miyoshi *et al.*, 1998; Zufferey *et al.*, 1998). Also, excisable lentivirus could be developed with a Cre/LoxP system (Salmon *et al.*, 2000). Using an inducible recombinase system, the deletion of the Ψ encapsidation signal could prevent the rescue of vector RNA molecules by endogenous retroviruses. Although such systems might be efficient *in vitro*, their use *in vivo* may be limited by the relatively poor efficiency of the Cre recombinase.

In contrast to MLV vectors, lentiviral vectors seem to maintain long-term expression of a transgene in many tissues, and particularly in the nervous system (Blomer *et al.*, 1997; Kafri *et al.*, 1997) including the retina (Lotery *et al.*, 2002; Miyoshi *et al.*, 1997; Takahashi *et al.*, 1999). This may be due to the absence of immune/inflammatory reactions to lentiviral vectors which also allows repeated injection of the vector into the same animal (Kafri *et al.*, 1997) (C. Sarkis, personal data). Expression can be further increased by optimizing the expression cassette by using different promoters, or the *woodchuck post-transcriptional regulatory element* (WPRE), which enhances the expression of transgene by RNA processing (Brun *et al.*, 2003; Ramezani *et al.*, 2000; Zufferey *et al.*, 1999). The transduction efficacy of lentivirus is limited in most tissues by the lack of nuclear transportation functions of the provirus. The incorporation into the vector genome of the flap cis element that was previously deleted, re-established the normal level of nuclear transport of provirus genome, and thus improved the transduction efficiency by a factor of 2 to 10, including in the brain *in vivo* (Follenzi *et al.*, 2000; Zennou *et al.*, 2000, 2001).

The tropism of VSV pseudotyped lentiviral vectors in the brain has been reported as being mainly neuronal

(Blomer *et al.*, 1997). However, in our hands it seems that the tropism depends on the promoter used for the expression of the transgene (C. Sarkis, personal data). Also, discordant results have been published concerning the retina, suggesting that VSV-HIV preferentially infects the retina pigment epithelium or the photoreceptors after subretinal injection, depending on the promoter (Auricchio *et al.*, 2001; Miyoshi *et al.*, 1997). Several factors may influence the type of cells transduced, such as the dose of vector, the preparation protocol, and the injection procedure. Like other enveloped vectors, lentiviral vectors can be pseudotyped using various envelopes, of which the lyssavirus (rabies) glycoproteins are the most interesting for neural applications (Auricchio *et al.*, 2001; Desmaris *et al.*, 2001; Mitrophanous *et al.*, 1999; Mochizuki *et al.*, 1998; Reiser, 2000). The pseudotyping of an EIAV vector with the rabies glycoprotein seems to target the transduction to neuronal cells, and to allow the retrograde transport of the vectors, which does not occur with other vectors (Mazarakis *et al.*, 2001). VSV pseudotyped lentiviral vectors do not undergo axonal transport, and it is not clear if lyssavirus glycoprotein pseudotyping can confer axonal transportation properties to non-EIAV lentiviral vectors.

Lentiviral vectors are very suitable for the transduction of neuronal cells. The lack of toxicity and the stability of expression of the transgene make them, like AAV vectors, valuable tools for chronic neurological applications. Moreover, their cloning capacity is higher than that of AAV vectors (around 7 kb). However, continued efforts are required to reduce as far as possible all risks associated with these vectors. As for all randomly integrative vectors, the risk of insertional mutagenesis exists, and must be addressed. Engineered specific integrases constructed by fusing specific binding domains to the HIV integrase (Holmes-Son *et al.*, 2001; Holmes-Son & Chow, 2000, 2002) or ectopic integrase such as the Φ C31 integrase (Olivares *et al.*, 2002) could be used.

Examples of therapeutic strategies

Gene transfer methods can be envisaged for therapy in the nervous system for both chronic and acute affections. However, the complexity of the brain, the variable and often poorly understood pathological basis of the diseases, the availability of animal models, the difficulty of targeting neural genes, the limitations of vectors and many other difficulties have impeded successful application of these techniques.

As examples, we will describe the use of gene transfer strategies on two chronic affections of the central nervous

system: Parkinson's disease; and mucopolysaccharidosis type VII (MPS-VII). For both diseases, both in vivo and ex vivo strategies have been explored. We will focus on the direct transfer strategy, because another chapter is dedicated to transplantation procedures.

Parkinson's disease

PD is a neurological disorder which involves the progressive loss of dopaminergic neurones from the SN (substantia nigra), a brain structure which innervates the striatum, leading to specific motor impairment (tremor, rigidity and akinesia) sometimes associated with cognitive impairment (Poewe & Wenning, 1996). Usually, clinical symptoms do not appear until about 70% of the dopaminergic neurones have been lost (McGeer *et al.*, 1977). Standard oral administration of L-dopa (a substance that crosses the blood-brain barrier and is transformed into the neurotransmitter dopamine) can significantly improve motor function during the first years of treatment. However, as the neurodegeneration progresses, higher doses of L-dopa are required leading to deleterious side effects such as dyskinesia. L-dopa or other related drugs can prevent the apparition of symptoms (tremor, rigidity), but these drugs do not treat the cause or progress of the disease. Electrical deep brain stimulation of the subthalamic nucleus reduces dyskinesia and the amount of drugs needed for PD treatment by 50% (Benabid *et al.*, 1998; Limousin *et al.*, 1998). However, this method has drawbacks: the stimulating apparatus requires battery charging and can be perturbed by magnetic waves. Thus, a gene therapy treatment that could be administered once and work for a long period of time would be a major leap forward.

Gene therapy studies for PD have been facilitated by the availability of animal models in rats and primates. Both restorative and protective strategies have been investigated. The restorative approach consists of focal and sustained delivery of L-dopa or dopamine into the striatum. This has been done by transfer of the genes encoding the L-dopa and/or dopamine synthetic enzymes. The tyrosine hydroxylase gene, coding the enzyme that transform tyrosine to L-dopa, has been introduced into the striatum of PD animal models (Horellou *et al.*, 1994), and the system optimized by regulating the level of enzyme synthesized (Corti *et al.*, 1999) and by combining different enzymes such as AADC (transforming L-dopa into dopamine) and GCH (synthesizing BH₄, the cofactor of TH) using various vectors (adenovirus, AAV, HSV and lentivirus) to obtain physiological levels of dopamine (for review see (Costantini *et al.*, 2000) and (Hsich *et al.*, 2002)). Delivery by AAV vectors of the genes coding for the three enzymes resulted

in functional recovery (reduced rotational behavior) lasting at least 12 months and elevated striatal dopamine production in the rat PD model (Shen *et al.*, 2000). Alternatively, transfer of AADC coupled with L-dopa administration could counteract the loss of AADC activity during the progression of the disease which results in increasingly high L-dopa requirements and associated side effects (Bankiewicz *et al.*, 2000). These approaches address the reduction of motor symptoms after the onset of the disease. However, a preferred solution would be to prevent the death of the dopaminergic neurones before the disease onset or to protect the remaining neurones immediately after diagnosis. This requires protective strategies.

The protective strategy offers a better prospect for the long-term treatment of the disease. Many genes have been envisaged to protect against neuronal death, including those coding for neurotrophic factors, anti-apoptotic factors or anti-oxidative enzymes. The genetic transfer of GDNF, a neurotrophic factor, has been the most studied and results in many animal models of PD are encouraging. GDNF promotes the survival and neurite outgrowth of embryonic dopaminergic (DA) neurones in vitro (Lin *et al.*, 1993). Intracerebral administration of GDNF into the substantia nigra (SN) via adenoviral gene transfer completely prevents nigral cell death and atrophy in a rat model of Parkinson's disease (Sauer *et al.*, 1995). GDNF acts on several levels. It can prevent neuronal death of dopaminergic neurones if expressed directly in the neurones of the SN. It can also prevent axonal degeneration when expressed in the projection area of the degenerating neurones (striatum), and induces sprouting, compensating for the deficit of dopaminergic neurones. Work in animal models of PD suggests that the intrastriatal delivery of the GDNF is the best strategy. The proof of principle of this strategy was obtained by intrastriatal injection of an adenoviral vector encoding the GDNF into a rat model of PD. When Ad-GDNF was injected into the same site 6 days before the 6-OHDA lesion, production of GDNF was observed at both the DA nerve terminal and nigral cell bodies following retrograde transport of the virus. Three weeks after the lesion, there were twice as many TH-immunoreactive cell bodies in the SN of the Ad-GDNF treated animals than in control animals. Furthermore, amphetamine-induced behavioral asymmetry (a behavioral marker for DA depletion) was markedly reduced in the Ad-GDNF treated rats (Bilang-Bleuel *et al.*, 1997). Recently, Kordower *et al.* injected lentiviral vector expressing GDNF (lenti-GDNF) into the striatum and substantia nigra of nonlesioned aged rhesus monkeys and young adult rhesus monkeys treated 1 week prior with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)

(Kordower *et al.*, 2000). Extensive GDNF expression with anterograde and retrograde transport was observed in all animals. In aged monkeys, lenti-GDNF augmented dopaminergic function. In MPTP-treated monkeys, lenti-GDNF reversed functional deficits and completely prevented nigrostriatal degeneration. Additionally, lenti-GDNF injections to intact rhesus monkeys resulted in long-term gene expression (8 months). In MPTP-treated monkeys, lenti-GDNF treatment reversed motor deficits in a hand-reach task.

As GDNF can be secreted and subsequently captured by the neuronal terminals of the dopaminergic neurones, it does not need to be expressed inside the neurones. Astrocytic expression was compared to neuronal expression in the striatum in a rat model of PD, by injection of Ad-GDNF under the control of either a glial (GFAP) or a neuronal promoter (NSE). The Ad-GFAP-GDNF was more effective than Ad-NSE-GDNF in inducing sprouting of the innervating dopaminergic terminations and behavioral recovery (A. Do Thi, personal data). Thus, the expression of the GDNF in striatal astrocytes is preferable to expression in neurones.

Both restorative and protective approaches might be viable therapeutic strategies for PD patients. The choice of the strategy will be governed by the onset of detection of the disease.

Mucopolysaccharidosis type VII (MPS-VII)

In mammals, recessive mutations in the autosomal β -glucuronidase gene and the consequent loss of protein activity induce a lysosomal distension due to the storage of undegraded products. This defect affects both systemic and central tissues, and is associated with growth and mental retardation, hepatosplenomegaly and skeletal deformity. MPS-VII has also been described in mice (Birkenmeier *et al.*, 1989), cats (Schultheiss *et al.*, 2000) and dogs (Haskins *et al.*, 1984), with common manifestations, thus providing various animal models for preclinical applications of gene transfer. Another interesting feature of the syndrome is that the β -glucuronidase is a secreted enzyme that can be captured by distant cells through the ubiquitous mannose-6-phosphate receptor (M6PR) (Kornfeld & Mellman, 1989). Moreover, partial activity of the enzyme (about 10%) is sufficient to reverse the lysosomal storage. This phenomenon has been used in various experimental works to provide the missing enzyme in animal models, including by gene transfer. However, there is a major hurdle to the success of pharmacological treatment: β -glucuronidase cannot cross the blood–brain barrier. Thus, two independent therapies could be used: one for peripheral tissues (by bone marrow

transplantation, enzyme replacement, gene transfer), and another for the CNS.

The blood–brain barrier is completed in mammals after birth, during the first weeks of postnatal development in humans. This postnatal window of opportunity has been used for gene transfer into the CNS by intravenous injection of newborn MPS-VII mice with an AAV encoding the β -glucuronidase. Distribution of the vector at therapeutic levels was widespread throughout the body, including in the brain, and there was phenotypic improvement (Daly *et al.*, 1999, 2001). If these results can be repeated in large animals (dog), it could be clinically relevant for humans. A single injection would treat both peripheral and central tissues. However, success would require lifetime expression of the transgene, and very early detection of the disease (preferably before birth). Gene transfer could be performed in utero to bypass the blood–brain barrier. Recent findings have proven the relevance of the murine model for embryonic onset of MPS-VII, and gene transfer in utero could be tested in this model (Casal & Wolfe, 2000). Although in utero gene transfer is feasible with several viral and non-viral vectors (Gallot *et al.*, 2002; Lai *et al.*, 2002; MacKenzie *et al.*, 2002; Saito & Nakatsuji, 2001; Shen *et al.*, 2002; Waddington *et al.*, 2003), it still needs optimization for high-level transduction in the brain. In addition, this strategy raises ethical concerns (Would germ-line cells be transduced? Is it dangerous for the mother?).

Once the BBB is formed, gene transfer could be performed by direct injection of a vector to transduce the CNS cells. It should not be necessary to transduce every cell because of the recapture of secreted β -glucuronidase by surrounding cells, but the transduction should ideally be widely spread throughout the CNS. Intraparenchymal injections have been performed using a variety of vectors and led to lysosomal clearance in the brain and the elimination of related neurological deficits, but the effect was relatively local because both the virus and the enzyme cannot diffuse sufficiently in the parenchyma (Bosch *et al.*, 2000a,b; Brooks *et al.*, 2002; Ghodsi *et al.*, 1998). To improve diffusion of the enzyme, mannitol can be injected after viral infection, as it induces wider diffusion of the enzyme. Injection of a vector into the CSF might then be more efficient in terms of distribution of the transduced cells. Combining intraventricular injection of adenoviral vector and mannitol treatment led to wide distribution of the enzyme in the brain (Ghodsi *et al.*, 1999). Similarly, intrathecal injection of AAV led to a global distribution of the enzyme in the CNS (Elliger *et al.*, 1999). However, such approaches may not be relevant in larger animals because of the much greater size of the brain and spinal cord.

Another approach would be to give a vector the ability to cross the blood-brain barrier. There are several ways to do this, as summarized by Partridge (Partridge, 2002a,b). Plasmid DNA encapsulated inside a nanocontainer composed of PEGylated immunoliposome (PILs) targeted across both the blood-brain barrier and the neuronal cell membrane by receptor-specific monoclonal antibodies can be delivered intravenously and transduce the whole CNS (Shi *et al.*, 2001a,b; Zhang *et al.*, 2002, 2003). Although this approach does not allow long-term expression because the formulated DNA is not stable, it might be applicable to the formulation of PILs containing a stable vector such as AAV, lentivirus or transposons. This approach may allow rapid progress towards global and stable gene transfer into the CNS.

Conclusions

The development of a successful gene therapy for any application is dependent on the many critical issues described above: choice of vector, choice of therapeutic gene, vector production process, immune reaction and safety concerns. Moreover, depending on the pathology, several other issues have to be addressed such as the duration of the expression, the targeting of the vector and the regulation of the transgene expression. The duration of the expression can be achieved by the use of stable viral vectors such as AAV or lentivirus-derived vectors and the optimization of the expression cassette by the inclusion of sequences that stabilize the expression such as MARs or SARs. In contrast, short-term expression might be wanted (for seizure or trauma for example) and can be achieved by the use of transient vectors derived from poliovirus or alphavirus or the use of synthetic vectors. Although we did not describe these vectors in the previous chapters, they are gaining importance in terms of development and potentiality of use. The duration of expression can be regulated by turning off or on the transgene expression using regulatable expression systems such as the tetracycline or the rapamycin systems. These systems also have the advantage of regulating the level of transgene expression by external factors to obtain physiological levels of the therapeutic product.

Great efforts from the scientific community involved in the field of gene therapy have led to the first successful human trial for the correction of the SCID (severe combined immunodeficiency) phenotype in two patients (Cavazzana-Calvo *et al.*, 2000). Since then, this result has been confirmed in four of five patients with the disease (Hacein-Bey-Abina *et al.*, 2003), but a severe adverse event tempered the initial excitement. Two patients developed

symptoms similar to acute lymphoblastic leukemia, resulting from insertional mutagenesis of the retroviral vector used in this therapy. Thus, although the proof of the principle of successful gene therapy for humans was established, it is essential for the researchers and clinicians to work with caution.

Very few clinical trials concerning in vivo gene therapy have been initiated for neurological affections, except for gliomas. A database of gene therapy clinical trials can be accessed on the web site of the *Journal of Gene Medicine* (<http://www.wiley.co.uk/genetherapy/clinical/>). Ongoing phase I clinical trials for neurological affections concern the treatment of Canavan disease using adenovirus-mediated transfer of the aspartoacylase gene and PD involving subthalamic AAV-mediated GAD (glutamic acid decarboxylase 65–67) gene transfer to patients who are candidates for deep brain stimulation. Another trial involves the intrathecal administration of AAV carrying the EEAT2 gene for the treatment of the amyotrophic lateral sclerosis (ALS). For the treatment of age-related macular degeneration, intravitreal delivery of an adenoviral vector coding the PEDF gene is being tested for inducing neovascularisation.

Gene therapy must be considered as the ultimate solution for treating diseases for which “classical” treatment is either not available or unsatisfactory. Efforts are still needed to obtain feasibility of gene therapy for many applications, and its scaling-up will require further developments.

Stem cells and cell-based therapy in neurodegenerative disease

Eva Chmielnicki¹ and Steven A. Goldman²

¹Department of Neurology and Neuroscience, Cornell University Medical College, USA

²Department of Neurology, University of Rochester Medical Center, NY, USA

Neurodegenerative diseases are characterized by the gradual loss of functional neuronal populations within the nervous system (Cummins *et al.*, 1998; Jenner & Olanow, 1998; Kowall *et al.*, 1987). While all other organs of the body typically replace lost cells by proliferation and differentiation of resident tissue-specified stem cell populations, the adult central nervous system does not appear capable of regenerating dying neurons to any clinically significant degree. Historically, this inability of the mammalian nervous system to regenerate had led to the conclusion that the adult CNS did not contain competent neuronal progenitor or stem cells. However, a number of studies over the past two decades have refuted this dogma, by identifying significant and heterogeneous populations of both neural stem and progenitor cells in the adult brain (Altman & Das, 1966; Bayer *et al.*, 1982; Goldman & Nottebohm, 1983; Goldman *et al.*, 1992; Kirschenbaum *et al.*, 1994; Lois & Alvarez-Buylla, 1993; Luskin, 1993; Reynolds & Weiss, 1992; Richards *et al.*, 1992). These discoveries have led to the suggestion that induced compensatory neurogenesis by endogenous progenitor cells should be experimentally and therapeutically feasible, regardless of whether compensatory neurogenesis proves to be a natural occurrence of any clinical significance (Gage, 2000; Goldman *et al.*, 2002; Goldman & Luskin, 1998; Weiss *et al.*, 1996b). A number of recent studies have supported this concept, in that neurogenesis from resident progenitors has now been induced in the rodent forebrain in response to exogenous factor administration (Aberg *et al.*, 2000; Benraiss *et al.*, 2001; Chmielnicki & Goldman, 2002; Kuhn *et al.*, 1997; Pencea *et al.*, 2001), injury (Arvidsson *et al.*, 2002; Magavi *et al.*, 2000), or both (Fallon *et al.*, 2000; Nakatomi *et al.*, 2002).

This chapter will discuss the potential utility of both resident and introduced neural progenitor cells in the treatment of neurodegenerative disease. After presenting a synopsis of our current understanding of neural progenitor

cell phenotypes in mammals, and of the persistence and distribution of each in adults, we will focus on transplant-based strategies for neural repair. We will then consider current strategies for inducing neuronal replacement from endogenous stem cells, and disease settings within which induced neuronal replacement might be therapeutically efficacious.

Neural stem cells of the mammalian forebrain

Tissue-specified stem cells are multipotential cells capable of giving rise to the resident phenotypes of a given organ, which retain the capacity for long-term self-renewal. Neural stem cells, the resident multipotential progenitors of the central nervous system, have been isolated from various regions of the fetal and adult mammalian nervous system (Gritti *et al.*, 1996; Kilpatrick & Bartlett, 1993; Palmer *et al.*, 1997; Reynolds & Weiss, 1992; Temple & Davis, 1994; Weiss *et al.*, 1996a). Neural stem cells can give rise to neural progenitor cells, which possess a more limited capacity for self-renewal, and may have a more restricted differentiation potential (Kilpatrick & Bartlett, 1995). These neural progenitors may include multipotential progenitors incapable of sustained self-renewal (Nunes *et al.*, 2003b), or committed neuronal (Luskin, 1998; Roy *et al.*, 2000a,b; Wang *et al.*, 2000) or glial progenitors (Rao & Mayer-Proschel, 1997).

To determine the lineage potential of putative stem and progenitor cells, single cells can be infected with a genetic tag, typically by means of a genomically integrating retroviral or lentiviral infection, and their progeny monitored for the expression of markers characteristic of oligodendrocytes, astrocytes, or neurons. In vitro, self-renewal capacity may be then monitored by clonal analysis, in which primary neurospheres derived from a single stem/progenitor cell are then re-dissociated to determine whether

sphere-generating cells can be formed again from clonogenic founders (Morshead *et al.*, 1998; Reynolds & Weiss, 1996). By such clonal lineage analysis, resident multipotential neural progenitor cells have now been identified and isolated from both the fetal (Keyoung *et al.*, 2001; Uchida *et al.*, 2000) and adult human forebrain (Arsenijevic *et al.*, 2001; Nunes *et al.*, 2003b). In each, a mixture of uncommitted stem cells and phenotypically restricted progenitors appears to reside within the wall, in the ventricular/subventricular zone of fetal development, or in its adult derivative, the subependymal zone.

Neuronal progenitor cells of the adult brain

Three major populations of neural progenitor cells persist into adulthood: the subgranular zone in the dentate gyrus of the hippocampus, the subventricular zone (SVZ) of the lateral ventricle (Alvarez-Buylla *et al.*, 2000; Alvarez-Buylla & Lois, 1995; Goldman & Luskin, 1998; Palmer *et al.*, 1997), and the nominally glial progenitor pool of the brain parenchyma. Although the latter have traditionally been considered glial progenitors, these cells have recently been shown to be neurogenic as well. This population thus at least includes a pool of multipotential progenitors, and as such may serve as an additional source of neuronal progenitor cells in the adult brain. Among these diverse reservoirs of potentially neurogenic progenitors, only two pools appear to generate neuronally committed progenitors and their neuronal daughters *in vivo* in the adult. First, the subependymal zone of the anterior surface of the lateral ventricle (SVZa; Luskin, 1993) generates neurons that migrate in closely associated chains via the rostral migratory stream to the olfactory bulb, where they differentiate into GABAergic interneurons (Goldman & Luskin, 1998). Second, the progenitor pool of the hippocampal dentate gyrus, localized to the subgranular zone (SGZ) of the hippocampus, is similarly neurogenic, with neurons arising from what appear to be phenotypically restricted neuronal progenitors (Roy *et al.*, 2000a,b; Seaberg & van der Kooy, 2002). In both the forebrain SVZa and the hippocampal SGZ, however, residual multipotential stem cells can be demonstrated *in vitro* (Seri *et al.*, 2002), and likely give rise to the neuronally restricted progenitor pools of these loci. Thus, while potentially neurogenic progenitor cells are distributed throughout the rostral two-thirds of the SVZ, the regions of actual neuronal recruitment are very few and are segregated from one another (Kirschenbaum & Goldman, 1995). The establishment of neurogenesis *in vivo* in these few discrete niches, despite the prevalence and widespread distribution of potentially neurogenic progenitor cells, suggests the establishment and maintenance of discrete

niches for neurogenesis (Lim *et al.*, 2000; Louissaint *et al.*, 2002; Palmer *et al.*, 2000), similar to those that have been described for hematopoiesis in the bone marrow (Lim *et al.*, 2000).

Stem cell-based transplant strategies in the neurodegenerative diseases

Derivation and expansion of implantable human neural stem cells

Neurogenesis persists through mid-gestational ontogeny in humans. The fetal human brain thus represents a plentiful source of both neural stem cells and more lineage-restricted neuronal and glial progenitor cells (Keyoung *et al.*, 2001). As a result, the implantation of both gross tissue dissociates and specifically extracted neural progenitors has become an important strategy for the experimental therapy of a variety of CNS disease models (Bjorklund & Lindvall, 2000). In addition, propagated neural stem cells have been derived from both fetal and adult human brain tissue (Arsenijevic *et al.*, 2001; Caldwell *et al.*, 2001; Keyoung *et al.*, 2001; Nunes *et al.*, 2003b; Pincus *et al.*, 1996; Roy *et al.*, 2000b; Svendsen *et al.*, 1999; Vescovi *et al.*, 1999). Each constitute a potential source of transplantable cells, since the persistent propagation and expansion of these cells mitigates the ongoing need for new tissue acquisition. If cultured in the presence of appropriate growth factor mitogens, such as fibroblast growth factor-2 (FGF-2) or epidermal growth factor (EGF), neural stem cells can be induced to divide (Gritti *et al.*, 1996; Kilpatrick & Bartlett, 1995). Importantly, propagated neural stem cells may be biased strongly towards neuronal differentiation and survival, most notably by the neurotrophins NT3 (Collazo *et al.*, 1992; Ghosh & Greenberg, 1995) and brain-derived neurotrophic factor (BDNF) (Ahmed *et al.*, 1995; Goldman *et al.*, 1997; Kirschenbaum & Goldman, 1995; Shetty & Turner, 1998). As a result, propagated neural stem cells may represent a renewable source from which to derive implantable neural cell populations.

