The concept of MCI is an important one for all neurodegenerative disorders. It allows us to conceptualize a transitional zone, not only in dementing diseases, but also in disorders of motor dysfunction, for example, idiopathic Parkinson's disease where early therapeutic intervention may halt further development of end-stage disease. The concept of MCI is evolving. We are in the process of identifying normal patients who are at risk for the later development of MCI and dementia. Our ability to predict which group of the population is at risk for developing MCI will allow early detection and intervention.

Further development in better imaging techniques, neuropsychological batteries and biomarkers are currently under way and will further refine and improve our diagnostic sensitivities and specificities.

Dementia

Dementia, itself, neither implies a specific disease nor implies a specific underlying pathology. It refers to a change in cognitive function that is severe enough to compromise an individual's daily function. The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) defines dementia as an acquired impairment of cognitive function that includes a decline in memory beyond what would be expected for age and at least one other cognitive function, such as attention, visuospatial skills or language, or a decline in executive functioning such as planning, organization, sequencing, or abstracting. The decline cannot only affect emotional abilities, but must also interfere with work or social activities. The deficits should not be accompanied by an impairment of arousal (delirium) or be accounted for by another psychiatric condition, such as depression or schizophrenia. Dementia can further be defined by a *possible*, *probable*, or *definite* etiologic diagnosis. A degenerative dementia implies disease progression over time.

While the DSM-IV criteria are generally useful, one problem with the criteria is that memory impairment is an essential feature. While this is common in most dementias, other dementias may present with impairment in a non-memory cognitive domain. If the initial presentation is a change in personality or behavior, rather than memory, a frontotemporal dementia may be the diagnosis. In subjects with parkinsonism, hallucinations and fluctuations in behavior, dementia with Lewy bodies may be more likely than AD. Vascular dementia can involve abrupt changes in function for large vessel or embolic disease or can present insidiously if subcortical ischemia is responsible for the changes in function. A prominent anomia with other features of language impairment can signal a primary progressive aphasia. A dementia evolving rapidly over

weeks to months with psychiatric symptoms and motor function abnormalities suggests a prion disorder such as Creutzfeldt–Jakob disease.

First description/historical overview

The current understanding of AD evolved in three stages (Munoz & Feldman, 2002): (i) the initial description of AD, (ii) the association between the degree of pathology and disease severity, and (iii) the genetic and biochemical advances.

In 1907, Dr Alois Alzheimer published a report concerning “an usual illness of the cerebral cortex” (Stelzmann *et al.*, 1995). He described the case of a 51-year-old woman, Auguste D, who initially developed a delusional disorder but then developed a “rapid loss of memory.” Postmortem examination of her brain revealed an atrophic brain without evidence for focal degeneration. Microscopically, he described neuronal cell loss and “only a tangle of fibrils [that] indicates the place where the neuron was previously located.” In addition, “distributed all over the cortex . . . are minute military foci which are caused by the deposition of a special substance in the cortex” (Förstl & Levy, 1991; Stelzmann *et al.*, 1995; Klünemann *et al.*, 2002).

In the 1960s, Blessed and colleagues (Blessed *et al.*, 1968) reported the association between the number of senile plaque counts in sections of the cerebral cortex and decline in measures of intellectual functioning among the elderly. He also recognized that AD was the most common cause of dementia.

Recently, genetic advances further impacted on the current knowledge of AD. Mutations of the β -amyloid precursor protein on chromosome 21 and the *presenilin* genes 1 and 2 were associated with familial autosomal dominant AD (Sherrington *et al.*, 1995; Alzheimer's Disease

Collaborative Group, 1995; St George-Hyslop *et al.*, 1996; Hardy & Gwinn-Hardy, 1998). The inheritance of the $\epsilon 4$ allele of apolipoprotein E (ApoE) is considered as a risk factor for the late-onset inheritance and/or pathogenesis of AD (Corder *et al.*, 1993). Furthermore, there may be other genetic contributors to AD such as chromosome 10 (Ertekin-Taner *et al.*, 2000).

Epidemiology

AD is an age-related phenomenon and is the most common cause of dementia in the elderly, accounting for more than half of all cases (Small *et al.*, 1997). It is estimated that there will be 360 000 incident cases of AD each year and is expected to rise over the subsequent 50 years to 1.14 million in 2047 (Brookmeyer *et al.*, 1998). There is a greater prevalence of AD in women than in men (1.2–1.5: 1) reflecting the greater longevity of women (Evans *et al.*, 1989; Kokmen *et al.*, 1989; Bachman *et al.*, 1992; Canadian Study of Health and Aging Working Group, 1994a; Hendrie *et al.*, 1995; White *et al.*, 1996; Hofman *et al.*, 1997; Gao *et al.*, 1998). Both the incidence and prevalence of AD increases dramatically with age and exponentially increases after the age of 65 (Kokmen *et al.*, 1996; von Strauss *et al.*, 1999; Kukull & Ganguli, 2000). It is estimated that the prevalence of dementia over the age of 65 years is 4% and 20% over the age of 85 years. It is rare below the age of 40 but can be seen and in such circumstances, consideration to a mutation in *presenilin-1* is entertained. It is uncertain as to whether the actual incidence of AD continues to rise into the 90s, but the incidence of dementia increases rapidly in that age range.

The combination of the facts that AD is an age-related disease and increasing numbers of individuals are living longer, has made this disease a common and important public-health problem. Some estimate that the present day cost of AD is \$100 billion per year. (Small *et al.*, 1997).

Risk factors for Alzheimer's disease

Increasing age is the most important risk factor of AD. Following age, the presence of the apolipoprotein E $\epsilon 4$ (ApoE $\epsilon 4$) allele is another major risk factor. There are 3 forms of ApoE alleles, $\epsilon 2$, $\epsilon 3$ and $\epsilon 4$, but only the $\epsilon 4$ allele increases the risk of both familial late-onset (Corder *et al.*, 1993) and sporadic cases (Saunders *et al.*, 1993) of AD, while $\epsilon 2$ allele decreases risk (Corder *et al.*, 1994). A similar pattern of age-related risk for decline associated with the $\epsilon 4$ allele and the apparent protective effect of the $\epsilon 2$ allele is observed in

African-Americans (Graff-Radford *et al.*, 2002). The lifetime risk of AD in an individual without a family history is 9% without an Apo E $\epsilon 4$; however, the lifetime risk increases to 29% if an individual is carrying at least 1 $\epsilon 4$ allele (Seshadri *et al.*, 1995).

Other putative risk factors of AD are implicated and include cardiovascular disease, traumatic brain injury, depression, lower educational achievement and/or occupational status, parental age at time of birth, smoking, first-degree relative with Down syndrome, low levels of folate and vitamin B12, and elevated plasma and total homocysteine levels (Mortimer, 1995; Clarke *et al.*, 1998; Evans *et al.*, 1997; Hofman *et al.*, 1997; Fratiglioni *et al.*, 1993; Guo *et al.*, 2000; Launer *et al.*, 1999; Seshadri *et al.*, 2002; Green *et al.*, 2003).

Putative protective factors include higher educational status, regular use of anti-inflammatory agents, use of cholesterol lowering agents (statins), estrogen replacement therapy in postmenopausal women, antihypertensive therapy, and diet of fish (Wolozin *et al.*, 2000; in't Veld *et al.*, 2001; Cummings & Cole, 2002; Qiu *et al.*, 2003).

Currently, controversy exists with estrogen and progestin and subsequent development of AD. Prior long-term hormone replacement therapy use was associated with reduced risk of AD (Zandi *et al.*, 2002). Recently, however, the Women's Health Initiative Memory Study revealed that estrogen and progestin therapy increased the risk of probable dementia in postmenopausal women aged 65 years or older and did not prevent mild cognitive impairment (MCI) (Shumaker *et al.*, 2003). Included in the causes of probable dementia were vascular dementia, mixed-type dementia, normal pressure hydrocephalus, frontal lobe type, alcohol related, other/unknown, and AD. It is uncertain if estrogen and progestin have an effect on AD alone. This controversy will probably continue as additional studies will likely be published that examine the effects of estrogen or estrogen and progestin on AD and other dementias.

Clinical features

The clinical evolution of AD can be divided into three categories: (i) progressive memory impairment, (ii) progressive cortical dysfunction (aphasia, apraxia, visuospatial dysfunction) and (iii) neuropsychiatric disturbances. The typical clinical scenario of AD is the insidious onset and gradual progression of an amnesic memory disturbance with difficulties of learning and recall. In the initial stages of the disease, the memory impairment is for newly acquired information with relative sparing for remote events. The patient

is typically unaware of memory or cognitive compromise (anosagnosia). Memory impairment alone, however, is not sufficient to make the diagnosis of dementia. NINCDS-ARDA criteria require that two or more other spheres of cognition be compromised, such as aphasia, apraxia and agnosia (McKhann *et al.*, 1984). The diagnosis of dementia is made on the basis of the fulfilment of clinical criteria, and as such constitutes a positive diagnosis rather than one of exclusion (Small *et al.*, 1997). The clinical–pathological correlation is actually quite high, in the 80–90% range (Galasko *et al.*, 1994; Gearing *et al.*, 1995).

As the disease evolves, patients will typically develop a progressive language disturbance beginning with anomia (“word finding difficulties”) and progressing to a fluent aphasia. The patient may be unable to multitask or perform complex mental tracking tasks as other cognitive domains become impaired. This may be reported as diminished concentration, difficulty with mental arithmetic or tendency to become confused. Patients become less able to carry out the more demanding tasks of daily living, such as managing finances and driving, as disturbance of abstract reasoning, executive dysfunction (such as planning, insight and judgment), and disturbance of visuospatial skills (manifested by geographic or environmental disorientation and difficulty copying figures) evolve.

All cognitive deficits worsen over time. The patient will become progressively more dependent on the caregiver for feeding and hygiene. Plateaus can occur where cognitive impairment may not change for a period of 1 to 2 years, but resumption of progression does occur.

Neuropsychiatric symptoms are common in patients with AD (Chung & Cummings, 2000). There are four major groups of neuropsychiatric symptoms in AD: (i) mood disturbance, (ii) delusions and hallucinations, (iii) personality change, and (iv) disorders of behavior.

Personality change may be the first clinical change seen in AD and can be seen in at least 75% of patients. Most prominent is the apathy that appears early in the course with symptoms of diminished interests and concerns and may be associated with depression.

As the disease progresses, agitation and aggression may appear. Behavioral disturbance can be observed in 30–85% of patients and positively correlates with severity of dementia. Among all the neuropsychiatric symptoms, this may be the most difficult to manage. Patients may be both physically and verbally abusive, may wander, and may be incontinent of urine.

As dementia progresses, delusions, hallucinations and other psychotic behaviors may develop. Simple delusions of theft and suspicion are common, as are visual, auditory hallucinations. Misidentification of persons can

also occur (for example, claiming one’s spouse is an imposter) and incorrect identification of place is also reported.

Mood disorders can occur at any point throughout the illness, especially depression. Rates of depression can range from 25–30% with probable and possible AD to as high as 50% (Zubenko *et al.*, 2003). It is speculated that depression may be related to both structural and biochemical degenerative changes in the brain with neuronal loss in adrenergic, cholinergic and serotonergic systems (Tekin & Cummings 2001).

Motor abnormalities are absent in AD until the last few years of the disease. The presence of focal abnormalities, gait abnormalities, or seizures early in the clinical course makes AD unlikely.

Patients with AD usually survive 7 to 10 years (range 2–20 years) after the onset of symptoms. Average annual rate of reported decline on the MMSE is 4 to 5 points. Patients typically die from medical complications (bronchitis or pneumonia).

Clinical diagnosis

Clinical criteria of Alzheimer’s disease

Diagnosis of AD can be made using criteria from either the National Institute of Neurologic, Communicative Disorders and Stroke/Alzheimer’s Disease and Related Disorders Association (NINCDS-ADRDA) work group (Table 28.1) (McKhann *et al.*, 1984) or *Diagnostic and Statistical Manual*, Fourth Revision (DSM-IV). Assessment and diagnosis of AD require identifying the core clinical features and excluding other common causes of dementia. The American Academy of Neurology guidelines report that the DSM-III-R and the NINCDS-ARDA criteria for the diagnosis of AD have sufficient reliability and validity and should be used (Knopman *et al.*, 2001).

History, bedside mental status examination, neurological examination

An essential element in establishing the diagnosis of dementia is obtaining the history from not only the patient themselves but also from someone who knows the patient quite well. Information to obtain in the history include a change and a decline in the level of a patient’s ability to execute decisions, to plan (e.g. meals/recipes), to manage finances (e.g. payment of bills, balancing chequebook, payment of taxes), and to drive (e.g. getting lost while driving, new accidents or traffic tickets). Also pertinent is a history

Table 28.1. National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's and Related Diseases Association (NINCDS-ARDA) Criteria

Clinical diagnosis of **probable** Alzheimer's disease

- Dementia established by clinical examination and mental status testing and confirmed by neuropsychological testing
- Deficits in at least two cognitive domains
- Progressive cognitive decline, including memory
- Normal level of consciousness
- Onset between ages 40 and 90 (most common after 65) years
- No other possible medical or neurological explanation

Probable Alzheimer's disease diagnosis supported by

- Progressive aphasia, apraxia, and agnosia
- Impaired activities of daily living
- Family history of similar disorder
- Brain atrophy on CT/MRI, especially if progressive
- Normal CSF, EEG

Other clinical features consistent with probable Alzheimer's disease

- Plateau in course
- Associated symptoms: depression, insomnia, incontinence, illusions, hallucinations, catastrophic verbal, emotional, or physical outbursts; sexual disorders; weight loss; during more advanced stages increased muscle tone, myoclonus, and abnormal gait
- Seizures in advance disease
- CT normal for age

Features that make Alzheimer's disease uncertain or unlikely

- Acute onset
- Focal sensorimotor signs
- Seizures or gait disorder early in course

Clinical diagnosis of **possible** Alzheimer's disease

- Dementia with atypical onset or course in the absence of another medical/neuropsychiatric explanation
- Dementia with another disease not felt otherwise to be the cause of dementia
- For research purposes, a progressive focal cognitive deficit

Definite Alzheimer's disease

- Meets clinical criteria for **probable** Alzheimer's disease
- Tissue confirmation (autopsy or brain biopsy)

Research classification of Alzheimer's disease should specify

- Familial?
- Early onset (before age 65)?
- Down's syndrome (trisomy 21)?
- Co-existent with other neurodegenerative disease?

McKhann, G. *et al.* (1984).

of the patient repeating himself. Although there are several instruments which can be used to obtain this information, one can inquire about the patient's ability and new onset difficulties to carry out typical activities of daily living.

In addition to the history, a cognitive assessment with an instrument designed for assessing mental function can be quite useful. Instruments designed for this purpose include the Mini-Mental State Examination (MMSE) (Folstein *et al.*, 1975), the modified Mini-Mental State (3MS) (Teng & Chui, 1987), the Blessed Orientation Memory Concentration Test (Katzman *et al.*, 1983) and the Short Test of Mental Status (Kokmen *et al.*, 1991). The structured interview provided by the Clinical Dementia Rating scale (CDR) (Morris, 1993) is helpful to further characterize the demented patient's ability in various domains of cognitive and functional performance. While these can be useful, none is superior to the others.

Individuals being evaluated for dementia should also have a general neurologic examination. Typically in early AD, this exam is largely normal with the exception of the mental status evaluation. However, in the course of the examination, other features suggesting other contributing factors to the dementia can be elucidated. For example, the findings of parkinsonism can suggest a Lewy body component or the presence of asymmetric reflexes or a visual field cut or other lateralizing signs can suggest a vascular component. Similarly, if there are other neurologic features such as a peripheral neuropathy, these may suggest toxic or metabolic problems. Assessment of sensory function is important since sensory deprivation can affect the mental status and neurologic examination. Finally, the neurologic examination should be complemented by a general medical examination looking for other systemic contributions to the cognitive impairment.

Laboratory evaluation

The utility of a variety of laboratory tests in evaluating a patient with dementia was assessed by the American Academy of Neurology practice parameter paper. Both vitamin B12 levels and thyroid functions should be assessed in cases of dementia since these are common co-morbidities that appear in the elderly. They can influence cognitive function and, while the treatment of these disorders may not completely reverse the dementia, their recognition and assessment are important. Screening for syphilis in patients with dementia is not justified unless there is a clinical suspicion for neurosyphilis. It is uncertain if routine screening for homocysteine is warranted at this time (Knopman *et al.*, 2001).

Table 28.2. Laboratory evaluation of patients with dementia

Routine	Optional
Chemistry group	Sedimentation rate
Complete blood count	Chest x-ray
Vitamin B ₁₂ level*	Electrocardiogram
Thyroid function studies*	Urinalysis
Syphilis serology	Drug levels
CT/MRI*	HIV testing
	Lyme serology
	24hr -urine for heavy metal
	Electroencephalogram
	Cerebrospinal fluid
	PET/SPECT

* Suggested by the American Academy of Neurology.

It has been common practice, however, to assess a variety of tests to determine if there are other contributing factors. Table 28.2 lists suggested tests for a dementia evaluation. However, it should be emphasized once again that a few of these have been demonstrated to have an impact on improving the dementia; nevertheless, since other medical conditions can present with alterations in cognitive function, consideration to these tests can be given in the appropriate clinical setting.

Spinal fluid examination

There is little evidence to recommend the routine use of a lumbar puncture in the routine evaluation of elderly patients for dementia (Becker *et al.*, 1985). However, in the absence of contraindications, there may be certain clinical circumstances where spinal fluid examination is recommended. The clinician may suspect an alternative contributing process in dementias characterized by a subacute change in mental status, chronic encephalopathy, unusual clinical presentation, young onset (<65 years), the presence of fever and/or nuchal rigidity, systemic cancer, immunocompromised host or collagen vascular diseases. If spinal fluid examination is performed, in addition to routine tests such as total protein, glucose, cell count, cytology, and syphilis serology, consider cultures for bacteria, fungus and mycobacteria and immunological indices such as IgG index, IgG synthesis rate and oligoclonal bands. Positivity of any of the immunological indices would indicate inflammation and not AD. Opening pressure should also be recorded especially in patients with suspected communicating hydrocephalus.

Fig. 28.1 Coronal T₁-weighted MRI image of the brain demonstrating hippocampal atrophy in a patient with clinically probable AD.

Other testing

Additional testing may be necessary in evaluating a patient with dementia and include EEG, overnight oximetry, psychiatric evaluation, small bowel biopsy, and paraneoplastic serologies. EEG abnormalities can be seen in toxic, metabolic, inflammatory, infectious and neoplastic encephalopathies. Overnight oximetry is a useful screening test for obstructive sleep apnea where patients may present with hypersomnolence, inattentiveness and mild memory impairment. Depression is common among individuals with coexistent cognitive impairment and should be screened (Knopman *et al.*, 2001). Psychiatric evaluation should be considered if depression is suspected or if psychotic symptoms complicate the clinical picture. If CNS Whipple's disease is suspected, small bowel biopsy should be considered.

Neuroimaging

Structural neuroimaging with either a non-contrast computer tomography (CT) or magnetic resonance imaging (MRI) scan is recommended in the routine evaluation of patients with dementia and can be useful in excluding reversible and treatable causes of dementias (Knopman *et al.*, 2001). Findings of subdural hematomas, neoplasms, infarct prior traumatic encephalomalacia, relevant focal atrophy and meningeal enhancement would lend a diagnosis other than AD. Bilateral atrophy of medial temporal lobe structures, such as the hippocampus, has been found in patients with AD (Fig. 28.1) (Jack *et al.*, 1997; Fox

et al., 2001). However, this atrophy may be non-specific and may be seen in other conditions but is certainly consistent with AD and is a fairly sensitive marker of the pathologic AD stage and consequent cognitive status (Fox *et al.*, 1999; Jack *et al.*, 2002). Recent data on longitudinal volumetric measurements of the hippocampal formation have also indicated that the rate of progression of atrophy of persons with AD exceeds that of normal controls (Jack *et al.*, 1999) and may precede the clinical symptoms of cognitive decline (Fox *et al.*, 1996). Investigations assessing the utility of volumetric measurements of the entorhinal cortex have been controversial (Killiany *et al.*, 2000; Xu *et al.*, 2000). Some investigators feel that the entorhinal cortex is superior in assessing early changes in the AD process, while others have found that the hippocampus and entorhinal cortex are equally efficacious (Xu *et al.*, 2000). Nevertheless, a structural imaging test of the brain should be done early in the assessment of persons with suspected AD.

Functional imaging with either single photon emission computed tomography (SPECT) or positron emission tomography (PET) typically reveal bilateral temporoparietal and posterior cingulate hypoperfusion and hypometabolism in AD. Several of SPECT studies have been suggestive of functional imaging's value in augmenting the clinician's acumen in the diagnosis of AD and may also correlate with Braak pathological stage (Van Gool *et al.*, 1995; Clauss *et al.*, 1994; Johnson *et al.*, 1990, 1993; Bartenstein *et al.*, 1997; Jagust *et al.*, 2001; Bradley *et al.*, 2002). Yet, based on Class II studies, the sensitivity of SPECT was lower than that of the clinical diagnosis (Knopman *et al.*, 2001). PET scanning has shown promise in its ability to differentiate among dementias and there is some evidence to indicate that FDG-PET may be useful in assessing the people who are at risk for developing AD but the longitudinal outcome of these persons is not yet known. One additional functional imaging modality to consider in the future is the use of functional MRI to discriminate normal subjects from those with either the prodromal stages of AD or MCI (Machulda *et al.*, 2003).

Functional imaging tests may also be particularly useful in the differential diagnosis of dementia. In particular, the ability of SPECT and PET to differentiate frontotemporal dementia from AD can be useful with the frontotemporal dementia subjects showing predominant hypoperfusion and hypometabolism in the frontal lobes with relative sparing of posterior structures.

While functional imaging tests are intriguing and show great potential, at present, the American Academy of Neurology practice parameter paper indicated that neither SPECT nor PET were recommended for routine use in

the initial or differential diagnosis of dementias (Knopman *et al.*, 2001).

Neuropsychological testing

Neuropsychological testing can be particularly useful in evaluating cognitive function in a suspected dementia and can also be useful in providing a baseline for a subject who might be re-evaluated at some point in the future. Neuropsychological testing can help determine if the subject is experiencing cognitive changes of normal aging, MCI, or the earliest signs of AD. The particular profile of cognitive function can also be useful in differential diagnosis. While not diagnostic, the various clinical profiles can be useful to the clinician in helping to distinguish among various dementias.

Neuropsychological findings of AD mirror what one sees clinically. In the typical early stages, there is difficulty remembering or rapidly forgetting word lists, stories, designs after a delay, and possibly naming (which may be clinically elicited with word-finding difficulties). As the disease progresses from mesial temporal lobe to surrounding association areas, cognitive impairment becomes more widespread with decline in other areas of higher cortical function (Kramer & Miller, 2000). Visuospatial skills deteriorate and they may have impairment with copying designs. Reasoning becomes more concrete with impairment of novel-problem solving or abstract thinking. Problems with executive functioning becomes evident as patients lose inhibition abilities and the capacity to coordinate simultaneously storage and processing of information. Impairment of remote memory emerges with relative preservation of oldest memories. In severe stages, patients become apraxic, agnostic and aphasic (Kramer & Miller, 2000).

Pathogenesis/mechanisms of disease

Pathogenesis of AD can be subdivided into several interacting mechanisms: (i) aging influences, (ii) environmental influences (including inflammation, toxic exposures, infection, homocysteine), (iii) genetic influences (amyloid precursor protein, apolipoprotein E, presenilins), (iv) cerebral infarcts, (v) microscopic structural changes. There is no single mechanism that causes AD but rather it is the relative contributions of each component known this far that influences an individual to develop the symptoms of AD.

The major pathological findings in AD are generalized cerebral atrophy (Fig. 28.2) and widespread cortical

Fig. 28.2 Generalized cerebral cortical atrophy in Alzheimer's disease (Courtesy of D. W. Dickson M. D., Mayo Clinic, Jacksonville FL.)

Fig. 28.3 Photomicrograph demonstrating a neuritic plaque composed of amyloid core surrounded by dystrophic neurites and dense flame-shaped neurofibrillary tangles in the entorhinal cortex in Alzheimer's disease. Bielschowsky silver stain; 200X. (Courtesy D. W. Dickson M. D., Mayo Clinic, Jacksonville FL.)

neuritic amyloid plaques and neurofibrillary tangles (Fig. 28.3). Other neuropathological findings include neurofibrillary tangles, granuovacuolar degeneration, lipochrome accumulation, and Hirano bodies.

A major theory in the pathogenesis of AD is all or in part due to abnormal processing or deposition of amyloid (Selkoe, 2000). A β 40 and A β 42 are derived from differential proteolytic cleavage of the amyloid precursor protein (β APP), a transmembrane protein with an extracellular amino terminal and intracellular carboxyl terminus. After initial cleavage of β APP by β -secretase at amino acid 671, γ -secretase can cleave at either amino acid 711 or 713 resulting in the formation of A β 42 and A β 40, respectively. Although both species are detected in plasma and CSF, it is the A β 40 which is found more often with a small component being A β 42. However, it is the lesser common species, A β 42, that is important in the pathogenesis of AD in that in vitro fibrils composed of A β 42 form more rapidly than those composed on A β 40, and A β 42 may be deposited earlier in the genesis of an insoluble senile plaque. This deposition presumably initiates a cascade of events which result in inflammatory responses and cell destruction. While this may not be the only pathologic process, it is believed to be an important component of the degenerative cascade.

The other primary pathologic feature of AD involves the abnormal processing of tau and neurofibrillary tangle formation. Tau is an axonal phosphoprotein important for the binding and stabilization of microtubules (Spillantini & Goedert, 1998; Lee *et al.*, 2001). Alternative splicing of the tau mRNA, from the *tau* gene on chromosome 17q21.2, produces six isoforms in the central nervous system with either 3 tandem repeat sequences (3-repeat or 3R-tau) or with 4 tandem-repeat sequences (4-repeat or 4R-tau) (van Slegtenhorst *et al.*, 2000). The tandem repeat sequences represent key microtubule-binding sites. It is through both alternative splicing and degree of phosphorylation of tau that regulates its binding to microtubules. Neurodegeneration and pathology occur when one or both of these mechanisms are disrupted, either through mutations or other mechanisms, resulting in abnormal tau aggregation. In AD, neurofibrillary tangles are composed of paired helical filaments which, in turn, have been found to be mainly composed of hyperphosphorylated tau (Lee *et al.*, 2001). In other disorders, the normal 1:1 ratio of 3R- and 4R-tau in the human adult brain is disrupted, producing other neurodegenerative disorders, such as corticobasal degeneration, progressive supranuclear palsy and argyrophilic grain disease where the predominant form of is 4R tau (Dickson, 1999).

Biomarkers

An AD biomarker would provide clinicians increased accuracy of diagnosis of the disorder, identify those individuals at risk in the hopes of employing early therapy, and to determine if treatment is effective. A working group on biological markers for AD described the features of an ideal biomarker (The Ronald and Nancy Reagan Research Institute of the Alzheimer's Association and National Institute on Aging Working of Group, 1998):

- to be able to detect a fundamental feature of Alzheimer's neuropathology
- to be validated in neuropathologically confirmed cases
- to be able to detect AD early in its course and distinguish it from other dementias
- to be reliable
- to be non-invasive
- to be simple to perform
- to be inexpensive.

Several biomarkers have been investigated thus far and include CSF tau, plasma and CSF A β levels, platelet APP isoforms, and neuronal thread protein.

CSF A β and tau

Several studies have shown that CSF levels of A β 42 are reduced in AD relative to normal control subjects (Andreasen *et al.*, 1999a; Galasko *et al.*, 1998; Hulstaert *et al.*, 1999; Shoji *et al.*, 1998), but it is unclear whether these levels are useful in the very early diagnosis. Similarly, CSF tau levels have been shown to be elevated in AD relative to controls (Arai *et al.*, 1997; Galasko *et al.*, 1997; Kurz *et al.*, 1998; Andreasen *et al.*, 1999b). The simultaneous measurement of CSF A β 42 and tau may be a useful diagnostic marker, and studies have indicated sensitivities and specificities of 85 and 87%, respectively. However, it is not known if these biomarkers augment the diagnostic accuracy of the clinician.

Amyloid precursor protein isoforms in platelets

The β APP can also be found in peripheral tissues, including platelets. Three major APP isoforms are present in membranes of resting platelets (Bush *et al.*, 1990) and patients with AD show specific alteration of levels of these platelet APP isoforms. Measurement of the ratio of the isoforms have been shown (i) to differentiate AD from normal controls and non-AD dementias (Di Luca *et al.*, 1998), (ii) to

correlate with decline in cognition in AD and thus may be a biological index of the severity of cognitive loss in AD (Baskin *et al.*, 2000) and (iii) to change with administration of cholinesterase inhibitors, such as donepezil, suggesting it may be a marker for pharmacological activity (Padovani *et al.*, 2001; Borroni *et al.*, 2001). While a promising biomarker, it also has some drawbacks. Patients on medication that affects platelet function, such as anticholinergic, antiplatelet agents, serotonergic medications, anticoagulants and steroids, need to be off the medication for at least 2 weeks. Drawing the blood for harvesting platelets is complicated. Nonetheless, this test is certainly worthy of further study.

Neuronal thread protein (NTP)

The neural thread proteins are a family of proteins that is normally expressed in the brain and, especially, brains of AD patients (de la Monte & Wands 1992). Increased levels of NTP were found in advanced AD cases and correlated with progression of dementia (de la Monte *et al.*, 1992, 1997). NTP can be measured in both spinal fluid and urine and is higher in AD patients than controls (de la Monte *et al.*, 1992; Ghanbari *et al.*, 1998). Furthermore, NTP may distinguish individuals without dementia from those with AD and non-AD pathology (Kahle *et al.*, 2000).

AAN guidelines on biomarkers

Although promising, the American Academy of Neurology states that no biomarkers have emerged as being appropriate for routine use in the clinical evaluation of patients with suspected AD. While several of the approaches mentioned above including quantitative neuroimaging, genotyping and biomarkers are being actively investigated, at this point, none has achieved sufficient stature that it replaces or significantly augments the ability of the clinician to use the standard DSM IV or NINCDS/ADRDA criteria to diagnose AD (Knopman *et al.*, 2001).

Clinical variants of Alzheimer's disease

The typical presentation of AD is impairment of anterograde episodic memory. However, AD can present as a focal degenerative disease (Caselli 1995). In addition to the focal amnesic form, three other focal patterns of presentation have been described: (i) progressive aphasia, (ii) progressive visual dysfunction, and (iii) progressive bi-parietal/aprasic motor dysfunction. Variants of AD can be clinically similar and have overlap among other neurode-

generative diseases, such as corticobasal degeneration and frontotemporal dementia. Yet despite the varied presentations, the pathology can reveal findings of typical AD (Galton *et al.*, 2000). It is the distribution of the AD pathology that dictates the clinical syndrome and not the disease itself (Galton *et al.*, 2000; Tang-Wai *et al.*, 2003a,b). Understanding the progression of typical AD from the initial amnesic syndrome to latter involvement of visual, language, executive impairment, praxis, it is not surprising that the disease can present with one of those impairments and yet can still be AD. AD should be clinically considered in any focal cortical syndrome.

Progressive aphasia

Although pathologies of progressive aphasia syndromes either reveals dementia lacking distinctive histology or Pick's disease, there are postmortem cases of AD. AD presenting as a focal language disturbance can be either a fluent or non-fluent syndrome. Non-fluent forms can mimic the clinical presentation of primary progressive aphasia (PPA) and can fulfil the diagnostic criteria of PPA (Mesulam, 1982, 2001). Over time, there is a general cognitive decline with progressive memory and visuospatial impairment. Fluent forms can mimic the clinical presentation of semantic dementia, however, they would not have met diagnostic criteria as there is typically evidence for additional impairments in episodic and working memory and deficits in visuospatial functioning (Hodges *et al.*, 1992; Garrard & Hodges, 2000). As the disease progresses, the patient becomes mute and memory becomes impaired. Neuroimaging typically reveals left temporal or more general asymmetric left hemisphere atrophy. Functional imaging mirrors the structural findings with temporal hypoperfusion. Pathologically, there is widespread involvement of plaques and tangles in the temporal lobe (Galton *et al.*, 2000).

Progressive visual disturbance

Posterior cortical atrophy (PCA) or the "visual variant" of AD is a clinical syndrome of visual agnosia, some or all of the components of Balint's syndrome, transcortical sensory aphasia, and Gerstmann's syndrome (Benson *et al.*, 1988). There have been other terms used to describe this syndrome, including the "visual variant of AD" (Levine *et al.*, 1993) and asymmetric cortical degeneration syndrome of the visuo-perceptual subtype (Caselli, 1995). The syndrome is dictated by the prominent dysfunction of bi-parietal and occipital cortices. By the time PCA has run its course, many patients develop dementia more typical of

Alzheimer's disease. Neither ApoE allele nor *Tau* haplotype frequencies differ between PCA and AD (Tang-Wai *et al.*, 2003c). Although pathologically heterogeneous, several postmortem studies on PCA have shown AD pathology. The greatest involvement of plaques and tangles have been found in the primary and visual association cortices in the occipital lobes with lesser involvement in the parietal lobes (Hof *et al.*, 1997). Other documented neuropathologic findings of PCA include non-specific degenerative changes, with gliosis, neuronal loss, and vacuolation of superficial cortical layers, Creutzfeldt–Jakob disease (CJD) (Victoroff *et al.*, 1994), and corticobasal degeneration (Tang-Wai *et al.*, 2003b).

Progressive apraxic syndrome

Ross Mackenzie *et al.* (1996) published a case of a man with progressive difficulties performing manual tasks and an inability to write. Memory was initially preserved; however, over time he progressed from the initial biparietal syndrome to a more global dementia. MRI revealed left parietal and temporal atrophy while SPECT revealed biparietal hypoperfusion. Neuropathology revealed changes of AD affecting predominantly the superior parietal lobes. Predominant left focal anterior parietal dysfunction can lead to symptoms of ideomotor apraxia. Although apraxia is commonly seen in advanced stages of AD, it can be a presenting feature of the disease and can cause confusion with corticobasal degeneration (Boeve *et al.*, 1999). Unlike AD, corticobasal degeneration commonly presents with asymmetric parkinsonism, ideomotor apraxia and alien limb phenomenon with less severe memory deficits. Although the presence of a significant memory disturbance may differentiate AD from CBD or other neurodegenerative cases, this is not always the case.

Treatments of Alzheimer's disease

The strategies of pharmacological treatment of AD are (i) disease prevention, (ii) symptomatic treatment, and (iii) disease modification. Currently, only two types of treatment of AD are in use: disease modifying, with the use of antioxidants, and symptomatic treatment with anticholinesterase inhibitors (AChEI) (Table 28.3). Although other potential medications, such as cholesterol lowering agents, memantine and non-steroidal anti-inflammatory drugs, have shown an association to slow or delay the onset of AD, randomized blinded drugs trials are currently under way to evaluate their efficacy. Estrogen replacement therapy has not been shown to slow disease progression or

improve cognitive function in women (Henderson *et al.*, 2000; Mulnard *et al.*, 2000).

Symptomatic treatment: acetylcholinesterase inhibitors

Acetylcholine is involved in many aspects of cognition, including memory and attention. The use of anticholinergic medications, however, can produce learning and recall deficit that is similar to the cognitive changes seen in AD (Petersen, 1977). Patients with AD have a cholinergic deficit due to reduction of choline acetyltransferase, the synthetic enzyme for acetylcholine (Bowen *et al.*, 1976; Davies & Maloney, 1976) and deposition of plaques and tangles causing damage and loss of cholinergic neurons in the basal forebrain (Whitehouse *et al.*, 1981, 1982). Based on these findings, there has been a longstanding effort to try to augment cholinergic functioning in the brains of patients with AD. By administering an AChEI, the acetylcholine increases and memory improves. Currently, the only approved Food and Drug Administration (FDA) medication for the treatment of clinically probable AD are AChEIs, tacrine, donepezil, rivastigmine, and galantamine. All of the AChEI have similar clinical profiles and have been shown in careful, double-blind, placebo-controlled studies to significantly improve memory in AD patients.

Tacrine (Cognex) was the first approved compound for the symptomatic treatment of AD. Although helpful, it was cumbersome to use with four times a day dosing and liver toxicity, necessitating regular monitoring of liver functions. Tacrine is rarely used for the treatment of AD currently as newer drugs without these limiting features have been introduced.

Donepezil (Aricept) was the next AChEI approved by the FDA in the mid-1990s. Its single daily dose and no laboratory monitoring requirement provide advantages over tacrine. The typical starting dose is 5 mg per day and if well tolerated in 4 to 6 weeks, the dose is increased to 10 mg per day. There have been several studies on the efficacy of donepezil and most show a modest improvement in cognitive function as measured by scales such as the Alzheimer's Disease Assessment Scale–Cognitive Subscale (ADAS–Cog) and the Clinician's Interview-Based Impression of Change (CIBIC Plus) (Rogers *et al.*, 1998; Doody *et al.*, 2001). The drug has been approved for mild to moderate AD and the length of the response has been documented up to 52 weeks. However, studies have indicated that, when donepezil is discontinued, performance of the subject returns to the same as in the untreated state. Furthermore, when used for 1 year, patients on donepezil revealed continued progression of the disease but it was

Table 28.3. Pharmacological treatment of Alzheimer's disease

Drug	Mechanism	Initial dose	Target dose	Titration interval	Side effects
Tacrine (Cognex)	AChEI	10 mg QID	40 mg QID	4 wks	Liver function test evaluations, diarrhea, anorexia, nausea, vomiting, myalgia
Donepezil (Aricept)	AChEI	5 mg QD	10 mg QD	4–6 wks	Nausea, vomiting, diarrhea, muscle cramps, anorexia, vivid dreaming
Rivastigmine (Exelon)	AChEI	1.5 mg BID	6 mg BID	2–4 wks	Nausea, vomiting, diarrhea, weight loss, dizziness
Galantamine (Reminyl)	AChEI	4 mg BID	12 mg BID	4–6 wks	Nausea, vomiting, diarrhea, anorexia, dizziness
Vitamin E	Antioxidant	1000 IU QD	1000 IU BID	2–4 wks	Liver function, hemorrhage
Memantine*	NMDA receptor antagonist	5 mg QD	10 mg BID or 20 mg QD	2–4 wks	Agitation, urinary incontinence, urinary tract infection, nausea, diarrhea, insomnia, tachycardia

* Not FDA approved.

associated with a reduction in the risk of functional decline compared to placebo (Mohs *et al.*, 2001). These indicate that donepezil has a symptomatic effect on the disease but does not affect the underlying pathophysiologic process.

The other AChEIs, rivastigmine (Exelon) and galantamine (Reminyl) have been approved by the FDA as well (Rosler *et al.*, 1999; Tariot *et al.*, 2000). While galantamine is a reversible inhibitor of acetyl cholinesterase, rivastigmine is pseudo-irreversible as it dissociates from the enzyme slowly. Unique biochemical features to either AChEI are that rivastigmine is also an inhibitor of butyrylcholinesterase and galantamine has some nicotinic receptor activity. These features are proposed to provide additional benefits of one AChEI over another. Both rivastigmine and galantamine are dosed twice daily and have similar dosing schemes. The dosing of rivastigmine begins with 1.5 mg twice a day and increases in increments of 1.5 mg per dose to a maximum of 6 mg twice daily. The starting dose of galantamine is 4 mg twice daily and increases in increments of 4 mg per dose twice a day to a maximum of 12 mg twice daily if tolerated. Dose escalation of either medication should be done on a 4-week basis to minimize side effects. Both of these medications afford greater dosing flexibility but may be somewhat more difficult for the patients because of the twice daily dosing schedule. Although they may provide greater cholinesterase inhibition at the highest dose, they are also prone to have an increased frequency of side effects. The effect size of either rivastigmine or galantamine on the ADAS-Cog and the CIBIC Plus is approximately the same as donepezil (Doody *et al.*, 2001).

All AChEI have a similar side effect profile including increase in bowel frequency, nausea and vomiting. Theoretically, all AChEI can influence cardiac rhythm but this is not commonly encountered unless a person has an underlying disturbance in cardiac conduction. An electrocardiogram prior to initiating an AChEI may be recommended. Cholinesterase inhibitors may also have an effect on respiratory conditions, such as chronic obstructive pulmonary disease or asthma, or gastrointestinal diseases, such as gastric ulcer. Occasionally, patients experience vivid dreaming and cholinesterase inhibitors can theoretically interfere with the administration of anesthesia during surgery. The absorption of AChEI is not influenced by food intake.

There have been few studies in which these drugs have been compared to each other so there is little to recommend one over the other. While the effects are modest, they do appear to enhance the cognitive function in subjects with AD and are recommended for the treatment for patients with mild to moderate AD (Doody *et al.*, 2001).

Disease modifying

Selegiline and alpha-tocopherol (vitamin E)

In a two-year double-blind study, 341 moderately severe AD patients (average MMSE of 12) participated in a placebo-controlled study comparing placebo with 2000 IU of alpha-tocopherol, 10 mg of selegiline and both medications (Sano *et al.*, 1997). In each of the three treatment groups compared to the placebo group, there was a significant delay in reaching the primary endpoints of death, institutionalization,

loss of basic activities of daily living, or severe dementia, defined as progression from CDR-2 to CDR-3. However, the results for selegiline were less convincing and with its potential toxicities and drug interactions, large dose of vitamin E was recommended in AD patients. Long-term side effects of large doses of vitamin E are still unknown but it is generally well tolerated. However, in a recent study, small doses (50 mg) of vitamin E in almost 30 000 Finnish men, decreased heart attacks, strokes and prostate cancer but increased cerebral hemorrhage (The Alpha-Tocopherol Beta Carotene Cancer Prevention Study Group 1994). Vitamin E thus has anticoagulant properties and interacts with warfarin. The American Academy of Neurology has indicated that vitamin E, 1000 IU p.o. b.i.d. can be considered in an attempt to slow the progression of AD (Doody *et al.*, 2001). The risk to benefit ratio for selegiline was felt to be less favorable.

Memantine

The glutamatergic hypothesis of dementia forms the rationale in the use of memantine, a non-competitive *N*-methyl-D-aspartate (NMDA) antagonist, in the treatment of AD (Müller *et al.*, 1995). The basis for the glutamatergic hypothesis of dementia is based on the following facts (i) glutamate is the main fast excitatory neurotransmitter in regions associated with cognition and memory (the cerebral cortex and hippocampus); (ii) cortical and subcortical structures that contain glutamatergic receptors are structurally damaged during the course of AD; (iii) glutamate acts as an excitotoxin causing neuronal death when excessive levels are chronically released; (iv) the neurochemical changes and some of the clinical symptoms seen can be induced experimentally with potent glutamate agonists; and (v) clinical signs of dementia correlate with deficits of glutaminergic association fibers (Winblad & Poritis, 1999). Memantine blocks NMDA receptor channels in the resting state and can leave the channel upon physiological activation during memory formation but does not leave under pathological activation (Winblad & Poritis, 1999). Memantine treatment of 10 mg per day has been shown in a few double-blind, placebo-controlled trials to maintain or improve functional level in patients with severe dementia (Winblad & Poritis, 1999; Reisberg *et al.*, 2003). Side effects of memantine were comparable to placebo. The most frequent side effects included vertigo, restlessness, hyperexcitation and fatigue.

Secretases and immunotherapy

Since the role of beta amyloid (A β) is considered to be paramount in the development of AD, several research strategies have been undertaken to alter the biochemistry of A β in the brain through interference of either the forma-

tion or the deposition of A β . Beta amyloid is processed by several proteases to various non-amylogenic (α -secretase) and amylogenic pathways (β -secretase and γ -secretase) (Selkoe, 2000). Consequently, strategies have been developed in an attempt to inhibit the activities of both β -secretase and γ -secretase (Hussain *et al.*, 1999; Sinha *et al.*, 1999; Vassar *et al.*, 1999; Yan *et al.*, 1999) and thus inhibit the formation of A β . The β -secretase enzyme termed BACE is one target and γ -secretase is another. Clinical trials are being designed to assess the viability of these approaches, but currently no data are available.

Another therapeutic approach involves immunization therapy. When transgenic mice over-expressing a human mutant form of APP and demonstrating many of the pathologic features of AD were actively immunized against A β at birth, they demonstrated significantly reduced A β plaque formation later in life (Schenk *et al.*, 1999). In addition, mice immunized in mid-life showed a reduction in further progression of the disease with a suggestion of regression of the underlying pathology.

Recently, a double-blind Phase II clinical trial was initiated testing the active immunization therapy approach in humans with mild to moderate AD. Despite the initial Phase I human safety trials revealing minimal side effects (Schenk, 2002), the trial was discontinued early due to development of postvaccination subacute meningoencephalitis in 18 of the 298 patients who received the active vaccine 3 to 6 months after their last injection (Senior, 2002; Orgogozo *et al.*, 2003). The development and severity of the aseptic meningoencephalitis did not correlate with levels of antibody titres. Postmortem examination of a brain from one patient who received the active vaccine in the Phase I trial revealed widespread T-lymphocyte meningoencephalitis but, when compared to unimmunized cases of AD, there were extensive areas of neocortex with very few A β plaques (Nicoll *et al.*, 2003). In areas of the cortex devoid of A β plaques, there were densities of tangles, neuropil threads and cerebral amyloid angiopathy similar to unimmunized AD, but lacking plaque-associated dystrophic neurites and astrocyte clusters; and in some regions, A β -immunoreactivity was associated with microglia (Nicoll *et al.*, 2003). Although this postmortem case may have had an unusual pattern of AD pathology, the authors also report that these findings were similar to the murine models of A β immunotherapy and suggest an immune response was generated and elicited clearance of A β plaques in this patient (Nicoll *et al.*, 2003).

Passive immunization can be another approach, as passively immunized mice also revealed reversal of memory deficits but not brain A β burden (Dodart *et al.*, 2002) but with increased cerebral hemorrhages (Pfeifer *et al.*,

2002). Immunotherapy may remain a potential therapeutic option; however, there are concerns related to this approach and the potential side effects from the chronic immunization against A β in humans.

Conclusions

AD is a common disorder of aging and can be reliably diagnosed clinically. Since Alois Alzheimer's initial description of the disease, research on diagnosis, etiology and treatments is advancing. Although the clinical description will unlikely change, our understanding of this disorder will likely expand and change as various theories and observations continue to evolve.

The neuropathology of Alzheimer's disease in the year 2005

Colin L. Masters¹ and Konrad Beyreuther²

¹Department of Pathology, The University of Melbourne and the Mental Health Research Institute of Victoria, Parkville, Australia

²Centre for Molecular Biology, the University of Heidelberg, Heidelberg, Germany

Introduction

The current molecular era of the neuropathology of Alzheimer's disease began in the early 1970s with the first attempts to characterize the biochemical basis of the amyloid deposits (now designated A β), which remain the pathognomic feature of this illness (Nikaido *et al.*, 1971). Subsequent dramatic progress in amino acid sequencing (Glennner & Wong, 1984; Masters *et al.*, 1985), gene cloning (Kang *et al.*, 1987), and elucidation of the biogenesis of the A β amyloid protein (for recent reviews see Beyreuther *et al.*, 2001; Cummings & Cole, 2002; Hardy & Selkoe, 2002; Ines Dominguez & DeStrooper, 2002; McLean *et al.*, 2001; Sisodia & St George-Hyslop, 2002) have led to a coherent picture of the pathogenesis of AD. However, this explosion of knowledge on AD still has not been fully translated back into the clinic, the pathology laboratory, or the mortuary, where diagnostic criteria remain subjective and ambiguous. As the natural history of AD becomes better understood at the molecular level, it would be highly desirable to develop standardized protocols for diagnosis based around the principal biochemical pathway: the biogenesis and accumulation of A β amyloid in susceptible areas of the brain (Fig. 29.1). This chapter outlines the traditional methods of neuropathologic diagnosis, together with some approaches to the contemporary molecular diagnosis of AD both during life and after death (Fig. 29.2), which should have general applicability to the other major diseases caused by the toxic gains-of-function of α -synuclein (Parkinson's disease; diffuse Lewy body disease; multiple system atrophy), prion protein (Creutzfeldt-Jakob and related diseases); Cu-Zn superoxide dismutase (amyotrophic lateral sclerosis); polyglutamine expansions (Huntington's disease and mechanistically related illnesses) and the tau microtubule associated protein (frontotemporal degenerations; Pick's

disease; cortico-basal degeneration; progressive supranuclear palsy).

The A β theory of Alzheimer's disease and the problem of selective vulnerability

One of the dominant themes of classical neuropathology has been that of selective vulnerability, incorporating the Vogts' concept of "pathocllisis", in which the spectrum of regional-to-cellular graduation of vulnerability requires explanation. As the severity and duration of AD increases, the areas of brain involved appear to spread from temporal to frontal/parietal, then move posteriorly towards the occipital regions. In the more aggressive cases (particularly those with an early age of onset, often on a background of a pathogenic mutation in the APP/PS1,2 genes), then other subcortical structures (striatum, thalamus, cerebellum) become involved. This pattern of topographic vulnerability has eluded a rational explanation. The only clue that has emerged involves the glutamatergic system and the distribution of free vesicular zinc required for its operation (Hashemzadeh-Gargari & Guilarte, 1999; Weiss & Sensi, 2000). There is at least a superficial correspondence between the tissue content of free zinc ions and the regional vulnerability in AD. Our studies over the last eight years (Bush *et al.*, 1993, 1994; Cherny *et al.*, 1999, 2001; Jobling *et al.*, 2001; Opazo *et al.*, 2002) have indicated that Zn²⁺ and other metal ions have the capacity to induce aggregation of A β . These properties have recently been confirmed using biological models in which A β -overexpressing mice, when crossed into a background deficient in a synaptic vesicle zinc transporter (ZnT3), have decreased amounts of A β plaques (Lee JY *et al.*, 2002). The metal-induced aggregation of A β is therefore suggested to be the initial event which leads to the toxic-gain-of-function of A β . The immobilized

A β theory of Alzheimer's disease

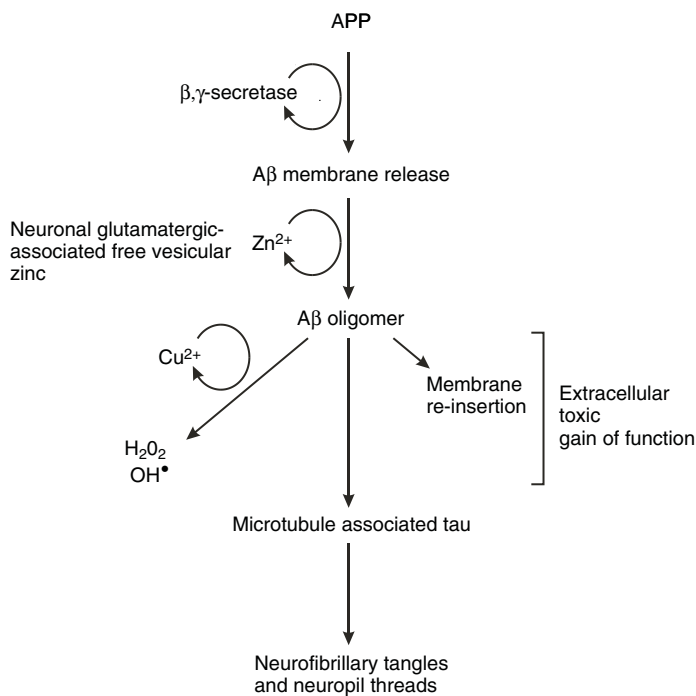

Fig. 29.1 The pathway downstream of APP (amyloid precursor protein), which leads to the neurodegeneration characteristic of Alzheimer's disease. A β is generated and released from the membrane through the actions of β - and γ -secretases; in a zinc-rich microenvironment, A β may oligomerize and either re-insert into a membrane or radicalize to form toxic reactive oxygen species. Further downstream, tau polymerizes to form tangles and threads.

A β can then react with redox-active ions such as Cu²⁺ or Fe³⁺, generating H₂O₂ or OH[•] or potentially interact with lipid membranes (Curtain *et al.*, 2001). In both cases the neuron is subjected to damaging stresses which, over time, result in dysfunction. How neurons develop neurofibrillary tangles and neuropil threads (containing polymerized tau) remains unclear, but we would suggest that this process lies downstream of the A β -induced toxic insult. Again, partial confirmation of this pathway has emerged from cell and animal models (Rapoport *et al.*, 2002).

The basic neuropathology of Alzheimer's disease

The neuropathologic diagnosis of Alzheimer's disease still revolves around the morphologic assessment of A β amyloid accumulation within the brain, either as "senile"

plaques or as perivascular amyloid angiopathy. Quantitative biochemical assays of A β accumulation may eventually replace the standard morphologic approach, but this is unlikely to occur in the near future. In vivo neuroimaging techniques for A β amyloid, rather than biochemical assays, may well supersede the traditional neuropathologic assessment within the next decade.

Macroscopic changes

There are no macroscopic changes that are specific for AD. The brain may appear quite normal, or may show extreme atrophy in most cortical areas with concomitant dilation of the ventricular system. The degree of atrophy does seem to correlate partially with the "aggressiveness" of the disease process, being more pronounced in the younger, often familial, cases with rapid deterioration and prolonged vegetative state. Loss of white matter may also be apparent in such cases. Variation in regional areas of atrophy may also be related in some cases to the type of clinical presentation (frontal, temporal, left or right hemispheric predominance).

In cases where small vessel β -amyloid angiopathy is a feature, evidence of focal, old or fresh cortical and subpial hemorrhages may be seen. Concomitant large vessel atherosclerotic disease occurs at a rate expected in the general population, and does not appear to be particularly associated with AD.

Classical histological changes – A β amyloid plaques

The cardinal, pathognomic, feature of AD is the accumulation of A β amyloid, which with today's technology, is best evaluated by using sensitive immunocytochemical methods. There is still no agreement on what constitutes a "normal" or "threshold" level of A β deposition beyond which a diagnosis of AD can be entertained. Working backwards, however, the complete absence of A β deposits in the presence of other major histologic changes (neurofibrillary tangles, gliosis, neuronal loss) should mandate that a diagnosis of AD cannot be made.

The A β -amyloid plaque is the most easily identifiable structure using light microscopy. Attempts to classify these plaques as "senile," "neuritic," "amorphous," "diffuse," "cotton-wool," "primitive/early," "classical/mature," "burned-out/compact" remind us of the proverbial blind person describing an elephant. Immunocytochemistry has identified A β -amyloid at the nidus of all these structures, which have been partially re-created in the transgenic mouse models of AD. A seminal recent observation has been that some aspects of the "amorphous/ diffuse/

Contemporary neuropathology of Alzheimer's disease

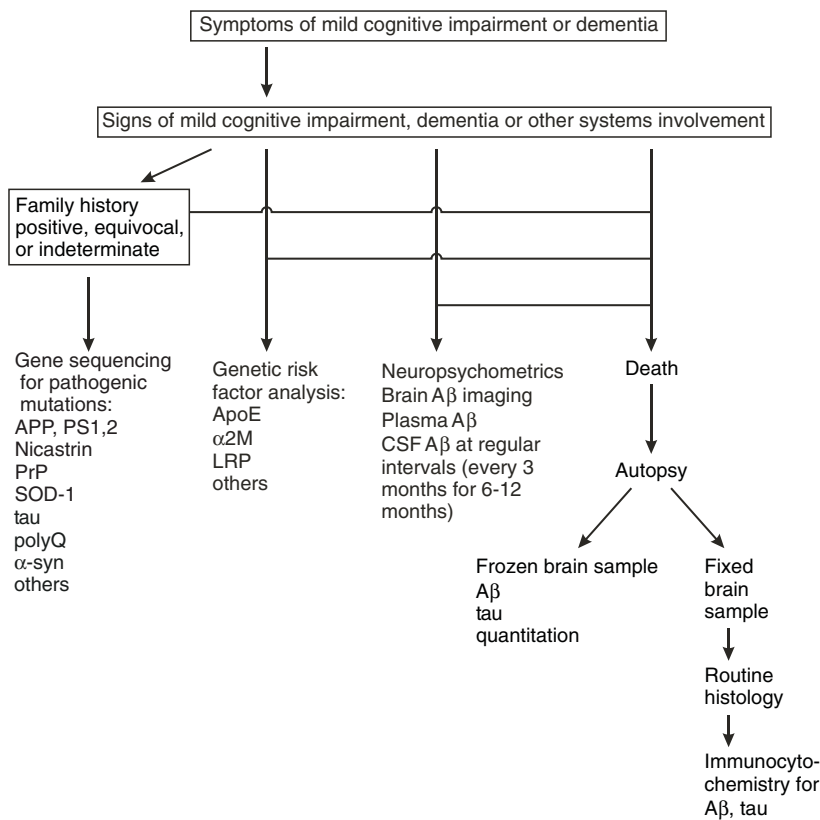

Fig. 29.2 A scheme of the clinical neuropathological work-up in the current time, with application of quantitative and qualitative molecular techniques to assign a diagnosis.

cotton-wool” morphology may actually represent intracellular A β aggregates. This would be consistent with the lack of any appreciable surrounding glial or microglial change. If confirmed, the presence of aggregated A β intraneuronally may provide the missing-link for an explanation of how the tau protein aggregates into the neurofibrillary tangle. At the very least, the tau-positive neuritic changes surrounding the extracellular A β deposits confirm the current theory that tau aggregation is down-stream of A β deposition/accumulation. It is sobering to recall that most of these morphological changes associated with A β plaques have been described for many years (for example, neuritic changes by Cajal, Drusige Entartung by Scholtz), and yet the molecular bases underlying them remain elusive.

Use of sensitive and specific immunocytochemical techniques for visualization of A β amyloid deposition has also disclosed the vast, unanticipated, extent of A β deposition in the subpial extracellular spaces, together with the

perpendicular streaking patterns seen in the molecular layers of the cerebellum, and the laminar patterns within the central cortex, consistent with current ideas on the bulk flow of A β in the extracellular and perivascular spaces of the brain. These morphologic changes also support the idea that neuronally generated A β can be transported across the blood-brain-barrier into the general circulation.

Tau-related neurofibrillary tangles (NFT)

Often thought of as an hallmark of AD, these NFT structures (which also include neuritic changes in the neuropil and the Drusige Entartung around the A β amyloid plaques) are now seen as rather non-specific changes provoked by the upstream toxic effects of A β amyloid. They occur in other unrelated conditions (for example, the tauopathies including progressive supranuclear palsy). The intracellular tangles and neurites contain filamentous aggregates of the

tau microtubule-associated protein, which also have the tinctorial properties of an amyloid substance. By electron microscopy, a very characteristic paired helical (twisted) filament substructure is seen, together with straight filaments. The structural basis for the differences between a twisted and straight filament remains unanswered, as both appear to be composed solely of the tau protein.

Granulovacuolar degeneration (GVD) and Hirano bodies

The GVD of Simchowicz and Hirano bodies are often seen in hippocampal neurons in AD, changes which still remain enigmatic in nature, and of little diagnostic value.

Neuronal and synaptic loss

As part of the A β -induced neurodegenerative process, synaptic dysfunction occurs at an early stage. The morphologic correlate of this may lie in the loss of markers of synapses (e.g. synaptophysin). As the disease progresses, neuronal death occurs, but is often difficult to quantitate, being apparent only in the more severe cases with extensive gliosis.

Astrocytic and microglial changes

The A β -induced damage to neurons provokes secondary glial and microglial reactive changes, easily observed with appropriate immunocytochemical markers, but rarely necessary for diagnosis. It is also possible that the soluble and insoluble forms of A β directly activate glial and microglial responses, as seen by the vigorous glial changes which often surround the "neuritic" plaque. More recent evidence of the reactive nature of microglia has come from the studies of immunization of experimental animals and humans with A β itself, as a method of promoting its clearance from the brain (Nicoll *et al.*, 2003; Orgogozo *et al.*, 2003).

The morphometric approach to the neuropathology of AD

The mainstay of current neuropathologic evaluation is still the microscopic demonstration of A β and tau accumulation. Utilization of specific immunocytochemical labels has permitted the unequivocal identification and semi-quantitation of these lesions (Gold *et al.*, 2001; Kraszpulski *et al.*, 2001; Parvathy *et al.*, 2001). With the widespread availability of specific A β and tau antibodies, most cases coming to biopsy or autopsy can be categorized on these

histologic criteria. Similarly, for the other major classes of neurodegeneration, the immunocytochemical demonstration of aggregates of α -synuclein, PrP, SOD-1, polyglutamine and tau should permit an efficient method for diagnosis and classification.

There is still a need, however, for more accurate and quantitative estimates of the degrees of cerebral involvement with A β . The spectrum of A β accumulation varies widely, ranging from subtle intracellular immunoreactivity of uncertain significance through to massive clouds of A β in the neuropil (amorphous or cotton wool plaques, Davies *et al.*, 1988; Smith *et al.*, 2001) or to perivascular congophilic deposits (Revesz *et al.*, 2002). At the morphometric level, image analysis and stereologic techniques may have some useful properties (Bussière *et al.*, 2002; Fishman *et al.*, 2001), but practically the methods are too time consuming and require a large input of effort in cross-validation from one laboratory to the next.

The clinical biochemistry of A β in AD

Since A β lies in the centre of the pathway, it seems irrefutable that biochemical measurements of A β loads in the brain should provide the best estimate of disease activity. The physical forms of A β being assayed (soluble vs insoluble (McLean *et al.*, 1999); monomer, dimer, oligomer (Walsh *et al.*, 2002); oxidized or reduced (Kanski *et al.*, 2002); metallated vs non-metallated (Cherny *et al.*, 2000; Curtain *et al.*, 2001); lipid-associated or -free (Oshima *et al.*, 2001); and length of peptide, A $\beta_{x-40/42}$) and the tissue sources of A β (brain grey matter; CSF; plasma, etc.) need to be defined and validated in the clinical context.

While we and others have demonstrated the feasibility of measuring brain levels of A β (McLean *et al.*, 1999), such measurements have yet to be trialled in a practical way. We would propose, in the first instance, a simple ELISA-based measure of total A β species (A $\beta_{\xi-40/42}$) in the soluble and insoluble fractions of grey matter homogenate. Our preliminary studies do not suggest that the area of cortex sampled is critical, but for the sake of consistency, a limited number of easily accessible and identifiable cortical sites could be selected (inferior temporal; superior frontal; parietal).

For obvious reasons, much attention has been given to assaying A β levels in CSF (Andreasen *et al.*, 2001a, b; Maruyama *et al.*, 2001; Mehta *et al.*, 2001; Okamura *et al.*, 2001; Riemenschneider *et al.*, 2002a; Rösler *et al.*, 2001; Shoji & Kanai 2001; Shoji *et al.*, 2001; Sjögren *et al.*, 2001) with a consensus emerging that while elevated levels may

exist in the early phases of AD (especially an increased ratio of A β ₄₂ to A β ₄₀, Jensen *et al.*, 1999), and as the disease progresses, CSF levels of A β decrease and tau levels increase. The value of CSF A β levels in discriminating AD from other causes of dementia is beginning to emerge (Kapaki *et al.*, 2001; Riemenschneider *et al.*, 2002b; Sjögren *et al.*, 2002; Tschampa *et al.*, 2001). Much larger data sets need to be reported, and comparisons made between in vivo levels and diagnostic outcomes obtained post mortem.

Better than CSF, plasma A β could yet prove to be an accurate surrogate marker for cerebral A β . While early studies were disappointing, with large inter-subject variability (Mehta *et al.*, 2001), more recent results suggest that plasma A β _{40/42} is in a dynamic equilibrium with cerebral A β turnover (DeMattos *et al.*, 2001, 2002 a, b), and that the inter-subject variability of plasma A β levels is under genetic control (Ertekin-Taner *et al.*, 2001; Schupf *et al.*, 2001). Understanding this genetic variability may lead to processes that determine cerebral A β turnover and clearance mechanisms. Our own preliminary observations suggest that plasma A β will prove to be a valuable guide to therapeutic intervention (Ritchie *et al.*, 2003), and others are also beginning to evaluate this aspect (Tokuda *et al.*, 2001). The early indications are that serial estimations of plasma A β over a period (possibly 3 to 12 months) will provide a guide to cerebral A β turnover, both for steady-state levels and for a guide to A β -targeted therapeutic interventions.

Besides A β levels, estimates of markers upstream or downstream of A β could prove to be complimentary. Upstream, γ -secretase and β -secretase (BACE1) can now be measured using both functional assays and immunoassays. Since β -secretase activity appears to be increased in sporadic AD (Holsinger *et al.*, 2002), this would be an obvious candidate for an upstream assay, particularly in CSF or plasma if this enzyme were released from the cerebral compartment. There is, as yet, no evidence for an increased function in the γ -secretase complex (presenilin 1,2; nicastrin; APH-2; PEN2) in any form of AD, so this would appear to be an unlikely object of assay development.

The place of genetic diagnostics in the neuropathology of AD

A full family history is now essential for a complete evaluation of anyone with adult-onset dementia, but it is disappointing to see how poorly this is documented in most neuropathologic reports on individual subjects. In most (if

not all) pedigrees in which a clear history of autosomal dominant inheritance is obtained, a pathogenic mutation in one of the genes for APP, PS1,2 will be found. Screening of other relevant genes (Prnp, tau, SOD, Htt, α -syn) should be considered when an AD-causative mutation is not evident in an autosomal dominant pedigree.

While genetic risk factors such as ApoE allotype have a clear impact on the age of expression of AD, the full spectrum of risk factors (such as polymorphisms in the genes encoding IDE, α 2Macroglobulin and LRP) have yet to be elucidated, and their practical contributions to diagnosis have yet to be demonstrated, both during life and at postmortem. It could be envisaged that a full evaluation of these risk factors in any given individual will eventually have a major role to play in neuropathologic diagnosis.

Neuroimaging of A β

Persistent attempts to develop labelled-ligands for A β which can cross the blood-brain-barrier are beginning to yield encouraging results (Helmuth, 2002). Beginning with compounds which share properties with Congo Red or thioflavin-T (Klunk *et al.*, 2001; Lee C. W. *et al.*, 2001; Mathis *et al.*, 2002; Schmidt *et al.*, 2001; Zhuang *et al.*, 2001a,b), which have long been known to have an increased affinity for all types of amyloid, other A β ligands have emerged (Bading *et al.*, 2002; Kung *et al.*, 2001; Lee H. J. *et al.*, 2002; Shoghi-Jadid *et al.*, 2002). The physical properties of A β have suggested many possible leads, including A β (or subfragments thereof) itself. As a proof-of-concept, the imaging of A β (Helmuth, 2002) will now open a major avenue of diagnostic evaluation, with immense therapeutic-monitoring implications.

Genetics of Alzheimer's disease

Lars Bertram and Rudolph E. Tanzi

Genetics and Aging Research Unit, Department of Neurology, Massachusetts General Hospital, Charlestown, MA, USA

Introduction

Alzheimer's disease, the most common form of age-related dementia, is characterized by progressive and insidious neurodegeneration of the central nervous system eventually leading to a gradual decline of cognitive function and dementia. The key neuropathological features of AD are abundant amounts of neurofibrillary tangles and β -amyloid ($A\beta$) deposited in the form of senile plaques. Although the knowledge of disease pathophysiology still remains fragmentary, it is now widely accepted that, similar to other common diseases like diabetes, coronary artery disease, or breast cancer, genes play an essential role in predisposing to onset and/or in modifying the progress of the disease.

Genetically, AD is a complex and heterogeneous disorder: it is complex because there is no single mode of inheritance that accounts for its heritability. Moreover, disease inheritance shows an age-related dichotomy in which rare but highly penetrant mutations transmitted in an autosomal dominant manner are almost exclusively responsible for the early-onset familial forms of AD (EOFAD), while common polymorphisms with low penetrance appear to have their greatest effect on the more frequent late-onset form of the disease (LOAD; Tanzi, 1999). It is heterogeneous because genetic variants in multiple genes on several chromosomes throughout the genome are involved together with non-genetic factors. All of the known factors contribute to the increased accumulation of $A\beta$ (more specifically: $A\beta_{42}$) owing to an imbalance in production vs degradation/clearance in the cell (Fig. 30.1, 30.2). Several additional characteristics aggravate the identification and consistent replication of AD genes or other complex disease genes across studies and populations (Bertram & Tanzi, 2001a; see also Chapter 17: "Strategies for molecular genetics in neurodegenerative disease"). These

difficulties are evidenced by the fact that of almost 100 potential AD genes analyzed in the literature to date, only four have been proven to either play a direct role in AD pathogenesis (*APP*, *PSENI*, *PSEN2*) or to significantly increase disease susceptibility in almost every study population worldwide (*APOE*; Table 30.1; for review see Bertram & Tanzi, 2001b).

Despite the complexities of AD genetics, tremendous progress has been made over the past two decades. The knowledge gained from genetic studies of AD was and remains the essential prerequisite for our current understanding of the etiological and pathophysiological mechanisms leading to neurodegeneration in AD as well as for the development of novel approaches for disease treatment and prevention. In this chapter we present a brief history of the genetics of Alzheimer's and discuss its current status and future outlook, focusing on recent findings suggesting the existence of several novel AD genes.

Early-onset Alzheimer's disease

Only a fraction of all AD cases can be explained by familial early-onset AD (EOFAD; Tanzi, 1999). Unlike the situation for the much more common late-onset form of AD, genetic studies of EOFAD are considerably facilitated by the availability of large multigenerational pedigrees allowing genetic linkage analysis and subsequent positional cloning to be carried out successfully. In 1987, initial results showed EOFAD linkage to the long arm of chromosome 21 encompassing a region that harbored the gene encoding the amyloid precursor protein (APP; gene: *APP*), a compelling candidate gene for AD (Tanzi *et al.*, 1987). The same chromosomal area also overlapped with the obligate region for Down's syndrome (DS), a disease where affected individuals almost invariably develop AD after a certain age. In

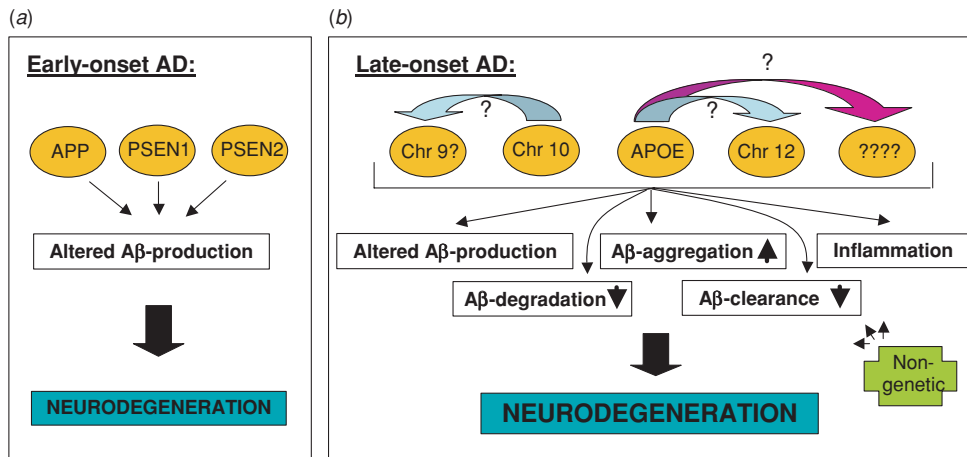

Fig. 30.1 Scheme of contribution and interaction pattern of known and putative AD genes. (a) Mutations in the early-onset AD genes *APP*, *PSEN1*, *PSEN2* all lead to an increase in A β -production without any known interaction with other factors. (b) Simplified scheme of the interaction pattern of known and proposed late-onset AD genes. It is likely, these risk-factor genes each affect one or more of the known pathogenic mechanisms leading to neurodegeneration in AD. Their effects are further influenced by gene-gene interactions and the contribution of non-genetic risk-factors. Note that none of the interaction patterns outlined here for didactic purposes has actually been established. (Reproduced from Bertram & Tanzi, 2003, with permission.)

Fig. 30.2 Possible pathogenic routes of A β production, clearance, and degradation. Early-onset AD genes *APP*, *PSEN1*, and *PSEN2* along with *BACE* (β -secretase) are involved in the production of A β . The late-onset AD gene *APOE* and the putative AD gene, α -1-antichymotrypsin (*ACT*) have been proposed to play roles in the aggregation and fibrillogenesis of A β . *APOE* and putative AD genes, *LRP* and *A2M* may play roles in the clearance of A β as follows. Once α 2M-A β or apoE-A β complexes are internalized by LRP they may be targeted for endosomal recycling, lysosomal degradation, or undergo transcytosis across the blood-brain barrier to the plasma. Membrane APP containing an alternatively spliced Kunitz protease inhibitor (KPI) domain may also undergo internalization by LRP and generate A β (dotted-arrows) via the endocytic pathway (Note: APP has also been shown to undergo LRP-independent endocytosis). Extracellular degradation of A β can occur via binding of the peptide to α 2M followed by degradation by an active protease (e.g. trypsin) bound to the bait region of α 2M. Alternatively, A β may be degraded by “free” proteases such as the insulin degrading enzyme (*IDE*) or neprilysin (*MME*). Asterisk (*) denotes established AD genes. (Reproduced from Tanzi & Bertram, 2001, with permission.)

Table 30.1. Overview of the established Alzheimer's genes and their functional relevance

Gene (Protein)	Chromosomal location	Mode of inheritance	Number of pathogenic mutations (affected families) ^a	Mean familial onset age ^{a,b} (range)	Relevance to AD pathogenesis
<i>APP</i> (β-amyloid precursor protein)	21q21.3	autosomal-dominant	15(39)	51.5 years (35–60)	increase in Aβ (Aβ ₄₂ /Aβ ₄₀ -ratio); mutations close to γ-secretase site
<i>PSEN1</i> (presenilin 1)	14q24.3	autosomal-dominant	128(258)	44.1 years (24–60)	increase in Aβ (Aβ ₄₂ /Aβ ₄₀ -ratio); essential for γ-secretase activity
<i>PSEN2</i> (presenilin 2)	1q31–42	autosomal-dominant	9(15)	57.1 years (46–71)	increase in Aβ (Aβ ₄₂ /Aβ ₄₀ -ratio); essential for γ-secretase activity (?)
<i>APOE</i> (apolipoprotein E, ε4-allele)	19q13.32	complex (risk increase)	<i>n.a.</i>	onset-age modifier	increase in Aβ aggregation; via lipid/cholesterol transport (?)