Huntington's disease as a prototypic target for neural stem cell-based therapy

Among the degenerative disease targets of greatest interest for transplantation-based therapy has been Huntington's disease. Pathologically, this uniformly fatal condition is characterized by a progressive motor deficit resulting from the degeneration of neostriatal medium spiny neurons, and by severe cognitive and behavioral deficits

accompanied by both cortical and subcortical neuronal loss (Kowall *et al.*, 1987). The motor deficits of Huntington's disease have been considered a feasible target for transplantation-based repair, because the region of relevant neuronal degeneration is initially delimited, both geographically and phenotypically, to the medium spiny neurons of the caudateputamen (Mitchell *et al.*, 1999). Huntington's disease is characterized by the expansion of CAG repeats in the Huntington's disease gene, resulting in long polyglutamine stretches that are toxic to their host neurons (Gusella *et al.*, 1983). Implanted wild-type cells may escape this CAG repeat-associated toxicity, since it appears to be cell-autonomous (Bjorklund & Lindvall, 2000), although deleterious effects of Huntington's disease cortical neurons on their striatal targets – including implanted wild-type neurons – may result from deficient neurotrophic support from the Huntington's disease cortical efferents (Canals *et al.*, 2001). Notwithstanding the latter caveat, several groups have attempted stem and progenitor cell transplantation as a strategy for treating Huntington's disease.

Initial attempts at stem and progenitor cell transplantation were in excitotoxic models of Huntington's disease, in which neuronal destruction was induced by intrastriatal injections of ibotenic acid (IA) (Isacson *et al.*, 1984). IA-lesioned rats exhibit motor abnormalities similar to those seen in Huntington's disease, and as such, represent a model whereby the effect of transplantation therapy on the motor deficit can be tested. On that basis, neural stem and progenitor cells derived and cultured from the embryonic rat striatum were grafted into IA-lesioned rats. The neurons that developed from these grafts were found to receive appropriate dopaminergic afferent connections from the host substantia nigra, and to make appropriate efferent connections to the globus pallidus and substantia nigra pars reticulata (Campbell *et al.*, 1993; Pritzel *et al.*, 1986). In addition, a significant attenuation of motor abnormalities was seen in IA-lesioned animals that received these striatal progenitor implants (Isacson *et al.*, 1984).

On the basis of these initial studies in rats, fetal striatal progenitor cells were then implanted into IA-lesioned primates. The implanted recipients were reported to exhibit a significant decrease in the incidence of abnormal motor behaviors, including dyskinesia, chorea and dystonia (Hantraye *et al.*, 1992). When fetal human striatal progenitor cells were also noted to ameliorate symptoms in IA-lesioned rats (Pundt *et al.*, 1996), human clinical trials were then initiated to assess the potential utility of progenitor transplantation in the treatment of Huntington's disease. In the first such study reported, an open-label unblinded and uncontrolled trial, human fetal neuronal

progenitor cells derived from the ganglionic eminence were implanted bilaterally into the striata of five Huntington's disease patients. Two years after the initial grafting, motor and cognitive improvement was seen in three of the five (Bachoud-Levi *et al.*, 2000). Striatal glucose metabolism in these three patients remained steady or increased, as assessed by ^{18}F -fluorodeoxyglucose PET. Moreover, PET and MRI showed small regions of elevated metabolic activity, which suggested the presence of “metabolically active neural grafts” (Bachoud-Levi *et al.*, 2000). The improvement of these three patients compared with the progressive decline of a matched cohort of non-grafted control Huntington's disease patients, as well as with the two grafted patients who did not show any clinical benefit (Bachoud-Levi *et al.*, 2000). However, the unblinded nature and small size of this initial trial demands cautious interpretation. Tellingly, in a subsequent study in which seven patients received bilateral human fetal progenitor implants, three subjects experienced subdural hemorrhages, and no amelioration of Huntington's disease symptoms was observed (Hauser *et al.*, 2002).

Many variables may account for the overall lack of efficacy thus far observed in transplanted Huntington's disease in these patients. First, the donor cell populations used thus far have been notably heterogeneous. Human striatal primordia contain progenitor cells for a variety of neuronal cell types, including medium spiny projection neurons as well as striatal interneurons. As such, it has been unclear how many medium spiny cells at what developmental stages, and with what neuronal and glial accompaniments, have been implanted in the transplant trials thus far conducted. Furthermore, the adult human striatum may lack developmentally restricted signals necessary for the appropriate differentiation and functional integration of the implanted fetal progenitor cells. As such, the progenitor cells may have to be primed first *in vitro* before implantation.

These are approachable issues, which would bear further evaluation before future trials of experimental transplantation. For instance, transplant homogeneity, or at least high-grade enrichment, may now be achieved through several means of phenotypic selection. Techniques such as promoter-based antibiotic selection (Li *et al.*, 1998), or fluorescence-activated cell sorting (Keyoung *et al.*, 2001; Roy *et al.*, 2000b; Wang *et al.*, 2000), are readily adapted to the preimplantation enrichment of defined progenitor pools, such as those for medium spiny cells. That beingsaid, it is not yet clear if purified cell populations are actually optimal as transplant vehicles, or whether instead mixed populations intentionally spiked with glial and endothelial elements might prove superior graft populations. To date, surprisingly few studies have systematically assessed

the role of such variables in determining neural transplant efficacy.

For now then, the ability of implanted progenitors to restore normal structure and function to a region of brain disease or injury remains to be demonstrated in humans. Thus, although stem and progenitor cell transplantation may yet prove a useful modality for the treatment of Huntington's disease and PD, the need for developing alternative strategies for striatal restoration, such as inducing neurogenesis from endogenous progenitors (see below), has become clear.

Progenitor cell-mediated restoration of striatal dopamine: Parkinson's as a disease target

Fetal cell and tissue grafts have also been studied extensively in Parkinson's disease (Bjorklund & Lindvall, 2000). Several distinct strategies of introducing fetal mesencephalic grafts to the diseased striatum have been attempted, and each has thus far yielded disappointing results, characterized in broad terms by both unimpressive efficacy and overt iatrogenic morbidity. This is particularly disappointing since Parkinson's disease is a better-understood and anatomically more discrete degeneration than Huntington's. Parkinson's is characterized by the progressive deterioration of dopaminergic neurons in the substantia nigra (Jenner & Olanow, 1998). As these mid-brain dopaminergic neurons project to the striatum, there is a significant decrease in striatal dopamine levels over time. Therapeutic transplantation has thus far focused on implantation of fetal ventral midbrain progenitor cells heterotopically into the neostriatum (Lindvall, 1999; Olanow *et al.*, 1996). These donor dopaminergic neurons are able to ameliorate Parkinsonian symptoms only when a sufficient number of them survive, avoid immune rejection and make appropriate postsynaptic connections with striatal neurons (Bjorklund & Lindvall, 2000). Despite promising studies in experimental models, fetal mesencephalic tissue and cell grafts to adult Parkinson's patients have yielded poor results thus far, characterized by limited efficacy and significant morbidity, the latter manifested as refractory, medication-independent dyskinesias (Hagell *et al.*, 2002). To date, the cause of these morbid side effects of dopaminergic engraftment is unclear, as is the overall lack of therapeutic efficacy of fetal mesencephalic transplantation, which has yielded limited benefit despite FDG-PET and histological data suggesting significant striatal dopaminergic engraftment (Hauser *et al.*, 1999; Kordower *et al.*, 1995, 1998).

The potential causes of this disappointment are legion; they include donor cell heterogeneity, inhomogeneities in the tissue distributions of the successfully implanted cells,

a lack of appropriate afferent control, of the engrafted nigral cells, and disturbed presynaptic receptive thresholds on the part of the implanted dopaminergic cells, among others. At the very least though, the heterotopic nature of these grafts, which are delivered to the striatum rather than to their native substantia nigra, suggests that the implanted cells may fail to acquire appropriate afferent control. This, in turn, suggests that strategies based upon implanting dopaminergic neurons into diseased striatal targets, whether tissue or stem-cell derived, may be doomed to failure. Rather, in order to achieve physiologically appropriate dopaminergic function by engrafted cells, donor cells may need to be implanted into recipient substantia nigra. As a result, long-distance nigrostriatal axogenesis and reformation of the nigrostriatal tract may well be needed to assure proper regulation of the implanted dopaminergic cells. That being said, no technology currently permits the long-distance extension of tracts within the adult brain, at least not over the many cm distances that separate the ventral mesencephalon and the caudate-putamen. Until this capability is achieved, one must be circumspect about the potential for tissue or stem cell-derived dopaminergic neurons for safely mediating functional restoration in human Parkinson's disease.

Embryonic stem cells as a replenishable source of dopaminergic neurons

The failure of fetal nigral grafts to ameliorate Parkinson's disease symptoms or progression has, if anything, spurred research into generating more homogeneous and accessible populations of human dopaminergic neurons. Weaknesses of tissue-derived progenitor grafts included not only the heterogeneity of the implants, which included not only non-dopaminergic as well as dopaminergic neurons, but also both glial and vascular cells, all in relative proportions that varied from one donor to the next. Most troubling perhaps was the relatively low proportion of dopaminergic neurons in the mixture, which may have varied significantly as a function of the gestational age and dissection accuracy of each sample. These factors conspired to limit the extent to which one donor sample could be compared to the next, and made comparisons between recipient patients—whose variability was already high by virtue of their unique disease histories—difficult.

To address this issue of the non-uniformity of donor cell populations, and their minor representation of dopaminergic derivatives, a number of groups explored the possibility of generating highly enriched populations of dopaminergic neurons from mesencephalic progenitors (Sawamoto *et al.*, 2001; Studer *et al.*, 1998). These studies

demonstrated that tissue-derived mesencephalic progenitors were capable of giving rise to functional dopaminergic neurons, in sufficient numbers and uniformity so as to permit the functional recovery of rats rendered Parkinsonian by 6-hydroxydopamine (6-OHDA) injection (Sawamoto *et al.*, 2001; Studer *et al.*, 1998). Yet enriching engraftable quantities of primary dopaminergic progenitors from human fetal tissue has proven difficult, because of both the small numbers of mesencephalic neural stem cells that may be purified as such from first trimester human abortuses, and the impracticability of high-volume sampling of human abortuses for this purpose.

To address these concerns, a number of groups have begun to assess the feasibility of using human embryonic stem cells as a potential source of dopaminergic progenitor cells. This possibility was opened by an elegant series of developmental studies, in which FGF8 and sonic hedgehog (SHH) were implicated as tandem initiators of dopaminergic neurogenesis during early midbrain development (Ye *et al.*, 1998). On this basis, McKay and colleagues first attempted to generate dopaminergic neurons from embryonic stem cells, by recapitulating the environment of the developing midbrain *in vitro* (Lee *et al.*, 2000). To this end, they added FGF8, SHH and ascorbate to cultures of embryonic stem cells. By this means, cultures were generated in which over 30% of the total neuronal population expressed tyrosine hydroxylase, a marker of catecholaminergic neurons (Lee *et al.*, 2000). In subsequent studies, these authors achieved even greater degrees of dopaminergic enrichment in ES culture by also mimicking the oxygen tension and redox state of the developing midbrain (Studer *et al.*, 2000). When implanted into 6OHDA-lesioned rats, in which nigrostriatal dopaminergic afferents are largely lost, these ES cells restored functional normalcy to the dopamine-depleted animals (Kim *et al.*, 2002). This result suggested that the dopaminergic neuronal cohort within the engrafted ES cell pool were at least sufficient to ameliorate the effects of catecholaminergic deafferentation on the adult rodent striatum. However, whether and to what degree the induction of dopaminergic phenotype is needed prior to implantation remains controversial, since naïve ES cells injected into the lesioned striatum may also become dopaminergic, and in sufficient numbers as to ameliorate amphetamine-induced rotational behavior after 6-OHDA lesion (Bjorklund *et al.*, 2002).

The use of ES cell-derived and FGF8/SHH-induced dopaminergic neurons, although both elegant and operationally significant, remains limited by some of the same caveats discussed in regards to tissue-derived progenitor implantation. First, the ES-derived dopaminergic cell populations achieved are by no means purified, and at the very least may be contaminated with serotonergic and

GABAergic neurons, as well as by glia. Second, the cells must still be injected into the recipient striatum, given their apparent inability to extend processes through normal adult brain parenchyma. Other considerations unique to the use of ES cells may also limit the utility of directed dopaminergic differentiation. Induction of ventral mid-brain phenotypes by FGF8/SHH is associated not only with dopaminergic neurogenesis, but also with the generation of GABAergic and serotonergic neurons (Goridis & Rohrer, 2002). The co-introduction of these other transmitter phenotypes, without further dopaminergic selection, might yield as yet unpredictable interactions among the engrafted cells, both synaptic and presynaptic. These interactions might serve at the very least to minimize the efficacy of the engrafted dopaminergic neurons. In addition, undifferentiated ES cells that have escaped the differentiating steps of embryoid body formation and FGF8/SHH induction may produce teratomas upon implantation, with such high frequency that their complete abolition from donor cell grafts would appear a reasonable prerequisite to the use of ES-derived dopaminergic neurons. The advent of promoter-based selection strategies, based on both GFP-based sorting and antibiotic selection (Wang *et al.*, 1998), has made high-grade purification of prospectively identified target phenotypes possible. Nonetheless, whether either of these approaches is sufficient to achieve the complete abolition of undesired phenotypes – such as undifferentiated ES cells – remains to be seen.

Stem and progenitor cell-mediated treatment of Alzheimer's and the cholinergic depletions

In Alzheimer's disease, degeneration of neurons in the basal forebrain cholinergic system, as well as in the cortex and hippocampus, results in a progressive dementia characterized by memory loss and dysphasia, often accompanied by personality changes and spatial disorientation (Cummings *et al.*, 1998). Since cholinergic neurons in the basal forebrain innervate the cortex and hippocampus, acetylcholine levels in these regions fall in Alzheimer's patients, and are inversely correlated with their degree of dementia (Wilcock *et al.*, 1982). As a result, central acetylcholinesterase inhibition has become the principal treatment for human Alzheimer's disease; the efficacy of this approach is limited, however, emphasizing the need for additional therapeutic strategies.

In animals, heterotopic transplantation of fetal forebrain cholinergic neurons into the neocortex results in significant behavioral improvements in animals subjected to lesions of the basal forebrain cholinergic projection, a traditional model of Alzheimer's disease (Dunnett, 1990; Fine *et al.*, 1985; Welner *et al.*, 1988). Despite these early promising

studies, little effort has been made since to attempt the structural reconstitution of the basal forebrain cholinergic projection, even though subsequent studies served only to emphasize the importance of the cholinergic innervation of the neocortex to memory consolidation and recall (Winkler *et al.*, 1995). However, any past experimental therapeutic strategy based upon cholinergic progenitor implantation would have been limited by the unavailability of appropriately enriched populations of human cholinergic neuronal progenitors. Yet recent studies have begun to define the developmental environment in which cholinergic neurons are generated, with the intent of being able to selectively generate them from both embryonic and neural stem cells (Blackshaw & Cepko, 2002; Wu *et al.*, 2002).

Indeed, spinal motor neurons, another ventral cholinergic neuronal population, can already be specifically induced from undifferentiated ES cells, under the tandem influences of retinoic acid and sonic hedgehog activation (Wichterle *et al.*, 2002). These neurons, of critical importance in any cell-based strategy for treating amyotrophic lateral sclerosis and the primary motor neuron diseases, may share ontogenetic determinants with their more rostrally-situated forebrain counterparts. One might expect that as we better understand the patterning factors regulating cholinergic neurogenesis in the telencephalon, then basal forebrain cholinergic neurons may prove as amenable to *in vitro* production as their spinal counterparts. In addition, our evolving understanding of transcripts specifically expressed by developing cholinergic progenitors – forebrain as well as spinal – should permit their promoter-based isolation, from fetal tissue as well as from ES cell culture. The acquisition of cholinergic progenitor cells by either of these means – induction, selection, or both – may open up entirely new avenues in the treatment of diseases of the cholinergic neuron. Diseases as distinct yet related as the cortical dementias and ALS may prove approachable via cell-based therapy, as position-defined human cholinergic neuronal progenitors become available in both purity and quantity.

Neurogenesis from endogenous progenitor cells in the adult brain

Compensatory neurogenesis as a predictor of inducible neuronal replacement

As a result of the regionally heterogeneous nature of stem and progenitor cells within both the forebrain subependyma and hippocampal subgranular zone (Seaberg & van der Kooy, 2002), compensatory

neurogenesis in response to injury or disease may be limited by the regionally-specified inhibition of migration, differentiation, or survival of SVZ progenitor cells and their neuronal progeny. That being said, examples now abound of such compensatory neurogenesis from resident progenitor cells in higher vertebrates. In birds, lesion of the adult song nucleus HVC, a highly neurogenic region of the songbird brain (Goldman, 1998; Goldman & Nottebohm, 1983), leads to compensatory neurogenesis with regeneration of lost HVC projection neurons to its efferent target, nucleus RA (Scharff *et al.*, 2000). In mice, similar phototoxic lesion of cortical callosal projection neurons leads to the recruitment of new cortical neurons, though in small numbers (Magavi *et al.*, 2000). Similarly, striatal neurogenesis has been demonstrated in response to middle cerebral artery occlusion, even though neither experimental nor clinical stroke appear to be associated with clinically significant neuronal replacement (Arvidsson *et al.*, 2002; Nakatomi *et al.*, 2002). Indeed, none of these mammalian instances of attempted compensatory neurogenesis appears to be of sufficient quantitative magnitude to afford clinical benefit. Yet infusion of neurotrophic mitogens during the degenerative process may potentiate the replenishment of the dying neurons, sufficiently so to yield significant structural and behavioral recovery. Nakatomi *et al.* (2002) reported in this regard that concurrent administration of FGF2 and EGF permitted the recruitment of new hippocampal pyramidal neurons after ischemia, in numbers sufficient to mediate both structural and behavioral recovery. Fallon and colleagues similarly demonstrated that concurrent administration of TGF α , a membrane-linked congener of EGF, was associated with compensatory striatal neurogenesis in response to 6-OHDA-induced nigrostriatal deafferentation (Fallon *et al.*, 2000). In this study, animals infused with TGF α after 6-OHDA lesion exhibited not only the local proliferation of SVZ cells, but also the directed migration of SVZ progeny to the TGF α infusion site. These cells expressed neuronal β III-tubulin, and some co-expressed the dopamine transporter protein and tyrosine hydroxylase, markers of dopaminergic cells. Most remarkably, the TGF α -treated 6-OHDA-lesioned animals exhibited functional improvement in apomorphine-induced rotational behavior, that was significantly improved relative to that exhibited by their untreated controls. Thus, growth factor application in this disease environment resulted in the expansion and local recruitment of new neurons from SVZ progenitor cells (Fallon *et al.*, 2000). Together, these studies suggest that neuronal degeneration may be associated with the release of signals competent to induce otherwise latent local progenitor cells to generate new neurons able to

replace their dying kindreds. They also show that the environment in which a progenitor resides might be dramatically changed in injury or disease, and that this alone may substantially alter the response of resident progenitor cells to both endogenous and introduced neurotrophic growth factors.

To capitalize upon the neurogenic capability of endogenous progenitor cells, several strategies have been proposed. First, redirection of SVZ progenitor-derived neurons from the olfactory stream to the septum and striatum have been employed to achieve neuronal recruitment to otherwise non-neurogenic regions of the adult forebrain (Nait-Oumesmar *et al.*, 1999; Parent *et al.*, 2002). Second, since the local recruitment and survival of newly generated neurons may be limited by the availability of postmitotic neurotrophic factors, the provision of these agents might achieve heterotopic neuronal addition in response to injury or disease (Benraiss *et al.*, 2001; Pencea *et al.*, 2001). Third, since most SVZ progenitor cells appear to give rise to glial cells, an inhibition of glial differentiation provided in tandem with neuronal instructive signals might provide another means by which to potentiate neuronal recruitment (Chmielnicki & Goldman, 2002; Lim *et al.*, 2000; Shah *et al.*, 1996). Indeed, recent evidence suggests that targeted ventricular administration of growth factors known to induce neuronal differentiation and survival from SVZ progenitors, as well as the redirected migration of their neuronal progeny, may be viable strategies for inducing neuronal replacement in the adult mammalian brain (Benraiss *et al.*, 2001; Pencea *et al.*, 2001).

Forebrain progenitor cells can be induced to expand and generate neurons in vivo

Neuroepithelial stem cells have been found to proliferate in response to EGF, FGF, or TGF α in vitro (Anchan *et al.*, 1991; Gensburger *et al.*, 1987; Reynolds *et al.*, 1992). On the basis of these studies, several groups have assessed the effects of these growth factors on mobilizing progenitor cell populations in the adult rodent SVZ (Craig *et al.*, 1996; Kuhn *et al.*, 1997). Intraventricular infusions of both EGF and FGF have each been found to increase SVZ cell proliferation. However, whereas EGF infusion has been associated only with astrocytic expansion, FGF does appear to increase neuronal addition to the olfactory bulb, a normally neurogenic region (Craig *et al.*, 1996; Kuhn *et al.*, 1997). Nonetheless, FGF administration has failed to induce the recruitment of neurons to any other regions of the adult forebrain. Thus, neither EGF nor FGF, at least when used in isolation, have yet proven useful in

inducing heterotopic neuronal addition to the uninjured brain.

In contrast, the neurotrophin BDNF has been found by several groups to induce heterotopic neuronal addition to the normal adult brain. In broad terms, members of the neurotrophin family, which includes NGF, BDNF, NT3, and NT4/5, are capable of enhancing progenitor-derived neuronal differentiation and/or survival throughout development, and over the entire geographic extent of the nervous system (Hyman *et al.*, 1991; Lindsay *et al.*, 1985; Tuszynski, 2000). On this basis, the specific role of neurotrophin family members on SVZ progenitor-derived neurogenesis and recruitment was assessed in explants of the adult rat SVZ. In this model, BDNF, but not NGF or NT3, promoted both the maturation and survival of SVZ-derived neurons in a dose-dependent fashion, for as long as 2 months in vitro (Kirschenbaum & Goldman, 1995). Accordingly, full-length trkB, the high affinity BDNF receptor, was heavily expressed by the SVZ progenitor-derived neurons. Since virtually none of these neurons incorporated [3 H]thymidine in vitro, BDNF appeared to exert its effects on the postmitotic neuronal progeny of SVZ cells, rather than upon the dividing progenitors themselves (Kirschenbaum & Goldman, 1995).

As further studies corroborated the role of BDNF as a differentiation and/or survival factor for neurons newly generated from the adult subependyma (Ahmed *et al.*, 1995; Shetty & Turner, 1998), an important question in the field became whether BDNF administration might mediate neuronal commitment and recruitment from SVZ progenitors in vivo. To address this issue, Zigova *et al.* (1998) postulated that intraventricular administration of BDNF protein would be sufficient to induce neuronal recruitment in vivo. They first established that full-length trkB is expressed in the SVZ and rostral migratory stream, suggesting that SVZ progenitors and their progeny would be BDNF responsive in vivo as in vitro. Zigova *et al.* (1998) then showed that intraventricular infusion of BDNF resulted in a doubling in the rate of addition of BrdU $^+$ / β III-tubulin $^+$ neurons to the olfactory bulb. These data demonstrated that the infusion of BDNF, a prototypic neurotrophic growth factor, could be used to augment neuronal addition to neurogenic regions of the adult CNS.

Intraventricular viral expression vectors can target subependymal progenitor cells

BDNF's potentiation of adult neuronal recruitment suggested the potential utility of maintaining BDNF administration over prolonged periods of time in vivo. Yet chronic infusion of proteins necessitates transcranial implantation of intraventricular mini-pumps, whose useful life is

delimited by the quantity of protein that may be stored therein, the stability of that protein at body temperatures, and the inefficient bioavailability of protein delivered to the ventricular lumen. In addition, chronic infusion via minipump is a more practicable experimental than clinical strategy for drug delivery, since chronic intraventricular protein administration to adult patients may be complicated by both infection and catheter occlusion, both of which typically limit the effective life of ventricular catheters. Parenchymal protein delivery is not a viable option for targeting subependymal progenitor cells with neurotrophins. Subependymal cells and subventricular glia express high amounts of truncated *trkB*, which limit the access of parenchymally-delivered BDNF access to the subventricular zone progenitor population (Biffo *et al.*, 1995; Yan *et al.*, 1994). Thus, too much brain tissue would be nonspecifically and unnecessarily accessed by the delivered drug, while the periventricular target region would be insufficiently accessed.

To devise a better means of protein delivery to the restricted region of the subependymal cell population, we chose to infect the ependymal wall with a replication-defective adenovirus engineered to overexpress the gene encoding BDNF (AdBDNF) (Bajocchi *et al.*, 1993; Yoon *et al.*, 1996). By this means, the ventricular wall was subrogated to serve as a secretory source of high levels of BDNF for the subependymal progenitor population – thereby utilizing the transduced ependymal layer as a drug delivery vehicle, yet without having to transduce the progenitors themselves. As a proof-of-principle, AdBDNF, containing hGFP as a reporter gene, was injected into the lateral ventricles of adult rats. *In situ* hybridization of sagittal brain sections three weeks after the adenoviral injections showed that BDNF mRNAs were restricted to the ventricular wall (Benraiss *et al.*, 2001). The selective targeting of viral transgene expression to the ventricular wall was thus accomplished by the spatial restriction of adenoviral infection, which was limited to the ependymal cells. ELISA then confirmed that while BDNF was undetectable in the CSF of control rats, the AdBDNF-injected animals averaged >2 ng BDNF/ml (Benraiss *et al.*, 2001), a level sufficient to elicit neurotrophic effects *in vitro* (Kirschenbaum & Goldman, 1995; Lindsay *et al.*, 1994). CSF BDNF levels remained elevated relative to controls for up to 2 months after injection, with a steady decline in the second month. Thus, a single intraventricular injection of an adenoviral vector proved able to target viral transgene expression to the ventricular wall, effectively recruiting the ventricular ependyma to serve as a source of a secreted protein intended to activate subependymal progenitor cells (Benraiss *et al.*, 2001).

This strategy may be extended to include serial infections by different viruses, encoding transgenes that sequentially influence SVZ progenitor division, differentiation, neurotransmitter phenotype, migration, and neurite extension. By so doing, we may hope to direct neuronal recruitment and fiber projection to pre-specified targets in the injured or diseased brain.

BDNF overexpression induces heterotopic neuronal recruitment to the adult neostriatum

On this basis, Benraiss *et al.* (2001) then asked if the periventricular overexpression of BDNF might be associated with neuronal recruitment to otherwise non-neurogenic regions of the adult brain, such as the striatum and cortex. They assessed whether adenovirally delivered BDNF stimulated the production of new neurons in nominally non-neurogenic brain regions, by tagging mitotic SVZ progenitor cells with bromodeoxyuridine (BrdU), a thymidine analogue, and then following these BrdU-tagged SVZ cells after either AdBDNF or control AdNull injection. In particular, all BrdU-tagged cortical, septal and striatal cells were individually assessed for their expression of neuron-specific markers. Whereas no BrdU⁺/βIII-tubulin⁺ cells were found in the septum or cortex of AdBDNF-injected animals, the neostriata of these animals harbored >140 newly generated neurons/mm³. This contrasted to the absence of any such neuronal addition to the striata of animals that had received PBS as a control (Benraiss *et al.*, 2001).

Thus, adenoviral overexpression of BDNF led to the induction of neuronal addition to the adult neostriatum. BDNF's effect in this regard appeared to derive from its signaling of neuronal differentiation and survival (Ahmed *et al.*, 1995; Kirschenbaum & Goldman, 1995), as well as its direct promotion of migration into the subjacent parenchyma (Behar *et al.*, 1997; Borghesani *et al.*, 2002). Of note, Luskin and colleagues similarly demonstrated that chronic intraventricular infusions of BDNF protein yielded striatal neurogenesis (Pencea *et al.*, 2001). Using much larger effective doses of BDNF than those used by Benraiss *et al.* (100 μg/ml CSF, in contrast to the 2 ng/ml achieved in the CSF of rats given AdBDNF), Pencea *et al.* noted other sites of heterotopic subcortical neurogenesis. These included the otherwise non-neurogenic septum and thalamus, as well as the hypothalamus. The latter observation, if otherwise confirmed, opens the possibility that broader subcortical neurogenesis may be achieved through the parenchymal delivery or overexpression of BDNF.

Induced neurogenesis may be a therapeutic strategy in animal models of Huntington's disease

The BDNF-induced addition of new neurons to the adult neostriatum may prove of specific therapeutic interest in regards to Huntington's disease. Huntington's disease is characterized by the gradual loss of striatal medium spiny neurons (Mitchell *et al.*, 1999). BDNF overexpression has already been found to decrease striatal neuronal loss in animal models of Huntington's disease (Martinez-Serrano and Bjorklund, 1996; Perez-Navarro *et al.*, 2000), an effect that has been attributed to the improved survival of BDNF-exposed striatal neurons. Yet since BDNF overexpression can also induce the addition of new neurons to the adult neostriatum, we postulated that it might be competent to induce the specific replacement of striatal neurons lost to Huntington's disease. We further postulated that new neurons arising from the endogenous progenitor pool of the striatal subependyma might contribute meaningfully to the BDNF-associated attenuation of neuronal loss that had previously been noted in experimental Huntington's disease, and which had been attributed to the trophic dependence of DARPP32⁺ medium spiny cells upon BDNF (Nakao *et al.*, 1995; Ivkovic & Ehrlich, 1999; Ivkovic *et al.*, 1997).

A key assumption of these postulates is that a significant portion of newly generated striatal neurons must integrate as medium spiny neurons, the major striatal victim of Huntington's disease, which normally serve as the pallidal projection neuron of the caudate-putamen. Benraiss *et al.* (2001) first reported that most AdBDNF-induced striatal neurons in adult rats, as defined by their incorporation of BrdU and co-expression of neuronal antigens, indeed expressed the phenotypic markers characteristic of medium spiny neurons. Moreover, these investigators reported that the overwhelming majority of AdBDNF-induced neurons were recruited as MSNs. Perhaps this should not have been surprising: Although the neostriatum includes a complex array of phenotypes, the overwhelming majority of caudate-putamen neurons are GABAergic medium spiny projection neurons to the globus pallidus (Mitchell *et al.*, 1999). These cells are defined by their expression of calbindin, a calcium binding protein, and DARPP-32, a dopamine- and cAMP-regulated phosphoprotein (Ouimet *et al.*, 1998). Thus, BDNF appeared to play an important role not only in the recruitment of new neurons from striatal precursors, but in their specific recruitment as medium spiny cells. As such, most BrdU⁺ cells in AdBDNF-treated brains co-expressed GAD, calbindin, and/or DARPP-32, prototypic markers of these cells

(Benraiss *et al.*, 2001). Together, these observations suggest that BDNF overexpression may be a viable means of triggering the addition of new medium spiny neurons to the adult neostriatum.

Thus far, the effect of BDNF overexpression in experimental Huntington's disease has only been assessed in a single transgenic line, that of the R6-2 mouse. R6-2 is a relatively dramatic model of Huntington's disease, in which the affected mice harbor a roughly 150-polyglutamine repeat in the huntingtin gene (Mangiarini *et al.*, 1996; Samdani *et al.*, 2002). Their disease course is truncated such that they become symptomatically ill by 6–8 weeks of age, and typically die by 12–14 weeks. When these mice were treated with AdBDNF, a substantial number of BrdU/ β III-tubulin⁺-defined newly generated neurons were recruited to their neostriata. These newly-generated neurons expressed DARPP-32 as well as other markers of medium spiny neurons. In addition, they were found to backfill with FluoroGold introduced into the globus pallidus, indicating their establishment of appropriate efferent connections. These observations suggested to us that the functional replacement of striatal cells lost in Huntington's disease might be accomplished through such a strategy of induced medium spiny neurogenesis (Mitchell *et al.*, 1999). Although the critical studies testing this hypothesis are ongoing, preliminary studies strongly suggest that AdBDNF-induced striatal neuronal recruitment from endogenous progenitor cells may prove a viable experimental therapeutic strategy for Huntington's disease.

Synergistic strategies for inducing striatal neurogenesis from endogenous progenitor cells

Striatal neuronal addition may therefore be accomplished through the BDNF-mediated mobilization and neuronal differentiation of SVZ progenitor cells. Yet as a corollary strategy, the inhibition of glial differentiation by SVZ cells may also serve to enhance neuronal production from endogenous progenitor cells. Several agents have been shown to induce astroglial differentiation from VZ progenitor cells *in vitro* (Hughes *et al.*, 1988; Lillien *et al.*, 1988). The bone morphogenetic proteins (BMPs) in particular have been found to instruct late fetal VZ progenitors to the glial lineage (Mehler *et al.*, 2000). Since both the BMPs and their receptors are present in high concentrations in the adult forebrain subependyma, the abrogation of BMP signaling by these cells might effectively inhibit astroglial differentiation, allowing instead neuronal differentiation (Gross *et al.*, 1996). On this basis, we postulated that the glial

differentiation of ventricular zone progenitor cells might be disrupted and the cells redirected to neuronal lineage, if the dividing progenitors and their daughters were exposed to a suitable neuronal differentiation agent during glial suppression.

To test this hypothesis, noggin protein was overexpressed, with the intention of actively suppressing glial differentiation. Noggin is one of a class of diffusible competitive antagonists that prevent BMPs from binding to their receptors (Zimmerman *et al.*, 1996). It is synthesized tonically in neurogenic regions of the adult rat SVZ (Lim *et al.*, 2000), and may provide a critical aspect of the periventricular niche for adult neurogenesis. We found that ventricular noggin overexpression indeed led to a substantial fall in gliogenesis within the adult subependyma, and was associated with a sharp and concomitant increase in olfactory neuronal recruitment from the SVZ. Moreover, this effect was accentuated by BDNF overexpression, such that the concurrent suppression of gliogenesis and promotion of neuronal differentiation by SVZ progenitor cells proved a powerful means of potentiating neuronal addition to both the neostriatum and olfactory bulb *in vivo*. Indeed, intraventricular noggin and BDNF co-overexpression resulted in a two- to threefold increase in the number of new neurons recruited in response to BDNF alone (Chmielnicki *et al.*, 2001). As in response to BDNF alone, most of these noggin/BDNF-stimulated neurons were recruited as medium spiny neurons, and projected to the globus pallidus. In light of BDNF and noggin's collaborative effects on striatal SVZ progenitor cells, their co-overexpression would seem a reasonable strategy by which to induce and maximize neuronal addition to the diseased Huntington's neostriatum.

Additional strategies for mobilizing striatal progenitor cells

A variety of soluble differentiation agents may prove suitable candidates for inducing neuronal addition to the adult neostriatum. EGF- or FGF-mediated expansion of endogenous progenitor cells may potentiate neuronal replacement in the presence of permissive signals for neuronal differentiation (Kuhn *et al.*, 1997). This may occur in the setting of injury, or in concert with factors such as BDNF, which can independently stimulate neuronal recruitment from endogenous progenitor cells (Benraiss *et al.*, 2001). TGF α has also been shown to achieve a similar effect in the adult striatum, in which TGF α exposure in the setting of catecholaminergic cell injury appears sufficient to induce the heterotopic recruitment of new dopaminergic neurons to the striatum (Fallon *et al.*, 2000).

Among agents not yet studied in the context of striatal regeneration, IGF1 may have particular promise as a co-agonist for neuronal recruitment. IGF1, classically designated as somatomedin C, has been found to be an important agent in neuronal recruitment in both adult birds (Jiang *et al.*, 1997) and rodents (Arsenijevic & Weiss, 1998; Brooker *et al.*, 2000; Jiang *et al.*, 1998). IGF-1 mutant mice display neocortical hypoplasia despite a thickening of the VZ, while transgenic IGF1-overexpressors display neocortical hyperplasia (D'Ercole, 1993). In addition, IGF1 is expressed selectively by neurogenic radial cells of the adult avian forebrain, and its addition to explants of the neurogenic ventricular zone substantially increases *in vitro* neuronal recruitment (Jiang *et al.*, 1998). As noted, IGF1 mobilizes endogenous dentate progenitors, and can thereby potentiate hippocampal neurogenesis (Aberg *et al.*, 2000). Moreover, since IGF1 induces expression of trkB in SVZ progenitor cells (Arsenijevic & Weiss, 1998), mIGF and BDNF might operate synergistically to induce neuronal production from resident progenitors of the adult striatum, as they appear to do *in vitro* (E. Chmielnicki, Harrison & S. A. Goldman, unpublished data). Together, these data across multiple species and models suggest that IGF1 overexpression might stimulate or enhance neuronal production from SVZ progenitor cells (Arsenijevic & Weiss, 1998; Liu *et al.*, 1993). Accordingly, the co-expression of these two agents might be predicted to enhance the induction of striatal neurons from resident VZ progenitor cells. Since IGF1 and noggin-mediated enhancement of BDNF's induced-neuronal recruitment appear to utilize different mechanisms, the concurrent overexpression of all three of these agents may prove a viable means of achieving clinically useful numbers of neurons to the diseased adult neostriatum.

Beyond the VZ: induction of non-striatal progenitor cell pools

Induction of resident progenitors as a means of restoring dopaminergic input to the striatum

Just as in Huntington's disease, nigral neurons lost to Parkinson's disease might optimally be regenerated from a patient's own store of endogenous progenitors, rather than delivered as an allograft. But in regions discontinuous with a source of ventricular zone progenitors, it remains unclear whether an inductive approach to regeneration is biologically feasible. The mesencephalic ventricular zone continues to harbor neural stem cells (Weiss *et al.*, 1996a,b), and these are especially biased towards dopaminergic

neurogenesis (Sawamoto *et al.*, 2001). When isolated and expanded *in vitro*, mesencephalic neural stem cells give rise to dopaminergic neurons in sufficient numbers and proportions that they may be used to restore dopaminergic innervation to the 6-OHDA-lesioned striatum. Nonetheless, no means of inducing the endogenous mesencephalic stem cell pool to *in situ* neurogenesis has yet been identified, so that no strategy of induced neuronal recruitment comparable to that established in the neostriatum has yet been defined.

As an alternative approach, a number of groups have begun to focus on inducing dopaminergic neurogenesis from resident progenitors within the parenchyma of the substantia nigra. As noted, parenchymal progenitor cells able to generate neurons persist throughout the adult brain (Kondo & Raff, 2000; Palmer *et al.*, 1997), in humans as well as in rodents (Nunes *et al.*, 2003a). These cells persist in the substantia nigra (Lie *et al.*, 2002) as well as the forebrain, and can readily be stimulated to generate neurons, despite their nominally glial phenotype *in vivo*. However, whether these cells may be induced to generate neurons *in vivo* remains unknown, and moreover, whether they may be stimulated specifically to generate dopaminergic neurons is even more problematic. While astrocytes derived from fetal ventral mesencephalon have been shown to potentiate the maturation of dopaminergic neurons (Johansson & Stromberg, 2002), specific factors that are necessary and sufficient for dopaminergic induction from parenchymal progenitors have not yet been elucidated. As noted previously, embryonic stem cells can be induced to differentiate as dopaminergic neurons upon treatment with SHH and FGF8, and these cells can ameliorate amphetamine-induced rotational behavior in an animal model of Parkinson's disease (Kim *et al.*, 2002). One might predict that the co-overexpression of FGF8 and SHH in the ventral midbrain might induce dopaminergic differentiation from neural progenitor cells in the substantia nigra. However, whether these parenchymal progenitors may respond to the same signals as their much less differentiated ES cells counterparts is unknown. Moreover, one can only presume that additional factors may prove necessary to guide the axons of any such newly generated nigral neurons to their neostriatal targets.

Progenitor stimulation as a restorative strategy for the hippocampal atrophies

The adult dentate gyrus exhibits persistent constitutive neurogenesis throughout life in animals and appears to do so as well in humans (Altman & Das, 1965; Eriksson *et al.*, 1998; Roy *et al.*, 2000b), although the natural history

of hippocampal neurogenesis in adult humans remains largely unexplored. New neurons are added to the adult dentate from progenitors in the subgranular zone of the hippocampus, a layer which is developmentally contiguous with the most posterior reaches of the subependymal zone of the lateral ventricle (Gage *et al.*, 1998). The subgranular zone progenitors appear committed to neuronal phenotype, although they may derive from less committed multipotential progenitors (Seaberg & van der Kooy, 2002). The regulatory control of these cells remains unclear. Although they respond to both FGF2 and IGF1 with mitotic expansion, neither of these agents seems to exert robust effects *in vivo*, although their relative potency may increase in the setting of antecedent factor depletion or injury (Aberg *et al.*, 2000; Palmer *et al.*, 1995). Sonic hedgehog, a prototypic morphogen more often implicated in phenotypic induction and regionalization of the developing nervous system, also appears able to regulate both the proliferation and differentiation of adult neural progenitor cells (Rowitch *et al.*, 1999). SHH remains active in the adult forebrain, where it is transported from the septum to the hippocampus, in which it appears to regulate neurogenesis from endogenous subgranular progenitor cells (Lai *et al.*, 2003). Other than SHH though, little has been learned of protein growth factors necessary or sufficient for hippocampal neurogenesis *in vivo*.

Besides the peptide growth factors, hippocampal neurogenesis may be normally regulated – and therefore potentially modified – by a great number of pharmacological agents and processes. Negative regulators of hippocampal neurogenesis include stress, corticosteroids, and alcohol, all of which may be associated with deficits in memory acquisition and storage (Cameron & Gould, 1994; Gould *et al.*, 1992; Nixon & Crews, 2002; Pham *et al.*, 2003). Positive regulators include environmental enrichment, exercise, and serotonin agonists, all of which have been associated with mood elevation and improved cognitive performance in a variety of memory-dependent tasks (Brezun & Daszuta, 2000; Gould, 1999; Nilsson *et al.*, 1999; van Praag *et al.*, 1999). The malleability of hippocampal neurogenesis in adult animals, and the persistence of competent dentate neuronal progenitors in the adult human hippocampus, argue that therapeutic stimulation of endogenous progenitor cells in the adult human hippocampus should be feasible. Current investigation is proceeding on precisely those lines with regards to the potentiation of hippocampal neurogenesis by serotonin reuptake inhibitors (Malberg *et al.*, 2000). Such an approach may prove beneficial not only in the affective disorders, but also as adjunctive therapy in the degenerative dementias associated with hippocampal atrophy.

Conclusions

Neural stem and progenitor cells comprise a potential source of new neurons to replace those lost in neurodegenerative diseases. Both transplanted and endogenous progenitor cells can be induced to divide, differentiate as neurons, survive and make appropriate postsynaptic and presynaptic connections. Experimentally, both implanted and resident progenitor cells have proved able to replace neurons lost to either experimental injury or disease. Yet the marginal results of neural cell and tissue grafts in Parkinson's disease provide a cautionary tale, and serve to remind clinicians of the unpredictable nature of perturbing the circuitry of the adult brain. To be sure, contemporary advances in both embryonic and neural stem cell biology, as well as in targeted progenitor isolation, serve to assure us more uniform and well-characterized populations of donor cells for future engraftment studies. Nonetheless, the compromised and compensated neural circuits of the diseased brain may prove even more fragile and prone to iatrogenic disruption than their healthy counterparts. As such, the future may prove brighter for strategies intended to induce endogenous progenitor cells. The studies discussed in the latter half of this chapter suggest that targeted periventricular delivery of diffusible factors, rationally designed to capitalize upon the known responsiveness of resident progenitor cells, will prove a viable strategy for inducing neuronal production from endogenous progenitor cells in the adult mammalian brain.

Introduction

New therapeutic non-pharmacological methodology involves cell and synaptic renewal or replacement in the living brain to restore function of neuronal systems, including the dopaminergic (DA) system in Parkinson's disease. Understanding the cell biological principles for generating functional DA neurons in lieu of the diseased can provide many new avenues for better treatment of patients with PD. Recent laboratory work has focused on using stem cells as a starting point for exogenous or endogenous derivation of the optimal DA cells for repair (Fig. 24.1). Using fetal DA cell therapy in PD patients (Piccini *et al.*, 1999, 2000; Freed *et al.*, 2001; Isacson *et al.*, 2001; Mendez *et al.*, 2002a) and stem cell-derived DA neurons in animal models (Bjorklund *et al.*, 2002; Kim *et al.*, 2002), it has been demonstrated that functional motor deficits associated with PD can be reduced after application of this new technology. Evidence shows that the underlying disease process does not destroy the transplanted fetal DA cells, although the patient's original DA system degeneration progresses (Piccini *et al.*, 1999, 2000). The optimal DA cell regeneration system would reconstitute a normal network capable of restoring feedback-controlled release of DA in the nigro-striatal system (Bjorklund & Isacson, 2002). The success of cell therapy for neurological diseases is limited by access to preparation and development of highly specialized dopaminergic neurons found in the A9 and A10 region of the substantia nigra (SN) in the ventral mesencephalon,

as well as technical and surgical steps associated with transplantation.

New neurons can grow to replace adult brain damaged or degenerated neuronal pathways. In clinical trials (Table 24.1), despite technical shortcomings, human fetal dopamine (DA) specified phenotypic ventral mesencephalic (VM) neurons have shown functional capacity in Parkinson's disease patients (Piccini *et al.*, 1999, 2000; Lindvall & Hagell, 2000; Freed *et al.*, 2001; Mendez *et al.*, 2002a; Ramachandran *et al.*, 2002 (Fig. 24.2)). Recently, it has been suggested that unregulated production of DA from grafted fetal neurons is the cause of unwanted dyskinesias seen in a subset of transplanted PD patients (Freed *et al.*, 2001; Olanow, 2002a) (Table 24.1). This is quite possible in a scenario of a "primed" dyskinetic circuitry produced by prior L-dopa treatment in a patient. Nonetheless, preclinical and clinical transplantation work demonstrates that striatal DA terminal release from appropriately grafted fetal DA neurons is regulated by both cell intrinsic and extrinsic synaptic and autoreceptor mechanisms and therefore, at least theoretically, the risk for dyskinesias should be less than with drug treatments (Piccini *et al.*, 1999; Bjorklund & Isacson, 2002). In animal models, fetal DA grafted neurons can reduce L-dopa induced dyskinesias (Lee *et al.*, 2000a). In grafted DA neurons, pre-synaptic DA auto-receptors regulate excess DA release and in vivo infusion of the full DA agonist apomorphine can block spontaneous DA release (Zetterstrom & Ungerstedt, 1984; Strecker *et al.*, 1987; Bjorklund & Isacson, 2002).

Fig. 24.1 Cell sources of dopamine neurons for neural transplantation into Parkinson's disease patients. (A) From the fetal brain dopamine neurons are obtained from the ventral midbrain (VM) at 6 to 9 weeks post-conceptional age. The VM is dissected and the tissue is prepared for transplantation following different methods, such as enzymatic and mechanical trituration to obtain a cell suspension, mincing into minute solid pieces or extruding through a glass pipette to form tissue strands. In any of these forms, the dopamine neurons are only a small fraction of the cells. Fetal VM can be maintained for some time (hours to days) *in vitro* (strands) or under special conditions such as hibernation media and be exposed to trophic factors and anti-apoptotic agents to promote survival. (B) From embryonic stem cell lines dopamine neurons (and other neural phenotypes with therapeutic potential) can be obtained *in vitro* through inductive protocols combining co-culture systems and sequential exposure to signaling and trophic factors that mimic the normal events during brain development. These cells can be characterized extensively *in vitro* and purified, using fluorescence activated cell sorting (FACS) or magnetic cell separation, before transplantation.

It is necessary to obtain structural reconstitution of terminal synaptic function and regulated dopamine release by new dopamine neurons

The scientific and clinical field of neural and cell repair has experienced the typical conceptual hurdles of major discoveries. The primary conceptual challenge is the idea that drugs (substance delivery) are a panacea for treatment of brain disorders. The initial success of L-dopa for

PD and growth of pharmacology as a discipline in some ways may have retarded the development of molecular, cell biological and regenerative strategies. Simplistic reasoning suggesting that a "biological pump" of dopamine would be sufficient for functional recovery in PD led to several unsuccessful clinical trials, for example those involving autologous transplantation of catecholamine-containing adrenal medulla cells (Backlund *et al.*, 1985; Madrazo *et al.*, 1988). The absence of objective reductions of PD signs, the low adrenal medulla graft survival and the reported morbidity of patients strengthened, however, the scientific rationale for using dopamine producing and striatally adapted fetal neural mesencephalic donor cells (instead of adrenal medulla that produces minute non-synaptic DA even after NGF stimulation). Since the 1990s, some success has been achieved by using such a fetal DA prototype cell replacement treatment, but the quality of cell implantation technology and cell preparations using fetal DA cells have so far been variable (Fig. 24.1, Table 24.1), and highly experimental.