^a Source: "AD Mutation Database" (as of 04/01/2003).

^b Not all familial onset ages were available for these genes.

1991, the first *APP* missense mutation in patients with EOFAD was described (Goate *et al.*, 1991), shortly after a report on a different variant in the same exon leading to Dutch-type hereditary cerebral hemorrhage with amyloidosis (for review see Hardy, 1997; Tanzi, 1999). Since then, 15 additional AD mutations have been reported in *APP* which, in total, account for approximately one-tenth of all early-onset AD families with known mutations (Table 30.1). Most of the *APP*-variants occur near the putative γ-secretase site between residues 714 and 717 ('AD Mutation Database'), suggesting that especially the γ-cleavage event of *APP* and/or its (dys-)regulation are critical for the development of AD.

A second AD linkage region, on chromosome 14q24, was reported almost simultaneously by four independent laboratories only 1 year after the discovery of the first *APP* mutation (Mullan *et al.*, 1992; Schellenberg *et al.*, 1992; St George-Hyslop *et al.*, 1992; Van Broeckhoven *et al.*, 1992). However, it took 3 more years to clone the responsible gene (*PSEN1*) and identify the first disease-causing mutations (Sherrington *et al.*, 1995). It is now known that *PSEN1* encodes a highly conserved polytopic membrane protein, presenilin 1 (PS1, for review, see Haass & De Strooper, 1999), which is required for γ-secretase activity necessary to liberate Aβ from *APP* (see below). Even a decade after the discovery of *PSEN1*, there are new AD-causing mutations reported in this gene almost every month, currently counting a total of nearly 130 (Table 30.1; "AD mutation database"). But despite the observation that, by far, most AD mutations are located in *PSEN1*, it soon became obvious that this gene together with *APP* does not account for all cases of EOFAD. A database search initiated in 1995 revealed a second member of the PS family of proteins that displayed very high homology to *PSEN1* at the genomic as well as at the

protein level (Levy-Lahad *et al.*, 1995; Rogaev *et al.*, 1995), and consequently, this gene was named "*PSEN2*" (protein: PS2). *PSEN2* maps to the long arm of chromosome 1 and mutations in this gene account for the smallest fraction of all EOFAD cases. On average, they also display a later age of onset and slower disease progression than *APP* or *PSEN1* mutations (Table 30.1).

Despite these seminal advances in understanding the genetics and pathophysiology of EOFAD, several lines of evidence suggest that additional genetic factors remain to be identified for this form of the disease: (i) numerous early-onset families do not show mutations in any of the three EOFAD genes despite extensive sequencing efforts of open reading frames and adjacent intronic regions; (ii) beyond *APP* and *PS1* there are several additional key proteins involved in the γ- and β-secretase cleavage events and other aspects leading to the aggregation and deposition of Aβ (e.g. nicastrin, aph-1, pen-2, BACE; see below), as well as the hyperphosphorylation of tau and the development of neurofibrillary tangles; (iii) a recent full genome screen has identified at least four early-onset AD linkage regions in addition to chromosome 14q24 (Blackner *et al.*, 2003), some of which coincide with the pathophysiological factors mentioned above. Of these, two deserve particular attention. First, the gene encoding nicastrin (*NCSTN*) located on the long arm of chromosome 1. Nicastrin is a type 1 transmembrane glycoprotein and an essential component of the γ-secretase complex that cleaves *APP* and notch (Yu *et al.*, 2000). Although analyses aimed at identifying functionally important sequence variants in early- as well as late-onset AD patients were largely unsuccessful to date (e.g. Dermaut *et al.*, 2002; Orlicchio *et al.*, 2002), a four-locus haplotype that appears to be associated with EOFAD was identified (Dermaut *et al.*,

2002). Interestingly, no association with the same haplotype was observed in LOAD patients in the same study, despite previous positive linkage (Blacker *et al.*, 2003) and association (Hiltunen *et al.*, 2001) results with LOAD in the region. The second gene, encoding “ β -secretase” or BACE (β -site APP-cleavage enzyme; gene: *BACE*), is an aspartic protease located within cell membranes and is highly expressed in brain (for review, see Vassar, 2001). Although a recent genome screen reports linkage only ~20 million base-pairs (Mb) upstream of *BACE* on chromosome 11q25 (Blacker *et al.*, 2003), none of the six independent association studies have found evidence for a genetic involvement of variants in this gene and AD (consult *AlzGene* database <http://www.alzgene.org/>). None withstanding, further research is needed to clarify whether or not possibly rare variants in these two genes may play a significant role in individual AD families, preferably those linked to the respective chromosomal regions, and confer risk similar to the other three established EOFAD genes.

Late-onset Alzheimer’s disease

As outlined above and also in Fig. 30.1, late-onset Alzheimer’s (LOAD) is characterized by a considerably more multifaceted and interwoven pattern of genetic and non-genetic factors that is only poorly understood. Adding to these complexities are methodological difficulties inherent to common diseases in general and late-onset diseases like AD in particular. Family data, for instance, is more often than not incomplete (e.g. owing to relatives who died before the family-specific age of risk and/or the lack of genotypic information for parents). Another complication is the unknown number of “phenocopies”, i.e. subjects with a non-genetic form of the disease or subjects suffering from other forms of age-related cognitive decline. These and other characteristics largely reduce the power to detect new loci in reasonably sized samples and make the identification and, equally important, independent replication of genetic factors of only moderate or small effect very difficult if not impossible. This is evidenced by the fact that even 10 years after the first reports suggesting genetic association between AD and the common ϵ 4-variant in the gene encoding apolipoprotein E (apoE; gene: *APOE*), no other genetic risk factor has been found to consistently confer susceptibility to AD, despite intensive efforts in many laboratories worldwide (Bertram & Tanzi, 2001b). And although none of the almost 100 genes that have been tested for association with AD have yielded consistent results, yet a recent study (Daw *et al.*, 2000), modeling AD as a quan-

titative trait locus, suggests that further gene hunting in LOAD is worthwhile: the authors found evidence for the existence of four to seven additional AD susceptibility loci (or onset age modifiers) besides *APOE*. This is in agreement with recent full genome screens in AD, in which regions on at least nine chromosomes emerge that show evidence for genetic linkage or association with P -values ≤ 0.01 in at least two studies (Table 30.2). In the remainder of this chapter we will discuss the relevance of *APOE* and then focus on two additional, novel AD candidate gene regions on chromosomes 10 and 12. An up-to-date overview on the status of all published case-control AD association studies can be found at the Alzheimer’s Research Forum Genetic database, <http://www.alzgene.org>.

The APOE locus on chromosome 19

The first and, to date only, proof of principle for applying the “positional candidate gene strategy” (i.e. testing biologically plausible candidate genes in promising linkage regions, see also chapter 17) to identify novel AD loci was provided by the identification of genetic association between *APOE* and AD. The positional evidence arrived almost simultaneously with the identification of the first APP mutations, when Pericak-Vance and colleagues reported suggestive linkage of a locus on chromosome 19q to predominantly late-onset AD (Pericak-Vance *et al.*, 1991). Two years later, after $A\beta$ was found to bind apoE (Strittmatter *et al.*, 1993a) which was the first evidence for a functional involvement of apoE in AD, a common polymorphism in its gene, which maps near the linkage region, was tested and shown to be associated with increased risk for AD (Saunders *et al.*, 1993; Strittmatter *et al.*, 1993). In contrast to all other reports of genetic association in AD, this result has been overwhelmingly replicated in a large number of studies across many ethnic groups worldwide (for a meta-analysis see: Farrer *et al.*, 1997). Three major alleles occur at the *APOE* locus, ϵ 2, ϵ 3 and ϵ 4, which translate into combinations of two amino acid changes at residues 112 and 158 of the apoE-protein (ϵ 2: Cys/Cys; ϵ 3: Cys/Arg; ϵ 4: Arg/Arg, respectively), and it is the phylogenetically oldest variant, ϵ 4, that is over-represented in cases of AD. The least frequent allele, ϵ 2, has been associated with a decreased risk for AD, although these findings were replicated in fewer studies than the more predominant ϵ 4 effect (Farrer *et al.*, 1997).

Although the association between ϵ 4 and AD is robust, it is not specific. In contrast to the genetic variants in EOFAD, the presence of ϵ 4 is neither necessary nor sufficient to actually cause the disease. Rather, it appears to

Table 30.2. Overview of concordant linkage/association regions observed in full genome screens published to date

Only results reflecting a *P*-value ≤ 0.01 (i.e. TLS or MLS ≥ 1.4) in at least two studies were considered. TLS = two-point lod score, MLS = multi-point lod score. Shading indicates chromosomes with significant findings using published criteria (Lander & Kruglyak, 1995). Note that samples in Pericak-Vance (2000), Myers (2002), Li *et al.* (2002) and Blacker *et al.* (2003) partly overlap.

^a Stage-I linkage results from this group (Kehoe *et al.*, 1999) were used whenever they exceeded the results of the Stage II findings. (Current on 04/01/2003. For a more up-to-date overview, please consult the *AlzGene* database, <http://www.alzgene.org>.)

be a genetic risk-modifier (or susceptibility factor), that predominantly acts through decreasing the age of onset in a dose-dependent manner, in the sense that homozygous carriers on average show a younger onset age than carriers of just a single copy (Blacker *et al.*, 1997; Meyer *et al.*, 1998). Expressed in terms of overall disease risk, this effect translates into an increased relative risk (as measured by the odds ratio [OR]) of roughly threefold for heterozygous, and almost 15-fold for homozygous carriers as compared to the $\epsilon 3/3$ genotype in Caucasians (Farrer *et al.*, 1997). Similar trends can be seen across different ethnic groups, ranging from ORs of around twofold in Hispanic to more than 33-fold in Japanese $\epsilon 4/4$ individuals. However, due to the non-specific nature of the $\epsilon 4$ -effect, there is widespread consensus within research as well as clinical communities to not use *APOE* genotyping as a sole diagnostic or prognostic test for AD, but only for scientific purposes (Burke *et al.*, 2001).

Despite the established genetic role of *APOE* in AD, only little is known about its potential pathophysiological effects and mechanisms. The most straightforward hypothesis assumes that the different variants directly influence A β -accumulation (Strittmatter *et al.*, 1993), and several lines of evidence support this notion, e.g. an increase of the number of A β -plaques in the brain of $\epsilon 4$ -allele carriers

vs. non-carriers, and marked differences in the deposition of A β -plaques depending on the presence or absence of human *APOE* in transgenic mice over expressing *APP* (for a recent review on *ApoE* function, see Poirier, 2000). Further, there is evidence for a decrease in onset age depending on *APOE*- $\epsilon 4$ in EOFAD caused by *PSEN1* mutations (Nacmias *et al.*, 1995). No consensus has yet been reached regarding the predominant mechanism(s) underlying these effects, although systemic dysfunction in lipid transport, and more specifically cholesterol homeostasis are likely pathways, especially since high plasma cholesterol levels are associated with increased β -amyloid in the brain (Poirier, 2000). Thus, it is possible that *APOE*- $\epsilon 4$ confers risk for AD via mechanisms that are shared with its effects on cardiovascular disease, e.g. by increasing a carrier's risk for hypercholesterolemia.

Chromosome 12

Of the novel putative AD loci to be discussed in the remainder of this chapter, the locus on chromosome 12 was described first, when in 1997 and 1998 three independent laboratories reported evidence for linkage with AD near the p-telomere and the centromeric region of this chromosome (Pericak-Vance *et al.*, 1997; Rogaeva

et al., 1998; Wu *et al.*, 1998). Subsequent analyses revealed strong association with biologically highly plausible and related candidate genes in both regions, which are separated by ~50 Mb. The first gene, located on the proximal end of chromosome 12 (at approx. 10 Mb), encodes alpha2-macroglobulin (α 2M; gene: *A2M*) a pan-protease inhibitor that has been found to potentially modify A β -catabolism in several ways, including the prevention of A β -fibril formation and fibril associated neurotoxicity, protease mediated degradation of A β , and LRP (see below) mediated endocytosis and subsequent lysosome degradation of A β (Fig. 30.2; for a recent review of α 2M function, see Saunders *et al.*, 2003). Almost simultaneously, two papers were published shortly after the initial linkage findings reporting strong and significant association with separate polymorphisms in *A2M*. The first one used family-based methodologies and found an overrepresentation of a 5-bp deletion just upstream of exon 18, near the “bait” region of α 2M, i.e. near the potentially functional region of the protein in mostly small LOAD families (Blacker *et al.*, 1998). The second study employed a case-control design, and reported association with an amino acid substitution at residue 1000 (Val→Ile), near the thiolester active site of α 2M. In a small series of cases, this study also showed a small but significant increase in A β -burden in carriers of the risk allele, i.e. Val (Liao *et al.*, 1998).

The combination of promising and independent linkage and association findings has initiated a huge set of follow-up investigations, only exceeded in number by the studies on *APOE*. However, more often than not, subsequent attempts to corroborate the original findings in independent laboratories have failed. A recent meta-analysis even concluded that “*A2M* is not genetically associated with LOAD in white patients or mixed populations as found in the United States” (Koster *et al.*, 2000). This conclusion stands in contrast to at least ten independent reports beyond the two initial papers demonstrating significant association between polymorphisms in *A2M* and AD in US Caucasians and other ethnic groups, using both case-control and family-based designs (see *AlzGene* for an up-to-date overview). Eventually, more detailed and sufficiently-sized analyses will be necessary to indicate the extent to which variations in *A2M*, or possibly a gene nearby, confer risk for AD. The growing number of confirmatory reports, even amidst multiple refutations, make it unlikely that the initial findings are due to type I error alone. Further analyses in a greatly enlarged sample of NIMH families, including those for which the initial association was described, have revealed novel exonic and intronic polymorphisms in *A2M* that appear to be equally or stronger

associated with disease than the 5-bp deletion upstream of exon 18 (Saunders *et al.*, 2003). In addition, haplotype analyses including all or only subsets of these polymorphisms, revealed even more pronounced association signals than the individual polymorphisms alone. Along these lines, recent case-control as well as family-based studies using SNP-haplotypes in or around *APOE* revealed strongly positive findings for polymorphisms that, individually, were either not or only weakly associated with AD (Martin *et al.*, 2000; Fallin *et al.*, 2001). It is noteworthy that the only haplotype-based case-control study on *A2M* in the AD literature to date supports an association of this locus and AD (Verpillat *et al.*, 2000).

The second gene reported to be associated with AD on chromosome 12 encodes the low-density lipoprotein receptor-related protein (LRP; gene: *LRP*), and resides approximately 50 Mb downstream of *A2M* in the more centromeric region of the chromosome (Kang *et al.*, 1997). LRP exerts its potentially pathophysiological effects by participating in two opposing mechanisms: first, by mediating the internalization of APP which can subsequently lead to an increase in A β -production, second, it has been shown that LRP also mediates the internalization of extra cellular A β bound to α 2M and apoE, followed by lysosomal degradation, endosomal recycling or transcytosis via the blood-brain barrier (Fig. 30.2; for recent review, see Ulery & Strickland, 2000). Initial reports showing significant association between polymorphisms in this gene and AD (Kang *et al.*, 1997), remained largely unconfirmed in follow-up analyses (see *AlzGene* for an up-to-date overview). It was, once again, the analysis of multi-locus haplotypes that recently led to significant positive findings in the same sample (Scott *et al.*, 2000) that had previously yielded only negative results analyzing polymorphisms individually (Scott *et al.*, 1998). Mapping only ~7 Mb proximal of *LRP1* is the gene encoding the transcriptional factor LBP-1c/CP2/LSF (*TFCP2*), which has been found to be significantly decreased in AD patients in three independent case-control series (Lambert *et al.*, 2000; Taylor *et al.*, 2001; Luedeking-Zimmer *et al.*, 2003). Suggested roles for this protein in AD neuropathogenesis are the regulation of transcription/expression of other AD-related proteins, APP binding and internalization (via Fe65) or the regulation of inflammatory processes.

Although the findings on chromosome 12 require further investigation and clarification in larger samples, it is unlikely that the positive associations reported for the genes associated with AD to date (*A2M*, *LRP*, and *TFCP2*) reflect linkage disequilibrium between the two loci, i.e. *A2M* on the one and *LRP1* and/or *TFCP2* on the other end, given

the large chromosomal distance in between the implicated regions (i.e. ~50 Mb). More likely, these results suggest the existence of two separate AD genes on chromosome 12, one near *A2M*, or *A2M* itself, and one near *LRP1*. Along these lines, only *TFCPZ* (L.B. and R.E.T., unpublished observations), but not *LRP1* (Bertram *et al.*, 2000a) appear to be associated in the same family sample (NIMH AD Genetics Initiative Study Sample) which continues to show strong association with *A2M* (see above).

Chromosome 10

There is emerging evidence that the long arm of chromosome 10 also harbors one or more AD loci. The situation is reminiscent of that encountered on chromosome 12; three independent laboratories initially reported significant linkage of AD to two general and possibly distinct regions on chromosome 10. The study by Myers and colleagues (Myers *et al.*, 2000) followed up on their own prior suggestive linkage results around ~65 Mb on 10q21–22 by genotyping additional markers and increasing the size of the study population. Interestingly and importantly, the linkage peak in this enlarged sample was found to be stronger than the linkage signal around *APOE* on chromosome 19 in the same dataset. A second study (Ertekin-Taner *et al.*, 2000) showed that upon using plasma $A\beta_{42}$ levels as quantitative phenotype in five large and multi-generational pedigrees, there is strong evidence for linkage in a very similar region on chromosome 10. In this study the same phenotype yielded no linkage within or near the *APOE* region on chromosome 19, nor in three other previously reported linkage regions on chromosomes 1, 5 and 9. Our group (Bertram *et al.*, 2000b) performed a hypothesis-driven linkage analysis on six genetic markers in a region some 30–40 Mb distal, in between 93 and 106 Mb on chromosome 10q23–24. Markers in this region were chosen because they map close to the gene encoding insulin-degrading enzyme (*IDE*; protein: IDE), for which several studies have suggested a principal role in the degradation and clearance of $A\beta$ in brain (for a recent review, see Selkoe, 2001). Two of the six markers showed significant linkage to AD by parametric and non-parametric analyses independent of the mode of inheritance, and one marker also showed evidence for association in the full and unstratified sample, a finding that was recently replicated in an independent case-control study (Ait-Ghezala *et al.*, 2002). The linkage findings, in combination with the positive association results, could be an indication of linkage disequilibrium with a disease modifying variant located nearby. Specifically, three genes (*IDE*, *KNSL1*, *HHEX*) are known in the immediate vicinity of

these markers and could be responsible for the observed effects.

Almost 2 years after the initial linkage reports, a second linkage study lent support to the more distal putative AD locus; as a matter of fact, the peak region of this most recent paper (Li *et al.*, 2002) coincides almost precisely with the distal bounds of the region implied by our study (Bertram *et al.*, 2000b), i.e. between 102 and 115 Mb. This study is also interesting because instead of using a conventional binary phenotype definition, the authors chose to analyze age at onset as quantitative trait. The linkage signal on chromosome 10 was not only the strongest observed in their full genome screen (excluding linkage at the *APOE* locus), but also emerged as an onset age modifying locus for Parkinson's disease, which was evaluated simultaneously. In fact, the linkage signal was strongest when both disease populations were combined into one analysis. At this time, it cannot be excluded that methodological or sampling/stratification differences across studies are responsible for the discrepant localization of the two linkage peaks which, in fact, could all be caused by the same gene. Another possible explanation is the presence of two loci, of which one primarily influences disease risk while the other acts more like a modifier of onset age (Li *et al.*, 2002). In any event, even though the actual disease gene(s) and its function remain(s) elusive, the fact that several independent laboratories have reported similar findings using different methodologies considerably increase the likelihood of at least one major late-onset AD locus on chromosome 10q.

Literally hundreds of genes have been mapped or predicted in the chromosomal stretch between 60 and 115 Mb, several of which are functionally plausible candidate genes for AD and are currently under investigation. Two of these candidates encode enzymes involved in the degradation of $A\beta$: *IDE* and *PLAU* (urokinase-type plasminogen activator [uPA]). According to some investigators, IDE displays the strongest $A\beta$ degrading activity in vitro (Selkoe, 2001). It is a 110 kDa thiol zinc-metalloendopeptidase located in the cytosol, peroxisomes and the cell surface and degrades several small proteins all of which share the characteristic to form β -pleated sheet-rich amyloid fibrils, including $A\beta$ and insulin (Kurochkin, 2001). In addition to $A\beta$, IDE has also been reported to degrade the APP intracellular domain (AICD), a fragment liberated after the γ -secretase cleavage of APP that has been suggested to play an important role in the regulation of transcriptional activity in the cell nucleus (Edbauer *et al.*, 2002). Besides the well characterized in vitro data, there is also growing evidence that IDE plays a role in the degradation of $A\beta$ in vivo. First, naturally occurring missense mutations in *IDE* in a diabetic rat-model (GK rat)

lead to a decrease in A β degrading activity in cultured fibroblasts and brain membranes (Farris *et al.*, 2002). Secondly and more importantly, *IDE* knockout mice not only show a significant decrease in A β -degradation in vivo, but also a significant increase in brain A β and AICD levels as compared to wild-type animals (Farris *et al.*, 2003). Finally, thus far, two groups have reported evidence for genetic association of haplotypes in *IDE* with AD in human study populations as well, although no single disease-modifying variants or mutations have been identified to date (Bertram *et al.*, 2002; Feuk *et al.*, 2002). These positive reports stand opposed by two fairly small negative case-control studies which did not see any evidence of association (Abraham *et al.*, 2001; Boussaha *et al.*, 2002, see *AlzGene* for an up-to-date overview).

Similar arguments have been put forward for *PLAU*, although in particular the evidence of in vivo relevance on A β -catabolism is less well established. *PLAU* encodes uPA which is a serine protease that converts plasminogen to plasmin, which in return is able to degrade both monomeric and oligomeric forms of A β , although the efficiency to carry out the latter is only about 1% as compared to monomeric A β . Both proteins are highly expressed in the brain, and uPA activity to generate plasmin is actually triggered by A β aggregates (for review, see Selkoe, 2001). Thus far, there exist only meeting reports both suggesting and refuting genetic association of this candidate gene with AD in human populations. Eventually, only sufficiently sized and appropriately designed studies will reveal whether or not *IDE* or *PLAU* (or both) are functionally, epidemiologically, and clinically relevant genetic risk factors for AD.

Findings on other chromosomes

In addition to the putative AD loci mentioned above, there have been several reports suggesting the existence of additional AD genes on various other chromosomes. Only a fraction of these can be considered positional candidate genes, i.e. not only has a biological relevance in AD pathogenesis been suggested, but they also map in or near previously reported linkage regions (Table 30.1). Examples of these are the tumor necrosis factor- α (*TNFA*) on chromosome 6q15 (Collins *et al.*, 2000), ubiquilin-1 (gene: *UBQLN1*) on 9q21 (Bertram *et al.*, 2003), or as mentioned earlier, nicastrin (*NCSTN*) on 1q23 (Dermaut *et al.*, 2002). The majority of the published AD association analyses targeted candidate genes solely on biological grounds, i.e. usually by testing functionally plausible candidates that do not map near any of the proposed linkage peaks. Examples of suggested associations are with the genes encoding cathepsin D (located on chromosome 11p15, proposed to display

γ -secretase like activities), α -synuclein (chromosome 4q22, involved in the binding and aggregation of A β), members of the interleukin-1 cluster genes (chromosome 2, involved in inflammatory processes) and the angiotensin-converting enzyme (chromosome 17, possibly also involved in inflammation and the regulation of the brain's renin-angiotensin system). In fact, by the end of 2001, over 60 candidate genes on 21 chromosomes had been tested for genetic association with AD, most of these involving fairly small case-control studies. With the exception of *APOE*, none of these risk factors has yet been shown to play a more than minor role in contributing to population-wide AD risk, and it is likely that most of the initial results will in fact prove to be false-positive findings (i.e. type I errors). More systematic and rigorous criteria for the design and publication of future genetic studies are needed to keep the research community focused on confirming and elucidating the most promising of the putative candidate genes, because it is these genes that will eventually broaden our understanding of the pathophysiology of AD neurodegeneration and allow the development of potential treatment strategies.

Conclusions

Despite the great progress in the field of AD genetics that has led to the discovery and confirmation of three autosomal-dominant early-onset genes and a late-onset risk factor, at least four additional major AD loci are predicted to exist. The hunt for these putative AD genes is aggravated by several factors that generally complicate the identification of complex disease genes: locus and/or allelic heterogeneity; only minor to modest effect size of any given variant; unknown, and difficult to model, interaction patterns; population differences and stratification; insufficient sample sizes/sampling strategies; the possibility of false positive results and, last but not least, linkage disequilibrium among polymorphisms other than those initially associated with the disease. The emergence of more powerful and efficient genotyping and analytic tools will ultimately enable us to disentangle the genetics of this and other complex diseases to the point where reliable and responsible genetic risk profiling will be possible. At that time, systematic assessment of individual genetic risk will dovetail with new and powerful means for therapeutically delaying or even preventing the onset of this devastating disease. This will enable a strategy of "early prediction, early prevention" forming the cornerstone of the genomic medical approach.

The role of β -amyloid in Alzheimer's disease

Roger M. Nitsch

Division of Psychiatry Research, University of Zurich, Switzerland

Introduction

β -Amyloid is a central element of the histopathology of Alzheimer's disease. It damages neurons and it causes the formation of neurofibrillary tangles. It is genetically linked to mutations that cause familial Alzheimer's disease, and it is associated with polymorphisms that increase the risk for developing Alzheimer's disease. β -Amyloid can be imaged by positron emission tomography in living people, and it is a major therapeutic target for the development of disease-modifying therapies (Selkoe, 2004).

β -amyloid plaques are major histopathological hallmarks of Alzheimer's disease

The neuropathological diagnosis of Alzheimer's disease is based upon the presence in brain of β -amyloid plaques and neurofibrillary tangles (Duyckaerts & Dickson, 2003). β -Amyloid deposits occur within the neuropil in several forms depending upon the degree of aggregation and fibrillization of the amyloid β -peptides $A\beta_{40}$ and $A\beta_{42}$, their principal proteinaceous components. The two most abundant, albeit different, forms of amyloid plaques are neuritic β -amyloid plaques and diffuse plaques. Neuritic, or "senile," β -amyloid plaques occur rarely in healthy subjects, they are an early histopathological sign of Alzheimer's disease (Tiraboschi *et al.*, 2004). Neuritic β -amyloid plaques are composed of higher-order β -amyloid fibrils that can be detected by Thioflavin S or Congo red, as well as by silver-based stains and by immunohistochemistry. Amyloid fibrils within the cores of neuritic β -amyloid plaques visualized by electron microscopy have diameters of up to 10 nm, and often occur in radiating, star-like assemblies. Neuritic β -amyloid plaques are closely associated

with dystrophic neurites, with defective cell membranes and with cytoskeletal abnormalities pointing to the possibility that their components have neurotoxic activities. Neuritic β -amyloid plaques are surrounded by reactive, GFAP-positive astrocytes. Frequently, these form a cellular outer layer separating the plaques from the surrounding tissue. In this form, reactive astrocytes may function as part of a physiological defence mechanism that protects healthy tissue from β -amyloid-related pathology. In addition, activated microglia, the brain-resident macrophages, are frequently found within the plaques, and in close association with amyloid fibrils. Sometimes, microglia are filled with β -amyloid fibrils. This association has led to the idea that microglia could possess a capacity of phagocytosing β -amyloid fibrils, and thus may have a role in the natural turnover of brain β -amyloid. In addition to $A\beta$ peptides, there are many other non-amyloid components associated with β -amyloid plaques. This is due to the hydrophobic, sticky, nature of β -amyloid that gives rise to hydrophobic interaction with multiple other proteins, proteoglycans, lipoproteins, cholesterol and lipids. The non-amyloid proteins include proinflammatory cytokines that are most likely microglia-derived, pointing to two parallel roles of β -amyloid-associated microglia: phagocytosis and proinflammatory signalling. The possible beneficial or toxic consequences of this dual microglia function are still controversial.

Additional forms of β -amyloid deposits include cotton-wool plaques, these are large spherical structures composed of $A\beta_{42}$ with dense cores that are stained by H&E stains. Like neuritic plaques, cotton wool plaques are often accompanied by neuritic dystrophy, and they are infiltrated by microglia. In contrast, diffuse plaques, also referred to as "preamyloid," are deposits of soluble and oligomeric forms of $A\beta$ peptides with low degrees of fibrillization. In the

histopathological routine, diffuse plaques are detected only by immunohistochemistry; they are negative for β -amyloid-staining dyes including Thioflavin S or Congo red. Diffuse plaques often have irregular contours; some forms are fleecy and lake-like, they are usually not accompanied by dystrophic neurites or other obvious signs of neuronal pathology, and they can also occur in healthy aged subjects without Alzheimer's disease (Delaère *et al.*, 1991, 1993).

In four out of five patients with Alzheimer's disease, β -amyloid fibrils are also deposited around cerebral blood vessels at the external face of perivascular smooth muscle cells. Perivascular β -amyloid fibrils lead to cerebral amyloid angiopathy, replace perivascular smooth muscle cells, causing vessel wall fragility, with occasional leakage and microhemorrhages. Moreover perivascular β -amyloid deposits may hinder perivascular interstitial fluid drainage into the cervical lymph system (Nicoll *et al.*, 2004).

Neurofibrillary tangles

A histopathological diagnosis of Alzheimer's disease is made in a case of progressive dementia when β -amyloid plaques co-occur with neurofibrillary tangles. These are intracellular accumulations of paired helical filaments composed of the microtubule-binding protein tau. Under physiological conditions, tau plays a role in stabilizing axonal microtubules that are essential for axonal transport. Paired helical filament formation is associated with detachment of tau from their axonal microtubule binding sites, re-localization to the cell bodies and dendrites, abnormal phosphorylation and fibril formation. Neurons with neurofibrillary tangles degenerate and die, leaving within the neuropil a residual "ghost tangle," sometimes with flame-shaped contours reminding of the pyramidal cell body in which it was initially formed. Dendritic tau filaments often occur as "neuropil threads." Both neurofibrillary tangles and neuropil threads are readily stained with silver-based protocols, as well as with antibodies against phosphorylated tau. NFT occur in many neurodegenerative diseases, in a group of diseases that is referred to as "taupathies" (Giasson *et al.*, 2003). These include frontotemporal dementia, Pick's disease and boxer's dementia. This broad spectrum of diseases suggests that tau pathology along with the formation of NFT is a fairly general reaction of neurons to damage, and that many different toxic events can end up in the formation of neurofibrillary tangle. The co-occurrence of neurofibrillary tangles and β -amyloid plaques in Alzheimer's disease suggests

the possibility that β -amyloid-related toxicity could be the toxic event that triggers the formation of neurofibrillary tangles.

β -Amyloid-related toxicity causes the formation of neurofibrillary tangles

The formation of β -amyloid plaques occurs early in the pathophysiological cascade leading to Alzheimer's disease. β -Amyloid plaque formation precedes the onset of clinical signs by a long pre-clinical time period of several decades, and β -amyloid plaque burden reaches a maximum by the time the initial clinical signs begin to show (Ingelsson *et al.*, 2004). Overwhelming experimental evidence suggests that accumulation of β -amyloid is paralleled by neurotoxicity that causes many – if not all – of the multiple abnormalities observed in Alzheimer's disease. These include neurodegeneration, inflammation, oxidative stress, cytoskeletal abnormalities, synaptic dysfunction, deficits in neurotransmission, homeostasis of ions and metabolism (Greeve *et al.*, 2004; Dudal *et al.*, 2004; Lewis *et al.*, 2001; Götz *et al.*, 2001; Stern *et al.*, 2004; Chapman *et al.*, 1999; Walsh *et al.*, 2002; Mattson and Chan, 2003; Mattson, 2004). In the brains of transgenic mice both endogenously expressed A β as well as microinjected synthetic β -amyloid fibrils can cause the formation of neurofibrillary tangles (Götz *et al.*, 2001; Lewis *et al.*, 2001). Other models using triple transgenic mice or tissue culture support this mechanism (Ferrari *et al.*, 2003; Oddo *et al.*, 2003, 2004). In human brains with Alzheimer's disease, a pathomechanistic link between β -amyloid and neurofibrillary tangles is underscored by clinico-pathological correlations suggesting that β -amyloid-induced cognitive decline is mediated by the formation of neurofibrillary tangles (Bennett *et al.*, 2004). Microinjections of β -amyloid into brains of transgenic mice have demonstrated a special separation of β -amyloid and neurofibrillary tangles formed in the cell bodies of neurons projecting with their axons to the microinjection sites of β -amyloid. This observation suggested that β -amyloid-related neurotoxicity is causing retrograde axonal degeneration, and formation of neurofibrillary tangles within the bodies of the neurons projecting to β -amyloid. Neuropathological evidence in human patients demonstrating neurofibrillary tangles in subcortical projection neurons that project to cortical areas with high β -amyloid burden supports this view of anatomical separation (Duyckaerts & Dickson, 2003). The molecular mechanisms of β -amyloid-related toxicity are not well understood. They may involve the generation of reactive oxygen species as well as increased cytoplasmic Ca²⁺ concentrations within

neurons caused either by increased influx or increased release from the ER or by mitochondrial dysfunction (Mattson, 2004).

Genetic evidence links β -amyloid formation to familial Alzheimer's disease

Familial forms of Alzheimer's disease are caused by mutations in the APP, presenilin 1 and 2 genes (Tanzi & Bertram, 2001). These mutations cause the formation of more, or C-terminally extended, A β peptides that lead to accelerated aggregation and β -amyloid formation. The triplication of the APP gene in Down's syndrome invariably results in a histopathology of Alzheimer's disease in adults, with both β -amyloid and neurofibrillary tangles. Moreover, several susceptibility genes including ApoE, leading to an increased risk for Alzheimer's disease, are also associated with accelerated β -amyloid formation. Thus, the available genetic evidence points to the possibility that increased generation of β -amyloid caused by genetic variations increases the risk for Alzheimer's disease. It is noteworthy that mutations that cause increased β -amyloid are also associated with the formation of neurofibrillary tangles, whereas mutations in the tau gene cause "tangle-only" frontotemporal dementia, without β -amyloid plaques. Thus, while neurofibrillary tangles are clearly related to neurodegeneration in the tauopathies, they hardly induce β -amyloid plaque formation.

A β peptides are generated by β - and γ -secretases that function in APP signalling

The generation of A β from its precursor, the β -amyloid precursor protein (APP) was extensively reviewed (Marjaux *et al.*, 2004; Koo & Kopan, 2004; Aguzzi & Haass, 2003; Selkoe & Kopan, 2003). Briefly, A β is generated by proteolytic processing of APP by a sequential cleavage event mediated by β -secretase, or β -APP cleaving enzyme (BACE) and γ -secretase, a transmembrane multiprotein complex composed of presenilin, nicastrin, Aph-1, and Pen-2. Amyloidogenic APP processing initiated by BACE-mediated cleavage at the ectodomain, resulting in ectodomain shedding and in the generation of a membrane-bound carboxyl-terminal fragment that is a substrate for γ -secretase processing within the membrane via a proteolytic mechanism referred to as regulated intramembrane proteolysis. Regulated intramembrane processing by γ -secretase is non-selective as it cleaves many substrates including the E- and N-cadherins, notch1–4, delta, jagged, CD44, EbrB4

and many others. γ -secretase cleavage of the membrane-bound APP carboxyl-terminal fragment results in the secretion of A β , that can potentially aggregate and form β -amyloid fibrils, as well as in the liberation of the APP intracellular domain (AICD) into the cytoplasm where it binds to the adaptor proteins Fe65, Jip 1b or X11 α – MINT1 that result either in cytoplasmic retention or translocation into the nucleus where the shuttle complex associates with Tip60 to function in transcriptional regulation (Von Rotz *et al.*, 2004). The AICD complex increases the transcription of the APP gene, thereby regulating the concentrations of its own precursor (Von Rotz *et al.*, 2004). Other functions of the APP include a potential neurotrophic, growth-promoting activity of its ectodomain. The ectodomain includes, at its N-terminal end, a heparin-binding domain with possible roles in interacting with components of the extracellular matrix and with cell-surface molecules. It is also possible that this domain functions in cell surface-associated full-length APP in forming *trans*-homodimers with a role in cell–cell interactions (Rossjohn *et al.*, 1999).

Aggregation of soluble A β into insoluble β -amyloid fibrils

The formation of β -amyloid fibrils found in β -amyloid plaques from the soluble monomeric A β peptides A β ₄₀ and A β ₄₂ involves oligomerization and nucleation leading to larger-order aggregates with conformational changes that are associated with increasing insolubility and ultimately, the precipitation of β -amyloid fibrils that can grow further by the addition of soluble A β peptides or oligomers.

The temporal sequence of aggregation into oligomers, proto-fibrils and fibrils is paralleled by increasing signs of neurodegeneration in human brains. Early, diffuse A β deposits are often present in brains of cognitively healthy aged subjects, and they are not associated with neuropathology, but their further aggregation into insoluble fibrils is accompanied by neuritic dystrophy, neurodegeneration and functional loss (Knopman *et al.*, 2003). Thus, the neurotoxicity of the various forms of A β aggregates is related to their degree of fibrillization. This does not exclude the possibility that soluble oligomers of A β can also be causing neuronal dysfunction as suggested by their suppressing activities on long-term potentiation in experimental animals (Walsh *et al.*, 2002). The principle of confirmation-dependent insolubility paralleled by neurotoxicity may be a more general principle of neurodegenerative diseases underlying many other disorders as exemplified by α -synuclein deposits in Lewy bodies in

Parkinson's disease, Huntingtin inclusions in Huntington's disease, PrP^{Sc} plaques in BSE, scrapie and CJD, as well as neurofibrillary tangles in tauopathies including fronto-temporal dementia.

Imaging of β -amyloid in living people

β -amyloid can be imaged by PET in living people (Klunk *et al.*, 2004). This possibility puts researchers in the fortunate position of testing whether treatments designed to reduce brain β -amyloid work as expected. When correlated with clinical efficacy, PET imaging of β -amyloid will become an important primary outcome variable for future clinical trials designed to reduce brain β -amyloid. Moreover, preclinical detection of β -amyloid by PET in preclinical AD may ultimately identify an aged population with brain β -amyloidosis who is at high risk for developing clinical signs of AD. If safe, β -amyloid-lowering treatments could be a future option for prevention in these subjects at risk.

β -Amyloid is a therapeutic target for the treatment and prevention of AD

The reduction of β -amyloid is a major goal for the current development of novel strategies for the treatment and prevention of Alzheimer's disease. The principal idea common to these therapeutic approaches is based upon the hypothesis that lowering in brain the amount of β -amyloid will lead to reduced β -amyloid-related toxicity, and ultimately, to the disruption of the cascade leading to neuronal damage, neurofibrillary tangles, and neurodegeneration. In the absence of β -amyloid-related toxicity, regeneration may occur to repair some of the tissue damage previously caused by β -amyloid. A large variety of diverse possibilities to reach this goal is being currently pursued. It ranges from inhibitors of BACE and γ -secretase inhibitors, to stimulators of α -secretase by neurotransmitter receptor agonists (Nitsch *et al.*, 1992, 2000), acceleration of A β degradation by A β -cleaving enzymes including neprilysin and insulin-degrading enzyme, inhibition of A β -aggregation with A β -binding compounds or metal ion chelators, and removal of β -amyloid by antibodies against β -amyloid, to name just a few. Initial early phase studies of β -amyloid-lowering treatments with either the metal ion chelator clioquinol or the glycosaminoglycan mimetic Alzhemed, or β -amyloid immunotherapy consistently show signs of clinical efficacy (Aisen *et al.*, 2004; Ritchie *et al.*, 2003; Hock *et al.*, 2003; Gilman *et al.*, 2004). Larger studies are now performed to

confirm these initial positive findings. Moreover, the developments of BACE- and γ -secretase inhibitors are reaching clinical study phases.

Despite the fact that the toxic mechanisms linking β -amyloid to neurodegeneration are incompletely understood, several therapeutic approaches were designed to block such suspected toxic consequences of β -amyloid as oxidation and inflammation. Vitamin E alone, or together with vitamin C, tested in human trials had some, albeit small, degree of clinical efficacy (Sano *et al.*, 1997; Zandi *et al.*, 2004). In contrast, clinical trials of anti-inflammatory agents including either steroidal or non-steroidal anti-inflammatory agents were consistently negative (van Gool *et al.*, 2003). These results clearly emphasize the need for better understanding of the molecular mechanisms of β -amyloid-related toxicity, as well as the need for identifying therapeutic targets within this cascade.

Immunization against β -amyloid

Immunotherapy protocols are currently developed both in experimental animals and in initial clinical trials. Either active immunization with β -amyloid-related epitopes or passive antibody transfer consistently reduce brain β -amyloid load, followed by reductions in tau phosphorylation, protection of neurons and by improvements in β -amyloid-related behavioral deficits. (Schenk *et al.*, 1999; Bard *et al.*, 2000; Morgan *et al.*, 2000; Mohajeri *et al.*, 2002, Lombardo *et al.*, 2003; Wilcock *et al.*, 2004; Oddo *et al.*, 2004; Lemere *et al.*, 2004). Moreover, initial data from the first clinical immunotherapy trial suggest clinical efficacy in human patients with Alzheimer's disease. In this trial, β -amyloid fibrils generated by aggregation of synthetic A β ₄₂ peptides were used as an immunogen to stimulate a humeral immune response and the generation of antibodies against β -amyloid. Episodes of meningoencephalitis in some of the participants unfortunately caused the trial to be interrupted, but careful analyses of the immunized patients showed clinical efficacy in patients with Alzheimer's disease (Hock *et al.*, 2003; Gilman *et al.*, 2004). In particular, the presence of antibodies against β -amyloid was associated with clinical stabilization and with slowed rates of cognitive decline over more than 2 years. Remarkably, a fraction of the IgG antibodies against β -amyloid were present in CSF, suggesting that they are able to cross the blood-brain barrier (Hock *et al.*, 2003). The mechanisms for blood-brain barrier passage of plasma-derived IgG are incompletely understood, they may include increased blood-brain barrier permeability, possibly related to disease- or vaccination-induced

inflammatory responses, passive diffusion, and active shuttling, possibly via F_{CN} -mediated transcytosis. These initial clinical data are supported by neuropathological analyses in four brains obtained at autopsy. Consistently, these studies showed reduced β -amyloid pathology in extended brain areas, accompanied by reduced astrogliosis and maintained tangle pathology (Nicoll *et al.*, 2003; Ferrer *et al.*, 2004). Together with the stabilization of the clinical signs, these data could be indicative of initial proof of principle that links removal of β -amyloid with clinical efficacy. Importantly, removal of β -amyloid was also observed in the absence of prior episodes of meningoencephalitis strongly suggesting that meningoencephalitis is not required for β -amyloid removal. Therefore, the previously raised speculation that clinical inflammation is required to clear β -amyloid is not supported by the existing clinical and neuropathological data. There are three mechanisms currently discussed to explain the therapeutic response to immunotherapy, and all involve removal, or reduction, of brain β -amyloid: microglia-mediated removal of amyloid, removal by peripheral amyloid sink, and antibody-mediated disaggregation of amyloid. These mechanisms may play in concert, but microglia-mediated uptake is almost certainly involved as indicated by the presence of microglia filled with β -amyloid in brain areas that have been cleared of β -amyloid following immunotherapy (Nicoll *et al.*, 2003).

Possibly related, exciting new features of antibodies against β -amyloid are their effects on brain volume in patients with Alzheimer's disease. Results from two studies independently demonstrated that hippocampal volumes decrease more rapidly in the presence of antibodies against β -amyloid during the initial year following vaccination, as compared to patients without antibodies against β -amyloid (Fox *et al.*, 2004; Hock *et al.*, submitted). At first glance, these results may be counterintuitive. But they also raise the possibility of reflecting clearance of β -amyloid plaques accompanied by a concurrent loss in astrocyte activation. Brain β -amyloid burden in brain cortex can exceed 5% of the cortical volume, and reactive astrocytes in AD are hypertrophic with volumes that exceed many-fold their volumes in dormant states, therefore clearance of β -amyloid and reduction in astrocyte hypertrophy may sufficiently explain initial volume losses. An additional factor that may underlie initial volume losses following immunotherapy was recently observed in transgenic mice where antibodies against A β straightened out neurites that had been previously curvy and distorted due to an Alzheimer's disease-causing mutation (Lombardo *et al.*, 2003). Thus, initial brain volume losses in patients with Alzheimer's disease after vaccination may prove to

be the first objective signs of relief: It should be followed, however, after a first clearance phase of β -amyloid, by a second phase of stabilization, or even slight increases in brain volume, as signs of recovery and regeneration. In the first long-term follow-up analyses of hippocampal volumes in patients with antibodies against β -amyloid, this pattern of initial volume loss followed by compensatory increases was actually observed. Combined with MRI volumetry, amyloid PET imaging will allow to address this possibility further during the upcoming clinical immunotherapy trials.

Other treatments of Alzheimer's disease

Novel disease-modifying approaches for the treatment and the prevention of Alzheimer's disease has replaced the attitude of therapeutic nihilism that clouded the field for a long time. Neurotransmitter-based therapies with Acetylcholine esterase inhibitors and NMDA receptor antagonists are now in current use; anti-inflammatory and antioxidative approaches as well as compounds that inhibit A β aggregation, passive transfer of antibodies against β -amyloid as well as active immunization against β -amyloid are being tested in the clinic; β - and γ -secretase inhibitors designed to reduce generation of A β peptides are under development and will reach the clinic soon. Together, and possibly combined, these efforts are likely to generate better treatments for Alzheimer's disease in the near future.

Acknowledgements

I thank my many colleagues who participated in generating a wealth of knowledge on the role of β -amyloid in Alzheimer's disease, and Dr. Christoph Hock for continued collaboration. This work was supported by grants from the NCCR on Neural Plasticity and Repair, EU-APOPIS and the Stammbach foundation.

Treatment of Alzheimer's disease

Mary Sano

Alzheimer's Disease Research Center, Department of Psychiatry, Mount Sinai School of Medicine, New York NY and Bronx VA Medical Center, Bronx, NY, USA

Overview

Over the past decade medications have been approved for the treatment of Alzheimer's disease (AD). The first of these worked via cholinergic stimulation, and targeted the symptoms of attention and memory. More recently Memantine, an NMDA receptor antagonist, has been added to the list of approved medications for AD. These treatments provide symptomatic benefits. Initiative for new therapeutics target the characteristic neuropathological features of AD or other biological mechanisms that may reflect the etiology of the disease in the hope of identifying preventative or curative agents.

Research into treatment of AD tends to focus on interventions at the earliest stage of the disease and the concept of mild cognitive impairment (MCI), a prodrome to dementia, has become the target of many interventions. This approach has the added challenge of determining diagnostic specificity of an entity, which does not yet constitute a diagnosis. At the same time, interest in treating the more impaired patient has grown with the approval of the first drug with an indication for moderate to severe AD and with new studies examining cholinesterase inhibitors in more advanced patients.

Awareness that AD may coexist with other CNS diseases or be difficult to distinguish from dementia of other etiologies may have contributed to the interest in treatments for individuals with other conditions including vascular and mixed dementia.

The neurobiology of AD, models of disease mechanisms, and epidemiological data, have been the backbone of many hypotheses for etiology and the basis for both planned and completed trials of AD treatment and prevention. The greatest hope lies in exploring these mechanisms to find better treatments and possibly preventative strategies.

Introduction

Alzheimer's disease is a devastating illness characterized by loss of memory and other cognitive functions, leading to functional disability and significant dependence. While there are a growing number of approved treatments, there is no cure and little is known about prevention. The prevalence of AD increases with age with estimates of 2.8 to 9.4 million over the next 50 years (Brookmeyer *et al.*, 1998). AD is associated with an increase in the need for healthcare services (Torian *et al.*, 1992) and is the third most costly disease in the United States behind heart disease and cancer (Kirchstein, 2002). While nearly 60% of all care to AD patients is delivered by informal caregivers, the projected costs may underestimate the true cost of the disease. As the population ages, finding treatment and prevention for Alzheimer's disease becomes a compelling public health mandate.

The first treatment for AD received regulatory approval over a decade ago. Some improvements have been made in this first class of agents and a drug from another class has also been approved. The progress has been aided by regulatory definition of efficacy and safety. For an indication of symptomatic benefit in the treatment of AD, the Food and Drug Administration (FDA) requires evidence of cognitive and 'clinical global' benefit. European approval requires benefit in two of three domains; the third is functional benefit usually assessed with a measure of activities of daily living. As awareness of the breadth of symptomatology and social and economic impact has grown, clinical trials for AD have come to include measures of behavioral disturbance, quality of life, and cost effectiveness.

Several studies have examined the breadth of efficacy of approved agents and trials have been reported in advanced stages of Alzheimer's, vascular, and mixed dementia. One

limitation of the studies examining non-AD dementia is that outcome measures are typically those used in mild to moderate AD, which may not be the most appropriate for capturing benefit to other diseases.

Interest in the prevention of AD has grown and the identification of mildly symptomatic individuals typically labelled with the condition mild cognitive impairment (MCI) has provided a model for trials of secondary prevention of AD. While few results of these trials are currently available, early methodological reports describe these individuals and have estimated the likelihood of their progression. There are few studies that examine treatments of mild cognitive impairment and clinical practice is often directed by anecdotes, impressions, and untested hypotheses. The absence of adequate data makes it difficult to assess efficacy and safety. By and large, the agents under study have been agents that have been used to treat AD or which theoretically could treat AD.

Treatment with agents approved for Alzheimer's disease

Cholinergic stimulation

Tacrine

The first approved treatments for AD were cholinesterase inhibitors which enhance cholinergic transmission by inhibiting the breakdown of acetylcholine in the synaptic cleft. At this writing there are four agents approved in the US. Tacrine, the first approved agent in this class, required multiple daily dosing (QID), slow titration of dose into the effective range (i.e. 16 weeks), had limited tolerability of about 65% at the highest dose, and required monitoring of liver enzymes (Knapp *et al.*, 1994).

Donepezil

The second agent, Donepezil (Rogers *et al.*, 1998), has several advantages including once daily dosing, with no required medical monitoring for toxicity. Donepezil is a pseudo-irreversible acetyl cholinesterase inhibitor. It is well absorbed with oral bioavailability of 100% and the pharmacokinetics are linear in the 1 to 10 mg dose ranges. The elimination half life is approximately 70 h; with multiple doses it accumulates in plasma four- to sevenfold, reaching a steady state in 15 days. Efficacy has been demonstrated at 5 and 10 mg. Dosing recommendations indicate initiation with 5 mg/day and escalating dosage only after 4 to 6 weeks at the lower dose. Adverse events include diarrhea, nausea, vomiting, insomnia, muscle cramps,

and anorexia with more study withdrawals from those on 10 mg than 5 mg. However, side effect rates were reduced at the 10 mg dose when the interval between 5 and 10 mg was increased from 1 to 6 weeks. Postmarketing information has identified sleep disturbance as a possible phenomenon, perhaps because recommended dosing instructions suggest evening administration (Geldmacher, 1997). A review examining 16 double-blind clinical trials of Donepezil in patients with mild, moderate, or severe AD summarized data involving 4365 participants in studies ranging from 12 to 52 weeks duration (Birks & Harvey, 2003). Outcome data from each trial covered at minimum, cognitive function, and global clinical state. This review found systematic support for cognitive benefit with evidence of statistically significant improvement for both 5 and 10 mg/day of Donepezil. Clinical global measures also showed systematic benefit and some studies reported benefit in activities of daily living and behaviour.

Rivastigmine

The next agent to appear on the market was Rivastigmine, which reports both acetyl and butyryl cholinesterase inhibition, but there is little information on the relationship of each mechanism to the clinical impact of the drug. Rivastigmine is a reversible, acetylcholinesterase inhibitor. It is well absorbed and at a 3 mg dose the oral bioavailability is 40%. It has a half-life of 1.5 hours and recommended doses are from 6 to 12 mg/day, administered twice daily. Dose titration begins at 1.5 mg b.i.d. with a minimum of 2-week intervals between dose increases and longer intervals may reduce tolerability problems. If medication is discontinued at any point for more than a few days, it is recommended that the treatment be re-initiated at the lowest dose and titrated as described above.

A review of eight trials, involving 3450 participants, with a treatment interval of 26 weeks found high-dose Rivastigmine (6 to 12 mg daily) provided benefit in cognition, clinical global measures, and activities of daily living. At lower doses (4 mg daily or lower) differences were in the same direction but were statistically significant only for cognitive function. High dose Rivastigmine was associated with nausea, vomiting, diarrhea, anorexia, headache, syncope, abdominal pain, and dizziness. There is some evidence that adverse events might be less common with dosing regimens that use smaller doses more frequently (Birks *et al.*, 2004).

Galantamine

The newest of the cholinesterase inhibitors to receive approval in the United States for use for AD is Galantamine. The drug was originally isolated from several plants,

including daffodil bulbs, but is now synthesized. Galantamine is a specific, reversible, competitive acetylcholinesterase inhibitor. It is also an allosteric modulator at nicotinic cholinergic receptor sites potentiating cholinergic nicotinic neurotransmission. It is well absorbed with high oral bioavailability (90%). It has a half-life of about 7 hours and recommended doses are 16 to 24 mg/day administered twice daily. A review of seven trials of various lengths from 12 weeks to 6 months yielded similar results to those seen with other cholinesterase inhibitors. In general, daily doses of 16 to 32 mg demonstrated efficacy over placebo in cognitive and functional abilities. Doses of 8 mg/day consistently failed to show statistically significant benefit. Adverse effects appear similar to those of other cholinesterase inhibitors, in that it tends to produce gastrointestinal symptoms acutely and with dosage increases. In clinical trials, dosage increases were associated with greater discontinuation in the Galantamine treated groups compared to the placebo groups. However, in the one trial with a slow rate of titration (4 weeks vs. 2 weeks) the discontinuation rate was not significantly greater than placebo for the 16 mg/day dose (Olin & Schneider, 2004).

Quality of life and economic benefit of cholinesterase inhibitors

There is no agreed upon method for assessing quality of life (QOL) in clinical trials of AD. Few AD specific measures of QOL exist, and those that have been published focus on domains that may not be modified by pharmacologic interventions (Logsdon *et al.*, 2002). These scales observe mood, social interaction, or behavior to make an estimate of QOL. However, since measures of behavioral symptoms and functional measures such as those assessing activities of daily living are commonly included in clinical trials, QOL is often assessed by examining these outcome measures. In a systematic review of randomized clinical trials of cholinesterase inhibitors in AD, published between 1966 and 2001, the authors identified 29 reports that assessed functional impairment ($N=18$) and behavioral symptoms ($N=16$) (Trinh *et al.*, 2003). For behavioral outcomes, ten trials included the ADAS-non-cog and six included the NPI. Compared with placebo, patients randomized to cholinesterase inhibitors improved 1.72 points on the NPI (95% CI, 0.87–2.57 points), and 0.03 points on the ADAS-cog (95% CI, 0.00–0.05 points). For functional outcomes, 14 trials used ADL and 13 trials used instrumental ADL (IADL) scales. Compared with placebo, patients randomized to cholinesterase inhibitors improved 0.1 SDs on ADL scales (95% CI, 0.00–0.19 SDs), and 0.09 SDs on IADL scales (95% CI, 0.01 to 0.17 SDs). There was no difference in efficacy among various cholinesterase

inhibitors, although there is very little power to observe such effects. There are several limitations to this review including the incorporation of trials of agents that failed in the development process, the absence of trials with Rivastigmine, and the consideration of relatively few measures of behavior and function. Despite this, it appears that cholinesterase inhibitors may affect these domains that are so relevant to QOL.

Much of the economic assessment of benefit of cholinesterase inhibitors is predicated on models which examine delay to nursing home placement. Longitudinal data from open label follow-up of clinical trials have been used to support a benefit for delaying nursing home placement for Tacrine and Donepezil (Knopman *et al.*, 1996; Geldmacher *et al.*, 2003). This type of data is seriously confounded by the large number of cases that discontinue from the treatment group leaving the remaining cases to inflate the apparent effect. Reduction of caregiver time has been associated with treatment with a cholinesterase inhibitor (Sano *et al.*, 2003), though this effect is more observable as disease severity increases. Other studies have reported longitudinal effect on delaying cognitive decline and have used these cognitive benefits to model time savings by caregivers (Marin *et al.*, 2003) and delay to need for full-time care (Caro *et al.*, 2002). A single double-blind trial of long-term outcomes has been published and, while this indicates small but persistent cognitive and functional benefit for up to 2 years, no effect was observed in outcomes such as delaying stage of disease, need for nursing home placement or caregiver outcomes (AD 2000 Collaborative Group, 2004). While this study may have been underpowered to observe benefit in important clinical outcomes, it does cast doubt on many of the models of disease progression and economic impact.

Considerations for cholinesterase inhibitor use in AD

In general, clinical improvement with the cholinesterase inhibitors is robust though the effect size is modest. The side effect profile is relatively benign with gastrointestinal disturbances the most likely problem. These drugs are currently approved for the treatment of individuals in the mild to moderate stages of the disease. Given that these treatments have proven efficacy, it is reasonable to initiate a trial of cholinesterase inhibitors in patients with AD. There are no guidelines for selecting among the available agents. Since all medications have only been tested in situations where a caregiver administers the drug and monitors side effects, practical issues, such as the availability of someone to administer medication multiple times a day, may be a limiting factor for choosing an agent. At this writing, only a single agent, Donepezil, is administered once a day.

In general, it appears that slower titration may minimize cholinergic side effects. Most patients demonstrate stabilization or mild improvement and, in most studies, these benefits are not seen until 3 to 6 months of exposure. Therefore, it is important to attempt a reasonable length of treatment exposure before making a decision about continuing on a given agent. In addition, objective, placebo-controlled data from exposure of up to 1 year indicates that benefits continue though they may be smaller (Winblad *et al.*, 2001). Several agents may need to be tried since tolerance of side effects of each agent may differ among patients. Generally, the experience of the family members as well as patients will play a key role in weighing benefits of any treatment. While data supports benefits in areas that should have an important impact on quality of life and indications of an economic value, no such result has yet been observed and greater exposure may be needed to provide convincing evidence of benefit.

Glutamate and the NMDA receptor

Memantine

Memantine, a newly approved agent for the treatment of moderate to severe AD, has a novel mechanism of action. It is a low to moderate affinity uncompetitive (open-channel) NMDA receptor antagonist which selectively binds to the cation channels. Glutamate excitotoxicity may be mediated through the post synaptic NMDA receptor. Memantine is an uncompetitive NMDA-receptor antagonist and presumably this antagonism blocks glutamate damage. The half-life is 60 to 80 hours with the peak concentration reached in 3–7 hours. The recommended starting dose is 5 mg once a day with an increment of 5 mg/day at weekly intervals until the maximum dose of 20 mg/day is achieved. With the first dose escalation it is recommended that BID dosing be observed.

Three trials, including 973 patients with moderate to severe AD, lasting 12 to 28 weeks have been published. In one, Memantine alone demonstrated benefits in cognition over placebo (Reisberg *et al.*, 2003). Additionally, in a randomized trial of Memantine plus Donepezil compared to Donepezil alone, the combination demonstrated benefits in cognition, a clinical global measure, and behavior (Tariot *et al.*, 2004). While a third study did not have a cognitive measure (Winblad & Poritis, 1999), all three studies assessed clinical global benefits and 2 of 3 demonstrated a statistically significant benefit of Memantine over placebo (or Donepezil plus placebo) in ITT analysis and all three demonstrated efficacy in completers analyses. In clinical trials Memantine was well tolerated. An increase in

confusion (7.9 vs 2%) was reported in one study (Tariot *et al.*, 2004) but no consistent pattern of side effects has emerged. Clinical exposure to this agent is minimal compared to cholinesterase inhibitors and it may be too early to know the complete side effect profile.

The effect of Memantine in mild to moderate AD is not yet clear. Early reports of the use of Memantine in mild to moderate AD in combination with a cholinesterase inhibitor failed to demonstrate efficacy, though the details of the study are not available at this writing. A study examining the effect of Memantine in this patient population in the absence of other treatments yields small but significant effect on cognition and on clinical global measures (Peskind *et al.*, 2004). Additional studies are needed to provide support for the use of this agent in patients at these stages of the disease.

Treatment of vascular and mixed dementia with agents approved for AD

The ability to distinguish between different types of dementia is complicated by the lack of biomarkers. Thus much of the diagnosis is based on clinical evaluation and while the research diagnostic criteria required in clinical trials may provide some added assurance, it is unclear if such criteria can be practical in a typical clinical setting. One of the most difficult distinctions to make clinically is between AD and vascular disease, primarily because the two entities frequently coexist and it is not obvious to what degree each contributes to the dementia symptomatology. Given this dilemma of clinical practice, it is important to know to what degree the agents approved in the treatment of AD may have efficacy in other conditions. To this end, several studies have examined agents in patients with AD and some degree of vascular disease as well as in individuals described as having probable or possible vascular disease. Perhaps the largest data base exists for Donepezil, with published clinical trials including over 1200 individuals with possible or probable vascular dementia or cognitive decline (Birks *et al.*, 2003). Donepezil, at doses of 5 or 10 mg a day, was compared with placebo for 24 weeks. In general, significant effects on cognition, measured with the ADAS-cog, have been observed in ITT analyses at nearly every time point. Clinical global improvement in the ITT analysis was observed in one study (Wilkinson *et al.*, 2003) but not in others, although significance was observed at 5 mg but not at 10 mg in an observed case analysis. In a trial of patients with AD plus vascular disease and vascular dementia alone Galantamine was shown to be superior to placebo on cognitive outcomes but not on clinical global

outcomes. Subgroup analysis suggested that the effect was more pronounced in the AD plus vascular disease group than in the VAD group (Erkinjuntti, 2002).

Taken together, these studies suggest a beneficial effect of approved AD treatments in patients with vascular dementia. However, these effects are small and there is a need for instruments better suited for assessing vascular dementia.

Other pharmacologic approaches to treating AD

Anti-oxidants

The role for oxidative stress as a pathological mechanism in aging and dementia is supported by several lines of evidence. Biological studies demonstrate that the accumulation of free radicals is associated with damage to lipids, cell membranes, and proteins including DNA and RNA. These oxidative byproducts induce the production of the Amyloid Precursor Protein (APP), the protein precursor to the amyloid plaque, the hallmark of AD pathology. The accumulation of A β fragments may reduce compensatory anti-oxidant ability resulting in further increases in A β deposition, synapse loss, DNA damage, neuronal dysfunction, and cell death. Free radical scavengers sequester free radicals rendering them impotent, minimizing oxidative reactions, and minimizing cellular damage. (For a review of these potential mechanisms see Butterfield, 2002.)

Compelling support for the link between oxidative stress and A β comes from a recent study which crossed mice with a knockout of one allele of a critical anti-oxidant enzyme (manganese superoxide dismutase: MnSOD) with a mouse that overexpressed a doubly mutated human β -amyloid precursor protein (i.e. Tg19959). Previous work established the MnSOD to cause elevated oxidative stress and the mice of the resulting cross demonstrated increases in both amyloid plaque burden and amyloid levels (Li *et al.*, 2004).

Evidence for a benefit of anti-oxidant agents comes from observational studies. Most recently, two prospective studies examined the association of dietary anti-oxidants and incident AD and provided evidence of reduced risk of Alzheimer's disease (Morris *et al.*, 2002; Engelhart *et al.*, 2002). Daily intake of antioxidants including vitamin E, vitamin C, beta carotene, and flavonoids was assessed with food frequency questionnaires. In one study of over 800 subjects followed for a mean of nearly 4 years the group in the highest quintile of vitamin E intake had a relative risk of AD of 0.36 (95% CI: 0.11–1.17) compared to the group in the lowest quintile (Morris *et al.*, 2002). Other anti-oxidants had no effect. In another study

of more than 5000 individuals followed for a mean of 6 years, a reduced risk of AD was reported with vitamin E and with vitamin C intake (RR = 0.82; 95% CI: 0.66–1.00). Both reports failed to demonstrate a benefit to the use of anti-oxidant supplements, though they increased the intake levels by 50% or more (Sano, 2002). Data from the multi-ethnic cohort of Washington Heights, in New York City, examined both dietary intake and supplemental use of antioxidant vitamins. Elderly subjects ($N = 980$) were followed for a mean of 4 years and nutrient data was gathered with a standardized food-frequency questionnaire which also gathered data on supplement intake. This report found no evidence of risk reduction nor a trend toward reduction with vitamin E, C, or carotenoids in any combination. Recently, a study from the well-described cohort from Cache County of Utah, examined the effect of supplement intake on both prevalent and incident dementia. This report described a reduction in both prevalence and incidence with the combination of vitamins C and E, but not with either alone (Zandi *et al.*, 2004). A trend toward lower incidence of AD was associated with vitamin E in combination with a multi-vitamin possibly containing C, but not with a multivitamin alone.

Typically, we move from observational studies to clinical trials to test hypotheses about potential treatments. A range of agents has been tried in clinical trials for the treatment of AD. As described below, early trials provided promising evidence of benefit with anti-oxidant therapies, but longer and larger trials have been disappointing.

Vitamin E

As evidence for a benefit to AD, vitamin E was found to delay clinical milestones in moderately impaired patients with AD though no benefit was observed on standardized cognitive tests (Sano *et al.*, 1997). In the same study, Selegiline, a selective inhibitor of monoamine oxidase-B, was also effective but the combination of drugs had no additional benefit. Physicians commonly recommend vitamin E as treatment for AD. While no data is available for the combination, it is often given along with cholinesterase inhibitors, probably based on its perceived safety.

Two trials have reported the outcome of cognitive additions to other studies. One is the anti-oxidant arm of the Heart Protection Study (Heart Protection Study Collaborative Group 2002). This large trial of over 20000 enrollees, aged 40 to 80 years, selected subjects who were at risk for cardiovascular disease. The study used a 2 \times 2 factorial design in which one agent was Simvastatin and the other was an anti-oxidant combination of vitamin E (600 mg), vitamin C (250 mg), and beta carotene (20 mg). While no initial cognitive assessment was conducted, at the

final visit the modified Telephone Interview for Cognitive Status (TICS-m) questionnaire was administered. Using an established cut-off score to identify cognitive impairment (22 of 39) no significant difference was found between the treatment groups in the percentages of the cognitively impaired (23.4% vitamin group vs. 24.4% vitamin placebo group). There was also no difference in the mean TICS-m score and similar numbers of participants in each treatment group were reported to have developed dementia (0.3%) or other psychiatric disorder (0.6%). This rate of incident cases appears quite low, given the age range of the subject population, suggesting that this methodology may have been inadequately sensitive to cognitive change. Interestingly, these supplemental doses are far above the range in which dietary anti-oxidants were reported to have an effect.

The DATATOP study was a trial of over 800 subjects, newly diagnosed with Parkinson's disease, who were treated with Selegiline or vitamin E (2000 International Units (IU)) in a 2 × 2 factorial design. Cognitive assessments consisted of a battery of tests, including memory tests. No significant difference was noted among the groups (Kieburtz *et al.*, 1994). Whether these results from this specialized population can be generalized is difficult to know since the study population was relatively young and all had early/mild Parkinson's disease. Nevertheless, in this cognitively fragile cohort, high dose vitamin E was unable to modify cognition.

An ongoing study known as PREADVISE is an 'add-on' study, which will examine the preventative effect of various anti-oxidants on prostate cancer. The parent study recruits men, age of 60 or greater who are randomly assigned to receive 200 micrograms of selenium and 400 IU of vitamin E per day and monitors for prostate cancer. Participants randomized to assess anti-oxidant effects on prostate cancer may enroll in this cognitive 'add-on' study which will assess cognition and dementia with a brief screen followed by a more comprehensive work-up. The relatively young age of the cohort may make it difficult to observe a cognitive change and follow-up may be confounded by results or new findings with bearing on prostate treatment. Nevertheless, this represents an opportunity to observe cognition in this unique cohort.

Ginkgo biloba

Ginkgo biloba is a plant extract containing flavenoids which act as free radical scavengers that may protect cells from excessive lipid peroxidation and neuronal membrane breakdown (Scholtyssek *et al.*, 1997). Clinical trials of this drug in cognitively impaired populations have yielded mixed results with reports of benefit in some but not all outcomes (van Dongen *et al.*, 2000). Benefits on

cognitive measures in patients with AD have been demonstrated with Ginkgo biloba (Le Bars *et al.*, 1997). These trials suggest that anti-oxidants, which appear to be well tolerated, may have a role in the treatment of AD, though sufficient evidence is not yet available (Oken *et al.*, 1998). However, a recent randomized, double-blind, placebo-controlled trial evaluated elderly individuals with memory impairment, living in a residential setting and compared two doses of Ginkgo biloba (160 mg/day and 240 mg/day) to placebo and found no significant effect on cognition, function, or mood (van Dongen *et al.*, 2000). A systematic review of published trials identified 33 studies using double-blind placebo-controlled designs in a range of cognitively impaired populations, most of which had a dementia resembling AD. The studies used treatment exposure intervals from 3 to 52 weeks, with a modal exposure of 12 weeks. Few studies used rigorous Intent to Treat analysis and thus conclusions were based on a completers analysis. In general, doses less than 200 mg per day were associated with benefits in cognition, mood and improved activities of daily living. Longer exposures and higher doses did not systematically increase these benefits. There was no significant difference between Ginkgo biloba and placebo in adverse events and no data on quality of life, depression, or dependency (Birks *et al.*, 2002).

Laboratory studies indicate that Ginkgo biloba may maintain neuronal function in the hippocampus with evidence of neurotrophic effects in mossy fibers and maintenance of age-related adrenergic and serotonergic receptor loss (Barkats *et al.*, 1995). A primary prevention trial sponsored by the National Center for Complementary and Alternative Medicine and the National Institute on Aging is ongoing. The trial (Ginkgo for the Evaluation of Memory study; GEMS) is recruiting those over 75 years of age into a double-blind placebo-controlled study of Ginkgo biloba (240 mg/day) for 3 years or more. The primary outcome measure is dementia with a specified analysis for the diagnosis of Alzheimer's disease and secondary outcome measures include a cognitive battery and other domains typically used in clinical trials for AD.

In general, while anti-oxidant treatments appear safe, results from supplement trials in the area of cognition have been disappointing. There appears to be many methodological challenges to previously reported trials, so hopefully future studies will focus on definitive trial designs.

Anti-inflammatory agents

Several lines of evidence support the notion that locally mediated, non-immune, chronic, inflammatory processes may play a role in AD pathology. A wide range of

inflammation-related proteins appear in proximity to A β plaque including α 1-antichymotripsin, ICAM-1, α 2-macroglobuline and they are presumed to be locally produced, as they do not pass the blood-brain barrier. In addition, mRNA for complement factors and complement proteins are found in neurons but not in glial cells, supporting the notion that they are in response to the neural injury. Data from animal studies using human APP transgenic mice suggests that (i) inflammation related proteins are associated with higher amyloid load (Nilsson *et al.*, 2001) and (ii) inhibition of complement factors lowers amyloid burden (Bales *et al.*, 1997). Human postmortem tissue analysis has identified correlations with microglial cells and plaque deposits in the cerebral cortex of AD brains but not with A β or tau markers of disease progression (Arends *et al.*, 2000). One interpretation of these data is that the inflammatory process is an early response to disease (Eikelenboom & van Gool, 2004).

Epidemiologic data supporting the connection between inflammatory mechanisms and AD is based on the finding of reduced dementia in cohorts using nonsteroidal anti-inflammatory drugs (NSAIDs) (in t' Veld *et al.*, 2001; Zandi *et al.*, 2002; Etminan *et al.*, 2003). One study, which examined pharmacy records of a cohort of over 2000 elders, demonstrated a reduction in dementia among those with 2 or more years of exposure to NSAIDs (in t' Veld *et al.*, 2001). Similar results were reported by Zandi *et al.* (2002) in the Cache County cohort. The strength of the association in both studies was best observed when the analysis only included NSAID exposure 1 to 2 years prior to the onset of disease, leading to the impression that NSAID protection can only be observed in the intact brain and is not likely to be apparent as a treatment effect. A recent meta-analysis of six cohort studies totalling over 13 000 individuals projects that the effect size for dementia protection is approximately 30% reduction in incidence with significant results in those with use greater than 24 months (Etminan *et al.*, 2003).

It is possible that the epidemiological effect observed with the NSAIDs is not due to the anti-inflammatory properties. In a recent paper, Weggen *et al.* (2001) reported that, in cell cultures Ibuprofen and Indomethacen, but neither Naproxen nor the COX 2 inhibitors, reduced the amyloidogenic A β 42 formation in a variety of cell culture models (Weggen *et al.*, 2001). These authors postulate that this effect may come from subtle mediation of secretase activity. Unfortunately, the epidemiologic data is not available to make distinctions between the NSAIDs.