The development of brain cell transplantation with embryonic neurons and glia is innovative both from a technical and biological standpoint and thus will require much work to optimize. The scaling up of this method from rodents to primates and humans has proved very challenging, particularly in obtaining an acceptable, abundant and reliable donor cell source and preparation (Table 24.1). Early studies indicated some motor improvement in association with increased fluorodopa uptake (Widner *et al.*, 1992). Longitudinal and validated data from Lindvall and colleagues indicate stable DA cell survival and function in patients for almost a decade after surgery and substantially reduced need for pharmacological substitution by dopaminergic drugs (Piccini *et al.*, 1999, 2000). The transplantation of non-dissociated human VM tissue pieces has also provided benefits to many patients (Freed *et al.*, 1992; Freeman *et al.*, 1995). In a series of pilot transplantation studies carried out by Olanow and colleagues in the US, autopsy from two bilaterally transplanted (6.5–9 week human fetal VM) patients who died 18–19 months after surgery showed over 200000 surviving DA neurons, which *partially* reinnervated the right putamen (about 50%) and the left putamen (only about 25%) (Kordower *et al.*, 1996). Electron microscopy revealed axo-dendritic and occasional axo-axonic synapses between graft and host was possible, and analysis of tyrosine hydroxylase (TH) mRNA revealed higher expression within the fetal neurons than within the residual host nigral cells (Kordower *et al.*, 1996). Autopsy of another patient in this surgical group showed over 130000 surviving DA neurons, reinnervating almost 80% of the putamen (Kordower *et al.*, 1998).

Not included are trials from New Haven, US, using cryopreserved tissue (no TH cells in autopsy), (Redmond *et al.*, 1990; Spencer *et al.*, 1992) and Birmingham, UK, using tissue from embryos over 10 weeks old, as well as open procedures.

* Includes patients previously reported. Susp: cell suspension, solid tissue pieces or strands. IS = immunosuppression. C: Caudate nucleus; P: Putamen; SN: Substantia nigra reticulata; Bi: bilateral. Clinical benefit was rated in most studies as mild or moderate (+) corresponding roughly to 30% improvement in the UPDRS motor scores in OFF, – however, different studies based outcome on scores or % time in ON or in OFF and rating was performed on different medication regimens. In general, all studies reported a decrease in the amount of L-DOPA and dopaminomimetic drugs, although there is great variability in the amount of the reduction and the time after transplantation when it happened; only exceptionally patients have been off medication (3 in the Lund series although in one it was reintroduced 3.5 years after the transplant and the other 2 had MPTP-induced parkinsonism).

F-DOPA PET uptake was increased (+) in most studies (average 40–60%) but again PET studies were performed at variable time points. Although F-DOPA PET is considered a good indicator of dopamine cell survival in the graft, the sensitivity is debated because of lack of good clinical and pathological correlation (one of the patients in Freed's study who died had symmetric uptake in spite of a five-fold difference (6000/30 000) in the number of TH+ cells between sides, (Freed *et al.*, 2001)).

Notably, both patients had shown major improvements in motor function and increases in fluorodopa uptake in the putamen on PET scanning (Table 24.1). Nevertheless, these and other detailed observations indicate that many specific regions of the human putamen may not be innervated by such non-specific VM grafts unless they contain the appropriate number and type of the A9 dopamine neuronal phenotype (Isacson, unpublished observations).

The most important factor in obtaining optimal functional effects (and minimal side effects) in PD by brain repair is in our opinion the presence of new synapses or DA transmission that adequately adapt to the local milieu and provide physiologically appropriate DA release in the host caudate-putamen and substantia nigra (Piccini *et al.*, 1999, 2000; Bjorklund & Isacson 2002). Fetal DA neurons have been shown to accomplish functional connections with the mature host striatal neurons. Synaptic contacts between transplanted fetal DA cells and host cells, as well as afferent contact by host neurons to transplanted cells, have been extensively documented (Mahalik *et al.*, 1985; Doucet *et al.*, 1989). Of both theoretical and practical relevance are analyses showing that pharmacological delivery into the striatum may not be as effective in ameliorating the motor symptom of PD, as regulated, synaptic release obtained with transplanted DA neurons (Bjorklund & Isacson, 2002). When DA is directly administered into the ventricle of PD patients, serious psychosis and motor abnormalities can develop (Venna *et al.*, 1984). The biological necessity for normal range DA release is illustrated by molecular differential display experiments that show abnormal upregulation of over ten genes within the striatum after abnormal DA exposure *in vivo* (Gerfen *et al.*, 1998). Complications associated with unregulated DA levels are obvious when observing effects of long-term L-dopa administration in patients as PD progresses, and the DA neuron and its synapses continue to degenerate, the non-physiological levels of DA within the striatum and abnormal down-stream activity in the basal ganglia seem to produce severe motor abnormalities such as dyskinesias. In neurophysiological recordings, it is clear that dopamine provides a modulatory role for the glutamate-mediated transmission, so that it appears to have a form of a gating function at that important striatal synapse (Freeman *et al.*, 1985; Strecker & Jacobs, 1985; Grace, 1991; Johnson *et al.*, 1992; Ljungberg *et al.*, 1992; Nutt *et al.*, 2000; Onn *et al.*, 2000). Physiologically appropriate DA functions can be achieved by normal DA synapses or, alternatively, cells which express the complete set of feedback elements required to regulate release and uptake of DA (Zetterstrom *et al.*, 1986; Strecker *et al.*, 1987; Isacson

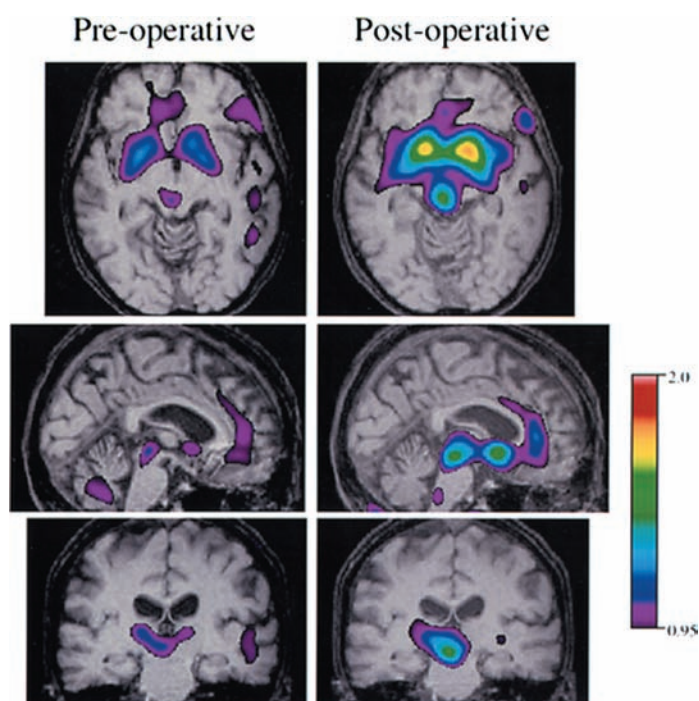

Fig. 24.2 Preoperative and postoperative fluorodopa PET scans obtained in a patient with Parkinson's disease who received simultaneous intrastriatal and intranigral fetal VM grafts. These images consist of parametric maps of fluorodopa K_i transformed into stereotactic space and overlaid on the patient's MR image (also in stereotactic space). The parametric maps were smoothed using an 8 mm gaussian filter. The axial, coronal, and sagittal sections demonstrate an increase in K_i in the midbrain and putamen bilaterally, likely resulting from surviving grafted dopamine neurons (Mendez *et al.*, 2002, with permission).

& Deacon, 1997). The evidence for the importance of DA-mediated regulation of striatal neuronal and network interactions indicate that, unless there is a regulated and tonic release of DA that is approximately regulated at the synaptic cleft by afferents, glutamatergic synapses will be less effective in control of the striatal GABAergic output neurons (Nutt *et al.*, 2000; Onn *et al.*, 2000). Discontinuous stimulation of dopamine receptors such that may occur after degeneration and L-dopa treatment is probably a major cause of dyskinesia induction. Normally, there are small basal increases in firing by mesencephalic dopamine neurons in a number of situations, at least as has been tested in animal models (Strecker & Jacobs, 1985; Ljungberg *et al.*, 1992). Nonetheless, such frequency stimulation does not raise the extracellular concentration of dopamine because the synaptic network and terminals work to reduce

fluctuations in DA concentration by reuptake mechanisms and possibly other autoreceptor mediated functions (Freeman *et al.*, 1985; Strecker & Jacobs 1985; Grace, 1991; Johnson *et al.*, 1992; Ljungberg *et al.*, 1992; Nutt *et al.*, 2000; Onn *et al.*, 2000). Fetal DA transplants have been shown to reduce the incidence of L-dopa induced dyskinesias in animal models (Lee *et al.*, 2000a). Several clinical studies have also shown normalized metabolic and brain functional activity throughout the basal ganglia after DA neural transplantation (Piccini *et al.*, 1999, 2000). In rodent studies, using cytochrome oxidase histochemistry as an indicator of neuronal metabolism in the 6-OHDA-lesioned rat; the lesion-induced increases in cytochrome oxidase activity of the entopeduncular nucleus and SN reticulata were finally eliminated by intrastriatal VM grafts, whereas the lesion-induced increases in globus pallidus and subthalamic nucleus were not changed by grafting (Nakao *et al.*, 1998). Similarly, in MPTP-treated monkey receiving VM transplants, DA cell implants increased the metabolic activity of the implanted striatum, particularly in the region of grafts containing greater numbers and innervation by DA neurons (Collier *et al.*, 1997).

Positron emission tomography (PET) and carbon-11-labeled 2B-carbomethoxy-3B-(4-fluorophenyl)tropane (11C-CFT) can also be used to visualize and quantify striatal presynaptic DA transporters in PD patients and PD degeneration models. In one such study of unilateral lesion of the SN DA system in rodents, the binding ratio was initially reduced to 15–35% of an intact side. After fetal DA neuronal transplantation, behavioral recovery occurred gradually and only after the 11C-CFT binding ratio had increased to 75–85% of the intact side, revealing a threshold for functional recovery in the lesioned nigrostriatal system after neural transplantation that fits our understanding of the normal DA system requirements (Brownell *et al.*, 1998). Importantly, autoregulation of DA release and metabolism by intrastriatal DA cell containing grafts has been shown by *in vivo* microdialysis in the striatum. Infusion of a non-selective DA agonist (apomorphine) almost abolishes endogenous DA release in the DA neuron-grafted striatum (Strecker *et al.*, 1987; Galpern, 1996), showing a normal auto-regulation of DA levels by the implanted cells. Further proof for the formation of functional DA terminals and synapses and appropriate DA release and regulation of transplanted fetal DA neurons have been studied in rodents after repeated L-dopa injections (Gaudin *et al.*, 1990; Lee *et al.*, 2000a). L-dopa-induced dyskinesias in non-human primates are also reduced after fetal DA cell transplantation (H. Widner, personal communication). These data indicate that DA levels within the transplanted striatum can be regulated in a functional manner by

correctly transplanted DA neurons if they appropriately innervate and form functional cellular communication with their normal target areas (Isacson & Deacon, 1997; Bjorklund & Isacson, 2002). Below, we describe some of these important variables in detail as they have been evaluated in animal model experiments and early observations in clinical applications.

Therefore, the current state of the art cell therapy for PD appears to require transfer of appropriate and selectively placed DA neurons in patients that are responsive to DA substitution therapy. Possibly, the emergence of stem cell generated DA neurons in concert with improved surgical and technical approaches may provide a more optimal intervention.

Technical developments of a new technology for regeneration of neural function and pathways in patients

The specific preparations of donor cells and associated procedures are very important in cell-based therapies and there are major differences in cell preparations for transplantation in Parkinson's disease in clinical trials to date (Fig. 24.1). The most successful method involves freshly dissected fetal tissue pieces (minute cubic millimeter pieces) that can be treated with proteolytic enzymes, then dissociated into a cell suspension (Brundin *et al.*, 1985; Piccini *et al.*, 1999; Lindvall & Hagell 2000; Piccini *et al.*, 2000; Mendez *et al.*, 2002a; Ramachandran *et al.*, 2002) (Fig. 24.1, Table 24.1). Other less effective procedures have included untreated tissue pieces, minced from the ventral mesencephalon of aborted fetuses (Henderson *et al.*, 1991; Freeman *et al.*, 1995; Kordower *et al.*, 1995; Olanow, 2002b). A third type, the so-called "noodle" technique (Freed *et al.*, 2001) includes a cell culture step. Such culture steps may alter the cells and select for cell types that are different than the populations obtained by fresh preparations, since storing or cell culture of DA neurons prior to transplantation may cause *in vitro* based selection favoring the A10 neurons that are less sensitive to oxidative stress than A9 (German *et al.*, 1992). These three different techniques produce different grafts. Only the cell suspension grafts grow to slender deposits that do not disrupt or displace the host target tissue (Brundin *et al.*, 1985; Piccini *et al.*, 1999, 2000; Mendez *et al.*, 2002a,b; Ramachandran *et al.*, 2002). In any event, all the current PD transplantation studies have employed rather crude cell preparations, since the starting point for all work are the pieces dissected from fetal tissue, which only contain about 10% newborn dopamine (DA) neurons; the rest are cells of types not generally relevant to PD

degeneration (Brundin *et al.*, 1985). In addition, while there is selective degeneration of substantia nigra pars compacta (SNc; A9) neurons, with a relative sparing of ventral tegmental area (VTA; A10) neurons in PD (Iacopino & Christakos, 1990; Yamada *et al.*, 1990; Gibb, 1992; Ito *et al.*, 1992), both of these DA cell groups are currently transplanted as a mixture (Lindvall *et al.*, 1988; Kordower *et al.*, 1996; Hauser *et al.*, 1999; Freed *et al.*, 2001). Notably, these two subpopulations of DA neurons within the SN have very different functions and project to different brain areas (importantly also within the SN through dendritic release). The midline positioned DA neurons (known as area A10) (Dahlstrom & Fuxe, 1964) selectively send axons to limbic and cortical regions (Gerfen *et al.*, 1987) while the adjacent A9 DA neurons (the major dysfunction in PD) grow selectively to putamen motor areas (Damier *et al.*, 1999). Thus, the differences between A10 and A9 DA neurons (Costantini *et al.*, 1997; Haque *et al.*, 1997) are potentially very important for understanding how to make cell replacement strategies work in patients. In summary, while current work demonstrates a clear capacity of fetal dopamine cell transplants to repair PD brains (Piccini *et al.*, 1999; Mendez *et al.*, 2000a; Piccini *et al.*, 2000), there are technical limitations with available prototypes of this technique. Both animal model experiments and clinical trials are limited by today's mixed cell preparations of low DA neuronal yield, inappropriate surgical placements and potentially the loss of DA cell subpopulations of therapeutic interest during tissue incubation, cell culture and preparation steps. Practically and ethically it is not possible to use fetal tissue as a source for transplantation for PD in more than rare experimental situations. For example, to replace a sufficient number of DA neurons, one needs 6–8 fetal tissue pieces per patient, primarily due to low post-transplantational survival of the grafted fetal DA neurons. In addition, current surgical techniques are inconsistent with respect to placement, volume and type of cells grafted. It is, however, encouraging that recent research in stem cell biology may provide a solution to this problem of low cell access and yield (Bjorklund *et al.*, 2002; Kim *et al.*, 2002).

Subpopulations of midbrain dopaminergic neurons perform different functions and reach different targets: its potential relevance to repair of PD brains

An important question in neural transplantation is the capacity for specific neuronal cell types to selectively reinnervate denervated host target regions (Schultzberg *et al.*, 1984; Nilsson *et al.*, 1988; Isacson *et al.*, 1995; Isacson &

Deacon, 1996). Neurons developed from fetal or embryonic stem cell stages, when transplanted into host targets display a relative specificity in axonal outgrowth into regions typical of their mature phenotype (Schultzberg *et al.*, 1984; Nilsson *et al.*, 1988; Isacson *et al.*, 1995; Isacson & Deacon, 1996). Midbrain DA neurons can be clearly categorized into subpopulations based on differences in the expression of certain proteins such as the dopamine transporter, TH, calbindin and cholecystokinin (CCK) and target neuron selection (Schultzberg *et al.*, 1984; Blanchard *et al.*, 1994; Haber *et al.*, 1995). The biochemical markers used reflect specific projection areas reached by the different categories of DA SN neurons. In rodents, Schultzberg *et al.* (1984) demonstrated, by grafting embryonic VM tissue into the dorsal deafferented striatum, that subsets of SN DA neurons have specific final patterns of axonal terminal networks. CCK-negative/TH (A9) cells extend their axons into the motor striatum, while CCK-positive/TH neurons (A10) do not. Instead, A10 DA neurons project their axons in cortical areas and limbic striatal regions. Another interesting protein is the retinoic acid-generating enzyme, aldehyde dehydrogenase 2 (AHD2), which is expressed only in a subset of A9 DA neurons in the substantia nigra (McCaffery & Drager, 1994). The AHD2 DA neurons project to the dorsal and rostral regions of the striatum and have a reduced DA terminal density gradient ventrally. Transplanted DA neurons at first appear to extend fibers in a non-specific heliocentric fashion around the graft; however we have shown that the subset of transplanted DA fibers expressing AHD2 preferentially reinnervate the dorsolateral part of striatum (Haque *et al.*, 1997). Histological observations of post-mortem patient tissue (O. Isacson, unpublished data) also indicate that transplanted human DA neurons will only seek their normal targets; and actively avoid innervation of other caudate-putamen regions according to their specific neuronal phenotype. The AHD2 enzyme is very sensitive to oxidation, which may correlate with increased vulnerability of A9 neurons seen in PD (McCaffery & Drager, 1994). Since only 2–10% of neurons normally in the dissected VM are of a phenotype DA, hypothetically after transplantation they may compete for trophic support with the majority of the transplanted non-DA neurons. It is well known that midbrain DA neurons are positively influenced by growth factors such as bFGF (Mayer *et al.*, 1993) and GDNF (Granholtm *et al.*, 1997; Meyer *et al.*, 1999). Such trophic dependency may vary between midbrain DA cell subpopulations, and it is likely that a limited supply of trophic molecules influences DA cell survival and growth. In addition, 20–80% of the SN cell population normally undergoes a period of programmed cell death between P2 and P14 (Janec & Burke, 1993).

Transplanted fetal VM derived DA neurons develop extensive axonal terminal networks, in the host striatum and nucleus accumbens in a normal, dense, homogeneous fashion (Bjorklund *et al.*, 1980; Dunnett *et al.*, 1984). In contrast, identical phenotypic DA neurons (from fetal or stem cell derivation) only extend a few axons into the host brain when transplanted into non-target areas such as cortex, thalamus and hypothalamus (Abrous *et al.*, 1988). Ultrastructural data show that grafted DA neurons are able to form appropriate and abundant synaptic connections with medium-sized spiny striatal neurons, which are the primary target of the mesencephalic DA afferents (Clarke *et al.*, 1988). The molecular mechanisms defining anatomical specificity of the DA projections have not been fully elucidated but they are likely to involve target-derived trophic signals and recognition of target-specific cell surface molecules by growth-cones (Isacson & Deacon, 1997).

Evidence that tissue type, surgical cell preparation or specific surviving dopaminergic neuronal phenotype influence the degree of functional recovery

We have demonstrated (Haque *et al.*, 1997) that a non-linear regression function exists between DA neuron survival and extent of functional motor recovery. For example, approximately 590 rat-derived DA cells in the graft were necessary to obtain a 50% reduction in motor asymmetry using solid piece VM transplants. A plateau in motor recovery was reached at about 1200 TH-positive neurons. Using pieces (non-dissociated grafts), the number of cells required for a 50% reduction in rotation is higher than comparable values in the literature for cell suspension grafts (Haque *et al.*, 1997). There may be several reasons for differences in efficacy between single cell suspension grafts and tissue pieces. Single cell suspension grafts become more vascularized than multiple-fragment transplants (Leigh *et al.*, 1994). Further, Nikkah *et al.* (1994) showed that smaller suspension grafts show relatively better axonal coverage of the striatum compared to larger grafts. Large grafts, whether transplanted as cell suspensions or as tissue pieces, may actually limit the direct access to host tissue cues causing grafted cells to have less interaction with the host and integrate more within the actual transplanted tissue. These data and reasons indicate that single fetal cells in smaller deposits or possibly endogenous progenitor cells integrate better into the host brain and elicit behavioral recovery more efficiently (Brundin *et al.*, 1985; Sotelo & Alvarado-Mallart, 1987; Hernit-Grant & Macklis, 1996). Co-grafting

of embryonic striatal tissue with fetal VM show that such grafts result in enhanced DA neuronal survival and function through trophic support (Costantini & Snyder-Keller, 1997). Thus, graft–host interaction and graft–graft interaction are both factors regulating fetal VM transplant development. We established that the percentage reduction in rotations at 10 weeks post-transplantation is mostly associated with the proportion of AHD2-positive A9 DA neurons in the grafts (Haque *et al.*, 1997). An inverse tendency was also apparent with the presence of A10 neurons. This observation suggests that the greater the proportion of A9 neurons in cell transfer or repair, the greater the degree of symptomatic recovery of motor signs or abnormalities.

The importance of proper development of appropriate molecular and phenotypic cell characteristics can be observed in the functional effects of transplanted xenogeneic DA neurons. In xenografting experiments in a rat model of parkinsonism, recovery from amphetamine induced motor asymmetry is tightly linked to the normal developmental rate of the species from where the grafted DA neurons are derived (Isacson & Deacon, 1997; Bjorklund *et al.*, 2002). Galpern *et al.* (1996) reported that between 80–120 TH-positive neurons were required to see the same effect using 120–140 rodent DA neurons, which is consistent with larger species-determined axonal growth areas in animals with larger brains.

Can we produce better therapies with fewer side-effects by accomplishing a more specific cellular and synaptic dopamine replacement?

Recently, it has been postulated that excess and unregulated production of DA from grafted fetal neurons could be responsible for some unwanted side effects seen in transplanted PD patients (Freed *et al.*, 2001). However, it has been convincingly demonstrated that striatal DA release normally is tightly regulated by both intrinsic and extrinsic mechanisms. Presynaptic dopamine autoreceptors regulate excess DA release and administration of the DA agonist apomorphine can inhibit spontaneous DA release up to 100% (Zetterstrom & Ungerstedt, 1984). It is believed that approximately 50% of this inhibition can be contributed to a direct effect on DA autoreceptors and 50% involves postsynaptic neurons engaged in short and long distance feedback circuits (Zetterstrom & Ungerstedt, 1984). Subsequently, it has been shown that grafted fetal DA neurons display similar autoinhibition mechanisms as demonstrated by a 40% reduction in spontaneous DA release when grafted animals are treated with apomorphine (Strecker *et al.*, 1987;

Bjorklund & Isacson, 2002). These basic studies are important as they provide evidence contrary to current theories that implanted DA neurons may release excess amounts of DA in an unregulated manner, thereby contributing to side effects such as dyskinesias (Freed *et al.*, 2001). Instead, such side effects may have several alternative explanations (Isacson *et al.*, 2001). DA released from nerve terminals into the synaptic cleft is normally rapidly taken up and transported back into the terminals by the dopamine transporter (DAT). This mechanism is important for appropriate temporal regulation of DA concentration in the synaptic cleft. When the DAT is blocked by agents such as cocaine, DA will remain in the synaptic cleft in higher concentrations and for longer time periods than normal thus allowing increased binding and activation of postsynaptic receptors. When fetal ventral midbrain is dissected prior to transplantation, most published protocols do not make any distinction between the DA neurons residing in the VTA (A10) and those in the SNc (A9) (Lindvall *et al.*, 1988; Kordower *et al.*, 1996; Hauser *et al.*, 1999; Freed *et al.*, 2001). These two midbrain subpopulations of DA neurons express different levels of the DAT (Blanchard *et al.*, 1994), project to different areas (Graybiel *et al.*, 1990) and show different response to growth factors (Johansson *et al.*, 1995; Meyer *et al.*, 1999). In addition Parkinson's disease patients show a relative sparing of DA neurons in the VTA compared to the SNc indicating that the VTA DA neurons are less vulnerable compared to their SNc counterparts (Iacopino & Christakos, 1990; Yamada *et al.*, 1990; Gibb, 1992; Ito *et al.*, 1992). One possible explanation for the reported dyskinesias in five out of 37 patients in the study by Freed *et al.* (2001) and 13 out of 23 patients in the study by Olanow (2002b) could be that unselective preparations of fetal tissue pieces containing fetal dopamine neurons prior to implantation may result in selective survival of the less vulnerable, but inappropriate VTA DA neurons (Isacson *et al.*, 2001). When such neurons are implanted into the putamen of PD patients, they may form inappropriate connections with, or avoid, the projection neurons of the putamen, since these are not their normal targets (Isacson & Deacon, 1997; Isacson *et al.*, 2001). In addition, differences in DAT expression between subpopulations of DA neurons (Blanchard *et al.*, 1994; Sanghera *et al.*, 1997; Ciliax *et al.*, 1999) may also result in abnormal dendritic DA release in the putamen (Falkenburger *et al.*, 2001) and uptake patterns that could cause suboptimal DA transmission. Another likely reason for uncontrolled motor response after transplantation is that location and size of tissue pieces implanted may in some cases create small lesions in the putamen with subsequent dysregulation of the GABAergic output neurons (as seen in Huntington's chorea). This theory is supported by the fact

that small lesions in the striatum of primates (modeling Huntington's disease) make these animals severely dyskinetic in response to DA agonist treatment (Hantraye *et al.*, 1990, 1992; Burns *et al.*, 1995), that would also occur in a situation of diffuse release from inappropriate DA neurons placed as tissue pieces in the lateral putamen (Freed *et al.*, 2001; Olanow, 2002a). Supporting such a view is the relative absence of side effects from transplanted fetal DA cells to humans, when donor cells are prepared and placed as liquid cell suspension into PD putamen (Lindvall & Hagell, 2000; Mendez *et al.*, 2000a,b; Schumacher *et al.*, 2000; Ramachandran *et al.*, 2002). Such grafts typically reach less destructive size, but are better integrated in the host with more extensive axonal and synaptic outgrowth into appropriate target zones (I. Mendez, O. Isacson *et al.*, in preparation).

Finally, of significance, the importance of appropriate cellular and biochemical characteristics of transplanted DA cells has also been shown by behavioral experiments. In a rodent model of parkinsonism, recovery from movement asymmetry is correlated with the rate of cellular maturation of the donor species (Isacson & Deacon 1997; Bjorklund & Isacson, 2002). Embryonic stem (ES) cells generating DA neurons also abide by such biological principles (Bjorklund & Isacson, 2002; Bjorklund *et al.*, 2002). Multiple anatomical analyses have demonstrated that specific axon guidance and cell differentiation factors remain in the adult and degenerating brain, providing growth and axonal guidance cues for fetal or ES cells (Isacson *et al.*, 1995; Isacson & Deacon 1996; Haque *et al.*, 1997).

In summary, the pathology of PD reveals a relatively selective loss of DA neurons in the substantia nigra pars compacta (SNc; A9) with a relative sparing of ventral tegmental area (VTA; A10) neurons. Our preliminary studies and reasoning suggest that selective repair by A9 DA cells in the putamen is more likely to contribute to symptomatic relief and prevent motor side effects compared to implantation of the A10 DA cell group (Haque *et al.*, 1997; Isacson & Deacon, 1997). For example, transplanted A9 (AHD2+ and dopamine D2 receptor+) neurons selectively reinnervate the appropriate motor regions of the affected putamen and correlate better with improved behavioral function in rodent models (Haque *et al.*, 1997) than non-A9 SN DA neurons. Since the A9 DA neurons have a better capacity to downregulate dopamine release than A10 DA neurons by synaptic mechanisms, the A9 neurons are also *a priori* less likely to have unregulated DA release, that may cause too high or low and unstable DA levels provoking motor side effects, such as dyskinesia in patients as typically seen after long-term L-dopa or DA agonist treatment (Olanow & Obeso, 2000; Olanow & Tatton, 2000; Isacson *et al.*, 2001).

Fig. 24.3 Dopamine neurons derived in vivo from mouse embryonic stem (ES) cells. This confocal image shows numerous dopamine cells in the striatum of a 6-OHDA-lesioned rat, 11 weeks post-transplantation of undifferentiated ES cells (~2000 cells). Dopamine neurons co-expressed the synthetic enzymes tyrosine hydroxylase (TH, green) and aromatic amino acid decarboxylase (AADC, blue) and the neuronal nuclei marker (NeuN, red). Animals with ES cells derived dopamine neurons in the grafts showed recovery of motor asymmetry (Bjorklund *et al.*, 2002).

Generation of a stem cell derived therapy for Parkinson's disease

Previous work has shown that DA neurons can be expanded in a cell culture dish from growth factor expanded embryonic day 12 (E12) VM precursor cells (Studer *et al.*, 1998) or ES cells (Kawasaki *et al.*, 2000; Lee *et al.*, 2000b), as well as from Nurr-1 transfected mouse progenitor clones cultured with midbrain type 1 astrocytes (Wagner *et al.*, 1999). Remarkably, by injecting the undifferentiated ES cell directly into living tissue (brain or kidney capsule) ES cells or embryoid body cells can spontaneously differentiate into neurons (Deacon *et al.*, 1998). We have recently demonstrated that naïve ES cells implanted in low numbers into a DA depleted striatum can develop and function as replicas of the DA neurons lost in PD (Fig. 24.3). These new cells restore amphetamine induced motor symmetry and cortical activation (Bjorklund *et al.*, 2002) lost both in

PD and PD animal models. Such findings suggest that ES cells are a reasonable cell source for PD transplantation and could overcome the problem associated with using fetal primary neuron (predifferentiated) or the fetal VM expanded precursor cells (Studer *et al.*, 1998), which both show low in vivo survival rates after transplantation (3–5% of the grafted DA neurons) (Brundin & Bjorklund, 1998; Studer *et al.*, 1998). In contrast, the direct ES cell transfer to brain has a high in vivo yield (up to four-fold) expansion and differentiation into DA neurons from a small number of implanted cells (1000 ES cells) (Bjorklund *et al.*, 2002) (Fig. 24.3). Vigorous basic research that defines the developmental sequences and repair mechanisms involved in fetal and stem cell derived DA neuron cell therapy will likely provide a future modality for the treatment of PD. Nonetheless, the growth potential of the cell source (ES) also needs to be tempered and controlled (Bjorklund *et al.*, 2002). The risk for growth of non-neural tissues from the endodermal and mesodermal germ-layers needs to be eliminated (Bjorklund *et al.*, 2002). This can be accomplished by blocking activation or influence of meso- and endodermal cell fate inducers (Bjorklund *et al.*, 2002).

How can stem cell biology research help Parkinson patients?

Most living systems undergo continuous growth. In humans, bone marrow stem cells are capable of dividing into most of the cells necessary for blood and immune systems. Even entire tissues or organs, such as the liver, can be regrown. Cells in the lining of the gut are shed and replaced on a daily basis, and in the skin, the basal cell layers of the dermis provide a continuous supply of growth. In adult mature mammalian cell systems, it is however typical that only organ-specific and specialized progenitor cells divide to maintain growth of organ systems in the body, while pathological processes can limit such replenishment. A fertilized cell is capable of cell divisions that grow logarithmically and in the early cluster of cells (in the range of 250 cells) each cell is capable of (or appears to be) forming any germ layer and part of the body plan (Hemmati-Brivanlou & Melton, 1997). This type of cell is therefore denoted stem cell, or in this case, embryonic stem cells. Recently, such divisible (yet non-malignant and non-carcinogenic) cells have gained increased attention. In a more limited scientific context, the concept and methodology of stem cell-derived dopamine cells intrigues both neurobiologists and clinically oriented scientists, insofar as it could both explain the biology of the developing dopamine cells and what controls its function, as well as generating a

Table 24.2. Candidate fate-determining factors that may play critical role in development and phenotypic specification of dopaminergic neurons

Factor	Embryonic day (mouse)	Comments	References
Wnt	8.0	Homozygous mutant mice lack the midbrain and adjacent cerebellar component of the metencephalon. Transgenic mice expressing En1 under the Wnt1 promoter rescues the phenotype of Wnt ^{-/-} mice, indicating that En1 gene may be downstream of Wnt.	(Danielian & McMahon, 1996) (McMahon <i>et al.</i> , 1992)
Engrailed-1 (En-1)	8.0	En 1 ^{-/-} mice die shortly after birth and lack most of the colliculi and cerebellum and third and fourth cranial nerves. The absence of mid-hindbrain areas is evident as early as E9.5 and the phenotype resembles that of Wnt ^{-/-} mice.	(Wurst <i>et al.</i> , 1994)
Engrailed-2 (En-2)	8.5	En 2 ^{-/-} mice viable but have an altered adult cerebellar foliation pattern. A recent analysis of En 1 ^{-/-} , En 2 ^{-/-} double null mutant mouse showed that the midbrain DA neurons are generated and differentiate their dopaminergic phenotype but disappear soon thereafter. Thus, En1/En2 genes may be important for maintenance of DA phenotypes.	(Millen <i>et al.</i> , 1994) (Simon <i>et al.</i> , 2001)
Nurr1	10.5	Gene inactivation studies have established that Nurr1 is a critical fate-determining factor for DA neurons. In Nurr1 ^{-/-} mice, precursors are developed but DA phenotype such as TH is not expressed. In a gain-of-function analysis in mouse embryonic stem cells, Nurr1 overexpression resulted in upregulation of all known DA marker genes such as TH, DDC, and DAT. Nurr1 appears to transactivate the 5' promoter activity of the TH gene.	(Zetterstrom <i>et al.</i> , 1997) (Saucedo-Cardenas <i>et al.</i> , 1998) (Castillo <i>et al.</i> , 1998) (Chung <i>et al.</i> , 2002) (Kim <i>et al.</i> , 2003)
Lmx1b	7.5	Lmx1b is a LIM homeodomain transcription factor that is critical for dorsoventral patterning of the developing limbs and is involved in the nail patella syndrome. Re-evaluation of Lmx1b ^{-/-} null mice showed that TH ⁺ midbrain neurons form but soon disappear. Ptx3 gene is not induced indicating that Lmx1b is upstream of Ptx3. Thus, Lmx1b along with Ptx3 may constitute a molecular cascade independent of Nurr1 and TH.	(Smidt <i>et al.</i> , 2000)
Pitx3	11.5	Pitx3 and its rat homologue Ptx3 are selectively expressed in developing lens and in the midbrain. Pitx3 was mapped to the aphakia region on mouse chromosome 19 and the homozygous ak mouse was characterized by a small eye missing the lens. The human homologue PITX3 gene was mutated in two unrelated families with congenital cataracts and anterior segment mesenchymal dysgenesis. In regard to its potential role for DA development, loss-of-function or gain-of-function data are not yet available.	(Semina <i>et al.</i> , 1997; Semina <i>et al.</i> , 1998) (Smidt <i>et al.</i> , 1997)

procedure for obtaining such cells in abundance for clinical applications.

Starting at the genetic level, a number of genes related to the development or control of dopaminergic identity and specialization (e.g. sonic hedgehog protein, Pitx3 and Nurr-1) (Table 24.2) act in concert with other transcription factors to activate specific transmitter enzymes (for

instance TH, DAT and dopa-decarboxylase) (Fig. 24.3) in dopaminergic neurons (Marsden, 1982; Montgomery *et al.*, 1996; Mandel *et al.*, 1998). An alternative or different route to cell repair is the possibility of manipulating inherent neurogenesis in the adult brain (Rakic, 2002). For example, in the adult brain exists neural precursor cells embedded in the subventricular zone (SVZ) that are capable of

migration and differentiation into different neural cell types (Alvarez-Buylla & Garcia-Verdugo, 2002). These neural progenitor cells can be expanded and studied, possibly even as a neuronal repair tool (Flax *et al.*, 1998). The expansion of SVZ neuroprecursor cells is stimulated by delivery of basic fibroblast growth factor (bFGF), brain-derived neurotrophic factor (BDNF) (Benraiss *et al.*, 2000), noggin (Lim *et al.*, 2000), ciliary neurotrophic factor (CNTF) (Shimazaki *et al.*, 2001) or epidermal growth factor (EGF) (Craig *et al.*, 1996) to the CSF. Migration into the parenchyma can be stimulated by infusion of transforming growth factor- α (TGF- α) into a target region (Fallon *et al.*, 2000). Neuronal differentiation from precursors is enhanced by GDNF, BDNF (Zurn *et al.*, 2001) and natural BMP receptor antagonists (Lim *et al.*, 2000). Expression of a dopaminergic phenotype can be driven by transcription factors such as Pitx3 (Lebel *et al.*, 2001) and Nurr1 which drive genes of the full DA neuronal phenotype such as TH, DAT and components of trophic factor receptors (Saucedo-Cardenas *et al.*, 1998; Wallen *et al.*, 2001; Tornqvist *et al.*, 2002) (Table 24.2). Further, release of GDNF or BDNF by genetically modified cells in the caudate-putamen can increase survival of precursor cells and of dopaminergic neurons in the SN following lesions (Akerud *et al.*, 2001), and the programmed cell death process can also be temporarily suspended by anti-apoptotic factors, e.g. XIAP (Eberhardt *et al.*, 2002). Interestingly for novel therapies, genetically modified cells can also serve as biologic pumps to produce growth factors that sustain neurons on site in the striatum or projecting dopaminergic neurons from the SN (Schumacher *et al.*, 1991; Frim *et al.*, 1994; Akerud *et al.*, 2001).

In summary, stem cell biology is valuable in a discovery process of several new and potential treatments for Parkinson's disease. For example, research on ES cells may demonstrate the genetic transcription factors that control the specific genes participating in DA orchestrated neuronal function and cell development (Table 24.2). Genetic programs have dynamic components; for example, concerted actions of growth factors or neurotrophic factors that act as molecular switches required for initiating and maintaining the function of a DA neuron. The knowledge of how DA neurons can be formed would allow a reasonable process to be established for industrially producing a large number of such cells for transplantation or their regeneration inside the living brain. The stem cell biology related to brain development and repair can be approached by methods using either adult or embryonic stem cells potentially capable of generating new neurons, after selective engineering, expansion in cell culture systems or in the living brain. The investigation of embryonic stem cells also pro-

vides a system in which transcription factors responsible for directing the typical dopaminergic cell fate in the nigrostriatal systems can be determined. This allows a sophisticated understanding of the factors controlling the specialization and health of such cells. All of these investigations help clarify pathological, toxic or genetically induced cell dysfunction.

In conclusion, recent discoveries elucidating the cell biology of dopaminergic neurons allow both sequential and parallel strategies for protection of remaining cells and treating with new cells to restore function in Parkinson's patients (Check, 2002). The rapidly developing understanding of pathological mechanisms in Parkinson's disease and the life cycle of the dopamine neuron from stem cells, via progenitor cells, to adult and later aging dopamine neurons provides reasonable opportunities for new interventions to reverse the effects of this disease. Nonetheless, detailed knowledge is necessary about the appropriate neurons, correct brain locations for repair and responsive PD patients for these regeneration therapies to become successful.

Normal aging

Clinical aspects of normal aging

Marilyn S. Albert

Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Overview

It is now widely understood that the number of persons living into old age increased dramatically during the last century. In 1900, the average life expectancy at birth was 47 years. By 1950, this had increased to 68 years. In the year 2000, the average life expectancy for males was estimated at slightly over 74 years, and for females it was almost 80 years of age. There is thus increasing interest in understanding the normal changes that occur with age. Along with this has come an interest in developing ways to maintain function at its maximum. This chapter will describe epidemiological aspects of aging, cognitive and motor changes that are associated with aging, the underlying neurobiologic alterations that are thought to be responsible for age-related changes in cognitive and motor function, and the implications of these alterations for the clinical evaluation of an older person.

Epidemiologic aspects of aging

The numbers of persons living to an old age has risen dramatically, and this is expected to continue until at least 2050, as noted above. During the first half of the twentieth century, the increase in life expectancy was largely the result of decreased mortality early in life. The continued expansion of life expectancy during the last half of the twentieth century was largely the result of increased survival during middle and old age. At the same time, virtually all developed countries experienced decreases in the birth rate. Therefore, older persons became an ever-increasing portion of the population, as shown in Table 25.1, which provides data for the US population in particular. In 1900, slightly over 4% of the population was 65 and older. This

percentage had doubled by 1950, when 8% of the population was 65 or above, and in the year 2000 almost 13% was in this age range (Guralnik & Ferrucci, 2003). The projections for the year 2050, when the baby boomer generation will be 65 and over, are equally dramatic. Estimates indicate that one in five Americans will be 65 and older by 2050.

The portion of the population represented by those 85 and over, the so-called “oldest old,” shows a similarly striking pattern. In 1900, those 85 years of age and older represented 0.1% of the population. In 1950, this percentage continued to be low, at 0.6%. In 2000, almost 4½% of the population was 85 and older. By 2050, this number is expected to grow exponentially, and is estimated to be almost 20% of the population (Guralnik & Ferrucci, 2003).

The number of individuals aged 100 and older is projected to follow similar trends in the next 50 years. In the USA, the number has doubled every decade since 1980. In 2050, it is estimated that there will be 1 million centenarians in the USA (Guralnik & Ferrucci, 2003).

This increased aging of the population is seen most clearly in developed countries, and is most striking in Europe. Twenty-four of the 25 oldest countries are in eastern or western Europe, with Japan being the 25th. Italy has the oldest population, with over 18% aged 65 and older. The percentage of older persons in underdeveloped countries (such as Asia, Latin America, and North Africa) although low at the present time, is expected to double by the year 2030.

The speed with which countries have aged varies widely. One can see this by examining the time it has taken (or will take) for 14% of the population to be 65 and older. Some countries, such as Sweden and the United Kingdom, reached this level in the mid 1970s, taking approximately 85 years to double in size (from 7% to 14%). Japan took 26 years to do so. The USA is expected to reach this

Table 25.1. Actual and projected growth of the US population, 1900–2050 (millions)

Year	Total population (all ages)	65 years and older		85 years and older	
		Number	Percent of total population	Number	Percent of 65 years and older population
1900	76.1	3.1	4.1	0.1	3.2
1950	152.3	12.3	8.2	0.6	4.9
2000	276.1	34.9	12.6	4.4	12.6
2050	403.7	82.0	20.3	19.4	23.7

Source: Population Division. US Census Bureau, Washington, DC. Reprinted with permission from Guralnik & Ferrucci, *Demography and Epidemiology*, 2003.

level by 2013, taking 69 years. The developing countries are expected to have a pattern much like Japan's, and are expected to reach the 14% level by 2030 (Guralnik & Ferrucci, 2003).

Females have a greater life expectancy than males at all ages. At birth this differential is estimated to be about 5 1/2 years. Whites have a greater life expectancy than blacks until age 75. However, once individuals have lived to age 75, life expectancy is similar for whites and blacks. It is assumed that the differential in life expectancy between whites and blacks relates to the higher prevalence of illnesses among blacks, such as heart disease and diabetes, as well as access to health care and the use of healthcare prevention strategies. Information concerning Hispanics is less clear, since Hispanic status has been ascertained in varying ways in recent years.

When one has lived to age 75, life expectancy remains substantial. The average 75-year-old will live another 10–12 years. The average 85-year-old will live another 5–6 years (Guralnik & Ferrucci, 2003).

Changes in cognitive function with age

A number of aspects of cognitive function show alterations with advancing age. The focus of this section will be on age-related changes in memory and executive function because these have been the focus of intense investigation in recent years. Moreover, these two areas of cognition are the two that have been studied across species. This makes it possible to determine the degree to which age-related changes in cognition found in one species are corroborated in another. When such parallels are found, it strengthens the likelihood that the cognitive change is related to age, and not to early signs of a neurodegenerative disorder, such as Alzheimer's disease. Since there is an increas-

ing focus on identifying patients as early as possible in the course of AD (for example, see Chapter 27), distinctions between age-related and disease-related changes in cognition are of great practical, as well as theoretical, interest. Other aspects of age-related changes in cognition, such as alterations in language, visuospatial processing, and general intelligence are reviewed elsewhere (Albert & Moss, 1999).

Memory

Workers in the field of memory have concluded that memory is not a unitary phenomenon, and most models of memory function hypothesize that memory consists of a series of specific yet interactive stores (e.g. Waugh & Norman, 1965; Tulving, 1972). They include, at a minimum: sensory memory, primary memory, and secondary memory. In addition, a distinction has been made between information that is consciously learned (called explicit or declarative memory) and information that is acquired over time, unrelated to specific conscious effort of episodes (called implicit or procedural memory) (Reber & Squire, 1994).

Memory in humans

There are minimal changes with age in sensory and primary memory, but substantial age-related changes occur in secondary memory (for a review, see Craik, 1977 and Poon, 1985). The age at which changes in secondary memory occur depends upon the methods that are used to test the memory store. Difficult explicit memory tasks (e.g. delayed recall) demonstrate statistically significant differences by subjects in their 50s, in comparison to younger individuals (Albert *et al.*, 1987).

A close examination of memory performance in the older individuals shows, however, that they are not more rapidly

forgetting what they learned, but rather they are taking longer to learn the new information. For example, if one compares the difference between immediate and delayed recall over the lifespan, there are no statistically significant age differences (Petersen *et al.*, 1992). Thus, if one allows older subjects to learn material well (i.e. to the point where few errors are made), they do not forget what they have learned more rapidly than the young. However, if older subjects are not given the ability to learn material to the same level of proficiency as younger individuals, after a delay, less information will be retained by the average older person.

However, there is considerable variability among older subjects on tasks of this sort. There are many healthy older subjects who have test scores that overlap those of subjects many years younger than themselves (e.g. about one-third of healthy 70-year-old humans have delayed recall scores that overlap those of 30-year-olds, equated for education).

Memory in non-human primates

Similar findings have emerged from studies in monkeys. Since free recall cannot be easily tested in monkeys, considerable effort has gone into developing a memory task that uses recognition, but determines the quantity of information aging monkeys can retain across varying delay intervals. The delayed non-matching to sample task (DNMS) is the most widely used method for assessing recognition memory in the nonhuman primate. This task relies upon a two-alternative forced choice paradigm in which the monkey is required to discriminate which of two objects was recently presented. By using the delayed non-matching to sample task, many studies have shown that aged monkeys are impaired at learning the non-matching principle but are, at best, only mildly impaired across the delay conditions of the test (Moss *et al.*, 1988; Arnsten & Goldman-Rakic, 1990; Bachevalier *et al.*, 1991; Presty *et al.*, 1987; Rapp & Amaral, 1989). Thus, like humans, the old monkeys take longer to learn something new but do not appear to forget this information more rapidly over lengthening delays than younger monkeys.

Moreover, on a very difficult memory task, such as the delayed recognition span test (DRST) (Moss, 1983), age-related changes are seen among middle-aged monkeys. This test requires a monkey to identify a novel stimulus from an increasingly large array of previously presented stimuli. The goal is to keep track of as many stimuli as possible without making a mistake. Middle-aged monkeys (16–23 years) are impaired on the spatial version of the DRST but not on the color version (Moss *et al.*, 1988). Aged

monkeys (25–27 years) are impaired relative to young adults (5–7 years) under both conditions of the task. This suggests that the performance of monkeys on the spatial version of the DRST may be functionally equivalent to the performance of humans on difficult delayed recall tasks. Longitudinal assessment of young and aged monkeys (after an interval of 4 years) confirm the findings of the cross-sectional data (Moss, 1993). Young animals show either slight improvements or slight declines on the DRST, while aged monkeys show either slight declines or severe declines over time.

A more recently developed task, the visual paired-comparison test (VPC), was developed to study memory without requiring the subject to make a conscious response. Subjects are first shown a picture of a stimulus item (e.g. an object); after a delay, they are shown the same image paired with a novel image. By measuring the length of time the subject looks at a stimulus (by recording their eye movements) one can show that normal subjects spend more time looking at a novel stimulus than a familiar one (McKee & Squire, 1993). Young monkeys spend longer looking at a novel stimulus than aged monkeys (Eriksson & Barnes, 2003).

Like aging humans, there is also considerable variability in the performance of aging monkeys. Among the oldest animals there are subjects who perform within the range of younger animals, even though the mean performance of the group declines significantly. For example, on DNMS, the number of trials to criterion ranges from 50 to 220 and the number of errors range from 29–60. Among the older monkeys, the trials to criterion range from 200–516 and the number of errors range from 50 to 115.

Memory in rodents

Since rats can be trained on tasks that are almost identical to those given to monkeys, parallels between the two species are clear. When young, middle-aged and elderly rats are tested on the delayed non-matching to position task, older rats show age-related deficits with increasing delay intervals (Dunnett *et al.*, 1988). Aged rats show less exploration than young rats in a task that is similar to the Visual Paired Comparison task (Cavoy & Delacour, 1993). Aged rodents are also impaired, relative to young and middle-aged rats, on the Morris water maze (Gallagher *et al.*, 1993), in which animals are required to find a platform that is submerged under water, after having first learned its location when it was visible (Morris, 1981). These deficits are highly stable over time, when a specific combination of learning trials and probe trials are used. Moreover, as with humans, there is considerable variability in performance

among older animals. A substantial subgroup shows age-related declines in performance, but some aged animals perform on a par with young animals (Gallagher & Rapp, 1997).

Executive function

The complex set of abilities sometimes referred to as “executive functions” include abilities such as: abstraction, maintenance of set, shifting of set, and cognitive flexibility. The term “executive function” derives from the fact that these abilities play a major role in problem solving, planning and adaptation to one’s environment.