Clinical trials to date have been disappointing, although many have been designed as treatment studies in patients with AD rather than as prevention trials. Glucocorticoids,

which are known to be effective anti-inflammatory agents in the CNS, acting on several of the hypothesized inflammatory processes, have not been proven to be beneficial in treating AD in clinical trials. In a multicenter, randomized clinical trial of Prednisone no benefit was seen and significant side effect was observed (Aisen *et al.*, 2000). Non-steroidal agents have been studied in several trials. An early, single site trial demonstrated borderline benefit in the presence of significant side effect with Indomethacin (Rogers *et al.*, 1993). A more recent study examined the NSAID Diclofenac in combination with Misoprostol and also found no benefit and reported nearly a 50% withdrawal rate (Scharf *et al.*, 1999). A recent multi-center trial of Naproxen was also unable to demonstrate benefit in patients with AD (Aisen *et al.*, 2003a,b). Selective COX 2 inhibitors, effective anti-inflammatory agents with minimal gastrointestinal disturbances, have reasonable CNS penetrability. However, well-designed, year-long, multi-centre trials of these agents have not demonstrated efficacy in the treatment of AD (Aisen *et al.*, 2003; Reines *et al.*, 2004).

Taken together, the present state of knowledge provides no data to support the use of anti-inflammatory agents for the treatment of AD, and the known side effect profile suggests that the risks may be considerable, particularly in an elderly population. Interest in these agents for the prevention of AD has led to several secondary and primary prevention trials. The selective COX II inhibitor, Rofecoxib, was used in a trial of prevention of AD among individuals with Mild Cognitive Impairment (MCI) and results indicated no benefit either in reduced conversion or in performance on cognitive testing (Visser *et al.*, 2003).

It has been suggested that, despite failure in treatment and secondary prevention, there is hope that primary prevention may be the challenge for demonstrating efficacy with anti-inflammatory agents. A primary prevention trial known as Alzheimer Disease Anti-inflammatory Prevention Trial (ADAPT), is a multicentre trial based on observational data (Martin *et al.*, 2002). The primary outcomes are to reduce incident dementia and cognitive decline. The study will enrol 2625 individuals aged 70 and older with a family history of AD in a first-degree relative. This study will examine two anti-inflammatory agents, the conventional NSAID, Naproxen sodium (220 mg bid) and the selective COX 2 inhibitor Celecoxib (200 mg bid) and to achieve 80% power to detect a 30% reduction in AD incidence, will follow subjects over 7 years.

Lowering homocysteine

Homocysteine, an amino acid involved in methionine and cysteine metabolism, plays a role in methylation reactions.

The role of homocysteine as a cardiac disease and stroke risk factor has been well established. Several studies have demonstrated that hyperhomocysteinemia is associated with Alzheimer's disease (AD) in the absence of folate or B₁₂ deficiency. When age-based norms for plasma homocysteine are divided into tertiles, the risk of AD in subjects in the highest tertile of homocysteine levels is more than four times higher than those in the lowest (McCaddon *et al.*, 1998; Seshadri *et al.*, 2002). Other evidence for a role for homocysteine in AD comes from data indicating that elevated plasma homocysteine occurs in neuropathologically confirmed cases of AD, in the absence of any vascular neuropathology (Clarke, 1998). Also, among AD cases, higher levels of homocysteine are associated with more rapid radiological disease progression.

Folate, as well as vitamins B₁₂ and B₆ are cofactors in metabolic reactions involving homocysteine and are very effective in lowering homocysteine levels. In addition, folate improves nitric oxide availability in the brain. It also plays a number of other roles, such as acting as a coenzyme in the synthesis of serotonin and catecholamine neurotransmitters and also of S-adenosylmethionine, and these have been reported to have antidepressant properties. Thus, the use of folate may have benefit through several mechanisms. It is therefore reasonable to postulate that lowering homocysteine with these vitamins would provide cognitive benefit or protection from cognitive decline. It has been demonstrated that supplementation with folate, vitamin B₁₂ and vitamin B₆ can lower homocysteine in patients with AD even in those with already normal levels, although the ability to affect cognition has not yet been demonstrated.

Several clinical trials have assessed folate effects on cognition in a range of populations. Four randomized trials were identified in a recent review; one enrolled healthy women only and three others recruited people with mild to moderate cognitive impairment or dementia. While folic acid plus vitamin B₁₂ was effective in reducing serum homocysteine concentrations, a meta-analysis of these studies found no benefit from folic acid with or without vitamin B₁₂ in comparison with placebo on any measures of cognition or mood for healthy, cognitively impaired, or demented people. Folic acid was well tolerated and no adverse effects were reported. Several limitations of these studies include brief exposure periods, lack of standardized diagnosis, and lack of surety about appropriate outcome measures.

Effective lowering of homocysteine levels can be achieved with folate, vitamins B₁₂ and B₆, even when levels are in the relatively normal range and in the presence of fortified grain (Aisen *et al.*, 2003). On this basis and given its

relative safety it is reasonable to hypothesize vitamin supplementation may lower the risks of cognitive decline and dementia in the elderly. Since ongoing trials of high doses of supplementation continue to prove to be safe in aging populations, intervention with these supplements are worthy of study as a treatment strategy for primary prevention of cognitive loss and dementia in aging.

Lowering lipids

There is compelling evidence from laboratory research in animal model and cell culture systems, observational epidemiological studies, and small clinical trials that lowering cholesterol may reduce the pathology of Alzheimer's disease (AD). In support of the link between cholesterol and AD there are *in vitro* studies demonstrating that cholesterol levels modulate the enzymatic processing of the amyloid precursor protein (APP) and consequently, A β production. Dietary manipulation to increase cholesterol in rabbits, rats, and transgenic mice demonstrate that high cholesterol yields increased secretion of amyloidogenic A β 1–40 and 1–42, as well as increasing size and number of amyloid plaques. Lipid lowering agents can reduce these findings both in cell cultures and in animals. It is not clear that cholesterol lowering can help patients with AD, and retrospective studies have not supported that connection. However, well-controlled clinical trials could answer this question directly.

Recent epidemiological data have suggested that use of some lipid lowering drugs was associated with a reduced risk of Alzheimer's disease. Observational studies using existing clinical practice registries have reported an inverse association between statin use and risk of AD. Wolozin *et al.* (2000) reported cross-sectional examination of computerized medical records from three hospitals and demonstrated that the prevalence of diagnosed AD in patients taking Lovastatin or Pravastatin was 60–73% lower than the entire patient population during the period from 1996–1998. Jick and colleagues (2000) examined the General Practice Research Database in the United Kingdom and reported reduced risk of AD with statin use. In this study, the 284 cases were patients who developed a first-time diagnosis of dementia or Alzheimer's disease between 1992 and 1998. Rockwood and colleagues reported a reduced risk of AD among those using statins and other lipid lowering agents (OR = 0.26; 95% CI 0.08–0.88) (Rockwood *et al.*, 2002). These authors noted no effect of statins among those over 80, though very few in that age group were taking statins.

Despite these epidemiological findings, two recent large scaled trials conducted 'add-on' studies to assess cognition.

The Heart Protection Study (HPS) also examined the effect of Simvastatin, a cholesterol lowering agent, on the large cohort with the Telephone Interview for Cognition (TIC) as described above (Heart Protection Study Collaborative Group, 2002). There was no difference in the percentages of participants classified as cognitively impaired, (23.7% simvastatin allocated vs. 24.2% placebo allocated) or having incident dementia during follow-up (0.3% vs. 0.3%). In a trial of Pravastatin in over 5000 individuals age 70 to 82, cognitive testing administered before and after found no effect on measures of learning, memory, attention, speed of processing, mental status, or activities of daily living (Shepherd *et al.*, 2002). While these studies use large sample sizes, the observation study may be too brief to observe the transition from normal cognition to dementia, resulting in insufficient power to observe an effect in this intact population.

The relative safety of these drugs has led to their use in trials to slow disease progression in AD. A single site study of Atorvastatin in patients with mild to moderate AD was recently presented suggesting a beneficial effect in cognitive and clinical global outcome measures (Sparks *et al.*, 2004). At this writing there are two ongoing multicentre trials of statins that will examine the rate of change on cognition and clinical global benefit over an 18-month period with patients with mild to moderate disease. The advantage to trials conducted with patients with AD is that the rate of progression in cognition and other clinical measures is relatively well established and rapid enough to permit sufficient power to observe an effect, if it exists.

Theoretical approaches based on attacking amyloid

The amyloid plaque in neurons remains the hallmark pathology of AD and the formation of the plaque is nearly universally considered the primary underlying mechanism and etiology of the disease. As such, interventions that could reduce amyloid plaque burden either by altering amyloid metabolism or by maximizing clearance are widely proposed though not so widely realized. Metabolism of amyloid precursor protein (APP) may determine the likelihood of the plaque formation. Cleavage of APP by the enzyme, α -secretase, leads to the formation of non-amyloidogenic, soluble APP (sAPP). A β , the building block of amyloid plaque is the result of APP cleavage by β -secretase. It also appears that the enzyme, γ -secretase, has a cleavage site within the intramembranous domain and it results in the formation of a small but potent peptide A- β 42, which is highly likely to aggregate. From this scenario, at least in theory, modulation of these enzymes might result

in differential rate of amyloid plaque formation. Unfortunately, these enzymes have many components and many substrates making it difficult to select a manipulation that will yield efficacy and avoid mechanism-related toxicity. To this end, selective enzyme inhibitors have been proposed, but to date none have advanced to clinical trials for efficacy.

Protein phosphorylation apparently regulates APP cleavage, by stimulating the α -secretase pathway leading to the relatively non-toxic sAPP. Stimulation of protein kinase-C through steroid hormones such as 17- β -estradiol or DHEA have been shown to stimulate this pathway and similar signal transduction systems have been proposed as treatment intervention, despite the fact that clinical trials examining these approaches have not yielded benefits (Gandy *et al.*, 2003).

Vaccination strategies have focused on vaccination with A- β . It is clear that A- β antibodies can be generated and can achieve clearance of plaque with some behavioral benefit in animal models and there is implication of clearance in pathology reports from human trials. While clinical benefit in humans has not yet been confirmed, anecdotal reports suggest an association between anti-amyloid response and slowed cognitive decline. These strategies have been associated with significant side effect probably resulting from pathologic immune response.

Conclusions: the challenge of managing a neurodegenerative disease

A growing awareness of the impact of cognitive impairment has led to our ability and willingness to diagnose and offer treatment to individuals with Alzheimer's disease. However, disease detection remains inadequate and it is estimated that only a third to a half of prevalent cases are identified. The initiation of clinical attention is often via a concerned family member or friend and seldom by any routine screening. This illustrates the lack of prominence given to this disease in the overall context of medical evaluation and management of the elderly. Elevating the importance of diagnosing this disease may encourage a willingness to acknowledge cognitive deficits at early stages of dementia and increase public motivation for prevention.

Understanding the pathology and how to manipulate it in a clinically relevant way remains elusive. However, the efforts of basic scientists to elucidate disease mechanisms is an essential requirement for progress in developing interventions. One emerging theme is that results of clinical trials in AD do not match results of risk reduction reported in observational studies. This dichotomy occurs with

anti-inflammatories, anti-oxidants, and statins. While mechanisms have been proposed to explain observational findings of well known agents in AD, direct use of these agents in AD patients have provided disappointing results. This has led to the idea that once the disease is present, manipulation of the pathology cannot provide a benefit and an inevitable cascade of deterioration is in place. This reasoning does not adequately value the clinical observation that patients with AD may live for years, some leading relatively independent lives. Clinical progression is well characterized and theories of pathology and mechanisms of intervention must model a continuum of disease from presymptomatic through early and middle disease stages. Biological models, which address the full spectrum of disease, may provide drugs for common targets both in treatment and prevention.

Dementia with Lewy bodies

Norman Relkin

Weill Cornell Medical College, New York, NY, USA

Introduction

“Lewy bodies” are proteinaceous intraneuronal inclusions that were first described by F. H. Lewy in 1912 in neurons of the basal forebrain and thalamus of patients with Parkinson’s disease (PD) (Lewy, 1913). More than eight decades after Dr. Lewy’s original report, international consensus criteria (see Table 33.1) were created that formally acknowledged the existence of a syndrome of dementia with parkinsonism associated with LBs in other brain areas such as the limbic system and neocortex (McKeith *et al.*, 1996). This condition, known as Dementia with Lewy bodies (DLB), is now recognized to be the second most common cause of neurodegenerative dementia in older adults. Lewy body neuropathology is found in the brains of 15% to 28% of dementia patients that undergo autopsy (Jellinger, 2003; Rahkonen *et al.*, 2003), and DLB accounts for nearly half as many cases of dementia as Alzheimer’s disease (Barker *et al.*, 2002). Despite its considerable prevalence and morbidity, DLB is a relatively unknown entity to a large segment of the general public as well as many physicians.

In its most recognizable form, DLB presents as a hypokinetic movement disorder associated with progressive cognitive decline. Other core features include delirium-like fluctuations of attention/arousal, autonomic and sleep disturbances as well as idiosyncratic delusions and hallucinations. While the clinical features of DLB can resemble those of Alzheimer’s and Parkinson’s disease, possible demographic distinctions have been reported among these disorders. In one autopsy series, DLB was found to be over-represented in men relative to women (Rahkonen *et al.*, 2003), the reverse of the gender ratio generally observed for Alzheimer’s disease. However, this finding has not been generally replicated in subsequent clinical studies. DLB has a predilection to take onset in the

seventh and eighth decades of life, similar to Alzheimer’s disease but later than is typical for idiopathic Parkinson’s disease (McKeith, 2000). A recent study found comparable life expectancies in Alzheimer’s disease and DLB, as well as similar age of onset and duration of illness until death (Weiner *et al.*, 2003). Across studies there has been sufficient overlap between Alzheimer’s, Parkinson’s and DLB to suggest they might be part of a single disease continuum rather than discrete diseases, although there is no clear consensus on that issue.

It is very important from a clinical standpoint to distinguish DLB from diseases such as Alzheimer’s and Parkinson’s disease because of differences in the course of DLB and its response to treatment. From the onset, DLB patients often exhibit hallucinosis and behavior disturbances that are unexpected at a comparably early stage of Alzheimer’s or Parkinson’s disease. These psychiatric disturbances can be especially difficult to treat because DLB patients exhibit idiosyncratic reactions to medications that can be prescribed with relative impunity in other conditions. For example, up to a half of patients with DLB show a pathologic sensitivity to the types of antipsychotic medications that are typically used to treat hallucinations and delusions (Ballard *et al.*, 1998). Although the risk is greatest for conventional high-potency neuroleptics, even newer antipsychotics may cause adverse events such as coma after a single dose of clozapine reported in a DLB patient (Sadek & Rockwood, 2003). Anti-parkinsonian medications, particularly dopamine agonists, may worsen confusion in DLB patients and tend to be less effective in treating rigidity and postural instability than in patients with Parkinson’s disease (Kaufer, 2002). These and other treatment distinctions underscore the importance of recognizing DLB in the clinical setting and managing it appropriately.

Table 33.1. Lewy body consensus criteria

1. Progressive cognitive decline of sufficient magnitude to interfere with normal social function.
 - Memory loss may not be persistent or prominent in earliest stages but generally becomes evident with disease progression.
 - Deficits on tests of attention, frontal executive and visuospatial abilities may be especially prominent.
2. Two core features necessary for a diagnosis of probable DLB, one for possible DLB:
 - (a) fluctuating cognition with pronounced variations in attention and alertness.
 - (b) recurrent visual hallucinations which are typically well formed and detailed.
 - (c) spontaneous motor features of parkinsonism.
3. Features supportive of diagnosis:
 - (a) repeated falls
 - (b) syncope
 - (c) transient loss of consciousness
 - (d) neuroleptic sensitivity
 - (e) systematized delusions
 - (f) hallucinations in other modalities.
4. A diagnosis of DLB is less likely if:
 - (a) stroke disease is evident as focal neurological signs or on brain imaging.
 - (b) evidence on physical examination and investigation of any physical illness or other brain disorder is sufficient to account for the clinical picture.

From McKeith *et al.* (1996).

While DLB can present difficult treatment challenges, it can also be gratifyingly amenable to certain interventions. Acetylcholinergic deficiency is reportedly more profound in DLB than in Alzheimer's disease, and alterations in both the muscarinic and nicotinic cholinergic system have been reported (Ballard *et al.*, 2002). Treatment with acetylcholinesterase inhibitors such as tacrine, rivastigmine and donepezil have been reported to reduce the behavioral and cognitive symptoms associated with DLB without a marked proclivity to worsen extrapyramidal symptoms or cause other severe side effects (Wild *et al.*, 2003). Unfortunately, the use of cholinesterase inhibitors to treat DLB has not been formally approved by major regulatory bodies at this time. Treatment of DLB with this class of medications is often delayed or neglected. For these and other reasons, it is important to increase recognition of DLB as well as the awareness of availability of effective pharmacologic interventions.

Pathogenesis and heritability

Despite ongoing studies of its molecular pathogenesis, relatively little is known about the primary causes of DLB. The constituents of Lewy bodies include several cytoskeletal elements and components of proteosomal degradation pathways such as alpha-synuclein, ubiquitin and intermediate neurofilament proteins. This may imply that DLB, like several other central neurodegenerative disorders, is associated with disturbances in protein folding and aggregation. However, more research is needed to identify the precise mechanisms involved.

Genetic studies often provide clues to the pathogenic mechanisms underlying human disorders. Because DLB was not commonly diagnosed before the 1980s, data on familial inheritance patterns and genetic linkage is more limited than for disorders such as Parkinson's and Alzheimer's disease. There is emerging evidence of heritable factors in DLB based on linkage studies carried out in a limited number of reported familial cohorts (Trembath *et al.*, 2003). To date, only one autosomal dominant genetic mutation (the E46K mutation of the α -synuclein gene) has been identified as a specific cause of DLB (Zarranz *et al.*, 2004). This was discovered in a Spanish family in which multiple affected individuals developed parkinsonism, dementia, and visual hallucinations. At postmortem, the brains of those affected showed lack of Alzheimer pathology and numerous Lewy bodies which were immunoreactive to α -synuclein and ubiquitin in cortical and subcortical areas. The mutation that was found in all affected family members results in substitution of lysine for glutamate in the α -synuclein protein. The alpha-synuclein protein is a central component of the Lewy bodies, and other mutations in the alpha-synuclein gene have been previously reported to cause early onset forms of parkinsonism associated with dementia. Transgenic animal models using alpha-synuclein mutations have been created in mice and flies that manifest several of the features of human DLB neuropathology (for review, see Sommer *et al.*, 2000).

The APOE- ϵ 4 allele is modestly over-represented among patients with DLB, although the strength of the association is less than with Alzheimer's disease. Autopsy studies have suggested a correlation between Alzheimer's disease pathology in DLB patients and possession of the APOE- ϵ 4 allele, but have failed to demonstrate a dose-dependent effect on either senile plaque burden or neurofibrillary tangle density (Singleton *et al.*, 2002). Other genetic polymorphisms have been studied in relation to DLB, but as yet none has been strongly associated with risk of this disorder.

Fig. 33.1 18 Fluorodeoxyglucose PET scans in patients with dementia with Lewy bodies and Alzheimer's disease respectively. Sagittal images of cerebral glucose metabolism in severity matched patients imaged with eyes open using identical scanner. Arrows denote area of hypometabolism in occipital cortex of DLB patient and occipital sparing in Alzheimer's disease case. Hypoperfusion and hypometabolism in the occipital lobe has been found in more than half of DLB patients, and can assist in differential diagnosis of DLB from Alzheimer's disease.

Neuropathology

The acceptance of DLB as a clinical disease entity over the last two decades is in part a consequence of improvements in the techniques used to identify its associated neuropathology. Brainstem LBs were readily detected by the conventional histochemical stains of the kind available to Dr. Lewy in the 1910s (see Fig. 33.1). However, cortical LBs have different staining properties that make them harder to detect by these methods. Immunohistochemical methods for identifying ubiquitin and other minor LB components became available in the 1980s. These immunostains helped to better identify the burden of Lewy bodies in individual cases and revealed other elements of DLB pathology such as "Lewy neurites," dystrophic neuronal elements that classically stain positive for ubiquitin and occur prominently in the CA2/CA3 region of the hippocampus. In addition to a central core of α -synuclein, LBs contain ubiquitin, neurofilament protein, tubulin, microtubule associated protein (MAP) and amyloid precursor protein.

Use of ubiquitin stains and characterization of the distribution of Lewy bodies and associated pathology are part of the recommended procedures for the neuropathological diagnosis of DLB. Consensus criteria have drawn distinctions between cases in which Lewy bodies are found predominately in the brainstem vs. limbic structures vs. the neocortex. A recent study in Japan (Marui *et al.*, 2002) suggests that Lewy body neuropathology may progress in a spatially and cytopathologically specific pattern. Post-mortem examination of the brains of 27 patients indicated that the earliest occurrence of Lewy neurites was in the

amygdala, followed by limbic cortex and subsequently the neocortex. Within the neocortex, there was evidence of a sequential involvement of cortical layers V–VI, then layer III followed by layer II. Intraneuronal alterations were seen first in the axonal terminal, followed by the cell body and ultimately dendrites. Further studies are needed to establish the reproducibility of these findings and their relevance to the symptomatic progression of DLB.

Clinical characterization

DLB is diagnosed directly based on findings derived from the clinical history and neurologic examination. Consensus clinical criteria are listed in Table 33.1, and include primary as well as supportive symptoms. The features that are most typical of DLB include a parkinsonian extrapyramidal movement disturbance, visuospatial and executive functional cognitive impairments that wax and wane over time, and neuropsychiatric symptoms such as visual hallucinations with fixed delusions. The order of emergence of these symptoms is variable, but by convention cognitive disturbances and parkinsonism are usually expected to appear within a year of one another in DLB. In contrast, the very similar form of dementia associated with idiopathic Parkinson's disease can emerge several years after the onset of the movement disorder. Extrapyramidal abnormalities in Alzheimer's disease are expected predominantly in late stages of the disease.

The extrapyramidal disturbance in DLB is typically described as parkinsonism without tremor. The complete

absence of resting tremor in DLB is not uniformly observed, but in most cases tremor is not a prominent feature. Other extrapyramidal symptoms may include increased tone, retropulsion or other postural instability, shortened steps, bradykinesia and masked facies. The reported frequency of parkinsonian symptoms at onset of DLB ranges from 10–100%, which varies with the referral base of the clinical population studied (e.g. greatest in Neurologic clinics, least in General Practice) (McKeith *et al.*, 2003). Parkinsonian symptoms may be symmetric or asymmetric in DLB, and may wax and wane in much the same manner as cognitive and behavioral disturbances. Myoclonus is infrequently observed in DLB patients, and in rare cases supranuclear gaze palsies have been observed. DLB symptoms sometimes respond positively to levo-dopa therapy, but the therapeutic window is generally narrow. Confusion and other cognitive changes can be exacerbated by dopaminergic treatments, particularly with dose escalation (Kaufer, 2002).

Patients with DLB show a variety of cognitive symptoms that overlap with those observed in Alzheimer's disease and the dementia of Parkinson's disease, as well as some features that are relatively distinctive. Performance on verbal memory tests and tests of orientation are often better in DLB than at comparable stages of Alzheimer's disease, but may be worse than in patients with Parkinson's disease at otherwise comparable stages of disease. DLB patients often do less well than Alzheimer's disease patients on performance-based tests and visual recognition tasks, while Parkinson's disease patients may show even greater weaknesses on such tests. Frontal executive functions are generally impaired in all of these disorders, but tend to fluctuate more in patients with DLB. Fluctuation in attention can be detected by repeated administration of timed tests in a clinical setting, and reportedly show a greater degree of variation in DLB and Parkinson's disease than Alzheimer's disease (Ballard *et al.*, 2002a,b).

With progression of disease, dementia in DLB can progress through mild to moderate and severe stages characterized by progressively greater cognitive deficits as well as increasing functional dependency. Eventually, patients tend to lose all independent function in the disease's final stages. Rate of decline has been reported to be slightly greater in DLB than Alzheimer's disease, averaging 4–5 minimal state exam (MMSE) points per year in comparison to the expected 3 points per year decline on the MMSE in Alzheimer's disease (Helmes *et al.*, 2003). Formal testing by a neuropsychologist familiar with disorders such as DLB can be helpful in characterizing the cognitive status of patients with presumed DLB, which can be

difficult in the context of fluctuation arousal and co-morbid psychiatric symptoms.

Fluctuations in attention and arousal occur on multiple time scales in patients with DLB. This includes millisecond to millisecond variations in the EEG and long latency evoked response measurements to changes in state spanning weeks to months in some cases. While specific tests can be brought to bear to document these fluctuations, their physiologic and neurochemical basis remains uncertain. It has been observed that treatment with cholinesterase inhibitors may dampen the oscillations in some patients with DLB, suggesting a role for the cholinergic system in their etiology (Ballard *et al.*, 2002a,b). Disease-related fluctuations can be mistaken for willful dissemblance on the part of patients, and may confound assessment of progression of disease and response to treatment over time. Patients and caregivers should be alerted to the tendency of DLB symptoms to fluctuate and encouraged not to assume disease progression has been accelerated when symptoms wax as part of this cycle.

The neuropsychiatric manifestations of DLB are among the most fascinating aspects of the illness and can provide extremely useful clues to the diagnosis. A majority of patients with DLB experience some psychiatric disturbance, and at least half develop characteristic visual hallucinations during the course of their illness. These hallucinations are most commonly fully formed and animate, often involving deceased relatives, complete strangers or animals. In most cases the hallucinations are not perceived as threatening by the patient, but there are clear exceptions. It is unusual although not unprecedented for these visual hallucinations to have auditory components, and some DLB patients express their frustration that their hallucinations do not respond to their overtures to conversation. The hallucinations are occasionally triggered by comparably shaped or patterned objects in the immediate environment, and may move away or disappear when approached. The so-called "extracampine" hallucination is another common occurrence, in which affected individuals have the sense that someone else is in the room with them, or perhaps briefly glimpsed out of the corner of their eye (Chan & Rossor, 2002). A common feature of DLB is the elaboration of systematized delusions that often center around the hallucinations. Patients may acknowledge that the hallucinated relative is deceased, but nevertheless treat them as though they are alive. The combined occurrence of visual hallucinosis and circumscribed delusions in the context of dementia and/or an extrapyramidal disorder should trigger consideration of DLB. Depression, apathy, anxiety, insomnia, paranoia and paramnesic phenomena also occur in DLB with some

frequency and require sensitive management particularly owing to the pharmacological sensitivities DLB patients often manifest.

A number of other findings have been associated with DLB but are variable in their occurrence. When present these features are considered supportive of the diagnosis, but are not required according to consensus criteria. This includes Rapid Eye Movement Sleep Behavior Disorder (REMSBD), orthostatic hypotension and other autonomic dysfunction, unexplained falls or syncope, and neuroleptic sensitivity.

Onset of REMSBD may precede symptoms of DLB by several years, and is more likely to be associated with DLB than any other form of dementia (Boeve *et al.*, 2001; Turner, 2002). This disorder is characterized by a failure of the normal mechanisms of sleep paralysis resulting in vocalizations, gesticulations and other behaviors associated with patients acting out their dreams while asleep. One proposed mechanism is loss of neurons in monoaminergic brainstem nuclei such as the locus ceruleus and substantia nigra causing decreased inhibition of the cholinergic pedunculopontine nucleus which is a mediator of the atonia of sleep (Turner *et al.*, 2000). Treatment with the cholinesterase inhibitor donepezil has been reported to decrease symptoms of REMSBD in some cases (Ringman & Simmons, 2000).

Orthostatic hypotension may be a contributing factor in syncope and falls among DLB patients, and can be treated with pressure stockings, increased salt intake and if necessary, mineralocorticoids. Increased neuroleptic sensitivity is frequently observed but is not something that should be tested for provocatively, since relatively dire consequences have been reported in some DLB patients after receiving even a single dose of antipsychotics. Some of the symptoms of DLB have been found to correlate with the burden of LB in relatively circumscribed neuratomic regions (McKeith *et al.*, 2003). Cortical LB in DLB tend to be found in the greatest density in the anterior cingulate gyrus, the transentorhinal region of the medial temporal lobe and portions of the frontal lobes. Overall dementia severity has been found to correlate with LB burden in frontal and temporal cortices. Visual hallucinations have been found to correlate with LB density in the amygdala, parahippocampal gyrus and inferior temporal cortex. Degenerative changes in the cholinergic pedunculopontine nucleus may be associated with postural instability and with REM Sleep Behavior Disorder.

Advanced stages of DLB are associated with relatively global cognitive and functional impairments. Death, as in other central neurodegenerative disorders, is usually not the direct consequence of progressive brain failure but

rather the co-morbid medical conditions to which it predisposes the patient, such as aspiration pneumonia and sepsis.

Laboratory evaluations and brain imaging

While blood tests are a part of the routine evaluation of DLB, they are primarily used for identifying co-morbid conditions rather than direct diagnosis. Despite the reported association between APOE- ϵ 4 and DLB, genetic testing is not part of the routine diagnosis of DLB. APOE genotyping could conceivably provide information relevant to differential diagnosis of Parkinson's disease and DLB. Lumbar puncture and analysis of cerebrospinal fluid (CSF) is not currently recommended for routine evaluation since as yet there are no CSF markers that have been unequivocally linked to DLB.

Both structural and functional brain imaging can provide information supportive of a DLB diagnosis. For example, SPECT studies of clinically diagnosed DLB patients have identified resting occipital hypoperfusion in some patients, in addition to a pattern of temporoparietal and prefrontal hypoperfusion typically seen in Alzheimer's disease (Lobotesis *et al.*, 2001) (see Fig. 33.1). Occipital hypoperfusion on HMPAO SPECT scans was also found in 57% of DLB patients with visual hallucinations (Pasquier *et al.*, 2002). Although occipital hypoperfusion and hypometabolism does not occur ubiquitously in patients with DLB, it is useful when present for distinguishing suspected DLB from Alzheimer's, since occipital metabolism is generally preserved in Alzheimer's. Use of dopaminergic ligands for functional brain imaging in this context is under study and may further assist in the differentiation of DLB and Alzheimer's (Marshall & Grosset, 2003).

Cerebral atrophy is a feature of both Alzheimer's and DLB. Annualized rates of atrophy are comparable in the two conditions. Voxel-based morphometry, an image quantification technique that is less prone to operator bias than manual volumetric measurements, has been used to demonstrate regional differences in the pattern of cerebral atrophy in Alzheimer's disease and DLB (Marshall & Grosset, 2003). Hippocampal atrophy in DLB is reported to be greater than that of age-matched normal controls but less than that of Alzheimer's disease patients with a comparable duration of disease. As many as 40% of DLB patients have no discernable hippocampal atrophy relative to age-matched controls. VBM also shows greater preservation of the medial temporal lobe, amygdala and thalamus in DLB relative to Alzheimer's. This "sparing" of the hippocampus may explain the relative preservation of verbal

Fig. 33.2 (a) Hematoxylin and eosin staining of a Lewy body (arrow) within a pigmented neuron of the substantia nigra in Parkinson's disease. (b) Hematoxylin and eosin staining of a cortical Lewy body (arrow) in dementia with Lewy bodies.

memory observed early in the course of DLB compared to Alzheimer's at the same stage of illness.

Management

Optimal management of DLB is facilitated by early and accurate diagnosis. While patients at any stage of the disease may still be responsive to treatment, early diagnosis can help to reduce the likelihood of adverse occurrences such as inappropriate neuroleptic exposure, wandering and other risky behaviors, as well as caregiver burnout. Patients with DLB may already have been treated by other physicians under the mistaken belief that they were suffering from another disorder such as Alzheimer's, Parkinson's or a primary psychiatric disturbance. It is therefore good practice to review the medications already prescribed to confirm their appropriateness, and when indicated, judiciously reduce or withdraw those medications known to adversely affect cognition in DLB patients. A brief drug holiday (e.g. 3–7 days) may be a useful means of assessing the degree to which individual medications are contributing positively or negatively to the patient's clinical status, but must be carefully considered based on whether those medications are medical necessities. For maintenance therapy, high potency neuroleptics such as haloperidol should generally be discontinued if possible, substituting other medications as needed to address the patient's behavioral state. Dopaminergic therapies such as levodopa, dopamine agonists and COM-T inhibitors can in some cases exacerbate DLB symptoms and should be reduced in dose or temporarily withdrawn if problematic behaviors are

present. If withdrawal of these medications fails to yield behavioral improvement, low doses of novel neuroleptics such as quetiapine that have a relatively low propensity for EPS can be prescribed on a temporary or as need basis. However, other medications such as cholinesterase inhibitors (see below) should be considered for long-term treatment.

Only one large-scale double-blind, placebo-controlled treatment trial with DLB patients was completed prior to 2004, and in this study rivastigmine was found to significantly improve behavior but not cognition (McKeith *et al.*, 2000). Based on the results of a limited number of open label prospective treatment trials completed to date, cholinesterase inhibitors such as donepezil, galantamine and tacrine administered at the same doses as are used to treat Alzheimer's disease may improve cognition and behavior in DLB patients. Delusions tend to be more refractory to treatment but in some cases improve considerably over time. Improvements in MMSE scores can be dramatic as can restoration of functional and behavioral status. In studies completed to date, speed of movement increased and only minimal evidence of worsening of parkinsonism has been observed after cholinesterase treatment, largely confined to exaggeration of existing tremors. The symptomatic improvement observed in some DLB patients after treatment with cholinesterase inhibitors has been documented to persist for up to one year (Grace *et al.*, 2001). Although longer-term benefits can be expected in analogy to Alzheimer's disease, this has yet to be demonstrated in controlled clinical trials. As of 2004, the NMDA receptor antagonist Memantine, which has been approved in the United States and Europe for treatment of advanced

Alzheimer's, has yet to be tested as a treatment for DLB in a large-scale randomized prospective study. Based on the available data, cholinesterase inhibitors should be considered the current treatment of choice for symptoms of DLB and should be initiated as soon as possible after diagnosis.

In addition to cholinesterase therapy, treatment must be individualized to the needs of the particular patient. A profoundly depressed DLB patient may not improve from cholinesterase inhibitors alone, but may benefit from the combined use of these agents with a conventional antidepressant such as an SSRI that has relatively little cholinergic side effects. While benzodiazepines are generally not recommended in the context of dementia, there are advocates of the use of low doses of clonazepam to treat symptoms of REM Sleep Behavior Disorder that are refractory to cholinesterase inhibitors or melatonin (McKeith *et al.*, 2003). There is only limited experience in using mood stabilizing anticonvulsants such as depakote and topiramate in the treatment of DLB, and while they may worsen cognitive impairments and EPS in some cases, they may have a role in reducing aggressive and other socially unacceptable behaviors. Other symptoms such as apathy, insomnia and agitation may be targeted for treatment, keeping in mind that DLB patients may exhibit altered dose responses to conventional medications and should be treated with the lowest effective dose whenever possible.

Conclusions

Although acceptance of DLB as a clinical entity has increased in the past two decades, there are many issues that remain unresolved. One major question is whether cortical LBs actually cause dementia. There is not a one-to-one relationship between DLB symptoms during life and LB neuropathology at autopsy. Postmortem studies have documented extensive numbers of cortical LBs in the brains of some individuals who survived to advanced ages without developing dementia. Likewise, patients meeting clinical criteria for probable DLB are sometimes found to have exclusively Alzheimer's or Parkinson's neuropathology at autopsy in the absence of cortical LBs. Only limited reports have documented exclusively neocortical LBD pathology in association with dementia in the absence of Alzheimer's pathology (Uchikado *et al.*, 2002). The pathophysiological relevance of LBs is incompletely understood, and some lines of evidence even suggest that LBs may be the byproduct of mechanisms that protect neurons against toxic injury rather than an actual cause of neurodegeneration (McNaught *et al.*, 2002).

Another ambiguity about DLB is its relationship to other neurodegenerative disorders. Although LB pathology can occur in isolation, it is more commonly found in combination with Alzheimer-related brain changes. One recent review of cases from a Florida brain bank found concomitant Alzheimer pathology in 66% of DLB cases at autopsy (Jellinger, 2003). Some authors have even advocated use of the term "Lewy body Variant of Alzheimer's" as an expression of the frequency with which Alzheimer's neuropathology accompanies that of DLB. Hardy has argued that Alzheimer's, DLB and Parkinson's disease should be considered disease processes on a continuum rather than separate diagnostic entities (Rahkonen *et al.*, 2003). While this viewpoint is consistent with evidence from a variety of molecular, genetic and neuropathological studies, it is difficult to operationalize in clinical practice.

Until molecular diagnostic techniques permit more objective diagnoses in individual cases, the accurate clinical diagnosis of DLB will continue to require clinical acumen. By following the formal clinical diagnostic guidelines, accuracy in the range of 75–80% relative to autopsy can be expected. While this may seem a less than satisfying percentage, it represents a sizeable number of cases in which management and outcome can be improved as a result of a previously unrecognized disorder being properly identified. In light of its prevalence, the difficulties inherent in management of untreated cases, the adverse effects of neuroleptics observed in this population, and the responsiveness to treatment with cholinergic agents, DLB is unquestionably an important disease entity meriting increasing efforts towards diagnosis, treatment and future study.

Introduction

Frontotemporal lobar degeneration, formerly called Pick's disease, is a progressive dementia that is associated with focal atrophy of the frontal and/or temporal lobes. For over 100 years, the key clinical and pathological feature of this disease has been recognized to be focal, often asymmetric cortical involvement. Histopathologically, frontotemporal lobar degeneration (FTLD) is distinct from Alzheimer's disease but heterogeneous, even among similar clinical syndromes. Recently, with the advent of specialized immunohistochemical stains and insights gained from molecular genetics, it has been recognized that FTLD is closely related to, and sometimes overlaps with three other neurodegenerative diseases: corticobasal ganglionic degeneration (CBD), progressive supranuclear palsy (PSP), and motor neuron disease (MND). The central role of the microtubule-associated protein, tau, in the pathogenesis of FTLD, has led to classification as a "tauopathy."

First description and history of FTLD

The first case of what is now called frontotemporal lobar degeneration (FTLD) was described by Arnold Pick in 1892 (Pick, 1892). His subsequent description of six similar patients emphasized a language impairment, which he termed "amnesic aphasia," and a focal pattern of brain atrophy involving the temporal and/or frontal lobes. A lack of senile plaques and tangles in the brains of similar patients was noted by Alzheimer in 1911. He and Altman provided the first histopathological description of argyrophilic inclusions (later termed Pick bodies) and swollen achromatic cells (later termed Pick cells) (Altman, 1923). Onari and Spatz, two of Pick's students, later introduced the term Pick's disease to describe cases of

circumscribed atrophy lacking plaques and tangles (Onari & Spatz, 1926). The later insistence by some researchers that a diagnosis of Pick's disease requires the presence of Pick bodies on histopathology led to an underestimation of the prevalence of cases of FTLD and most likely hindered research into this disorder.

In 1974, Constantinidis *et al.* (1974) documented three types of histopathology in cases clinically defined as having Pick's disease. The first group of patients had classic Pick bodies and Pick cells. The second group of patients had pathology similar to what is now called corticobasal ganglionic degeneration (CBD). The last group was more heterogeneous, and would include what is now termed dementia lacking distinctive histopathology. The recognition that it was difficult to distinguish histological subtypes of Pick's disease eventually led to a focus on clinical symptoms associated with circumscribed lobar atrophy.

In the late 1980s, Arne Brun and Lars Gustafson, working in Lund, Sweden, and David Neary and Julie Snowden working in Manchester, England began studying non-Alzheimer's degenerative dementias. Both groups described clinical, neuroimaging and histopathological features of dementia patients with progressive frontal lobar degeneration (Snowden *et al.*, 1996a). Although the patients studied by both groups clinically resembled those originally described by Pick, most lacked classic Pick bodies. Instead, Brun noted the presence of prominent astrocytic gliosis and spongiosis of layers I–III in the frontal cortex in typical cases, without the plaques and tangles found in AD (Brun, 1987). He suggested the name *frontal dementia of the non-Alzheimer type* for these patients, while Neary coined the term *dementia of the frontal type* (Miller *et al.*, 1998a). In 1994, the Lund and Manchester groups published consensus research criteria for what they termed frontotemporal dementia (FTD) (Lund & Manchester Groups, 1994).

Fig. 34.1 Pathology of FTLD.

A. Gross pathological specimen from patient with Pick's disease. Note frontal and temporal lobar atrophy, with less significant atrophy of inferior parietal lobule and sparing of pre- and post-central gyri.

B. Gross pathological specimen from a patient with corticobasal ganglionic degeneration demonstrating circumscribed atrophy of the parasagittal superior frontal gyrus and superior parietal lobule, including the pre- and post-central gyri (arrows).

C. Tissue section from the hippocampus of a patient with Pick's disease demonstrating Pick bodies stained with an anti-ubiquitin monoclonal antibody.

D. Tissue section from layer IV frontal cortex of a patient with Pick's disease demonstrating Pick bodies stained with an anti-tau antibody (Mab PHF1).

E. Electron micrograph of isolated tau filaments stained with uranyl acetate from a Pick's disease brain.

(A & B from (Trojanowski and Dickson, 2001), C–E from (Zhukareva *et al.*, 2002) with permission)

Also during the 1980s, Mesulam described a group of patients who developed a progressive aphasia with few other cognitive symptoms, which he termed primary progressive aphasia (Mesulam, 1982). He noted that there were two subtypes of patients, one with a primary non-fluent aphasia associated with atrophy of the left frontal lobe, and a second type with a primary fluent aphasia associated with degeneration of the left anterior temporal lobe. This latter group was similar to the original patients described by Pick. The majority of patients in both groups lacked Alzheimer's pathology, and instead showed neuropathological features similar to the frontal disease described by Brun. During the same period of time, Snowden and colleagues described the linguistic deficits of patients with left anterior temporal lobe degeneration (Snowden *et al.*, 1992). These patients also lacked Alzheimer's disease pathology and instead resembled FTD. Because the language disorder was primarily due to a loss of semantic information

in these patients, the disorder was later termed semantic dementia (Hodges *et al.*, 1992).

Taking into account the clinical and pathological similarities between frontotemporal dementia, semantic dementia and primary progressive aphasia, the Lund-Manchester criteria were further refined by Neary *et al.* in 1998 to provide descriptions of these three common clinical presentations of FTD, which was renamed frontotemporal lobar degeneration (FTLD) (Neary *et al.*, 1998). Recent evidence of pathological and genetic overlap between FTLD and corticobasal ganglionic degeneration (CBD) suggested to Kertesz and colleagues that these clinical syndromes may be one pathological entity (Kertesz *et al.*, 2000). The most recent clinicopathological criteria for FTLD reflect this association, as well as the overlap between FTLD and Progressive Supranuclear Palsy (PSP), and FTLD and motor neuron disease (MND) (McKhann *et al.*, 2001).

Gross morphological pattern of vulnerability

Focal brain atrophy is apparent both macroscopically and microscopically in FTLN brains. Severe brain atrophy may result in postmortem brain weights as low as 750 grams (Dickson, 2001). Quantitative volumetric assessments of brain atrophy have demonstrated tissue loss in the frontal lobes, the anterior, medial and inferior temporal lobes, including the amygdala and hippocampus, the insula, and variably in subcortical structures such as the caudate, putamen, thalamus and substantia nigra (Mann *et al.*, 1993). Of these regions, the frontal and anterior temporal lobes usually show the largest volume losses. Based on patterns of brain atrophy measured at autopsy in patients with fvFTD, four stages of disease severity have been proposed: (i) mild atrophy of the orbital and superior medial frontal cortices and hippocampus, (ii) progression of mild atrophy to the anterior frontal and temporal cortices and basal ganglia, (iii) progression of mild atrophy to other cortical regions and (iv) severe, cortical atrophy (Broe *et al.*, 2003).

In classic Pick's disease, gross pathology demonstrates predominantly frontal and/or temporal atrophy (Figure 34.1(a)). Primary motor and sensory cortex are invariably spared in Pick's disease. Pathological changes similar to that seen in corticobasal ganglionic degeneration (CBD) may be found in most FTLN clinical syndromes, however CBD pathology is most commonly associated with patients who present with language impairment (Kertesz *et al.*, 2000). Gross pathology usually demonstrates superior frontal and parietal atrophy in these patients (Fig. 34.1(b)).

Biochemical findings (microscopic pattern of vulnerability)

Pick's disease

A minority of patients who are clinically diagnosed with FTLN will be found to have classic Pick's disease pathology. Microscopically, areas of cortex most severely affected in Pick's disease show a severe loss of large pyramidal neurons with diffuse spongiosis and gliosis. Pick cells, ballooned neurons that stain weakly with silver stains, are found in the deeper cortical layers. These ballooned neurons are filled with granulofilamentous material that is best demonstrated with antibodies to phosphorylated neurofilament, low molecular weight stress protein, $\alpha\beta$ -crystallin and ubiquitin hydrolase. Focal tau and/or ubiquitin hydrolase immunoreactivity is sometimes present in ballooned neurons (Dickson, 2001).

In Pick's disease, superficial cortical layers in affected areas contain small neurons with round inclusions that are intensely argyrophilic on silver stains called Pick bodies (Fig. 34.1(c), (d)). Brain regions rich in Pick bodies show extensive loss of large neurons as well as evidence of synapse loss as demonstrated by loss of synaptophysin immunoreactivity (Masliah *et al.*, 1990). Pick bodies are most commonly found in limbic, paralimbic and ventral temporal lobe cortex. Smaller numbers of Pick bodies are found in the anterior frontal and dorsal temporal lobes, and are rarely found elsewhere. Like the neurofibrillary tangles found in Alzheimer's disease (AD), the hippocampus and amygdala have the largest numbers of Pick bodies. Unlike the neurofibrillary tangles in Alzheimer's disease, which spare the dentate gyrus, Pick bodies are frequently found there. Also in contrast to AD, the nucleus basalis of Meynert is relatively spared in Pick's disease. Consistent with this observation, cholinergic markers are relatively preserved in Pick's disease (Wood *et al.*, 1983). In contrast, dopaminergic neurons in the substantia nigra are frequently affected in Pick's disease.

Pick bodies stain with antibodies to the paired helical filaments (PHF) that make up the neurofibrillary tangles observed in AD and progressive supranuclear palsy (PSP), although ultrastructurally the arrangement of tau filaments is different. Pick bodies are composed of randomly arranged filaments of tau, as opposed to PHF (Fig. 34.1(e)) (Pollock *et al.*, 1986). The most sensitive stain for Pick bodies is the anti-tau antibody (Dickson, 2001). Western blot analysis of hyperphosphorylated tau protein in Pick's brains demonstrates a different pattern of abnormal variants than in AD. In Pick's disease, there are two abnormal bands that migrate at 55 and 66 kDa, whereas in AD there are three bands: 55, 66, and 69 kDa. Recent analysis of Pick's brains, using phosphorylation-state specific antisera to tau, has demonstrated large amounts of insoluble tau protein in subcortical white matter, consistent with the predominantly axonal localization of tau in normal neurons (Zhukareva *et al.*, 2002).

Corticobasal ganglionic degeneration (CBD; see also Chapter 45)

CBD brains have ballooned neurons similar to classic Pick's brains, however there are no Pick bodies. Atrophy and ballooned neurons are found throughout the neocortex, and are most abundant in the superior frontal and parietal lobes, unlike Pick's disease, which tends to spare these regions. Unlike Pick's disease, ballooned cells may be found in primary motor or sensory cortex. There is prominent neuronal loss and gliosis in areas most affected by CBD

pathology. In many cases, there is significant involvement of basal ganglia structures. Astrocytic plaques that stain with anti-tau antibodies are a hallmark of CBD (Dickson *et al.*, 2002).

Demential lacking distinctive histopathology (DLDH)

DLDH is a common pathological finding in patients with the clinical symptoms of sporadic FTL (Knopman *et al.*, 1990; Bird & Schellenberg, 2001). There is a variable pattern of brain involvement in DLDH. These patients have significant neuronal loss and gliosis, without Pick bodies, ballooned neurons, neurofibrillary tangles or other inclusion bodies. There may be spongiform changes in the superficial cortical layers. In contrast to classic Pick's disease, in which there are abnormal accumulations of tau protein, there is a dramatic reduction of tau protein expression in DLDH brains. This most likely represents a post-transcriptional effect on tau gene expression, since mRNA for tau is present in these brains (Zhukareva *et al.*, 2001).

Frontotemporal dementia with motor neuron disease (FTD-MND)

Frontal lobe degeneration may occur in patients with motor neuron disease (MND; amyotrophic lateral sclerosis). In addition, two series of FTL patients, one with semantic dementia (Rossor *et al.*, 2000), the other with frontotemporal dementia (Forno *et al.*, 2002), both lacking clinical features of MND, were found to have this pattern of neuropathology. Three families with autosomal dominantly inherited frontotemporal dementia, lacking mutations in tau, have also been described with FTD-MND pathology (Rosso *et al.*, 2001). Like DLDH, there are no Pick bodies or ballooned neurons, however immunohistochemical stains reveal ubiquitin-positive, tau-negative neuronal inclusions in affected areas of cerebral cortex, as well as in anterior horn cells (Jackson *et al.*, 1996).

Molecular biology

The role of tau protein in FTL pathogenesis

Advances in the molecular biology of the tau protein have led to a better understanding of the molecular pathogenesis and histopathology of FTL (Hutton, 2001). Tau is a neuronal protein that binds to microtubules, and is thought to be involved in assembly, and maintaining the stability of these cytoskeletal structural elements. In the normal adult human brain, tau is a soluble protein that is expressed as

six major protein isoforms that are generated by alternative splicing of the tau gene. The alternative splicing of exon 10 controls the number of microtubule binding domains. If exon 10 is included in the mRNA (exon10+), there will be 4 microtubule binding domains in the translated protein (4R tau). If exon 10 is excluded in the mRNA (exon 10-), there will be 3 microtubule binding domains (3R tau). In the normal adult human brain, there is an approximately 1:1 ratio of 3R tau to 4R tau.

The tau gene is found on chromosome 17q21. Mutations in the tau gene lead to FTD and Parkinsonism linked to chromosome 17 (FTDP-17, see chapter 35 for a more detailed discussion). Most patients with tau gene mutations develop an autosomal dominantly inherited syndrome with features of FTL. Analysis of tau mutations found in FTDP-17 has provided insight into the pathogenesis of FTL. Tau gene mutations that produce this clinical syndrome are clustered around exon 10, and alter the microtubule binding affinity of the translated protein (missense mutations in exon 10) or the ratio of 3R to 4R tau (splice site mutations flanking exon 10) that is expressed (Hong *et al.*, 1998). Changes in tau isoform expression are thought to eventually result in the formation of insoluble protein aggregates, which in turn lead to neuronal dysfunction and death. Histopathologically, tau mutations (FTDP-17) may result in the formation of different forms of insoluble protein aggregates, including Pick bodies, ballooned neurons and neurofibrillary tangles.

Biochemical analysis of tau protein extracted from Pick's brains has suggested that Pick bodies consist of deposits of predominantly 3R tau. Ballooned neurons found in Pick's and CBD are thought to contain predominantly 4R tau, as are tau deposits identified in the brains of patients with progressive supranuclear palsy (PSP). Neurofibrillary tangles in AD contain an equal mixture of 3R and 4R tau. Other disorders, such as post-encephalitic parkinsonism (Bussiere *et al.*, 1999), neurofibrillary tangle dementia (Reed *et al.*, 1997), Lytico-bodig disease (Hof *et al.*, 1994), and Niemann Pick C disease (Love *et al.*, 1995) also produce insoluble protein aggregates containing equal ratios of 3R and 4R tau. FTL and other primary neurodegenerative disorders with prominent tau pathology have been grouped together as "taupathies," to distinguish them from other protein aggregate diseases such as Parkinson's and Lewy body disease, which display protein aggregates composed of alpha synuclein (Hardy & Gwinn-Hardy, 1998).

A recent consensus statement on clinical and pathological diagnosis of FTL emphasized the composition of insoluble tau deposits found in brains at autopsy (McKhann *et al.*, 2001). For example, it was suggested that

if the insoluble tau aggregates contained predominantly 3R tau, the most likely diagnosis would be Pick's disease or FTDP-17. However, a study of tau isoform expression in sporadic Pick's disease, using exon 10-specific tau antibodies has demonstrated cases with predominantly 3R tau, 4R tau or an equal ratio of both (Zhukareva *et al.*, 2002). This study calls into question the utility of classifying FTLD pathology by tau isoform expression ratio. Further studies will be necessary to fully understand the relationship between tau isoform expression and clinical disease.

Pathogenesis/mechanisms of disease (animal models)

The molecular pathogenesis of both sporadic FTLD and FTDP-17 is poorly understood. The discovery of pathogenic mutations in tau as a cause of FTLD has led to attempts to develop transgenic mouse models of the disease. Lines of transgenic mice have been constructed that overexpress a single tau protein isoform (3R or 4R), a mutant tau protein or protein kinases thought to be upstream in the development of hyperphosphorylated tau. So far, no transgenic model has been completely successful in recapitulating the FTLD phenotype and associated pathology observed in humans (Hutton *et al.*, 2001).

Transgenic mice that overexpress wild-type 4R tau at up to ten times the level of endogenous mouse tau develop motor disturbances in tasks involving balancing on a rod or hanging from a grid. Histopathologically, these mice display dilated axons containing neurofilament and tubulin and dystrophic neurites that stain with an antibody to hyperphosphorylated tau (Probst *et al.*, 2000). Transgenic mice that overexpress 3R tau also develop motor symptoms, however they do not show clear neuropathological abnormalities until late in life. These mice develop neurofibrillary tangles similar to those observed in AD (Ishihara *et al.*, 1999). A transgenic mouse line that overexpresses an exon 10 mutant tau (P301L) which causes FTDP-17 in humans, develops motor and behavioral deficits, with early hind limb dysfunction, followed by dystonic posturing, docility, reduced weight and decreased vocalization. These mice show profound neuronal loss in the spinal cord and tau-positive neurofibrillary tangles throughout the brain (Lewis *et al.*, 2000). Glial tau deposits and motor deficits, similar to those seen in CBD and PSP, have been observed in a transgenic mouse line that overexpresses human tau in both neurons and glia (Higuchi *et al.*, 2002).

A number of transgenic mouse lines have been developed that express protein kinases upstream of tau, and thus might serve as model systems for the molecular pathogenic mechanisms that underlie sporadic tauopathies. One line expresses glycogen synthase kinase-3 β (GSK-3 β),

under the control of an inducible promoter system targeted to CA1 hippocampal neurons. When GSK-3 β expression is induced, the mice produce hyperphosphorylated tau and evidence of increased neuronal apoptosis, however no FTLD phenotype (Lucas *et al.*, 2001). A second transgenic line that expresses p25, a positive regulator of cyclin-dependent kinase 5 (cdk5), under the control of the platelet derived growth factor promoter, has increased cdk5 kinase activity and develops motor symptoms at 3 months of age. These p25 mice show widespread axonal degeneration, with focal accumulation of tau in multiple brain and spinal cord regions. However, ultrastructurally, the tau deposits do not resemble those found in AD or FTLD (Ahlijanian *et al.*, 2000).

Molecular genetic experiments performed in fruit flies (*Drosophila melanogaster*) transgenic for tau and protein kinases may prove to be a powerful system to dissect the molecular pathogenesis of FTLD. Recently, one such line that expresses wild type human tau has been shown to develop neurofibrillary tangles and progressive neurodegeneration by a mechanism involving the Wnt signaling pathway (Jackson *et al.*, 2002). A second transgenic *Drosophila* line expressing human tau, shows adult onset of progressive neurodegeneration leading to early death. These flies have accumulations of insoluble tau protein in anatomically appropriate regions (Wittmann *et al.*, 2001).

Clinical picture

Core clinical characteristics of FTLD

FTLD clinical syndromes

The 1998 consensus criteria for FTLD list three clinical syndromes: frontotemporal dementia (FTD; sometimes referred to as frontal variant FTD), semantic dementia (SD; sometimes referred to as temporal variant FTD) and progressive nonfluent aphasia (PNFA). One study has suggested that FTD and SD each account for approximately 40% of FTLD cases, and PNFA makes up the remaining 20% (Hodges & Miller, 2001). Patients with tau gene mutations are classified as having frontotemporal dementia with Parkinsonism linked to chromosome 17 (FTDP-17), although clinically they are often indistinguishable from patients with sporadic FTLD. Motor neuron disease (amyotrophic lateral sclerosis (ALS)), most commonly with prominent bulbar symptoms, is associated with FTD in approximately 10% of patients (Miller *et al.*, 1995a). In a series of 36 patients with FTLD, five met clinical criteria for FTLD, and an additional 11 patients had at least

one clinical sign of ALS (Lomen-Hoerth *et al.*, 2002). Likewise, almost one third of a series of 100 ALS patients were found to meet clinical criteria for FTLD (Lomen-Hoerth *et al.*, 2003). Patients who meet clinical criteria for FTLD, especially those with prominent language impairment, and who develop movement disorder symptoms within 2–7 years after diagnosis are often found to have CBD at autopsy (Kertesz *et al.*, 2000).

Clinical presentation and differentiation from AD

Frontotemporal lobar degeneration is caused by progressive dysfunction of the frontal and/or anterior temporal lobes. The most severely involved areas are different in each patient, and may be initially unilateral or bilateral, with different degrees of frontal and/or temporal involvement. For this reason initial symptoms may be heterogeneous. Careful neurological examination of patients with FTLD often reveals mild ocular motor abnormalities (such as breakdown of smooth pursuit or mild ocular apraxia), subtle reflex asymmetry, primitive reflexes (grasp or snout), or mild Parkinsonism (slow finger tapping, slight rigidity or decreased arm swing). At the bedside, tasks such as the Luria (fist-hand-palm) and the Frontal Assessment Battery (Dubois *et al.*, 2000) often reveal abnormalities in these patients.

Historically, many cases of pathologically verified FTLD were diagnosed with AD during life (Mendez *et al.*, 1993). Two recent studies of pathologically verified cases of FTLD have identified clinical and neuropsychological features which differentiate FTLD from AD. The presence of a social conduct disorder, hyperorality or akinesia, and the absence of amnesia or a perceptual disorder correctly classified 93% of patients with FTLD in one series of 30 autopsy-proven cases of FTLD cases and 30 cases of AD (Rosen *et al.*, 2002b). Patients with autopsy-proven FTLD performed worse on letter and category fluency tests, but better on the Mattis Dementia Rating Scale memory subscale, block design test and clock drawing test than patients with AD (Rascovsky *et al.*, 2002).

Clinical variants

Frontotemporal dementia (frontal lobe variant FTLD; fvFTD)

The insidious onset of behavioral abnormalities and personality changes are initially the most prominent features of fvFTD. Patients with evidence of right brain involvement on neuroimaging studies tend to have the most severe behavioral symptoms (Mychack *et al.*, 2001). Orbito-basal (ventromedial) frontal lobe dysfunction leads to

disinhibition, poor impulse control, antisocial behavior and stereotyped behaviors. Disinhibition or distractibility may manifest as restlessness, pressured speech, impulsivity, irritability, aggressiveness, violent outbursts, or excessive sentimentality (Rosen *et al.*, 2000). Hypersexuality and sexual disinhibition are commonly seen in fvFTD. Other socially inappropriate behaviors include theft, assault, inappropriate or offensive speech, public urination or masturbation (Miller *et al.*, 1995a). Criminal behavior is common in fvFTD. Stereotyped or perseverative behaviors may include impulse buying, hoarding or compulsions. Other stereotyped behaviors include counting, repetitive cleaning, pacing, organizing objects into groups or rows or the use of a “catch phrase.” Features of obsessive-compulsive disorder are very common in fvFTD, and some patients may initially be given this psychiatric diagnosis (Ames *et al.*, 1994). Compulsions were the presenting symptoms in 30–60% of patients in three clinical series of fvFTD patients (Perry & Miller, 2001). Delusions are common in fvFTD, and tend to be jealous, somatic, religious or bizarre, but are rarely persecutory. Euphoric symptoms, such as elevated mood, inappropriate jocularity and exaggerated self-esteem were found in 30% of fvFTD patients in one clinical series (Levy *et al.*, 1996).

Poor insight, loss of personal awareness, loss of social awareness and blunting of affect are common behavioral changes in fvFTD. Patients may deny the existence of deficits and often show a lack of concern about their illness (Rosen *et al.*, 2000). Increased submissiveness, a lack of empathy, self-centeredness, emotional coldness and decreased concern about family and friends is also common (Rankin *et al.*, 2003). Apathy is frequently seen in patients with fvFTD who have involvement of the anterior cingulate and medial frontal lobes. This may be mistaken for depression in some patients. Unlike in AD, depression is uncommon in fvFTD. Apathy and emotional withdrawal are often punctuated with outbursts of disinhibited behavior (Swartz *et al.*, 1997a). Patients with right frontal involvement may undergo dramatic changes in beliefs, attitudes and/or religious sentiment leading to the emergence of a new personality as the disease progresses (Miller *et al.*, 2001). With more advanced disease, many patients develop language dysfunction, with features of progressive nonfluent aphasia (see below) if disease involves left frontal/insular cortex, and/or akinetic mutism with progressive medial frontal/cingulate cortex involvement.

Dietary changes, especially cravings for sweets, are common in FTLD (Miller *et al.*, 1995b). Decreased satiety and food cravings often lead to a weight gain in many patients. As the disease progresses, features of the Klüver-Bucy

syndrome, such as hyperorality and oral exploratory behaviors may arise. Reduced sexual drive is a common finding in FTLT, and impotence may be an early feature of disease in men (Miller *et al.*, 1995b).

Semantic dementia (temporal lobe variant FTD; SD)

Semantic dementia is a syndrome of progressive loss of semantic knowledge, or knowledge about people, objects, facts and words (Snowden *et al.*, 1996b). The syndrome was first described in patients with progressive anomia who were recognized to have lost not only the ability to name objects, but also fundamental information about each item, leading to difficulties with category-specific comprehension and object recognition (Warrington, 1975). Many of the patients with the fluent subtype of primary progressive aphasia, described by Mesulam (Mesulam, 2001), would now be classified as having SD (Grossman, 2002).

Most patients diagnosed with SD have prominent involvement of left temporal lobe structures. The most common presenting complaint in SD involves language, and is often described as a loss of memory for words or a loss of word meaning. While SD patients are aware of their expressive deficits, they are often unaware of their comprehension difficulties (Hodges, 2001). Speech is fluent but there are frequent semantic paraphrasias, and use of substitute phrases such as “thing” or “stuff.” Repetition, prosody, syntax and verb generation are preserved. Associative agnosia may lead to difficulty with object recognition. This may manifest as misuse of or an inability to recognize household items such as a can-opener or pliers. An emergence of artistic talent has been observed in some patients with SD who have significant language impairment (Miller *et al.*, 1998b).

Patients with more significant right brain involvement may present with prosopagnosia (Evans *et al.*, 1995). Unlike the prosopagnosia caused by right occipito-temporal strokes, which is limited to the visual domain, the prosopagnosia of SD extends to other sensory modalities such as the association of names with voices (Hodges, 2001). Behavioral changes similar to those seen in fvFTD often arise as the disease progresses. Patients with right-sided disease tend to have more severe behavioral abnormalities than patients with left-sided disease (Edwards-Lee *et al.*, 1997).

In contrast to patients with AD, recent memory tends to be preserved early in the course of SD. Instead, there is more difficulty with distant memory, such as autobiographical events. Thus in SD there is a reversal of the temporal gradient of memory impairment that is observed in AD (Hodges and Graham, 2001).

Progressive non-fluent aphasia (PNFA)

Unlike other FTD syndromes, PNFA has been associated with either FTLT pathology or AD pathology in approximately 50% of cases (Weintraub *et al.*, 1990). PNFA may be the presenting complaint in patients with ALS (Rakowicz & Hodges, 1998; Caselli *et al.*, 1993). PNFA is also a frequent presenting symptom of CBD.

Patients typically present with complaints involving changes in fluency, pronunciation or word finding difficulty. Anomia in PNFA is more significant for verbs than for nouns, and has been associated with motor neuron disease pathology involving Brodman's areas 44 and 45 (Bak *et al.*, 2001). Unlike FTD and SD, PNFA patients do not display typical behavioral abnormalities until late in the course of the disease (Neary *et al.*, 1998). Insight and personal awareness are often normal. Depression and social withdrawal are common features of PNFA.

Time course of the disease

The mean age of onset for FTD has been estimated to be 52.8 to 56 years old (Miller *et al.*, 1998a). Mean duration of illness is approximately 8 years, with considerable variability depending on underlying pathology (Snowden *et al.*, 1996a). A study of presymptomatic family members of patients with FTDP-17, who carry the tau mutation, has demonstrated frontal-executive dysfunction on neuropsychological tests decades before the onset of FTLT symptoms (Geschwind *et al.*, 2001). This suggests that there may be a neurodevelopmental component in some cases of FTLT, and raises the question whether there is a premorbid phenotype.

Epidemiology

FTLT is a common cause of presenile dementia, or dementia that occurs in patients less than 65 years of age. FTLT is thought to account for up to 20% of all cases of dementia, irrespective of age (Grossman, 2001). The prevalence of FTLT in patients aged 45 to 64 from a population of approximately 300 000 individuals in Cambridgeshire, England has been estimated to be 15 (95% CI: 8.4 to 27) per 100 000 (Ratnavalli *et al.*, 2002). This was identical to the prevalence of early-onset AD in the same population. Overall, the proportion of AD cases to FTD cases was 1.6 : 1 in this study. A different study, using the older Lund–Manchester clinical criteria for FTD, found a similar prevalence of 9.3 (95% CI: 5.5 to 14.7) per 100 000 in a group of patients who were 65 or younger (Harvey, 1998). In most case series there is no gender predominance.

Fig. 34.2 MRI findings in FTLD. FTD: Parasagittal and coronal images from T₁-weighted MRI scan of a patient with frontotemporal dementia. Note asymmetric right frontal atrophy on coronal image, and lack of significant atrophy posterior to frontal lobe on sagittal image. SD: Axial and coronal images from a patient with semantic dementia. Note that atrophy is most severe anteriorly and involves both medial and lateral temporal lobe structures. PNFA: Axial and coronal images from a patient with progressive nonfluent aphasia. Note asymmetric left frontal atrophy with minimal temporal lobe involvement.

Investigations

Imaging

Frontotemporal dementia (fvFTD)

Functional neuroimaging of blood flow abnormalities using Tc₉₉-hexamethylpropyleneamine (HMPAO)-SPECT shows bilateral frontal hypoperfusion early in the course of fvFTD, and reliably differentiates patients with FTD from patients with AD (Miller *et al.*, 1991; Miller & Gearhart, 1999; Miller *et al.*, 1997). Fluorodeoxy glucose (FDG)-PET demonstrates frontal hypometabolism in

patients with FTD (Hoffman *et al.*, 2000). Unbiased analysis of T₁-weighted MRI scans from patients with fvFTD has identified regions of significant cortical atrophy in the ventromedial frontal cortex, the posterior orbital frontal regions bilaterally, the insula bilaterally, the left anterior cingulate cortex, the right dorsolateral frontal cortex and the left premotor cortex as compared with controls and patients with SD (Rosen *et al.*, 2002a) (see also Fig. 34.2).

Longitudinal measurements of MRI scans of patients with fvFTD show faster rates of frontal atrophy (4.1–4.5% per year), and similar rates of parieto-occipital atrophy (2.2–2.4% per year) as compared to patients with AD (2.4–2.8% per year, globally) (Chan *et al.*, 2001a). Parkinsonism in FTD has been associated with reduced uptake of the dopamine transporter ligand [¹¹C]CFT in the caudate and putamen on PET imaging (Rinne *et al.*, 2002).

Semantic dementia (SD)

SD patients often have severe, bilateral, but asymmetric atrophy of anterior temporal lobe (“knife edge atrophy”) as well as medial temporal lobe structures (Fig. 34.2). These findings may be preceded by hypoperfusion on HMPAO-SPECT (Edwards-Lee *et al.*, 1997; Garrard & Hodges, 2000). Anterior temporal lobe atrophy is easily appreciated on MRI scans, and visual inspection may be sufficient to accurately differentiate SD from AD patients (Galton *et al.*, 2001a). More detailed volumetric measurements of temporal lobe structures have demonstrated that hippocampal atrophy is often more severe in SD than in AD patients, but is usually more asymmetric, and accompanied by more severe atrophy of the amygdala, temporal pole, fusiform and inferolateral temporal gyri (Chan *et al.*, 2001b; Galton *et al.*, 2001b). Unbiased measurements of T₁-weighted MRI scans suggest that atrophy in SD is much more significant in temporal than extra-temporal brain regions (Rosen *et al.*, 2002a; Mummery *et al.*, 2000). FDG-PET studies during semantic memory tasks in SD patients show brain activation changes outside the areas of brain atrophy, suggesting that neuronal networks involving the temporal lobes are disrupted in SD (Mummery *et al.*, 1999).

Progressive non-fluent aphasia (PNFA)

Atrophy of the left frontal, insular, anterior parietal and superior temporal cortices is found in PNFA (Mesulam, 2001). Structural neuroimaging demonstrates left perisylvian atrophy in PNFA (Hodges & Patterson, 1996; Rosen *et al.*, 2002c) (Fig. 34.2).

Neuropsychology

Frontotemporal dementia (fvFTD)

Impairment on tests of executive function and working memory is the most common deficit in fvFTD. Memory and visuospatial function are relatively spared in fvFTD, and screening tests such as the Mini-Mental State Examination often remain normal even after patients require nursing home care (Gregory *et al.*, 1999). This is in striking contrast to AD, where there is early impairment of memory and visuospatial function (Perry & Hodges, 2000). Patients may have difficulty with set shifting, concept formation, abstraction and reasoning, inhibition of over-learned responses, response generation, organization, planning, self-monitoring and using feedback to guide behavior (Rosen *et al.*, 2000). Tasks such as the Wisconsin Card Sorting Test, Trailmaking Test, Stroop Category Test, verbal and design fluency, and proverb interpretation are sensitive to frontal executive dysfunction in patients with fvFTD (Hodges, 2001).

Semantic dementia (SD)

Due to their language difficulties, patients with SD may score poorly on bedside screening measures such as the Mini Mental State Exam. However, more detailed testing reveals a loss of semantic knowledge, with relatively preserved episodic memory for recent events (Graham *et al.*, 2000). Patients are most impaired on tests such as category fluency (i.e. the number of animals or musical instruments generated in one minute), picture naming (Boston Naming Test), and generation of verbal definitions of words and pictures. Hodges and colleagues have shown that errors on these tasks initially reflect a loss of subordinate knowledge, or detailed items within categories, followed by a loss of more superordinate knowledge (the categories, themselves). For example, a patient may initially misidentify an orange as an apple; however with time, both are identified only as fruit, and eventually, only as food (Hodges *et al.*, 1995). Non-verbal semantic knowledge may be assessed with tests such as the Pyramids and Palm Trees Test, in which the subject is asked to judge which of two pictures is related to a third picture. For example, a pyramid is shown, and the subject is asked whether a picture of a pine tree or a palm tree best goes with the pyramid (Bozeat *et al.*, 2000).

Language testing in SD reveals preserved phonology and syntax. However, surface dyslexia is commonly found in SD patients, and presents as difficulty in reading or spelling irregular words that sound different than they are spelled (“pint” read as hint or lint). SD patients also have diffi-

culty with generating past tenses from low frequency verbs, which has implications for the role of semantic knowledge in basic linguistic functions (Patterson *et al.*, 2001).

Progressive non-fluent aphasia (PNFA)

Episodic memory, semantic memory and visuospatial function are preserved in PNFA. Executive function and working memory are often impaired. Language difficulties include aggrammatism, phonemic paraphrasias and anomia. Aggrammatism is defined as the presence of grammatical errors in speech, such as the omission or incorrect usage of articles (“cow jumped over moon”), prepositions (“dog walk bridge”), or verbs (“cat eated mouse”). Phonemic paraphrasias are errors involving use of the incorrect phoneme (“head” instead of “bed”) or transposition of a phoneme (“efelant” for “elephant”) (Hodges, 2001). Other language problems may include stuttering, impaired repetition, apraxia of speech, alexia and agraphia.

Genetics

Approximately 29% to 38% of patients with FTLD have a positive family history of dementia, and it has been estimated that first-degree relatives of patients with FTD are at a 3.5 times higher risk of developing dementia than the general population (Stevens *et al.*, 1998). A more recent study suggests that 38% to 45% of patients with FTLD have a strong hereditary component, with an autosomal dominant inheritance pattern in 80% of cases (Chow *et al.*, 1999). Chromosome 17 tau gene mutations are thought to be present in 10% to 50% of FTLD patients with a positive family history of dementia (Morris *et al.*, 2001). To date, most cases of familial FTLD with tau pathology identified at autopsy have been found to have a tau mutation. In contrast, analysis of two series of sporadic FTLD patients suggests that only 5.9 to 13.6% of all FTLD patients will be found to have a tau mutation (Rosso & Van Swieten, 2002). At this time, routine clinical testing for tau mutations is not available.

In addition to tau mutations, mutations in other genes are likely to be involved in the development of FTLD. A different locus on chromosome 17q21–22 may lead to familial FTLD in one Dutch family (Rosso *et al.*, 2001). Familial FTLD associated with motor neuron disease has been linked to chromosome 9q21–22 (Hosler *et al.*, 2000). Hereditary FTLD associated with inclusion body myopathy and Paget’s disease has been linked to a different locus on chromosome 9 (9p13.3–p12) (Kovach *et al.*, 2001). A locus in the pericentromeric region of chromosome 3 has also been

identified in a Danish FTLD family (Rosso & Van Swieten, 2002).

Treatment

Currently there are no treatments that alter the progression of FTLD. Instead, medications and behavioral interventions are targeted to specific neuropsychiatric symptoms. Although theoretically, acetylcholinesterase inhibitors developed for use in AD, such as donepezil, might be expected to improve attention and working memory in FTLD, most patients experience no benefit from these agents. This finding may be related to the relative sparing of cholinergic neurons in the nucleus basalis of Meynert in FTLD as compared to AD. Additionally, clinical experience suggests that many patients will become more agitated when placed on acetylcholinesterase inhibitors. Finally, acetylcholinesterase inhibitors may cause increased production of oral secretions, which is undesirable in patients with dysphagia due to MND or PSP symptoms. For these reasons, acetylcholinesterase inhibitors are not indicated in most cases of FTLD. A minority of PNFA patients, who are believed to have underlying AD pathology, may benefit from treatment with an acetylcholinesterase inhibitor.

Practical and theoretical evidence suggests that deficits in serotonergic neurotransmission may be responsible for some of the behavioral abnormalities observed in FTLD (Perry & Miller, 2001). Compulsions and carbohydrate craving improved in a group of FTLD patients who were treated with a selective serotonin reuptake inhibitor (SSRI) and assessed for a change in behavior 3 months later (Swartz *et al.*, 1997b). SSRIs are well tolerated in patients with FTLD, and are currently the best available medications for behavioral control. Patients with aggressive or delusional behavior that does not respond to treatment with an SSRI may benefit from use of low doses of an atypical antipsychotic such as olanzepine, quetiapine or risperidone. Valproic acid and carbamazepine may also be useful in treating refractory agitation or aggressiveness in FTLD. Typical antipsychotics such as haloperidol should be avoided since FTLD patients are more likely to experience Parkinsonian side effects. The cognitive side effects of benzodiazepines outweigh their usefulness in FTLD. Although there are no studies of exercise in FTLD, clinical experience suggests that a regular cardiovascular exercise program may help to maintain motor function in these patients.

Behavioral symptoms, lack of empathy, poor insight and communication difficulties create a unique constellation of stressors for the caregivers of FTLD patients that is different from the stressors experienced by AD caregivers. Caregiver

distress is associated with earlier nursing home placement of dementia patients (Litvan, 2001), and thus an important role of the physician is to support the caregiver as well as the patient. Caregivers should be educated about FTLD and given anticipatory guidance as to what problems will likely arise with time. Efforts to increase detection of caregiver depression, and to treat psychiatric morbidity in caregivers with support groups, psychiatric referrals and respite care may delay patient institutionalization and improve the quality of life for both patients and caregivers (Talerico & Evans, 2001). Environmental, behavioral and psychosocial strategies have been developed to aid in management of FTLD both at home and if institutionalization becomes necessary (Talerico & Evans, 2001).

Frontotemporal dementia with parkinsonism linked to chromosome 17

Mark S. Forman, Virginia M.-Y. Lee, and John Q. Trojanowski

Center for Neurodegenerative Disease Research, Department of Pathology and Laboratory Medicine
University of Pennsylvania, PA, USA

Introduction

A variety of sporadic and familial neurodegenerative disorders, characterized clinically by dementia and/or motor dysfunction, demonstrate intracellular accumulations of filamentous material composed of the microtubule-associated protein (MAP) tau (See chapters 29, 'Neuropathology of Alzheimer's disease', 34, 'Pick's and other frontotemporal dementias', 44, 'Progressive supranuclear palsy', and 45, 'Corticobasal degeneration'). The term 'tauopathies' was coined to refer to this seemingly heterogeneous group of neurodegenerative disorders with filamentous tau deposits as their predominant histopathological feature. The progressive accumulation of filamentous tau inclusions in the absence of other disease-specific neuropathological abnormalities provided circumstantial evidence implicating tau dysfunction in disease onset and/or progression. However, the discovery of pathogenic *tau* mutations in a heterogeneous group of disorders termed frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17) provided unequivocal confirmation of the central role of tau abnormalities in the etiology of neurodegenerative disorders (Foster *et al.*, 1997; Poorkaj *et al.*, 1998; Hutton *et al.*, 1998; Spillantini *et al.*, 1998c). This seminal finding has opened novel areas of investigation into the pathophysiologic mechanisms of tau dysfunction and the relationship of tau abnormalities to brain degeneration.

Familial frontotemporal dementia

In 1892, Arnold Pick described a woman with lobar brain atrophy, who presented clinically with presenile dementia and aphasia (Pick, 1892). Thus, this was the first description of what is now classified clinically as frontotemporal

dementia (FTD) (McKhann *et al.*, 2001). The clinical syndromes of FTD are associated with several neuropathological abnormalities including disorders with tau pathology such as Pick's disease (PiD), corticobasal degeneration (CBD), progressive supranuclear palsy (PSP), neurofibrillary tangle dementia, argyrophilic grain disease, and FTDP-17, as well as several without tau aggregates including frontotemporal lobar degeneration (FTLD, also known as dementia lacking distinctive histopathology) and FTLD with motor neuron disease-type inclusions (FTLD-MND) (see chapter 34, Pick's and other frontotemporal dementias) (Lund and Manchester Groups, 1994; McKhann *et al.*, 2001). In addition, Alzheimer's disease (AD) and other neurodegenerative diseases such as dementia with Lewy bodies may manifest an FTD-like clinical picture. However, specific sets of pathological findings do not correlate with the particular clinical manifestations.

In 1939, Sanders provided the first description of familial FTD in a Dutch kindred with behavioral and language abnormalities including disinhibition, aggression, and an obsessive personality (Sanders *et al.*, 1939; Schenk, 1959). However, localization of a genetic abnormality in FTD was not identified until 1994 when Wilhelmsen *et al.* demonstrated linkage to chromosome 17q21–22 in a large family with an autosomal dominant disorder named 'disinhibition–dementia–parkinsonism–amyotrophy complex' (Wilhelmsen *et al.*, 1994). Subsequently, a number of related neurodegenerative disorders were linked to a similar locus on chromosome 17 and a consensus conference convened in Ann Arbor, Michigan, coined the term FTDP-17 (Wijker *et al.*, 1996; Foster *et al.*, 1997; Bird *et al.*, 1997; Heutink *et al.*, 1997; Murrell *et al.*, 1997; Baker *et al.*, 1997; Lendon *et al.*, 1998). Since the *tau* gene also mapped to chromosome 17q21–22, it was an obvious candidate gene for the disease locus. In 1998, several groups identified pathogenic mutations in the *tau* gene that

Table 35.1. Tau mutations identified in FTDP-17

E = exon; I = intron; R = MT binding repeat; IR = inter-repeat regions; ND = not determined; NA = not applicable.

Effects on tau fibril formation in vitro.

±Homozygous mutation.

*Increased indicates enhanced exon 10 utilization.

+Decreased indicates reduced exon 10 utilization.

#Variable indicates conflicting data in literature.

segregated with affected individuals and not in control subjects (Table 35.1, Fig. 35.1) (Poorkaj *et al.*, 1998; Hutton *et al.*, 1998; Spillantini *et al.*, 1998c).

However, it is evident that *tau* mutations are not present in all kindreds with familial FTD. While there is a positive family history of a similar dementing illness in ~38–50% of patients with FTD (Knopman *et al.*, 1990; Stevens *et al.*, 1998; Chow *et al.*, 1999), the incidence of *tau* mutations in different studies is quite variable (Houlden *et al.*, 1999; Rizzu *et al.*, 1999; Fabre *et al.*, 2001; Poorkaj *et al.*, 2001; Morris *et al.*, 2001). For instance, in two studies of community-based practices, mutations were not identified in *tau* despite a positive family history in ~38% of patients (Houlden *et al.*, 1999; Fabre *et al.*, 2001). In contrast, in

studies of referral populations with FTD, the proportion of kindreds with *tau* mutations ranged from 3.6% to 17.8%, and if there was a positive family history of a similar dementing illness, the incidence increased to as much as 50% (range 9.4% to 50%) (Houlden *et al.*, 1999; Rizzu *et al.*, 1999; Poorkaj *et al.*, 2001; Morris *et al.*, 2001). Moreover, if tau pathology was present at autopsy, the incidence of *tau* mutations increased further, from 33% to 100% (Poorkaj *et al.*, 2001; Morris *et al.*, 2001).

While mutations in additional genes that lead to FTD have not been identified, linkage analysis implicated several other genetic loci in specific kindreds. Chromosome 3 was linked to a large Dutch kindred with FTD and autosomal dominant inheritance (Brown, 1998; Ashworth *et al.*,

Fig. 35.1 Schematic representation of mutations in the tau gene identified in FTDP-17. The structure of the largest tau isoform is shown with known coding region mutations indicated above. The gray boxes near the amino terminus represent the alternatively spliced inserts encoded for by exons 2 and 3, while the black boxes represent each of the four MT binding repeats (not drawn to scale). The second MT binding repeat is encoded by exon 10. Part of the mRNA sequence encoding exon 10 and the intron following exon 10 are enlarged to visualize the 5' splice site as well as the mutations in both exon 10 and within the 5' splice site. Nucleotides that are part of intron 10 are shown in lower case. Nucleotides that are colored blue represent the approximate positions of the ESEs while those colored in red represent the ESS (see text).

1999). This pedigree shows anticipation suggestive of a trinucleotide repeat disorder. Hosler and colleagues demonstrated linkage to chromosome 9q21–q22 in a kindred with both ALS and FTD, but not ALS or FTD alone (Hosler *et al.*, 2000). A second genetic loci was identified on chromosome 9p13.3–p12 in 4 unrelated United States families (Kovach *et al.*, 2001). These kindreds also show autosomal dominant inheritance with a unique constellation of clinical findings including FTD, inclusion body myopathy, and Paget's disease of bone. Finally, two large kindreds with FTD showed linkage to chromosome 17q21–22, a locus which is similar to FTDP-17, but mutations in *tau* were not identified (Lendon *et al.*, 1998; Rosso *et al.*, 2001). These kindreds showed distinct pathology, one classified as FTLN-MND and the other as FTLN (Rosso *et al.*, 2001; Zhukareva *et al.*, 2001). Moreover, one of these kindreds that presented clinically with what has been termed 'hereditary dysphasic disinhibition dementia' showed reduced levels of tau protein, a biochemical feature of a FTLN (Zhukareva *et al.*, 2001). Currently, efforts are focused on identifying the genes implicated in these kindreds as well as identifying additional genetic factors involved in the pathogenesis of familial FTD. One candidate gene is the serine threonine protein kinase, myotonic dystrophy protein kinase (MDPK) (Kiuchi *et al.*, 1991; Sergeant *et al.*, 2001). In patients with myotonic

dystrophy type I, there is an unstable CTG repeat expansion in the 3'-untranslated region of this protein kinase. Furthermore, there are abundant neurofibrillary tangles (NFTs) in the brains of many affected individuals, thus suggesting a relationship between the expanded trinucleotide repeats of MDPK and tau pathology.

Frontotemporal dementia with parkinsonism linked to chromosome 17

The initial identification of mutations in *tau* led to a flurry of research activity that attempted to identify additional FTDP-17 mutations. At least 28 distinct pathogenic mutations have been identified in *tau* in a large number of families with FTDP-17 (Table 35.1, Fig. 35.1). Sixteen missense mutations in coding regions of *tau* are known, including missense mutations in exon 1 (R5H (Hayashi *et al.*, 2002) and R5L (Poorkaj *et al.*, 2002)), exon 9 (K257T (Pickering-Brown *et al.*, 2000; Rizzini *et al.*, 2000), I260V (Reed *et al.*, 2001), and G272V (Hutton *et al.*, 1998; Spillantini *et al.*, 1998b)), exon 10 (N279K (Clark *et al.*, 1998; Yasuda *et al.*, 1999; Delisle *et al.*, 1999; Arima *et al.*, 2000), N296H (Iseki *et al.*, 2001), P301L (Dumanchin *et al.*, 1998; Hutton *et al.*, 1998; Clark *et al.*, 1998; Mirra *et al.*, 1999; Houlden

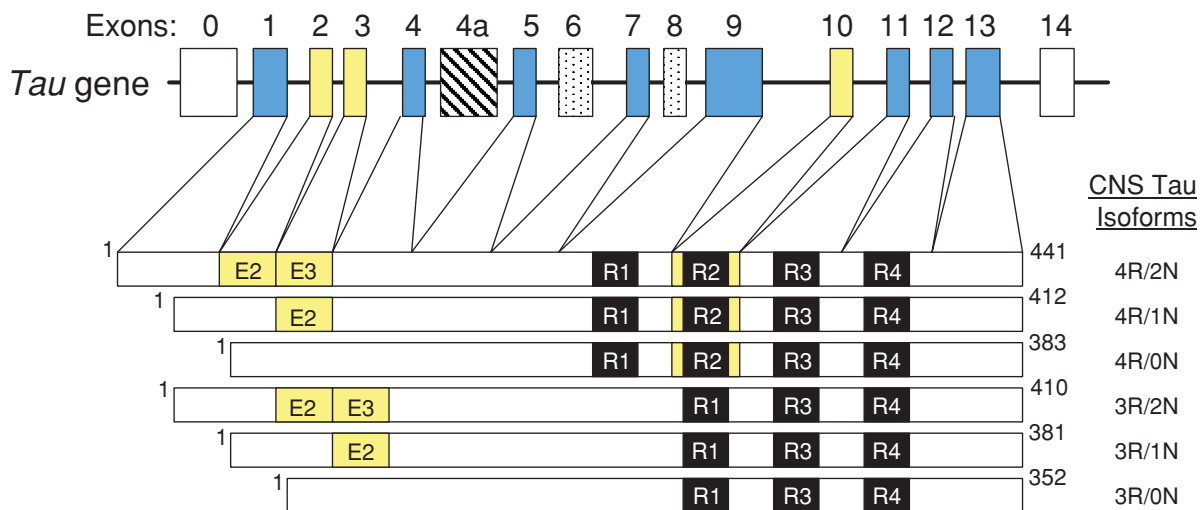

Fig. 35.2 Schematic representation of the human tau gene and six human CNS tau isoforms generated by alternative splicing. The human tau gene contains 16 exons, including exon 0 that is part of the promoter. Exons 1, 4, 5, 7, 9, and 11 to 13 (blue boxes) are constitutively expressed. Alternative splicing of exons 2 (E2), 3 (E3) and 10 (yellow boxes) produces the six tau isoforms observed in the CNS. Exons 6 and 8 (stippled boxes) are not transcribed in the human CNS. Exon 4a (striped box), which is also not transcribed in the human CNS, is expressed in the PNS leading to the larger tau isoforms, termed 'big tau'. The black bars depict the 18 amino acid MT binding repeats and are designated R1 to R4. The relative sizes of the exons and introns are not drawn to scale.

et al., 1999; Bird *et al.*, 1999; Kodama *et al.*, 2000; Tanaka *et al.*, 2000), P301S (Bugiani *et al.*, 1999; Sperfeld *et al.*, 1999; Yasuda *et al.*, 2000b), and S305N (Iijima *et al.*, 1999)), exon 11 (S320F (Rosso *et al.*, 2002)), exon 12 (V337M (Poorkaj *et al.*, 1998), E342V (Lippa *et al.*, 2000), and K369I (Neumann *et al.*, 2001)), and exon 13 (G389R (Murrell *et al.*, 1999; Pickering-Brown *et al.*, 2000) and R406W (Hutton *et al.*, 1998; Van Swieten *et al.*, 1999; Saito *et al.*, 2002)). Three silent mutations in exon 10 (L284L (D'Souza *et al.*, 1999), N296N (Spillantini *et al.*, 2000), and S305S (Stanford *et al.*, 2000)) as well as two single amino acid deletions (Δ K280 (Rizzu *et al.*, 1999) and Δ N296 (Pastor *et al.*, 2001)) have also been identified; however, the Δ N296 does not show autosomal dominant inheritance. In addition, seven different nucleotide substitutions were identified in the introns following exons 9 (+33 (Rizzu *et al.*, 1999)) and 10 (+3 (Spillantini *et al.*, 1998c; Tolnay *et al.*, 2000), +11 (Miyamoto *et al.*, 2001), +12 (Yasuda *et al.*, 2000a), +13 (Hutton *et al.*, 1998), +14 (Hutton *et al.*, 1998; Clark *et al.*, 1998), and +16 (Hutton *et al.*, 1998; Morris *et al.*, 1999; Hulette *et al.*, 1999; Goedert *et al.*, 1999b)) that presumably play a role in the regulation of the alternative splicing of exon 10, which will be discussed below.

Biology of the tau protein

Tau proteins are low-molecular-weight MAPs that are abundant in the central nervous system (CNS) where they

are expressed predominantly in axons (Cleveland *et al.*, 1977; Binder *et al.*, 1985), and at low levels in astrocytes and oligodendrocytes (Shin *et al.*, 1991; LoPresti *et al.*, 1995). They are also expressed in axons of peripheral nervous system neurons (Couchie *et al.*, 1992). Human tau proteins are encoded by a single copy gene on chromosome 17q21 composed of 16 exons with the CNS isoforms generated by the alternative mRNA splicing of 11 of these exons (Fig. 35.2) (Neve *et al.*, 1986; Goedert *et al.*, 1988; Andreadis *et al.*, 1992). In adult human brain, alternative splicing of exons 2, 3, and 10 generates 6 tau isoforms ranging from 352 to 441 amino acids in length which differ by the presence of either 3 (3Rtau) or 4 (4Rtau) carboxy-terminal tandem MT binding motifs of 31 or 32 amino acids each that are encoded by exons 9 to 12 (Goedert *et al.*, 1989a,b). Additionally, alternative splicing of exons 2 and 3 leads to the absence (0N) or presence of inserted sequences of 29 (1N) or 58 (2N) amino acids in the amino-terminal third of the molecule. In the adult human brain, the ratio of 3Rtau to 4Rtau isoforms is approximately 1:1, while the 0N, 1N, and 2N tau isoforms comprise about 37%, 54%, and 9%, respectively, of total tau (Goedert & Jakes, 1990; Hong *et al.*, 1998).

Since its discovery over 25 years ago, a number of functions of tau have been characterized (for review see Buée *et al.*, 2000; Lee *et al.*, 2001). Most notably, tau binds to and stabilizes microtubules (MTs) and promotes MT polymerization (Weingarten *et al.*, 1975; Cleveland *et al.*, 1977). The

MT binding domains of tau are localized to the carboxy-terminal half of the molecule within the 4 MT binding motifs (Figs. 35.1 and 35.2). These motifs are composed of highly conserved 18-amino acid binding elements separated by less conserved 13 or 14 amino acid flexible inter-repeat sequences (Himmler *et al.*, 1989; Lee *et al.*, 1989; Butner & Kirschner, 1991). The binding of tau to MTs is a complex process that is mediated by a flexible array of weak binding sites that are distributed throughout the MT binding domain delineated by these repeats and their inter-repeat sequences (Lee *et al.*, 1989; Butner & Kirschner, 1991).

The function of tau as a MT binding protein is regulated by phosphorylation (Drechsel *et al.*, 1992; Yoshida & Ihara, 1993; Bramblett *et al.*, 1993; Biernat *et al.*, 1993). There are 79 potential serine (Ser) and threonine (Thr) phosphate acceptor residues in the longest tau isoform, and phosphorylation at approximately 30 of these sites has been reported in normal tau proteins (for review see Billingsley & Kincaid, 1997; Buée *et al.*, 2000; Hong *et al.*, 2000). Furthermore, at least 12 Ser/Thr protein kinases and 4 Ser/Thr protein phosphatases have been implicated in regulating the phosphorylation state and thus the function of tau. The phosphorylation sites are clustered in regions flanking the MT binding repeats, and increasing tau phosphorylation at multiple sites negatively regulates MT binding (Drechsel *et al.*, 1992; Yoshida & Ihara, 1993; Bramblett *et al.*, 1993; Biernat *et al.*, 1993). However, in both sporadic and familial tauopathies including AD and FTDP-17, tau is hyperphosphorylated, and it is this 'abnormal' tau that is the principal component of the filamentous aggregates in neurons and glia that are the pathological hallmarks of these disorders (Hasegawa *et al.*, 1996; Hoffmann *et al.*, 1997; Zheng-Fischhofer *et al.*, 1998).

Clinical features of FTDP-17

The term FTDP-17 was coined in 1997 to describe the common features found in the affected members of kindreds that demonstrated linkage to chromosome 17 (Foster *et al.*, 1997). The individuals in these FTDP-17 kindreds all exhibited autosomal dominant inheritance with age-dependent penetrance typically in the third to sixth decade of life. Duration of disease is approximately 10 years but with wide variability ranging from as little as 3 years to as long as 30 years. The disease commonly presents insidiously with behavioral, language, and/or motor abnormalities. However, in one study, cognitive deficits particularly involving executive function were observed in presymptomatic subjects decades before the onset of dementia in FTDP-17 patients (Geschwind *et al.*, 2001). The behavioral

abnormalities are typical of FTD, including alterations in personality, impaired social or occupation functioning, hyperorality, hyperphagia, and psychosis associated with disturbed executive function on neuropsychologic examination (Lund & Manchester Groups, 1994; McKhann *et al.*, 2001). In most patients, visuospatial function, orientation, and memory are preserved until late in the course of disease, features that are distinct from that of AD. Language disorders are typical of either an expressive or semantic aphasia, while motor abnormalities consist principally of L-dopa-unresponsive parkinsonism including bradykinesia, rigidity, and postural instability.

With reports of additional kindreds, it became apparent that the clinical presentation is highly variable, reflecting the specific pattern of neuronal loss in affected individuals (Table 35.2) (for review see Foster *et al.*, 1997; Spillantini *et al.*, 1998a; Reed *et al.*, 2001). The clinical phenotype of patients with different mutations, as well as occasionally with the same mutation, is quite variable ranging from FTD to CBD to PSP to AD to a multisystem degeneration. However, some *tau* mutations cause a relatively similar phenotype. For instance, the N279K missense mutation typically causes a phenotype reminiscent of PSP with superimposed dementia (Reed *et al.*, 1998; Yasuda *et al.*, 1999; Delisle *et al.*, 1999). Similarly, the +16 mutation in the intron following exon 10 described in at least ten kindreds causes a very characteristic FTD with disinhibition and affective disturbances presenting in the fourth to sixth decade of life (Baker *et al.*, 1997; Morris *et al.*, 1999; Hulette *et al.*, 1999; Goedert *et al.*, 1999b; Janssen *et al.*, 2002). In contrast, there are numerous clinical and pathologic descriptions of families with P301L mutations that demonstrate a highly variable clinical phenotype including PSP, CBD, and PiD (Spillantini *et al.*, 1998b; Mirra *et al.*, 1999; Nasreddine *et al.*, 1999; Bird *et al.*, 1999). Similarly, while several kindreds with the R406W mutation present with relatively late-onset, slowly progressive memory deficits similar to AD, other kindreds present with early-onset, rapidly progressive FTD (Reed *et al.*, 1997; Van Swieten *et al.*, 1999; Saito *et al.*, 2002). Even more perplexing is a FTDP-17 family with the P301S mutation in which one individual presented clinically with FTD while his son presented clinically with CBD (Bugiani *et al.*, 1999). The Δ N296 mutation is unique in that it gives rise to atypical progressive supranuclear palsy in individuals homozygous for the mutation, but in heterozygous individuals this mutation is incompletely penetrant and associated with a phenotype similar to idiopathic Parkinson's disease (Pastor *et al.*, 2001). These reports, albeit anecdotal, suggest tremendous overlap between the various tau-related disorders, and the clinical distinctions between them may be due to other genetic

Table 35.2. Tau pathology in FTDP-17

Mutation	Regional distribution	Neurons	Glia	Biochemistry*	Ultrastructure
R5H	FT, MT, SN	Pretangles (+/-)	Oligodendrocytes Astrocytes (+/-)	4Rtau	Straight tubules, 15–20 nm

R406W	FT, MT	NFTs Pretangles	Oligodendrocytes (+/-)	3Rtau = 4Rtau	PHF-like Twisted ribbons Straight filaments

BG = basal ganglia; BS = brainstem; Ca = caudate; CB = cerebellum; FT = frontotemporal lobe; GP = globus pallidus; Hip = hippocampus; MT = medial temporal lobe (hippocampus, entorhinal cortex and amygdala); NFTs = neurofibrillary tangles; PHF = paired helical filaments; PR = peri-Rolandic cortex; SN = substantia nigra; STN = subthalamic nucleus; NA = not available; ND = not detected; Temp = temporal lobe; Th = thalamus; +/- = scattered tau positive inclusions. *Refers to the predominant tau isoforms detected in the analysis of insoluble (filamentous) tau extracts.

Fig. 35.3 Neuropathology of FTDP-17. **A-B.** FTDP-17 brain with intron 10, +16 mutation showing prominent frontal and temporal lobe atrophy with relative sparing of parietal and occipital lobes. Coronal sections (**B**) show marked hydrocephalus of the lateral ventricles and moderate atrophy of the head of the caudate nucleus (arrowhead). (**C**) Severe neuron loss with spongiosis of upper cortical lamina and prominent gliosis in frontal cortex of patient with P301L mutation (H&E). The surface of the brain is in the upper left corner while the subcortical white matter is in the lower right corner. Inset shows a ballooned neuron identified in the deep cortical layers. (**D**) Marked depletion of pigmented neurons in the substantia nigra of patient with N279K mutation. There is prominent gliosis with extravasation of neuromelanin and uptake into macrophages (arrowheads) (H&E). (**E**) Frontal cortex with numerous tau positive inclusions (pretangles) in patient with P301L mutation (IHC with anti-tau antibody). (**F**) Thread pathology in subcortical white matter of the frontal lobe in a patient with the P301L mutation (IHC with anti-tau antibody). (**G**) NFTs in the hippocampus of patient with R406W mutation (IHC with anti-tau antibody). (**H**) Granular astrocytic inclusion (left) and ballooned neuron (right) in the frontal cortex

and/or epigenetic factors that modify the effects of the *tau* mutations.

Neuropathology of FTDP-17

Similar to the clinical phenotypes, the neuropathology of FTDP-17 is quite variable (Table 35.2) (Reed *et al.*, 2001; Pickering-Brown *et al.*, 2002). The most characteristic gross neuropathologic feature is severe frontotemporal atrophy involving both cortex and the underlying white matter with relative sparing of the parietal and occipital lobes (Fig. 35.3) (Foster *et al.*, 1997). The pathology in the medial temporal lobe including the hippocampus, amygdala, and entorhinal cortex is highly variable ranging from minimal involvement to marked atrophy. The basal ganglia often exhibit severe degeneration, while involvement of the thalamus and subthalamus is typically not prominent. The substantia nigra is characteristically depigmented, while atrophy of the remainder of the brainstem and cerebellum is variable, typically mirroring the clinical phenotype of the patient (Fig. 35.3). Microscopically, there is marked neuron loss in effected brain regions similar to that observed for sporadic tauopathies (Fig. 35.3). In affected cortices, the neuron loss is associated with rarefaction and spongiosis of the superficial cortex with gliosis of both the gray and underlying white matter. Similarly, there is atrophy and neuron loss in the basal ganglia and substantia nigra (Fig. 35.3). Neuron loss in other brain regions is highly variable, paralleling both the clinical phenotype and pattern of gross atrophy. For instance, kindreds with the R406W mutation show profound neuron loss with severe gliosis in the medial temporal lobe including the amygdala, hippocampus, and entorhinal cortex with relative sparing of the basal ganglia and brainstem (Table 35.2) (Reed *et al.*, 1997; Van Swieten *et al.*, 1999; Rosso *et al.*, 2000; Saito *et al.*, 2002). In contrast, the N279K mutation causes neuron loss in subcortical and brainstem nuclei with variable pathology in the medial temporal lobe structures (Table 35.2) (Kawai *et al.*, 1993; Reed *et al.*, 1998; Delisle *et al.*, 1999; Arima *et al.*, 2000).

Despite the regional heterogeneity of the pathology of FTDP-17 kindreds, there is extensive neuronal or glial and neuronal fibrillary pathology composed of hyperphosphorylated tau protein in all cases, in the absence of β -amyloid ($A\beta$) deposits or other disease-specific brain

← **Fig. 35.3** (*cont.*) of a patient with intron 10, +16 mutation (IHC with anti-tau antibody). The astrocytic inclusion resembles the tufted astrocyte typical of PSP. (**I**) Coiled bodies and threads in the globus pallidus of patient with N279K mutation (IHC with anti-tau antibody).

lesions (Fig. 35.3) (for review see Spillantini *et al.*, 1998a; Reed *et al.*, 2001). These pathological inclusions are only variably identified with amyloid binding dyes such as Congo red and ThioflavinS as well as silver stains including Bodian, Bielschowsky and Gallyas. However, the inclusions are most consistently identified by immunohistochemistry (IHC) for tau protein, particularly with antibodies specific for phosphorylation-dependent epitopes that are characteristic of the insoluble inclusions.

The filamentous aggregates exhibit remarkable heterogeneity in both neurons and glia. The neuronal tau pathology frequently demonstrates a granular staining pattern, often referred to as 'pretangles' (Fig. 35.3) (Spillantini *et al.*, 1998a; Reed *et al.*, 2001). Classic NFTs, similar to that observed in AD, are abundant in several of the FTDP-17 mutations (Fig. 35.3) (Sumi *et al.*, 1992; Spillantini *et al.*, 1996; Foster *et al.*, 1997; Bird *et al.*, 1997; Reed *et al.*, 1997; Van Swieten *et al.*, 1999; Saito *et al.*, 2002). In addition, Pick bodies similar to those observed in PiD are a neuropathological feature associated with several mutations including K257V (Pickering-Brown *et al.*, 2000; Rizzini *et al.*, 2000), G272V (Spillantini *et al.*, 1998b), S320F (Rosso *et al.*, 2002), K369I (Neumann *et al.*, 2001), and G389R (Murrell *et al.*, 1999; Pickering-Brown *et al.*, 2000). Ballooned neurons and corticobasal bodies similar to those originally described in CBD are also detected with many of the mutations (Foster *et al.*, 1997; Spillantini *et al.*, 2000; Reed *et al.*, 2001). The tau pathology in astrocytes typically demonstrates a granular staining pattern (Fig. 35.3). However, occasional glial inclusions are observed that are reminiscent of the astrocytic plaques and tufted astrocytes described in CBD and PSP, respectively (Foster *et al.*, 1997; Spillantini *et al.*, 1998a; Komori, 1999; Reed *et al.*, 2001). With many *tau* mutations, there is abundant tau pathology in oligodendrocytes, similar to the coiled bodies observed in many sporadic tauopathies (Fig. 35.3) (Foster *et al.*, 1997; Spillantini *et al.*, 1998a; Komori, 1999; Reed *et al.*, 2001). Finally, tau-positive threads are abundant in either the gray matter or both the white and gray matter within the processes of both neurons and glia (Fig. 35.3) (Komori, 1999).

Ultrastructural analysis of the tau filaments in FTDP-17 also demonstrates marked heterogeneity in the tau pathology (Table 35.2). In two mutations, R406W and V337M, paired helical filaments (PHFs) with a diameter of 8 to 20 nm and a periodicity of 80 nm as well as straight filaments (SFs) nearly identical to those present in AD are observed (Sumi *et al.*, 1992; Spillantini *et al.*, 1996; Reed *et al.*, 1997). However, in the majority of mutations, the filaments demonstrate a range of morphologies including wide and narrow twisted ribbons, twisted filaments, paired tubules, and

SFs that range in width from 8 to 25 nm typically with longer periodicities than that observed in the PHFs of AD (Spillantini *et al.*, 1998a; Yen *et al.*, 1999b; Reed *et al.*, 2001).

Perhaps the most unique feature of the pathology of FTDP-17 is that the pattern and nature of the tau inclusions fail to fit neatly into any of the known categories of sporadic tauopathies. However, the FTDP-17 mutations can be loosely categorized based on the tau immunostaining and biochemical profile (Table 35.2 and Fig. 35.4). In one group, the tau aggregates are primarily within neurons. By IHC, the tau pathology is localized predominantly in gray matter, although biochemically there is aggregation of all 6 tau isoforms (or predominantly 3Rtau with the K257T mutation) within both gray and white matter (Table 35.2, Figs. 35.4 and 35.5). In contrast, the second group shows extensive tau pathology within both glia and neurons in gray and white matter that is composed of 4Rtau only (Table 35.2, Figs. 35.4 and 35.5).

Effects of FTDP-17 mutations

FTDP-17 mutations lead to tau dysfunction and presumably disease by several distinct mechanisms (Table 35.1). Intronic and some exonic mutations affect the alternative splicing of exon 10 and consequently alter the relative proportions of 3Rtau and 4Rtau. The other exonic mutations impair the ability of tau to bind MTs and to promote MT assembly. Some of the mutations also promote the assembly of tau into filaments. Moreover, additional mechanisms may play a role in the case of some coding region mutations (reviewed in Lee *et al.*, 2001). The intronic mutations clustered around the 5' splice site of exon 10, as well as several mutations within or near exon 10 (N279K, L284L, N296N, N296H, S305N, S305S, and G342V), increase the ratio of 4Rtau to 3Rtau by altering the splicing of this exon (Hutton *et al.*, 1998; Yasuda *et al.*, 1999; Delisle *et al.*, 1999; Varani *et al.*, 1999; Grover *et al.*, 1999; D'Souza *et al.*, 1999; Hasegawa *et al.*, 1999; Stanford *et al.*, 2000; D'Souza & Schellenberg, 2000; Gao *et al.*, 2000; Spillantini *et al.*, 2000; Yasuda *et al.*, 2000a; Miyamoto *et al.*, 2001; Grover *et al.*, 2002). As a result of these mutations there is a relative increase in mRNA containing exon 10, reflecting increased utilization of the 5' splice site of exon 10 as demonstrated in exon trapping experiments. Biochemical analysis of insoluble tau extracted from autopsied FTDP-17 brain tissue of patients with these mutations reveals predominantly 4Rtau isoforms (Figs. 35.4 and 35.5) (Clark *et al.*, 1998; Reed *et al.*, 1998; Hong *et al.*, 1998; Spillantini *et al.*, 1998c; Hulette *et al.*, 1999; Goedert *et al.*, 1999b; Arima *et al.*, 2000; Yasuda *et al.*, 2000a; Iseki *et al.*, 2001). Furthermore, 4Rtau

Fig. 35.4 Schematic representation of Western blot banding patterns of soluble and insoluble tau from different tauopathies. The cartoon depicts the typical banding pattern of soluble tau (top panels) and insoluble/filamentous tau (bottom panels) from the brains of patients with FTDP-17 as well as sporadic tauopathies following resolution with SDS-PAGE and immunoblotting with anti-tau antibodies. The FTDP-17 mutations show several different Western blot banding patterns of soluble and insoluble tau protein that are depicted as groups A to D. The soluble fraction from the brains of unaffected (normal) individuals, sporadic tauopathies, and FTDP-17 with mutations that do not effect tau splicing (Groups A, B, and C) show expression of all 6 tau isoforms. Non-phosphorylated insoluble tau from the brains of patients with group A variants of FTDP-17 (S320F, V337M, K369I, G389R, and R406W) resolve as 3 major proteins of 68-, 64- and 60-kDa; and a minor band of 72 kDa similar to that observed in AD. When dephosphorylated, they resolve into 6 proteins that correspond to all 6 tau isoforms similar to the soluble fraction. In group B variants of FTDP-17 (R5H, P301L, and G342V) 2 prominent 68- and 64-kDa protein bands are detected (the 72 kDa minor band is variably detected) that align with 4Rtau following dephosphorylation similar to that observed in PSP and CBD indicating the selective aggregation of 4Rtau. In the group C variant of FTDP-17 (K257T) and PiD the 64 and 60 kDa insoluble tau protein isoforms predominate and align with 3Rtau isoforms following dephosphorylation indicating selective aggregation of 3Rtau. In contrast, in group D variants of FTDP-17 mutations that effect mRNA splicing (N279K, L284L, N296N, N296H, S305S, S305N, and intron 10 mutations), there is expression of predominantly 4Rtau throughout the entire brain which is reflected in the insoluble tau aggregates. Note that normal brains do not contain insoluble species of tau.

protein levels are increased in both affected and unaffected regions of FTDP-17 brains (Hong *et al.*, 1998; Spillantini *et al.*, 1998c; Goedert *et al.*, 1999b; Yasuda *et al.*, 2000a).

The regulation of splicing of exon 10 of *tau* is complex, and may involve multiple *cis*-acting regulatory elements that either enhance or inhibit the utilization of the 5' splice site, many of which are affected by mutations identified in *tau* (Varani *et al.*, 1999; D'Souza *et al.*, 1999; Hasegawa *et al.*, 1999; D'Souza & Schellenberg, 2000; Jiang *et al.*, 2000; Gao *et al.*, 2000; Grover *et al.*, 2002). Splicing regulatory elements within exon 10 include an exon-splicing enhancer (ESE) and an exon-splicing silencer (ESS) (Fig. 35.1) (D'Souza *et al.*, 1999; D'Souza & Schellenberg, 2000; Gao *et al.*, 2000). The ESE consists of three domains, a potential SC35 binding

element, a purine rich sequence, and an AC-rich sequence (D'Souza & Schellenberg, 2000). Immediately downstream of the ESE within exon 10 is the purine-rich ESS followed by a second ESE. The flanking exons of *tau* also affect exon 10 splicing (Gao *et al.*, 2000). Exons 9 and 11 exert opposite effects; exon 9 promotes splicing of exon 10, while exon 11 suppresses it. Lastly, intronic sequences immediately downstream of exon 10 inhibit its splicing (Varani *et al.*, 1999; D'Souza *et al.*, 1999; Hasegawa *et al.*, 1999; D'Souza & Schellenberg, 2000; Jiang *et al.*, 2000; Gao *et al.*, 2000; Grover *et al.*, 2002). The inhibition may be secondary to the formation of a stem-loop structure that sequesters the 5' splice site from the splicing machinery including the U1- and U6-snRNP (Fig. 35.1) (Varani *et al.*, 1999; Grover *et al.*, 1999;

A. Soluble Tau

B. Insoluble Tau, R406W

C. Insoluble Tau, Intron +16

Fig. 35.5 Western blots of soluble and insoluble tau from FTDP-17 brains. Soluble (A) and insoluble (B,C) tau fractions extracted from gray (G) and white (W) matter of patients with FTDP-17 were dephosphorylated with *E. coli* alkaline phosphatase, resolved by SDS-PAGE and immunoblotted with phosphorylation-independent tau antibodies. (A) Soluble fractions from the frontal cortex of patients with the R406W show all 6 tau isoforms. In contrast, in patients with the intron 10, +16 mutation, there is selective overexpression of 4Rtau isoforms. (B,C) The insoluble tau protein from the indicated cortices are composed of either equimolar amounts of both 4Rtau and 3Rtau (R406W) or predominantly 4Rtau only (intron 10, +16). With both mutations the tau pathology is most abundant in the frontal and temporal lobes with relative sparing of the occipital lobe. In addition, there is abundant insoluble tau in the white matter of the brain with the R406W mutation that is not detected by IHC. Recombinant tau isoforms (rTau) are as indicated. Fr = frontal lobe; Te = temporal lobe; Pa = parietal lobe; Oc = occipital lobe.

Jiang *et al.*, 2000). The relative proportions of 3Rtau and 4Rtau from other species correlates with the predicted stability of this stem-loop structure (Grover *et al.*, 1999). However, another study concluded that the inhibitory effect of the intronic sequence is due to a linear sequence array that is independent of the stem-loop structure (D'Souza & Schellenberg, 2000).

FTDP-17 mutations in *tau* may alter exon 10 splicing by affecting several of the regulatory elements described above. For example, the intronic mutations as well as the exonic mutations at codon 305 (S305N and S305S) may destabilize the inhibitory stem-loop structure (Fig. 35.1) (Hutton *et al.*, 1998; Grover *et al.*, 1999; D'Souza *et al.*, 1999). The S305N and the +3 intronic mutations may also enhance exon 10 splicing by increasing the strength of the 5' splice site (GUGugagu to AUGugagu) (Senapathy *et al.*, 1990). However, the finding that the S305S mutation weakens the 5' splice site (GUGugagu to GCgugagu) and also leads to predominantly 4Rtau argues against this effect of the mutation (Stanford *et al.*, 2000). The N279K mutation may improve the function of the ESE by lengthening the purine-rich sequence within this regulatory element (UAAGAA to GAAGAA), and thus enhance exon 10 splicing (D'Souza & Schellenberg, 2000). Moreover, the thymidine nucleotide present in the wild-type (WT) sequence may function as an inhibitor of splicing (Tanaka *et al.*, 1994). This hypothesis is supported by the observation that the Δ K280 mutation, which deletes the three adjacent purine residues (AAG), reduces exon 10 splicing. The silent L284L mutation that enhances exon 10 splicing may do so by disrupting a potential exon splicing inhibitor (UUAG to UCAG) (Si *et al.*, 1998; D'Souza *et al.*, 1999). However, since mutation of this consensus sequence does not increase exon 10 splicing, a second possibility is that the mutation lengthens the AC-rich element within the ESE (Si *et al.*, 1998; D'Souza & Schellenberg, 2000). Thus, the L284L mutation may affect either an enhancing or inhibitory splicing element. Lastly, the effect of the N296N and N296H mutations on splicing of exon 10 is due to disruption of the ESS or conversely the creation of a novel splice enhancer sequence (D'Souza & Schellenberg, 2000; Grover *et al.*, 2002).

The mechanisms by which these changes in the ratio of 3Rtau to 4Rtau (3R/4Rtau) lead to neuronal and glial dysfunction and cell death remain unclear. However, 3Rtau and 4Rtau may bind to distinct sites on MTs (Goode & Feinstein, 1994), and it is possible that a specific ratio of tau isoforms is necessary for normal MT function (Goode *et al.*, 1997). Thus, the altered ratio of 3R/4Rtau may directly affect MT function. In addition, overproduction of 4Rtau isoforms may lead to an excess of free tau in the cytoplasm that is prone to aggregate and polymerize into filaments over time.

Another subset of the *tau* mutations has no effect on *tau* splicing but instead alters the ability of tau to interact with MTs. Specifically, missense mutations K257T, G272V, Δ K280, Δ N296, P301L, P301S, V337M, G389R, and R406W reduce the binding of tau to MTs and decrease its ability to promote MT stability and assembly in vitro (Hong

et al., 1998; Hasegawa *et al.*, 1998; Bugiani *et al.*, 1999; Rizzu *et al.*, 1999; Pickering-Brown *et al.*, 2000; Rizzini *et al.*, 2000; Barghorn *et al.*, 2000; Grover *et al.*, 2002). In contrast to other mutations that affect the splicing of *tau*, these mutations do not alter the expression pattern of 3Rtau and 4Rtau (Hong *et al.*, 1998). However, the P301L mutation causes a moderate (25%) decrease in soluble 4Rtau due to the selective aggregation of mutant 4Rtau isoforms (Hong *et al.*, 1998; Rizzu *et al.*, 2000; Miyasaka *et al.*, 2001). Biochemical analysis of insoluble tau extracted from brain tissue of patients with these mutations reveals a variety of patterns. Several mutations including S320F, V337M, K369I, G389R, and R406W are characterized by the aggregation of equal amounts of both 3Rtau and 4Rtau (Figs. 35.4 and 35.5) (Spillantini *et al.*, 1996; Hong *et al.*, 1998; Murrell *et al.*, 1999; Neumann *et al.*, 2001; Rosso *et al.*, 2002). A second group (R5H, R5L, P301L, and G342V) leads to the selective aggregation of 4Rtau isoforms similar to that observed in PSP and CBD (Fig. 35.4) (Clark *et al.*, 1998; Spillantini *et al.*, 1998b; Bugiani *et al.*, 1999; Mirra *et al.*, 1999; Nasreddine *et al.*, 1999; Lippa *et al.*, 2000; Hayashi *et al.*, 2002). In contrast, the K257T mutation causes the selective aggregation of 3Rtau similar to PiD (Fig. 35.4) (Rizzini *et al.*, 2000). This is intriguing because the neuropathology of both kindreds identified with the K257T mutation is characterized by the widespread deposition of Pick bodies comparable to those observed in PiD (Pickering-Brown *et al.*, 2000; Rizzini *et al.*, 2000).

The effects of these FTDP-17 mutations on MT binding, assembly, and stability are not observed with the tau missense mutations that directly affect exon 10 splicing (Hong *et al.*, 1998; D'Souza *et al.*, 1999; Hasegawa *et al.*, 1999). The effects of these FTDP-17 mutations on MT function are observed when mutant *tau* is expressed in a variety of cell lines including SHSY5Y neuroblastoma cells (Dayanandan *et al.*, 1999), Chinese hamster ovary (CHO) cells (Matsumura *et al.*, 1999; Dayanandan *et al.*, 1999; Vogelsberg-Ragaglia *et al.*, 2000), monkey kidney (COS) cells (Arawaka *et al.*, 1999; Sahara *et al.*, 2000), human embryonic kidney (HEK293) cells (Sahara *et al.*, 2000; Nagiec *et al.*, 2001), and SF9 insect cells (Frappier *et al.*, 1999). Expression of a variety of *tau* missense mutations including G272V, P301L, V337M, and R406W in these cells caused reduced MT binding, MT instability, disorganized MT morphology, and defects in MT assembly to varying degrees. However, in two studies, many mutations had either no or only a modest effect on MT binding and/or function both in *in vitro* assays and in transfected cell lines (DeTure *et al.*, 2000; Sahara *et al.*, 2000). The discrepancies between these and other studies are most likely due to either differences in the levels of tau expression, the specific cells in which the FTDP-17

mutations were expressed, and/or the binding of tau to MTs. Nevertheless, even if the FTDP-17 mutations cause only a modest reduction in MT binding affinity, this effect could lead to large cumulative effects on neurons over the human life span. Furthermore, increased cytosolic concentrations of unbound mutant tau may facilitate aggregation of these abnormal proteins into filamentous inclusions. In support of this hypothesis, Yen and colleagues demonstrated that several mutations lead to decreased susceptibility to calpain I digestion, an enzyme involved in the normal degradation of tau, which might lead to an increase in the concentration of cytosolic tau (Yen *et al.*, 1999a). The loss of function of tau could also cause a variety of toxic effects within affected cells. For example, the reduced capacity of these mutants to stabilize MTs might affect axonal transport in neurons. Alternatively, impairments in tau functions could lead to increased apoptotic vulnerability as suggested in a recent study in which 2 of the FTDP-17 mutations (N279K and V337M) showed increased cell death upon serum withdrawal in transfected neuroblastoma cell lines (Furukawa *et al.*, 2000).

A subset of missense *tau* mutations may cause FTDP-17, at least in part, by promoting tau aggregation (Table 35.1). Several studies demonstrated that numerous mutations, including K257T, G272V, Δ K280, Δ N296, P301L, P301S, V337M, and R406W, promote heparin- or arachidonic acid-induced tau filament formation *in vitro* relative to WT tau (Arrasate *et al.*, 1999; Nacharaju *et al.*, 1999; Goedert *et al.*, 1999a; Rizzini *et al.*, 2000; Barghorn *et al.*, 2000; Gamblin *et al.*, 2000; Grover *et al.*, 2002). The Δ K280 and P301L promote *in vitro* filament formation more readily than other missense mutations and WT tau (von Bergen *et al.*, 2001). This effect is most likely due to the enhancement of β -structure around 2 hexapeptide motifs that are strong promoters of tau fibrillization (von Bergen *et al.*, 2000). Additionally, the P301L mutation causes the selective deposition of mutant tau in the pathologic intracellular inclusions with corresponding depletion in the soluble fraction (Rizzu *et al.*, 2000; Miyasaka *et al.*, 2001). The aggregation of mutant tau in intact cells has also been demonstrated. Thus, CHO cells expressing tau with the Δ K280 mutation, but not other mutations (V337M, P301L and R406W), formed insoluble aggregates (Vogelsberg-Ragaglia *et al.*, 2000).

It is unclear whether the filaments composed of mutant tau proteins are similar to those composed of WT tau. Goedert *et al.* reported that, while a subset of the *tau* mutations stimulated filament formation, they were structurally identical to WT tau filaments as assessed by circular dichroism (Goedert *et al.*, 1999a). However, Jicha *et al.* reported altered physical and structural properties of filaments

composed of mutant tau as assessed by both circular dichroism and reverse phase high performance liquid chromatography (Jicha *et al.*, 1999).

The missense *tau* mutations may also effect tau function, and thus contribute to the pathogenesis of FTDP-17, by altering the phosphorylation of tau. Numerous mutations decreased the binding affinity of tau for protein phosphatase 2A, a major phosphatase implicated in the regulation of the MT-binding activity of tau (Goedert *et al.*, 2000). Goedert and colleagues suggest that this leads to both tau hyperphosphorylation and dissociation of tau from MTs therefore altering the normal balance between free and MT-bound tau. However, expression of several mutations, particularly R406W, both in vitro and in transfected cell lines led to reduced levels of tau phosphorylation relative to WT tau, suggesting that increased tau phosphorylation is not required for pathogenesis of disease (Matsumura *et al.*, 1999; Dayanandan *et al.*, 1999; Sahara *et al.*, 2000; Perez *et al.*, 2000; Vogelsberg-Ragaglia *et al.*, 2000; Connell *et al.*, 2001).

The biochemical and structural characteristics of the tau aggregates in FTDP-17 are somewhat predictable based on our understanding of the functions of tau proteins and *tau* splicing. However, the basis for the clinical phenotypes and topographical distributions of pathology of individuals with the various FTDP-17 mutations remains enigmatic. This finding suggests that the phenotypic differences may be due to other genetic and/or epigenetic factors that modify the effects of the primary mutation. The specific modifiers that mediate the 'selective vulnerability' of specific regions and/or cells associated with either a specific mutation or even of a specific individual remain unknown, but these are fields of active investigation and the generation of animal models of tau-mediated neurodegeneration may facilitate this research.

Animal models of FTDP-17

Experimental and transgenic (TG) models of tauopathies will serve as informative systems for elucidating the role of abnormalities in tau in the onset and progression of disease as well as providing useful models for the development of novel therapies. Several models of tau pathology were produced by overexpressing human tau proteins in mice (for review see Götz, 2001). However, these mice were either asymptomatic or developed pathology that was localized to the spinal cord and/or lacked many of the key features of tau-based disorders. In contrast, the introduction of the P301L mutation led to the development of TG mice that develop age- and gene dose-dependent accumulation of tau tangles in the brain and spinal cord with

associated nerve cell loss and gliosis as well as behavioral abnormalities (Lewis *et al.*, 2000; Götz *et al.*, 2001a). Similar to human disease, the tau aggregates were composed of only mutant human tau further implicating the P301L change in promoting the selective aggregation of mutant tau. Gene expression profiling of brain tissue from these mice showed altered expression of genes contributing to the inhibition of apoptosis, inflammation, and intracellular transport (Ho *et al.*, 2001). The co-expression or injection of A β in mice expressing P301L mutant tau led to enhanced neurofibrillary degeneration with preferential involvement of the limbic system similar to that observed in AD (Lewis *et al.*, 2001; Götz *et al.*, 2001b). This observation suggests that there may be a mechanistic interaction between the A β and tau pathologies that influence their distribution and abundance. Subsequently, TG mice were developed with different FTDP-17 mutations that also lead to neurodegeneration in either neurons (V337M) (Tanemura *et al.*, 2001; Tanemura *et al.*, 2002) or oligodendrocytes (G272V) (Götz *et al.*, 2001c).

Other systems were also developed to model various aspects of human tauopathies. Overexpression of tau in lamprey reticulospinal neurons led to the formation of PHF-like tau inclusions with degeneration of a subset of neurons (Hall *et al.*, 1997, 2000). In addition, overexpression of either WT or FTDP-17 mutant tau (R406W and V337M) in *Drosophila melanogaster* demonstrated key features of tauopathies including adult-onset progressive neurodegeneration with accumulation of abnormal tau (Wittmann *et al.*, 2001). However, the neurodegeneration occurred in the absence of NFT formation. More recent studies demonstrated NFT-like pathology when tau was co-expressed with *shaggy* that is homologous to glycogen synthase 3-kinase implicated in tau phosphorylation (Jackson *et al.*, 2002). Nonetheless, all of these models show various features of tau-related disorders that will hopefully facilitate an understanding of the molecular mechanisms underlying tau neurotoxicity.

Conclusions

The accumulation of filamentous tau inclusions is a common feature of a wide variety of sporadic and familial neurodegenerative disorders that present clinically with FTD. These tauopathies are distinguished by the distinct topographic and cell type-specific distribution of inclusions. The biochemical and ultrastructural characteristics of the tau pathology also reveal a significant phenotypic overlap. The discovery of multiple mutations in *tau* that lead to the abnormal aggregation of tau and cause FTDP-17

demonstrates that tau dysfunction is sufficient to produce neurodegenerative disease. The mutations lead to specific alterations in the expression, function, and biochemistry of the tau protein. Furthermore, in light of the similarities between FTDP-17 and other tauopathies, it is likely that elucidation of this perplexing enigma will provide important clues into mechanisms underlying the interaction between genetic and environmental factors in neurodegenerative disease. The identification of additional gene mutations or polymorphisms at distinct genetic loci in families with FTD that either cause or are risk factors for disease will provide additional insights into disease pathogenesis as well as in the development of novel strategies for treatment and prevention.

PRION DISEASES

I The clinical approach to human prion diseases

Hayrettin Tumani and Albert C. Ludolph

Department of Neurology, University of Ulm, Germany

Introduction

Prion diseases represent a disease complex that is clinically rare. However, they are epidemiologically important severe diseases, and very likely to be important for our basic understanding of neurodegeneration in principle. This is reflected in this introductory clinical overview, which presents the clinical diagnostic and differential diagnostic approach to the patient; then a review follows which focuses on the current status of the field of basic sciences of prion diseases.

The history of prion diseases started in the year 1920 when Hans Gerhard Creutzfeldt described a mysterious focal disease of the central nervous system of a 22-year-old female patient, which clinically was characterized by progressive psychomotor disturbances and cortical symptoms (Creutzfeldt, 1920). In his autopsy he observed a pronounced gliosis which accompanied non-inflammatory focal lesions of the cortex. One year later, Alfons Jakob saw three similar cases which he also considered a new entity – he described a spastic pseudosclerosis and encephalomyelitis with disseminated focal degeneration (Jakob, 1921). Based on the similarity of the reported cases, Walter Spielmeier suggested the name Creutzfeldt–Jakob disease (CJD). In 1936, the Gerstmann–Sträussler–Schenker (GSS) syndrome was first described and in 1957 fatal familial insomnia (FFI) (Gerstmann & Sträussler 1936; Lugaresi *et al.*, 1986). In the 1960s, interest in the epidemiology of prion diseases increased when Gajdusek and Gibbs showed that Kuru – a disease first observed by the German Walter Zigas and Carleton Gajdusek among the Fore in Papua New Guinea and thought to be associated with cannibalism – could be transmitted to non-human primates and had similarities with the spongiform encephalopathy of sheep-scrapie (Zigas & Gajdusek, 1957; Hadlow,

1959; Gajdusek & Gibbs, 1966). However, studies in the United Kingdom showed no evidence that sporadic CJD is in any way related to scrapie (Harries-Jones *et al.*, 1988).

Nevertheless, knowledge of the transmissibility of spongiform encephalopathies stimulated research into iatrogenic CJD, which comprises more than 180 cases following medical manipulations ranging from surgical procedures such as epilepsy surgery and cornea transplants to the administration of human growth factor. The prion diseases once again came into the center of public interest when in the late 1990s evidence accumulated that the bovine spongiform encephalopathy (BSE) in the United Kingdom was causally related to a new variant of CJD (vCJD) which predominantly affected young adults (Will *et al.*, 2000). In the year 2004, it seems that the threat of a large vCJD epidemic – which was predicted by many – is getting smaller (Andrews *et al.*, 2003; Collins *et al.*, 2004).

Epidemiology

The epidemiological assessment of cases of CJD is most reliable in countries that have set up a surveillance unit. Subsequent prospective studies conducted by surveillance units allowed a reliable assessment of incidence, prevalence, mortality, clinical symptoms and ultimately risk factors. Since CJD patients die within a few months, the annual statistics for incidence, prevalence and mortality are very similar. In general, the worldwide incidence is estimated as 1/million/year; however, experience shows that, in countries with a high autopsy rate or with a surveillance unit, incidence rates may reach 1.3 or 1.4 patients/1 million inhabitants/year. Based on prospective epidemiological

Table 36.1. Types of Creutzfeldt–Jakob Disease (CJD)

CJD type	Prevalence	Age (years)	Disease duration (months)
Sporadic (sCJD)	90%	60	4–5
Genetic (gCJD)	10%	50	21
Iatrogenic (iCJD)	<i>n</i> = 180	4–60	10
Variant (vCJD)	<i>n</i> = 153*	30	14

* reported by December 2003 worldwide.

studies, there has been a clear increase of annual incidence rates of CJD from less than 0.4 before 1990 to more than 1.0 after 1995 in many European countries (Poser *et al.*, 1999; Mollenhauer *et al.*, 2002). The increased incidence is primarily a consequence of improved diagnostic criteria as well as of increased awareness of CJD since the onset of BSE.

Overall, the incidence is not sex specific. Both males and females are affected equally, with a slight female excess reported in some studies. CJD is predominantly a disease of late middle age with highest mortality rates in the age groups between 60 and 70 years. Cases below 50 and above 80 years are very rare.

Four CJD phenotypes are known (Table 36.1):

- **Sporadic CJD** is the most common (85–90%) human prion disease with unknown cause.
- **Genetic CJD** is the second most common type (15–10%) comprising familial CJD, Gerstmann Sträussler–Schenker syndrome (GSS), fatal familial insomnia (FFI) which is always related to an underlying prion protein gene (*PRNP*) mutation. Meanwhile, more than 20 *PRNP* mutations are known with an autosomal dominant pattern of inheritance.
- **Iatrogenic CJD** cases are much more rare and are induced by accidental transmission of CJD during surgical or medical treatment (human dura mater implants, corneal grafting, contaminated neurosurgical instruments, human cadaveric growth hormone and human pituitary gonadotropine). The – few – iatrogenic cases cannot be clinically distinguished from the genetic and sporadic forms.
- **Variant CJD** (“human BSE”) is a relatively new disease known since 1996 and showing a striking geographical distribution. From 153 registered cases worldwide, only 14 patients were outside UK (France, Ireland, Italy, Canada, USA) (<http://www.doh.gov.uk/cjd/stats/feb04>).

Transmissibility and neuropathology

All human prion diseases are progressive and fatal neurodegenerative disorders with transmissibility to a range of laboratory animal hosts and with broadly similar neuropathological features consisting of neuronal degeneration, reactive astrogliosis and extensive vacuoles subsuming in spongiform changes (Kretzschmar *et al.*, 1996). The most specific immunohistochemical feature is the PrP^{Sc} deposition. Intracerebral inoculation of minor concentration of PrP^{Sc} containing tissue material will induce a spongiform encephalopathy in various animal hosts. A horizontal transmissibility has been postulated only in cases of Kuru.

Transmissibility has been successfully achieved after inoculation of the following tissues from CJD patients: brain, eye, spinal cord, lung, CSF and lymphoreticular organs. Other organs proved to be non-infectious: peripheral nerves, whole blood and blood components, bone marrow, muscle, sputum, urine and milk (Kretzschmar *et al.*, 1996).

Despite the uniformity in certain aspects, the human prion diseases are associated with diverse clinicopathological phenotypes, mainly dependent upon two factors: (i) the specific confirmation of the Scrapie protein PrP^{Sc} and (ii) the genotype at codon 129 of the prion protein gene. In sCJD two isotypes of PrP^{Sc} are known, with differing electrophoretic patterns.

At codon 129 there is a polymorphism coding for valine (V) or methionine (M). In the normal population the distribution is 40% MM, 10% VV, and 50% MV. All variant CJD cases so far, and 80% of sCJD victims, were homozygous for MM. This indicates that MM homozygotes are at higher risk for CJD, while MV heterozygotes seem relatively protected.

The combination of the PrP^{Sc} isoform pattern and the codon 129 polymorphisms results in six different molecular phenotypes (Fig. 36.1), which correlate with clinical, neuropathological and diagnostic (EEG and CSF) findings, and which allow a new classification of the clinico-pathological diversity on the molecular basis (Parchi *et al.*, 1999).

Clinical diagnostic features

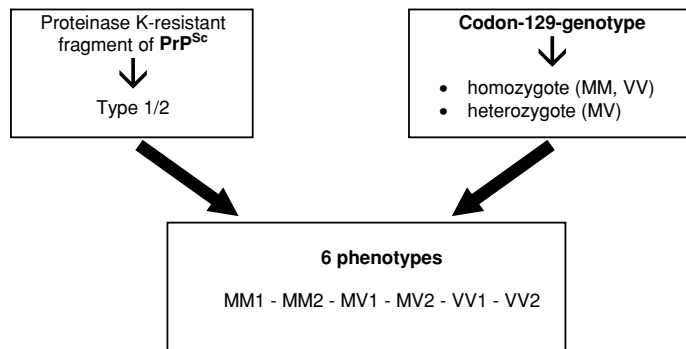

Sporadic CJD

Early symptomatology (Table 36.2., Brown *et al.*, 1994)

Early symptoms of sCJD are quite non-specific comprising various prodromi, including depressive alterations

Table 36.2. Clinical features in sCJD ($n = 232$ Pat.) (Brown *et al.*, 1994)

Features	early (%)	late (%)
Cognitive impairment	69	100
• Memory deficits	48	100
• Behavioral alteration	29	57
• Decline in cortical functions	16	73
Cerebellar disturbance	33	86
Visual defects (cortical blindness)	17	42
Dizziness	13	19
Headaches	11	18
Vegetative symptoms	3	7
Extrapyramidal signs	2	73
Myoclonus	5	90
Typical periodic EEG	0	60

**Fig. 36.1** Molecular classification of sCJD resulting from the combination of polymorphism at codon 129 of the prion protein gene and the electrophoretic pattern of PrP^{Sc}.

of personality, sleep and appetite disturbance, loss of body weight, anxiety and social regression. None of these symptoms is specific for CJD. In the majority of the patients, the presenting neurological symptoms consist of psychopathological alterations, including memory deficits and behavioral alterations subsumed in a rapidly progressive global encephalopathy. About one-third of the patients present with pure neurological symptoms – mostly cerebellar gait ataxia. The remaining patients present with mixed features consisting of cognitive decline and focal neurological deficits.

Patients may first see a neurologist when they complain of visual disturbances – mostly cortical blindness, gait ataxia or psychotic episodes. Psychotic disturbances consist of optic hallucinations with scenic pictures occurring primarily at night. After a mean time of 4 months, patients are admitted to a neurological department where CJD is

first considered. The combination of rapidly progressive cognitive impairment and myoclonus leads in most cases to the suspect diagnosis of CJD.

Clinical variants

There are two – but relatively rare – particularly known CJD variants (Heidenheim and Brownell–Oppenheimer). The Heidenheim variant is associated with neuropathological changes most predominantly occurring in the occipital cortex resulting in primarily visual symptoms (cortical blindness, optic hallucinations, agnosia). The Brownell–Oppenheimer variant presents with a pure cerebellar syndrome related to extensive neuropathological involvement of the cerebellum.

Late symptomatology, course of the disease

The subsequent clinical course is represented by a rapidly progressing disease surprising the clinician and dismaying the relatives. The evolving clinical picture always includes dementia, myoclonus, and ataxia. Depending on the CNS region involved, additional symptoms may occur such as primitive reflexes, paratonic rigidity, cortical blindness, oculomotor disturbances, and other pyramidal and extrapyramidal (e.g. parkinsonism, chorea, dystonia) signs. In the terminal state, patients often show an akinetic mutism (lack of spontaneous movement or verbal utterance, lack of voluntary reaction to external stimuli) accompanied by stimulus-sensitive myoclonus and less often vegetative disturbances and epileptic events. Eventually, CJD patients suffer from respiratory infections and thrombotic complications, which mostly are the immediate cause of death. The mean disease duration is around 7 months. In less than 15% of cases patients show a relatively long duration of more than 12 months. Disease duration of more than 2 years is extremely rare (<5%).

Major pyramidal weakness, lower motor features, sensory disturbance and epileptic seizures are uncommon clinical features with a frequency of less than 20%.

Diagnostic procedures

While none of the above-mentioned single clinical features is specific for CJD, a typical pattern of symptoms has been identified to be helpful in the clinical diagnosis of CJD. Based on these clinical patterns and on typical EEG findings, diagnostic criteria were developed first by Masters *et al.*, 1979. These criteria were later extended by addition of the CSF parameter 14-3-3 (WHO, 1998; Zerr *et al.*, 2000b).

According to these criteria the diagnosis of CJD can be categorized as in Table 36.3:

Fig. 36.2 Typical EEG-findings in sCJD at different disease stages (modified from Steinhoff *et al.*, *Arch Neurol*, 1996).

Table 36.3. Diagnostic criteria for sporadic CJD according to (Masters *et al.*, 1979; WHO, *Weekly Epidemiol Rec.* 1998; 47:361–365)

I	Neuropathological confirmation including immunohistochemical detection of PrP ^{Sc}
II	Rapidly progressing dementia (duration < than 2 years)
III	<ul style="list-style-type: none"> • Myoclonus • Visual and cerebellar features • Pyramidal and extrapyramidal signs • Akinetic mutism
IV	Typical periodic EEG
V	Positive proteins 14-3-3 in CSF
Definite:	I
Probable:	II and 2 of III and IV or V
Possible:	II and 2 of III (EEG and CSF normal)

- **definite** (neuropathologically confirmed);
- **probable** (dementia with a course less than 2 years, two of four defined neurological symptoms and presence of typical EEG pattern and/or 14-3-3 proteins in CSF);
- **possible** (typical clinical features and absence of typical EEG and CSF findings).

Probable and possible CJD are clinical diagnoses based on the exclusion of alternative diseases and the presence of supportive findings in EEG or CSF. A probable classification according to these criteria is quite reliable with a certainty of 95%. However, since there is no pathognomonic clinical test, confirmation by autopsy or biopsy is still necessary to achieve diagnostic certainty.

EEG (Fig. 36.2)

The EEG shows characteristic discharges (periodic bi- and triphasic sharp wave complexes (PSWC)), originally described in the 1950s, at some stage of the disease (Levy *et al.*, 1986). A standardized evaluation showed that typical EEG findings in patients with CJD are found with a sensitivity of 67% and specificity of 86% if the following criteria were present (Steinhoff *et al.*, 1996):

Stereotypic sharp-wave complexes occurring at least 5 times with an interval of 500–2000 ms and duration of 100–600 ms. These data can be improved by standardized repeat recordings. In early stages of the illness these characteristic EEG findings may be absent so that repeat EEG recordings may be necessary. The characteristic EEG changes occur after a median of 12 weeks from disease onset, and they do not correlate with clinical severity of CJD. Their absence

does not exclude the diagnosis of CJD, however, a persistently normal EEG despite clinical progression is incompatible with CJD. On the other hand, the characteristic EEG discharges may also be seen in conditions other than CJD, such as viral encephalitis, hepatic encephalopathy, epileptic seizures, Alzheimer disease, etc. (Zerr *et al.*, 2000a).

Magnetic resonance imaging (MRI)

MRI findings contribute to the diagnosis and differential diagnosis of CJD. Progressive global cerebral atrophy is a consistent finding, which is often accompanied by symmetric hyperintensities in the putamen and the caudate nuclei (up to 67%). These alterations are best demonstrated by using T₂-, proton-density, FLAIR and diffusion-weighted sequences. A major advantage of the diffusion-weighted sequence is its short investigation time allowing brain images in agitated patients with less artefacts. The MRI signal alterations correlate significantly with brain regions neuropathologically characterized by extensive astrocytosis and vacuoles. A significant decrease of brain volume related to cortical atrophy is seen after a disease course of 4 months. In early disease stages (<3 months) MRI may often reveal normal brain imaging despite rapidly progressing and devastating illness (Finkenstedt *et al.*, 1996; Gertz *et al.*, 1988; Röther *et al.*, 1992; Tartaro *et al.*, 1993; Urbach *et al.*, 1998; Samman *et al.*, 1999; Schröter *et al.*, 2000).

Cerebrospinal fluid (CSF) analysis

The routine CSF parameters reveal mostly normal results. Signs of inflammation such as oligoclonal IgG bands or lymphocytic pleocytosis occur in about 7% and are not a typical feature of CJD. However, a disturbed blood–CSF barrier function or elevated total protein level is more common (up to 25%) (Jacobi *et al.*, 2000). Elevated CSF concentration of specific brain derived proteins such as 14-3-3 (Harrington *et al.*, 1986; Hsich *et al.*, 1996; Zerr *et al.*, 1996 and 1998), neuron-specific enolase (Zerr *et al.*, 1995), tau-protein (Otto *et al.*, 1997) and S100b (Otto *et al.*, 1998) represent valuable supportive investigation and thereby contribute significantly to the diagnosis and differential diagnosis of CJD. The increase of their CSF concentrations is related to the rapid neuronal destruction and reactive astrogliosis inherent to the neuropathological disease process. Increased CSF levels of these markers may also be found in conditions other than CJD such as viral encephalitis, intracerebral bleeding, subarachnoid hemorrhage and several other neurodegenerative diseases. Although these surrogate markers are not causally related to the pathogenetic process, in the appropriate clinical context they show a remarkably high diagnostic sensitivity and speci-

Table 36.4. Diagnostic value of various paraclinical tests

Test	Sensitivity (%)	Specificity (%)
MRI (<i>n</i> = 208) (symmetrical SI in basal ganglia)	67	93
EEG (<i>n</i> = 805) (PSWC)	65	86
Cerebrospinal fluid markers		
• 14-3-3 proteins (<i>n</i> = 1532) (Western blot)	94	93
• Tau-Protein (<i>n</i> = 290) (>1400 pg/ml)	93	91
• NSE (<i>n</i> = 1276) (>35 ng/ml)	81	92
• S100b (<i>n</i> = 135) (>4.2 ng/ml)	84	91
• PrP ^{Sc} (<i>n</i> = 34)	20	100

ficity (>90%) even in early disease stages of CJD (Table 36.4) (Zerr *et al.*, 2000a).

The diagnostic certainty of suspect CJD cases can be improved significantly if the CSF 14-3-3 is included as a diagnostic test. According to the extended diagnostic criteria (WHO, 1998; Zerr *et al.*, 2000b) a probable CJD can be established based on typical clinical features and a positive CSF 14-3-3 despite absence of typical EEG changes. A test to detect the abnormal prion protein (PrP^{Sc}) would be a valuable specific diagnostic tool, which could allow confirmation of CJD without neuropathological analysis of brain tissue. There are new and ultrasensitive methods (fluorescence correlated spectroscopy, capillary electrophoresis, plasminogen precipitation, prion protein amplification) in experimental or developmental stages aiming to detect very low concentrations of PrP^{Sc} in bodily fluids including CSF and urine (Bieschke *et al.*, 2000; Schmerr *et al.*, 1999; Maissen *et al.*, 2001; Saborio *et al.*, 2001; Shaked *et al.*, 2001). So far, their sensitivity is still too low (20%) to reach sufficient clinical significance (Zerr *et al.*, 2002).

Detection of PrP^{Sc} in extracerebral compartment has been possible in tonsils of patients with vCJD but not in those with sCJD (Brown *et al.*, 2001).

Genetic CJD (gCJD)

About 15–10% of the CJD patients have a positive family history. The autosomal-dominant pattern of inheritance dictates that 50% of the children of the victim will suffer from the disease. More than 20 mutations of the prion protein gene are responsible for the phenotype. The Gerstmann–Sträussler–Scheinker (GSS) syndrome and fatal familial insomnia are also hereditary forms of prion

diseases. An HD-like disease in a single pedigree was mapped to chromosome 20p12 (Moore *et al.*, 2001), the site of the prion protein PrP gene, and found to segregate with a 192 nucleotide insertion in the PrP gene, encoding eight octapeptide repeats. This disease was called HD-like 1 (HDL1). In the future, it is likely that these diseases will be reclassified according to their genotype. The transmissibility of genetic CJD to non-human primates was first reported in 1973.

The clinical presentation depends on the underlying mutation and other factors such as the polymorphism in codon 129. Genetic CJD tends to occur in clusters. Most known geographical concentrations involving the E200K mutation are (i) a community of Libyan Jews in Israel with annual incidence of 50 per million and (ii) two foci in Slovakia with annual incidences ranging between 4 and 17 per million.

The spectrum of symptoms of gCJD is mostly similar to that of sCJD. However, a sensory-motor polyneuropathy is an additional clinical feature. Since apparently sCJD cases occasionally turn out to have an underlying mutation, prion protein gene sequencing is the only method to exclude genetic cause of CJD.

GSS

GSS was first described around 1930 in a large Austrian family with several affected generations (Gerstmann, 1928; Gerstmann & Sträussler, 1936). However, its classification as prion disease was achieved much later (Masters *et al.*, 1981). Originally, GSS was clinically described as predominantly progressive cerebellar ataxia. Meanwhile it has been associated with a more diverse clinical spectrum including dementia, spastic paraparesis and extrapyramidal symptoms. Neuropathological findings include, in addition to spongiform changes that occur most extensively in patients with the mutation P102L, large multicentric amyloid plaques containing PrP^{Sc}. Furthermore, neurofibrillary tangles (mainly in those with the mutations Y145*, F198S, and Q217R) and amyloid angiopathy (mutation Y145*) have been described to be part of the neuropathologic phenotype. The considerable phenotypic heterogeneity varying from typical CJD to classic GSS even within a pedigree can be partly explained by the genetic heterogeneity comprising several prion protein gene mutations. The more typical GSS cases may have their disease onset in the early middle age, and their mean illness duration is around 5–6 years. Diagnostic tools such as MRI brain imaging and EEG are not helpful in the diagnosis of GSS revealing normal or non-specific findings.

Fatal familial insomnia (FFI)

FFI was first described in 1986 afflicting five members of a large Italian family. The initial pathological classification was “selective thalamic degeneration” (Lugaresi *et al.*, 1986). A few years later it was reported to be a genetically determined prion disease with a mutation at codon 178 (Medori *et al.*, 1992). Soon after it was confirmed to be transmissible (Tateishi *et al.*, 1995). Since then, a number of additional pedigrees manifesting with FFI have been described; nevertheless this remains a very rare disorder.

According to the name of the disease, the main clinical feature of FFI is a profound disruption of the sleep-wake cycle. Additional symptoms are dysautonomia (most prominent sympathetic overactivity), diverse endocrine disturbances and cognitive impairment (mnestic difficulties).