Executive function in humans

Tests evaluating concept formation and set shifting uniformly show significant changes with age, primarily when subjects are in their late 60s or 70s. For example, the similarities subtest of the Wechsler Adult Intelligence Scale (WAIS), which asks subjects to identify how two objects (e.g. a table and a chair) are similar to each other, is the subtest on the Verbal scale of the WAIS that shows the greatest decline with age (Heaton *et al.*, 1986). Education appears to be a modifier of this decline, in that subjects with lower amounts of education demonstrate declines at younger ages; however, all subjects in the oldest group (mean age 68 years), regardless of educational level, show significant declines in performance.

Series completion tests also show substantial age declines. These tests generally require the subject to examine a series of letters or numbers and determine the rule that governed the sequencing of the items in the series. Cross-sectional and longitudinal data demonstrate age-related declines on tasks of this sort (e.g. Lachman & Jelalian, 1984; Schaie, 1983).

Proverb interpretation tests, which require the subject to provide the general meaning of a proverb (e.g. “barking dogs seldom bite”), also demonstrate age-related declines (Albert *et al.*, 1990). This is true whether or not subjects are asked to provide the meaning of the proverb themselves or are given alternate choices among which to choose. Similarly, set shifting tasks, such as the Visual-Verbal test (in which subjects are asked to look at a series of cards and indicate how three of the four objects on each card are alike in one way, and then how three of the objects are alike in another way), also show substantial age-related declines. These changes appear to be related to the fact that older subjects have difficulty switching from one abstract answer to another (i.e. they tend to get the first item in the set correct but the second one wrong). Slowness in establishing mental set (i.e. getting the first item in the set wrong but the

second one right) and failure to establish set (i.e. getting both items in the set wrong) did not increase differentially with age (Albert *et al.*, 1990).

Executive function in monkeys

Changes in executive function in monkeys have been examined primarily by using reversal learning paradigms (Bartus *et al.*, 1979; Rapp, 1990), or a form of delayed response (Bachevalier, 1993). Reversal learning involves responding to a change in reinforcement contingencies by first “unlearning” or breaking the initial stimulus-reinforcement bond, and then acquiring, or “shifting” to a new one. In this way, reversal learning can be considered a measure of executive function. Data have accumulated to suggest that aged monkeys have difficulty in reversing established stimulus-reward contingencies, particularly when based on spatial location. Thus, compared to young adult monkeys, aged monkeys, as a group, are impaired on spatial, but not on object reversal learning (Lai *et al.*, 1995). Moreover, aged monkeys tend to make more perseverative responses than young adults on both spatial and object reversal learning.

Recently, a task called the Conceptual Set Shifting Task (CSST) was developed for non-human primates, as an equivalent of the Wisconsin Card Sorting task in humans (Moore *et al.*, 2003). In the monkey version, a pattern of responding is developed on the basis of rewards for responses to a specific visual pattern, the animal maintains this response pattern for a while, and then the reward contingency changes. One can therefore examine the number of errors prior to attainment of the initial “abstraction rule”, as well as the number of perseverative responses after the rule changes. Aged monkeys are impaired, in comparison to young, on both the concept formation and set shifting aspects of the task (Moore *et al.*, 2003).

Imaging studies of age-related changes in cognition

Recent advances in brain imaging have begun to provide insights into the changes in brain structure and function that underly age-related changes in cognition. These include studies using magnetic resonance imaging (MRI) scans, as well as positron emission tomography (PET) and functional MRI (fMRI).

Structural imaging – MRI

MRI studies of healthy adults across the age range have shown that, regardless of the sequence type, overall brain volume shows a decrease with age, while the amount of

Fig. 25.1 An example of a structural MRI (a) in a healthy young and (b) healthy older individual. H-hippocampus, TH-thalamus, SC-suprasellar cistern.

CSF increases, even if individuals are healthy (Christiansen *et al.*, 1994; Coffey *et al.*, 1992; Harris *et al.*, 1994; Jernigan *et al.*, 1990, 1991; Lim *et al.*, 1992; Murphy *et al.*, 1992; Matsumae *et al.*, 1996; Pfefferbaum *et al.*, 1994; Tanna *et al.*, 1991) (see Fig. 25.1).

The volume of brain tissue decreases with advancing age. Several structural MRI studies have shown that the prefrontal cortex undergoes disproportionate shrinkage as people get older (Raz *et al.*, 1998; Resnick *et al.*, 2003). The largest declines in volume are seen in the lateral prefrontal cortex (Tisserand *et al.*, 2002). Studies using diffusion tensor imaging have also shown selectively greater declines in white matter tracts in the prefrontal cortex (Head *et al.*, 2004). These findings are consistent with the theory that normal aging is associated with declines in frontal-striatal systems (see Hedden & Gabrieli, 2004). The underlying neurobiological alterations responsible for this brain atrophy is, however, unlikely to be neuronal loss, as discussed below.

Functional imaging – PET and fMRI

One of the most important innovations for the study of brain–behavior relationships has been the development of functional imaging, initially using PET and more recently fMRI. In PET scanning, a radioactive isotope is either injected or inhaled by the subject, and the scanning machine evaluates the differential decay of radioactivity in order to assess regional changes in blood flow in the brain. The blood flow is considered a surrogate for neuronal activity. Likewise, fMRI uses the magnetic qualities of water molecules to evaluate the differential distribution of oxygenated blood in the brain, and the ratio of oxygenated

to deoxygenated blood is thought to be an indirect measure of neuronal activity. Since fMRI does not involve exposure to radioactivity, and measurements are closer to real time, many investigators who previously employed PET are turning to fMRI.

To obtain information about how the brain performs cognitive tasks, these imaging techniques are combined with cognitive paradigms, which produce a range of brain activations. Through careful design of such paradigms, it becomes possible to obtain information about the brain regions that are involved in a specific cognitive activity. Perceptual and emotional experience can also be interrogated in a similar manner. When such functional imaging procedures are combined with structural imaging, one can obtain data with highly accurate anatomical detail. The newest of these approaches, fMRI, provides such information in close to real time (i.e. the latency between stimulus onset and fMRI response is typically 2 seconds).

The most important general concept to emerge from such studies is that multiple brain regions are essential for encoding or retrieving new information. Moreover, some of the brain regions that appear to be integral to “memory networks” have not been easy to evaluate by other imaging modalities. The most important in this regard is the frontal lobes, which are activated during both encoding and retrieval in normal young individuals (Kapur *et al.*, 1994, 1996; Demb *et al.*, 1995; Fletcher *et al.*, 1995; Wagner *et al.*, 1998a; Madden *et al.*, 1999; Buckner *et al.*, 1999).

The hippocampus, known to be essential for normal memory based primarily on lesion studies (Squire *et al.*, 1988), was initially more difficult to activate than many other brain regions, for reasons that are not entirely clear.

Nevertheless, many recent PET and fMRI studies have shown that significant activations of the hippocampus may be demonstrated when an individual is attempting to learn or retrieve new information. (Schacter & Wagner, 1999; Gabrieli *et al.*, 1997; Brewer *et al.*, 1998; Martin *et al.*, 1997; Stern *et al.*, 1996; Wagner *et al.*, 1998a), as is the prefrontal cortex (e.g. Haxby *et al.*, 1996; Wagner *et al.*, 1998b).

The most consistent finding to emerge from PET and fMRI studies of aging is that there are alterations in the activation of the frontal lobes during encoding and/or retrieval of new information (e.g. Cabeza *et al.*, 1997, 2000; Hazlett *et al.*, 1998; Grady *et al.*, 1999; Stebbins *et al.*, 2002; Logan *et al.*, 2002). Some have found increased activity, while others have found decreases. The increases in prefrontal activity are often observed in areas contralateral to those activated in the young. This has been interpreted as evidence of age-related reductions in hemispheric asymmetry (Cabeza, 2002).

An age-related reduction in hippocampal activation has also been demonstrated during episodic memory tasks, but the differences are much less striking than what is seen in the frontal lobes. Reductions have been seen primarily in the left parahippocampal gyrus (Daselaar *et al.*, 2003; Morcom *et al.*, 2003).

Taken together, these findings indicate that normal memory function requires integrated activation of a network of brain regions that involves the hippocampus and the prefrontal cortex. It has been hypothesized for some time that alterations in frontal systems play a major role in cognitive changes with age (Albert & Kaplan, 1980), and the recent imaging findings cited above, support this hypothesis. It has been hypothesized that the functional impact of these changes is that elderly subjects, in comparison to young, use differing strategies to perform memory tasks (e.g. Cabeza, 2002; Rosen *et al.*, 2002). This is consistent with numerous previous reports showing that elderly individuals are less likely to spontaneously use mnemonic strategies than the young, when trying to learn new information (for reviews see Craik, 1977; Arenberg & Robertson-Tchabo, 1977). An alternative possibility is that the same strategy is being applied in different ways by the two age groups. (For a more detailed discussion of hypotheses regarding age-related alterations in frontal systems and their impact on cognition see Hedden & Gabrieli, 2004 and Tisserand & Jolles, 2003.)

It should also be noted that some investigators have reported differences between the young and the elderly in hemodynamic response (D'Esposito *et al.*, 1999, 2003). While the nature of these changes is still controversial, ranging from the possibility of decreased hemodynamic response (and therefore signal change) in the elderly, to increased noise with no absolute reduction in the magni-

tude of signal change, it is possible that these differences are, at least in part, responsible for some of the fMRI differences between healthy young and older individuals.

Changes in motor function with age

As people get older, they also have increasing difficulty with mobility, including the ability to perform common tasks, such as walking, rising from a chair, or regaining balance when it has been disturbed. Although there are age-related changes in muscle reaction time, proprioception, range of motion and muscle strength and power, it is the latter that appears to be most strongly related to declines in mobility.

Several factors related to muscle strength decline with age, even in healthy and physically active older adults (Schultz, 1992). Many of these declines are related to the ability to recover one's balance after some perturbation, and thus are likely related to falls. There is a decline in muscle strength of approximately 30% by age 65 (with women having less strength than men at all ages, even when normalized for body size). For example, hip flexor muscles, that are critical for recovery of balance, decline with age. There is also a decline in fast motor units with age, which are important for hip flexion. Joint torque (or the strength developed about a joint) is also necessary for the restoration of balance after instability. Healthy older adults are slower to develop joint torque than young adults, and older women are slower than older men. Declines also occur in the ability of muscles to produce power. For example, well-trained runners over 70 years of age are 30% slower than younger runners with equivalent training. Healthy rodents, likewise, show a decline in muscle output with advancing age. Impairments in muscle strength also affect the ability to rise from a chair. Taken together, these findings suggest that it is important to assess and train muscle power in order to maintain muscle function that is critical for a variety of daily activities (Ashton-Miller & Alexander, 2003).

Despite the fact that there are systematic increases in reaction time as people get older, it has been argued that these are not sufficient to interfere with rapid responses in time-critical situations. For example, healthy older adults require about 400 ms to fully contract a muscle and 200–400 ms to take a quick step. However, myoelectric reaction times (or the time from the stimulus cue to the first measurable change in electrical activity in a muscle) are about 10–20 ms longer in healthy older adults than in young adults. Likewise, movement-to-target reaction times increase about 2 ms per decade from the 20s to the 90s. Thus, these differences are not considered critical for mobility function (Ashton-Miller & Alexander, 2003).

A number of studies have shown that body joint range of motion decreases with advancing age. For example, there is a 20% decline in hip rotation between the ages of 45 and 70, and a 10% decline in wrist and shoulder range of motion. These types of decreases appear related to limitations in activities of daily living. The ability to bend down correlates with hip flexion range of motion and ability to do activities involving the hands and arms correlates with range of motion of these upper extremities.

Studies of proprioception (one's awareness of body position and orientation) have shown slight decreases in joint position sense in the knee and declines in vibration sense. As these studies are few in number, it remains unclear if these declines have functional consequences.

Among adults free of overt disease, there are also changes in gait (Odenheimer *et al.*, 1994). After approximately aged 60, self-selected gait speed (i.e. comfortable gait) declines by 1–2% per year. Most of the decline in speed is attributable to a decline in stride length. Muscle strength may be a factor in this decline in gait speed as well, since walking speed is related in a non-linear fashion to leg muscle strength (Buchner *et al.*, 1996). Reductions in gait speed do not appear to be related to falls, but increases in stride time variability are associated with a five times greater risk of falls.

Finally, there are changes in postural control with advancing age that have a functional impact in daily life. Postural tasks that are demanding (e.g. standing on one leg with eyes open) show declines by aged 50 (Bohannon *et al.*, 1984). Postural tasks that are relatively undemanding (e.g. standing on two feet with eyes open) show minimal changes until aged 70, and decrease thereafter.

Thus, the primary age-related changes that have substantial impact on function are alterations in gait and postural control. The reasons for these changes are not entirely clear, but it has been hypothesized that age-related decreases in dopamine play an important role (Odenheimer *et al.*, 1994). These declines in dopamine also appear to play a role in cognitive changes with age, as described below.

Underlying neural mechanisms that contribute to age-related changes in cognitive and physical function

Neuronal number

Given the cognitive and motor changes discussed above, it is striking that the wealth of recent morphological data in humans (Haug, 1984; Leuba & Garey, 1989; Terry *et al.*, 1987), indicate that, with advancing age, neuronal loss in

the cortex is either not significant or not as extensive as reports prior to 1984 had suggested (Brody, 1955, 1970; Colon, 1972; Shefer, 1973; Henderson *et al.*, 1980; Anderson *et al.*, 1983). While large neurons appear to shrink, few are lost (Terry *et al.*, 1987).

There are, in addition, comparable data in monkeys. Minimal neuronal cortical loss with age in monkeys has now been demonstrated in the striate cortex (Vincent *et al.*, 1989), motor cortex (Tigges *et al.*, 1992), frontal cortex (Peters *et al.*, 1994; O'Donnell *et al.*, 1999), and the entorhinal cortex (Amaral, 1993). These general conclusions have been reached not only on the basis of a comparison of counts of neurons in young (5 to 6 years) and old (over 25 years of age) monkeys, but also on the basis of an examination of the cortical tissue by electron microscopy (Peters *et al.*, 1994). Beyond an accumulation of lipofuscin granules in the cell body of some neurons and some cellular debris in neuroglial cells, there is very little evidence of changes with age in the neurons of these cortical regions (Peters *et al.*, 1991). Morphological studies in rodents have reported comparable findings (Rapp *et al.*, 2000).

The weight of the evidence from postmortem studies also supports the conclusion that the hippocampus shows minimal structural change with advancing age. The postmortem data in humans and monkeys indicate that neuronal loss is surprisingly low in most subfields of the hippocampus. For example, the subiculum shows a significant age-related loss in humans, with a similar trend in monkeys, however, the CA1, CA2 and CA3 subfields of the hippocampus show no evidence of age-related neuronal loss (Amaral, 1993; Rosene, 1993; West *et al.*, 1994; Gomez-Isla *et al.*, 1996). Equivalent data have been reported in rodents, where it has been shown that even in the subset of animals with declines on a memory task, there was no decrease in the number of neurons in the various hippocampal subfields (Rapp & Gallagher, 1996; Rapp *et al.*, 1999). (See Morrison & Hof, 1997 for a more detailed discussion of these issues.)

Neuronal loss and neurotransmitter changes

There is substantial neuronal loss in selected subcortical regions that is likely responsible for decreases in the production of neurotransmitters important for cognitive function, such as in the basal forebrain and the locus coeruleus (e.g. Chan-Palay & Asan, 1989; Rosene, 1993). For example, in humans and monkeys there is approximately a 50% neuronal loss with age in the basal forebrain and 35–40% loss in the locus coeruleus and dorsal raphe (Kemper, 1993). This compares with an approximate loss of 5% in the CA1 subfield of the hippocampus. The neuronal loss in these

subcortical nuclei may be very important for memory function, as these brain regions influence the production of several neurotransmitters important for memory (such as acetylcholine, dopamine and serotonin). Though subcortical, these nuclei have extensive connections with the cortex, and thus are responsible for the level of many neurotransmitters within the cortex. For example, treatment of rhesus monkeys with a D2 receptor agonist improves performance on a delayed memory task in aged monkeys (Arnsten *et al.*, 1995). As mentioned above, age-related declines in dopamine may also play a role in the alterations in motor function seen with advancing age.

Synaptic integrity

Even though there does not appear to be enough neuronal loss to account for age-related cognitive change, there are changes in other aspects of neuronal function, specifically the number and/or function of synapses. Most of the studies that have explored this question with respect to aging pertain to learning and memory in rodents. It has been demonstrated that there are synaptic changes in the CA3 region of the hippocampus when one compares older rodents who are memory impaired with younger rodents (Smith *et al.*, 2000). Specifically, older rodents with spatial learning deficits display significant reductions in synaptophysin immunoreactivity in the CA3 region of the hippocampus, but not in other subfields. This region receives its input from layer II of the entorhinal cortex. Thus, it has been hypothesized that there are circuit-specific changes involving the entorhinal input to CA3 that influence the computational function of the hippocampus and are thereby related to age-related memory change (Smith *et al.*, 2000). There are, in addition, alterations in long-term potentiation and long-term depression in aged rodents with learning deficits (Barnes, 2003; Norris *et al.*, 1996), and alterations in at least one receptor type (i.e. NMDA receptors) (Gazzaley *et al.*, 1996; Barnes *et al.*, 1997). These results suggest that the variability seen in memory changes with advancing age among healthy individuals is related to variations in synaptic integrity and activity-dependent synaptic plasticity in specific brain circuits related to learning and memory. (See Rosensweig & Barnes, 2003 for a detailed discussion of this issue.)

Neuronal proliferation in the adult brain

One of the most strongly held dogmas of neurobiology was the concept that once nerve cells were formed they could only die. There was no such thing as endogenous neuronal replacement. There is increasing evidence that concept is

incorrect. The work of Altman over 30 years ago suggested that, in the rodent, neurogenesis could continue in selected regions of the brain into adulthood, particularly the dentate region of the hippocampus, the olfactory and cerebellum (Altman & Das, 1965). In recent years, this issue has been revisited in rodents and there is ample evidence, based on the DNA marker, bromodeoxyuridine, that neurogenesis occurs in the hippocampus and olfactory system. Similar findings have also been demonstrated in monkeys (Kornack & Rakic, 1999; Gould *et al.*, 1999), and even in the human (Eriksson *et al.*, 1998).

In the dentate gyrus of the macaque monkey, labeled cells are thought to proliferate in the border zone between the hilus and granular cell layer, and then to migrate and differentiate in the granule cell layer. The proliferation of new neurons decreases with age. In the rodent there appears to be a gradual increase in total numbers of neurons; in primates, such an accumulation is less certain. It has been suggested (Kornack & Rakic, 1999) that the number of neurons in the hippocampus is constant, but with a fixed replacement rate – neurogenesis balanced by the rate of apoptosis and cell removal.

The source of these new neurons may be pluripotential stem cells. In the rodent it has been shown that physical activity stimulates this neurogenesis from stem cells (Kemperman *et al.*, 2000). Since pluripotential stem cells have been identified in areas other than the hippocampus, where neurogenesis has not been demonstrated to occur normally, investigators are exploring ways to cause these cells to produce new neurons. This is an active area of research in neurodegeneration.

White matter changes

In addition, age-related alterations in the white matter have recently been described in some detail (Peters *et al.*, 1994; Peters, 1996; Nielson & Peters, 2000). At first glance, the data suggesting loss of white matter in the brain but only loss of synapses (with minimal loss of neurons cortex) can be difficult to understand. Conventional knowledge suggests that white matter consists of the axons of neurons and that if there is a loss of axons, there should be cell death and a substantial loss of grey matter. However, the white matter of the brain is also composed of a number of glial elements, particularly oligodendrocytes. Evidence from the non-human primate suggests that the oligodendrocytes, that are responsible for forming the myelin sheath surrounding the axons, may be less efficient with age. For example, when the oligodendrocytes of young and old monkeys were compared (Peters, 1996) it was found that the myelin sheaths in the old monkeys were abnormal and

appeared to be degenerating. However, when the number of axons in old and young monkeys was compared by the same investigators (Nielsen & Peters, 2000) relatively few degenerating axons were found in the old monkeys. Taken together, these findings suggest changes in myelin, rather than axonal loss, are at least in part responsible for age-related changes in white matter observed with advancing age. As mentioned above, imaging studies in humans suggests that these alterations may be greater in some regions, such as the frontal lobes, than in others. Thus, having a selective impact on cognition.

Implications for clinical evaluation of older persons

As the foregoing review demonstrates, there are significant cognitive and motor changes as people get older. The fact that comparable changes are found among healthy non-human primates and rodents emphasizes the likelihood that they are not the result of a neurodegenerative disorder such as Alzheimer's disease.

Perhaps surprisingly, these changes in function are not associated with frank neuronal loss, but rather with changes in synaptic function and plasticity that have an impact on the integrated function within neuronal networks. These alterations have a clear impact on the learning and retention of new information. It is likely that alterations in executive function are the result of similar age-associated changes.

The practical implication of these findings is that very mild declines in memory and executive function should be considered within the normal range. Very high functioning older persons are often aware of such changes, despite the fact that they do not have an impact on instrumental activities in daily life. This complicates the ability to detect declines that are a harbinger of disease, suggesting that it might be very beneficial to include a simple memory test as part of a routine annual evaluation to improve the ability to detect disease-related declines, if they occur.

The increased prevalence of medical diseases among older individuals adds to the difficulty of conducting a clinical evaluation. The average 75-year-old suffers from at least three chronic diseases. The distinguishing feature of the evaluation of an older person is, therefore, the presence of multiple chronic conditions, each of which must be evaluated and weighed for importance. This is because these diseases often interact, so that clinical manifestations are less straightforward. Some symptoms, such as a cognitive disorder, may result from more than one disease. When

multiple diseases coexist, it is often difficult to assess the severity of one particular disease, and to determine how that disease effects overall functional status. Likewise, the treatment of one disease may make another worse.

There are several additional factors that complicate the clinical evaluation of an older person. First is the under-reporting of symptoms. This may occur because older persons, as well as their physicians, conclude that a symptom which may be treatable is an age-related change for which no treatment is warranted. Cognitive impairment and/or depressive symptoms may also reduce the ability of the individual to accurately report symptoms that are present. Moreover, diseases often present differently in the elderly than in the young. For example, pneumonia or a urinary tract infection may present as confusion. Finally, advancing age brings with it general predisposing factors, such as a gait disorder, which predisposes the individual to an acute disorder (such as fall, which can precipitate a subdural hematoma, causing confusion). It has, therefore, been suggested that evaluation of an older person should focus less on the "chief complaint" and instead on a general review of systems (Tinetti, 2003).

Neuropathology of normal aging in cerebral cortex

John H. Morrison^{1,2}, Patrick R. Hof^{1,2,3}, and Peter R. Rapp^{1,2}

¹Department of Neuroscience ²Department of Geriatrics and Adult Development ³Department of Ophthalmology, Mount Sinai School of Medicine, NY, USA

Introduction

In order to understand the neuropathology of normal aging, it is instructive to review the major elements of circuit degeneration associated with Alzheimer's disease. AD is characterized by senile plaque (SP) and neurofibrillary tangle (NFT) formation and extensive, yet selective, neuron death in the hippocampus and neocortex that leads to dramatic decline in cognitive abilities and memory. A more modest disruption of memory, referred to as mild cognitive impairment (MCI) or age-associated memory impairment (AAMI), occurs often in the context of normal aging, in humans, monkeys and rodents. However, unlike AD, significant neuron death does not appear to be the cause of AAMI. In AD, the neurons providing the connection between the entorhinal cortex and the dentate gyrus (e.g. the perforant path) are devastated, as are the neurons providing corticocortical circuits that interconnect association regions. Whereas the death of these same neurons appears to be minimal in normal aging, these same circuits and the corresponding circuits in animal models are vulnerable to sublethal age-related alterations in morphology, neurochemical phenotype and synaptic integrity that might impair function. Biochemical alterations of the synapse, such as shifts in distribution or abundance of NMDA receptors, may also contribute to memory impairment. The same brain regions are also responsive to circulating estrogen levels, and thus, critical interactions between reproductive senescence and brain aging may affect excitatory synaptic transmission in the hippocampus. Importantly, some of the effects of estrogen on these neurons imply that certain synaptic alterations that accompany aging may be reversible. Thus, the aging spine and synapse may be the key to age-related memory decline, whereas the loss of select cortical circuits is the more prominent substrate for functional decline in AD.