The autonomic dysfunction occurs early in the disease course and may be the presenting symptom. The sleep disturbance may initially be minor, but progresses over weeks to months accompanied with vivid dreams and somnolence. Prompt arousal with light stimuli is characteristic. A variety of hallucinations occur in addition to the parasomnias contributing to the bizarre nocturnal behaviors. A range of motor abnormalities (cerebellar and pyramidal dysfunction, spontaneous and reflex myoclonus) evolve in variable combinations.

Eventually, patients become confused and disoriented, progressing to stupor and coma. The routine EEG in the early stages is usually normal, while in progressed stages it becomes non-specifically altered with slower frequencies and generalised less responsive alpha activity. PSWC are not typically associated with FFI. Routine laboratory parameters including CSF analysis are typically normal. Circadian oscillations of various hormones including growth hormone, prolactin, gonadotrophins and thyrotrophin-releasing hormone are disturbed. Polysomnographic recordings reveal reduced total sleep time and absence of REM periods. Pharmacologic agents such as benzodiazepines and barbiturates seem unable to induce sleep-like EEG activity.

vCJD

Epidemiology

The current public interest in CJD is explained by the accumulating evidence on the causal relationship between BSE and vCJD. The most remarkable epidemiological feature of vCJD is its geographical distribution. By December 2003, 153 cases had been confirmed worldwide, from which 139 were registered in UK with a decreasing north-south

Table 36.5. Differences between sCJD and vCJD

	vCJD	sCJD
Early symptoms	Sensory disturbance, psychiatric symptoms	Dementia, focal neurological signs
Disease duration (months)	14	7
Age at death (years)	30	67
EEG (PSWC)	0%	67%
MRI (symmetrical SI)	“Pulvinar sign”	Nucl. Caudatus, Putamen
14-3-3 (positive)	45%	94%
Neuropathology (amyloid plaques)	Prominent and diffuse	Sparse (10%)
Extracerebral distribution of PrP ^{Sc}	Tonsil, appendix, spleen, lymph node	Negative
PrP ^{Sc} -Pattern in Western blot	Type 4 (as in BSE)	Type 1 and 2

gradient (<http://www.doh.gov.uk/cjd/stats/feb04>). In contrast to sCJD, vCJD patients are younger with an age range of 14–53 years, and the median age of onset is 28 years. Females and males are affected equally (Will *et al.*, 2000).

Early symptomatology (dysesthesias, psychiatric symptomatology) (Table 36.5.)

In contrast to sCJD presenting with rapidly progressive cognitive impairment, vCJD presents with relatively slowly progressive clinical features comprising sensory and psychiatric symptoms. The most common symptoms are psychiatric/behavioral disturbances (depressive states requiring antidepressant treatment, anxiety, agitation, delusions and hallucinations), and unpleasant sensory features including pain, mostly worse at night. Neurological abnormalities are not usually evident at disease onset. Affected individuals are mostly referred to a psychiatrist by their family doctors. While nerve conduction is usually normal, somato-sensory evoked potentials may show minor abnormalities suggesting central affection of the sensory pathways and thalamic origin of the pain.

Course of the disease – late stages

Subsequent symptoms include neurological features which develop more than 6 months after onset of first symptoms. Most commonly, gait ataxia is a prominent feature, followed by involuntary movements (myoclonus,

chorea, dystonia), dementia and upgaze paresis. The terminal state of vCJD with predominant dementia, multiple neurological deficits and akinetic mutism resembles that seen in sCJD. The median disease duration in vCJD is twice as long as in sCJD with a median of 14 months (range 6–38 months).

Relation to BSE

There is now increasing evidence from experimental studies that BSE and vCJD have a causal link. It seems most likely that vCJD is due to infection of humans with the BSE agent via contaminated food. The greatest incidence of BSE in UK is a relevant epidemiological clue, indicating that the agent passed from cattle to man. However, an absolute proof that the zoonotic link was via food has not been provided to date. The most reasonable hypothesis is that the agent was transmitted via mechanically recovered meat containing spinal cord material from infected cattle (Brown *et al.*, 2001).

Diagnostic procedures (MRI, tonsil biopsy, neuropathology)

The cerebral MRI scan appears to be very useful in vCJD with bilateral signal intensities in the dorsal thalamus (“pulvinar sign”) in the majority of cases (Zeidler *et al.*, 2000). Unlike the diagnostic criteria for sCJD, the diagnostic criteria for vCJD include MRI features.

Cerebral biopsy shows, in addition to the spongiform changes, extensive PrP^{Sc} deposition with the so-called “florid-plaque” diffusely occurring throughout the cerebrum and cerebellum. Based on the extracerebral distribution of PrP^{Sc} mainly in lymphoreticular organs, tonsillar biopsy has been proposed potentially useful in the ante mortem diagnosis of vCJD (Ghani *et al.*, 2000; Brown *et al.*, 2001).

CSF, EEG

CSF and EEG measures are less helpful in the diagnosis of vCJD as compared to sCJD. CSF 14-3-3 is less sensitive being positive in only half of the affected individuals. EEG recordings do not show the typical PSWC typical of sCJD.

Kuru

Kuru is the only human prion disease with a naturally occurring horizontal transmission from man-to-man. It was first identified in the mid-1950s in Papua New Guinea and was recognized to be endemic among the Fore tribe

resident in the Eastern Highlands of New Guinea (Zigas & Gajdusek, 1957; Hadlow, 1959).

The majority of the Kuru victims were adult females and children of either sex. Eventually, epidemiological and scientific data suggested that Kuru had been transmitted by cannibalistic rituals observed in funeral ceremonies. It is hypothesized that a cannibalistic passage of a sporadic CJD case most likely occurred, although the ultimate cause remains unclear (Gajdusek *et al.*, 1966).

Epidemiological data from pregnant women delivering healthy infants remaining asymptomatic do not provide evidence for vertical transmission. At the end of the 1960s, after ritual cannibalism was not practiced any longer, Kuru disappeared almost completely.

The clinical picture was characterized by the insidious onset of a predominant progressive cerebellar dysfunction. Symptoms of pyramidal or extrapyramidal functions were not prominent, and cognitive functions remained relatively spared or were impaired in terminal disease stages. Within a few months, affected patients were not able to sit unsupported and became bedridden, totally dependent for feeding and personal care. Patients died from complications such as bronchopneumonia, infected pressure sores or undernutrition. The total disease duration was reported to be around 6–9 months ranging from 4–24 months, a little longer than sCJD.

There are no typical changes of routine biochemical laboratory parameters or of CSF analysis as for other prion diseases. For unequivocal confirmation of Kuru, a neuropathological examination is required. Neuropathological findings are dominated by mainly cerebellar spongiform changes containing so called “Kuru-plaques,” which are found in Kuru cases more frequently than in CJD types. This may be explained by the relatively higher frequency of valin at codon 129 of the prion protein gene. Kuru plaques are detectable by HE and PAS staining as homogenous and eosinophilic PrP-depositions. They are mainly found in the granular cell layer of the cerebellum. In sCJD cases Kuru plaques occur exclusively in certain molecular phenotypes: MV-heterozygotes and PrP^{Sc}-type 2 (Kretzschmar, 1996).

Differential diagnosis (Table 36.6)

The differential diagnosis of sCJD is of clinical importance. Depending on the disease stage and on the initially prominent symptom a number of different differential diagnoses with psychiatric and neurological origin have to be considered.

Table 36.6. Spectrum of important differential diagnoses in cases of suspect sCJD

Degenerative brain disorders	Alzheimer dementia
	Parkinson syndromes with dementia
	Frontotemporal dementia
	Chorea Huntington
	Multisystem atrophy
	Cerebellar atrophy
Inflammatory encephalopathies	Encephalitis (viral, autoimmune)
	AIDS-encephalopathy
	multiple sclerosis
	progressive multifocal leukoencephalopathy
Metabolic encephalopathies	Hepatopathic, uremic, Korsakow syndrome, Wernicke-encephalopathy
Toxic encephalopathy	Intoxication with metals and drugs
Paraneoplastic encephalopathies	Limbic encephalomyelitis paraneoplastic cerebellar atrophy

The rapidly progressive Alzheimer disease, Lewy body dementia and frontotemporal dementia represent the most frequent differential diagnosis in clinically advanced cases. In patients with predominant cerebellar dysfunction or extrapyramidal symptoms other neurodegenerative disorders such as multiple system atrophy, PSP or CBD have to be considered (Lopez *et al.*, 1999; Verghese *et al.*, 1999; Zerr *et al.*, 2000b and 2002). In younger patients with suspect CJD chronic encephalitis or Hashimoto encephalopathy as a potentially treatable cause may be important differential diagnoses (Seipelt *et al.*, 1999).

Therapeutic aspects

Symptomatic treatment

Current therapy is confined to symptomatic treatment. Myoclonus may respond to benzodiazepines. Agitation and psychotic features can be treated with neuroleptic drugs, whereby drug-induced rigidity may appear and cause difficulties in interpretation of disease-related rigidity.

Disease-specific treatment, anti-prion approach

There are a number of promising anti-prion agents that are effective in animal models and are shown in cell culture experiments to influence aggregation of PrP^{Sc}. In cell culture even "clearance" of PrP^{Sc} has been shown to be possible. However none of these substances has shown convincing therapeutic results in clinical trials in CJD victims.

A partial list of potential anti-prion compounds includes:

acridine and phenothiazine derivatives (Korth *et al.*, 2001),
amphotericin B (Pocchiari *et al.*, 1987),
anti-Prion antibodies (Peretz *et al.*, 2001; Enari *et al.*, 2001),
branched polyamines (Supattapone *et al.*, 2001),
Congo red (Caughey & Race, 1992)
quinacrin (Collins *et al.*, 2002).
synthetic beta-sheet breaker peptides (Soto *et al.*, 2000).

II The pathogenesis and mechanisms of prion diseases

Adriano Aguzzi

Institute of Neuropathology, University of Zürich, Switzerland

Introduction

For more than two decades it has been contended that prion infection does not elicit immune responses: transmissible spongiform encephalopathies do not go along with conspicuous inflammatory infiltrates, and antibodies to the prion protein are typically undetectable. Why is it, then, that prions accumulate in lymphoid organs, and that various states of immune deficiency prevent peripheral prion infection? This review revisits the current evidence of the involvement of the immune system in prion diseases, while attempting to trace the elaborate mechanisms by which peripherally administered prions invade the brain and ultimately provoke damage. The investigation of these questions leads to unexpected detours, including the neurophysiology of lymphoid organs, and even the function of a prion protein homologue in male fertility.

Prion biology: some basic facts

Prion diseases are inevitably fatal neurodegenerative conditions that affect humans and a wide variety of animals (Aguzzi *et al.*, 2001c). Although prion diseases may present with certain morphological and pathophysiological parallels to other progressive encephalopathies, such as Alzheimer's and Parkinson's disease (Aguzzi & Raeber, 1998), they are unique in that they are transmissible. Homogenization of brain tissue from affected individuals and intracerebral inoculation into another individual of the same species will typically reproduce the disease. This important fact was recognized more than half a century ago in the case of scrapie (Cuille & Chelle, 1939), a prototypic prion disease that affects sheep and goats.

In the 1960s and 1970s, the work of Gajdusek on Kuru and Creutzfeldt–Jakob disease (Gajdusek *et al.*, 1966; Gibbs

et al., 1968), partly inspired by a suggestion of Hadlow (Hadlow, 1959) on the similarity of scrapie and Kuru, established that these diseases are also transmissible to primates, to mice, and in some unfortunate iatrogenic instances, also to other humans (Brown P. *et al.*, 2000). Therefore, prion diseases are also called transmissible spongiform encephalopathies (TSEs), a term that emphasizes their infectious character.

While only less than 1% of all reported cases of Creutzfeldt–Jakob disease (CJD) can be traced to a defined infectious source, the identification of bovine spongiform encephalopathy (BSE) (Wells *et al.*, 1987) and its subsequent epizootic spread has highlighted prion-contaminated meat-and-bone meal as a tremendously efficient vector for bovine prion diseases (Weissmann & Aguzzi, 1997), which does not completely lose its infectious potential even after extensive autoclaving (Taylor, 2000). BSE is most likely transmissible to humans, too, and strong circumstantial evidence (Aguzzi, 1996; Aguzzi & Weissmann, 1996b; Collinge *et al.*, 1996; Bruce *et al.*, 1997; Hill *et al.*, 1997a) suggests that BSE is the cause of variant Creutzfeldt–Jakob disease (vCJD) which has claimed more than 130 lives in the United Kingdom (Will R. G. *et al.*, 1996; <http://www.doh.gov.uk/cjd/stats/aug02.htm>, 2002) and, to a much smaller extent, in some other countries (Chazot *et al.*, 1996). When transmitted to primates, BSE produces a pathology strikingly similar to that of vCJD (Aguzzi & Weissmann, 1996b; Lasmez *et al.*, 1996b). While there is no direct indication yet that variant Creutzfeldt–Jakob disease has been transmitted from one human to another, this is certainly a very worrying scenario (Aguzzi, 2000). Not only surgical instruments may represent potential vectors of transmission, but possibly also transfusions. Significantly, sheep infected with BSE can efficiently transmit the agent to other sheep via blood transfusion (Houston *et al.*, 2000; Hunter *et al.*, 2002).

Several aspects of CJD epidemiology continue to be enigmatic. For example, CJD incidence in Switzerland has risen two-fold in 2001, and appears to be increasing even further in the year 2002 (Glatzel *et al.*, 2002). A screen for recognized or hypothetical risk factors for CJD has, to date, not exposed any causal factors. Several scenarios may account for the increase in incidence, including improved reporting, iatrogenic transmission, and transmission of a prion zoonosis.

Prion diseases typically exhibit a very long latency period between the time of infection and the clinical manifestation: this is the reason why these diseases were originally thought to be caused by “slow viruses”. From the viewpoint of interventional approaches, this peculiarity may be exploitable, since it opens a possible window of intervention after infection has occurred, but before brain damage is being initiated. Prions spend much of this latency time executing neuroinvasion, which is the process of reaching the central nervous system after entering the body from peripheral sites (Aguzzi, 1997a; Nicotera, 2001). During this process, little or no damage occurs to brain, and one might hope that its interruption may prevent neurodegeneration.

Stanley Prusiner’s protein-only hypothesis

The most widely accepted hypothesis on the nature of the infectious agent causing TSEs (which was termed prion by Stanley B. Prusiner) (Prusiner, 1982) predicates that it consists essentially of PrP^{Sc}, an abnormally folded, protease-resistant, beta-sheet rich isoform of a normal cellular protein termed PrP^C. According to this fascinating theory, the prion does not contain any informational nucleic acids, and its infectivity propagates simply by recruitment and “autocatalytic” conformational conversion of cellular prion protein into disease-associated PrP^{Sc} (Aguzzi & Weissmann, 1997).

A large body of experimental and epidemiological evidence is compatible with the protein-only hypothesis, and very stringently designed experiments have failed to disprove it. It would go well beyond the scope of this article to review all efforts that have been undertaken to this effect. Perhaps most impressively, knockout mice carrying a homozygous deletion of the *Prnp* gene that encodes PrP^C, fail to develop disease upon inoculation with infectious brain homogenate (Büeler *et al.*, 1993), nor does their brain carry prion infectivity (Sailer *et al.*, 1994). Reintroduction of *Prnp* by transgenesis – even in a shortened, redacted form – restores infectibility and prion replication in *Prnp*⁰ mice (Fischer *et al.*, 1996; Shmerling *et al.*, 1998; Supattapone *et al.*, 1999; Flechsig *et al.*, 2000). In addition, all familial

cases of human TSEs are characterized by *Prnp* mutations (Aguzzi & Weissmann, 1996a; Prusiner *et al.*, 1998).

Informational nucleic acids of >50 nucleotides in length do not participate in prion infectivity (Kellings *et al.*, 1993; Riesner *et al.*, 1993), but shorter non-coding oligonucleotides have not been formally excluded – a fact that may have some relevance in view of the surprising discoveries related to RNA-mediated gene silencing. *Prnp* exhibits a long reading frame on its non-coding strand (Moser *et al.*, 1993) which is conserved among mammals (Aguzzi, 1997b; Rother *et al.*, 1997), suggesting that it may be transcribed – maybe only in specific pathological situations. One might wonder, therefore, whether this peculiar property of *Prnp* might result in the production of double-stranded transcripts with silencing properties. However, *bona fide* antisense transcription of the *Prnp* locus has never been demonstrated in vivo, nor in cultured cells.

Some major open questions in prion biology

In recent years, prion research has progressed at a faster pace than many of us would have thought possible. As a consequence, many enigmas surrounding prion diseases have now been solved. However, the areas that are still obscure do not relate only to the details: some of these concern the core of the prion concept (Chesebro, 1998). In my opinion, there are four large groups of questions regarding the basic science of prion replication and of development of transmissible spongiform encephalopathies diseases that deserve to be addressed with a vigorous research effort.

- Which are the molecular mechanisms of prion replication? How does the disease-associated prion protein, PrP^{Sc}, achieve the conversion of its cellular sibling, PrP^C, into a likeness of itself? Which other proteins assist this process? Can we inhibit this process? If so, how?
- What is the essence of prion strains, which are operationally defined as variants of the infectious agent capable of retaining stable phenotypic traits upon serial passage in syngeneic hosts? The existence of strains is very well known in virology, but it was not predicted to exist in the case of an agent that propagates epigenetically.
- How do prions reach the brain after having entered the body? Which molecules and which cell types are involved in this process of neuroinvasion? Which inhibitory strategies are likely to succeed?
- The mechanisms of neurodegeneration in spongiform encephalopathies is not understood. Which are the pathogenetic cascades that are activated upon accumulation of disease-associated prion protein, and ultimately lead to brain damage?

- What is the physiological function of the highly conserved, normal prion protein, PrP^C? The *Prnp* gene encoding PrP^C was identified in 1985 (Oesch *et al.*, 1985; Basler *et al.*, 1986), *Prnp* knockout mice were described in 1992 (Büeler *et al.*, 1992), and some PrP^C-interacting proteins have been identified (Oesch *et al.*, 1990; Rieger *et al.*, 1997; Yehiely *et al.*, 2002; Zanata *et al.*, 2002). Yet the function of PrP^C remains unknown.

The present review article will discuss some of the progress recently achieved in some of the areas delineated above, with special reference to the topics that have directly interested my laboratory.

Brain damage in prion diseases

An interesting question regards the molecular mechanism underlying neuropathological changes, in particular cell death, resulting from prion disease. Depletion of PrP^C is an unlikely cause, in view of the finding that abrogation of PrP does not cause scrapie-like neuropathological changes (Büeler *et al.*, 1992), even when elicited postnatally (Mallucci *et al.*, 2002). More likely, toxicity of PrP^{Sc} or some PrP^C-dependent process is responsible.

To address the question of neurotoxicity, brain tissue of *Prnp*^{0/0} mice was exposed to a continuous source of PrP^{Sc}. To this purpose, telencephalic tissue from transgenic mice overexpressing PrP (Fischer *et al.*, 1996) was transplanted into the forebrain of *Prnp*^{0/0} mice and the “pseudo-chimeric” brains were inoculated with scrapie prions. All grafted and scrapie-inoculated mice remained free of scrapie symptoms for at least 70 weeks; this exceeded at least sevenfold the survival time of scrapie-infected donor mice (Brandner *et al.*, 1996a). Therefore, the presence of a continuous source of PrP^{Sc} and of scrapie prions does not exert any clinically detectable adverse effects on a mouse devoid of PrP^C. On the other hand, the grafts developed characteristic histopathological features of scrapie after inoculation. The course of the disease in the graft was very similar to that observed in the brain of scrapie-inoculated wild-type mice (Brandner *et al.*, 1998). Importantly, grafts had extensive contact with the recipient brain, and prions could navigate between the two compartments, as shown by the fact that inoculation of wild-type animals engrafted with PrP-expressing neuroectodermal tissue resulted in scrapie pathology in both graft and host tissue. Nonetheless, histopathological changes never extended into host tissue, even at the latest stages (>450 days), although PrP^{Sc} was detected in both grafts and recipient brain, and immunohistochemistry revealed PrP deposits in the hippocampus, and occasionally in the parietal cortex, of all

animals (Brandner *et al.*, 1996a). Thus, prions moved from the grafts to some regions of the PrP-deficient host brain without causing pathological changes or clinical disease. The distribution of PrP^{Sc} in the white matter tracts of the host brain suggests diffusion within the extra-cellular space (Jeffrey *et al.*, 1994) rather than axonal transport.

These findings suggest that the expression of PrP^C by an infected cell, rather than the extracellular deposition of PrP^{Sc}, is the critical prerequisite for the development of scrapie pathology. Perhaps PrP^{Sc} is inherently non-toxic and PrP^{Sc} plaques found in spongiform encephalopathies are an epiphenomenon rather than a cause of neuronal damage. This hypothesis appears to be supported by the recent data (Ma and Lindquist, 2002; Ma *et al.*, 2002) indicating that exaggerated retrograde transport of the prion protein from the endoplasmic reticulum into the cytosol, or functionally equivalent inhibition of proteasome function, might induce a self-propagating, extremely cytotoxic cellular form, which may ultimately be responsible for neuronal damage. These results are very exciting, and it will be important to validate them by investigating whether the aggregated self-propagating material can also be transmitted between individual animals in a classic transmission experiment.

One may therefore propose that availability of PrP^C for some intracellular process elicited by the infectious agent, perhaps the formation of a toxic form of PrP (PrP* (Weissmann, 1991)) other than PrP^{Sc} is responsible for spongiosis, gliosis, and neuronal death. This would be in agreement with the fact that in several instances, and especially in fatal familial insomnia, spongiform pathology is detectable although very little PrP^{Sc} is present (Aguzzi & Weissmann, 1997).

Peripheral entry sites of prions

The fastest and most efficient method for inducing spongiform encephalopathy in the laboratory is intracerebral inoculation of brain homogenate. Inoculation of 1 000 000 infectious units (defined as the amount of infectivity that will induce TSE with 50% likelihood in a given host) will yield disease in approximately half a year; a remarkably strict inverse relationship can be observed between the logarithm of the inoculated dose and the incubation time (Prusiner *et al.*, 1982) (Fig. 36.3).

However, the above situation does not correspond to what typically happens in the field. There, acquisition of prion infectivity through any of several peripheral routes is the rule. However, prion diseases can also be initiated by feeding (Wells *et al.*, 1987; Kimberlin & Wilesmith, 1994;

Fig. 36.3 Prion bioassay by the incubation time method. This Figure is reproduced from an important study by Prusiner and colleagues that demonstrates an inverse logarithmic relationship between size of infectious inoculum and latency period of scrapie in experimental animals (Prusiner *et al.*, 1982). The relationship is so precise that incubation time can actually be used to back-calculate the prion titer of a test article, e.g. for inactivation studies. Measurement of prion titers by the incubation time method has become a standard procedure which can be used for both wild-type and transgenic animals.

Anderson *et al.*, 1996), by intravenous and intraperitoneal injection (Kimberlin & Walker, 1978) as well as from the eye by conjunctival instillation (Scott *et al.*, 1993), corneal grafts (Duffy *et al.*, 1974) and intraocular injection (Fraser, 1982).

The pathway of orally administered prions

Upon oral challenge, an early rise in prion infectivity can be observed in the distal ileum of infected organisms: this applies to several species but was most extensively investigated in the sheep (Wells *et al.*, 1994; Vankeulen *et al.*, 1996). There, Peyer's patches acquire strong immunopositivity for the prion protein. Immunohistochemical stains with antibodies to the prion protein typically reveal a robust signal in primary B-cell follicles and germinal centers, which roughly colocalizes with the complement receptor, CD35,

in a wide variety of secondary lymphoid organs including appendix and tonsils (Hill *et al.*, 1997b). Although conventional light microscopy does not allow differentiating between PrP^C and PrP^{Sc}, Western blot analysis has not left any doubt about the fact that Peyer's patches do accumulate the disease-associated form of the prion protein.

The latter is true also in the mouse model of scrapie, which is being used as a convenient experimental paradigm by many laboratories including ours. Administration of mouse-adapted scrapie prions (Rocky Mountain Laboratory or RML strain, originally derived from the Chandler sheep scrapie isolate) induces a surge in intestinal prion infectivity as early as a few days after inoculation (Marco Prinz, Gerhard Huber and AA, unpublished results).

All of the above evidence conjures the suggestion that Peyer's patches may represent a portal of entry for orally administered prions on their journey from the luminal aspect of the gastrointestinal tube to the central nervous system. However, the question as to whether the same applies for BSE-affected cattle has been answered less unambiguously.

In a monumental study of BSE pathogenesis in cattle carried out at the UK Veterinary Laboratory Agency, cows of various ages were fed with 100 g, 10 g, 1 g, or 100 mg of brain homogenate derived from BSE-sick cows (Bradley, 2000). A large variety of tissues was taken at various points in time, homogenized, and transmitted intracerebrally to indicator organisms in order to assess their prion content. This study was designed to be performed over a time frame of more than a decade and is still underway at the time of writing: it has uncovered a transient surge in infectivity in the distal ileum of cows at approximately 6 months post-infection. Infectivity then subsides, but it appears to return to the terminal ileum at the end stages of disease, maybe by means of some sort of retrograde transport (Wells *et al.*, 1998). Although this was not formally confirmed, it appears likely that Peyer's patches are the sites of prion accumulation in the gastrointestinal tract of cattle challenged orally with prions.

Oral prion susceptibility correlates with number but not structure of Peyer's patches

Reduced mucosal lymphocyte trafficking does not impair, as expected, the susceptibility to orally initiated prion disease. In contrast, mice deficient in both tumor necrosis factor and lymphotoxin- α (TNF $\alpha^{-/-}$ x LT $\alpha^{-/-}$) or in lymphocytes (RAG-1 $^{-/-}$, μ MT), in which numbers of Peyer's patches are reduced in number, are highly resistant to oral challenge, and their intestines were virtually devoid of prion infectivity at all times after challenge. Therefore,

lymphoreticular requirements for enteric and for intraperitoneal uptake of prions differ from each other and that susceptibility to prion infection following oral challenge correlates with the number of Peyer's patches, but is independent of the number of intestinal mucosa-associated lymphocytes (Prinz *et al.*, 2003).

Diagnosis of prion disease: identification of the infectious agent

As explained in the glossary, the term "prion" is used here in an operational meaning: it is not meant to be necessarily identical with PrP^{Sc}, but it simply denotes the infectious agent, whatever this agent exactly consists of (Aguzzi & Weissmann, 1997). If one takes this viewpoint, PrP^{Sc} defined originally as the protease-resistant moiety associated with prion disease would be a mere surrogate marker for the prion. Even if this position may seem all too negativistic in view of the wealth of compelling evidence in favor of the protein-only hypothesis, it is still advisable to maintain that we do not understand any of the molecular details of prion replication. In other words, we still need to be open to the possibility that infectivity might be brought about by a conformer of PrP^C that is not identical with what was originally defined as PrP^{Sc} (see Glossary). This position appears to gain increasing acceptance, as documented by the recent description of "protease sensitive PrP^{Sc}" by the group of Stanley Prusiner (Safar *et al.*, 1998, 2000).

Because protease resistance and infectivity of PrP^{Sc} may not necessarily be congruent, it is desirable to expand the range of reagents that will interact specifically with disease-associated prion protein, but not (or to a lesser degree) with its counterpart, PrP^C. One IgM monoclonal antibody termed 15B3 has been described a few years ago to fulfill the above conditions (Korth *et al.*, 1997), but this antibody has not become generally available, and no follow-up studies have been published. Disappointingly, expression of the complementarity-determining regions of 15B3 in the context of a phage, as well as expression of its heavy chain variable region in transgenic mice, failed to reproduce the specificity of PrP^{Sc} binding (Heppner *et al.*, 2001b).

We have described the puzzling phenomenon that a prevalent constituent of blood serum, plasminogen, captures efficiently PrP^{Sc} but not PrP^C when immobilized onto the surface of magnetic beads (Fischer *et al.*, 2000; Maissen *et al.*, 2001). The significance of this phenomenon *in vivo* has yet to be addressed, and it has been claimed on the basis of experiments that binding occurs only in the presence of specific detergents (Shaked *et al.*, 2002). While the latter study was performed only *in vitro*, and related only to the binding of a mixture of serum proteins rather than puri-

fied plasminogen, this does not detract from the usefulness of the binding phenomenon for diagnostic purposes: plasminogen binds to PrP^{Sc} from a variety of species and genotypes (Maissen *et al.*, 2001), and the captured PrP^{Sc} retains the glycoform profile characteristic of the prion strain from which it was isolated (M. Maissen and AA, unpublished data).

Transepithelial enteric passage of prions: a role for M cells?

We have set out to investigate some of the preconditions of transepithelial passage of prions. Membranous epithelial cells (M cells) are key sites of antigen sampling for the mucosal-associated lymphoid system (MALT) and have been recognized as major ports of entry for enteric pathogens in the gut via transepithelial transport (Neutra *et al.*, 1996). Interestingly, maturation of M cells is dependent on signals transmitted by intraepithelial B cells. The group of Jean-Pierre Kraehenbuhl (Lausanne) has developed efficient *in vitro* systems, in which epithelial cells can be instructed to undergo differentiation to cells that resemble M cells by morphological and functional-physiological criteria. Therefore, we investigated whether M cells are a plausible site of prion entry in a co-culture model (Kerneis *et al.*, 1997) in which colon carcinoma cells are seeded with B-lymphoblastoid cells, inducing differentiation of M cells. After 24h, scrapie infectivity was determined within the basolateral compartment by bioassay with *tga20* mice, which overexpress a *Prnp* transgene and develop scrapie rapidly after infection (Fischer *et al.*, 1996). Even at low prion doses (3 logLD₅₀), we found infectivity in at least one M cell-containing co-culture. In contrast, there was hardly any prion transport in Caco-2 cultures without M cells (Heppner *et al.*, 2001a).

These findings indicate that M cell differentiation is necessary and sufficient for active transepithelial prion transport *in vitro*. M cell-dependent uptake of foreign antigens or particles is known to be followed by rapid transcytosis directly to the intraepithelial pocket, where key players of the immune system, e.g. macrophages, dendritic cells and lymphocytes (Neutra *et al.*, 1996), are located. Therefore, prions may exploit M cell-dependent transcytosis to gain access to the immune system.

While these findings suggest that M cells are a plausible candidate for the mucosal portal of prion infection, it still remains to be established whether the pathway delineated above does indeed represent the first portal of entry of orally administered prions into the body. This will necessitate *in vivo* experimentation, for example by ablation of M-cells

Table 36.7. Susceptibility of various strains of immunodeficient mice to intracerebrally or intraperitoneally administered prions (Klein *et al.*, 1997)

Defect	Genotype	Intracerebral route		Intraperitoneal route	
		Scrapie	Time to terminal disease	Scrapie	Time to terminal disease
T	CD-4% [§]	7/7	159±11	8/8	191±1
T	CD-8% [§]	6/6	157±15	6/6	202±5
T	β ₂ -μ% [§]	8/8	162±11	7/7	211±6

T and B	SCID [§]	7/8*	160±11	6/8**	226±15
T and B	RAG 2% [§]	7/7	167±2	0/7	healthy (>504)
T and B	RAG 1% [§]	3/3	175±2	0/5	healthy (>258)
T and B	AGR% [@]	6/6	184±10	0/7	healthy (>425)
B	IgM% [§]	8/8	181±6	0/8	healthy (>510)
IgG	t11umt [§]	5/5	170±3	4/4	223±2
FDC	TNFR1% [£]	7/7	165±3	9/9	216±4
Controls	129Sv	4/4	167±9	4/4	193±3
	C57BL/6	4/4	166±2	4/4	206±2

One perforin-deficient and one SCID mouse suffered from intercurrent death 135 and 141 days after inoculation, respectively.

§: genetic background was C57BL/6; £: genetic background was 129sv; @: genetic background was C57BL/6 x 129sv; ** two SCID mice remained healthy and were sacrificed 303 and 323 days after inoculation

through suicide transgenic strategies, or by M-cell specific expression of *Prnp* transgenes.

Lymphocytes and prion pathogenesis

Innate or acquired deficiency of lymphocytes impairs peripheral prion pathogenesis, whereas no aspects of pathogenesis are affected by the presence or absence of lymphocytes upon direct transmission of prions to the central nervous system (Kitamoto *et al.*, 1991; Lasmezas *et al.*, 1996a). Klein and colleagues were then able to pinpoint the lymphocyte requirement to B-cells (Klein *et al.*, 1997; Aguzzi, 1997a): at first blush this was very surprising, since there had been no suggestions that any aspect of humoral immunity would be involved in prion diseases. In the same study, it was shown that T-cells deficiency brought about by ablation of the T-cell receptor α (TCRα) chain did not affect prion pathogenesis (Table 36.7). We measured the latency of scrapie (days from inoculation to terminal disease) upon delivery of a standard prion inoculum. All mice developed spongiform encephalopathy after *i.c.* inoculation. In contrast, all mice that carried a defect in B-cell differentiation stayed healthy after *i.p.* inoculation of RML scrapie prions. Intriguingly, in this any in several subsequent study, TNF

receptor I deficient mice developed disease with the same kinetics as wild-type mice, although there are no morphologically detectable follicular dendritic cells in the spleens of TNFR1^{-/-} mice.

TCRα deficient mice, however, still contain TCRγδ T-lymphocytes. Although the latter represent a subpopulation of T-cells, the experiments described did not allow to exclude a role for TCRγδ T-lymphocytes. Therefore, we challenged also TCR TCRβ/δ deficient mice with prions. Incubation times after intracerebral and intraperitoneal inoculation of limiting or saturating doses of prions, however, elicited disease in these mice with the same kinetics as in wild-type mice (M. Klein and AA, unpublished data). Also, accumulation of PrP^{Sc} and development of histopathological changes in the brain were indistinguishable in these two strains of mice. We therefore conclude that the complete absence of T-cells has no measurable impact on prion diseases. Therefore, it is unlikely that the T-cell infiltrates which have been reported to occur in the central nervous system during the course of prion infections (Betmouni *et al.*, 1996; Betmouni & Perry, 1999; Perry *et al.*, 2002) represent more than an epiphenomenon.

In 1996–7, when the results of the studies described above were being collected, we had no precise idea of what the mechanistic role of B-cells might be in prion pathogenesis.

It had become rather clear, on the other hand, that lymphocytes alone could not account for the entirety of prion pathogenesis, and an additional sessile compartment had to be involved: adoptive transfer of *Prnp*^{+/+} bone marrow to *Prnp*^{0/0} recipient mice did not suffice to restore infectibility of *Prnp*-expressing brain grafts, indicating that neuroinvasion was still defective (Blättler *et al.*, 1997).

It then emerged that peripheral prion pathogenesis required the physical presence of B-cells, yet intraperitoneal infection occurred efficiently even in B-cell deficient hosts that had been transferred with B-cell from *Prnp* knockout mice (Klein *et al.*, 1998). Therefore, presence of B-cells – but not expression of the cellular prion protein by these cells – is indispensable for pathogenesis upon intraperitoneal infection in the mouse scrapie model (Aguzzi *et al.*, 2001a).

The above results have been reproduced and confirmed several times over the years by many laboratories in various experimental paradigms: the requirement for B-cells in particular appears to be very stringent in most instances investigated. However, it has emerged that not all strains of prions induce identical patterns of peripheral pathogenesis, even when propagated in the same, isogenic strain of host organism.

Straining the lymphocytes

Another interesting discrepancy that remains to be addressed concerns the actual nature of the cells that replicate and accumulate prions in lymphoid organs. Four series of rigorously controlled experiments over five years (Aguzzi *et al.*, 2000; Kaeser *et al.*, 2001; Klein *et al.*, 2001; Prinz *et al.*, 2002) unambiguously reproduced the original observation by Thomas Blättler and colleagues that transfer of wild-type bone marrow cells (or fetal liver cells) to *Prnp* deficient mice restored accumulation and replication of prions in spleen (Blättler *et al.*, 1997). By contrast, Karen Brown and colleagues reported a diametrically opposite outcome of similar experiments when mice were inoculated with prions of the ME7 strain (Brown *et al.*, 1999). Maybe this discrepancy may identify yet another significant difference in the cellular tropism of different prion strains.

Bone marrow transplantation may (1) transfer an ill-defined population with the capability to replenish splenic stroma and to replicate prions, or – less probably – (2) donor-derived PrP^C expressing hematopoietic cells may confer prion replication capability to recipient stroma by virtue of “GPI painting”, i.e. the post-translational cell-to-cell transfer of glycosphosphoinositol linked extracellular membrane proteins (Kooyma *et al.*, 1998). Some evidence might be accrued for either possibility: stromal splenic

follicular dendritic cells have been described by some authors to derive possibly from hematopoietic precursors, particularly when donors and recipients were young (Szakal *et al.*, 1995; Kapasi *et al.*, 1998). Conversely, instances have been described in which transfer of GPI-linked proteins occurs in vivo with surprisingly high efficiency (Kooyma *et al.*, 1995). Most recently, GPI painting has been described specifically for the cellular prion protein (Liu *et al.*, 2002).

The paradox described above may uncover an analogous phenomenon in peripheral prion pathogenesis. The latter question may be important, *since the molecular and cellular basis of peripheral tropism of prion strains is likely to be directly linked to the potential danger of BSE in sheep* (Glatzel and Aguzzi, 2001; Bruce *et al.*, 2002; Kao *et al.*, 2002), as well the potential presence of vCJD prions in human blood (Aguzzi, 2000).

Prion hideouts in lymphoid organs

Prion infectivity rises in a matter of days in the spleen of intraperitoneally infected mice. Although B-lymphocytes are crucial for neuroinvasion, the bulk of infectivity is not contained in lymphocytes. Instead, most splenic prion infectivity resides in a “stromal” fraction. Lymphocytes may be important for trafficking prions within lymphoid organs, but follicular dendritic cells are the prime candidate prion reservoir. Recently, elegant immuno electron microscopic studies have evidenced that prion immunoreactivity is situated in the immediate neighborhood of iccosomes (Jeffrey *et al.*, 2000).

A definitive assessment of the contribution of FDCs to prion pathogenesis continues to be problematic since the histogenesis and the molecular characteristics of these cells are ill-defined. FDCs express S-100 proteins, as well as the complement receptors 2 (CD35) and 4 (identical to the marker FDC-M2). All of these markers, however, are also expressed by additional cell types, even within lymphoid organs (Bofill *et al.*, 2000). The FDC-M1 marker recognized by hybridoma clone 4C11 appears somewhat more specific.

Gene deletion experiments in mice have shown that signaling by both TNF and lymphotoxins is required for FDC development (Fu *et al.*, 1997; Koni *et al.*, 1997; Endres *et al.*, 1999). Membrane-bound lymphotoxin- α/β (LT- α/β) heterotrimers signal through the LT- β receptor (LT- β R) (Ware *et al.*, 1995) thereby activating a signaling pathway required for the development and maintenance of secondary lymphoid organs (Mackay *et al.*, 1997; Matsumoto *et al.*, 1997). Membrane LT- α/β heterotrimers are mainly expressed by activated lymphocytes (Browning *et al.*, 1993, 1995).

Fig. 36.4 Depletion of follicular dendritic cells by pharmacological inhibition of lymphotoxin signalling. Time course of FDC depletion in spleen of $LT\beta R$ -Ig treated mice. Frozen sections of treated (left) and control mice (right) immunostained with follicular dendritic cell specific antibody FDC-M1 at different times points after injection of $LT\beta R$ -Ig (original magnifications: upper row 8x25; lower row 8x63). Germinal centers FDCs networks were depleted already one week after treatment as described (Mackay and Browning, 1998; Montrasio *et al.*, 2000). Some FDC-M1 positive cells, which may represent residual FDCs or tingible body macrophages, were still detectable in the spleens of treated mice.

Maintenance of pre-existing FDCs in a differentiated state requires continuous interaction with B lymphocytes expressing surface $LT-\alpha/\beta$ (Gonzalez *et al.*, 1998). Inhibition of the $LT-\alpha/\beta$ pathway in mice by treatment with $LT\beta R$ -immunoglobulin fusion protein ($LT\beta R$ -Ig) (Crowe *et al.*, 1994) leads to the disappearance of mature, functional FDCs (defined as cells that express markers such as FDC-M1, FDC-M2 or CD35) within one day, both in spleen and in lymph nodes (Mackay *et al.*, 1997; Mackay & Browning, 1998). Prolonged administration of the $LT\beta R$ -Ig protein leads to disruption of B cell follicles.

All of the above prompted us to study the effect of selective ablation of functional FDCs on the pathogenesis of scrapie in mice. FDC-depletion was maintained by weekly administration of the $LT\beta R$ -Ig fusion protein for 8 weeks. Histological examination of spleen sections revealed that FDC networks had disappeared one week after treatment (Fig. 36.4), as expected.

In mice, following peripheral inoculation, infectivity in the spleen rises within days and reaches a plateau after a few weeks (Bruce, 1985; Rubenstein *et al.*, 1991; Büeler *et al.*, 1993). Even after intracerebral inoculation, spleens of C57BL/6 animals contain infectivity already 4 days post-infection (p.i.), (Büeler *et al.*, 1993). However, Western blot analysis (Fig. 36.5) revealed that 8 weeks after inoculation spleens of control mice showed strong bands of

protease-resistant PrP, whereas mice injected weekly with $LT\beta R$ -Ig, starting either one week before or one week after inoculation, showed no detectable signal (<1/50th of the controls).

Prion infectivity in three spleens for each time point was assayed by intracerebral inoculation into indicator mice (Fischer *et al.*, 1996). In spleens of mice treated with $LT\beta R$ -Ig 1 week before intraperitoneal inoculation no infectivity could be detected after 3 or 8 weeks (<1.0 log ID₅₀ units/ml 10% homogenate). Traces of infectivity, possibly representing residual inoculum, were present in the 1-week samples. In mice treated with $LT\beta R$ -Ig 1 week after inoculation the titers were about 2.2 and 4.1 log ID₅₀ units/ml 10% homogenate at 3 weeks and at borderline detectability at 8 weeks after infection, suggesting that some prion accumulation took place in the first weeks after inoculation but was reversed under treatment with $LT\beta R$ -Ig by 8 weeks. Spleens of scrapie-inoculated control mice treated with unspecific pooled human immunoglobulins (huIgG) 1 week after inoculation had 4.5 and 5.5 log ID₅₀ units/ml 10% homogenate 8 weeks after intraperitoneal inoculation.

To assess whether prolonged depletion of mature FDCs would perturb the progression of the disease, C57BL/6 mice were subjected to weekly administration of the fusion protein up to eight weeks post inoculation and observed for more than 340 days. Mice receiving $LT\beta R$ -Ig starting one

Fig. 36.5 Inhibition of lymphotoxin signalling blocks prion replication in lymphoid organs. Accumulation of PrP^{Sc} in spleens of LTβR-Ig treated mice eight weeks after inoculation. Immunoblot analysis of spleen extracts (200 μg total protein) from LTβR-Ig-treated and control mice sacrificed 8 weeks after inoculation. All spleen samples were treated with proteinase K. Mice analyzed (left to right): *Prnp*^{0/0}; untreated, LTβR-Ig treated C57BL/6 mice either 1 week before (LTβR-Ig w-1) or after (LTβR-Ig w+1) prion inoculation. Spleens of two mice for each group were analyzed. Immunoreactive PrP was detected using a rabbit antiserum against mouse-derived PrP (1B3) (Farquhar *et al.*, 1994) and enhanced chemiluminescence. The position of the molecular weight standards (in kDa) is indicated on the left side of the fluorogram. The three diagnostic bands of PrP^{Sc} are only recognized in untreated mice. LTβR-Ig treatment led to complete disappearance of the signal (reduction >50 fold).

week after inoculation developed the disease with about 25 days delay as compared to control mice. Whenever FDC depletion was initiated 1 week before inoculation, the effect on incubation time was even more pronounced. Immunofluorescence analysis of spleen sections of terminally sick animals revealed that the FDC networks were reconstituted after interruption of LTβR-Ig administration at 8 weeks and that PrP^C and/or PrP^{Sc} co-localized with FDCs. Immunoblot analysis showed that PrP^{Sc} accumulation was restored upon reappearance of FDCs in the spleens of terminal sick LTβR-Ig treated mice.

Therefore, FDCs are essential for the deposition of PrP^{Sc} and generation of infectivity in the spleen and suggest that they participate in the process of neuroinvasion. PrP knockout mice expressing PrP transgenes only in B cells do not sustain prion replication in the spleen or elsewhere, suggesting that prions associated with splenic B cells (Raeber *et al.*, 1999a) may be acquired from FDCs. Finally, these results suggest that strategies aimed at depleting FDCs might be envisaged for post-exposure prophylaxis (Aguzzi & Collinge, 1997) of prion infections initiated at extracerebral sites.

Additional experimentation appears to indicate that PrP^C-expressing hematopoietic cells are required in addition to FDCs for efficient lymphoreticular prion propagation (Blättler *et al.*, 1997; Kaeser *et al.*, 2001). This apparent discrepancy called for additional studies of the molecular requirements for prion replication competence in lymphoid stroma. We therefore set out to study peripheral prion pathogenesis in mice lacking TNF α , LT α/β , or their receptors.

After intracerebral inoculation, all treated mice developed clinical symptoms of scrapie with incubation times, attack rates, and histopathological characteristics similar to those of wild-type mice, indicating that TNF/LT signaling is not relevant to cerebral prion pathogenesis. Upon intraperitoneal prion challenge, mice defective in LT signaling (LT $\alpha^{-/-}$, LT $\beta^{-/-}$, LT β R $^{-/-}$, or LT α TNF $\alpha^{-/-}$) proved virtually non-infectible with ≤ 5 logLD₅₀ scrapie infectivity, and establishment of subclinical disease (Frigg *et al.*, 1999) was prevented. In contrast, TNFR1 $^{-/-}$ mice were almost fully susceptible to all inoculum sizes, and TNF $\alpha^{-/-}$ mice showed dose-dependent susceptibility. TNFR2 $^{-/-}$ mice had intact FDCs and germinal centers, and were fully susceptible to scrapie. Unexpectedly, all examined lymph nodes of TNFR1 $^{-/-}$ and TNF $\alpha^{-/-}$ mice had consistently high infectivity titers. Even inguinal lymph nodes, which are distant from the injection site and do not drain the peritoneum, contained infectivity titers equal to all other lymph nodes. Therefore, TNF deficiency prevents lymphoreticular prion accumulation in spleen but not in lymph nodes.

Why is susceptibility to peripheral prion challenge preserved in the absence of TNFR1 or TNF α , whereas deletion of LT signalling components confers high resistance to peripheral prion infection? After all, each of these defects (except TNFR2 $^{-/-}$) abolishes FDCs. For one thing, prion pathogenesis in the lymphoreticular system appears to be compartmentalized, with lymph nodes (rather than spleen) being important reservoirs of prion infectivity during disease. Second, prion replication appears to take place in lymph nodes even in the absence of mature FDCs.

In Prnp^{0/0} mice grafted with TNFR1 $^{-/-}$ hematopoietic cells, high infectivity loads were detectable in lymph nodes but not spleens, indicating that TNFR1 deficient, PrP^C-expressing hematopoietic cells may support prion propagation within lymph nodes. The PrP signal colocalized with a subset of macrophages in TNFR1 $^{-/-}$ lymph nodes. Since marginal zone macrophages are in close contact to FDCs and also interact with marginal zone B cells, this cell type is certainly a candidate supporter in prion uptake and replication. On the other hand, it has been reported that in short-time infection experiments depletion of macrophages appears to enhance the amount of

recoverable infectivity, implying that macrophages may degrade prions rather than transport them (Beringue *et al.*, 2000). The finding that a cell type other than mature FDCs is involved in prion replication and accumulation within lymph nodes may be relevant to the development of post-exposure prophylaxis strategies.

Neuroinvasion proper: the role of sympathetic nerves

In the last several years, a model has emerged that predicts prion neuroinvasion to consist of two distinct phases (Aguzzi *et al.*, 2001c). The details of the first phase are discussed above: widespread colonization of lymphoreticular organs is achieved by mechanisms that depend on B-lymphocytes (Klein *et al.*, 1997, 1998), follicular dendritic cells (Montrasio *et al.*, 2000), and complement factors (Klein *et al.*, 2001). The second phase has long been suspected to involve peripheral nerves, and possibly the autonomic nervous system, and may depend on expression of PrP^C by these nerves (Glatzel & Aguzzi, 2000). We have been attempting to test the requirement for expression of PrP^C in peripheral nerves for several years, and have developed a gene transfer protocol to spinal ganglia aimed at resolving this question (Glatzel *et al.*, 2000); however, we were never able to recover infectivity in spinal cords of Prnp^{0/0} mice whose spinal nerves had been transduced by Prnp-expressing adenoviruses (M. Glatzel and A. Aguzzi, unpublished results). Also, fast axonal transport does not appear to be involved in prion neuroinvasion, since mice that are severely impaired in this transport mechanism experience prion pathogenesis with kinetics similar to that of wild-type mice (Künzi *et al.*, 2002).

There is substantial evidence suggesting that prion transfer from the lymphoid system to the CNS occurs along peripheral nerves in a PrP^C dependent fashion (Blättler *et al.*, 1997; Glatzel & Aguzzi, 2000; Race *et al.*, 2000). Studies focusing on the temporal and spatial dynamics of neuroinvasion have suggested that the autonomic nervous system might be responsible for transport from lymphoid organs to the CNS (Clarke & Kimberlin, 1984; Cole & Kimberlin, 1985; Beekes *et al.*, 1998; McBride & Beekes, 1999).

The innervation pattern of lymphoid organs is mainly sympathetic (Felten & Felten, 1988). Markus Glatzel and colleagues have shown that denervation by injection of the drug 6-hydroxydopamine (6-OHDA), as well as “immunosympathectomy” by injection of antibodies against nerve growth factor (NFG) leads to a rather dramatic decrease in the density of sympathetic innervation of lymphoid organs, and significantly delayed the development

Fig. 36.6 The sympathetic innervation of the spleen can be ablated by 6-hydroxydopamine. The density of sympathetic innervation correlates with the concentration of tyrosine hydroxylase, which was measured by Western blot analysis in spleens of adult 6-OHDA treated mice, K14NGF transgenic mice and controls. The two main tyrosine hydroxylase bands are visible at ca. 55 kDa. While, there is a certain increase in sympathetic innervation with age, it is obvious that 6-OHDA treatment depletes, and the K14NGF transgene increases sympathetic innervation. Lower panel: quantification of tyrosine hydroxylase content by chemiluminescence scanning. The bars represent the ratio between signal intensity of the tyrosine hydroxylase band and that of the corresponding beta-actin bands (arbitrary units).

of scrapie (Glatzel *et al.*, 2001). Sympathectomy appears to delay the transport of prions from lymphatic organs to the thoracic spinal cord, which is the entry site of sympathetic nerves to the CNS. Transgenic mice overexpressing NGF under control of the K14 promoter, whose spleens are hyperinnervated, developed scrapie significantly earlier than non-transgenic mice. No alteration in lymphocyte subpopulations was detected in spleens at any time point investigated. In particular, we did not detect any significant differences in the content of FDCs of treated and untreated mice, which negates the possibility that the observed protection may be due to modulation of FDC microanatomy.

While the sympathetic nervous system may represent a major component of the second phase of prion neuroinvasion, many details remain to be elucidated. It is not known whether prions can be transferred directly from FDCs to sympathetic endings, or whether additional cell types are

involved. The latter possibility is particularly enticing, since FDCs have not been shown to entertain physical contact with sympathetic nervous system terminals.

Moreover, it is unclear how prions are actually transported within peripheral nerves. Axonal and non-axonal transport mechanisms may be involved, and non-neuronal cells (such as Schwann cells) may play a role. Within the framework of the protein-only hypothesis, one may hypothesize a “domino” mechanism, by which incoming PrP^{Sc} converts resident PrP^C on the axolemmal surface, thereby propagating spatially the infection. While speculative, this model is attractive since it may accommodate the finding that the velocity of neural prion spread is extremely slow (Kimberlin *et al.*, 1983) and may not follow the canonical mechanisms of fast axonal transport. Indeed, recent studies may favor a non-axonal transport mechanism that results in periaxonal deposition

of PrP^{Sc} (Hainfellner & Budka, 1999; Glatzel & Aguzzi, 2000).

The fact that denervated mice eventually developed scrapie may be due to an alternative, low-efficiency route of entry that may become uncovered by the absence of sympathetic fibers. Entry through the vagal nerve has been proposed in studies of the dynamics of vacuolation following oral and intraperitoneal challenge with prions (Baldauf *et al.*, 1997; Beekes *et al.*, 1998).

The surprising finding that infectious titers in hyperinnervated spleens are at least two logs higher and show enhanced PrP^{Sc} accumulations compared to control mice suggests that sympathetic nerves, besides being involved in the transport of prions, may also accumulate and replicate prions in lymphatic organs (Clarke & Kimberlin, 1984). Obviously this finding has implications related to the permanence and possibly eradication of prions in subclinically infected hosts (Fig. 36.6).

Spread of prions within the central nervous system

Ocular administration of prions has proved particularly useful to study neural spread of the agent, since the retina is a part of the central nervous system and intraocular injection does not produce direct physical trauma to the brain, which may disrupt the blood-brain barrier and impair other aspects of brain physiology. The assumption that spread of prions occurs axonally rests mainly on the demonstration of diachronic spongiform changes along the retinal pathway following intraocular infection (Fraser, 1982).

To investigate whether spread of prions within the CNS is dependent on PrP^C expression in the visual pathway, PrP-producing neural grafts were used as sensitive indicators of the presence of prion infectivity in the brain of an otherwise PrP-less host. Following inoculation with prions into the eye of grafted *Prnp*^{0/0} mice, none of the grafts showed signs of scrapie. Therefore, it was concluded that infectivity administered to the eye of PrP-deficient hosts cannot induce scrapie in a PrP-expressing brain graft (Brandner *et al.*, 1996b).

Engraftment of *Prnp*^{0/0} mice with PrP^C-producing tissue might lead to an immune response to PrP which, in turn, was shown to be in principle capable of neutralizing infectivity (Heppner *et al.*, 2001b). In order to definitively rule out the possibility that prion transport was disabled by a neutralizing immune response, *Prnp*^{0/0} mice were rendered tolerant by expressing PrP^C under the control of the *lck* promoter. These mice overexpress PrP on T-lymphocytes, but are resistant to scrapie and do not replicate prions in brain, spleen and thymus after intraperitoneal inocula-

tion with scrapie prions (Raeber *et al.*, 1999b). Engraftment of these mice with PrP-overexpressing neuroectoderm did not lead to the development of antibodies to PrP after intracerebral or intraocular inoculation, presumably due to clonal deletion of PrP-immunoreactive T-lymphocytes. As before, intraocular inoculation with prions did not provoke scrapie in the graft, supporting the conclusion that lack of PrP^C, rather than immune response to PrP, prevented prion spread (Brandner *et al.*, 1996b). Therefore, PrP^C appears to be necessary for the spread of prions along the retinal projections and within the intact CNS.

These results indicate that intracerebral spread of prions is based on a PrP^C-paved chain of cells, perhaps because they are capable of supporting prion replication. When such a chain is interrupted by interposed cells that lack PrP^C, as in the case described here, no propagation of prions to the target tissue can occur. Perhaps prions require PrP^C for propagation across synapses: PrP^C is present in the synaptic region (Fournier *et al.*, 1995) and certain synaptic properties are altered in *Prnp*^{0/0} mice (Collinge *et al.*, 1994; Whittington *et al.*, 1995). Perhaps transport of prions within (or on the surface of) neuronal processes is PrP^C-dependent. Within the framework of the protein-only hypothesis (Griffith, 1967; Prusiner, 1989), these findings may be accommodated by a “domino-stone” model in which spreading of scrapie prions in the CNS occurs per continuitatem through conversion of PrP^C by adjacent PrP^{Sc} (Aguzzi, 1997a).

Innate immunity and antiprion defense

Macrophages and toll-like receptors

Cells of the monocyte/macrophage lineage typically represent the first line of defense against an extremely broad variety of pathogens. In the case of prions, it might be conceivable that macrophages protect against prions. However, it would be equally conceivable that macrophages, by virtue of their phagocytic properties and of their intrinsic mobility, may function as Trojan horses that transport prion infectivity between sites of replication within the body. This interesting question has not yet been fully resolved.

In a short-term prion infection paradigm, Beringue and colleagues administered dichloromethylene diphosphate encapsulated into liposomes to mice: this eliminates for a short period of time all spleen macrophages. Accumulation of newly synthesized PrP^{Sc} was accelerated, suggesting that macrophages participate in the clearance of prions, rather than being involved in PrP^{Sc} synthesis.

On the basis of the results presented above, Beringue and colleagues have suggested that activation or targeting of macrophages may represent a therapeutic pathway to explore in TSE infection. This suggestion was taken up by Sethi and Kretzschmar, who recently reported that activation of Toll like receptors (TLRs), which function as general stimulators of innate immunity by driving expression of various sets of the immune regulatory molecules, can effect postexposure prophylaxis in an experimental model of intraperitoneal scrapie infection (Sethi *et al.*, 2002). In this experimental paradigms, administration of prions intraperitoneally elicited disease after approximately 180 days, whereas the administration of CpG oligodeoxynucleotides 7 hours after prion inoculation and daily for 20 days led to disease-free intervals of “more than 330 days” – although it appears that all inoculated mice died of scrapie shortly thereafter (communicated by H. Kretzschmar at the TSE conference in Edinburgh, September 2002).

This finding is very surprising, since most available evidence indicates that general activation of the immune system would typically sensitize mice to prions, rather than protect them. The mechanism by which activation of toll-like receptor can result in post-exposure prophylaxis are wholly unclear at present, particularly in view of the fact that mice lacking Myd88 (Adachi *et al.*, 1998), which is an essential mediator of TLR signaling, develop prion disease with exactly the same sensitivity and kinetics as wild-type mice [Prinz *et al.*, 2003].

The role of the complement system

Another prominent component at the crossroad between innate and adaptive immunity is represented by the complement system. Opsonization by complement system components also appears to be relevant to prion pathogenesis: mice genetically engineered to lack complement factors (Klein *et al.*, 2001), or mice depleted of the C3 complement component by administration of cobra venom (Mabbott *et al.*, 2001), exhibit a remarkable resistance to peripheral prion inoculation. This phenomenon may, once again, be related to the pathophysiology of FDCs, which typically function as antigen traps. Trapping mechanisms essentially consist of capture of immune complexes by Fc γ receptors, and binding of opsonized antigens (linked covalently to C3d and C4b complement adducts) to the CD21/CD35 complement receptors.

Capture mediated by Fc γ receptors does not appear to be very important in prion disease: for one thing, knockout mice lacking Fc γ receptors (Takai *et al.*, 1994, 1996; Hazenbos *et al.*, 1996; Park *et al.*, 1998) are just as susceptible to intraperitoneally administered scrapie as wild-type

mice. Further, introduction into μ MT mice of a generic immunoglobulin μ chain fully restored prion neuroinvasion irrespective of whether this heavy chain allowed for secretion of immunoglobulins, or only for production of membrane-bound immunoglobulins. We therefore conclude that circulating immunoglobulins are certainly not crucial to prion replication in lymphoid organs and to neuroinvasion.

A second mechanism exploited by FDCs for antigen trapping involves covalent linking of proteolytic fragments of the complement components C3 and C4 (Szakal & Hanna, 1968; Carroll, 1998). The CD21/CD35 complement receptors on FDCs bind C3b, iC3b, C3d, and C4b through short consensus repeats in their extracellular domain. Ablation of C3, or of its receptor CD21/CD35, as well as C1q (alone or combined with BF/C2^{-/-}), delayed neuroinvasion significantly after *intraperitoneal* inoculation when a limiting dose of prions was administered. These effects suggest that opsonization of the infectious agent may enhance its accessibility to germinal centers by facilitating docking to FDCs.

Very large prion inocula ($\geq 10^6$ infectious units) appear to override the requirement for a functional complement receptor in prion pathogenesis. This is similar to systemic viral infections and coreceptor-dependent retention within the follicular compartment, whose necessity can be overridden by very high affinity antigens (Fischer *et al.*, 1998) or adjuvants (Wu *et al.*, 2000). Additional retention mechanisms for prions may therefore exist in FDCs, which are not complement-dependent, or depend on hitherto unidentified complement receptors.

Adaptive immunity and pre-exposure prophylaxis against prions

For many conventional viral agents, vaccination is the most effective method of infection control. But is it at all possible to induce protective immunity *in vivo* against prions? Prions are extremely sturdy and their resistance against sterilization is proverbial. Pre-incubation with anti-PrP antisera was reported to reduce the prion titer of infectious hamster brain homogenates by up to 2 log units (Gabizon *et al.*, 1988) and an anti-PrP antibody was found to inhibit formation of PrP^{Sc} in a cell-free system (Horiuchi & Caughey, 1999). Also, antibodies (Klein *et al.*, 2001) and F(ab) fragments raised against certain domains of PrP (Peretz *et al.*, 2001) can suppress prion replication in cultured cells. However, it is difficult to induce humoral immune responses against PrP^C and PrP^{Sc}. This is most likely due to tolerance of the mammalian immune system to PrP^C, which is an endogenous protein expressed rather ubiquitously. Ablation of the

Fig. 36.7 Affinity and avidity of antibodies against the prion protein. While the heavy chain is kept constant in the transgene, it may pair with a large repertoire of endogenous light chains. Some of the pairs will yield very high affinity antibodies, others will have low affinity, but the majority may have no affinity at all for the prion protein. It is possible that some degree of clonal deletion occurs, and that combinations with the highest affinity are eliminated.

Prnp gene (Büeler *et al.*, 1992), which encodes PrP^C, renders mice highly susceptible to immunization with prions (Brandner *et al.*, 1996b), and many of the best available monoclonal antibodies to the prion protein have been generated in *Prnp*^{0/0} mice (Prusiner *et al.*, 1993). However, *Prnp*^{0/0} mice are unsuitable for testing vaccination regimens since they do not support prion pathogenesis (Büeler *et al.*, 1993).

We have therefore asked whether genes encoding high-affinity anti-PrP antibodies (originally generated in *Prnp*^{0/0} mice) may be utilized to reprogram B cell responses of prion-susceptible mice that express PrP^C. Indeed, introduction of the epitope-interacting region the heavy chain of 6H4, a high-affinity anti-PrP monoclonal antibody

(Korth *et al.*, 1997) into the germ line of mice sufficed to produce high-titer anti-PrP^C immunity. The 6H4 μ heavy chain transgene induced similar anti-PrP^C titers in *Prnp*^{0/0}, *Prnp*^{0/+} and *Prnp*^{+/+} mice, indicating that deletion of autoreactive B-cells does not prevent anti-PrP immunity. The buildup of anti-PrP^C titers, however, was more sluggish in the presence of endogenous PrP^C, suggesting that some clonal deletion is actually occurring.

How can these observations be interpreted? The total anti-PrP^C titer results from pairing of one transgenic μ heavy chain with a large repertoire of endogenous κ and λ chains: some pairings may lead to reactive moieties, while others may be anergic (Fig. 36.7). Maybe the B cell clones with the highest affinity to PrP^C are being eliminated by the immune tolerization machinery, and only clones with medium affinity are retained. This would explain the delay in titer buildup in the presence of PrP^C, and would be in agreement with our affinity measurements – which indicate that the total molar avidity of 6H4 μ serum is approximately 100-fold lower than that of the original 6H4 antibody from which the transgene was derived. But most intriguingly, expression of the 6H4 μ heavy chain sufficed to block peripheral prion pathogenesis upon intraperitoneal inoculation of the prion agent (Heppner *et al.*, 2001a).

PrP^C is a normal protein expressed by most tissues of the body. Therefore an anti-PrP immune response may conceivably induce an autoimmune disease, and defeat any realistic prospect for prion vaccination. We did not observe any blatant autoimmune disease as a consequence of anti-prion immunization – unless PrP^C was artificially transgenically expressed at non-physiological, extremely high levels.

The strategy outlined above delivers proof-of-principle that a protective humoral response against prions can be mounted by the mammalian immune system, and suggests that B cells are not intrinsically tolerant to PrP^C. If the latter is generally true, lack of immunity to prions may be due to T-helper tolerance. The latter problem is not trivial, but may perhaps be overcome by presenting PrP^C to the immune system along with highly active adjuvants. These findings, therefore, encourage a reassessment of the possible value of active and passive immunization (Westaway and Carlson, 2002), and perhaps of reprogramming B cell repertoires by μ chain transfer, in prophylaxis or in therapy of prion diseases.

Prion immunization and its reduction to practice

Approximately one year later, a first example of a reduction to practice of the approach proposed by Heppner was demonstrated by the laboratory of Thomas Wisniewski

(Sigurdsson *et al.*, 2002). The authors have explored whether immunization with recombinant prion protein might be protective against prion diseases. Two paradigms were chosen: prophylactic immunization, and rescue after infection (post-exposure prophylaxis).

The first remarkable surprise of the study was that it was indeed possible to induce antibody responses in wild-type mice – although the actual titers were not determined. Immunization was simply achieved by injecting 50 µg of recombinant prion protein emulsified in Freund's adjuvant. This procedure had been utilized extensively in the Zurich laboratory (F. L. Heppner, M. Polymenidou, E. Pellicoli, M. Bachmann, & A. Aguzzi, unpublished observations), but had never produced any reasonable titers in wild-type mice.

Upon inoculation with a high dose or with a lower dose of prion inoculum, vaccinated mice exhibited a modest delay in development of prion disease. Although the success of the study, from the viewpoint of survival of the mice, might be regarded as limited, the study is in my view very promising in that it shows that vaccination approaches can be translated into models that are closer to the real-life situation than immunoglobulin-transgenic mice. The possibility of producing protective immunity against prions has captured the imagination of a considerable number of scientists, and additional reports are appearing of original ways to break tolerance and induce an immune response in animals that express the normal prion protein, including mixing of the immunogenic moiety with bacterial chaperons, among others (Koller *et al.*, 2002).

The prion doppelganger

Despite considerable efforts, the physiological function of PrP^C is still unclear. PrP^C was reported to have weak superoxide dismutase activity *in vitro* (a report that awaits independent confirmation) and evidence for a physiological relevance is scant (Brown *et al.*, 2001). PrP^C can bind copper (Brown *et al.*, 1997; Wadsworth *et al.*, 1999), but reports of increased copper content of neurons lacking PrP^C have been questioned by contradictory findings (Waggoner *et al.*, 2000). Similarly, a proposed role for PrP^C in synaptic function has been questioned by other investigators (Collinge *et al.*, 1994; Lledo *et al.*, 1996) and a possible regulation of circadian rhythm by PrP^C has remained more-or-less anecdotal (Tobler *et al.*, 1996). It is fair to say that if it was not for its role in prion diseases, the significance of PrP^C would be obscure and it might be viewed as just another one among many poorly understood GPI-linked proteins.

After the advent of large scale sequencing efforts and genome projects, it was realized that there is an open reading frame (ORF) directly adjacent of *Prnp* that encodes a protein sharing significant homology with PrP^C (Moore *et al.*, 1999). The novel gene, *Prnd*, is located 16 kb downstream *Prnp* in the mouse genome, and encodes a protein of 179 residues, which was termed Dpl ('downstream of the *Prnp* locus' or 'doppel', German for 'double') (Moore *et al.*, 1999; Weissmann & Aguzzi, 1999; Behrens & Aguzzi, 2002). The *Prnd* gene is evolutionarily conserved from humans to sheep and cattle, and shows roughly 25% identity with the carboxy-proximal two thirds of PrP^C. Structural studies indicate that Dpl contains three alpha helices like PrP^C and two disulphide bridges between the second and third helix (Lu *et al.*, 2000; Silverman *et al.*, 2000; Mo *et al.*, 2001).

Dpl mRNA is expressed at high levels in testis, less in other peripheral organs and, notably, at very low levels in brain of adult wild-type mice. However, significant *Prnd* mRNA transcripts were detected during embryogenesis and in the brains of newborn mice, arguing for a possible function of Dpl in brain development (Li *et al.*, 2000).

To better understand the function of Dpl, we have inactivated the *Prnd* gene in embryonic stem (ES) cells (Behrens *et al.*, 2001). Similarly to mice lacking PrP^C, mice devoid of Dpl survive to adulthood and do not show obvious phenotypic alterations, suggesting that Dpl is dispensable for embryogenesis and postnatal development (Behrens *et al.*, 2002). The similarities between PrP^C and Dpl in primary amino acid sequence, structure and subcellular localization suggest related biological functions. Therefore a possible role of PrP^C and Dpl during development may be masked by functional redundancy. To address this question it will be necessary to generate mice lacking *Prnp* as well as *Prnd* and to study whether the lack of both PrP^C and Dpl will result in an exacerbation of the mutant phenotypes. These double-mutant mice may finally reveal the true physiological function of PrP^C and Dpl, and pave the way for the long-awaited understanding of these proteins.

The Dpl protein resembles an N-terminally truncated PrP^C protein lacking the octamer repeats. But the latter version of PrP^C is actually capable of supporting PrP^{Sc} propagation (Flechsiger *et al.*, 2000), suggesting that the Dpl protein may in principle be susceptible to conversion into "Dpl^{Sc}". However, presently there is no evidence whether upon scrapie inoculation Dpl can be converted into a misfolded beta-strand-rich, protease-resistant conformation.

Embryonic stem (ES) cells carrying a homozygous null mutation of the *Prnd* locus, and a normal *Prnp* locus, were found to be capable of giving rise to all neural cell lineages when transplanted into host brains. After inoculation with scrapie prions, Dpl-deficient neural grafts showed

spongiosis, gliosis and unimpaired accumulation of PrP^{Sc} and infectivity similar to wild-type neuroectodermal grafts (Behrens *et al.*, 2001). Therefore in neural grafts *Prnd* deficiency does not prevent prion pathogenesis. It is important to note, however, that this experimental approach does not rule out a role for Dpl in peripheral prion pathogenesis and in PrP^{Sc} transport to the brain. The latter possibility is worth studying, because *Prnd* is expressed in the spleen, a major peripheral reservoir of PrP^{Sc} and prion infectivity (Li *et al.*, 2000).

Four polymorphisms in human *PRND* were detected, but no strong association was found between any of these polymorphisms and human prion diseases (Mead *et al.*, 2000; Peoc'h *et al.*, 2000). These findings further argue against an important function of Dpl in neurons during prion disease, at least in genetically determined forms of these diseases.

Phenotypes of *Prnp* deficient mice: a paradox resolved

Although this was not realized for quite some time, a Dpl-associated phenotype had been accidentally produced in knock-out mice lacking PrP^C. Several mouse lines with targeted disruptions of *Prnp* were independently generated. All mutant mouse lines lacked significant portions of the *Prnp* ORF and did not produce PrP^C protein, but showed two strikingly different phenotypes. Zrch *Prnp*⁰ and Edbg *Prnp*^{-/-} (termed after the city of origin) showed only minor defects (Büeler *et al.*, 1992; Collinge & Palmer, 1994; Manson *et al.*, 1994; Tobler *et al.*, 1996) whereas Nsgk *Prnp*^{-/-}, Zürich II and Rcm0 mice develop cerebellar Purkinje cell degeneration causing ataxia with advancing age (Sakaguchi *et al.*, 1996; Moore *et al.*, 1999; Rossi *et al.*, 2001). This conundrum was solved when David Westaway and colleagues realized that in the brain of ataxic, but not of healthy *Prnp*-mutant mice, *Prnd* mRNA was upregulated (Moore *et al.*, 1999; Li *et al.*, 2000). An intergenic splicing event places the Dpl locus under the control of the *Prnp* promoter, probably due to the deletion of the *Prnp* intron 2 sequence including its splicing acceptor (Moore *et al.*, 1999). This intergenic splicing event could be detected at very low levels also in wild-type mice, but was greatly enhanced by the absence of the intron 2 splice acceptor (Moore *et al.*, 1999). Whereas the *Prnp* promoter is strongly expressed in neuronal cells, the *Prnd* promoter is not (Moore *et al.*, 1999; Li *et al.*, 2000; Rossi *et al.*, 2001) and therefore *Prnd* expression from the *Prnp* promoter results in overproduction of Dpl in the brain (Moore *et al.*, 1999; Li *et al.*, 2000; Rossi *et al.*, 2001). Further experiments have demonstrated an inverse correlation between the mRNA levels of *Prnd* and the onset of

ataxia. Disease progression was accelerated by increasing *Prnd* levels, supporting the notion that ectopic Dpl expression, but not functional loss of PrP^C, may be responsible for neuronal degeneration in ataxic *Prnp*-deficient mice (Rossi *et al.*, 2001).

Consequences of Doppel deficiency: a detour to reproductive pathology

We then inactivated the *Prnd* gene. However, we have not been able to generate any progeny from intercrosses of *Prnd*^{-/-} mice. Female *Prnd*^{-/-} mice, when crossed to *Prnd*^{-/-} or *Prnd*^{+/-} mice, yielded litter sizes similar to those of wild-type. In contrast, male *Prnd*^{-/-} mice were infertile. Their sexual activity was similar to that of controls, as shown by a normal number of copulation plugs. However, the number of spermatozoa in the cauda epididymis of *Prnd*^{-/-} males was reduced, and motility of mutant sperm was decreased. Therefore, sterility of Dpl-mutant males is not due to behavioral abnormalities, but may be due to a spermatogenesis defect. Indeed, *Prnd*^{-/-} sperm heads were severely malformed and lacked a discernible well-developed acrosome (Fig. 36.8). As the acrosome is essential for sperm-egg interaction, this defect could explain the sterility of *Prnd* deficient males.