Selective vulnerability in Alzheimer's disease

Overview

Both structurally and functionally, AD is predominantly a disease of the cerebral cortex. However, only certain populations of neurons and circuits are affected, whereas other neuron types are spared. Generally, interneurons are spared whereas pyramidal neurons are vulnerable, yet the vulnerability is confined to key subsets of pyramidal cells. Clues as to which circuits are vulnerable are provided by the distribution of pathologic changes in AD and the correlation with specific elements of cortical circuitry. The vulnerable neurons also have a unique neurochemical phenotype, particularly with respect to cytoskeletal proteins such as neurofilament and tau. Through linking human neuropathology with animal data in experimental preparations, correlations have emerged between distribution of cellular pathologic changes, neurochemical characteristics related to vulnerability, and cortical circuits at risk (for review, see Morrison & Hof, 2002).

Hippocampal pathology in AD

The entorhinal cortex, subiculum, and CA1 within hippocampus represent particularly vulnerable regions that consistently display very high NFT densities and resultant neuron death in AD. The most consistent observation in AD cases is the presence of large numbers of NFT in layers II and V of the entorhinal cortex (Hyman *et al.*, 1984; Morrison & Hof, 1997). The distribution of SP in the hippocampal formation is variable, but often parallels the termination of vulnerable projections, such as a high density of SP in the molecular layer of the dentate gyrus, and the terminal zone of the projection from entorhinal cortex (Hyman *et al.*, 1990). Thus,

the perforant pathway that projects from layers II and III of the entorhinal cortex is severely compromised in AD, as reflected by NFT in the neurons of origin of this pathway and SP in the termination zone in the dentate gyrus (Hyman *et al.*, 1984). Extensive amyloid accumulation in the perforant path terminal zone has also been described in a transgenic mouse model of AD (Reilly *et al.*, 2003).

In the absence of AD, there does not appear to be significant neuron loss in entorhinal cortex (West, 1993; Gómez-Isla *et al.*, 1996; Hof *et al.*, 2003), nor is there loss of neurons in the entorhinal cortex in aged monkeys (Gazzaley *et al.*, 1997). However, a lack of quantifiable neuron loss does not necessarily mean that no degenerative changes are occurring in a given brain region and it does not negate non-degenerative changes that lead to compromised function. For example, while the neurons in layer II of entorhinal cortex are clearly devastated early in AD, their status in cognitively normal aged individuals and those with MCI has been more difficult to pinpoint. Neuron counts in neurologically normal individuals suggest that there is no neuron loss in entorhinal cortex (Gómez-Isla *et al.*, 1996); however, analyses of NFT, the classic reflection of a degenerating neuron in AD, suggest that virtually all humans over the age of 50 have some NFT in layer II of entorhinal cortex (Bouras *et al.*, 1994), making it difficult to distinguish qualitatively between age-related degenerative events in the entorhinal cortex that represent early progressive AD and those that are more stable. This distinction is critically important for patients with MCI where it is unclear whether their condition represents early AD or a more stable level of AAMI. The key to understanding the presence of NFT in this region lies in the “transitional neurons”, i.e., neurons that are still intact and included in an analysis of total neuron counts, yet have transitional intraneuronal pathology (Hof *et al.*, 2003). When neurons in layer II of entorhinal cortex are counted in three categories – ghost tangles, transitional neurons containing an intracellular NFT, and healthy neurons – the data are far more revealing with respect to early pathologic events in layer II of entorhinal cortex. Such transitional neurons may represent only 10% of the total in layer II of patients with MCI, but the majority of neurons in AD. However, the degree to which such “transitional” neurons are functional or able to be rescued is unclear, yet important to determine as interventions are introduced. Even a more precise delineation of the events surrounding degeneration will not provide a full understanding of the vulnerability of this circuit, because as described below, this circuit displays age-related changes short of degeneration that would also impact its function. In addition, as described below, the fully developed dementia of AD is unlikely to result from even mass destruction

of this circuit, if it occurs in the absence of neocortical involvement.

Neocortical pathology in AD

Lesion types and cortical distribution

The distribution and density of NFT and SP have been analyzed in great detail and constitute the basis of the neuropathologic diagnosis of AD (Arnold *et al.*, 1991; Mirra *et al.*, 1993). NFT are characterized by the accumulation of abnormal components of the neuronal cytoskeleton that form paired helical filaments, whereas SP are composed of dystrophic neurites and glial elements with or without a central amyloid core (Hof *et al.*, 1999). Both lesions are predominant in the cerebral cortex, where NFT are located in the perikarya of large pyramidal neurons, and SP are distributed throughout the cortical regions, but are particularly numerous in association areas (Rogers & Morrison, 1985; Arnold *et al.*, 1991; Hof *et al.*, 1999).

These visible reflections of pathology are particularly important in the degree to which each of them reflects neuron or synapse loss that amounts to the circuit disruption underlying dementia. Considerable neuronal loss occurs in the association regions of the neocortex in AD, leaving primary sensory and motor areas relatively spared (Morrison & Hof, 1997). Many studies of NFT and SP distribution have demonstrated strong correlations between the regional and laminar distribution of SP and NFT, and the presumed neurons of origin of certain long corticocortical and hippocampal projections (Pearson *et al.*, 1985; Rogers & Morrison, 1985; Hyman *et al.*, 1986; Lewis *et al.*, 1987; Hof *et al.*, 1990; Hof & Morrison, 1990). Overall, the distribution and severity of neuron loss follows closely that of NFT in the neocortex (Gómez-Isla *et al.*, 1996, 1997; Morrison & Hof, 1997). The regional and laminar distribution of SP suggests that they may be related to NFT formation. It has been proposed that SP reflect the degeneration of the terminations of projections from neurons that contain NFT (Pearson *et al.*, 1985; Lewis *et al.*, 1987; Vickers *et al.*, 2000), and that the slightly higher incidence of SP in the supragranular layers and in layer IV in the association cortex reflects the involvement of feedforward corticocortical projections (Lewis *et al.*, 1987). It is likely that degeneration of presumed corticocortical circuits within the neocortex is required for the clinical expression of dementia in AD (Morrison & Hof, 1997), since elderly individuals can maintain a high level of cognitive performance though with accompanied memory deficits, while sustaining significant compromise of hippocampal circuits. Thus, they

may rely more on neocortical than on hippocampal circuits for memories essential for daily activities (Albert, 1996).

Neurofilament protein is a marker of neuronal vulnerability in Alzheimer's disease

Certain pyramidal neurons in the neocortex of both human and monkeys have been shown to be enriched in nonphosphorylated epitopes of neurofilament protein (Campbell & Morrison, 1989; Hof *et al.*, 1990; Hof & Morrison, 1990, 1995). This pattern in the primate neocortex is restricted to the perikarya and dendrites of a subpopulation of large pyramidal neurons and is more concentrated in the cell body and dendrites of the largest of these neurons (Campbell & Morrison, 1989). Neurofilaments as well as other cytoskeletal proteins have been implicated in NFT formation (Morrison *et al.*, 1987; Trojanowski *et al.*, 1993; Morrison & Hof, 1997; Hof *et al.*, 1999), and pyramidal cells with a high content of non-phosphorylated neurofilament protein emerge as a neuron type highly susceptible to NFT formation (Bussière *et al.*, 2003).

The distribution of neurofilament protein-enriched neurons corresponds to the distribution of corticocortically projecting cells as demonstrated by transport studies in the macaque monkey cortex (Hof *et al.*, 1995, 1996, 1997; Nimchinsky *et al.*, 1996). Of direct relevance to AD, we have shown that, in the macaque monkey, many long association corticocortical projections originate from neurofilament protein-enriched neurons, and that in circuits interconnecting key prefrontal and temporal regions, 90–100% of the neurons of origin of the projection are neurofilament-enriched (Hof *et al.*, 1995). These circuits are known to be involved in networks subserving many aspects of cognition (Goldman-Rakic, 1988).

In AD, neurofilament protein-enriched neurons in certain neocortical and hippocampal areas are dramatically affected and die through NFT formation (Morrison *et al.*, 1987; Hof *et al.*, 1990; Hof & Morrison, 1990; Vickers *et al.*, 1992, 1994; Morrison & Hof, 1997; Vickers, 1997; Vickers *et al.*, 2000). The laminar distribution of neurofilament protein-enriched neurons in visual association, prefrontal, and anterior cingulate cortices in human is very similar to the distribution of NFT. Furthermore, the layers that have high NFT density in an AD brain no longer contain a high density of neurofilament protein-immunoreactive neurons (Hof *et al.*, 1990, 1999; Hof & Morrison, 1990). If the monkey data are considered within the context of the distribution of neurofilament protein-enriched neurons and NFT in human, it is likely that the human homologues of the neurofilament protein-enriched corticocortically projecting neurons in the macaque monkey are those that are highly vulnerable in human AD.

To test this correlation more directly in human aging and AD, we targeted layer III of area 9 as a focus for quantitative analysis in which total neuron counts were obtained, as well as NPNFP-immunoreactive neurons with no trace of tau accumulation and NPNFP-immunoreactive neurons with tau accumulation. All profile counts were correlated with clinical assessment as reflected in the Clinical Dementia Rating Scale (CDR). A CDR rating of 0.5 amounts to MCI, CDR 1 reflects probable AD, CDR 2 is mild AD, CDR 3 is moderate AD, and CDR 5 is severe AD (Hof *et al.*, 2003). The most recent data obtained indicate that, in area 9, neurofilament protein-enriched pyramidal cells are unaffected in CDR 0.5 cases, yet undergo notable tau accumulation in CDR 2 cases, and virtually all neurofilament-enriched neurons are in the process of degenerating by CDR 3 (Fig. 26.1) (Bussière *et al.*, 2003). However, the remaining non-neurofilament labelled neurons remain relatively unaffected even with well-established AD. This result suggests that tangle formation affects a well-defined subset of neurons, and CDR 2, which corresponds to mild AD, represents the clinical transition stage at which this subset of highly vulnerable neurons is profoundly affected (Hof *et al.*, 2003) in the prefrontal cortex.

Summary: AD and cortical circuitry

The relevance and impact of pathologic changes in AD have to be understood within the context of organized systems that underlie neocortical function. For instance, integrated processing in a given sensory modality such as vision involves the simultaneous activity of numerous separable visual areas that have extensive highly ordered interconnections that establish a distributed system subserving the proper integration of visual information. Similarly, cognition and language, which are not modality-specific functions, presumably depend strongly on the complex communication among neocortical regions provided by the corticocortical circuits which degenerate in AD, leading to a global neocortical disconnection syndrome that presents clinically as dementia (Morrison & Hof, 1997). Other degenerative processes occur in AD, and they may also contribute to the clinical characteristics of the disease, but the generalized loss of long corticocortical projections emerges functionally as the most devastating component of AD, and the pathologic outcome most directly related to dementia.

This interpretation of the pathological features of AD suggests that the debilitating dementia results from changes restricted to the association neocortex, whereas extensive hippocampal alterations can exist in absence of neocortical involvement and with only minor disruptions in

activities of daily living of the individual, whose memory deficits could be revealed by formal testing, but are not compatible with the diagnosis of dementing illness. As the elements of the biochemical and anatomical phenotype that are linked to differential cellular vulnerability in AD are increasingly recognized, hopefully it will be possible to develop therapeutic interventions to protect or rescue the neurons that are at high risk in AD. The protection of these neurons appears to be an attractive strategy for the management of AD, that may have the advantage of being more achievable than the development of a cure.

Age-associated memory impairment: functional decline without neuron loss

While NFT and SP are also present in the brains of humans without clinical AD, their presence is not associated with measurable neuron loss. While layer II of entorhinal cortex shows some pathology in virtually all humans over 55 years old (Bouras *et al.*, 1993, 1994), it is not sufficient to register as decreased neuron number in neurologically normal elderly subjects. In addition, CA1 and other hippocampal fields as well as neocortex do not display significant neuron loss in normal aging. If neuron loss cannot account for memory loss with aging in this population, then what is the neurobiological complement of such functional decline? Insight on this issue has been gained from animal studies of aging, where AAMI can be analyzed without the potential confound of early AD. Studies from both non-human primates and rodents have illuminated both neocortical and hippocampal changes associated with aging. These studies (reviewed below) suggest that age-related changes in key excitatory synaptic connections in the absence of frank circuit degeneration may be the primary neurobiological correlate of AAMI.

The aging synapse: non-human primate studies

Morphologic analyses of corticocortical circuits

As described above, a distinct subpopulation of neurons forming long corticocortical projections in the association neocortex is highly vulnerable to the degenerative process in AD (Lewis *et al.*, 1987; Morrison & Hof, 1997). However, the degree to which age-related molecular and morphologic alterations of these same circuits might lead to functional decline has not been investigated until recently. Whereas, no neuronal loss in neocortex is observed in the course of normal aging in non-human primates (Peters *et al.*, 1998b), significant cognitive

Fig. 26.1 Typical immunohistochemical patterns observed with an antibody to non-phosphorylated neurofilament protein (SMI-32, red fluorescence) and phosphorylated tau (antibody 988, green fluorescence). (A) Large SMI-32-immunoreactive neurons are seen in layer IIIc of a CDR 0.5 case with many neuropil threads but no NFT. Panels (B–D) display neurons with different degrees of NFT formation. Two intracellular NFT are seen in a CDR 2 case (layer IIIc; B). The tangled neuron in panel C shows faint immunoreactivity in its apical dendrite (arrows; CDR 2, layer Va). Panel D shows a large endstage NFT next to intact SMI-32-immunoreactive neurons (CDR 2, layer IIIc). Scale bar (on D) = 30 μ m. (Adapted from Bussière *et al.*, 2003.)

changes can be observed in animals older than 19 years of age (Gallagher & Rapp, 1997). Are the same corticocortical circuits that degenerate in human AD vulnerable to subtle alterations in normal aging? Electron microscopic investigations have demonstrated consistent changes in oligodendrocyte and axonal myelin sheath morphology in aged non-human primates (Peters *et al.*, 1996, 1998a, 2000), pointing to the possible involvement of certain cortical projection systems in aging. Several studies indicate that the cognitive processes mediated by the prefrontal cortex are impaired during the normal aging processes (Bartus *et al.*, 1978; Bachevalier *et al.*, 1991; Peters *et al.*, 1996; Rapp &

Fig. 26.2 Examples of apical and basal dendritic segments with spines plotted onto them from young and aged animals showing age-related differences in spine density. These neurons provide corticocortical connections between temporal and prefrontal association cortices. The dendritic segments shown are rendered at the same scaling factor. (A) and (B) are from the apical and basal dendritic trees, respectively, of a neuron from a young animal. (C) and (D) are from the apical and basal dendritic trees, respectively, of a neuron from an old animal. There are visible decreases in spine numbers on the apical and basal dendrites in the aged animals. Quantitative analyses of this material showed a 30–40% loss of spines in these neurons with aging. Scale bar (on D) = 20 μm . Adapted from Duan *et al.*, 2003.

Gallagher, 1997; O'Donnell *et al.*, 1999). In particular, aged macaque monkeys show consistently lower performance in delayed response (DR) tasks, which are sensitive to prefrontal cortical damage, when compared to young animals (Rapp & Gallagher, 1997). These and other data indicate that age-related cognitive deficits in nonhuman primates may be a consequence of abnormalities in cortical circuits that clearly do not include loss of neurons but rather involve subcellular compartments. In order to identify potential sublethal circuit-specific alterations, we quantified age-related morphological changes at the single cell level in identified populations of corticocortically-projecting neurons in monkeys (Page *et al.*, 2002; Duan *et al.*, 2003).

Neurons furnishing long corticocortical projections from parietal and temporal regions to area 46 in prefrontal cortex were targeted for these studies. These neurons were targeted through retrograde transport of fluorescent dyes following injections in area 46, followed by intracellular filling and 3-dimensional reconstruction of the retrogradely filled neurons (Fig. 26.2). This approach results in detailed quantitative data on the dendritic arbor and spine density

of the same corticocortically projecting neurons that we hypothesize to be vulnerable to AD in human cortex. Based on the three-dimensional reconstructions of these neurons, indices of dendritic arbor such as total dendritic length and number of dendritic segments were similar across ages, demonstrating that general dendritic morphology and extent in the neurons was not vulnerable to aging. However, aged animals showed a consistent reduction in dendritic spine numbers and densities along the dendritic branches (Fig. 26.2). Total spine number on these corticocortically-projecting neurons decreased by approximately 35% in the basal and apical dendrites of aged animals compared to young ones. The spine densities per μm of dendritic length decreased by about 25% overall and this decrease occurred throughout the entire dendritic arborization on apical dendrites and was more pronounced on distal dendrites in the basal dendrites (Page *et al.*, 2002; Duan *et al.*, 2003).

The observed change in spine numbers may lead to a potential deficit in the excitatory drive on the neurons that receive these inputs, leading to cognitive deficits such as those described in aged monkeys in the absence of neuron loss. These neurons also show decreases in glutamate receptors with aging (Hof *et al.*, 2002), which is a further reflection of alterations in excitatory inputs to these neurons with aging, and is excitatory related to the spine loss.

Circuit-specific shifts in NMDA receptors in hippocampus of aged monkeys

Spatial memory is vulnerable to aging (Gallagher & Rapp, 1997), and is also disrupted by pharmacological blockade of NMDA receptor function (Kentros *et al.*, 1998) or hippocampal knockout of NR1 (Tsien *et al.*, 1996). NMDA-receptor mediated functions such as maintenance and induction of long-term potentiation and maintaining stability of spatial information coding by “place cells” are compromised in aging (Barnes *et al.*, 1997). Given the selective vulnerability displayed by both neocortical and hippocampal circuits in aging and AD, high resolution analyses of receptors can be particularly informative, since the changes are very likely to be cell, circuit, and synapse specific and therefore difficult to resolve at the regional level.

Age-related shifts in NR1, the obligatory subunit of the NMDA receptors, in the molecular layer of the dentate gyrus have been reported in monkeys (Gazzaley *et al.*, 1996a). The projection from entorhinal cortex to the dentate gyrus is strictly confined to the outer molecular layer (OML), i.e. to the distal dendrites of granule cells, whereas other excitatory inputs terminate in a non-overlapping fashion in the inner molecular layer (IML), on the proximal dendrites (Witter & Amaral, 1991). This quantitative

Fig. 26.3 Scatter plots relating individual spatial learning index scores to levels of hippocampal synaptophysin-immunoreactivity (SYN-IR) in young and aged rats. Lower learning index scores, indicative of better learning, correlated with higher SYN-IR intensity values selectively in the dentate gyrus MML, OML, and CA3-LM, all termination zones for the perforant path. The statistical correlations refer to the relationship between individual performance and SYN-IR for the aged subjects alone. (Taken from Smith *et al.*, 2000.)

analysis demonstrated that aged monkeys, compared to young adult monkeys, exhibit a decrease in the fluorescence intensity for NR1 in the OML of the dentate gyrus as compared to the IML. Given the tight laminar organization of these circuits, this suggests that the decreased NR1 levels primarily affect the input from the entorhinal cortex, pointing to the entorhinal cortex input to the hippocampus as a key element in age-related changes. Parallel qualitative and quantitative studies with antibodies to AMPA and kainate subunits demonstrated that the intradendritic alteration in NR1 occurs without a similar alteration of non-NMDA receptor subunits. Further analyses, using markers for presynaptic terminals and dendritic markers demonstrated that the circuit is not grossly interrupted in these aged monkeys. These findings suggest that the intradendritic distribution of a neurotransmitter receptor can be modified in an age-related and circuit-specific manner.

Age-related changes in rat hippocampus

While neuroanatomic datasets and behavioral datasets can be compared across experiments, it is most powerful when the neuroanatomic and cellular analyses are done in the same animals that have been behaviorally characterized. This approach is also useful for behavioral screening of aged animals, so that the behaviorally impaired aged animals can be considered as a distinct group from those that are not behaviorally impaired (Gallagher & Rapp, 1997; Peters *et al.*, 1998a). This interdisciplinary approach has been applied with great success to the rat hippocampus and aging, and has led to the conclusion that, just as in AD in humans and aging in monkeys, the projection from entorhinal cortex to

dentate gyrus (i.e. the perforant path) is highly vulnerable to aging and directly linked to age-related memory defects.

Recently, a comprehensive analysis of several synaptic indices was performed in the hippocampus of behaviorally characterized young and aged rats (Smith *et al.*, 2000; Adams *et al.*, 2001). Young and aged rats were tested on a hippocampal-dependent version of the Morris water maze that reveals substantial variability in spatial learning ability among aged rats (Gallagher & Rapp, 1997). A quantitative confocal method was used to quantify changes in immunofluorescence staining for the presynaptic vesicle glycoprotein, synaptophysin, which is an established marker for presynaptic terminals and is required for synaptic release. Individual differences in spatial learning capacity correlated with levels of synaptophysin staining in three of the regions examined; the OML and MML of the dentate gyrus, and the CA3 stratum lacunosum-moleculare (Fig. 26.3). These changes in relative synaptophysin immunofluorescence intensity occur in the absence of any evidence of structural degeneration of the innervated dendrites, and thus would affect synaptic transmission perhaps through compromised glutamate release rather than degeneration of pre- or postsynaptic elements. Most importantly, all three of the regions displaying decreased levels of synaptophysin expression receive a major projection from layer II of entorhinal cortex, offering further evidence that this circuit is exquisitely sensitive to aging. These findings suggest that circuit-specific alterations in glutamate release in the rat hippocampus may contribute to the effects of aging on learning and memory, in the absence of frank degeneration.

In these same animals, the AMPA receptor subunit, GluR2, and the NMDA receptor subunit NR1 were investigated as well, to determine whether or not postsynaptic

shifts in receptors such as those observed in monkey (Gazzaley *et al.*, 1996b) might also be occurring in the context of aging that would further impact the functional status of the entorhinal inputs to dentate gyrus and CA3 (Adams *et al.*, 2001). There was no statistically significant decrease in NR1 directly associated with age-related memory impairment in rat hippocampus, although there was a direct correlation between NR fluorescence intensity and behavioral performance across all animals. While these studies require extensive ultrastructural analysis to confirm the synaptic nature of the receptor changes, it appears that both pre- and postsynaptic proteins (including GluRs) in specific circuits can be correlated with performance under many conditions, including decrements in performance associated with aging.

Interactions between neural and endocrine senescence

One of the most difficult challenges for research on brain aging over the next several decades will be to determine the critical points of interaction and influence between neural senescence and the aging of other systems. For example, it is particularly critical that we understand the interaction of reproductive senescence with the aging of the nervous system. At the turn of the century, the life expectancy of American women was roughly equivalent to the average age of onset of menopause. Currently, there is a 30-year discrepancy between these two demographic indices, with a life expectancy of approximately 80 years and the average onset of menopause remaining in the early 50s, making the issue of endocrine senescence particularly relevant to human aging.

The role of estrogen in controlling the reproductive axis at the level of the hypothalamus has been studied for many years and characterized in great detail (Fink, 1986). However, estrogens also impact synaptic communication in brain regions involved in cognitive processing, such as the hippocampus (Woolley, 1998), and these effects may be of particular importance in the context of aging when both circulating estrogen levels change and hippocampal-dependent functions decline (Sherwin, 2000). However, until recently, our understanding of estrogen effects on synaptic plasticity in the hippocampus was based primarily on data from young animals. For example, dendritic spine density in CA1 pyramidal cells is sensitive to naturally occurring estrogen fluctuations in young animals (Woolley *et al.*, 1990), as well as experimentally induced estrogen depletion and replacement (Gould *et al.*, 1990; Woolley & McEwen, 1992, 1993).

Fig. 26.4 A schematic of estrogen-induced plasticity in young and aged animals. Estrogen treatment increases NR1 expression per synapse in aged hippocampus, whereas it increases spine number but not synaptic NR1 in young female rat hippocampus. Small black dots represent immunogold particles labelling NR1 associated with the postsynaptic density, and open circles are synaptic vesicles. The grey zone indicates the postsynaptic density. (Adapted from Adams *et al.*, 2001.)