In vitro fertilization (IVF) experiments confirmed that spermatozoa isolated from *Prnd*^{-/-} males were unable to fertilize wild-type oocytes. Spermatozoa of *Prnd*^{-/-} males never penetrated the zona pellucida. However, if the zona pellucida was partially dissected and IVF was performed with sperm suspension from *Prnd*^{-/-} males, fertility was partially rescued. These data indicate that *Prnd*^{-/-} spermatozoa are capable of oocyte fertilization, albeit at a lower frequency than controls, but that they cannot overcome the barrier imposed by the zona pellucida (Fig. 36.9).

A significant amount of PrP^C is expressed in mature spermatozoa. The PrP protein found in testes was truncated in its C terminus in the vicinity of residue 200 (Shaked *et al.*, 1999). A protective role for PrP against copper toxicity has been proposed: sperm cells originating from *Prnp* ablated mice were more susceptible to high copper concentrations than wild-type sperm. However, male *Prnp*⁰ knock-out mice are not sterile and produce normal litter sizes. PrP expressed in testes is clearly not capable of compensating for the absence of Dpl, suggesting non-redundant functions for the two proteins. However, Dpl may mask a minor function of PrP^C in testes development or spermiogenesis: therefore it will be very interesting to explore whether males lacking both PrP^C and Dpl might display a more severe defect than *Prnd*^{-/-} single mutant mice.

Fig. 36.8 Morphology of sperm in mice lacking the Doppel gene. Spermatozoa from Dpl-deficient mice are often heavily malformed. (A, B) Photographs of bright field images of spermatozoa isolated from wild-type (A) and *Prnd*^{-/-} mice (B). (C, D) Spermatozoa isolated from *Prnd*^{+/+} (C) and *Prnd*^{-/-} mice (D) were stained with mitotracker to detect mitochondria (in green) and with the DNA stain Hoechst (in blue). (E–H) Photographs of bright field images of sperm heads from *Prnd*^{+/+} (E) and *Prnd*^{-/-} mice (F–H).

At present the molecular mechanism of Dpl-regulated acrosome development is unclear. Dpl may be present on the acrosomic vesicles through its GPI-anchor, and possibly participate in acrosome morphogenesis. Alternatively, Dpl may regulate acrosome function in a more indirect way. We have also observed that sperm isolated from *Prnd*^{-/-} mice is greatly impaired in sperm–egg interaction and that *Prnd*^{-/-} spermatozoa fail to trigger the acrosomal reaction. Oligosaccharides have been implicated in sperm binding and signaling for the acrosome reaction, but the composition and structure of the essential carbohydrate moieties remain controversial (Wassarman *et al.*, 2001). Dpl is a highly glycosylated protein located at the outside of the plasma membrane (Moore *et al.*, 1999; Silverman *et al.*, 2000). It is possible that Dpl present on the

sperm plasma membrane is directly involved in sperm–egg interaction.

In this context, it is interesting to mention that the laboratory of David Melton in Edinburgh has reported a slightly different phenotype of Dpl deficient mice (communicated by Derek Paisley and David Melton at the international TSE conference in Edinburgh, September 2002). In contrast to the mice generated in Zurich, Doppel deficient homozygous males in Edinburgh appear to be able to fertilize eggs. In a series of *in vitro* fertilizations, the Melton laboratory has reported that progression to the early cleavage divisions occurred, but was soon thereafter followed by death of the embryos at the preimplantation stage. Instead, there were no obvious malformations of sperm. Whether this discrepancy is related to a divergent genetic background

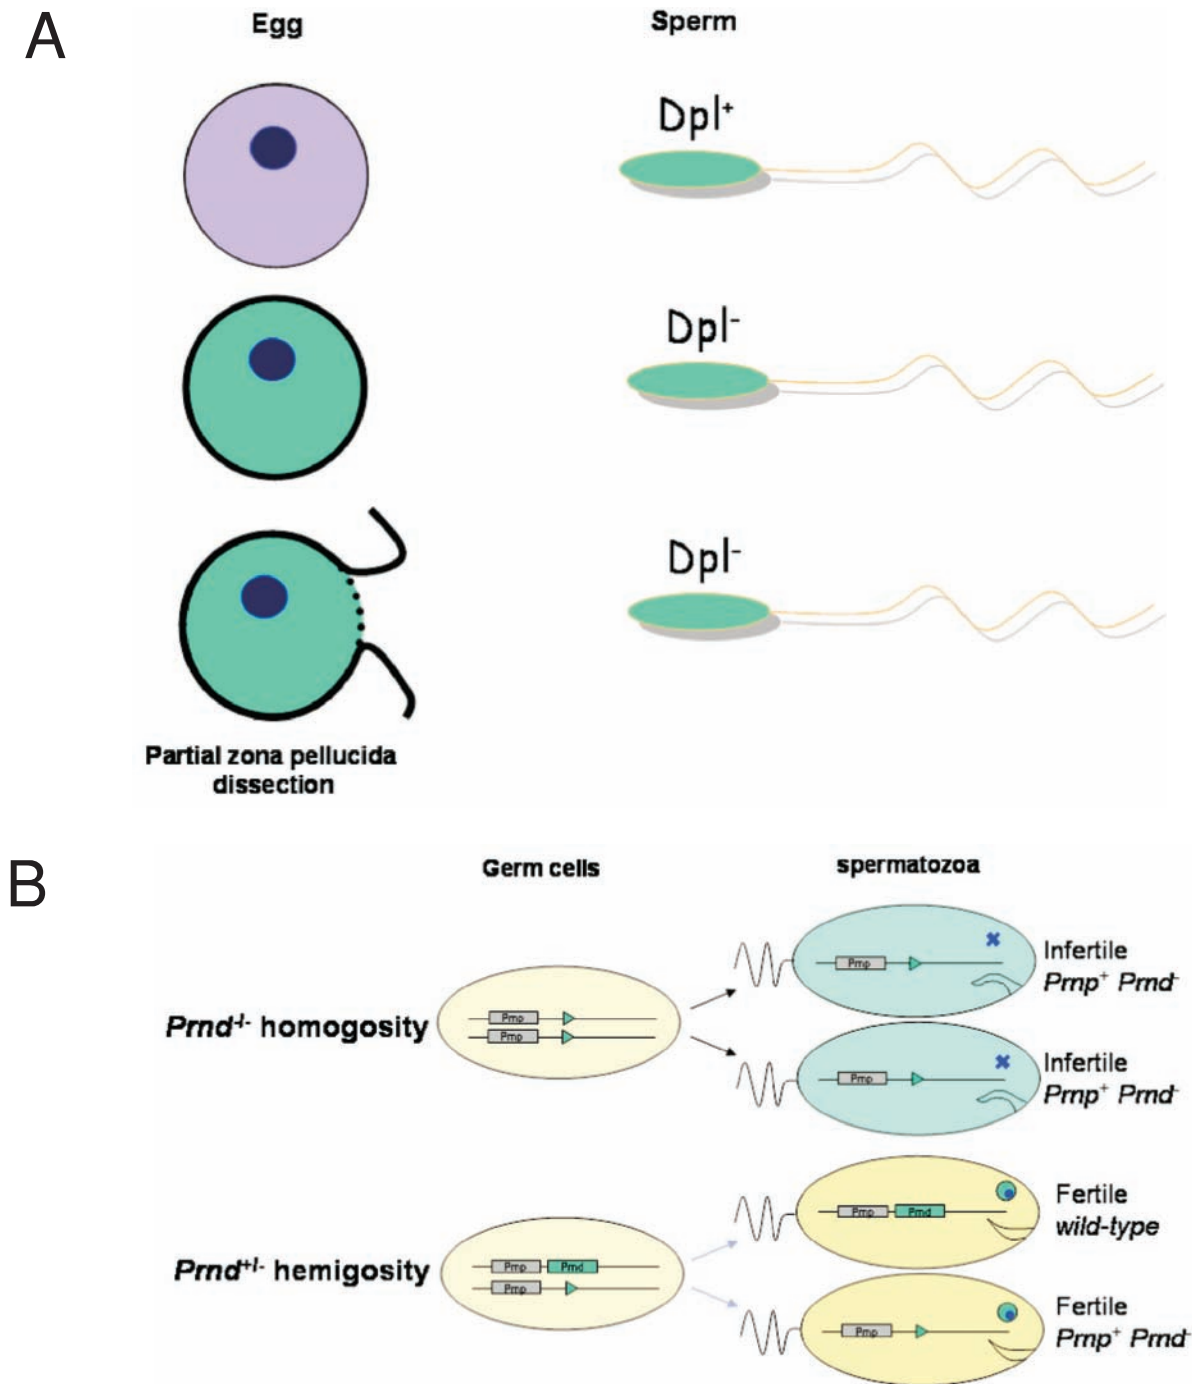

Fig. 36.9 A possible model for the function of Dpl in fertilization. (A) Male sterility in mice that lack the Doppel protein appears to come about because Doppel deficient sperms are incapable of fertilizing eggs. The process that appears to be disturbed relates to the acrosomal reaction and to the penetration of the zona pellucida. In fact, mechanical dissection of the zona pellucida restores, at least in part, fertility. (B) Interestingly, haploid spermatozoa lacking the Doppel gene ($Prnd^-$) are perfectly fertile when generated in the context of a heterozygous $Prnd^{+/-}$ mouse. Instead, $Prnd^-$ sperms are infertile when generated in a $Prnd^{-/-}$ mouse. This may be because sperms spend much of the maturation time in the form of syncytia, with maturing cells connected to each other by cytoplasmic bridges. This may allow sufficient amounts of Doppel protein to be transferred from $Prnd^+$ to $Prnd^-$ spermatids, and rescue fertility in *trans*.

of the mice utilized, whether it points to slightly different targeting strategies, or finally whether it might uncover yet another surprising phenomenon in the genetics of prion-related genes, is – at the time of writing – wholly unclear.

With regard to the keen interest in the development of new methods of contraception (in particular those targeting the male) the phenotype of *Prnd*^{-/-} mutant mice suggests that inhibition of Dpl function may provide a novel target for contraceptive intervention.

Perspectives in prion therapy

On the long run, one would hope that this accrued knowledge will be put into useful practice. To that effect, it is encouraging to note that a sizeable number of the steps in prion transport which have been discussed above appears to be rate-limiting. Because of that, these steps lend themselves as a target for interventions, which may be therapeutic or prophylactic (Aguzzi *et al.*, 2001b).

A number of substances appear capable of influencing the outcome of a contact of mammalian organisms with prions: a non-exhaustive list includes compounds as diverse as Congo red (Caughey & Race, 1992), amphotericin B (Pocchiari *et al.*, 1987), anthracyclin derivatives (Tagliavini *et al.*, 1997), sulfated polyanions (Caughey & Raymond, 1993), pentosan polysulphate (Farquhar *et al.*, 1999), soluble lymphotoxin-β receptors (Montrasio *et al.*, 2000), porphyrins (Priola *et al.*, 2000), branched polyamines (Supattapone *et al.*, 2001), and beta-sheet breaker peptides (Soto *et al.*, 2000). However, it is sobering that none of the substances have yet made it to any validated clinical use: quinacrine appears to represent the most recent unfulfilled promise (Collins *et al.*, 2002). On the other hand, the tremendous interest in this field has attracted researchers from various neighboring disciplines, including immunology, genetics, and pharmacology, and therefore it is to hope that rational and efficient methods for managing prion infections will be developed in the future.

A prion glossary

Prion: agent of transmissible spongiform encephalopathy (TSE), with unconventional properties. The term does not have structural implications other than that a protein is an essential component.

'Protein-only' hypothesis: Maintains that the prion is devoid of informational nucleic acid, and that the essential pathogenic component is protein (or glycoprotein). Genetic evidence indicates that the protein is an abnormal

form of PrP (perhaps identical with PrP^{Sc}). The association with other 'non-informational' molecules (such as lipids, glycosamino glycans, or maybe even short nucleic acids) is not excluded.

PrP^C: the naturally occurring form of the mature *Prnp* gene product. Its presence in a given cell type is necessary, but not sufficient, for replication of the prion.

PrP^{Sc}: an 'abnormal' form of the mature *Prnp* gene product found in tissue of TSE sufferers, defined as being partly resistant to digestion by proteinase K under standardized conditions. It is believed to differ from PrP^C only (or mainly) conformationally, and is often considered to be the transmissible agent or prion.

These definitions (Aguzzi & Weissmann, 1997) describe our terminology which is, however, not agreed on by convention and is not necessarily used by others.

Parkinson's and related movement disorders

Approach to the patient presenting with parkinsonism

Katie Kompoliti and Christopher G. Goetz

Section of Movement Disorders, Department of Neurological Sciences, Rush University Medical Center, Chicago, IL, USA

General symptomatology of patients with parkinsonism

In the nearly 200 years since James Parkinson's original essay on 'shaking palsy' (Parkinson, 1817), clinicians have learned that he described a syndrome rather than a specific disease and that Parkinson's has many imitators. As a syndrome, parkinsonism is characterized by tremor, bradykinesia, rigidity and postural reflex compromise. Parkinson's disease is one of many parkinsonian syndromes and is defined by the same clinical signs in association with a distinct type and pattern of cellular degeneration. Parkinsonism can occur as an isolated clinical syndrome, classified as primary when it is due to hereditary or idiopathic causes or secondary when it has another identifiable underlying etiology. When parkinsonism occurs in association with other neurological signs, it is classified as one of the well-defined parkinsonism-plus syndromes or as parkinsonism associated with defined hereditodegenerative disorders (Table 37.1). Parkinson's disease is the archetype of primary parkinsonism. A thorough history and comprehensive examination can usually differentiate Parkinson's disease from other parkinsonian syndromes. Nevertheless, clinicopathological studies have shown that 20% of patients thought clinically to have Parkinson's disease turn out to have pathological cellular changes suggestive of other diagnoses, and 5–10% of parkinsonian subjects with an atypical clinical picture for Parkinson's disease have the typical cellular changes of Parkinson's disease at autopsy (Hughes *et al.*, 2001).

Unilateral tremor is the most common initial symptom resulting in medical consultation for Parkinson's disease. Tremor is not the usual presenting sign in parkinsonism of other etiologies, and instead, gait impairment and slowness of movement are more typical early features. When the patient with parkinsonism first presents for evaluation,

more careful interview will often reveal that other symptoms of parkinsonism have been present for months and sometimes years. These components of the history include difficulty performing finger movements that require dexterity, uncomfortable sensations of tightness, stiffness, and aches, difficulty getting up, especially from deep chairs or couches, difficulty turning in bed, alteration in handwriting (micrographia), dragging of the involved leg(s), and a 'frozen shoulder' on the side of an affected limb that has led to prior orthopedic consultation, lack of spontaneous smile (masked face), absence of blinking (reptilian stare), 'bent over' (simian) posture, or simply the acknowledgment that there is an overall slowing and early fatigue when performing the activities of daily life (Weiner & Lang, 1989).

The earliest manifestation of gait involvement in parkinsonism is usually a subjective sense of imbalance resulting in stumbling, near-falls and falls. In Parkinson's disease, objective gait impairment is not a typical early disease manifestation. When present at the onset of the illness, the clinician should immediately consider diseases other than Parkinson's disease. Over time, however, Parkinson's disease patients start walking with a stooped posture and develop short-stepped, shuffling, uncertain steps, especially when pivoting. Gait initiation becomes particularly cumbersome, but once walking, the patient attains a forward momentum in a festinating manner. Freezing occurs often in late Parkinson's disease and can be especially pronounced at initiation of gait, turning, approaching a narrow or crowded space, and reaching an intended target.

When parkinsonian symptomatology is overshadowed by other complaints, alternative diagnoses involving multiple neuronal systems should be considered. These problems can be recurrent infections, speech and swallowing difficulties, vision problems, orthostatic dizziness, urinary urgency/frequency or incontinence, severe constipation, early impotence, cognitive impairment, depression,

Table 37.1. Parkinsonism

<i>Primary parkinsonism</i>
Dopa-responsive dystonia
Idiopathic Parkinson's disease
Juvenile parkinsonism
<i>Secondary parkinsonism</i>
Drugs
Antipsychotics, anti-emetics, tetrabenazine, reserpine, alpha-methyl-dopa, calcium channel blockers, lithium
Hemiparkinsonism–hemiatrophy syndrome
Hydrocephalus
Infectious
Encephalitis lethargica, acquired immune deficiency syndrome (AIDS), fungal, syphilis, subacute sclerosing panencephalitis (SSPE), subacute spongiform encephalopathy
Metabolic
Symptomatic basal ganglia calcification/parathyroid abnormalities
Acquired hepatolenticular degeneration
Neoplastic
Psychogenic parkinsonism
Toxins
1-methyl-4-phenyl-4-propionoxypiperidine (MPTP), Carbon monoxide (CO), manganese (Mn), cyanide, carbon disulfide, mercury (Hg), methanol, ethanol
Traumatic
'Punch drunk' syndrome
Vascular
<i>Parkinsonism-plus syndromes</i>
Corticobasal degeneration
Dementia syndromes
Alzheimer's disease, Dementia with Lewy bodies
Frontotemporal dementia–parkinsonism linked to chromosome 17
Multiple system atrophy
Olivopontocerebellar degeneration
Shy-Dragger syndrome
Striatonigral degeneration
Parkinsonism–dementia–amyotrophic lateral sclerosis complex of Guam
Progressive pallidal, pallidonigral, and pallidoluyisionigral degenerations
Progressive supranuclear palsy
<i>Hereditodegenerative disorders</i>
Ceroid lipofuscinosis
Familial basal ganglia calcification (Fahr's disease)
GM ₁ gangliosidosis
Gaucher's disease
Hallervorden Spatz disease
Huntington's disease
Mitochondrial encephalopathies
Neuroacanthocytosis
Spinocerebellar ataxia
Wilson's disease
X-linked dystonia–parkinsonism (Lubag)
Premutation carriers of fragile X

hallucinations or psychotic symptomatology and marked sleep disturbance. At times, the initial presentation of the patient with parkinsonism will suggest a specific diagnosis involving multiple neural pathways, but at other times, the full picture will remain obscure for some time. Even if patients are seen when their disease is already advanced, it may be difficult to arrive at the correct diagnosis, especially when the historical data regarding the sequence and time frame of events are lacking. The most instrumental tool available to the clinician in order to make the diagnosis of a parkinsonian patient is direct longitudinal observation over a period of years.

Clinical signs constituting the syndrome of parkinsonism

The four cardinal features of parkinsonism are tremor, bradykinesia, rigidity and postural reflex compromise. Tremor is the first motor manifestation in 75% of patients with Parkinson's disease, usually beginning in the distal limb unilaterally, in most cases an arm (Parkinson, 1817). The tremor of Parkinson's disease is termed rest tremor, because it is present when the involved body part is completely relaxed, and usually abates when the affected limb performs a motor task. Patients with Parkinson's disease commonly also have a postural or kinetic component to their tremor, and the presence of combined tremor types is consistent with the diagnosis, especially in more advanced stages of the disease. In contrast, tremor is not a prominent feature of other parkinsonian syndromes with the exception of drug-induced parkinsonism, and the parkinsonism associated with Wilson's disease.

Akinesia/bradykinesia refers to the difficulty patients with parkinsonism have in initiating and executing a motor plan. Early signs of bradykinesia may be confined to distal muscles (micrographia, difficulty buttoning a shirt, or executing movements with fine motor manipulations that require dexterity). Facial and vocal manifestations of bradykinesia begin early in the course of parkinsonism and masked facies, decreased blink rates and a hypophonic voice may be apparent to the clinician even before the formal examination begins. Sequential or rapid alternating movements are impaired with decreased amplitude and frequency (Weiner & Lang, 1989).

Rigidity is the increase in muscle tone that affects all muscle groups, axial and appendicular, flexors and extensors. In early Parkinson's disease, rigidity is more appendicular than axial. The opposite is true in several other parkinsonian syndromes, the classic being progressive supranuclear palsy, where axial rigidity occurs far out of

proportion to involvement of appendicular muscles. The rigidity in parkinsonism can be either smooth (lead pipe) or ratchety (cogwheel). Cogwheeling is felt by some to reflect in part the superimposed rest tremor. Rigidity can be reinforced by voluntary movements of the contralateral limb (Paulson & Sten, 1997).

Postural instability underlies much of the gait disorder or parkinsonism. It is the last cardinal feature of idiopathic Parkinson's disease to appear, but carries the most morbidity. In advanced disease, it is among the least responsive signs to pharmacological manipulation (Agid *et al.*, 1989). The examiner can elicit this finding by standing behind the patient and pulling backwards from the shoulders. In a normal response, patients will remain steady or take two steps backwards to catch themselves. With impaired postural reflexes, patients will take several steps or will fall if not caught by the examiner. Whereas bradykinesia and postural reflex impairment account for most aspects of the gait disorder of Parkinson's disease, when additional neurological signs are present and impede standing or ambulation, other syndromes should be considered more likely. In cases of multiple system atrophy of the olivopontocerebellar variant, additional midline ataxia with wide based gait and inability to stand with the feet together occurs. In corticobasal degeneration, a dystonic limb and dyspraxia can impair gait (Quinn, 1989). In progressive supranuclear palsy, poor downward control of eye movements causes added walking impairment.

Other signs to evaluate

The presence of early axial dystonia before initiation of levodopa treatment questions the diagnosis of idiopathic Parkinson's disease. Disproportionate anterocollis is suggestive of multiple system atrophy, while a retrocollis neck is suggestive of progressive supranuclear palsy (Colosimo *et al.*, 1995). Appendicular dystonia not associated with antiparkinsonian medication regimens can be seen in drug-induced parkinsonism, corticobasal degeneration and hereditodegenerative disorders (Table 37.1).

Cerebellar signs can herald the involvement of multiple neuronal systems typical of metabolic and toxic illnesses or be a clue to the specific diagnosis of multiple system atrophy. In the latter, cerebellar involvement presents as gait ataxia with less frequent appendicular dysmetria (Shulman & Weiner, 1997). Dysarthria is present in most patients, but the speech is not necessarily scanning. Ocular findings, such as nystagmus, jerky pursuit, ocular dysmetria, and fixation instability are common in patients with multiple system atrophy. Elderly men who carry the premutation

for fragile x have been reported to develop a mixed syndrome of parkinsonism, ataxia, dystonia and mild cognitive impairment. Pyramidal signs, including exaggerated deep tendon reflexes, extensor plantar responses, pseudobulbar palsy, and spasticity can be seen in multiple system atrophy, progressive supranuclear palsy, and vascular parkinsonism. The presence of prominent extrapyramidal rigidity and bradykinesia can often mask both the pyramidal and cerebellar findings.

Supranuclear ophthalmoplegia, initially affecting saccadic eye movements in the downward direction, is the hallmark of progressive supranuclear palsy (Golbe, 1997). In a study of 14 patients with Parkinson's disease, 14 patients with striatonigral degeneration, 10 patients with corticobasal degeneration, and 10 patients with progressive supranuclear palsy, vertical saccade paralysis was observed in 9 out of 10 patients with progressive supranuclear palsy but none in the other groups (Vidailhet *et al.*, 1994). In the corticobasal degeneration group, saccade latency was significantly decreased and correlated to an 'apraxia' score, whereas in the progressive supranuclear palsy group, saccade amplitude was significantly decreased. The percentage of errors in the anti-saccade task, an index of prefrontal dysfunction, was markedly increased only in the progressive supranuclear palsy group (Vidailhet *et al.*, 1994).

Autonomic dysfunction in a patient with signs and symptoms of parkinsonism does not immediately imply the diagnosis of multiple system atrophy, since it may also occur in Parkinson's disease. In a retrospective review of autonomic dysfunction in pathologically confirmed cases of multiple system atrophy and Parkinson's disease, autonomic failure occurred in 84% of the multiple system atrophy cases and 26% of the Parkinson's disease cases (Wenning *et al.*, 2000). Autonomic dysfunction in multiple system atrophy involved more autonomic functions and was more severe than that seen in Parkinson's disease, particularly with regard to inspiratory stridor (Magalhaes *et al.*, 1995). Although autonomic disturbance alone does not distinguish between multiple system atrophy and Parkinson's disease, the presence of severe autonomic dysfunction, preceding parkinsonism, and the specific occurrence of inspiratory stridor are more suggestive of multiple system atrophy (Magalhaes *et al.*, 1995). Signs of autonomic failure include orthostatic hypotension, urinary disturbance, constipation, male impotence, and dysphagia.

Mental status remains relatively intact in early idiopathic Parkinson's disease, although executive memory impairment can be detected with appropriate tests. Dementia occurs late in the course of idiopathic Parkinson's

disease in approximately 20 to 30% of patients (Mayeux *et al.*, 1981, 1990). Parkinsonian features in a patient associated with early-onset dementia should raise the possibility of dementia with Lewy bodies or, less commonly, atypical parkinsonian syndromes, including multiple system atrophy, progressive supranuclear palsy and corticobasal degeneration. Although prominent dementia or behavioral changes are uncommon early in multiple system atrophy and progressive supranuclear palsy, corticobasal degeneration and Alzheimer's disease with extrapyramidal features can often present as dementia or aphasia (Bergeron *et al.*, 1998).

Differential diagnosis of parkinsonism

During life, the diagnosis of the different parkinsonian syndromes relies on the clinician's expertise, but the ultimate diagnosis is made by neuropathological evaluation. For research purposes, arriving at the right diagnosis is important in order to be able to study neuroprotective treatments and conduct epidemiological studies. For patient care purposes, because the prognosis is different for the various disorders, an accurate diagnosis permits the physician to relay the most pertinent information to the patient and the family. Furthermore, treatment outcomes are different in the various parkinsonian syndromes and with an accurate diagnosis, the neurologist can tailor the management to address the specific disease entity and its clinical elements. Unfortunately, misdiagnosis is especially high during the early stages, even among movement disorder specialists, so continual vigilance and rethinking of diagnoses are essential in all parkinsonian patients (Hughes *et al.*, 1992; Rajput *et al.*, 1991; Litvan *et al.*, 1996, 1998; Hughes *et al.*, 1992).

Rajput *et al.* (1991) reported autopsy results in 59 patients with parkinsonism, followed longitudinally by a single neurologist, who based his original diagnosis on the presence of two out of three cardinal features (tremor, bradykinesia, rigidity). He excluded cases with evidence of any other identifiable cause of parkinsonism or other central nervous system lesions. Patients with postural instability as an original sign were also excluded, as the sign is not generally present in early Parkinson's disease. From this cohort, the clinical diagnosis of Parkinson's disease was retained over the study period in 41/59 but only 31 (75%) showed histopathological signs of Parkinson's disease at autopsy.

Another clinicopathological study found that only 69–75% of patients with autopsy-confirmed diagnosis of Parkinson's disease had at least two of the three cardinal features listed above, while 20–25% of patients who showed

two of these cardinal features had a pathological diagnosis other than Parkinson's disease. Furthermore, 13–19% of patients with all three cardinal features had another pathological diagnosis (Gelb *et al.*, 1990).

Based on multiple studies, the best predictive diagnostic variables for idiopathic Parkinson's disease compared to other diagnoses in studies with clinico-pathological correlation appear to be: asymmetrical parkinsonism, rest tremor, and levodopa response (moderate to excellent response or levodopa-induced dyskinesias) (Hughes *et al.*, 2001; Litvan *et al.*, 1998). Other significant predictors are the absence of atypical features, such as: extensor plantar response, early dementia, early marked autonomic disturbance, supranuclear gaze palsy, and bulbar palsy (Hughes *et al.*, 2001).

The epidemiology of the differential forms of parkinsonism

Signs of parkinsonism are frequently found on neurologic examination of older people. A stratified random sample of 467 residents of East Boston, Massachusetts, 65 years or older, was given structured neurological examinations in order to estimate the prevalence of parkinsonism in a community population (Bennett *et al.*, 1996). Parkinsonism was defined as at least two of the four cardinal features (bradykinesia, rigidity, tremor, and gait disturbance). The overall prevalence estimates of parkinsonism were 14.9% for people 65 to 74 years of age, 29.5% for those 75 to 84, and 52.4% for those 85 and older. Adjusted for age and sex, the overall risk of death among people with parkinsonism was 2.0 times that among people without it. Gait disturbance was the sign associated with this increased risk of death.

Although there is abundant literature on the epidemiology of idiopathic Parkinson's disease (Tanner & Goldman, 1996), the frequency of specific forms of atypical parkinsonism has rarely been estimated (Golbe, 1994; Bower *et al.*, 1997; Rajput *et al.*, 1984; Schrag *et al.*, 1999; Vanacore *et al.*, 2001a,b). In a postmortem cohort of 620 cases, with parkinsonian syndromes, parkinsonism-plus syndromes accounted for 10.2% and secondary parkinsonism for 10.8% (Jellinger, 1996). More specifically, progressive supranuclear palsy accounted for 2.7% of this series, multiple system atrophy 2.4%, Alzheimer's disease 3.5%, other degenerative syndromes (dementia with Lewy bodies, corticobasal degeneration, Pick's disease, and parkinsonism-dementia complex of Guam) 1.5%, vascular parkinsonism 3.2%, post-encephalitic 2.6%, toxic and drug-induced 1%, post-traumatic 0.6%, and symptomatic parkinsonism from

tumor, hydrocephalus and prion disease 0.8%. This series was collected from 1957–1993 and this time frame accounts for the higher than usual prevalence of post-encephalitic cases (Jellinger, 1996). This series is of interest in regards to the referenced population, but carries the limitation of referral bias.

Studies of the prevalence of progressive supranuclear palsy have estimated the age-adjusted prevalence rate between 1.4–6.4 per 100 000 (Schrag, 1999; Golbe, 1996). Since the diagnosis of progressive supranuclear palsy is frequently made several years after onset of symptoms, this figure probably underestimates the prevalence of progressive supranuclear palsy. The incidence of progressive supranuclear palsy has been measured directly in two populations: Perth, Australia (population 1 million) over 2 years and Rochester, Minnesota (population 50 000) over 13 years, giving crude incidences of 3.0–4.0 per million per year, approximately 5% of that of idiopathic Parkinson's disease (Rajput *et al.*, 1984; Mastaglia *et al.*, 1973).

Multiple system atrophy accounts for 8–22% of brains in parkinsonian brain banks (Colosimo *et al.*, 1995; Rajput *et al.*, 1991). The prevalence rate has been estimated to be 4–5 cases per 100 000 persons (Schrag *et al.*, 1999; Vanacore *et al.*, 2001a) and the incidence rate 0.6 cases per 100 000 persons per year (Vanacore *et al.*, 2001a). Data on other parkinsonism-plus syndromes, like corticobasal degeneration are largely based on biased samples derived from small autopsy series with cases originating from specialty clinics rather than from more widely dispersed or population-based sources.

Drug-induced parkinsonism is one of the most frequent causes of symptomatic parkinsonism (Bower *et al.*, 1999). The most commonly associated offending agents are neuroleptics. The reported prevalence of drug-induced parkinsonism in patients receiving neuroleptics is 10–15% (Moleman *et al.*, 1986). Infectious causes of parkinsonism are extremely rare with the obvious exception of post-encephalitic parkinsonism associated with encephalitis lethargica. It is remarkable that the encephalitis lethargica epidemic, reaching dimensions that justify the description of a pandemic, has all but completely disappeared. Other causes of secondary parkinsonism, such as vascular and trauma-related, have been a subject of debate, preventing any clarification of their prevalence and incidence. Finally, although the list is long (see Table 37.1), parkinsonism associated with hereditometabolic diseases is extremely rare with the exception of Wilson's disease. Estimates of the prevalence of Wilson's disease vary widely, but the most frequently quoted figure is 30 cases per million (Saito, 1981).

Anatomy, physiology and biochemistry as they apply to the clinical signs of parkinsonism

Advances in molecular genetics and pathology are leading to a new classification for degenerative diseases that damage the basal ganglia. Many forms of parkinsonism can now be viewed as being caused predominantly by the genetic or sporadic occurrence of conditions associated with either alpha-synuclein or tau protein deposition. For some parkinsonian syndromes, autosomal-dominant mutations have been identified with links to the genes encoding for these proteins (Polymeropoulos *et al.*, 1997; Hutton *et al.*, 1998). For the sporadic disorders, abnormal deposition of these proteins correlates with cell loss. Therefore, in both hereditary and sporadic diseases, abnormal protein–protein interaction and/or lesions that result from the aggregation of pathological protein fibrils could play a mechanistic role in the dysfunction and death of neurons or glial cells in neurodegenerative diseases (Trojanowski & Lee, 2000). In a large number of seemingly diverse neurodegenerative disorders, abnormal interactions among normal brain proteins alter their conformation and promote their assembly into filaments that progressively accumulate as intracellular or extracellular fibrous deposits in the central nervous system. Whether inclusion body formation is an adaptive response or is directly related to degeneration of neuronal and glial cells is a topic of current research.

Tau is a microtubule associated protein that plays an important role in neuronal axonal transport. Abundant tau-positive inclusions are found in several diseases presenting with parkinsonism. These include: progressive supranuclear palsy, corticobasal degeneration, postencephalitic parkinsonism, Alzheimer's disease, dementia pugilistica, Down syndrome, frontotemporal dementia-parkinsonism linked to chromosome 17, Pick's disease, subacute sclerosing panencephalitis, amyotrophic lateral sclerosis-parkinsonism-dementia complex of Guam, and Niemann-Pick disease type C. (Dickson, 1999; Feany & Dickson, 1996; Morris *et al.*, 1999; Lee *et al.*, 2000). Its specific role in the development of clinical signs of parkinsonism is under active investigation.

The synucleins are a family of soluble proteins that often occur in the brain of subjects with parkinsonian signs, but their specific function is not well understood. Beginning with the isolation of the fragment of alpha-synuclein known as the non-Abeta component of amyloid plaques from Alzheimer's disease brains, alpha-synuclein has been increasingly implicated in the pathogenesis of neurodegenerative diseases, which are now classified as synucleopathies (Duda *et al.*, 2000). Shortly thereafter,

alpha-synuclein was shown to be a major component of Lewy bodies and Lewy neurites in sporadic idiopathic Parkinson's disease (Dickson, 1999; Duda *et al.*, 2000; Galvin *et al.*, 2001). Diseases associated with abnormal alpha-synuclein depositions include: idiopathic Parkinson's disease, dementia with Lewy bodies, Alzheimer's disease, Down syndrome, multiple system atrophy, neurodegeneration with brain iron accumulation, type 1 (Hallervorden-Spatz, neuroaxonal dystrophy), Pick's disease, and traumatic brain injury (Galvin *et al.*, 2001). For several parkinsonism-plus syndromes, neuropathological criteria have been established, and clinical signs that best predict the neuropathological findings have been tested.

Neuropathological criteria for progressive supranuclear palsy have been outlined by a task force organized by the National Institute of Neurological Disorders and Stroke (NINDS). Typical, atypical and combined progressive supranuclear palsy has been distinguished. Typical progressive supranuclear palsy is marked by variable neuronal loss and gliosis with widespread neurofibrillary tangles and neuropil threads in the basal ganglia, brainstem, including oculomotor complex, inferior olives, and dentate nucleus. Involvement of the cerebral cortex mainly involves prefrontal/precentral regions with sparing of the association areas predominantly affected in Alzheimer's disease. In atypical progressive supranuclear palsy either the severity or the distribution of the lesions, or both, deviates from the typical pattern. In combined progressive supranuclear palsy, the typical pathology of progressive supranuclear palsy is accompanied by findings from other neurodegenerative diseases (Hauw *et al.*, 1994). The neurofibrillary tangles seen in progressive supranuclear palsy contain straight filaments composed of abnormally phosphorylated tau proteins (tau 64, 69) and ubiquitin, with few paired helical filaments, distinguishing them from neurofibrillary tangles in Alzheimer's disease, postencephalitic parkinsonism, and amyotrophic lateral sclerosis-parkinsonism-dementia complex of Guam, which are composed of paired helical filaments with few straight filaments (Jellinger, 1996).

Based on these pathological changes, clinical signs that best correlate with a final, accurate postmortem diagnosis of PSP have been studied. Two clinical categories, possible PSP and probable PSP, have differing sensitivity and specificity profiles (Litvan *et al.*, 1996). In the case of probable PSP, defined as a progressive disorder with onset at age 40 or greater and the presence of vertical gaze paresis, prominent postural instability, and falls in the first year of disease, these criteria accurately differentiate PSP from other parkinsonian syndromes. The sensitivity of this set of

clinical criteria is only 50%, but the specificity and positive predictive value are both 100%.

In multiple system atrophy there is gross atrophy and gliosis in substantia nigra and striatum, accompanied by deposition of granular lipofusin-iron pigment. Additional findings may include olivopontocerebellar and other brainstem nuclei degeneration, as is the case in olivopontocerebellar atrophy, or intermediolateral neuron loss combined with damage to the peripheral autonomous nervous system, as is the case in Shy-Drager syndrome (Jellinger, 1998). The characteristic inclusions of multiple system atrophy are cytoplasmic oligodendroglial inclusions, consisting of 25 nm tubules, reacting with antibodies to tau, ubiquitin, tubulin, α - β -crystallin, and rare ubiquitin-positive neuronal inclusions (Jellinger, 1998).

Clinical criteria to establish a high correlation with neuropathological changes typical of multiple system atrophy have also been studied (Quinn, 1989; Wenning *et al.*, 2000; Litvan *et al.*, 1997; Gilman *et al.*, 1999). Using a list of 17 clinical signs or symptoms, Wenning demonstrated that when at least 11 items were positive, the sensitivity of this criterion was 90% with a specificity of 93% (Wenning *et al.*, 2000). This study shows that, when a large series of clinical signs are assembled and analysed, accurate diagnosis during life is possible for this condition.

In corticobasal degeneration there is gross circumscribed/lobar frontal or parietal atrophy. Histologically, there is severe neuronal loss and astrogliosis in the frontal/parietal cortex, substantia nigra and basal ganglia. The cortex shows severe neuronal loss, astrogliosis, spongiosis and ballooned or achromatic tau and ubiquitin-positive neurons, neurofibrillary tangles and neuropil threads. Substantia nigra and basal ganglia reveal severe degeneration, and basophilic skein-like tau-positive, ubiquitin-negative inclusions composed of 15 nm straight filaments are distributed in the substantia nigra, subthalamic nucleus, striatum and pallidum (Wakabayashi *et al.*, 1994).

The clinical characteristics and the pathological lesions of vascular parkinsonism are still debatable (Yamanouchi & Nagura, 1997). While cerebrovascular lesions occur in 6–10% of idiopathic Parkinson's disease patients, vascular parkinsonism has a distinct clinical presentation characterized by predominantly lower body parkinsonism, early gait impairment and lack of response to levodopa (Jankovic, 1989). In autopsy series of patients with parkinsonism, vascular brain lesions are seen in 1–3.2% (Jellinger, 1996). These include multilacunar state, Binswanger's subcortical vascular lesions, and/or strategically placed infarcts in the basal ganglia or substantia nigra with little or no degeneration in the substantia nigra.

In parkinsonism due to carbon monoxide, carbon disulfide and cyanide lesions are found in globus pallidus, substantia nigra and other areas. In manganese-induced parkinsonism, there is neuronal loss and gliosis in the pallidum and striatum with little nigral damage with or without Lewy bodies. Parkinsonism associated with chronic lead intoxication is associated to lesions in the substantia nigra. The neuropathology of MPTP-induced parkinsonism shows neuronal loss and gliosis in the substantia nigra pars compacta without typical Lewy bodies and selective damage to the dopamine-containing neurons of A9 area with variable involvement of the other regions (Snow *et al.*, 2000). The neuropathology of neuroleptic-induced parkinsonism is poorly understood (Jellinger, 1998). Pugilistic encephalopathy or boxer's dementia shows diffuse cortical atrophy, severe cell loss in the substantia nigra, locus ceruleus and striatum with widespread neurofibrillary tangles and β -amyloid, similar to the ones seen in Alzheimer's disease, throughout the central nervous system (Jellinger, 1996).

Clinical approach to the investigation of parkinsonism

The diagnosis of the patient presenting with parkinsonism begins with a careful history and physical examination. One should view the first encounter with the patient as a snapshot of an evolving disease, revealing an isolated point in time. Knowledge on disease progression and response to treatment complement the picture and enhance more accurate conclusions. Laboratory and radiological surrogate investigations may help establish the diagnosis, especially when atypical features are seen in either the history or physical examination.

In a young patient presenting with parkinsonism, considerations include hereditodegenerative diseases as outlined in Table 37.1. Laboratory tests, investigating metabolic or genetic abnormalities can help diagnose most of the disease entities listed depending on the context of the patient's presentation and the age group. One important consideration when dealing with a patient with young onset parkinsonism is to rule out Wilson's disease, since it requires specific treatment. Serum ceruloplasmin, 24-hour urine collection for copper determination, and slit-lamp examination for Kayser–Fleischer ring detection can help reach the diagnosis most of the time. Additional tests include determination of the rate of incorporation of radiocopper into ceruloplasmin, neuroimaging studies, neurophysiological studies, free serum copper, and cerebrospinal fluid copper levels. If all of the above are inconclusive, determination of

hepatic copper content via liver biopsy is the single most sensitive and accurate test for Wilson's disease.

The role of structural imaging in the understanding and diagnosis of the patient with a hypokinetic movement disorder is a limited one. Computed tomography/magnetic resonance imaging (CT/MRI) findings rarely help establish the diagnosis in neurodegenerative diseases. An inconsistent finding in Parkinson's disease is increased signal on T₂-weighted images in the substantia nigra (Duguid *et al.*, 1986; Rutledge *et al.*, 1987). In striatonigral degeneration, significant hypointensity is observed in the putamen in T₂-weighted images, consistent with magnetic susceptibility effects of iron or other paramagnetic substances (Gorell *et al.*, 1995; Pastakia *et al.*, 1986). In the early stages of the olivopontocerebellar variant of multiple system atrophy, there is atrophy of the pons in the midline sagittal section in T₁-weighted images, seen as flattening of the inferior part, with loss of its normal bulging over the medulla oblongata. With advancing disease, proton density and T₂-weighted images show mild to moderate increases in signal intensity in the transverse pontine fibres, middle cerebellar peduncles, and cerebellar cortex. If the above findings are mild or poorly appreciable in transverse sections, coronal sections allow for easy comparison with the normal signal intensity of the supratentorial structures (Savoirdo *et al.*, 1990, 1993). Obvious midbrain atrophy is present in approximately half of the clinically diagnosed cases with progressive supranuclear palsy. This finding is better visualized in sagittal than in transverse sections. Also, a concaved floor of the third ventricle observed in axial sections, reflects atrophy of the diencephalon (Savoirdo *et al.*, 1994). The MRI findings of patients with corticobasal degeneration are consistent with cerebral atrophy, most marked in the superior frontal and parietal regions, and asymmetrical, with more marked degeneration on the side contralateral to the prominent clinical symptoms (Savoirdo *et al.*, 2000).

Two main abnormalities are expected on MRI scans of patients with Wilson's disease. The first is high signal intensity on proton density and T₂-weighted images in the putamen, lateral thalami, red nuclei and periaqueductal area, and pons. These abnormalities are caused by neuronal loss, gliosis and vacuolization. The second type of MRI changes consist of a decrease or loss of signal intensity on T₂-weighted images in the putamen, pallidum, and, more rarely, head of the caudate, likely caused by deposition of copper (van Wassenae-van Hall *et al.*, 1996). Finally, MRI can be very helpful in establishing the diagnosis in parkinsonian syndromes associated with cerebrovascular disease, hydrocephalus, neoplasms, trauma, symptomatic basal ganglia calcifications/parathyroid abnormalities or

Fahr's disease, hemiparkinsonism-hemiatrophy syndrome and certain infections.

Functional imaging techniques provide a new means of detecting and characterizing regional changes in brain metabolism and receptor binding. Although these neuroimaging tools offer future hope to explain the clinical symptomatology of parkinsonism in different diseases, they remain research strategies and offer only suggestive data for the individual patient. Among the several different approaches to functional imaging, positron emission tomography (PET) allows for quantitative examination of regional cerebral blood flow, glucose and oxygen metabolism, dopamine metabolism (the presynaptic and postsynaptic components of the dopaminergic system), and brain pharmacology. Single photon emission computed tomography (SPECT) is less sensitive but more widely available and can give estimates of regional blood flow, the function of the presynaptic dopaminergic system through measurements of the dopamine transporter, and receptor binding. Magnetic resonance spectroscopy (MRS) has a lower resolution than both of the above-mentioned techniques and provides measures of metabolite levels (*N*-acetyl-aspartate, lactate, phospholipids, adenosine triphosphate). Finally, functional MRI can be used to measure changes in brain activation (Brooks, 1997). Future refinements in functional imaging techniques may be valuable in the diagnosis of the patient presenting with parkinsonism and define the pathophysiology underlying the specific syndromes. Because the four primary features of parkinsonism are clinically distinct and may not present or progress in unison, these tools may help to track the specific lesions associated with individual parkinsonian signs. Furthermore, they may provide a means of detecting subclinical disease, measuring disease progression and investigating treatments designed to alter disease progression.

Parkinson's disease

Christopher G. Goetz and Katie Kompoliti

Department of Neurological Sciences Rush University Medical Center, Chicago, IL, USA

Historical background

James Parkinson, a London physician, first described Parkinson's disease in 1817, using the term *paralysis agitans* (Parkinson, 1817; Roberts, 1997). The distinctive features of tremor, rigidity, and gait difficulties were appreciated in this early monograph (Goetz *et al.*, 2001). Over 50 years later, in his teaching at the Salpêtrière Hospital, the world renowned French neurologist, Jean-Martin Charcot, was more thorough in describing the varied features of the illness and distinguished the hallmark of bradykinesia (Charcot, 1879). He recognized the arthritic changes, dysautonomia, and pain that can accompany the disease. Brissaud (1895) drew attention to midbrain lesions, but Greenfield and Bosanquet (1953) performed the most complete delineation of the selective cell loss, depigmentation and degeneration of the substantia nigra. In the 1960s, the biochemical and pharmacologic discoveries that dopamine was depleted in Parkinson's disease and that levodopa, as the precursor to this neurotransmitter, could improve Parkinson's disease signs were described in landmark studies (Barbeau, 1962; Birkmayer & Hornikewicz, 1962; Cotzias *et al.*, 1967). Besides pharmacological therapy, surgical interventions likewise have a long-standing history in Parkinson's disease treatment (Speelman & Bosch, 1998). Although public awareness of Parkinson's disease has been heightened by recognition of the disease in certain actors, political leaders, and public figures, probably the most notorious historical figure afflicted with parkinsonism was Adolph Hitler (Gerstenbrand & Karamat, 1999; Horowski *et al.*, 2000).

Morphological patterns of vulnerability (pathology)

Pathological findings of Parkinson's disease are discreetly dispersed in highly specific regions of the central nervous

system (see Chapter 39). The primary focus of disease involvement is the *pars compacta* portion of the substantia nigra in the midbrain where marked depigmentation and neuronal loss occur (Jankovic & Stacy, 1999). These cells project predominantly to the putamen. In addition to degeneration, intracytoplasmic eosinophilic inclusion bodies, termed Lewy bodies, are a hallmark of Parkinson's disease and occur in the substantia nigra as well as other pigmented nuclei like the locus ceruleus and the dorsal motor nucleus of the vagus nerve (Andersen, 2000). Lewy bodies are composed of neurofilament tubulin components, alpha-synuclein, ubiquitin and Torsin A, a protein product of the DYT1 gene (Lucking & Brice, 2000). Pale bodies are also characteristic of Parkinson's disease, are composed of neurofilament interspersed with vacuolar granules, and distribute themselves in the substantia nigra as well as the basal ganglia, cortex, brainstem and spinal cord (Shashidharan *et al.*, 2000). Because of the relatively discreet areas of neuronal loss, research efforts have been directed towards specific biochemical features of nigrostriatal cells in an effort to understand their selective vulnerability.

Biochemical patterns of vulnerability (neurochemistry)

Because the degenerating cells of the substantia nigra produce the neurochemical, dopamine, Parkinson's disease has become the prototypic disorder of a single neurochemical deficiency affecting a single primary anatomical system (see Chapter 39). Anatomical and physiological studies of parkinsonian animals and patients with Parkinson's disease confirm the important balance between two dopaminergic systems, termed the direct and indirect (Obeso *et al.*, 2000; Smith & Kieval, 2000; Beal, 2001). The prototypic

construct posits that in Parkinson's disease, activity in the direct pathway, linked to the D1 receptors, is diminished and activity in the indirect pathway, linked to D2 receptors, is enhanced (Graybiel, 2000). These effects cause aberrant outflow from the globus pallidus, subthalamic nucleus, and thalamus to decrease thalamo-cortical activation. Several other nuclei and transmitter receptor systems play indirectly into this basic system. Some inconsistencies in this archetypic schema exist and have prompted continual studies and resultant modifications (Blandini *et al.*, 2000; Rodriguez *et al.*, 2000).

A number of intertwining biochemical clues have suggested that Parkinson's disease involves free radical toxicity from oxidative reactions (Olanow, 1990). MPTP, a designer drug self-injected by drug addicts, causes a clinical syndrome closely resembling Parkinson's disease and represents the single best example of an environmental compound that can induce parkinsonism without marked accompanying signs of diffuse or multifocal neurotoxicity (Langston *et al.*, 1983). With the discoveries that MPTP is a protoxin, that MPP⁺ is the actual toxin, and that the conversion of MPTP to MPP⁺ involves the enzyme monoamine oxidase B, oxidative biochemistry gained increasing attention (Heikkila *et al.*, 1984). Based on the observation that animals treated with both MPTP and a monoamine oxidase B inhibitor did not develop parkinsonian toxic signs, a potential protective effect of monoamine oxidase B inhibition was suggested for Parkinson's disease.

Free radicals react almost instantaneously with membrane lipids and cause lipid peroxidation, membrane injury, and cell death (Grunblatt *et al.*, 2000). Dopamine is metabolized by oxidation reactions capable of generating free radical byproducts. Whereas the substantia nigra of Parkinson's disease patients contains high levels of iron, a facilitator of oxidation, and decreased levels of glutathione, a protector against free radical formation, these two features may explain in part the selective degeneration of nigral cells in Parkinson's disease (Youdim *et al.*, 1993). The specific interaction of dopamine and metal ions has been posited to activate an ordered cascade of events leading to cell death (Jimenez del Rio & Velez-Pardo, 2000). Mitochondrial respiratory failure and oxidative stress appear to be two important contributors to neuronal death in the substantia nigra of patients with Parkinson's disease. Complex I deficiency, reported by many investigators, appears to be one of the basic abnormalities related to this respiratory failure. It is not established whether Complex I deficiency is primary and inherited or secondary to environmental influences, and the deficiency may develop from a combination of the two. Second, it is still not established whether the identified Complex I deficiency is isolated,

diffuse, but more pronounced in the nigrostriatal system or equally distributed in all systemic cells. It is known that high dopamine content is in itself a high oxidative stress environment, suggesting at least one mechanism whereby the nigrostriatal system may be particularly vulnerable to degeneration by these mechanisms (Mizuno *et al.*, 1998b). These observations suggest that oxidative stress is a pivotal part of the biological basis of Parkinson's disease and that antioxidant therapies may slow down nigral degeneration in Parkinson's disease.

Other neurotransmitters besides dopamine, including norepinephrine and serotonin, are affected in Parkinson's disease, but unlike animal models of parkinsonism, human Parkinson's disease is not associated with changes in striatal expression of Substance P and methionine enkephalin (Levy *et al.*, 1995). New attention has particularly focused on the adenosine A2A receptor (Richardson, 2001), glutamate (Chase & Oh, 2000; Greenamyre *et al.*, 2001), neurotrophic factors (Howells *et al.*, 2000; Siegel & Chauhan, 2000), and more detailed analyses of the multiple subtypes of dopamine receptors (Oak *et al.*, 2000; Sealton & Olanow, 2000). The pedunculopontine nucleus, predominantly under cholinergic control, is a current focus of physiologic studies of the initiation of programmed movements and sleep function (Pahapill & Lozano, 2000).

Concepts regarding etiology

In the past, neuroscientists implicitly held to the concept that Parkinson's disease was a single and specific morbid entity with a particular, though not yet identified, etiology. This pillar has been questioned (Duvoisin, 1989), with suggestions that nigral cells can be killed from multidimensional factors that include genetic, endogenous biochemical derangements, and exogenous toxins (see Chapters 1 and 2). The role of genetics in Parkinson's disease has been argued for decades, and the follow-up study from the World War II Veteran Twins Registry demonstrated an overall similarity in concordance for monozygotic and dizygotic twins. The study concluded that genetic influences were not important to the etiology of typical Parkinson's disease with onset after age 50, but among the few pairs of early-onset Parkinson's disease, these genetic influences appeared to be stronger (Tanner *et al.*, 1999). Nonetheless, in the past several years, well-described pedigrees with Mendelian dominant inheritance have been reported, but this pattern is clearly exceptional (Barbeau & Pourcher, 1982; Golbe *et al.*, 1990). Several pedigrees of familial parkinsonism have been linked to a mutation of alpha-synuclein (Polymeropoulos *et al.*, 1997; Krüger *et al.*,

2001; Spira *et al.*, 2001). Alpha-synuclein catalyses the formation of hydrogen peroxide, a product known to damage neuronal membranes (Saha *et al.*, 2000; Turnbull *et al.*, 2001) and accumulation is associated with neuronal death in laboratory models of Parkinson's disease. These observations led to the logical search for this same defect among Parkinson's disease patients. Several other groups have failed to find this defect in subjects with nonfamilial and other familial forms of Parkinson's disease (Chan *et al.*, 1998; Wang *et al.*, 1998; Khan *et al.*, 2001). These studies have suggested that synuclein may be a key factor to a variety of neurodegenerative disorders, collectively termed synucleinopathies (Galvin *et al.*, 2001). Recessively inherited juvenile parkinsonism appears to be linked to the gene termed PARKIN (Leroy *et al.*, 1998; Mizuno *et al.*, 1998a; Tassin *et al.*, 1998). Exonic deletion mutations of the same gene have also been reported in some series of patients with typical sporadic Parkinson's disease (Wang *et al.*, 1999; Klein *et al.*, 2000; Kobayashi *et al.*, 2000), although other investigators have not found these associations.

The new appreciation of mitochondrial genetics, whereby inheritance of DNA is strictly maternal, may provide clues to the role of genetically determined alterations in the mitochondrial respiratory chain and detoxication pathways (Mizuno *et al.*, 1988; DiMauro, 1993; de la Fuente-Fernandez, 2000). In this context, among five families in which Parkinson's disease occurred in a parent and multiple offspring, the proband parent was always a woman. Furthermore, the age of Parkinson's disease onset in the offspring was younger than in the mother whereas this 'anticipation' pattern is not seen with paternal inheritance (Wooten *et al.*, 1997). The manganese superoxide dismutase gene (Grasbon-Frodl *et al.*, 1999), the E₂ subunit of the alpha-ketoglutarate complex (Kobayashi *et al.*, 1998), alpha-1-antichymotrypsin gene polymorphisms (Munoz *et al.*, 1999), monamine oxidase B intron 13 allele polymorphisms (Checkoway *et al.*, 1998), the alpha-2 macroglobulin gene (Kruger *et al.*, 2000), and the catechol-*o*-methyltransferase gene (Mizuto *et al.*, 2000) are among the current areas of active research interest. A number of observations suggest a link between mitochondrial genetic and environmental etiologic hypotheses in Parkinson's disease. First, Complex I activity of the respiratory chain is reduced in the brains of Parkinson's disease patients; second, MPP⁺ acts directly on Complex I to inhibit activity and produce synaptosomal adenosine triphosphate depletion (Nicklas *et al.*, 1985). Involvement of the mitochondria in Parkinson's disease could relate to putative mutations in mitochondrial DNA (DiMauro, 1993). Despite this interest in mitochondrial genetics, however, data do not support a maternal mode of inheritance for most patients with

Parkinson's disease. The polymorphic cytochrome P450 gene has been examined in numerous studies but also does not show a consistent pattern of defect (Bordet *et al.*, 1996; Diederich *et al.*, 1996). These studies underscore the likely complex genetic heterogeneity of Parkinson's disease, and each identified mutation may point towards an eventual common pathogenetic mechanism.

A major area of budding research is the identification of early diagnostic markers that might detect Parkinson's disease patients at a time when they are asymptomatic. The reports of diminished Complex I in platelets of Parkinson's disease patients are an example of these attempts, and numerous approaches with various biochemical products are being investigated (Parker *et al.*, 1989). The hypothesis that genetic susceptibility to Parkinson's disease was linked to chromosome 22q13 and the cytochrome P450 monooxygenase gene CYP2D6 has been argued for several years (Christensen *et al.*, 1998). Whereas most studies show no association between polymorphisms of CYP2D6 (Tsuneoka *et al.*, 1998), linkage disequilibrium with dinucleotide repeat markers mapping near CYP2D6 on ch22q13 may still be important (Wilhelmsen *et al.*, 1997; Kobayashi *et al.*, 1998). CYP2D6 polymorphisms have been associated with aging, a factor that may confound analyses of Parkinson's disease (Payami *et al.*, 2001). A meta-analysis of numerous prior publications suggested that polymorphisms of *N*-acetyltransferase-2, monoamine oxidase B, glutathione transferase and the mitochondrial gene tRNAGlu should be the primary focus of future linkage studies (Tan *et al.*, 2000). In one study of 137 Parkinson's disease patients, those with epsilon-4 apolipoprotein allele had a significantly earlier onset of parkinsonism than patients with epsilon3/epsilon 3 or epsilon2/epsilon 2. Such findings suggest apolipoprotein E genotypes may modulate age of onset of Parkinson's disease (Zarepari *et al.*, 1998). In contrast to Alzheimer disease, Apolipoprotein E₄ does not appear to be associated with dementia in Parkinson's disease (Inzelberg *et al.*, 1998). A new focus of study has been delineation of the pro-apoptotic protein, Bax. This protein accumulates in substantia nigra cells after MPTP treatment and in Parkinson's disease (Tatton, 2000; Hartmann *et al.*, 2001). Furthermore, in animals treated with the dopamine cell toxin MPTP, ablation of Bax prevents dopaminergic degeneration (Vila *et al.*, 2001). These combined observations suggest that Bax ablation strategies may be a future therapeutic aim in Parkinson's disease (Ploix & Spier, 2001). Special attention has been placed on homovanillic acid levels in the cerebrospinal fluid, since this chemical is the breakdown product of central dopamine. Although the absolute levels of homovanillic acid do not correlate with disease severity, the ratio of homovanillic acid/xanthine is

significantly different between patients with mild Parkinson's disease compared with controls (Litvan *et al.*, 1998).

Cardinal motor features

Parkinsonism is a clinical diagnosis based on the signs of resting tremor, bradykinesia or slowness of movement, rigidity, and loss of postural reflexes. Several diseases can be associated with these signs and are termed parkinsonian syndromes as a group; Parkinson's disease is the prototype, and in this condition, parkinsonian signs occur in isolation without other marked evidence of major neuropathologic change (Litvan *et al.*, 1998).

Of all the parkinsonian signs, tremor is the most distinctive. Tremor is a to-and-fro rhythmic involuntary movement, and the typical parkinsonian tremor occurs prominently at rest when the body part is completely relaxed. During activity or the maintenance of a posture, tremor may be modestly present, but these activities do not induce marked shaking. Resting tremor is primarily seen in the jaw, and extremities and when it affects the hands, the term 'pill-rolling' has been historically honored. Whereas the prototypic tremor occurs at rest, the tremor that can occur during activity may contribute to physiologic changes underlying bradykinesia (Carboncini *et al.*, 2001). Bradykinesia means slowness of movement in the absence of weakness and patients with Parkinson's disease initiate and carry out movements at a slow speed and with intermittent interruptions in the smooth rhythm of normal tasks. Buttoning buttons, writing, and performing fine motor tasks are affected as well as large body movements like rising from a soft chair or car seat. The third cardinal feature of Parkinson's disease is rigidity, or increased muscle tone that affects both agonist and antagonist muscles simultaneously. As the examiner moves the patient's arm, wrist or leg through the given joint's full range, the extremity moves with passive resistance and a give-and-take or ratchet-like movement, termed cogwheel rigidity. The final cardinal feature of parkinsonism is compromised postural reflexes with balance difficulties. The patient may experience this sign with a sense of unsteadiness, stumbling or falls. The examiner tests this feature by standing behind the patient and pulling briskly on the shoulders in order to displace the patient's frame of gravity. Whereas the normal response is one or two steps backwards, the parkinsonian subject takes several steps backwards and may even fall.

Whereas these cardinal signs are seen in Parkinson's disease as well as other parkinsonian syndromes distinct from Parkinson's disease, signs that additionally help the

clinician to distinguish Parkinson's disease clinically are asymmetry of parkinsonian signs, marked rest tremor, a clinically significant response to the dopaminergic medications, usually levodopa (see Chapter 42), and little or no balance problems in the first months and years of the disease (Lang & Lozano, 1998). The pattern of asymmetry persists throughout the disease, even as late as 15 years after onset (Lee *et al.*, 1995). These features are guidelines and although not foolproof, until an accurate biological marker of Parkinson's disease is discovered, clinical features are the best criteria for diagnosing the neurologic disorder during life (Weiner & Lang, 1989). Among Parkinson's disease specialists who diagnosed early Parkinson's disease in a large cohort of untreated patients, 8.1% were later found to have another diagnosis after 7.6 years of follow-up (Jankovic, 2000).

Especially in the early months of Parkinson's disease, parkinsonian signs may be particularly subtle and patients may only complain of slowness, stiffness, and trouble with handwriting, usually noting that their script has become small, cramped and tremulous (micrographia). Physicians are often tempted to diagnose arthritis, depression, or normal aging unless rest tremor is evident. Particular attention to the history of tremor, even if not visible in the office, to slowness of fine motor control, and to a hunched and slightly flexed posture may permit the clinician to diagnose Parkinson's disease in its very early phases.

Moderate and advanced Parkinson's disease patients develop increasing gait difficulty, bradykinesia and tremor, plus a number of motor and non-motor complications that relate to both the progressive disease and its treatment (see section 'Time course of the disease'). In the very late stages of the illness, sometimes tremor decreases. Although most aspects of Parkinson's disease are managed in an outpatient ambulatory setting, physicians can see Parkinson's disease patients in the emergency room because of falls, freezing, malignant neuroleptic-like syndromes due to decreasing or stopping medications, psychosis, and panic episodes (Factor & Molho, 2000). Falls can be associated with fractures, and resultant imposed immobility and pain medication utilization that can collectively compromise patient autonomy and independence (Gray & Hildebrand, 2000).

Other clinical features

Among the behavioral and cognitive troubles experienced by Parkinson's disease patients, depression occurs in approximately one third of patients, especially in

Parkinson's disease patients who have akinesia and rigidity as their predominant symptoms (Hoogendijk *et al.*, 1998; Starkstein *et al.*, 1998). Dementia occurs in approximately one-third of patients and hallucinations and psychotic behavior in approximately one fourth of chronically treated patients (Gotham *et al.*, 1986). Hallucinations in Parkinson's disease usually involve vivid images of people often familiar to the patient (Goetz, 1999; Fenelon *et al.*, 2000; Holroyd *et al.*, 2001). Several studies have linked hallucinations to co-existent REM-related sleep disorders (Pappert *et al.*, 1999; Arnulf *et al.*, 2000b). The biological basis of hallucinations has been studied with molecular biology techniques and, among Parkinson's disease patients with hallucinations, dopamine receptor gene polymorphisms do not differ from patients without hallucinations (Makoff *et al.*, 2000). Parkinson's disease patients with hallucinations do not have the dopamine receptor polymorphisms seen in hallucinating patients with Alzheimer's disease (Goetz *et al.*, 2001).

Dementia is more likely to develop in patients whose parkinsonism did not include tremor in the early phases of clinical disease (Roos *et al.*, 1996). A recent study showed that non-demented patients with Parkinson's disease had impaired ability to incrementally learn associations, which is a prerequisite for habit learning. This impairment is reversed by administration of levodopa, suggesting that association learning involves dopaminergic neostriatal pathways (Knowlton *et al.*, 1996). Tests that involve maintenance of attention, executive function, and working memory are particularly affected in Parkinson's disease (Dujardin *et al.*, 2001).

The retina is rich in dopamine, and contrast sensitivity and color discrimination are impaired in Parkinson's disease patients (Buttner *et al.*, 2000). Parkinson's disease subjects experience both physical and mental fatigue (Lou *et al.*, 2001). Quality of life measures demonstrate the marked impact of Parkinson's disease on the patient's life; and depression, stress, and insomnia or other sleep disorders account for many of these compromises (Tandberg *et al.*, 1998; Karlsen *et al.*, 1999; Schrag *et al.*, 2000b). Daytime sleepiness, due to Parkinson's disease itself, or secondary to poor nocturnal sleep or drug effects, can be particularly problematic and may affect driving safety (Frucht *et al.*, 2000; Lachenmayer, 2000; Olanow *et al.*, 2000; Razmy & Shapiro, 2000). Olfactory disturbances in odor identification, recognition, and detection thresholds occur in Parkinson's disease and resemble patterns seen in Alzheimer disease patients (Meshulam *et al.*, 1998; Liberini *et al.*, 2000; Tissingh *et al.*, 2001). Several studies have suggested that even before motor signs of parkinsonism develop, distinc-

tive personality traits, including introversion and low risk-taking, may be more frequent among Parkinson's disease subjects compared to other family members or the general population (Menza, 2000).

The autonomic nervous system is also affected by Parkinson's disease, and orthostatic hypotension, abnormal cardiac reflexes and aberrant perspiration responses are frequently encountered (Goetz *et al.*, 1986). Urological problems including urgency and nocturia, as well as sexual dysfunction, both impotence and hypersexual behaviour, can significantly impact on overall function and require pharmacological interventions (Araki *et al.*, 2000; Jacobs *et al.*, 2000). Dysautonomia is an inherent part of Parkinson's disease, but is also induced by dopaminergic and anticholinergic medications used to treat the motor elements of the disease.

Subtypes of Parkinson's disease

In a large US–Canadian database on 800 early Parkinson's disease subjects, three clinical subgroups were apparent early in the disease: those with tremor-predominance, those with bradykinesia, postural instability and gait difficulty, and the largest group with no specific predominance of symptoms. Postural instability and gait difficulty patients were motorically more functionally impaired early in their disease, and those who experienced balance problems within 1-year of symptom onset recalled experiencing gait and balance problems from the onset of their disease (Jankovic *et al.*, 1990). Whereas very early gait impairment can occur in Parkinson's disease, other parkinsonian syndromes, such as progressive supranuclear palsy, should be considered in subjects with this clinical presentation (Litvan *et al.*, 1996).

Clinical subgroups often used for comparisons include tremor-predominant versus akinetic/rigid-predominant variants, and young-onset (usually onset between age 21 and 40 years) vs. later onset Parkinson's disease. As a group, tremor-predominant patients progress in motor impairment slower than the akinetic/rigid patients, and young-onset patients have more preserved cognitive function and fewer falls than subjects with elderly disease onset (Schrag *et al.*, 1998; Colcher & Simuni, 1999). On the other hand, subjects with younger onset Parkinson's disease appear to be especially prone to dyskinesias or involuntary movements, although whether this problem relates to their early and prolonged use of medications or relates specifically to their Parkinson's disease has not been specifically determined.

Time course of the disease

Parkinson's disease is known to be a slowly progressive disorder (Poewe & Wenning, 1998; Muller *et al.*, 2000). The classic study by Hoehn and Yahr (1967) documented that disease duration is closely associated with progressive disability. Marttila and Rinne examined a large cohort of Parkinson's disease subjects and concluded that patients remain at mild stages (unilateral or bilateral, but with retained postural reflex responses) for approximately 5 years. One index of progression is the need for levodopa, the primary symptomatic treatment for Parkinson's disease. Among 100 consecutive patients with Parkinson's disease who were not receiving levodopa at their first university centre evaluation, the mean duration of symptoms until levodopa was needed was 48 months, but half the cohort met this milestone by 3 years. The primary reason for starting therapy was progression of balance and gait impairment (Goetz *et al.*, 1987). Other elements of disease progression that lead to the introduction of dopaminergic therapy include job insecurity, enhanced bradykinesia, and disabling tremor. Certain subgroups may have a more indolent course than others, and studies have suggested that young age of onset and tremor-predominant disease are less rapidly progressive (Wooten & Jankovic, 1992).

In addition to progressive tremor, slowness, and balance difficulties, the major problems that patients experience after 5 years of treatment for Parkinson's disease are motor fluctuations, dyskinesias and behavioural or cognitive changes. The mechanisms behind these complications relate both to the underlying Parkinson's disease and to the effects of medications. There are several forms of motor fluctuations. Most commonly, a predictable decline in motor performance occurs near the end of each medication dose. Patients change gradually from 'on' meaning a good medication response into an 'off' period motorically declining 30 minutes to 1 hour before the next medication dose is due. Often patients experience involuntary movements, termed dyskinesias, as a peak-dose complication, and sometimes similar movements occur at the end of the dose. Rarely, sudden and severe cataclysms of motor fluctuation occur, with ambulatory patients becoming immobilized over seconds (de Jong *et al.*, 1987). Because these fluctuations occur throughout the day, accurate detection requires cooperation by the patient who must be trained to complete diaries of functions (Hauser *et al.*, 2000). These journals generally divide the 24-hour day into 30-minute segments to detect good medication response ('on'), poor medication response ('off'), disabling dyskinesias and sleep. Some, but not all, dyskinesias and fluctuations

correlate with alterations in plasma levodopa levels (Kurth *et al.*, 1993), although the pharmacologic mechanisms underlying relief of parkinsonism and the production of dyskinesia appear to be different (Schuh & Bennett, 1993). Patients with motor fluctuations show presynaptic and postsynaptic central changes that occur in the dopaminergic striatal system (Colosimo & DeMichele, 1999). Studies have suggested that alterations of basal ganglion physiology in association with dyskinesia include overt changes in average firing rates of neurons and modulations of cell-to-cell communication within subregions of the basal ganglion circuitry (Brotchie, 2000; Hirsch, 2000). Additionally, the NMDA–glutamate system and striatal opioid transmission is involved in the pathophysiology of dyskinesia in Parkinson's disease (Greenamyre & O'Brien, 1991; Piccini *et al.*, 1997).

Whereas the cumulative medical literature derived largely from university-based populations suggests that dyskinesia and motor fluctuation are common among chronically treated patients with Parkinson's disease, one community-based study found that 78% of Parkinson's disease subjects did not have fluctuations (Larsen *et al.*, 2000; Ahlskog & Muenter, 2001).

Progressive compromise in quality of life occurs with prolonged Parkinson's disease (Schrag *et al.*, 2000). Over a 4-year period, 111 patients were examined with standardized measures and significantly declined in quality of life indices that reflected physical disability, but also emotional function, pain and social interaction (Karlsen *et al.*, 2000). Because the risk for dementia is approximately sixfold in Parkinson's disease compared with the general population, this factor impacts on caregiver stress and patient consent to medical treatment because of competency issues (Aarsland *et al.*, 2001; Dymek *et al.*, 2001). Progressive disease places patients at particular risk for hip fractures (Sato *et al.*, 2001) and nursing home placement especially when hallucinations are prominent (Goetz & Stebbins, 1992; Aarsland *et al.*, 2000).

After the discovery of specific therapy for Parkinson's disease (see Chapter 42), mortality figures changed. Prior to the availability of levodopa, observed-to-expected death ratio was 2.9, but with drug treatment, later reports argued that life expectancy in Parkinson's disease was normal (Joseph *et al.*, 1978). More recent studies, however, suggest that mortality may still be increased in Parkinson's disease relative to the general population (Uitti *et al.*, 1993; Clarke, 1995). Added dementia is the highest risk factor for shortened life (Louis *et al.*, 1996). In a community-based study, Parkinson's disease patients died more frequently from pneumonia and less frequently from cardiac disease than control subjects (Beyer *et al.*, 2001). Concerns that

selegiline exposure could enhance cardiac-related mortality in Parkinson's disease subjects has been refuted (Donnan *et al.*, 2000).

Numerous strategies have been suggested to attempt an interruption in the natural progression of Parkinson's disease (see Chapter 42). Treatment with monoamine oxidase inhibitors, selegiline, delayed the need to start levodopa by approximately 9 months, although the biochemical mechanism of this effect has been debated (Parkinson Study Group, 1993). Because clinical signs of Parkinson's disease do not develop until dopamine levels reach only 20% of the normal level at birth, a long preclinical period likely exists, suggesting that such strategies could be useful.

Epidemiology

Besides essential tremor, Parkinson's disease is the most common movement disorder and affects approximately 500 000 people in the United States (Kessler, 1978). It is most frequently seen after the age of 50, and approximately 1% of this age group has the disorder. There is a modest (1.5:1) male predominance (Kessler, 1978; Knopio *et al.*, 1999). The gender prevalence differences are not explained, although in animal models of parkinsonism, testosterone does not potentiate damage to the nigrostriatal system and estrogen has inconsistent effects (Gao & Dluzen, 2001). Among women with Parkinson's disease and motor fluctuations, estrogen and progesterone shifts that coincide with the normal menstrual cycles bear no relationship to clinical motor impairments (Kompolti *et al.*, 2000a). Several studies have suggested that Caucasians are affected more often than African-Americans, but this question is unsettled (Schoenberg *et al.*, 1988). Joint analysis of five European communities identified no substantial difference in prevalence of Parkinson's disease across European countries. The overall prevalence was 1.6 per 100 population, and a substantial proportion of patients with clear-cut clinical Parkinson's disease had never sought medical attention or been previously diagnosed (de Rijk *et al.*, 1997).