These effects of estrogen on hippocampal circuitry are NMDA receptor-dependent (McEwen, 2002), and estrogen replacement directly increases levels NMDA receptor levels in CA1 dendrites and soma (Gazzaley *et al.*, 1996a). Using quantitative postembedding immunogold electron microscopy, a recent study investigated estrogen's effects on axospinous synapse density and the synaptic distribution of the NMDA receptor subunit, NR1, within the context of aging (Adams *et al.*, 2001). As shown before (Woolley & McEwen, 1992) estrogen induced an increase in axospinous synapse density in young animals. However, it did not alter the synaptic representation of NR1 in young animals, in that the amount of NR1 molecules per synapse was equivalent across groups. Estrogen replacement in aged female rats failed to increase axospinous synapse density, however, estrogen upregulated synaptic NR1 expression compared to aged animals not receiving estrogen (Adams *et al.*, 2001). Therefore, the young and aged hippocampus react differently to estrogen replacement, with the aged animals unable to mount a plasticity response generating additional synapses, yet responsive to estrogen with respect to additional NMDA receptor content per synapse (Fig. 26.4) (Adams *et al.*, 2001). Thus, while estrogen affects the aged CA1 synapse in a manner that might enhance hippocampal function, it does so in the context of a synaptic

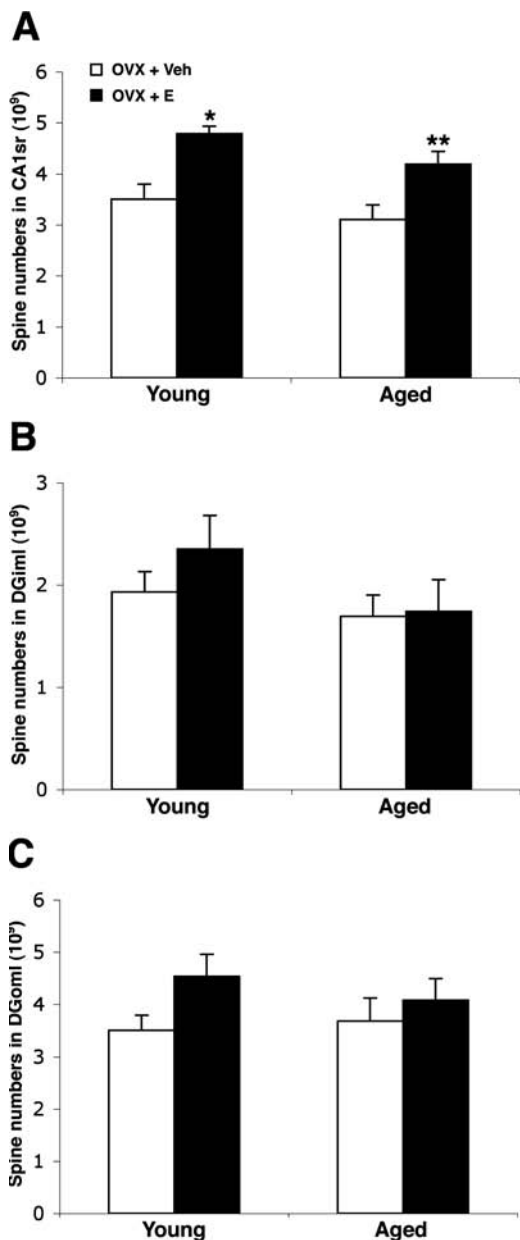

Fig. 26.5 A quantitative stereological analysis showed that estrogen significantly increased the total spine number of CA1sr (A) by 37% ($p < 0.005$) in young ovariectomized female rhesus monkeys and 35% in aged ovariectomized female monkeys ($p < 0.05$). No significant estrogen-induced changes in spine number were observed in the inner molecular layer of dentate gyrus (Dgiml) (B) and or the outer molecular layer of dentate gyrus (Dgoml), though a similar trend was observed in the young animals (C). Values represent means \pm SEM. Asterisk indicates a statistically significant difference between young OVX + Veh and young OVX + E, $p < 0.005$, two asterisks indicate statistically significant difference between aged OVX + Veh and aged OVX + E, $p < 0.05$. (Taken from Hao *et al.*, 2003.)

density compromised by age. What change in CA1 spines occurs with aging that makes the aged rat CA1 spine less responsive to estrogen? It was recently demonstrated that the key estrogen receptor, ER α is present in CA1 spines and synapses (Milner *et al.*, 2001; Adams *et al.*, 2002), and presumably has local effects on synaptic transmission in this case, rather than its more traditional role in gene regulation in the nucleus (McEwen, 2002). We recently demonstrated that the number of spines in CA1 that contain ER α decreases dramatically with age (Adams *et al.*, 2002), and this decrease may be the cause of the decreased sensitivity to estrogen with respect to formation of new spines that we reported in the aged rats.

Importantly, our early results in non-human primates show a similar increase in spines in CA1 in response to estrogen, however aged monkeys were just as responsive as young monkeys (Hao *et al.*, 2003, Fig. 26.5). In addition, prefrontal cortex in monkeys also displays an estrogen-induced increase in spine number (Tang *et al.*, 2003). A recent behavioral analysis in estrogen-induced demonstrated a significant enhancement of cognitive function in aged rhesus monkeys (Rapp *et al.*, 2003). Aged female rhesus monkeys were ovariectomized, and then treated with either vehicle or 100 μ g of estradiol cypionate every 21 days during an extended course of behavioral testing. The estrogen treated group showed enhanced performance on both a hippocampal-dependent task, delayed non-matching to sample, and on DR, the prefrontal task demonstrated to be sensitive to age. In fact, estrogen treatment restored performance to that of young animals (Fig. 26.6). These data are not only important as a demonstration of estrogen's impact on cognition in a non-human primate model, but also suggest that age-related decline in cognitive performance, is potentially reversible through pharmaceutical intervention.

Conclusions and future directions

The transition from fairly circumscribed memory impairment sometimes referred to as mild cognitive impairment to the dramatic loss of cognitive abilities that accompanies AD likely requires progressive development of neocortical pathology. The key vulnerable neocortical cell class has been characterized morphologically, neurochemically, and with respect to its connections. The demise of this cell class begins early in the transition to dementia; thus, interventions for AD should be aimed at protecting this cell class. Age-related memory impairment likely involves alternative mechanisms that do not involve frank neuron death, but rather involve alterations of spines and synapses. A

Fig. 26.6 Neuropsychological performance of aged OVX-veh and OVX-E monkeys relative to young intact subjects. *Top*: delay component of delayed response (DR). *Bottom*: delayed non-matching to sample (DNMS). Note that the estrogen treated group performed at a level nearly equivalent to young animals in the DR task. In the DNMS task, estrogen treated animals displayed enhanced performance at two delay intervals, 30 and 120 seconds. Error bars = SEM. (Modified from Rapp *et al.*, 2003.)

number of potential molecular and synaptic targets for such age-related decline have been identified, and the key circuits in which such changes occur have been delineated. An important interface exists between reproductive and neural senescence, with estrogen levels influencing many of the same circuits implicated in age-related memory impairment. Some of the synaptic alterations at this interface have been identified.

Future studies will require interdisciplinary approaches that reveal cellular and synaptic alterations that can be quantitatively linked to endocrine status and/or behavioral performance.

Alzheimer's disease

Mild cognitive impairment

Overview

As research in aging and dementia moves toward an earlier identification of individuals with a cognitive impairment, the concept of mild cognitive impairment (MCI) has received considerable attention. Mild cognitive impairment refers to an intermediate stage between the cognitive changes that are felt to be part of normal aging and those that represent the very earliest features of a dementia such as Alzheimer's disease. This stage of intermediate impairment is believed to be important, since several studies have indicated that these subjects are likely to progress to AD at an accelerated rate over the general population (Petersen *et al.*, 1999). The initial literature on the concept of MCI pertained to individuals with memory impairment beyond what would be expected for normal aging (Petersen, 1995). These subjects may have a mild impairment in other cognitive domains but performance is felt to be within the range of normal. Similarly, they may have slight difficulties with activities of daily living, but these are generally felt not to be significant. More recently, the construct of MCI has been broadened to include other presentations of persons with transitional cognitive impairment and these will be discussed below. Implicit in the discussion of MCI is an understanding of the concept of normal cognitive function. While we are learning a great deal about aging and cognitive function, this still remains an area of uncertainty.

Normal aging and evolution to MCI

Normal cognitive function has been the subject of a great deal of research and development in the last few decades (Rowe & Kahn, 1987). Yet, the concept of normal aging and what constitutes abnormal aging have remained contro-

versial. "Successful aging" can describe individuals without any functional impairment or significant medical comorbidities but probably does not represent the majority of elderly (Kaye *et al.*, 1994). "Typical aging" therefore can describe individuals who have comorbid medical illnesses and are functioning normally in society (Petersen *et al.*, 1990). However, performance in this group tends to decline with age, and is associated with both neuroradiologic and neuropathologic changes.

While a great deal of research has been conducted characterizing cognitive changes with aging, there is no agreement on the nature or degree of impairment or the pathophysiologic substrate for that clinical picture. Consequently, the lack of precise knowledge of cognitive changes in normal aging makes the characterization of very early changes of MCI challenging. Normal cognitive aging can be defined based on neuropsychological tests with published normative data on a variety of neuropsychological tests for individuals up to age 100 (Ivnik *et al.*, 1992). However, criticisms of these data exist including arguments that normative data are contaminated by the inclusion of persons with incipient cognitive impairment (Sliwinski *et al.*, 1996). Consequently, some investigators argue for the elimination of those people from the norms, as they incorporate more of an impairment than would be the case had these subjects not been included.

Several descriptive terms were used over the past 40 years to address memory and cognitive impairment that develops with aging. An early term that was used to draw attention to memory changes in aging was "benign senescent forgetfulness" (Kral, 1962), describing a condition whereby persons can experience a decline in memory function with aging that did not progress to a dementia. This was followed by the term, "age-associated memory impairment" (AAMI) by a National Institute of Mental Health work group (Crook *et al.*, 1986). One difficulty of this concept was an

Fig. 27.1 Hypothetical continuum from normal aging through mild cognitive impairment to dementia.

overinclusion of most of the population as having a memory impairment when these individuals were compared to younger adults. Revision of AAMI led to “age-associated cognitive decline” (AACD), which included impairment of cognitive domains other than memory. Finally, the Canadian Study of Health and Aging developed the concept of “cognitive impairment–no dementia” (Graham *et al.*, 1997) to capture intermediate stages of impairment.

Longitudinal studies of aging and dementia in various communities have identified individuals who developed memory impairment but did not satisfy the criteria for AD (Petersen & Morris, 2003). Over time, however, many of these individuals progress to probable AD. MCI is a clinical diagnosis describing the transitional state between normal aging and mild dementia. In this transitional stage, there are objective signs of mild memory impairment with preservation of other cognitive functions. These patients, who during neurological evaluation, were found to have objective mild episodic memory impairment, that is neither severe enough nor affecting lifestyle to warrant a diagnosis of dementia. More recently, however, the concept of MCI has become more heterogeneous in terms of etiology and clinical presentation (see below).

The actual transition between normal aging and MCI is also not well understood and remains in an area of debate. It is important, however, not to consider MCI as being a rigid separation between normal aging and mild dementia but rather a continuum or a transitional zone between normal and abnormal function in those subjects who are destined to develop dementia. This hypothetical functional decline from normal aging to dementia is depicted in Fig. 27.1. The

current challenge is to identify patients at the earliest point on this slope and try to prevent or alter progression.

Clinical description

The Mayo Clinic and others have been involved with studies on aging and dementia for at least the past decade (Ivnik *et al.*, 1992, Smith *et al.*, 1992). From these studies and vast clinical experience, others and we have devised clinical criteria for the diagnosis of amnesic MCI. The criteria used for diagnosis of MCI include the following:

- memory complaint, preferably corroborated by an informant
- memory dysfunction for age and education
- essentially normal general cognitive function
- largely intact activities of daily living
- not demented.

Other researchers have used rating scales to characterize subjects with intermediate impairment. The two most common alternative approaches involve the use of: the Clinical Dementia Rating scale (CDR) (Morris, 1993) and the Global Deterioration Scale (GDS) (Reisberg *et al.*, 1982). The CDR is a scale that classifies patients along a continuum from normal (CDR 0), to questionable dementia (CDR 0.5), mild dementia (CDR 1), moderate dementia (CDR 2) and severe dementia (CDR 3). The GDS is another scale similar to the CDR that classifies patients from normal (GDS 1), normal with subjective memory impairment

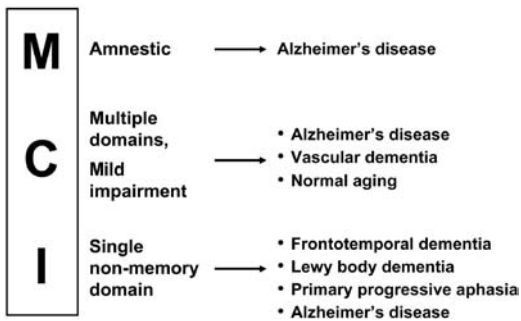

Fig. 27.2 Heterogeneity of mild cognitive impairment.

(GDS 2), mild dementia (GDS 3), up to very severe dementia (GDS 7). Some researchers have contended that MCI as defined above is equivalent to CDR 0.5 and GDS 3. On a sample of 76 consecutively evaluated patients with MCI, Mayo investigators showed that MCI patients with a CDR of 0.5 and AD patients with a CDR of 0.5 differed significantly on all measures of general cognitive functioning. From that study and others, some have concluded that all patients with MCI are CDR 0.5; however, not all patients classified as CDR 0.5 will be MCI, as some will be demented. Similarly, it was shown that MCI patients could either be categorized as GDS 2 or GDS 3 (Petersen *et al.*, 1999).

Heterogeneity of MCI

In its original description MCI implied mild dysfunction affecting only episodic memory. However, there has been concern about patients who present with either mild impairment in multiple cognitive domains or impairment in one non-amnesic cognitive domain. This has led to the conceptualization of three clinical subcategories or three variants of MCI (Fig. 27.2): amnesic MCI, multiple domain MCI and non-amnesic single domain MCI.

Amnesic MCI refers to patients with MCI, with cognitive impairment limited primarily to episodic memory. This form of MCI is the one most referenced in the literature and when it occurs on a degenerative basis most probably progresses to early AD. Multiple domain MCI, as the term implies, defines a group of patients with mild impairment in multiple domains without sufficient overall deficit to warrant a diagnosis of dementia. Patients with multiple domain MCI may have mild behavioral changes, executive dysfunction, dysphasia, apperceptive agnosia or visuospatial deficits. Causes of the multiple domain MCI include AD or vascular dementia. Single non-amnesic domain MCI is defined by mild isolated cognitive impairment of behavior, executive function, language,

visuospatial or visuo-perceptual processing, but not episodic memory. When non-amnesic domain MCI occurs on a degenerative basis, it may represent a precursor of dementia with Lewy bodies, or a frontotemporal lobar degeneration (frontotemporal dementia, primary progressive aphasia, semantic dementia or progressive non-fluent dysphasia).

Therefore, one can approach the diagnosis of MCI from a clinical perspective much the same as one would make the diagnosis of dementia. That is, if the subject meets the criteria for one of the subtypes of MCI, then a search for a likely etiology is pursued. Ultimately, a suspected cause for the clinical impairment is determined and this likely represents a precursor of one of the dementias.

Approach to the diagnosis of MCI

The concept of MCI is important as it currently defines a group of patients at the earliest stage in the development of AD. This group of patients most likely will be the focus of pharmaceutical therapeutic measures and therefore it is important that we develop highly sensitive and specific measures to correctly identify them. An accurate medical and neurological history, and clinical examination, needs to be completed. Ancillary testing is necessary and will complement clinical and physical examination. Ancillary testing also helps to eliminate other conditions that could mimic presentation of MCI, and aids in better identification of the subset of MCI patients that may be the ones at risk for future development of dementia.

History and examination

The history should focus on determining if there is any evidence for mild episodic memory impairment (Petersen, 2003b). From studies on familial AD, we know that verbal episodic memory is affected first (Newman *et al.*, 1994). Therefore, during history taking and cognitive examination, there should be emphases on determining the patient's ability for detailed recall. Episodic memory should be accessed by discussing specific recent events over the past weeks to months. Education and familiarity with subject matter is very important. It is important to remember that, when evaluating patients with MCI, only subtle abnormalities may be found. The fact that a patient looks to his or her spouse when asked a specific question should be considered a red flag. Patients must be thoroughly evaluated and questions should cover a broad range of topics that the patient should be familiar with.

The neurological examination should include at least mental status testing that can evaluate learning, recall, attention, language, problem solving, executive functioning and visuospatial function. Some of the screening measures recommended include the Mini-Mental State Examination (MMSE) (Folstein *et al.*, 1975) and the Short Test of Mental Status (STMS) (Kokmen *et al.*, 1991). Although both measures are effective, the STMS may provide additional sensitivity to determine and to predict those individuals with MCI because there are four words to recall with longer delayed recall (Tang-Wai *et al.*, 2003). Attention to behavior, dysexecutive symptoms, language difficulties, alien limb-like complaints, hallucinations, Parkinsonism and visuospatial complaints are also important. A complete neurological examination must be undertaken as some dementing illnesses may present with signs of motor and sensory deficits. It is particularly important to look for fasciculations, parkinsonism, signs of cerebral infarction, asymmetry, eye movement abnormalities, frontal release phenomena (including a snout and palmomental) and dysarthrias, dyspraxias and visual disorientation.

Laboratory tests

In addition to a thorough history and physical examination, we recommend the following routine screening studies (in uncomplicated cases) in all patients who are being evaluated for a possible diagnosis of MCI: chemistry panel, complete blood count, erythrocyte sedimentation rate (ESR), thyroid function studies, liver function tests, folic acid, vitamin B12 levels and syphilis serology. Additional testing may be necessary depending upon the clinical presentation of the individual patient and whether abnormalities are found on initial screening.

Neuropsychometric test

Neuropsychometric testing complements and extends the bedside mental status testing and provides an additional level of security in the diagnosis of MCI. Studies have demonstrated that patients with mild AD perform poorly on test of memory, delayed recall, language and executive functioning compared to controls. (Knopman & Ryberg, 1989; Storandt & Hill, 1989; Welsh *et al.*, 1991, 1992; Petersen *et al.*, 1994; Masur *et al.*, 1994). In amnesic MCI, clinicians should be interested in both learning and delayed recall as patients demonstrate slightly depressed learning curve and deficit in delayed recall. These measures may also be able to predict which normal subjects are at risk to progress to MCI or from MCI to AD (Petersen *et al.*, 2003). Because only mild cognitive deficits may be present, it is important that thorough neuropsychometric tests be performed in all patients.

The neuropsychological testing does not make the diagnosis of MCI. It is the clinician who must combine the features of the history, bedside mental status examination, the neurological and general medications examination, results of laboratory, neuropsychological, and imaging tests to arrive at a diagnosis.

Neuroimaging

Neuroimaging is another tool that can aid with the diagnosis of MCI (Jack, 2003). Computer tomography (CT) or magnetic resonance imaging (MRI) is useful in excluding structural causes of cognitive decline including brain tumors, subdural hematoma, ischemic and hemorrhagic infarcts and can also give us an idea of the density of silent vascular damage that may be present in both cortical and subcortical areas. They help us to localize anatomical damage that may be critical to the presenting complaint. Small thalamic damage, which may not be apparent on neurological examination, may be seen on MR imaging. Similarly, we are able to get a better understanding of changes that may be occurring in mesiotemporal lobe structures. Enlargement of focal peri-hippocampal spaces would be consistent with hippocampal atrophy and could explain subtle complaints of episodic memory impairment while findings, for example, of perisylvian atrophy or parietal atrophy would be in keeping with non-fluent aphasia and apraxia, respectively. Even though no imaging finding is specific for a diagnosis of MCI, a recent longitudinal study has shown that MRI hippocampal volumes in MCI are predictive of conversion to AD even when multivariate prediction equation has controlled for age, estrogen use, neuropsychological testing, apolipoprotein E status, history of ischemic heart disease, and hypertension (Jack *et al.*, 1999) and correlates with pathological evidence of atrophy and neuronal drop out (Bobinski *et al.*, 1998). Others and we have also demonstrated that measurements of the entorhinal cortex may be a better measure of early cognitive impairment (Bobinski *et al.*, 1999; Killiany *et al.*, 2000, Xu *et al.*, 2000). Functional neuroimaging is also an additional useful tool and aids with the detection of subtle abnormalities in patients with MCI (Johnson & Albert, 2000, 2003; Holman *et al.*, 1992; Johnson *et al.*, 1998). More recently, magnetic resonance spectroscopy (Kantarci *et al.*, 2000) and fMRI (Machulda *et al.*, 2003) have been assessed as a possible tool in evaluating MCI, but unfortunately studies have been limited.

Biomarkers

To date, there is no definitive test that allows us to predict which patients with a diagnosis of MCI will go on to develop

AD even though there are some suggestive findings on neuropsychometric testing and neuroimaging. Two biomarkers that have been used in studies in AD are tau and A β 42 in the cerebrospinal fluid (CSF). Both biomarkers have been assessed in patients with MCI and may improve positive predictive value (Graff-Radford *et al.*, 2003). CSF tau levels have been found not to be increased in patients with AD (Galasko *et al.*, 1997). However, recent longitudinal studies have demonstrated that tau level is increased in patients with MCI who later convert to AD but is not increased in the patients with MCI that do not convert (Sunderland *et al.*, 1990). Longitudinal analysis of plasma A β 42 in patients progressing from normal through MCI to AD revealed that plasma A β 42 declines in the year before MCI develops and continues to decline throughout the MCI stage (Graff-Radford *et al.*, 2003). These findings may later prove to be important prognosticators. As in amnesic MCI, one could speculate about similar findings with other biomarkers in non-amnesic and multiple domain MCI that may prove to be useful in the subclassification of MCI as well as in predicting which patients will later dement.

Neuropathology

Neuropathological substrate of MCI is uncertain. Patients with a diagnosis of MCI do not die unless from accidents or incidents unrelated to their disease. By the time they die, most have converted to having a dementia. One study from the Mayo Clinic on 15 subjects who died while their clinical classification was MCI reported that many subjects did not have the neuropathological features of AD at the time of death but were found to have heterogeneous pathologies including argyrophilic grain disease, hippocampal sclerosis and vascular disease (Petersen, 2002). Data from the Religious Orders Study indicated that approximately 60% of subjects with multi-domain MCI had AD changes at autopsy (DeKosky *et al.*, 2002).

Genetics and predictors of progression

The genetic features of amnesic MCI are also similar to those of clinically probable AD. In particular, there appears to be a higher representation of Apo E ϵ 4 carriers in MCI and in some studies, the presence of an E4 allele may predict progression (Petersen *et al.*, 1994; Grundman *et al.*, 2004). However, these data are only mildly positive and it is currently not recommended to use Apo E for either a diagnostic tool for MCI or as an indicator of progression. Additional research is progressing on this topic.

Clinical trials

Currently, there are no treatments available for arresting or reversing the progression that occur in patients with MCI. However, therapeutic clinical trials will continue to focus on this group of patients, as we know that by 6 years approximately 80% will have converted to AD. Current clinical trials in MCI are focusing on treatments that have demonstrated possible efficacy in slowing progression in patients with AD.

One class of drugs currently being tested is the cholinesterase inhibitors. Studies on cholinesterase inhibitors in patients with AD have shown some benefit in slowing progression (Rogers *et al.*, 1998). The cholinesterase inhibitors that are currently available for use with AD include tacrine, donepezil, rivastigmine and galantamine, and are currently being evaluated for efficacy in patients with MCI. Estrogens are another class of drugs that have shown to be associated with slowing progression of cognitive dysfunction in patients with AD (Yaffe *et al.*, 1998; Waring *et al.*, 1999). Another class of drugs includes the anti-inflammatory agents and clinical trials on the effect of cyclooxygenase-2 (COX-2) inhibitory are underway (Petersen, 2003a). One current study is the Alzheimer's disease Cooperative Study MCI trail, a placebo control trial, involving 68 centres; comparing therapeutic benefit of vitamin E vs donepezil vs placebo (Grundman *et al.*, 2004).

Finally, in the current era of amyloid and tau genetics, it is worth considering medications that can either prevent the formation of tau and amyloid aggregates or destroy the abnormal soluble protein polymers. An example is the recent vaccine trial that unfortunately was discontinued prematurely after many patients treated with the vaccine developed an encephalitis (Orgogozo *et al.*, 2003). Studies on these agents as well as other anti-amyloid agents are currently being developed and tested.

AAN practice parameters

In early 2001 the Quality Standards Subcommittee of the American Academy of Neurology (AAN) met to develop scientifically sound measures in evaluating patients with dementia. A work group was created to focus on two main questions that were felt very important for the enhancement of the field of dementia. First, they wanted to determine if the presence of MCI predict the development of dementia and second, whether screening at-risk subjects with a specific instrument in a specific setting led to the diagnosis of dementia. This group, after completing an evidence-based medicine literature search, put forth

the following guidelines (Petersen *et al.*, 2001). They felt that patients with MCI should be recognized and monitored for functional decline due to their increased risk for subsequent development of dementia. This risk was determined to be between 6% and 25% per year, much higher than the risk to conversion of the general population that ranges from 0.2% to 3.9% depending on the age group being studied. They also felt that general cognitive screening instruments should be considered for the detection of dementia in MCI. Some of the screening measures recommended included the Mini-Mental State Examination (Folstein *et al.*, 1975), the Short Test of Mental Status (Kokmen *et al.*, 1991), 7-Minute Screening Test (Solomon *et al.*, 1998) and the Memory Impairment Screen (Buschke *et al.*, 1999). They found that neuropsychological batteries should be considered in identifying patients with dementia, especially when the subpopulation in which one practises has an increased risk of cognitive impairment.

Future directions