Numerous population studies have documented that Parkinson's disease is more common in highly industrialized countries than in agricultural societies, and more frequent in Europe and North America than in the Far East (Tanner *et al.*, 1989; Rajput, 1993). Several studies suggest that exposure to chronic well water drinking and living near or working with industrial chemicals and pesticide or herbicide products increase the risk for early-onset Parkinson's disease (Tanner *et al.*, 1989; Rajput, 1993). Using an urban

United States multiethnic community, logistic regression models demonstrated that rural living, area farming, and well water drinking were associated with Parkinson's disease only in African-Americans, whereas in Hispanic areas, farming was protective, and drinking unfiltered water was a risk factor (Marder *et al.*, 1998a). In Denmark, a consistent pattern of high Parkinson's disease morbidity was found among occupational groups employed in agriculture and horticulture (Tuchsen & Jensen, 2000). The concept that well water might accumulate chemical products more readily than free-flowing water has indirectly supported an environmental hypothesis of Parkinson's disease. Of interest, MPTP, a selective dopaminergic cell toxin associated with parkinsonism, was industrially developed as a potential herbicide, but was never produced commercially. The herbicide, rotenone, with potent inhibitory activity on Complex I mitochondrial activity, is of particular current research interest (Adam, 2000; Greenamyre *et al.*, 2001; Jenner, 2001).

Epidemiological studies have confirmed that smoking is less frequent among subjects with Parkinson's disease (Benedetti *et al.*, 2000; Elbaz *et al.*, 2000). Coffee consumption was likewise less frequent among Parkinson's disease subjects (Benedetti *et al.*, 2000), whereas tea drinking has been reported to be more frequent (Preux *et al.*, 2000). Based on the observations that genetic polymorphisms of dopamine D2 receptors influence dopamine response and are associated with cigarette smoking, genetic and environmental factors have been suggested to interact in the pathogenesis of Parkinson's disease (Costa-Mallen *et al.*, 2000). Exposure to hydrocarbons has also been linked to Parkinson's disease (Pezzoli *et al.*, 2000) and the issue of chronic manganese exposure as a risk factor has been debated (Racette *et al.*, 2000).

Because epidemiology research usually involves the screening of large numbers of subjects, efforts have focused on the development of special assessment tools that maximize diagnostic sensitivity and specificity (Chan *et al.*, 2000; Reider & Hubble, 2000). These tests range from questionnaires to brief examinations or involve videotaping protocols that can be performed in the field and then evaluated by experts (Camicioli *et al.*, 2001).

Neuroimaging

PET is among the most important tools for studying the biological basis of changes in dopamine neurochemistry in sporadic Parkinson's disease and familial parkinsonism associated with the PARKIN gene (Eldelberg *et al.*, 1995; Hilker *et al.*, 2001). The development of radioligands for

dopamine transporters and receptors permits the study of both presynaptic and postsynaptic mechanisms in Parkinson's disease (Volkow *et al.*, 1998). For Parkinson's disease, PET studies of the effect of levodopa (L-[11C]-dopa) reflux show marked differences between patients with early versus late Parkinson's disease. In mildly affected patients, decreased putaminal influx occurs, whereas in advanced disease, a significant upregulation develops (Torstenson *et al.*, 1997). In subjects with motor fluctuations, putaminal [18F]Dopa uptake is reduced compared to non-fluctuators (Brooks, 2000a). As such, loss of striatal dopamine storage capacity in association with pulsatile exposure to exogenous levodopa may result in fluctuating and often aberrant synaptic dopamine levels, deranged basal ganglionic function, and both peak-dose dyskinesias and end-of-dose wearing off. Further studies using dopamine receptor ligands demonstrate that extrastriatal D2 receptor binding and D3 receptor binding markedly decrease in the dorsolateral prefrontal cortex, anterior cingulate cortex, and medial thalamus among patients with advanced Parkinson's disease (Kaasinen *et al.*, 2000). Additional PET studies of patients undergoing mental tasks that stress frontostriatal circuitry demonstrate marked deficits in Parkinson's disease patients and suggest that the dopamine depletion of Parkinson's disease disrupts basal ganglial outflow to the cortex through this pathway (Owen *et al.*, 1998).

Because an individual's severity of impairment in tremor, bradykinesia, rigidity, gait and balance are not equal, investigators have searched for the clinical signs that best correlate with the dopamine nigrostriatal lesion. In a combined clinical and PET analysis, bradykinesia was better correlated with changes in fluorodopa PET reduction than tremor, rigidity or postural disturbance. As an index of bradykinesia, performance in the Purdue Pegboard Test was the best indicator of fluorodopa PET changes (Vingerhoets *et al.*, 1997). Studies with dopamine transporter probes demonstrate reduced activity in the caudate nucleus and orbitofrontal cortex in association with walking in Parkinson's disease subjects (Ouchi *et al.*, 2001).

With SPECT scans, [123I]beta-CIT has been used as a ligand to measure presynaptic dopaminergic activity. In untreated Parkinson's disease patients, dopamine and serotonin transporter activity are decreased compared to healthy controls (Haapaniemi *et al.*, 2001). Decrements of approximately 10% each year occur in Parkinson's disease. Furthermore, dopamine transporter deficits correlate with motor impairment and disease duration. Similar dopamine transporter changes and correlation with clinical severity

and disease duration occur in treated Parkinson's disease subjects as well (Benamer *et al.*, 2000). Scans differentiate patients with Parkinson's disease from those with essential tremor and with clinically diagnosed progressive supranuclear palsy (Asenbaum *et al.*, 1998; Messa *et al.*, 1998).

Future perspectives

In light of the significant advances that have developed in the past 5 years, it is reasonable to hypothesize that the primary chemical cascade of biochemical reactions leading to nigrostriatal death in Parkinson's disease will be discovered shortly. Once this series of reactions is delineated, 'designer drugs' aimed at interrupting this sequence at one or many steps can be envisioned. The extent to which these lessons will be extrapolated to other neurodegenerative disorders will depend on whether the biochemical cascade that leads to cell death is a general neuronal one or highly specific to the cellular function of nigrostriatal cells. It is likely that some chemical reactions are shared by all neurons, but the relatively selective nigrostriatal dopaminergic cell loss of Parkinson's disease suggests that chemical reactions specific to these cells are important determinants of the pathogenesis of this unique neurodegenerative disease.

Neuropathology of Parkinson's disease

Dennis W. Dickson

Departments of Neuroscience and Pathology (Neuropathology), Mayo Clinic Jacksonville, FL, USA

Introduction

The clinical features of Parkinson's disease (PD) are bradykinesia, rigidity, tremor and postural instability, but increasingly recognized are non-motor manifestations, such as anosmia, autonomic dysfunction, sleep disorders, psychiatric symptoms (e.g. depression) and cognitive impairment. The typical clinical features of PD reflect well-known pathology in the dopaminergic nigrostriatal system, while extra-nigral pathology accounts for many of the non-motor features of PD. As will be subsequently discussed, the most characteristic pathologic feature of PD is neurodegeneration with Lewy body (LB) formation, but it must be acknowledged that occasionally other pathologic processes cause clinical features typical of PD. In particular, some cases of multiple system atrophy (MSA) or even progressive supranuclear palsy (PSP) may be clinically mistaken for PD (Bower *et al.*, 2002). More problematic are cases of PD with juvenile onset or those associated with an autosomal recessive pattern of inheritance, such as cases with Parkin and DJ-1 mutations (see below), in which LBs may not be present. Other early onset familial cases present with atypical clinical features such as early dementia and psychosis, which are not characteristic of typical PD (Gwinn-Hardy *et al.* 2000). Another diagnostic challenge is the relationship of cognitive dysfunction in PD to concurrent Alzheimer's disease and dementia with Lewy bodies (DLB) (McKeith *et al.* 1996).

As in all neurologic syndromes, the clinical presentation reflects the neuroanatomy of the disease process more than the nature of the underlying pathology. The typical and defining clinical features of PD stem from the fact that the pathology responsible for the typical clinical syndrome is due to selective involvement of the nigrostriatal dopaminergic neurons (Jellinger, 1999), but these neurons are vulnerable to degeneration in other disorders (Fig. 39.1).

Moreover, postmortem neuropathologic studies clearly show that neurodegeneration in clinically typical PD is more extensive than merely the substantia nigra dopaminergic neurons. The early and late clinical manifestations of PD may bear little resemblance to the typical clinical picture of PD. For example, the olfactory bulb and brainstem reticular neurons are affected in almost all cases early in the disease, while neocortical involvement is almost universal later in the disease (Braak *et al.*, 2003). Involvement of these structures may account for anosmia or autonomic features early and dementia later in the disease course, respectively.

Pathology of PD

The brain is usually grossly unremarkable until the brainstem is sectioned, and then loss of neuromelanin pigmentation in the substantia nigra and locus ceruleus becomes apparent (Fig. 39.2). Increase in rust color pigment is not uncommon in the substantia nigra and sometimes in the globus pallidus. Many cases, especially older patients, have varying degrees of frontal atrophy with mild dilation of the frontal horns of the lateral ventricle. None of these gross features is specific. Loss of pigment in the substantia nigra can be detected in many Parkinsonian disorders (Fig. 39.1). On the other hand, the relative involvement of the substantia nigra and locus ceruleus is sometimes helpful in the differential diagnosis. Many cases of Alzheimer's disease have pigment loss in the locus ceruleus, with normal pigmentation in the substantia nigra. In contrast, other Parkinsonian disorders have pigment loss in the substantia nigra with relatively normal pigmentation of the locus ceruleus (Table 39.1).

The histologic correlate of pigment loss in the substantia nigra and locus ceruleus is neuronal loss and gliosis with hyaline cytoplasmic inclusions (Fig. 39.3) first described

Fig. 39.1 Gross appearance of the midbrain is several disorders associated with Parkinsonism. Note normal pigment in substantia nigra in AD, but variable loss of nigral pigment in PD, MSA, PSP, CBD and FTD.

Fig. 39.2 Gross appearance of the midbrain (top pair) and pons (bottom pair) in typical PD (left) compared to age-matched control (right). Pigment loss is noted in both the locus ceruleus (vertical arrows) and the substantia nigra (horizontal arrows) in PD compared to normal.

Table 39.1. Differential diagnosis of Parkinsonism with respect to neuronal loss in the locus ceruleus and the substantia nigra

	Locus ceruleus	Substantia nigra
AD	↓↓	–
PD	↓↓	↓↓
PSP	↓	↓↓↓
CBD	↓	↓↓↓
MSA	–	↓↓
FTD	–	↓

(Severity of neuronal loss is indicated by '↓'. No significant neuronal loss is indicated by '–'.)

Fig. 39.3 Hyaline cytoplasmic inclusions, LBs (arrows), in substantia nigra with H&E (A) and synuclein immunostaining (B). Note also pale bodies considered to be precursors to LBs (arrow heads).

Fig. 39.4 Neuronal loss in substantia nigra. (A) extraneuronal neuromelanin in macrophages (arrows). (B) neuronophagia of a neuron with a LB (arrow). (C) microgliosis (reactive microglia – arrows) in the substantia nigra with HLA-DR immunostaining.

by Lewy in the early part of the twentieth century (Gibb & Poewe 1986). In typical PD, as in most other disorders associated with Parkinsonism, the neuronal loss in the substantia nigra is usually most marked in the ventrolateral tier of neurons (A9 dopaminergic neurons), which projects to the striatum, especially the putamen (Gibb & Lees, 1991). The more medial group of neurons (A10 dopaminergic neurons), which project to mesolimbic structures, is affected to a variable degree. Loss of neurons in the dorsal tier of the pars compacta may be more common in aging (Fearnley & Lees, 1991).

Neuronal loss in the substantia nigra is accompanied by astrogliosis and microglial activation (McGreer *et al.* 1998) (Fig. 39.4). The latter can be demonstrated with immunohistochemistry for class II major histocompatibility antigen, HLA-DR. The presence of HLA-DR in microglia indicates a state of functional activation typical of neuroinflammation, which may play a role in the progressive neuronal loss in the substantia nigra, although neuroinflammation is not currently considered to be a primary cause of degeneration (McGeer *et al.*, 2001). Neuromelanin pigment is often found in the cytoplasm of macrophages, which is a direct marker of loss of pigmented dopaminergic neurons, and occasionally neurons can be detected undergoing neuronophagia, or phagocytosis, by macrophages (Fig. 39.4). In most cases there is increased iron in the substantia nigra, which can be detected as a brown granular pigment and confirmed with special staining methods, such as Prussian blue stain. Iron pigment is almost always accompanied by swollen granular/foamy axonal spheroids (Fig. 39.5). The latter features are not specific to PD, but are also present in other parkinsonian disorders, most notably neuroaxonal dystrophies such as neurodegeneration with brain iron, formerly known as Hallervorden-Spatz disease (Jellinger & Duda, 2003).

The striatum is usually grossly normal in PD and with routine histologic methods there is usually no significant pathology. In contrast, immunohistochemical methods for synuclein often show lesions in the striatum in PD

Fig. 39.5 Iron pigment in the substantia nigra. (A) Iron pigment (arrows) in the neuropil amongst pigmented neurons. (B) Perivascular iron pigment within macrophages (arrows). (Prussian blue stain)

(Duda *et al.*, 2002). This applies not only to PD with Lewy bodies, but to virtually all of the other disorders associated with clinical Parkinsonism, including PSP, MSA, corticobasal degeneration (CBD) and frontotemporal degeneration (Fig. 39.6). Striatal synuclein lesions increase with disease duration in PD and are especially dense in cases with dementia and diffuse Lewy bodies (Tsuboi *et al.*, 2003).

Lewy bodies (LBs) and Lewy neurites (LNs)

As noted above, concentric hyaline cytoplasmic inclusions or LBs are the most characteristic neuronal alteration in PD and are considered by some to be a *sine qua non* for the pathologic diagnosis of Parkinsonism (Hughes *et al.*, 2001). The latter is now a topic of current debate since some of the genetically determined causes of early onset Parkinsonism, such as PARK2 and PARK 7 (Table 39.2), which are autosomal recessive disorders with mutations in *Parkin* and *DJ-1*, respectively, are not always associated with LBs (Hardy *et al.*, 2003).

While most LBs are single and spherical, some neurons have multiple or pleomorphic LBs (Fig. 39.7). In some regions of the brain, such as the dorsal motor nucleus of the vagus and the basal nucleus of Meynert, similar inclusions are more often detected within neuronal processes.

Fig. 39.6 Striatal pathology in parkinsonian disorders. (A) neuritic pathology revealed with synuclein immunohistochemistry in LBD. (B) Glial cytoplasmic inclusions in white matter bundles in multiple system atrophy revealed with synuclein immunohistochemistry. (C) Tufted astrocyte and threads in progressive supranuclear palsy revealed with tau immunohistochemistry. (D) Numerous threads in corticobasal degeneration revealed with tau immunohistochemistry.

The latter are sometimes referred to as ‘intra-neuritic’ LBs (Fig 39.8). Intra-neuritic-LBs can be detected in routine histopathologic preparations and should be distinguished from Lewy neurites (LNs), which are not visible in routine histopathology. Lewy neurites were first described in the hippocampus (Dickson *et al.*, 1991), but are also found in other regions of the brain, including the amygdala, cingulate gyrus and temporal cortex (Fig. 39.8). The density of LNs correlates with cognitive impairment (Churchyard & Lees, 1997).

Ultrastructural studies of LBs demonstrate non-membrane-bound, granulo-filamentous structures within the cytoplasm of neurons. The central region of the LB usually contains amorphous dense material that lacks discernible detail, while the periphery has radially arranged 10 nm diameter filaments (Galloway *et al.*, 1992). At the electron microscopic level, LNs also have 10 nm filaments, but they lack a dense core and the filaments are more haphazardly arranged (Dickson *et al.*, 1991). LBs are also detected in cortical neurons and the latter, so-called

‘cortical LBs’ (cLBs) may be difficult to detect with routine histologic preparations (Fig. 39.9). They tend to be found in small non-pyramidal neurons in lower cortical layers, but can also be detected in pyramidal neurons. Occasionally, cLBs have a hyaline appearance similar to brainstem LBs (Masliah *et al.*, 1990). Ultrastructural studies of cortical LBs demonstrate poorly organized granulo-filamentous structures, rather than the radial arrangement of filaments in classical LBs.

Composition of LBs

Immunohistochemical methods have indicated that, in addition to synuclein, LBs have other components (Pollanen *et al.*, 1993) (Table 39.3). Antibodies to neurofilament were first to be shown to label LBs (Goldman *et al.*, 1983), but most neurofilament antibodies label only a subset of LBs (Galvin *et al.*, 1997). Ubiquitin is present in most classical and cortical LBs (Kuzuhara *et al.*, 1988), but the

Table 39.2. Genetics and pathologic features of familial PD

Name	Locus and gene	Inheritance and clinical notes	Pathology	Comment
PARK1	4q21 α -synuclein	AD; early onset PD	LBD; diffuse cortical type	2 mutations (A53T, A30P); presynaptic protein
PARK2	6q25.2–27 Parkin	AR; juvenile onset PD; atypical features (dystonia & sleep benefit)	Nonspecific nigral loss; rare cases with LBs	Many mutations (substitutions, deletions, insertions); loss of function; ubiquitin E3 ligase
PARK3	2p13 unknown	AD; variable age of onset	LBD; typical brainstem type	
PARK4	4q21 α -synuclein	AD; early onset PD; dementia & dysautonomia	LBD; diffuse cortical type	Erroneous initial linkage to 4p15; SNCA multiplication & over-expression of α -synuclein
PARK5	4p14 ubiquitin C-terminal hydrolase	AD; late-onset PD	Unknown	Disputed as true linkage versus gene variant
PARK6	1p35–36 unknown	AR; early onset PD	Unknown	Compare PARK7 & PARK9 for linkage
PARK7	1p36DJ-1	AR; early onset PD	Unknown; heterozygous cases have LBs	DJ-1 function is unknown
PARK8	12p11.2–13.1 unknown	AD; late-onset PD	Variable pathology; some may have LBD, but nonspecific nigral degeneration may be more common	
PARK9	1p36 unknown	AR; early onset; parkinsonism with pyramidal syndrome	Unknown	Atypical parkinsonism phenotype; imaging studies
PARK10	1p32 unknown	Late-onset PD	Unknown	Population-based analysis (Icelandic)
PARK11	2q36–q37 unknown	AD; late-onset PD	Unknown	Sib-pair analysis

AR = autosomal recessive; AD = autosomal dominant; LBD = Lewy body disease.

Fig. 39.7 Multiple LBs (A) and an atypical cluster of LBs (B) in brainstem neurons.

most specific method of detecting LBs and LNs is synuclein immunocytochemistry (Izarray *et al.*, 1998). Other molecules shown to be present in a variable number of LBs include components of the ubiquitin-proteolytic pathway, certain kinases and stress or chaperone proteins (for review, see Pollanen *et al.*, 1993).

Only a few biochemical studies on LBs have been reported, due to the paucity of LBs in a given volume of brain tissue and their solubility properties. Specifically, LBs are structurally unstable and disrupted upon attempted

Fig. 39.8 Neuritic pathology in LBD. (A) LNs (arrows) in CA2 region of hippocampus. (B) LBs within cell processes (intra-neuritic LBs – arrowhead) in basal nucleus of Meynert. Note presence of LNs (arrows), as well.

biochemical purification (Iwatsubo *et al.*, 1996). Initial biochemical studies suggested that a major protein constituent of LBs was a 68 kDa protein that had cross reactivity with neurofilament protein (Pollanen *et al.*, 1992). The latter study raised the possibility that the microtubule associated protein tau, which is the major structural component of neurofibrillary tangles, was also a component of the LB, but subsequent studies indicated that the major structural

Fig. 39.9 Cortical LBs. (A) Round to pleomorphic inclusions within small non-pyramidal neurons (arrows). (B) Brainstem type LB (arrow) within a swollen pyramidal neuron. (C) Synuclein immunostain reveals cortical LBs (arrows).

Structural proteins

Synaptic proteins: α -synuclein, synaptophysin, chromogranin A
Cytoskeletal elements: neurofilament, tau protein, MAP1, MAP2, tubulin, tropomyosin

Ubiquitin-proteasomal components

Ubiquitin, ubiquitin C-terminal hydrolase, multi-catalytic proteinase, Parkin (E3 ubiquitin ligase)

Stress-related proteins/chaperones

Chaperones: torsinA, α B-crystallin, heat shock proteins (HSP70), 14-3-3

Stress-related: p38, glutathione S-transferase, heme oxygenase, superoxide dismutase-1

Neuroinflammatory

Immunoglobulins, complement, α 2-macroglobulin

Kinases

Cdk-5, calcium-calmodulin kinase, extracellular receptor kinase (ERK)

Miscellaneous

gelsolin-related amyloid protein, β APP, calbindin, tyrosine hydroxylase, retinoblastoma protein, ubiquitin, sphingomyelin, Bcl-2

component of LBs is α -synuclein (Baba *et al.*, 1998), rather than neurofilament or tau. In support of their importance to LBs in vitro studies have demonstrated that α -synuclein forms filaments similar to those seen in LBs (Conway *et al.*, 1998). On the other hand, recent immunohistochemical studies have shown tau in some LBs (Ishizawa *et al.*, 2003) and recent biochemical studies indicate that tau can promote α -synuclein fibrillogenesis and vice versa (Giasson *et al.*, 2003).

Biochemical changes in synuclein in PD

Changes in solubility of synuclein in PD and related disorders such as MSA and DLBD have been noted (Dickson

et al., 1999; Tu *et al.*, 1998). In brain tissue homogenates, synuclein is normally a soluble protein, with an electrophoretic profile consistent with a molecular weight of about 19 kDa. In LBD and MSA it becomes increasingly insoluble and is found in detergent extracts, whereas little or no synuclein from normal brains is detected in similar extracts. Moreover, in the detergent extracts synuclein has a higher molecular weight suggestive of post-translational modification, covalent cross-linking or an abnormal conformation leading to stable aggregates. Biochemical studies have demonstrated a number of post-translational modifications in synuclein, including phosphorylation, nitration and oxidative cross-linking (for review, see Dickson, 2001). It remains unclear if these modifications are directly linked to neurodegeneration or are merely epiphenomena.

What is the earliest pathology in PD?

PD is a progressive neurodegeneration, and at the cellular level synuclein modifications that eventually lead to fibrillar aggregates are reflective of this process. The use of immunostaining, with antigen retrieval methods such as protease treatment, reveals the earliest changes in neuronal cell processes and later LB in neuronal cell bodies (Neumann *et al.*, 2002; Braak *et al.*, 2003). While it has long been known that the neurons most vulnerable to LBs are monoaminergic neurons of the substantia nigra, locus ceruleus and dorsal motor nucleus of the vagus, as well as cholinergic neurons in the basal forebrain, immunohistochemistry with synuclein antibodies shows lesions in other areas not previously suspected, and at the earliest stage LNs are detected in the absence of LBs (Braak *et al.*, 2003).

While LBs are rarely detected in the basal ganglia or thalamus, synuclein immunohistochemistry often reveals neuritic changes in these areas (Duda *et al.*, 2002). LBs are common in the hypothalamus, especially the posterior and lateral hypothalamus, and in the brainstem reticular formation. The oculomotor nuclear complex is also vulnerable to LBs. In the pons, the dorsal raphe and subpeduncular

Table 39.4. Proposed staging of Lewy body PD

Stage	Anatomical distribution of LBs and LNs
1	Medullary tegmentum and the dorsal motor nucleus of the vagus; olfactory bulb
2	Locus ceruleus, caudal raphe and reticular nucleus of medullary and pontine tegmentum
3	Substantia nigra
4	Medial temporal (limbic) cortices, including the amygdala and CA2 region of the hippocampus
5	Multimodal association cortices, especially frontal and temporal lobes
6	Unimodal association cortices and occasionally primary cortices

nuclei are often affected, but neurons of the pontine base are not. LBs have not been described in the cerebellar cortex. In the spinal cord, the neurons of the intermediolateral cell column are most vulnerable. LBs can be found in the autonomic ganglia, including submucosal ganglia of the lower esophagus.

While LBs are increasingly recognized in the cortex, not all cortical regions are equally vulnerable. The frontal and temporal multimodal association and limbic cortices are most vulnerable. The amygdala is the most vulnerable of limbic structures. LBs are very uncommon in primary cortices, but neuritic pathology can be found in even the primary visual cortex. The cortical areas with the most cortical LBs are the insular cortex and the parahippocampal and cingulate gyri.

The selective vulnerability of various brain regions to LBs and LNs has been the focus of several recent studies. Of particular note is the attempt to develop a staging system for PD by Braak and co-workers (Braak *et al.*, 2003). In this staging system substantia nigra pathology occurs at a mid-stage of PD, whereas involvement of medulla and pontine tegmentum occur earlier (Table 39.4). The anterior olfactory nucleus is also affected early in the course. In the endstage PD, LBs involve cortical areas, and at this stage many patients with PD are expected to have significant cognitive problems. The pathology at this stage is similar to that found in diffuse LBD, an increasingly recognized late-life dementing disorder (Kosaka, 1990). Several studies suggest that the most common cause of later-developing dementia in patients who initially had typical PD is in fact diffuse LBD (Mattila *et al.*, 1998; Hurtig *et al.*, 2000; Apaydin *et al.*, 2002).

Despite the heuristic value of the Braak staging system for PD, it requires validation. A large cross-sectional study by Parkkinen and co-workers (Parkkinen *et al.*, 2003) of 904 brains studied with synuclein immunohistochemistry

largely concurred with the Braak staging scheme; however, in a small number of cases LBs were found in the substantia nigra without involvement of the medulla. These cases would seem to be exceptions. Another recent report by Jellinger of a large autopsy series also confirmed the general findings of the proposed staging, but also noted that there were some exceptions. Most notably were cases that had involvement of nigra and pons without medullary involvement. Medial temporal lobe pathology was also associated with variable involvement of lower parts of the neuraxis (Jellinger, 2003).

Another area in which the staging scheme breaks down is the presence of LBs in advanced Alzheimer's disease (AD). It is increasingly recognized that many cases of AD have LBs (Hamilton, 2000) and that the most common location for LBs in advanced AD is the amygdala (Lippa *et al.*, 1998). In a cross sectional study of 345 consecutive cases of AD in the Mayo Clinic Jacksonville neuropathology files, LBs were found in 94 cases in multiple brainstem, diencephalic and forebrain regions, but in the remaining 251 AD cases no brainstem LBs were detected. The amygdala was screened with synuclein immunohistochemistry in this group and 38 (15%) had Lewy bodies (DeLucia *et al.*, 2002). On re-examination the brainstem had only isolated and sparse LNs in eight cases, but the other cases did not have brainstem LBs. Thus, LBs in advanced AD begin *de novo* in the amygdala without progressing through the several brainstem stages that have been described for PD.

Other pathology in PD

Application of modern neuropathologic techniques has revealed additional pathology in PD that was not previously known. In particular, immunohistochemical stains for synuclein have shown that there is sometimes glial, as well as neuronal, pathology in PD (Wakabayashi *et al.*, 2000, Gwinn-Hardy *et al.*, 2000). Synuclein immunoreactive glial inclusions are the defining histopathologic lesions in MSA (Lantos, 1998). Occasionally, neuronal inclusions are detected in MSA (Kato & Nakamura, 1990; Dickson, 1999), and they have a number of features in common with cortical type Lewy bodies, including irregular shape, indistinct appearance of routine stains, cytoplasmic location and immunoreactivity with synuclein. While glial inclusions are not widely recognized in PD, they have been reported in previous studies using sensitive silver impregnation methods and more recently immunocytochemistry for synuclein (Wakabayashi *et al.*, 2000). They are within oligodendroglia, since they are negative for GFAP and positive with markers of pathologic oligodendrocytes, such as complement factor 4d (Gwinn-Hardy *et al.*, 2000).

Clinicopathologic correlations in PD

As discussed previously, the extrapyramidal motor signs of PD are best attributed to pathology in the nigrostriatal system. It has been estimated that pars compacta neuronal loss must exceed 50%, as estimated by loss of dopamine in the basal ganglia in PET scans, to be clinically apparent (Jellinger & Mizuno, 2003). This implies that considerable amount of pathology can be found in the substantia nigra and yet be subclinical. If the staging scheme proposed by Braak and coworkers is correct, then this stage of disease should also have been preceded by pathology in lower brainstem regions and by non-motor manifestations. In other words, PD patients should have had a history of non-motor signs and symptoms. The list of non-motor manifestations in PD is long and the correlation is imprecise and deserving of more detailed and ideally prospective clinicopathologic studies.

Anosmia is an early clinical feature of PD, although it is not specific and also detected in AD (Hawkes *et al.*, 1997). Neurodegeneration with LB formation is common in the anterior olfactory nucleus in the olfactory bulb, but also in the medial temporal lobe olfactory cortical areas, as well as the amygdala. These are areas that might have pathology before the substantia nigra.

Autonomic dysfunction is common in PD and can manifest as constipation, urinary frequency, impotence or orthostatic hypotension (Goetz *et al.*, 1986). Imaging studies of the heart show early involvement in PD (Taki *et al.*, 2000). The autonomic nervous system is diffusely affected, with neuronal loss and LBs in autonomic ganglia, spinal cord preganglionic nuclei, the medullary tegmentum and the hypothalamus.

Depression is common in PD and may antedate extrapyramidal motor problems (Koller, 1992), although this hypothesis has been difficult to test. The pathoanatomic basis for depression is unknown in general, but involvement of brainstem monoaminergic nuclei, in particular noradrenergic neurons in the locus ceruleus and serotonergic neurons in the raphe nuclei, have been implicated. These nuclei are also involved in sleep cycles. PD patients often experience insomnia, parasomnias, daytime somnolence and REM sleep behavior disorder (RBD) and it is intriguing to hypothesize that involvement of these nuclei may also be involved in sleep disorders. In addition, sleep is regulated by the hypothalamus and several neurotransmitters such as adenosine, dopamine, GABA, histamine and hypocretin, have been implicated (Salin-Pascual *et al.*, 2001). The relationship of pathology in these neuronal systems to sleep disorders in PD remains to be determined.

PD patients often have visuospatial dysfunction. The role of hypoperfusion in the primary visual cortex has not been systematically studied, but functional imaging studies show such deficits in DLB more often than in PD (Abe *et al.*, 2003).

Psychiatric manifestations, in particular visual hallucinations, which are not related to anti-PD drugs such as L-DOPA, are common in PD, especially in older patients or those with cognitive impairments. The pathologic correlate of visual hallucinations is unknown, but studies suggest that pathology in the temporal lobe and amygdala may be responsible (Harding *et al.*, 2002). There is also a correlation between sleep disorders and hallucinations and it has been hypothesized that visual hallucinations may be dream-like intrusions into wakefulness (dream intrusions) (Pappert *et al.*, 1999).

Dementia is common in PD and its relationship to dementia with LBs is an ongoing debate. In the London Parkinson brain bank series, pathological findings considered to account for dementia in PD included subcortical pathology (39%), coexistent AD (29%) and DLBD (26%) (Hughes *et al.*, 1993). The basal forebrain cholinergic system is the subcortical region most often implicated in dementia, and neurons in this region are damaged in both AD and LBD. Neuronal loss in the basal nucleus is consistently found in PD, especially PD with dementia (Whitehouse *et al.*, 1993). As previously mentioned, the basal nucleus is also vulnerable to LBs. Not surprisingly, cholinergic deficits are found in LBD (Dickson *et al.*, 1987). Cholinergic deficits may contribute to dementia in PD in those cases that do not have concurrent AD or cortical LBs.

While recent studies have shown that virtually all PD brains have a few cortical LBs, they are usually not widespread and not numerous in nondemented PD cases. When found in PD, cortical LBs are usually detected in the limbic cortices (e.g., cingulate gyrus) and not detected in association cortices of the frontal, temporal and parietal lobes (Harding & Halliday, 2001). In contrast, several studies have shown that cortical LBs can be numerous and widespread in PD with dementia. Furthermore, the density of cortical LBs has been shown to correlate with severity of dementia in some studies (Lennox *et al.*, 1989). Cases with widespread cortical Lewy bodies are referred to as diffuse Lewy body disease (DLBD). Kosaka and coworkers were the first to use the term DLBD, and he subsequently subdivided DLBD into pure and common forms (Kosaka *et al.*, 1984; Kosaka, 1990). The latter is associated with coexistent Alzheimer type pathology. Some investigators use of the term DLBD for cases in which cortical LBs are found in the absence of any Alzheimer type

pathology, referring to cases with LBs and Alzheimer type pathology as Lewy body variant of AD (Hansen *et al.*, 1990). Brains with cortical LBs confined to the limbic lobe are classified as 'transitional LBD', while cases with LBs confined to brainstem and diencephalon are referred to as 'brainstem LBD' (Kosaka *et al.*, 1984). Non-demented PD subjects have brainstem or occasionally transitional LBD, while PD with dementia have DLBD or transitional LBD.

Genetics of parkinsonism

Thomas Gasser

Department of Neurodegenerative Disorders, Hertie-Institute for Clinical Brain Research Center of Neurology, University of Tübingen, Germany, thomas.gasser@med.uni-tuebingen.de

Overview

Over the last few years, several genes for monogenically inherited forms of Parkinson's disease have been mapped and/or cloned. In a small number of families with autosomal dominant inheritance and typical Lewy body pathology, mutations have been identified in the gene for α -synuclein. Aggregation of this protein in Lewy bodies may be a crucial step in the molecular pathogenesis of familial and sporadic PD. On the other hand, mutations in the *parkin* gene cause autosomal recessive parkinsonism of early onset. In this form of PD, nigral degeneration is not accompanied by Lewy body formation. *Parkin* mutations appear to be a common cause of PD in patients with very early onset. *Parkin* has been implicated in the cellular protein degradation pathways, as it has been shown that it functions as a ubiquitin ligase. This potential importance of this pathway is also highlighted by the finding of a mutation in the gene for ubiquitin C-terminal hydrolase L1 in another small family with PD. The most recently identified PD-genes are DJ-1 and PINK1, again in families with autosomal-recessive inheritance and early onset. Other loci have been mapped to chromosome 2p and 12p, respectively, in a small number of families with dominantly inherited PD, but those genes have not yet been identified. These findings prove that there are several genetically distinct forms of PD that can be caused by mutations in single genes.

On the other hand, there is at present no strong evidence that any of these genes have a direct role in the etiology of the common sporadic form of PD. Epidemiologic, case control, and twin studies, although supporting a genetic contribution to the development of PD, all suggest a clear familial clustering only in a minority of cases. It is therefore widely believed that a combination of interacting genetic

and environmental causes may be responsible in the majority of PD cases.

Introduction and historical background

Parkinson's disease is traditionally defined as a clinico-pathologic entity, characterized clinically by a core syndrome of akinesia, rigidity, tremor and postural instability, and pathologically by a more or less selective degeneration of dopaminergic neurons of the substantia nigra, leading to a deficiency of dopamine in the striatal projection areas of these neurons. Characteristic eosinophilic inclusions, the Lewy bodies, are found in surviving dopaminergic neurons but also, although less abundantly, in other parts of the brain in most cases, and have been considered to be essential for the pathologic diagnosis of PD (Gibb & Lees, 1989).

Although early descriptions of the disease mentioned a familial aggregation in at least a subgroup of patients (Gowers, 1888), hereditary factors have until relatively recently been considered to play a minor, if any, role in the etiology of the disorder (Duvoisin, 1986).

The change of opinion that occurred mostly during the 1990s was based primarily on three different lines of evidence.

- (i) Case-control studies consistently showed that a positive family history is a major risk-factor towards the development of the disease (Bonifati *et al.*, 1995; Vieregge & Heberlein, 1995; Lazzarini *et al.*, 1994), with relative risks ranging from about 2.3 in a population-based sample (Marder *et al.*, 1996) to as high as 14 in a sample drawn from specialty clinics (De Michele *et al.*, 1995).

Table 40.1. Genetically defined forms of Parkinson's disease and parkinsonism

Locus/ gene	Inheritance	Onset	Pathology	Map position	Gene	Reference
PARK1	dominant	40s	nigral degeneration with Lewy bodies	4q21	α -synuclein	(Polymeropoulos <i>et al.</i> , 1997)
PARK2	recessive	20s	nigral degeneration without Lewy bodies	6q25	Parkin	(Kitada <i>et al.</i> , 1998)
PARK3	dominant	60s	nigral degeneration with Lewy bodies, Plaques and tangles in some	2p13	?	(Gasser <i>et al.</i> , 1998)
PARK4	dominant	30s	nigral degeneration with Lewy bodies, vacuoles in neurons of the hippocampus	4q21	α -synuclein	(Singleton <i>et al.</i> , 2003)
PARK5	dominant	~ 50	No pathology	4p14	Ubiquitin C-terminal hydrolase L1	(Leroy <i>et al.</i> , 1998)
PARK6	recessive	~ 40	No pathology	1p35–37	PINK1	(Valente <i>et al.</i> , 2004)
PARK7	recessive	~ 40	No pathology	1p38	DJ-1	(Bonifati <i>et al.</i> , 2002)
PARK8	dominant	~ 50	Degeneration of dopaminergic neurons without specific inclusions	12cen	?	(Funayama <i>et al.</i> , 2002)
PARK10	dominant	50–60	unknown	1p32	?	(Hicks <i>et al.</i> , 2002)

- (ii) New twin studies using ^{18}F -fluorodopa PET to identify individuals with subclinical disturbances of their nigrostriatal dopaminergic system demonstrated significantly higher concordance rate in monozygous as compared to dizygous twins (Burn *et al.*, 1992), contrary to previous studies (Ward *et al.*, 1983).
- (iii) Finally, several families were described in whom Parkinson's disease (or at least a disorder closely resembling PD) segregated as an apparently dominant (Golbe *et al.*, 1990; Wszolek *et al.*, 1993) or recessive (Takahashi *et al.*, 1994) trait with high penetrance.

It was the growing awareness of those families, combined with a rapid progress in molecular genetic techniques of gene identification, that led to one of the major breakthroughs in recent years in PD research: the mapping and cloning of an increasing number of genes that cause monogenically inherited forms parkinsonism with different associated pathologies and a variable, but overlapping, spectrum of clinical signs and symptoms (Gasser, 2003). In only a few years, these discoveries not only led to a reclassification of parkinsonian syndromes based on the underlying genetic defect, but also to an astonishing expansion of our knowledge of the molecular events that led to neurodegeneration in these disorders.

It has to be kept in mind, however, that all of the mutations and loci identified so far appear to be responsible

in only a relatively small number of families, and their relationship to the vast majority of sporadic patients with PD and other parkinsonian syndromes is still unknown. Nevertheless, there is considerable promise that the elucidation of the molecular pathways leading to monogenically inherited forms of parkinsonism will also allow important insight into the common sporadic disorders, and eventually allow the development of novel protective and therapeutic strategies.

Monogenic forms of Parkinson's disease

A relatively small minority of patients with a more or less typical clinical picture of Parkinson's disease have a positive family history compatible with a Mendelian (autosomal-dominant or autosomal-recessive) inheritance. As a rule, age at onset in most of these cases is earlier as compared to sporadic PD. In many of these families, clinical signs and symptoms are found, in addition to parkinsonism, which would be considered unusual, or in some cases even incompatible, with a diagnosis of classic idiopathic PD (Muentert *et al.*, 1998; Perry *et al.*, 1990). In other cases the disease seems to be indistinguishable clinically, and sometimes also pathologically, from typical PD (Wszolek *et al.*, 1993, 1995). It should therefore be kept in mind that monogenic forms of parkinsonism may serve as valuable models for

studying the molecular pathways involved in dopaminergic degeneration, but are not necessarily identical to the sporadic disease.

Autosomal dominant parkinsonism

Several genetic loci have been identified by linkage studies to cosegregate with parkinsonism in families with dominant inheritance.

PARK1: Parkinson's disease caused by mutations in the gene for α -synuclein (PARK1)

Mutations in the gene for α -synuclein on the long arm of chromosome 4 cause a disorder that resembles idiopathic PD in many ways, both clinically and pathologically (Polymeropoulos *et al.*, 1997). Patients have L-dopa-responsive parkinsonism, and neuropathological studies show the characteristic pattern of neuronal degeneration with α -synuclein-positive Lewy bodies in the substantia nigra. In the early descriptions it appeared that only the relatively early age at onset (with a mean 44 years in the large 'Contursi'-kindred) distinguished this disease from sporadic PD (Golbe *et al.*, 1996). Recently, it became clear, however, that patients with the most common mutation in the α -synuclein gene (the Ala53Thr mutation) can also exhibit clinical features, such as prominent dementia, hypoventilation and autonomic disturbances, which clearly exceed what is usually found in typical PD (Spira *et al.*, 2001). There are also differences in the pathologic picture (Duda *et al.*, 2002).

Despite these differences, the fact that the most conspicuous feature of the pathology in sporadic PD is the intracellular accumulation and aggregation of α -synuclein in a β -sheet configuration (Spillantini *et al.*, 1997) points to the central role of this protein in the disease process of PD in general. α -Synuclein is a relatively small protein that is abundantly expressed in many parts of the brain and localized mostly to presynaptic nerve terminals. Many aspects of the normal function of α -synuclein are still unknown. The protein may functionally be involved in brain plasticity and has been shown to bind to brain vesicles (Jensen *et al.*, 1998) and other cell membranes (McLean *et al.*, 2000). However, knockout mice for α -synuclein show only very subtle alterations in dopamine release under certain experimental conditions, but no other phenotype (Abeliovich *et al.*, 2000).

The currently favoured hypothesis states that the amino acid changes in the α -synuclein protein associated with PD may favor the β -pleated sheet conformation, which in

turn may lead to an increased tendency to form aggregates. This has been demonstrated in vitro (Biere *et al.*, 2000; Conway *et al.*, 2000; Conway *et al.*, 1998). However, the precise relationship between the formation of aggregates and cell death is unknown. It is possible that a failure of proteasomal degradation of α -synuclein and other proteins may lead to an accumulation of toxic compounds, ultimately leading to cell death (McNaught *et al.*, 2001). Formation of α -synuclein-containing aggregates would then be only a secondary effect (McNaught & Jenner, 2001).

However, other mechanisms of pathogenesis may also be important. Known α -synuclein mutations appear to alter the vesicle-binding properties of the protein (Jensen *et al.*, 1998), and the functional homology of α -synuclein to the 14-3-3 protein, a ubiquitously expressed chaperone, may indicate a more profound role for this protein in cellular metabolism and suggests still other possible pathogenic mechanisms.

Mutations in the α -synuclein gene clearly appear to be a very rare cause of the disease. Only three point mutations have been recognized (Polymeropoulos *et al.*, 1997; Krüger *et al.*, 1998; Zarranz *et al.*, 2004). The mutation that was found in the original Contursi family (Ala53Thr) has also been identified in several Greek kindreds (Polymeropoulos *et al.*, 1997; Markopoulou *et al.*, 1995; Papadimitriou *et al.*, 1999). Haplotype analyses support the hypothesis that this is due to a founder effect (Papadimitriou *et al.*, 1999).

Recently, the role of α -synuclein aggregation in PD was further substantiated by the finding of a triplication of a 2 Mb genomic region containing the α -synuclein gene in a large autosomal-dominant family with PD (Singleton *et al.*, 2003). This genomic aberration leads to an overexpression of the intact α -synuclein gene, indicating the susceptibility of neurons to an overload with this amyloidogenic protein. Interestingly, several affected members of this kindred, as well as later reported individuals with an A53T (Spira *et al.*, 2001) and B46K point mutation (Zarranz *et al.*, 2004) had prominent dementia and pathologic findings consistent with Lewy body dementia, supporting the close relationship of this disease entity with PD.

Cellular and animal models

To study the effect of α -SYN mutations in vivo, transgenic mice overexpressing this gene, both the normal and the mutated human sequence, under different promoters have been generated.

Some of the first transgenic mouse lines generated showed somatodendritic accumulation of α -synuclein, but no fibrillar inclusions resembling Lewy bodies (Kahle *et al.*, 2000a; Matsuoka *et al.*, 2001; Masliah *et al.*, 2000).

Other transgenic lines, however, recapitulated human Lewy pathology more faithfully (Giasson *et al.*, 2002; Lee *et al.*, 2002; Neumann *et al.*, 2002). These mice showed age-dependent formation of amyloid-like α SYN fibrils within neuronal perikarya (Lewy bodies) and dystrophic neurites, and developed a progressive locomotor phenotype characterized by dystonia, rigidity, paralysis, and ultimately death. However, neurodegeneration affected predominantly the brainstem and spinal cord, while dopaminergic neurons were spared. This observation may indicate that mice have developed mechanisms protecting their dopaminergic neurons from α -SYN toxicity. The identification of putative defence mechanisms that protect DA neurons throughout the relatively short life span of mice may also be effective in humans. Such cellular defence mechanisms might lose activity in the elderly, ultimately leading to PD in affected patients.

A lot of interest has been generated by an animal model expressing mutant and wt-human α -SYN in the fruitfly *Drosophila* (Feany & Bender, 2000). Not only do these flies show degeneration of dopaminergic neurons and filamentous inclusions resembling LBs, but also a progressive motor phenotype that can be partially corrected by pharmacologic dopaminergic stimulation (Pendleton *et al.*, 2002). The relative ease of developing a *Drosophila* model of α -synucleinopathy might be due to the fact that invertebrate genomes do not code for any synucleins. Thus, flies may not have evolved cellular defence mechanisms to suppress α SYN fibrilization. The *Drosophila* phenotype could be rescued by gene transfer of the molecular chaperone Hsp70 (Auluck *et al.*, 2002), pointing to the cellular protein folding machinery as a therapeutic target.

PARK3: Parkinson's disease linked to chromosome 2

Another autosomal-dominant locus has been described (PARK3), located on chromosome 2p13, in a subset of families with typical PD and Lewy body pathology (Gasser *et al.*, 1998). Clinical features resembling those of sporadic Parkinson's disease (Wszolek *et al.*, 1993) include a similar mean age of onset (59 years in these families). Follow-up examination of these families over the years showed that, in addition to parkinsonism, several members of chromosome 2-linked families showed signs of dementia, and neuropathology revealed, in addition to neuronal loss in the substantia nigra and typical brainstem Lewy bodies, the presence of neurofibrillary tangles and Alzheimer plaques (Wszolek *et al.*, 2002). Therefore, the underlying mutation may be associated with a range of phenotypes, that includes varying degrees of dementia and Alzheimer's disease pathology, as is also known for a subset of patients with idiopathic Parkinson's disease.

The disease gene has not yet been identified (West *et al.*, 2001; Zink *et al.*, 2001). However, two independent recent reports implicate the PARK3-locus as a disease modifying locus influencing age at onset in sib pair cohorts with PD (DeStefano *et al.*, 2002; Pankratz *et al.*, 2003).

PARK4: Parkinsonism-dementia caused by α -synuclein triplication

In a family with parkinsonism with autosomal-dominant inheritance, originally described in detail by Muentner *et al.* (1998) evidence for linkage was found on the short arm of chromosome 4 (Farrer *et al.*, 1999). Affecteds in this family have L-dopa-responsive parkinsonism, but age at onset is considerably younger (mean 33.6 years), and several atypical features are present, such as early weight loss, dysautonomia and dementia. Neuropathologic changes include, in addition to nigral degeneration and Lewy body formation, conspicuous vacuoles in the hippocampus and several other brain areas. Reinvestigation of this family showed that the original mapping to the short arm of chromosome 4 was due to a typing error. The disease locus was then located to the α -synuclein region, and a triplication in the α -synuclein gene was identified as causative in this family (Singleton *et al.*, 2003).

PARK5: Parkinsonism associated with a mutation in the gene for ubiquitin hydrolase L1

A missense mutation in the gene for ubiquitin carboxy-terminal hydrolase L1 gene (UCH-L1) has been identified in two affecteds of a single family of German ancestry (Leroy *et al.*, 1998). This mutation reduces the enzymatic activity *in vitro*, which could be consistent with a causative role of this alteration, as an important role of the proteasomal ubiquitination – protein degradation pathway is suggested by the study of parkin-related parkinsonism (see below). To date, however, no other potentially pathogenic mutations of this gene have been identified (Harhangi *et al.*, 1999a; Lincoln *et al.*, 1999). Another rare variant has been found in a family with PD, which did not segregate with the disease (Farrer *et al.*, 2000).

The observation of a polymorphism in the UCHL1-gene (S18Y) and its possible protective role in patients with sporadic PD (Maraganore *et al.*, 1999; Wintermeyer *et al.*, 2000) has been controversial (Mellick & Silburn, 2000). A recent meta-analysis, however, has again strengthened the link between this gene and PD (Maraganore *et al.*, 2004). A naturally occurring mouse mutant (the GAD-mouse), which shows a phenotype of neuronal degeneration (although predominantly of the peripheral nervous system), has been

found to be due to a deletion in the mouse homologue of the UCHL-1 gene (Saigoh *et al.*, 1999).

PARK8, PARK10

In a large Japanese family with dominant inheritance, the locus has been recently mapped to chromosome 12 (PARK8) (Funayama *et al.*, 2002). Affecteds in this family show typical PD with onset in the late forties and a relatively benign course. Autopsy in four affecteds revealed unspecific neuronal degeneration in the substantia nigra, but no LB-formation. Other dominant families are linked to this locus (Zimprich *et al.*, 2004), but no gene has yet been identified.

The Icelandic population is considered by many to be a genetic isolate, which may lend itself particularly to the study of genetically complex diseases. A clinico-genetic study has provided evidence for a significant familial aggregation of PD which may be caused, at least in part, by the segregation of a dominant gene with reduced penetrance (which may or may not be specific to this population) (Sveinbjornsdottir *et al.*, 2000). Linkage studies allowed the mapping of this locus to chromosome 1p32 (PARK10, (Hicks *et al.*, 2002)). Very recently the gene has been identified as a leucine-rich repeat kinase (LRRK2) (Zimprich *et al.*, 2004).

Autosomal-recessive forms of parkinsonism

One of the surprising developments of recent years was the recognition of the relatively high proportion of patients with early-onset parkinsonism being caused by recessive mutations in a number of genes. So far, three of them, parkin (PARK2), PARK6 (PINK1) and DJ-1 (PARK7) have been cloned.

PARK2: autosomal recessive juvenile parkinsonism (AR-JP) caused by mutations in the gene for parkin

Juvenile cases of parkinsonism with recessive inheritance (families with affected siblings, but usually no transmission from one generation to the next), were first recognized in Japan (Ishikawa & Tsuji, 1996). Clinically, these patients suffer from L-dopa-responsive parkinsonism and some show diurnal fluctuations with symptoms becoming worse later in the day. Dystonia at onset of the disease is quite common. In contrast to patients with dopa-responsive dystonia, which is caused by mutations in the gene for GTP-cyclohydrolase (Ichinose *et al.*, 1994), one of the genes involved in dopamine biosynthesis, patients with recessive parkinsonism develop early and severe levodopa-

induced motor-fluctuations and dyskinesias (Ishikawa & Tsuji, 1996).

The genetic locus for AR-JP has been mapped to chromosome 6 (Matsumine *et al.*, 1997), and mutations have been identified in a large gene in that region that was called *parkin* (Kitada *et al.*, 1998).

Parkin mutations turned out to be a common cause of parkinsonism with early onset, particularly in those with evidence for recessive inheritance. Nearly 50% of families from a population of sibling pairs collected by the European Consortium on Genetic Susceptibility in PD showed parkin mutations (Lücking *et al.*, 2000). The clinical picture is frequently indistinguishable from that of the sporadic disease, with the exception of an earlier mean age-at-onset. While parkin mutations seem to be responsible for the majority of sporadic cases with onset before age 20, and are still rather common (25%) when onset is between 20 and 30, prevalence in older patients is almost certainly well below 5% (Lücking *et al.*, 2000).

The European study population allowed the characterization of the clinical spectrum of parkin-associated parkinsonism. Mean age at onset in a European population was 32 years, progression of the disease was slow but L-dopa associated fluctuations and dyskinesias occurred frequently. Dystonia (usually in a lower extremity) at disease-onset was found in about 40% of patients and brisk reflexes of the lower limbs were present in 44% (Lücking *et al.*, 2000). There was no discernable difference in the clinical phenotype between patients with missense mutations, truncating point mutations or deletions, suggesting that a complete loss of parkin function is associated with all of these mutations and with the full phenotype of early-onset parkinsonism.

The question of whether heterozygous mutations in the parkin gene can cause parkinsonism, or are able to confer an increased susceptibility for typical late-onset PD, is still unsettled. There is evidence from imaging studies (Hilker *et al.*, 2001) that heterozygotes may have mildly reduced uptake of Fluorodopa in the basal ganglia. Furthermore, occasional families with heterozygous mutation carriers manifesting symptoms of PD have been described (Klein *et al.*, 2000a; Farrer *et al.*, 2001). In these cases, however, it is difficult to prove the causal relationship between genotype and phenotype. The obvious study to answer this question, the systematic examination of (heterozygous) parents of patients with parkin mutations, has not been performed.

There is still relatively little information available on the neuropathology of molecularly confirmed cases of AR-JP. Severe and selective degeneration of dopaminergic neurons and gliosis in the substantia nigra, but usually no Lewy bodies have been described (Takahashi *et al.*, 1994).

The fact that Lewy bodies do not appear to be necessary for the selective degeneration of nigral neurons raises the question whether this neuropathologic feature should be regarded as an essential component of the disease process. The recent observation of typical ubiquitin-positive LBs in a patient with a parkin mutation (Farrer *et al.*, 2001) is difficult to reconcile with present concepts of the molecular pathogenesis of the disorder (see below).

As mutations in parkin cause parkinsonism, in all likelihood, by a loss-of-function mechanism, the study of the normal function of parkin, should provide insight into the molecular pathogenesis of the disorder. Several groups have now shown that parkin, a protein that has been found in the cytosol, but also associated with membranes, functions in the cellular ubiquitination/protein degradation pathway as a ubiquitin ligase (Shimura *et al.*, 2000; Zhang *et al.*, 2000). It is therefore conceivable that the loss of parkin function may lead to the accumulation of a non-ubiquitinated substrate which is deleterious to the dopaminergic cell, but due to its non-ubiquitinated nature, does not accumulate in typical Lewy bodies (Kahle *et al.*, 2000b). Several proteins have been shown to interact with parkin and could possibly be its crucial partner with regard to neurodegeneration: an O-glycosylated form of α -synuclein (Shimura *et al.*, 2001), a protein associated with synaptic vesicles, CDCrel-1 (Zhang *et al.*, 2000), and a transmembrane protein, called the pael-receptor (Imai *et al.*, 2001) and synphilin (Chung *et al.*, 2001). The possible interaction with α -synuclein and synphilin is intriguing, as it may provide the link between parkin-associated juvenile parkinsonism and typical late-onset PD (Shimura *et al.*, 2001; Chung *et al.*, 2001). However, as both parkin and α -synuclein are widely expressed in the brain, this does not explain the striking selectivity of the degenerative process for dopaminergic neurons. However, regional selectivity may well be caused by other factors, for example, the high burden of oxidative stress in dopaminergic neurons, or by the lack of some, as yet undefined, compensatory mechanisms.

Recessive early-onset parkinsonism linked to chromosome 1 (PARK6 and PARK7)

Two other recessive loci have been linked in families with early-onset L-dopa-responsive parkinsonism, both to chromosome 1: one (PARK6) in a large Sicilian family with four definitely affected members (the Marsala kindred). The phenotype was characterized by early-onset (range 32–48 years) parkinsonism, with slow progression and sustained response to levodopa (Valente *et al.*, 2001), which is similar to parkin-associated parkinsonism. Preliminary

analyses suggest that this gene may also be responsible in more than a limited number of patients and families.

A second novel recessive locus, PARK7 has been mapped by van Duijn and coworkers (van Duijn *et al.*, 2001), also in a consanguineous Italian family. Again, the clinical picture is that of early-onset, L-dopa-responsive parkinsonism.

The gene responsible for PARK7-linked parkinsonism was the first of the two to be identified (Bonifati *et al.*, 2002). It was called DJ-1 and had originally been discovered as an oncogene. The reason why loss-of-function mutations in DJ-1 cause dopaminergic neurons to degenerate is unclear. The protein may play a role in the cellular response to oxidative stress, which may render dopaminergic neurons particularly vulnerable.

Very recently, a gene for a third form of autosomal-dominantly inherited early-onset parkinsonism has been identified (Valente *et al.*, 2004). Interestingly, it encodes a protein, which is likely to be located in the mitochondria, and possibly functions as a protein kinase. It is known as PINK1 (PTEN-induced kinase 1). The phenotype of patients carrying mutations in this gene resembles that of the other early-onset recessive forms of parkinsonism, in that the progression is slow, L-dopa response is often excellent, and dementia is not usually a part of the phenotype (in contrast to the dominant, α -synuclein-linked forms of parkinsonism).

Non-monogenic forms of familial PD

Monogenic forms of PD are rare and probably account for less than 5% of all of PD, with young-onset cases being clearly over-represented in this group. A larger proportion of cases, probably 10 to 15%, have affected family members, but a clear Mendelian pattern of inheritance cannot be demonstrated.

Segregation analyses have produced conflicting results suggesting autosomal dominant, autosomal-recessive (Maher *et al.*, 2002; Moilanen *et al.*, 2001) or non-Mendelian (Zarepari *et al.*, 1998) inheritance of disease susceptibility or age at onset. It is therefore widely believed that typical PD is a 'genetically complex' disorder with several common susceptibility genes, each conferring only a relatively slight increase of risk, possibly interacting with each other and/or with non-genetic risk factors. Depending on age-at-onset or other clinical characteristics, the relative contribution of these genetic risk factors may vary between different populations.

Several linkage studies have been conducted in large cohorts of small families with PD (mostly nuclear families and/or affected sib pairs) with interesting, but still

Table 40.2. Association studies in Parkinson's disease. Only a few studies are cited as representative examples

Candidate gene	Locus	Positive (or negative) association	No association
Dopaminergic transmission			
Dopamine-D2-receptor	11q22-23	(Plante Bordeneuve <i>et al.</i> , 1997)	(Nanko <i>et al.</i> , 1994)
Dopamine-D3-receptor	3q13.3		(Nanko <i>et al.</i> , 1994)
Dopamine-D4-receptor	11p15.5		(Nanko <i>et al.</i> , 1994)
Dopamine transporter	5p15.3	(Le Couteur <i>et al.</i> , 1997)	(Plante Bordeneuve <i>et al.</i> , 1997) (Leighton <i>et al.</i> , 1997)
Tyrosine hydroxylase			
Tyrosine hydroxylase	11p15.5		(Plante Bordeneuve <i>et al.</i> , 1997)
Catechol-O-methyltransferase	22q12.1	(Yoritaka <i>et al.</i> , 1997)	(Xie <i>et al.</i> , 1997)
Monoamine oxidase A	X		(Hotamisligil <i>et al.</i> , 1994)
Monoamine oxidase B	Xp11.3	(Costa <i>et al.</i> , 1997; Kurth <i>et al.</i> , 1993)	(Ho <i>et al.</i> , 1995)
Heme oxygenase-1	22q12		(Kimpara <i>et al.</i> , 1997)
Xenobiotic metabolism			
Debrisoquine-4-hydroxylase	22q13	(Wilhelmsen & Wszolek, 1995) (Armstrong <i>et al.</i> , 1992; Smith <i>et al.</i> , 1992)	(Diederich <i>et al.</i> , 1996) (Gasser <i>et al.</i> , 1996)
Cytochrome P4501A1			
Cytochrome P4501A1	5q22-24		(Takakubo <i>et al.</i> , 1996)
Paraoxonase 1	7q21.3	(Akhmedova <i>et al.</i> , 2001)	(Wang & Liu, 2000; Taylor <i>et al.</i> , 2000)
N-Acetyltransferase 2	8p23.1	(Agundez <i>et al.</i> , 1998; Bandmann <i>et al.</i> , 1998)	(Harhangi <i>et al.</i> , 1999b)
Protein aggregation			
Apolipoprotein E	19q13.2	(Kruger <i>et al.</i> , 1999)	(Whitehead <i>et al.</i> , 1996)
α -synuclein	4q21.3-22	(Kruger <i>et al.</i> , 1999)	(Parsian <i>et al.</i> , 1998)
UCH-L1	4p15	(Maraganore <i>et al.</i> , 2004)	(Mellick & Silburn, 2000)

inconclusive, results. Five different total genome screens in populations of 150 to 250 families have been performed (Scott *et al.*, 2001; DeStefano *et al.*, 2001; Pankratz *et al.*, 2002; Li *et al.*, 2002), and European Consortium on Genetic Susceptibility in PD (Martinez *et al.*, 2004). None of these genome screens could unequivocally map a novel locus. This may be due to a still insufficient statistical power of the studies in the face of the high degree of genetic heterogeneity that has to be assumed. In all of these studies, several regions were identified with some evidence for increased allele sharing, but failing to reach statistical significance. Except for a locus on chromosome 5, 9q, and on the X-chromosome, none of these loci showed any overlap between different studies.

One of those loci, however, on the long arm of chromosome 2, has been followed up in an expanded group of small families with an inheritance pattern, compatible (but not proving) autosomal-dominant inheritance. In this population, a lod score of > 5 has been calculated, assuming autosomal-dominant inheritance. Fine mapping of a linked region in a population of small families can be much more difficult than in large multicase pedigrees, as no individual recombination events can be used for narrowing the region.

Another approach to identify genes contributing to the etiology of familial PD is the investigation of candidate genes. One recent example is the gene for the nuclear receptor Nurr1. Nurr1 is a member of the nuclear receptor superfamily of transcription factors that is expressed predominantly in the central nervous system, including developing and mature dopaminergic neurons. Recent studies have demonstrated that Nurr1 is essential for the induction of phenotypic markers of ventral mid-brain dopaminergic neurons (Saucedo-Cardenas *et al.*, 1998). This gene, also called NR4A2 has been sequenced in individuals affected with Parkinson's disease and in controls. Two sequence variants have been identified (-291Tdel and -245T->G), located in the first exon of NR4A2 to affect one allele in 10 of 107 individuals with familial Parkinson's disease but not in any individuals with sporadic Parkinson's disease ($n = 94$) or in unaffected controls ($n = 221$). These variants resulted in a marked decrease in NR4A2 mRNA levels and also affected transcription of the gene encoding tyrosine hydroxylase. This observation supports the assumption (but does not prove) that the observed sequence variants are in fact functionally relevant (Le *et al.*, 2003).

However, other studies have failed to find any potentially pathogenic sequence variants in the Nurr1-gene, so the

relevance of the original finding remains to be determined (Nichols *et al.*, 2004; Zimprich *et al.*, 2003).

Genetic contribution to sporadic PD

Although molecular genetic analysis has produced significant progress in families with parkinsonian phenotypes with mendelian inheritance, it must be remembered that Parkinson's disease, in the great majority of cases, is a sporadic disorder. The type and the extent of a genetic contribution to non-mendelian PD is still controversial. A population based case-control study indicates that the relative risk for first-degree family members of PD patients is increased only in the order of 2 to 3 (Marder *et al.*, 1996).

Most attempts to identify the susceptibility genes in sporadic PD have followed a candidate gene approach. Based on pathological, pathobiochemical and epidemiologic findings, hypotheses on the etiology of Parkinson's disease can be generated and genetic polymorphisms within, or closely linked to, genes that are thought to be involved in these pathways have been examined (Table 40.2). Unfortunately, no consistent findings have emerged so far.

Studied genes include those identified in monogenic forms of PD, including α -synuclein and parkin (Kruger *et al.*, 1999; Maraganore *et al.*, 1999; Scott *et al.*, 1999; Satoh & Kuroda, 1999; Klein *et al.*, 2000b; Wang *et al.*, 1999; Parsian *et al.*, 1998), genes encoding enzymes involved in the detoxification of xenobiotic compounds, such as debrisoquine hydroxylase, *N*-acetyltransferase (Bandmann *et al.*, 1998) and paraoxonase (Akhmedova *et al.*, 2001), as well as genes involved in dopamine metabolism and neurotransmission. Despite a large number of initial positive results, findings have not been confirmed beyond doubt in any of these cases (Table 40.2), indicating that studies with improved methodology (e.g. transmission disequilibrium testing (Spielman & Ewens, 1998)), and the examination of haplotypes instead of single polymorphisms (Seltman *et al.*, 2001) are necessary.

Conclusions

The genetic findings in rare inherited forms of PD have contributed to our understanding of the clinical, neuropathologic and genetic heterogeneity of PD. The variability of clinical features, such as age at onset, occurrence of demen-

tia or other associated features that has been found within single families, suggests that a single genetic cause (the pathogenic mutation in a given family) can lead to a spectrum of clinical manifestations. On the other hand, individuals with different genetic defects and different neuropathology (e.g. some of those with mutations in the PARK1 and PARK2 genes) may be clinically indistinguishable from each other and fulfil all presently accepted criteria of idiopathic Parkinson's disease. It is therefore apparent that a new genetic classification of PD that is only partially congruent with the classic clinical-pathologic classification is about to emerge.

At present, there is convincing evidence that genetic factors play an important role in the etiology of at least a subset of patients with PD. Only a small percentage of cases with dominant or recessive inheritance can probably be explained by mutations in the genes that have been identified so far (the genes for α -synuclein, ubiquitin carboxy-terminal hydrolase L1, and parkin) or by mutations in the as yet unidentified genes on chromosome 1p, 2p and 4p, and 12. However, the study of wild-type and mutated gene products will provide important insight into the molecular pathogenesis of nigral degeneration and Lewy body formation. However, it appears that intense efforts are still needed to unravel the full spectrum of etiologic factors leading to the common sporadic form of this neurodegenerative disorder.

³Clinic and Policlinic of Psychiatry and Psychotherapy, University of Würzburg, Germany

Although the primary pathology and key defects of neurotransmission leading to the clinical picture of Parkinson's disease (PD) are known, initiation and nature of the neurodegenerative process are still obscure. However, it is becoming increasingly evident that the underlying pathophysiology is complex and in most cases probably multifactorial, differing among the individuals affected.

Only a very small percentage of Parkinsonian cases are caused by monogenic alterations (see Chapter 40). However, since the first description of a family in which 79 of 194 members suffered from PD (Mjörnes, 1949), it has become evident that the risk of developing the clinical picture of PD is three to four times higher in individuals with relatives with PD compared to those with a negative family history. Functional neuroimaging proved to be especially valuable for the detection of affected siblings: for monozygotic twins a concordance of 75% for PD or at least a subclinical dopaminergic deficit was detected by PET-studies, the rate for dizygotic was 22% (Piccini *et al.*, 1999). These and other findings provide strong evidence of a genetic contribution to idiopathic PD (Gasser *et al.*, 1998, 2001). However, only about 25% of PD patients report a relative affected by the same disease. Therefore, other factors are necessary to explain the selectivity and susceptibility of the disease on the basis of a genetic predisposition. Biochemical and histological investigations of the past decades have illuminated some of these factors.

Oxidative stress

Oxidative stress (OS) occurs when reactive oxygen species, such as the superoxide radical ($O_2^{\bullet -}$), nitric oxide (NO) and especially the hydroxyl radical ($\bullet OH$) due to an excessive production overwhelm the protective defense mechanisms of a cell resulting in functional disruption and ultimately in

cell death. OS is regarded as key event in the neurodegenerative process of PD. Because of their high reactivity, free radicals cannot be measured directly. However, there are a number of indices for OS in the substantia nigra (SN) of PD patients:

- increased levels of products of lipid peroxidation and decreased levels of polyunsaturated fatty acid levels, a peroxidation substrate (Dexter *et al.*, 1989; Yoritakta *et al.*, 1996),
- increased levels of 8-hydroxy-2'-deoxyguanosine, indicating DNA base damage (Sanchez-Ramos *et al.*, 1994; Alam *et al.*, 1997),
- detection of 3-nitrotyrosine, the marker of OS induced by peroxynitrite, in Lewy bodies (Giasson *et al.*, 2000)
- decrease in the level of reduced glutathione in SN of PD (Sofic *et al.*, 1992) and low activity of phospholipid-catabolizing enzymes in normal SN compared with other regions of the human brain, indicating a reduced repair capacity of oxidative damage (Ross *et al.*, 1998)
- upregulation of antioxidant enzymes like Mn-dependent superoxide dismutase and nonselenium glutathione peroxidase (Martilla *et al.*, 1988; Yoshida *et al.*, 1994; Power *et al.*, 2002)
- OS-dependent protein aggregation in the form of advanced glycation end products, already detectable within Lewy bodies at a time when no clinical sign of PD is obvious (Münch *et al.*, 2000).

Moreover, peripheral markers for oxidative stress like altered superoxide dismutase (SOD) activity, reductions in glutamate uptake and increased levels of malondialdehyde as well as thiobarbituric acid reactive substances have been detected in erythrocytes, serum and plasma of PD patients (Bostantjopoulou *et al.*, 1997; Nagatsu *et al.*, 1999; Ferrarese *et al.*, 2001; Serra *et al.*, 2001). These findings, as well as the demonstration of primary and oxidative DNA damage

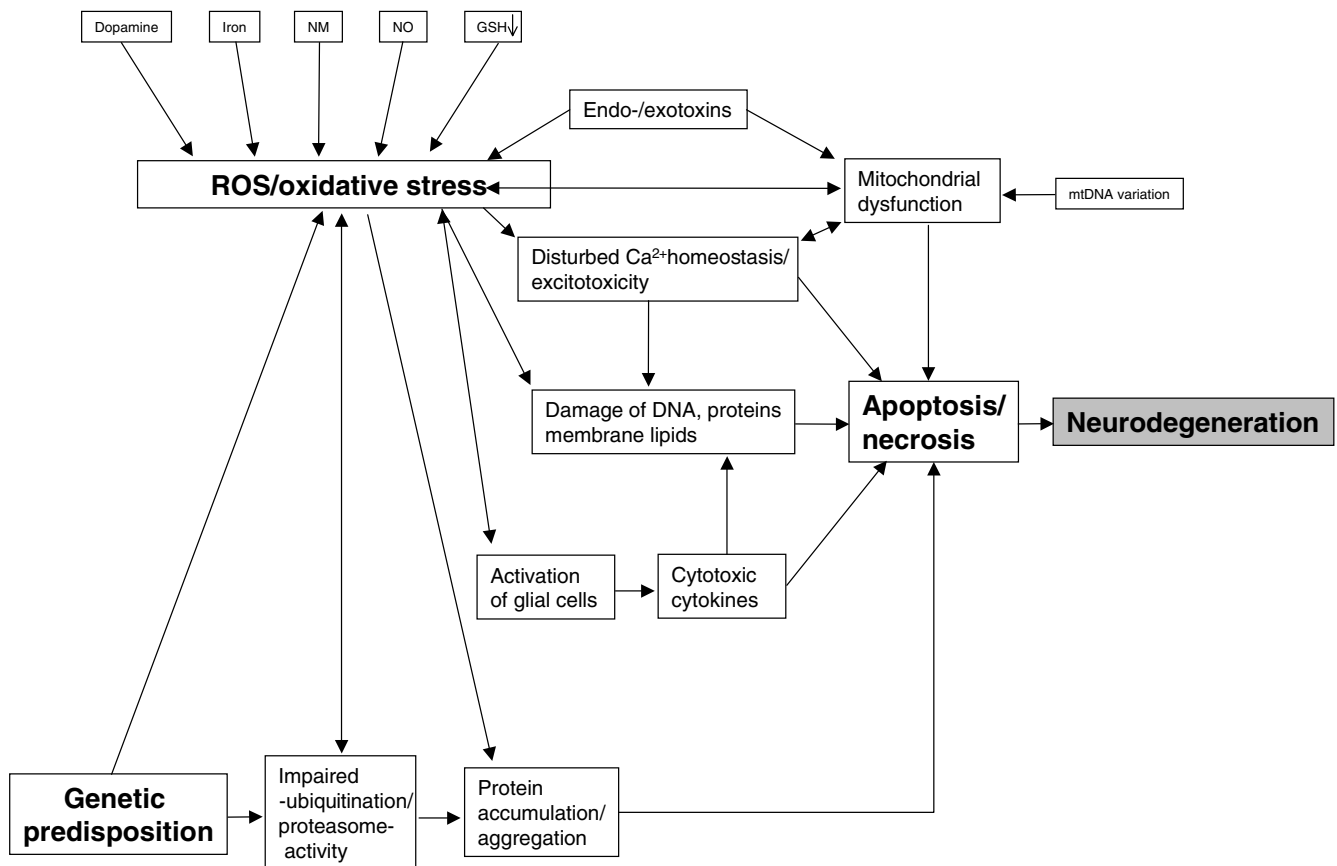

Fig. 41.1 Factors supposed to contribute to neurodegeneration in PD and their interaction. NM = neuromelanin, NO = nitric oxide, GSH = glutathione, ROS = reactive oxygen species.

in lymphocytes of untreated Parkinson patients (Migliore *et al.*, 2002), indicate a possible systemic affection related to the oxidative stress in the brain.

A number of factors have been shown to contribute to OS within the SN (Fig. 41.1).

Factors contributing to the generation of oxidative stress

Dopamine

Metabolism of dopamine, the main neurotransmitter of the neurons degenerating in PD, produces reactive oxygen species and might therefore account, at least in part, for the selective vulnerability of the SN pars compacta (SNc). After synthesis, dopamine is directly taken up into synaptic vesicles. Here dopamine is protected from catabolization, as there are no metabolizing enzymes (monoamine oxidase, MAO) and the pH is too low for autooxidation. In the cytoplasm, however, dopamine is either autooxidized or metabolized enzymatically (Lotharius & Brundin, 2002). Autooxida-

tion of dopamine leads to the production of dopaquinone and $O_2^{\bullet-}$. $O_2^{\bullet-}$ is either metabolized into H_2O_2 or it reacts with nitric oxide, generating the strongly reactive peroxynitrite ($ONOO^{\bullet-}$). Enzymatic metabolism of dopamine forms H_2O_2 , which is converted into $\bullet OH$ via the iron mediated Fenton reaction (Götz *et al.*, 1994; Antunes *et al.*, 2002; Maruyama & Naoi, 2002). Autooxidation may be increased in the early stages of the disease, when dopamine turnover increases to compensate for the dying dopaminergic neurons (Scherman *et al.*, 1989). Production of these reactive oxygen species has a detrimental effect on cellular macromolecules, damaging lipids, proteins and DNA (see above). Moreover, dopamine and various of its metabolites can inhibit complex I of the electron-transport chain (see below; Ben-Shachar *et al.*, 1995).

An additional toxic effect of the antiparkinsonian drug L-dopa has been the matter of discussion for many years. In vitro experiments seem to indicate an increase of OS and neurodegeneration after L-dopa administration (Spencer *et al.*, 1994; Walinshaw & Waters, 1995). In animal

experiments, however, no increased toxicity was seen after L-dopa application (Perry *et al.*, 1984). Also, the ELLDOPA clinical trial has not substantiated an L-dopa induced toxicity (Fahn, 1999).

As in PD only selective dopaminergic neuron populations degenerate and other factors contributing to OS need also to be taken into account.

Iron

Iron content of the basal ganglia and SN is already under physiologic conditions higher than in most other regions of the brain (Hallgren & Sourander 1958). This is important, as iron is required as a co-factor for the synthesis of dopamine by the enzyme tyrosine hydroxylase. In PD, however, iron content of the SNc is about 35% higher, with an elevation of the Fe(III)/Fe(II)-ratio from 2:1 to almost 1:2 (Riederer *et al.*, 1988, 1989; Sofic *et al.*, 1988; Dexter *et al.*, 1993; Gerlach *et al.*, 1994). Increased levels of iron and Fe(II) enhance the conversion of H₂O₂ to •OH via the Fenton reaction and favor a greater turnover in the Haber–Weiss cycle, which leads to an amplification of OS (Riederer & Youdim, 1993). Besides the contribution to the formation of highly reactive oxygen species iron has been shown to interact with α -synuclein (Hashimoto *et al.*, 1998, 1999; Paik *et al.*, 1999; Münch *et al.*, 2000; Osterova-Golts *et al.*, 2000; Golts *et al.*, 2002), one of the major components of Lewy bodies (see below). By catalyzing oxidative reactions, iron enhances the conversion of unfolded or α -helical conformation of α -synuclein to β -pleated sheet conformation, the primary form in Lewy bodies (Hashimoto *et al.*, 1998, 1999). Additionally, iron seems to play a pivotal role in the activation of NF-kappa B, a redox-sensitive transcription factor, which transactivates various genes of cytotoxic cytokines taking part in inflammatory responses (Youdim *et al.*, 1999). It is not entirely clear yet at what time in the pathophysiological cascade of PD iron accumulation occurs and whether it is a primary cause of neurodegeneration or rather reflects a secondary phenomenon. Iron accumulation induced by toxin-mediated neurodegeneration in animal models suggests it to be a secondary phenomenon (Mochizuki *et al.*, 1994; He *et al.*, 1996). However, high iron diet, fed to weanling mice, has been shown to lead to marked reduction of SN glutathione levels, a finding known to occur very early in PD (Lan and Jiang, 1997). Data from recent transcranial ultrasound studies also imply iron accumulation to occur very early in the disease process constituting rather a primary cause of the disease. In patients with PD a typical enhancement of SN echogenicity is visible on transcranial ultrasound, which has been shown to be caused

by increased iron levels (Becker *et al.*, 1995; Berg *et al.*, 1999a, 2002). This marker occurs very early in life in a subgroup of the population and is associated with impaired nigrostriatal function detected by 18F-dopa PET in some young healthy individuals (Berg *et al.*, 1999b, 2002). The ultrasound marker, indicating increased iron levels, might therefore serve as a marker for vulnerability early in life. This early occurrence of increased iron levels indicates possible alterations in brain iron metabolism. Alterations have been found in proteins involved in the uptake, storage and release of iron (for review see Berg *et al.*, 2001). These alterations might be due to mutations and polymorphisms in genes encoding for iron metabolizing proteins (Berg *et al.*, 2002; Borie *et al.*, 2002).

Neuromelanin

The role of this very strong iron chelator in the pathogenesis of PD has been the matter of debate for many years (Youdim *et al.*, 1994). Neuromelanin (NM), consisting primarily of an aliphatic chain structure with a smaller aromatic backbone, is generally regarded to be the result of the spontaneous autoxidation of dopamine and noradrenaline (Zecca *et al.*, 1992; Double *et al.*, 2000). This, however, has been questioned due to the fact that (i) not all dopaminergic neurons of the SN contain neuromelanin and (ii) long-term L-Dopa treatment does not seem to enhance neuromelanin concentration in surviving neurons. As in PD, primarily NM-containing neurons degenerate (Hirsch *et al.*, 1988), leading to the typical depigmentation of the SN, a cytotoxic effect of NM contributing to OS has been proposed. Neuromelanin is an excellent chelator of metal ions, especially iron (Ben-Shachar *et al.*, 1991), therefore a neuroprotective role of neuromelanin is discussed (Zecca *et al.*, 1993; Gerlach *et al.*, 1994). Iron bound to NM accounts for 10–20% of the total iron in the SN in normal subjects aged 70–90 years (Shima *et al.*, 1997; Zecca *et al.*, 2001). In PD, however, the absolute concentration of NM within the SN is dramatically decreased (Zecca *et al.*, 2002). Moreover, iron levels of NM are higher than in controls (Good *et al.*, 1992; Jellinger *et al.*, 1992). The amount of iron determines the role of NM: in the situation of normal iron levels this redox active metal is sequestered. In the presence of excess iron, however, NM promotes the formation of reactive oxygen species and fosters the release of iron into the cytoplasm (Zareba *et al.*, 1995; Zecca *et al.*, 1996; Double *et al.*, 1999; Lopiano *et al.*, 2000). Additionally, NM can bind a variety of potentially toxic substances like MPP⁺, the neurotoxic metabolite of MPTP or pesticides suggesting a contribution to neurotoxin-mediated neurodegeneration (D'Amato *et al.*, 1986; Gerlach *et al.*, 1994).

Nitric oxide

Nitric oxide (NO) is produced in the reaction of arginine with molecular oxygen to generate citrulline and NO (Bredt, 1999). Besides its function in immune modulation, it plays an important role as neurotransmitter in the central and peripheral nervous system (Grisham *et al.*, 1999). On one hand, NO acts as an antioxidant, scavenging free radicals (Rubanyi *et al.*, 1991). On the other hand, NO may contribute to a selective neurotoxicity during brain development, rendering brain differentiation possible (Bredt, 1991). In PD enhanced production of NO by activated glial cells has been observed (Hunot *et al.*, 1999). As a free radical, NO contributes to OS by reacting with proteins thereby altering their function and lipids, inducing lipid peroxidation (Beckmann, 1996; Iravani *et al.*, 2002). Additionally, highly reactive intermediates like peroxy-nitrite are formed in the presence of superoxide, inducing DNA damage and lipid peroxidation (Beckmann *et al.*, 1990; Liu *et al.*, 2002). NO also mediates iron release from ferritin (Reif & Simmons, 1990), which again may contribute to OS. Direct interaction of NO and the respiratory chain can induce additional cell damage (Cleeter *et al.*, 1994; Antunes *et al.*, 2002). In these and other studies it has become obvious that NO is necessary but not sufficient to induce neurodegeneration. Only in concert with oxygen free radicals, other proinflammatory or cytotoxic substances, is induction of neurodegeneration achieved (Liu *et al.*, 2002).

Factors diminishing oxidative stress

Protective defense mechanisms of cells against oxidative damage include enzymatic reactions by superoxide dismutase (SOD), glutathione peroxidase or catalase as well as non-enzymatic reactions by the antioxidants vitamin C and E, glutathione (GSH), cysteine or coenzyme Q (Gerlach *et al.*, 2001). In situations of increased oxidative stress like in PD an increased activity of these systems would be expected to counteract toxicity of free radicals. However, no difference in the levels of antioxidative vitamins was found between PD patients and controls (Riederer *et al.*, 1989). For catalase and glutathione peroxidase, almost equal or only slightly reduced levels and activities were found (Ambani *et al.*, 1975; Kish *et al.*, 1985; Martilla *et al.*, 1988; Sian *et al.*, 1994). However, increase of the antioxidant non-selenium glutathione peroxidase in astrocytes in PD brains (Power *et al.*, 2002) and a specific and unique increase of SOD in the SNc were detected (Martilla *et al.*, 1988; Yoshida *et al.*, 1994). H₂O₂ generated in the detoxification process of free radicals by SOD is normally further converted by the enzymes

catalase and glutathione peroxidase. The lack of increase of these enzymes in PD prevents this process leading to a deleterious increase of H₂O₂ (Foley & Riederer, 1999). Moreover, a reduction of total and reduced GSH is detectable in the SNc in PD (Riederer *et al.*, 1989; Sofic *et al.*, 1992) in the very early pathogenetic process rendering neurons more vulnerable to endo- or exotoxins (Jenner & Olanow, 1998). GSH depletion has been shown to cause a cascade of deleterious events like promoting the formation of defective proteins and thereby impairing the normal ubiquitin-proteasome pathway of protein degradation (Bharat *et al.*, 2002). Additionally, release of arachidonic acid by GSH depletion may cause cellular damage through its metabolism by lipooxygenase (Kramer *et al.*, 2002; Mytilineou *et al.*, 2002). GSH depletion may also have an inhibitory affect of mitochondrial complex I activity (Bharat *et al.*, 2002).

Mitochondrial dysfunction

A decline of about 30% in the activity of complex I, the first of five complexes of the mitochondrial respiratory chain, has been found in SNc of PD patients (Dexter *et al.*, 1989; Mizuno *et al.*, 1989; Reichmann & Riederer, 1989; Janetzky *et al.*, 1994). Immunohistochemical studies revealed that dopaminergic neurons with high contents of NM were associated with low levels of complex I activity (Hattori *et al.*, 1991). Because of the reduced activity less NAD is formed from NADH resulting in an impairment of proton pumping and electron transport, which in turn leads to an increase of reactive oxygen species, proteasome inhibition and cell death (Reichmann *et al.*, 1993; Betarbet *et al.*, 2000; Reichmann & Janetzky, 2000; Liu *et al.*, 2002). Decline of complex I activity is also followed by reduced ATP production resulting in decreased energy for the cell and DNA damage. The cause of complex I impairment in PD is not clear yet. On the one hand, a secondary phenomenon resulting from radical formation, which may itself contribute to further radical formation, is discussed (Gu *et al.*, 1998). On the other hand, changes in the mitochondrial genome have been found in the brain of PD patients with an increase of number and variety of mtDNA deletions/rearrangements compared to patients with other movement disorders, Alzheimer's disease and age-matched controls (Gu *et al.*, 2002). Moreover, a variety of amino acid variations have been detected in cytochrome b of the mitochondrial genome in PD patients compared to only few variations in centenarians (Tanaka, 2002). This might indicate that deviations

from standard amino sequence could be associated with increased production of reactive oxygen species. Besides an additional impairment of complex IV activity (Itoh *et al.*, 1997) no alterations in the functions of the other complexes of the respiratory chain have been detected, yet.

A specific role in determining survival and death in apoptosis induced by endogenous neurotoxins could be attributed to mitochondria (Naoi *et al.*, 2000, 2002). Additionally, exotoxins like the insecticide rotenone, a specific inhibitor of complex I, may produce features of PD, indicating that environmental exposure might lead to or superimpose with mitochondrial dysfunction resulting in neurodegeneration (Sherer *et al.*, 2002a,b).

Calcium homeostasis and excitotoxicity

Impaired calcium homeostasis with high levels of intracellular calcium may lead to uncontrolled stimulation of various calcium dependent enzymes and stimulation of mitochondrial generation of reactive oxygen species resulting in metabolic dysfunction and ultimately cell death (Gerlach *et al.*, 1996; Starkov *et al.*, 2002). The above mentioned loss of integrity of the cellular membrane due to destruction by free radicals and an increase of calcium influx due to disruption of the respiratory chain are sources of increased intracellular calcium levels. Another important cause is "excitotoxicity." Excitotoxicity means excitatory and toxic properties of a substance at the same time. Glutamate, the main excitatory transmitter in human central nervous system acts on NMDA, AMPA/kainate and metabotropic receptors (Plaitakis & Shashidharan, 2000). These receptors are not only activated by glutamate, but also by specific endo- and exotoxins (Spencer *et al.*, 1987; Shaw & Bains, 2002). Lasting excitation may lead to cell death via an increase of intracellular calcium levels. Impairment of calcium homeostasis and excitotoxicity have been detected in a number of neurodegenerative diseases including Alzheimer's disease, Huntington and ALS (Landfield *et al.*, 1991; Beal *et al.*, 1993). The role of excitotoxicity in the pathogenesis of PD is not clear yet. However, neurons positive for the calcium binding protein calbindin appear less susceptible to the neurodegenerative changes occurring in PD (Yamada *et al.*, 1990; Hirsch *et al.*, 1992). The reported significant loss of calbindin in the SN of PD brains (Chan-Paley *et al.*, 1991) might therefore indirectly argue for the contribution of excess calcium to neurodegeneration in PD. High levels of expression of the neuron-specific glutamate carrier EAAT3 and high

levels of the ATP-generating glutamate dehydrogenase in dopaminergic neurons of the SN demonstrate the need of high rates of energy. They may indicate a special vulnerability of these cells to excitotoxicity and impairment of glutamate metabolism (Plaitakis & Shashidharan, 2000). Studies on calcium binding to α -synuclein suggest that calcium ions may on the one hand participate in normal α -synuclein functioning, while on the other hand exercising pathological effects known to be involved in Lewy body formation (Nielsen *et al.*, 2001).

Exotoxins

First evidence of a contribution of exotoxins to the pathogenesis of PD came from the discovery of the toxicity of MPTP, an impurity formed during the preparation of meperidine, which provokes severe, progressive parkinsonism (David *et al.*, 1979; Langston *et al.*, 1983). Other substances known to cause or promote PD are CO, manganese, cyanide and methanol (Glass, 1983; Zayed *et al.*, 1990). Exposure to these substances might be at home, as seen in the case of drinking water from wells, polluted with heavy metals (Rajput *et al.*, 1986; Barbeau *et al.*, 1987). However, not all investigations corroborate these findings (Rajput *et al.*, 1987). At work, pesticides and herbicides are discussed to be the main substances of exposition (Sanchez-Ramos *et al.*, 1987; Secchi *et al.* 1992; Sherer *et al.*, 2002b). Chronic treatment with the insecticide rotenone has been shown to cause delayed oxidative damage and induce the formation of α -synuclein aggregates (Sherer *et al.*, 2002a). The latter, however, has not been confirmed in more recent studies (E. C. Hirsch, personal communication). Other toxins like chloralhydrate reacting with endogenous amines (Bringmann *et al.*, 1998) and dieldrin (Kitazawa *et al.*, 2001) are still being investigated. As not all individuals exposed to the same environmental toxins develop PD, a genetically determined susceptibility is probable (see above; Jenner, 2001).

Infections have also been argued to contribute to the pathogenesis of PD in specific cases. Indices for a possible link between PD and infections are

- acute, mostly transient Parkinson syndromes in the course of virus infections (Walters, 1960; Isgreen *et al.*, 1976; Solbrig, 1993)
- detection of the influenza-A-antigen in postmortem brains of patients with postencephalitic parkinsonism (Gamboa *et al.*, 1974)
- increase of PD in certain generations after pandemics (Poskanzer & Schwab, 1963).

However, the clinical and histopathological pictures of infection-associated parkinsonism differ from idiopathic PD (Duvoisin *et al.*, 1963), rendering a contribution of infections to idiopathic PD unlikely (see also Riederer & Foley, 2002).

Glial cells and inflammation

Lower frequencies of infections and cancer in PD patients suggest a stimulation of the immune system in PD (Czlonkowska *et al.*, 2002). In the brain there are two types of glial cells involved in immunologic processes: microglia and astrocytes. Owing to their ability to secrete diffusible factors, these cells are capable of exerting either a protecting or a deleterious influence on dopaminergic neurons in PD. In the SN of PD patients glial cell distribution is lowest in areas where dopaminergic neurons degenerate and highest in those regions where they are preserved (Damier *et al.*, 1996). From this observation a protective effect of glial cells is assumed that is attributed to their production of glutathione peroxidase and pyruvate, protecting cells from highly toxic free radicals (Damier *et al.*, 1993; Desagher *et al.*, 1997), and neurotrophic factors exerting a neuroprotective influence. GDNF (glial cell line-derived neurotrophic factor) and BDNF (brain-derived neurotrophic factor) produced by glial cells have proven neuroprotective against different neurotoxic substances in vitro and in vivo (Beck *et al.*, 1993; Lin *et al.*, 1993; Gash *et al.*, 1996). Additionally, astrocytes maintain ionic homeostasis and buffer neurotransmission signals (Liu *et al.*, 2002). On the other hand, activated glial cells may exert a detrimental influence on dopaminergic neurons (Hirsch, 2000). Activated by brain damage, glial cells, especially microglia, produce various proinflammatory and neurotoxic substances. In PD brains the density of glial cells expressing tumor necrosis factor α , interferon γ and interleukin 1β is increased (Boka *et al.*, 1994; Mogi *et al.*, 1994; Hunot *et al.*, 1999). These findings as well as elevated concentrations of interleukin 2, interleukin 4 and interleukin 6 in the ventricular cerebrospinal fluid of PD patients (Blum-Degen *et al.*, 1995; Mogi *et al.*, 1996), indicate a contribution of these proinflammatory cytokines to neurodegeneration in PD. The detrimental effect of cytokines on neurons is achieved by the release of glutamate (McNaught *et al.*, 2000; Koutsilieri *et al.*, 2002) leading to an elevation of OS (Gao *et al.*, 2002) and excitotoxicity, by increased production of NO (Minghetti & Levi, 1998; Hunot *et al.*, 1999; Liu *et al.*, 2002) or by the activation of pro-apoptotic mechanisms.

Apoptosis

Apoptosis refers to “programmed cell death,” a form of death in which intrinsic genetic programs of a cell act to attain its destruction (Jacobson *et al.*, 1997). Apoptosis of specific cells is not accompanied by negative effects, like inflammation, on other cells. The physiological function of apoptosis is elimination of cells either to enable differentiation during development or to get rid of noxious cells. Besides this physiological function, however, programmed cell death seems to play a role in different kinds of disorders either by insufficient (e.g. in cancer) or by enhanced apoptosis (e.g. in neurodegeneration) (Thompson, 1995). In PD the role of apoptosis remains controversial. In some studies typical evidence of apoptosis like fragmented nuclei and activation of caspase 3 has been detected (Mochizuki *et al.*, 1996; Anglade *et al.*, 1997; Tatton *et al.*, 1998; Tatton, 2000; Hartmann *et al.*, 2000). Other studies of end-stage PD patients, however, failed to demonstrate convincing evidence (Wüllner *et al.*, 1999; Jellinger, 2000). In vitro studies and animal models of PD, like the MPTP- or the NM(R)Sal-model, seem to favor the hypothesis of apoptosis mediated neurodegeneration in PD (for review see Burke & Kholodilov, 1998; Turmel *et al.*, 2001; Maruyama & Naoi, 2002; Nagatsu, 2002). The most corroborating evidence underlining that apoptosis might play an important role in PD comes from the investigation of chaperones. Chaperones are molecules with a multitude of different activities like mediation of proper protein folding, translocation of proteins across cellular membranes, signal transduction and mediation of transcriptional responses to stress (Muchowski, 2002). Immunohistochemical studies detected the 14–3–3 protein, a chaperone with seven known mammalian isoforms and 40% homology to α -synuclein (Osterova *et al.*, 1999), in Lewy bodies of PD brains (Kawamoto *et al.*, 2002; Ubl *et al.*, 2002). Normally, the pro-apoptotic protein BAD prevents the anti-apoptotic function of other proteins in the mitochondria. This process can be prevented by binding of 14–3–3 proteins to BAD in the cytoplasm of cells (Muslin & Xing, 2000), relieving anti-apoptotic proteins for their function (Tzivion *et al.*, 2001). Association of 14–3–3 with α -synuclein in a complex however, reduces this anti-apoptotic activity by increasing free BAD or other pro-apoptotic binding partners (Welch & Yuan, 2002; Xu *et al.*, 2002). Indeed, Xu *et al.* could demonstrate a selective increase of the 14–3–3 / α -synuclein complex in the substantia nigra of PD patients, rendering the cell more susceptible to apoptosis (Xu *et al.*, 2002). Furthermore, application of the neurotoxin rotenone has been shown to induce

selective oxidative damage in striatum (Sherer *et al.*, 2001) with chronic low dose application leading to low-level complex I inhibition resulting in delayed activation of the apoptotic pathway (Sherer *et al.*, 2002a).

Lewy bodies and protein aggregation

Lewy bodies are typical but not specific for PD. Lewy bodies or Lewy body-like inclusion bodies can also be found in other neurodegenerative diseases like multiple system atrophy, progressive supranuclear palsy, Alzheimer's disease, and other diseases affecting the brain like prion diseases, Down syndrome or subacute progressive panencephalitis (Lowe *et al.*, 1997; Goedert *et al.*, 1998; Trojanowski & Lee, 2001). More than 25 different protein components of Lewy bodies are known. One main group of components consists of neurofilaments, α -synuclein, β -amyloid, actin-like protein and many others, another group of proteins is expressed as a cellular response to the abnormal protein aggregation like ubiquitin, proteasome subunits and chaperones (Pollanen *et al.*, 1993; Galvin *et al.*, 1999). Dysbalance of protein accumulation/aggregation, on one hand, and impairment of protein degradation on the other seem to be responsible for the formation of Lewy bodies. Normally, proteins are ubiquitinated and degraded by proteasomes. This process becomes even more important under conditions of oxidative stress, when proteins are oxidized. However, under severe oxidative stress, particularly when GSH levels are reduced (Jahngen-Hodge *et al.*, 1997), the function of proteasomes may be insufficient. This might either be due to direct oxidative damage of the proteasomes, or to oxidative damage of the proteins, making them unrecognizable for the proteasomes or to an exceeding of the degrading capacity (Grune *et al.*, 1995; Jenner & Olanow, 1998). The result is an accumulation of oxidized proteins, which again can generate free radicals contributing to cell toxicity. Oxidative modified proteins are more prone to aggregation (Souza *et al.*, 2000). By further crosslinking, which may occur in the process of lipid peroxidation (Friquet & Szweda, 1997), oxidized proteins become insoluble with the result of protein deposition and ultimately cell death. Protein aggregation has also been shown to be induced by iron (Golts *et al.*, 2002) and by advanced glycation endproducts (AGEs) (Münch *et al.*, 2000). AGE formation is increased under conditions of increased iron levels and oxidative stress. Moreover, they contribute to OS by activating glial cells to produce superoxide and nitric oxide (Münch *et al.*, 1998). Besides OS, alteration of protein structure due to genetic variations may be another cause of protein aggregation. Genetic variations (see also

Chapter 40) might either affect proteins that are usually degraded by the proteasomes, like α -synuclein, or those playing a role in the ubiquitin/proteasome degradation pathway like ubiquitin or parkin (Krüger *et al.*, 2002).

In PD, brain areas with the highest levels of α -synuclein are those associated with Lewy bodies. This is also a reason why it has been speculated that Lewy bodies result from altered handling of oxidized proteins and may at least initially represent a protective mechanism of the cell from the toxicity of protein accumulation (Jenner & Olanow, 1998). Also, the sequestration of toxic iron by Lewy bodies indicates a protective role of these inclusions (Castellani *et al.*, 2000). New lines of evidence indicate that by increased expression even α -synuclein itself might protect cells from oxidative stress by inactivation of a stress-signaling pathway (Hashimoto *et al.*, 2002). Some investigations, however, indicate that Lewy bodies might contribute to the pathological cascade. In analogy to a model with transgenic mice (Tu *et al.*, 1997), it has been hypothesized that proteins usually transported by axons are accumulated in Lewy bodies leading to a lack of function of neurons and ultimately to degeneration (Trojanowski *et al.*, 2001). Moreover, it has been shown that α -synuclein overexpression may contribute to the formation of free radicals, thereby exaggerating the vulnerability of neurons to dopamine-induced cell death (Turnbull *et al.*, 2001; Junn & Mouradian, 2002). In the case of α -synuclein mutations, impaired neurotransmitter storage could be the source of cytoplasmic accumulation of dopamine (Lotharius & Brundin, 2002) which again promotes OS. However, it needs to be noted that the majority of degenerating neurons do not contain Lewy bodies. Therefore, these inclusions do not seem to be necessary for neurodegeneration (Tompkins & Hill, 1997).

One might argue that mutations in the α -synuclein gene are very rare and therefore of limited relevance to PD. However, the recent identification of a triplication of the normal α -synuclein gene causing PD (Singleton *et al.*, 2003) and the association of α -synuclein promoter polymorphisms causing a higher expression of α -synuclein mRNA in sporadic PD (Holzmann *et al.*, 2003; Chiba-Falek & Nussbaum, 2001; Krüger *et al.*, 1999; Farrer *et al.*, 2001) points to a more casual role of α -synuclein in the pathogenesis of PD. Notably, overexpression of wildtype α -synuclein is neurotoxic to human dopaminergic neurons but neuroprotective to non-dopaminergic neurons (Xu *et al.*, 2002). Dopamine-dependent neurotoxicity is mediated by a protein complex which also contains 14-3-3 protein which in turn binds tyrosine hydroxylase (Ichimura *et al.*, 1987). Like α -synuclein, 14-3-3 proteins are aggregated in Lewy bodies (Ubl *et al.*, 2002; Berg *et al.*, 2003a). The implication of 14-3-3 proteins in PD clearly needs further investigation

as 14-3-3 proteins might not only answer some questions on the selectivity of neurodegeneration in PD but also to neuronal apoptotic cell death (Berg *et al.*, 2003b). Alpha-synuclein itself is also upregulated by environmental factors such as herbicides (Manning-Bo *et al.*, 2001), which have been associated with an increased risk for PD (LeCouteur *et al.*, 2002). How these effects take place at the cellular level remains to be determined but it could be caused by an alteration of the ubiquitin-proteasome pathway therefore indirectly leading to a reduced clearance of α -synuclein finally leading to increased oxidative stress of dopaminergic neurons.

Taken together, different pathways seem to contribute to the pathogenesis of PD. Mounting evidence suggests that the marked heterogeneity in the clinical phenotype of PD patients might be caused by varying and sometimes multiple genetic factors rendering an individual susceptible to various endo- and environmental toxins. Then a pathological cascade is induced that includes oxidative stress, mitochondrial dysfunction, excitotoxicity, glial factors, protein aggregation and finally death of neurons (Fig. 41.1).

Current and potential treatments of Parkinson's disease

Clifford W. Shults

Department of Neurosciences, University of California, La Jolla, San Diego, CA, USA and VA San Diego Healthcare System, Dan Diego, CA, USA

Parkinson's disease (PD) is a progressive, degenerative neurological disorder characterized by rest tremor, bradykinesia, cogwheel rigidity and postural instability (Lang & Lozano, 1998). In the later stages of the illness approximately 30–40% of patients will develop cognitive compromise. The cardinal pathological features of PD are loss of neurons on the substantia nigra pars compacta (SNpc) and the presence of eosinophilic, intracytoplasmic inclusions, and Lewy bodies (Braak & Braak, 2000). The neurons of the SNpc project primarily to the caudate and putamen, which are referred to collectively as the striatum, and utilize the neurotransmitter dopamine. Dopamine is severely reduced in the SNpc and striatum in parkinsonian brains (Hornykiewicz, 2002). Although the loss of neurons is most conspicuous in the SNpc, neuronal loss and Lewy bodies are found in a number of brain regions, e.g. locus ceruleus, entorhinal region and amygdala (Braak & Braak, 2000). The neuronal loss and the presence of Lewy bodies in regions other than the SNpc suggest that although treatments that target only the nigrostriatal dopaminergic system may substantially benefit patients, they are unlikely to completely resolve the deficits of PD.

The following review presents a strategic framework through which to consider targets for therapies of PD. In some of the areas we are just beginning to have treatments, e.g. slowing the progression of the disease, and in others we have well-established therapies, e.g. augmentation of the function of the remaining dopaminergic system.

Slowing or stopping the progression of PD

No currently available treatments have been proven unequivocally to slow the degeneration of the nigrostriatal dopaminergic system and the functional decline of PD patients. However, recent research in PD has eluci-

dated a number of processes that appear to contribute to the degenerative process, and researchers have begun to identify interventions in these processes. These pathogenic mechanisms include mitochondrial dysfunction, oxidative stress, impaired protein degradation, abnormal protein aggregation, inflammation and apoptosis.

Mitochondrial dysfunction

A role for mitochondrial dysfunction was first suggested by the discovery that methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which injures the nigral dopaminergic system and causes a parkinsonian syndrome in human and non-human primates (Langston *et al.*, 1983), acts by inhibition of complex I of the mitochondrial electron transport chain (see review by Przedborski & Jackson-Lewis, 1998). Complex I activity was subsequently found to be reduced in the substantia nigra in Parkinsonian brains and in platelets from PD patients with early, untreated disease (Schapira *et al.*, 1990; Haas *et al.*, 1995). Shults *et al.* (1997) reported that mitochondria from patients with early untreated PD had significantly reduced levels of coenzyme Q₁₀, which is the electron acceptor for complexes I and II of the mitochondrial electron transport chain and a potent antioxidant. Recently, Shults *et al.* (2002) reported on a phase II trial of three dosages of coenzyme Q₁₀ (300, 600 and 1200 mg/d) vs. placebo in patients with early, untreated PD; all groups also received vitamin E at a dosage of 1200 IU/d. The study demonstrated a trend toward slowing the functional decline, as measured by the Unified Parkinson Disease Rating Scale (UPDRS); in patients treated with coenzyme Q₁₀ and in the group receiving the highest doses of coenzyme Q₁₀ (1200 mg/d) the difference from the placebo group was nominally significant ($P = 0.04$). These results need to be confirmed and extended in a larger trial before the recommendation can be made for widespread use of

coenzyme Q₁₀ in PD. Preclinical studies have indicated that other therapies directed at mitochondrial dysfunction, e.g. creatinine, might be neuroprotective in PD (Tarnopolsky & Beal, 2001).

Oxidative stress

Increased oxidative stress can lead to cellular dysfunction and death through oxidative damage to proteins, lipids and DNA (Halliwell, 2001; Beal, 2002). Studies from autopsy samples have revealed evidence of a number of markers of oxidative stress and damage in PD brains, including elevated malondialdehyde (an intermediate in lipid peroxidation) (Dexter *et al.*, 1989), decreased reduced glutathione in PD but not multiple system atrophy or progressive supranuclear palsy (Sian *et al.*, 1994), and increased 8-hydroxy-2'-deoxyguanosine (a marker of DNA damage) (Sanchez-Ramos *et al.*, 1994). Alam *et al.* (1997) reported an increase in protein carbonyls in PD brains but not brains with incidental Lewy bodies and considered that the increase was a late phenomenon and perhaps due to levodopa treatment. Reaction of superoxide with nitric oxide (NO) forms peroxynitrite, which can nitrate tyrosines. Giasson *et al.* (2000) reported the presence of nitrated alpha-synuclein in Lewy bodies.

Brains in which incidental Lewy bodies are found are thought to represent a presymptomatic phase of PD. A study of indices of oxidative stress and mitochondrial function in brains with incidental Lewy bodies revealed reduced levels of glutathione in the nigra but not other brain regions (Sian *et al.*, 1994). No difference between the incidental Lewy body and control brains were found in levels of dopamine in the striatum or levels of iron, copper, manganese, zinc or ferritin in the substantia nigra. The activity of complex I of the mitochondrial electron transport chain was reduced to a level intermediate between those in control and Parkinsonian brains, but the difference did not reach statistical significance. There was no reduction in other components in the electron transport chain. These data suggest that oxidative stress plays an early role in the pathogenesis of PD.

Despite considerable data that oxidative stress plays a role in the pathogenesis of PD, relatively few trials of antioxidants in PD have been undertaken. The DATATOP study demonstrated a benefit of deprenyl, which reduces oxidative stress through inhibition of monoamine oxidase B, but not of alpha-tocopherol (vitamin E) (Parkinson Study Group, 1993). However, benefit from deprenyl was noted at 1 month, which suggested that the benefit was due to a "symptomatic" effect due to inhibition of the metabolism of dopamine. The study of coenzyme Q₁₀ combined with

vitamin E (Shults *et al.*, 2002; please see above) supports the concept that antioxidant therapy may affect the progression of PD. New antioxidant agents have been shown to be promising in PD (Matthews *et al.*, 1999; Drukarch & Muiswinkel, 2000). Further clinical trials of antioxidants in PD appear warranted.

Impaired protein degradation

The stimuli for study of abnormal protein degradation in PD were the discoveries by Mizuno and his colleagues that mutations in the Parkin gene were linked to an autosomal recessive form of PD and that Parkin acts as an E3 ligase in the ubiquitin/proteasome pathway (Kitada *et al.*, 1998; Shimura *et al.*, 2000; Mizuno *et al.*, 2001). These discoveries have led to extensive studies of protein degradation in PD (Chung *et al.*, 2001; Giasson & Lee, 2001; McNaught *et al.*, 2001). However, not all investigators have found impaired protein degradation in PD brains (Furukawa *et al.*, 2002). Pathogenic mechanisms, other than mutations in the Parkin gene, which lead to impaired protein degradation, remain to be defined and possible therapies to overcome impaired degradation remain to be developed.

Protein aggregation

The presence of abnormal, intracytoplasmic aggregates, the Lewy body, as a cardinal pathological feature of PD has been known for almost a century (Galvin *et al.*, 1999). However, Lewy bodies are not limited to PD and can be found in a number of other disorders, including Alzheimer's disease, amyotrophic lateral sclerosis, and Hallervorden-Spatz disease. Lewy bodies are composed of a number of proteins but a prominent component is alpha-synuclein. Shortly after the discovery that a rare, familial form of PD was associated with a mutation in the gene for alpha-synuclein (Polymeropoulos *et al.*, 1997), a number of groups reported that a major component of Lewy bodies is alpha-synuclein (Spillantini *et al.*, 1997; Takeda *et al.*, 1998; Wakabayashi *et al.*, 1997). This observation led to intensive study of the role of alpha-synuclein, and development of treatments to interfere with this aggregation is an active area of research.

Inflammation

The substantia nigra in PD brains contains activated microglia (McGeer & McGeer, 1997), which can produce a number of potentially injurious compounds such as cytokines and nitric oxide (Hirsch *et al.*, 1998). Nitric oxide can combine with superoxide to form peroxynitrite, a

reactive oxygen species capable of nitration of proteins. Although there is little evidence that inflammation is a primary causative factor in PD, it is plausible that it may contribute to the ongoing injury to the nigral dopaminergic neurons injured by a primary insult. Also, it is conceivable that in some cases of PD there is an initial, limited insult to the nigral dopaminergic system that results in sustained inflammation in the substantia nigra, which persists past the initial insult. Langston *et al.* (1999) reported on three intravenous drug users, who had acutely become parkinsonian after exposure to MPTP. The three subjects died between 3 and 16 years after the presumed only exposure to MPTP but were found to have ongoing cell loss and microglia in the substantia nigra.

Preclinical studies have indicated that it may be possible to reduce inflammation associated with injury to the nigrostriatal dopaminergic system with minocycline (Du *et al.*, 2001; Wu *et al.*, 2002) or inhibitors of cyclooxygenases (COX) (Teismann & Ferger, 2001). Ascherio and colleagues (personal communication) studied the incidence of PD in two large cohorts (44 057 men in the Health Professionals Follow-Up Study and 98 845 women in the Nurses' Health Survey) and found that participants who reported regular use of nonsteroidal anti-inflammatory drugs (NSAIDs) at the beginning of the study had lower risk of PD than non-users (pooled relative risk 0.55, $P = 0.04$).

Apoptosis

The mechanisms that lead to death of the nigral, dopaminergic neurons are not fully understood. Evidence has accumulated to suggest that apoptosis is involved in this process, but this remains somewhat controversial (Kingsbury *et al.*, 1998; Anderson, 2001). Apoptosis is a part of the normal function of multicellular organisms (nearly one million cells commit "suicide" each second in the adult human body (Reed, 2002)) and plays a role in normal functions such as elimination of cells during development, removal of cells infected by viruses, and homeostasis in tissues in which production of new cells is balanced by elimination of older cells. Apoptosis is defined morphologically, and the characteristics of apoptosis include chromatin condensation, nuclear fragmentation, condensation of cell contents and formation of small membrane-bound vesicles, which are phagocytosed by nearby cells without accompanying inflammation (Zimmermann *et al.*, 2001; Nijhawan *et al.*, 2000).

Apoptosis can be triggered by external and internal pathways, which act through activation of cysteine aspartyl-specific proteases (caspases). The external pathways are activated through ligation of death receptors, such as tumor

necrosis factor receptor-1, and the internal pathway works through mitochondria and release of proapoptotic factors, such as cytochrome c. The Bcl-2 family members serve as pro-apoptotic or anti-apoptotic factors. Development of anti-apoptotic drugs is an active area of research (Reed, 2002). Development of anti-apoptotic therapies for PD will need to be mindful of the possibility of neoplasia, and treatments will optimally be selectively directed toward cells that degenerate in PD. Although the degenerative process affects extranigral neurons (Braak & Braak, 2000), one would anticipate that the first target for anti-apoptotic therapies in PD would be directed toward the nigral, dopaminergic neurons.

Augmentation of the function of the remaining nigrostriatal dopaminergic system

Levodopa

The introduction of levodopa revolutionized treatment of PD (Hornykiewicz, 2002). The work of Cotzias and colleagues (1969) demonstrated the benefit of levodopa alone or in combination with peripheral dopa decarboxylase inhibitor, which did not cross the blood brain barrier. There are few studies in which the efficacy of levodopa has been compared in randomized, double-blinded studies to placebo. The benefit of levodopa has been best evaluated recently in comparison to other agents, most commonly dopaminergic agonists. In a randomized, controlled study Rascol *et al.* (2000) treated patients with early PD with either levodopa/benserazide or ropinirole. In subjects who completed the study, the subjects treated with levodopa/benserazide had a greater reduction in the activity of daily living score and motor score on the Unified Parkinson Disease Rating Scale (UPDRS) than did the ropinirole group. In a similar prospective, double-blinded study in which the dosage of carbidopa/levodopa or pramipexole was titrated to a dosage that the patient and treating neurologist considered to provide satisfactory benefit, at the end of 23.5 months levodopa reduced the score on the UPDRS by 30% from the baseline score versus a 14% reduction in subjects who received pramipexole (Parkinson Study Group, 2000).

Unfortunately, patients treated with levodopa will often develop motor fluctuations (wearing off and sudden on-off) and dyskinesia within five years of beginning treatment. The Parkinson's Disease Research Group in the United Kingdom found that approximately one third of patients begun on levodopa developed motor oscillations within 3 years (1993). Hely *et al.* (1994) reported that

levodopa treated patients had an average incidence of newly arising dyskinesia of 7.4% for each 6 months of treatment with levodopa. Rascol *et al.* (2000) found that, after 5 years of treatment with levodopa, 34% of the patients had developed wearing off and 45% had developed dyskinesia. In the comparison of levodopa and pramipexole, the Parkinson Study Group (2000) reported that after 2 years of treatment 38% had developed wearing off and 31% had developed dyskinesia.

Standard formulations of levodopa have a short half-life of less than two hours. Controlled release formulations of levodopa were developed to reduce the number of doses needed and to overcome the problem of wearing off. A number of studies have documented that the controlled release formulations of levodopa do allow fewer doses to be taken. The increase of "on" time with controlled release levodopa is relatively modest (Hutton *et al.*, 1989; Wolters & Tesselaar, 1996). Two studies were carried out to determine whether initial treatment with controlled release formulations of levodopa could reduce the development of motor fluctuations, e.g. wearing off or on-off (Dupont *et al.*, 1996; Koller *et al.*, 1999). Neither study demonstrated any reduction in the incidence of fluctuations, and there is no reason to use controlled release levodopa for the initial treatment of PD.

Dopaminergic agonists

The first dopaminergic agonists used were ergoline compounds, such as bromocriptine and pergolide, and the ergots, in addition to being agonists for the D2 dopamine receptor, typically have mild 5-HT₂ antagonistic effects and mild adrenergic effects. More recently, nonergot dopaminergic agonists have been developed, such as pramipexole and ropinirole.

Dopaminergic agonists were introduced into the treatment of PD in the 1970s (Calne *et al.*, 1974) as a means to reduce the dosage of levodopa, and investigators found that addition of a dopaminergic agonist could reduce the dosage of levodopa needed and that dopaminergic agonists could provide satisfactory amelioration of symptoms.

A number of studies have evaluated the ability of dopaminergic agonists to be used as monotherapy in the initial treatment of PD. Riopelle (1987) reported that bromocriptine caused an improvement in clinical signs and disability, as did levodopa during the first 5.5 months after beginning therapy. Barone *et al.* (1999) found that initial treatment with pergolide was clearly superior to placebo as measured by the percentage of patients who had at least a 30% improvement on the UPDRS and other indices such as the UPDRS and the Schwab and England

Disability scale. Kieburtz and his colleagues in the Parkinson Study Group (1997a) compared the efficacy of four doses of pramipexole (1.5, 3.0, 4.5 and 6.0 mg/d) vs. placebo in patients with early PD and found that the benefit was equivalent across the four doses of pramipexole, and they showed approximately a 20% greater improvement in measurements of motor function than placebo. Adler *et al.* (1998) and Brooks *et al.* (1998) reported that compared to placebo ropinirole caused approximately a 20% improvement in the motor portion of the UPDRS.

A number of open label studies that compared initial treatment with bromocriptine suggested that early use of an agonist might reduce the incidence of dyskinesia and motor fluctuations, which often occur with levodopa treatment (Parkinson's Disease Research Group in the UK, 1993; Hely *et al.*, 1994; Montastruc *et al.*, 1994). This possibility led to prospective, randomized, double blind studies that compared the long-term outcome in patients with early PD who were initially treated with ropinirole (Rascol *et al.*, 2000) or pramipexole (Parkinson Study Group, 2000) compared to those treated with levodopa. In both studies open label levodopa could be added after the initial period of titration, if the response to the assigned treatment was no longer satisfactory. Interestingly, in both studies levodopa was significantly more effective in reducing the score on the UPDRS than the agonist (see above). Rascol *et al.* (2000) found that, after 5 years, 20% of the subjects initially assigned to ropinirole had developed dyskinesia while 45% of the subjects assigned to levodopa had developed dyskinesia. Wearing off was less frequent in the group initially treated with ropinirole, but the difference did not reach statistical significance. Similarly, the Parkinson Study Group (2000) found that 10% of patients initially randomized to pramipexole developed dyskinesia while 31% of patients initially assigned to carbidopa/levodopa developed dyskinesia. A number of conclusions can be drawn from the studies of Rascol *et al.* (2000) and the Parkinson Study Group (2000). First, treatment with a dopaminergic agonist or levodopa ameliorated the symptoms of PD to a level that the patient and enrolling investigator considered satisfactory. Second, both dopaminergic agonists and levodopa were typically well tolerated but side effects (nausea, hallucinations) were not uncommon and side effects were more common with the agonists than with levodopa. Third, in both studies levodopa reduced the score on the UPDRS more than the agonist did. Fourth, initial use of a dopaminergic agonist resulted in a lower incidence of dyskinesia. The fourth conclusion has raised some controversy because the groups were not comparable for effect of therapy (levodopa treated patients improved more), and the question has been raised whether agonist treated patients would have

had a lower incidence of dyskinesia if they had improvement commensurate to that of the levodopa-treated patients.

Dopaminergic agonists are often added to levodopa to treat PD, and a number of studies have demonstrated improvement. Guttman *et al.* (1997) added bromocriptine, pramipexole or placebo to patients treated with levodopa who fluctuated. They found that both bromocriptine and pramipexole significantly improved scores on the UPDRS part II (ADL) and part III (motor score) when compared to placebo. There was a nonsignificant trend for pramipexole to cause greater improvement than bromocriptine on the UPDRS, and pramipexole, but not bromocriptine, caused a significant reduction in the time spent in the off state. Olanow *et al.* (1994) conducted a randomized, parallel group comparison of pergolide and placebo in levodopa treated patients who had dyskinesia and end of dose deterioration and found that pergolide caused significant reduction in the daily dose of levodopa and a significantly greater improvement on ratings of parkinsonian findings and activities of daily living. Lieberman *et al.* (1997) and Wermuth *et al.* (1998) both reported that addition of pramipexole in patients with motor fluctuations significantly reduced the “off” time.

Similar to levodopa, dopaminergic agonists can cause nausea, vomiting, hypotension, confusion, dyskinesia and hallucinations. The agonists also appear to cause edema more commonly than levodopa. The ergot agonists can cause fibrosis. Clinicians have recently increasingly recognized that sleep disturbances are more frequent in PD patients (Kumar *et al.*, 2002) and that higher dosages of levodopa and particularly dopaminergic agonists, e.g. pramipexole and ropinirole, can cause somnolence and sudden sleepiness or sleep attacks (Etminan *et al.*, 2001; Tan *et al.*, 2002).

Catecholamine-o-methyl transferase (COMT) inhibitors

In the periphery dopa is metabolized by aromatic amino acid decarboxylase, which is inhibited by carbidopa and benserazide, and COMT. In the brain levodopa is also metabolized by monoamine oxidase B. Two COMT inhibitors are currently marketed, entacapone and tolcapone. At therapeutic doses entacapone works exclusively in the periphery, but at high doses tolcapone may also inhibit COMT in the brain. A number of studies have indicated that addition of tolcapone to patients on levodopa with fluctuations can decrease the percentage of off time by 2 to 3 hours (Rajput *et al.*, 1997; Adler *et al.*, 1998). Unfortunately, approximately 3–4% of patients on tolcapone developed an increase in liver function tests, and three deaths

from liver failure occurred in patients in the postmarketing period. This liver toxicity led to a ban of tolcapone in the European Union and to substantial controls over its use in the United States. The Parkinson Study Group (1997b) compared entacapone, at a dose of 200 mg with each dose of carbidopa/levodopa, and placebo in patients with wearing off and found that addition of entacapone caused a 5% increase in the on time (approximately one hour). The Nomecomt Study (Rinne *et al.*, 1998) reported a similar benefit. In both studies the dose of levodopa was reduced by approximately 12% with addition of entacapone. Common side effects of entacapone were an increase in dyskinesia and discoloration of the urine.

Monoamine oxidase B (MAO-B) inhibitors

A number of studies have evaluated the usefulness of MAO-B inhibitors both as monotherapy and as adjunctive therapy. Selegiline, which is also referred to as deprenyl, irreversibly inhibits MAO-B and thereby reduces the production of hydrogen peroxide by MAO-B. Because of its ability to reduce the formation of reactive oxygen species, selegiline was considered as a potential neuroprotective agent for dopaminergic neurons and a drug that might slow the progression of PD. Recently studies have indicated that deprenyl-like agents may have neuroprotective effects independent of MAO-B (Reed, 2002). The Parkinson Study Group (1993) carried out the DATATOP study, in which patients with early PD, who did not require treatment with levodopa, were randomly assigned to placebo, selegiline (5 mg twice each day), tocopherol (vitamin E; 1000 IU twice each day) or selegiline and tocopherol. The patients were followed until the point that they had reached disability sufficient to require treatment with levodopa. Selegiline delayed the time until levodopa was required by approximately nine months. However, improvement in the scores on the motor portion of the UPDRS 1 month after beginning selegiline (washin) and worsening after withdrawal of selegiline (washout) suggested that the effect was likely not due to a neuroprotective effect but more likely due to a symptomatic effect caused by reduction in the metabolism of dopamine in the brain. Olanow *et al.* (1995) used a different trial design and a 2-month washout period, but even this longer washout period might not have been sufficient. Pålhagen *et al.* (1998) conducted a study similar to the DATATOP study and found that again selegiline had a significant “washin” effect and postponed the time until treatment with levodopa was needed. However, no difference in the deterioration between the selegiline and placebo groups was noted during an eight-week “washout” phase. Pålhagen *et al.* interpreted the data as consistent with a

neuroprotective effect. The studies of selegiline have been confounded by the symptomatic effect of selegiline, and a neuroprotective effect has not been unequivocally demonstrated.

Anticholinergic drugs

Anticholinergic drugs were discovered by serendipity to be beneficial in PD in the nineteenth century by Charcot, when he administered *Atropa belladonna* to control the excessive salivation in PD patients. Cantello *et al.* (1986) compared biperiden to placebo in a randomized, double blind, crossover trial. They found the most substantial benefit to be in reduction of tremor, but they also noted benefit for bradykinesia and rigidity. This pattern reflects the general clinical experience with anticholinergic drugs. Unfortunately, anticholinergic drugs commonly have peripheral side effects such as blurred vision, urinary retention, nausea, constipation, and dry mouth. The central side effects can be more limiting and include memory impairment, confusion hallucinations and delirium.

Amantadine

Amantadine is another drug that was discovered by serendipity to be beneficial in PD, when Schwab *et al.* (1969) used it for influenza prophylaxis in Parkinsonian patients. The mechanism of action of amantadine is complex but it appears to enhance the release of dopamine from presynaptic terminals, an effect on postsynaptic dopaminergic receptors, an anticholinergic action and an antagonist to the NMDA glutamate receptor. Butzer *et al.* (1975) carried out a double-blind, placebo-controlled, crossover study and found a modest (12%) but statistically significant improvement in the clinical assessments of PD. Side effects of amantadine include peripheral edema, livido reticularis, rash and confusion.

More recently amantadine has been reported to reduce dyskinesia. Three studies have reported that treatment with amantadine at doses of up to 300 or 400 mg/day were able to reduce dyskinesia induced by intravenous levodopa or oral levodopa or as measured as cumulative dyskinesia recorded in diaries (Verhagen *et al.*, 1999; Luginger *et al.*, 2000; Snow *et al.*, 2000).

Treatments of cognitive and psychiatric complications

The prevalence of dementia in PD is approximately 25% and increases with advancing disease (Aarsland *et al.*,

2003), and approximately 15% of patients will develop hallucinations.

Aarsland and colleagues (2002) reported that treatment with donepezil statistically significantly but modestly improved the score on the mini-mental state examination in cognitively impaired PD patients.

Typical antipsychotic drugs, such as haloperidol, worsen parkinsonism and should be avoided in PD patients. Friedman and colleagues in the Parkinson Study Group (1999) reported that clozapine significantly improved drug-induced psychosis in PD patients without worsening of parkinsonism. Unfortunately, patients on clozapine can develop agranulocytosis, as well as seizures and myocarditis, and complete blood count must be monitored closely. Other atypical antipsychotic drugs have been studied in PD. Unfortunately, olanzapine worsens the parkinsonian features (Goetz *et al.*, 2000). Risperidone may also worsen parkinsonism and has recently been reported to be associated with an increase in the incidence of stroke when used in elderly, demented patients. Although controlled, randomized, prospective studies of quetiapine for the treatment of psychosis in PD have not been reported, it has been reported to reduce psychosis in PD patients without clinically significant worsening of parkinsonism.

Intervention in the malfunctioning circuitry

Three regions have been targeted for surgical interventions in PD – the thalamus, globus pallidus interna (GPI) and subthalamic nucleus (STN). Ablative procedures, e.g. thalamotomy, were initially employed but recently have been largely supplanted by deep brain stimulation (DBS). For excellent overviews of these therapies please see the reviews of Hallett and Litvan (1999) and Lang (2000).

Thalamotomy has been employed for management of PD tremor since the middle of the previous century. Ablative lesions, usually of the ventral intermediate nucleus, can strikingly reduce tremor in the contralateral arm but have little effect on the other signs of PD. Bilateral lesions typically lead to impairment in speech and swallowing and are avoided. DBS of the thalamus has the advantage that permanent complications are less common. In a randomized, prospective study, Schuurman *et al.* (2000) compared thalamotomy to DBS in patients with PD (45), essential tremor (13) and multiple sclerosis (10) and used videotapes to achieve blinded assessment of tremor. They concluded that both were equally effective in suppression of tremor, which was not adequately responsive to drug treatment, but that DBS had fewer adverse effects and resulted in greater functional improvement.

In the early 1990s, pallidal surgery for PD was revived by Laitinen *et al.* (1992). Most of the reports of pallidotomy for PD have not been prospective, randomized or blinded. De Bie *et al.* (1999) reported on a series of 37 cases of PD, which could not be managed satisfactorily with medical therapy. The patients were randomly assigned to receive unilateral pallidotomy or medical therapy and were assessed after 6 months. An assessor, who was blinded to the treatment, evaluated the patients. The primary response variable was the median change in the score on the motor portion of the UPDRS during a clinically defined off period, and the patients who underwent pallidotomy improved (47 to 32.5, 31%) and the medically treated group worsened slightly (52.5 to 56.5), and the difference was highly significant. Pallidotomy patients also had less dyskinesia and improvement in activities of daily living. However, two pallidotomy patients had major, persistent adverse events. These changes are similar to those reported in unblinded studies (for review see Lang, 2000). Unfortunately, bilateral pallidotomy is often accompanied by serious adverse events, most frequently impairments of speech and cognition (de Bie *et al.*, 2002).

DBS of the GPi or STN have largely supplanted unilateral pallidotomy because of ability to manipulate the circuitry bilaterally and a lower likelihood of permanent adverse events. DBS of the STN for PD was pioneered by Benabid and colleagues (Limousin *et al.*, 1998). Investigators have been reluctant to perform ablative procedures of the STN because of the possibility of causing hemibalismus. Burchiel *et al.* (1999) reported on a pilot study in which 10 PD patients were randomized to either bilateral GPi stimulation or bilateral STN stimulation and had data sufficient to report on four patients with pallidal stimulation and five patients with STN stimulation. They found that the improvement in the UPDRS motor scores during a clinically defined off period was equivalent at 12 months. Patients who received STN stimulation, but not those with pallidal stimulation, were able to reduce the dosages of their dopaminergic medications, and the patients with pallidal stimulation had greater improvement in bradykinesia. Both groups had reduction of dyskinesia, but the effect in this small, pilot study only reached significance for the STN group, which also had reduction in dosage of dopaminergic therapy.

The Deep-Brain Stimulation for Parkinson's Disease Study Group (2001) carried out a study in which 18 centers enrolled 143 PD patients and implanted bilateral electrodes in either the GPi (38) or STN (96) according to the experience and preference of the investigators at each site in 134 patients. At six months the patients were assessed with the motor portion of the UPDRS after medication and

stimulation had been discontinued overnight. Ninety-six of the patients were randomly evaluated in a crossover design with the stimulator either on or off with neither the evaluator nor patient informed as to whether the stimulator was on or off. Significant improvement was noted in both patients who received STN stimulation (51%) and GPi stimulation (33%). Home diaries indicated improvement in on time without dyskinesia. However, there were seven intracranial hemorrhages and two infections requiring removal of electrodes in the 143 patients.

The data suggest that in patients with advanced PD, who cannot be managed satisfactorily medically, DBS of either the GPi or STN can improve motor function and reduce dyskinesia. However, as with pallidotomy, there is the risk of intracranial hemorrhage and neuropsychological changes (Trepanier *et al.*, 2000) and the additional risks of infection and hardware failure (Oh *et al.*, 2002). The better site for DBS, GPi or STN, is uncertain, but the Dept. of Veterans Affairs is carrying out a prospective, randomized trial to address this question.

Regeneration

In the past decade considerable research has been directed to the development of therapies to induce regeneration of the nigrostriatal dopaminergic system in PD (Isacson, 2002). Much of this work has been directed to identification of trophic factors that can protect and/or induce regeneration of this system, and a number of trophic factors that have an effect on the nigrostriatal system have been identified, with the most promising being glial cell line-derived neurotrophic factor (GDNF) and other members of this family (Shults, 1998). This work led to a clinical trial of intraventricular infusion of GDNF in patients with PD, and the results of this study have been recently published (Nutt *et al.*, 2003). One report of a patient who came to autopsy indicated no improvement or signs of regeneration and adverse events (L'hermitte's sign and intermittent hallucinations) (Kordower *et al.*, 1999). This report underscores the needs for delivery of the trophic factor to the appropriate target, e.g. the striatum, and for delivery of the trophic factor in a controlled fashion. A recent, preliminary study suggests that direct delivery into the putamen may be beneficial (Gill *et al.*, 2003). Alternative delivery strategies, such as viral vectors, have been studied in MPTP-treated monkeys (Kordower *et al.*, 2000).

Neuroimmunophilin ligands, e.g. GPI-1046, have also been reported to promote regeneration of the injured nigrostriatal dopaminergic system, but this remains controversial (Zhang *et al.*, 2001; Eberling *et al.*, 2002). GPI-1046

has been studied in PD patients but the results have been disappointing (Gold & Nutt, 2002).

Replacement

During the past two decades, considerable effort has been directed to developing cells that can be implanted into the striatum of PD patients and serve as a source of dopamine. Fetal mesencephalic cells are the cells that have been studied most extensively (Björklund, 2000; Lindvall & Hagell, 2001). Studies in preclinical animal models of PD, mostly rodent models, have demonstrated that the dopaminergic cells can survive, form connections with striatal neurons and attenuate abnormal, parkinsonian behavior. Pilot studies in PD patients, which were not blinded and lacked control cases, suggested that transplantation of fetal, mesencephalic cells into the striatum in PD patients could reduce the need for dopaminergic therapy and improve function.

Transplantation of fetal mesencephalic cells in PD patients has been studied in two prospective, randomized, sham operation-controlled trials in PD patients (Freed *et al.*, 2000; Olanow *et al.*, 2003). Fluorodopa PET imaging in the patients indicated that the implanted cells had survived and were biochemically functional. Unfortunately, the primary analysis in both studies indicated that the implanted patients were not functionally improved by the procedure. Some of the patients developed disabling dyskinesia, which could not be controlled by adjustment of medication.

These studies underscore the need for properly conducted clinical trials in assessment of the usefulness of all new therapies in PD. It also appears that in the future cell replacement therapies should first be studied in non-human primate models of PD in which the animals have previously been exposed to levodopa and thereby primed for the development of dyskinesias. The previous studies also point out the challenges that will need to be met in cell replacement therapy in PD. The cells will need to survive and become somewhat integrated into targeted region (typically the striatum) so that they deliver dopamine to the denervated region of implantation in a fashion that approximates the normal, physiological delivery of dopamine. In addition, previous studies of transplantation of fetal cells have targeted the striatum because of the large projection of dopaminergic axons from the substantia nigra to the striatum and the profound depletion of dopamine in the striatum in PD patients. However, the mesencephalic dopaminergic neurons project to other regions, e.g. the globus pallidus and neocortex, and restitution of dopaminergic input in regions other than the stri-

tum may be necessary for improved function without side effects.

Recent research effort has been directed to development of stem cells as a source of dopamine producing cells for replacement. These efforts resulted in part from ethical and logistical concerns regarding procurement of the number of human embryos needed to provide enough fetal dopaminergic cells to adequately re-innervate the striatum in PD patients (some groups have used up to four fetuses per striatum). Although stem cells may provide an adequate supply of cells that can produce dopamine, use of stem cells will face the additional challenge that the stem cells must be differentiated into a phenotype similar to that of a dopaminergic neuron.

Historical review

The term multiple system atrophy (MSA) was introduced by Graham and Oppenheimer in 1969 to denote a neurodegenerative disease characterized clinically by various combinations of autonomic, parkinsonian, cerebellar or pyramidal symptoms and signs and pathologically by cell loss and gliosis in some or all of the following structures: putamen, caudate nucleus, globus pallidus, substantia nigra, locus ceruleus, inferior olives, pontine nuclei, cerebellar Purkinje cells, intermediolateral cell columns and Onuf's nucleus of the spinal cord.

Previously, cases of MSA were reported under the rubrics of olivopontocerebellar atrophy (OPCA), idiopathic orthostatic hypotension (IOH) or progressive autonomic failure (PAF), Shy-Drager syndrome (SDS) and striatonigral degeneration (SND). Although Dejerine and Thomas were the first to introduce the term OPCA in 1900 reporting two sporadic cases of late-onset ataxia, the case of Stauffenberg in 1918, diagnosed in life as OPCA, was the first to associate cerebellar, parkinsonian and autonomic features with identified pathological lesions not only of olives, pons and cerebellum, but also of basal ganglia pigmentation and atrophy of putamen, with additional cell loss in caudate and globus pallidus (Quinn, 1994).

The term SND was introduced in 1960 by van der Eecken, Adams and van Bogaert (van der Eecken *et al.*, 1960; Adams *et al.*, 1961, 1964) who noted pronounced shrinkage and brownish discoloration of the putamen and pallidum as well as depigmentation of the substantia nigra in three patients with progressive and severe parkinsonism associated with cerebellar, pyramidal and autonomic features. Earlier reports of SND include those of Fleischhacker (1924) and Scherer (1933a,b) (Berciano *et al.*, 1998; Wenning *et al.*, 2000b). In 1960 Shy and Drager reported two cases with

marked autonomic failure, slurred speech, ataxia, parkinsonian features, pyramidal signs and distal muscle wasting. Postmortem examination of case 2 demonstrated pathological lesions consistent with MSA, including involvement of the intermediolateral cell column. Subsequently, the term SDS was erroneously widened to include cases of Parkinson's disease (PD) and autonomic failure. Its further use has therefore been discouraged (Quinn *et al.*, 1995). In 1989 Papp and colleagues reported glial cytoplasmic inclusions (GCIs) in the brains of patients with MSA regardless of presentation (SND, OPCA and SDS). GCIs were not present in a large series of patients with other neurodegenerative disorders. The abundant presence of GCIs in all clinical subtypes of MSA introduced grounds for considering SDS, SND and sporadic OPCA as one disease entity characterized by neuronal multisystem degeneration based on unique oligodendroglial inclusion pathology. Subsequently, neuronal and axonal inclusions were also identified in MSA brains, however, they were less numerous compared to GCIs (Papp & Lantos, 1992, 1994). In the late 1990s α -synuclein immunostaining was recognized as the most sensitive marker of inclusion pathology in MSA, being superior to ubiquitin immunostaining that was previously used (Wakabayashi *et al.*, 1998c; Spillantini *et al.*, 1998). In parallel, the clinical recognition greatly improved following the introduction of diagnostic criteria. Quinn first proposed in 1989 a list of diagnostic criteria for MSA (Quinn, 1989b). The criteria were revised in 1994 to include sphincter EMG evidence (Table 43.5) (Quinn, 1994). In the late 1990s a number of pitfalls associated with the Quinn criteria were identified and Consensus diagnostic criteria were therefore developed in 1998 (Tables 43.6, 43.7 and 43.8) (Gilman *et al.*, 1998, 1999). The Consensus conference criteria have since been widely established in the research community as well as movement disorders clinics.

Morphological pattern of vulnerability

In MSA-P, the striatonigral system is the main site of pathology but less severe degeneration can be widespread (Tables 43.1 and 43.2) and usually includes the olivopontocerebellar system (Wenning *et al.*, 1996c). The putamen is shrunken with grey-green discoloration (Fig. 43.1). When putaminal pathology is severe there may be a cribriform appearance. In early stages the putaminal lesion shows a distinct topographical distribution with a predilection for the caudal and dorsolateral regions (Kume *et al.*, 1993). Later on during the course of disease, the entire putamen is usually affected with the result that bundles of striatopallidal fibres are narrowed and poorly stained for myelin. Degeneration of pigmented nerve cells occurs in the substantia nigra pars compacta (SNC), while non-pigmented cells of the pars reticulata are reported as normal. The topographical patterns of neurodegeneration involving the motor neostriatum, efferent pathways, and nigral neurones, reflect their anatomical relationship and suggest a common denominator or "linked" degeneration (Kume *et al.*, 1993). In MSA-C, the brunt of pathology is in the olivopontocerebellar system while the involvement of striatum and substantia nigra is less severe. The basis pontis

Fig. 43.1 Coronal slice of cerebrum. The putamena are symmetrically shrunken. Pallida are atrophic. PU: Putamen, GP: Globus Pallidus, TH: Thalamus.

is atrophic (Fig. 43.2), with loss of pontine neurones and transverse pontocerebellar fibers. In sections stained for myelin, the intact descending corticospinal tracts

stand out against the degenerated transverse fibers and the atrophic middle cerebellar peduncles. There is a disproportionate depletion of fibers from the middle cerebellar peduncles compared with the loss of pontine neurones, an observation consistent with a “dying back” process.

A supraspinal contribution to the autonomic failure of MSA is now well established. Cell loss is reported in dorsal motor nucleus of the vagus (Sung *et al.*, 1979) and involves catecholaminergic neurons of ventrolateral medulla (Benarroch *et al.*, 1998). It has also been described for the Edinger–Westphal nucleus and posterior hypothalamus (Shy & Drager, 1960) including the tuberomammillary nucleus (Nakamura *et al.*, 1996). Papp and Lantos (1994) have shown marked involvement of brainstem pontomedullary reticular formation with GCIs, providing a supraspinal histological counterpart for impaired visceral function. Autonomic neuronal degeneration affects the locus ceruleus, too (Wenning *et al.*, 1997b). Disordered bladder, rectal, and sexual function in MSA-P and MSA-C have also been associated with cell loss in parasympathetic preganglionic nuclei of the spinal cord. These neurons are localized rostrally in Onuf’s nucleus between sacral segments S2 and S3 and more caudally in the inferior intermediolateral nucleus chiefly in the S3 to S4 segments (Konno *et al.*, 1986). Degeneration of sympathetic preganglionic neurones in the intermediolateral column of the thoracolumbar spinal cord is considered contributory to orthostatic hypotension. Most of the cells lie within the lateral horn of grey matter where they are irregularly distributed and prone to shrink according to agonal state and postmortem fixation. If one considers only those reports in which formal cell counts have been made, with very few exceptions all cases of MSA with predominant pathology in either the striatonigral or olivopontocerebellar system show loss of intermediolateral cells (Daniel, 1999). However, it is noteworthy that there is not always a strong correlation between nerve cell depletion or gliosis and the clinical degree of autonomic failure. It is estimated, that more than 50% of cells within the intermediolateral column need to decay before symptoms become evident (Oppenheimer, 1980). In the peripheral component of the autonomic nervous system, Bannister and Oppenheimer (1972) have described atrophy of the glossopharyngeal and vagus nerves.

A variety of other neuronal populations are noted to show cell depletion and gliosis with considerable differences in vulnerability from case to case. These sites are listed in Table 43.2 and only a few of the reported lesions are discussed here. Various degree abnormalities in the cerebral hemisphere, including Betz cell loss, were detected

(a)

(b)

Fig. 43.2 Macroscopic appearance of the brainstem. When compared with normal (a), in MSA (b) the pons and middle cerebellar peduncles are atrophic and the trigeminal nerves (*) are prominent. (Reprinted with permission from Oxford University Press (www.oup.com), Daniel, 1999.)

in pathologically proven MSA cases (Tsuchiya *et al.*, 2000, Wakabayashi *et al.*, 1998b, Konagaya *et al.*, 1999, 2002). Fujita *et al.* (1993) demonstrated a distinct laminar astrocytosis of the motor cortices in the fifth layer in four of six sporadic OPCA cases and in none of five control cases by immunohistochemistry for glial fibrillary acidic protein. Furthermore, anterior horn cells may show some depletion but rarely to the same extent as that occurring in motor neurone disease (Konno *et al.*, 1986; Sima *et al.*, 1993). Depletion of large myelinated nerve fibers in the recurrent

laryngeal nerve which innervates intrinsic laryngeal muscles has been demonstrated in MSA patients with vocal cord palsy (Hayashi *et al.*, 1997). The neuropathological background of abnormal eye movements is ill defined, although Mizutani *et al.* (1988) describe degeneration in the pathways concerned with the cerebellar fugal control of ocular movement.

From a neuropathological viewpoint, there is little cause for confusion of MSA with other neurodegenerative conditions. The GCI is the hallmark that accompanies signs of degeneration involving striatonigral and olivopontocerebellar systems. GCI are distinctly different from filamentous oligodendroglial inclusions, called coiled bodies, found in other neurodegenerative diseases, including PSP, CBD and argyrophilic grain disease (Braak & Braak, 1989; Yamada & McGeer, 1990; Arima *et al.*, 1997; Chin & Goldman, 1996). Rarely, MSA may be combined with additional pathologies. Lewy bodies (LBs) have been reported in 8–10 per cent of MSA cases and show a distribution comparable with that of PD (Wenning & Quinn, 1994). This frequency is similar to that of controls and suggests an incidental finding related to aging and/or presymptomatic PD. Isolated reports of unusual clinicopathological cases occur and include overlap of MSA with PSP and CBD (Ansoerge *et al.*, 1997a, Takanashi *et al.*, 2002), MSA with Alzheimer's disease and PD (Ansoerge *et al.*, 1997b), and MSA with atypical Pick's disease (Horoupiian & Dickson, 1991).

The discovery of glial cytoplasmic inclusions (GCIs) in MSA brains in 1989 highlighted the unique glial pathology as biological hallmark of this disorder (Papp *et al.*, 1989). GCIs are argyrophilic and half moon, oval or conical in shape (Lantos, 1998) and are composed of 20- to 30-nm tubular filaments (Gai *et al.*, 2003). Although inclusions have been described in five cellular sites, i.e. in oligodendroglial and neuronal cytoplasm and nuclei as well as in axons (Papp & Lantos, 1992), glial cytoplasmic inclusions (GCIs) (Papp *et al.*, 1989) are most ubiquitous and appear to represent the subcellular hallmark lesion of MSA (Lantos, 1998). Their distribution selectively involves basal ganglia, supplementary and primary motor cortex, the reticular formation, basis pontis, the middle cerebellar peduncles and the cerebellar white matter (Lantos, 1998; Papp & Lantos, 1994). GCIs contain classical cytoskeletal antigens, including ubiquitin and tau (Lantos, 1998; Cairns *et al.*, 1997a). More recently, α -synuclein immunoreactivity has been recognized as the most sensitive marker of GCIs (Dickson *et al.*, 1999b) (Fig. 43.3). In fact, α -synuclein, a presynaptic protein which is affected by point mutations in some families with autosomal dominant PD (Goedert & Spillantini, 1998) and which is present in LBs (Spillantini

Fig. 43.3 α -Synuclein immunostaining reveals GCIs in subcortical white matter.

et al., 1997), has also been observed in both neuronal and glial cytoplasmic inclusions (Wakabayashi *et al.*, 1998a,c; Arima *et al.*, 1998; Tu *et al.*, 1998; Spillantini *et al.*, 1998) in brains of patients with MSA. GCI filaments are multilayered in structure, with alpha-synuclein oligomers forming the central core fibrils of the filaments (Gai *et al.*, 2003). The accumulation of α -synuclein into filamentous inclusions appears to play a key role not only in MSA, but also in a growing number of α -synucleinopathies such as Parkinson's disease, dementia with LBs, Down's syndrome, familial Alzheimer's disease, and sporadic AD (Trojanowski, 2002). The α -synuclein accumulation in GCIs as well as in neuronal inclusions associated with MSA precedes their ubiquitination (Gai *et al.*, 1998). Importantly, α -synuclein, but not ubiquitin, antibodies also reveal numerous degenerating neurites in the white matter of MSA cases (Gai *et al.*, 1998). This suggests that an as yet unrecognized degree of pathology may be present in the axons of MSA cases, although whether neuronal/axonal α -synuclein pathology precedes glial α -synuclein pathology has not been examined.

Biochemical/neuropharmacological findings

Biochemical findings

Neurochemical studies have shown alterations consistent with sites of major pathology. Calcineurin, a marker for medium-sized spiny neurons, is decreased in striosomes of the putamen and in the efferent pathway of the globus pallidus and substantia nigra (Goto *et al.*, 1989b). Regardless of clinical presentation, there is reduced immunoreactivity for additional markers of the striatal efferent system, including met-enkephalin, substance P, and calbindin (Ito *et al.*, 1996). In the SNC, tyrosine hydroxylase (TH)

containing dopaminergic neurons are depleted. Similar neurones in the C1 and A2 regions of the medulla also showed reduced TH activity, which has been associated with orthostatic hypotension (Kato *et al.*, 1995).

Biochemical analyses have found only minor differences in reduced striatal and nigral dopamine content in MSA when compared with PD (Brücke *et al.*, 1997). However, unlike PD, mitochondrial respiratory chain function in the substantia nigra is normal in MSA (Gu *et al.*, 1997). An increase in total iron content appears to reflect sites of primary damage and occurs in both PD and MSA substantia nigra, as well as in MSA striatum (Dexter *et al.*, 1991). Decreased noradrenaline levels are reported in septal nuclei, nucleus accumbens, hypothalamus, and locus ceruleus, while a consistent deficit of choline acetyltransferase is found in red nucleus, dentate, pontine, and inferior olivary nuclei, with variable involvement of the striatum and additional areas (Spokes *et al.*, 1979). Cerebellar and, in particular, Purkinje cell damage, has been indicated by reduced levels of glutamate dehydrogenase (Plaitakis *et al.*, 1993), amino acid binding sites (Price *et al.*, 1993), and cerebrospinal fluid calbindin-D (Kiyosawa *et al.*, 1993).

The content of neurofilament (NFL) in CSF was significantly higher both in PSP and MSA compared to PD patients (Holmberg *et al.*, 1998). The high values of NFL indicate an ongoing neuronal degeneration affecting mainly the axonal compartment in PSP and MSA patients, whereas there was no difference in glial involvement as measured by GFAP in PD, PSP, and MSA patients (Holmberg *et al.*, 1998). Furthermore, CSF-NFL and levodopa tests combined with discriminant analysis may contribute even better to the differential diagnosis of parkinsonian syndromes (Holmberg *et al.*, 2001). Whereas the CSF-NFL and levodopa tests predicted 79 and 85% correct diagnoses (PD or non-PD (MSA and PSP)), respectively, the combined test predicted 90% correct diagnoses.

Kuiper *et al.* (1994) investigated nitrite and nitrate in CSF of PD, AD, and MSA patients and controls. They found for all patient groups, compared with controls, significantly decreased levels of nitrate, but not nitrite. This finding seems to indicate a decreased NO production of the central nervous system (CNS) in these neurodegenerative disorders. Alterations in neuronal NO production may play a role in the pathophysiology of PD, AD, and MSA. The biosynthesis of NO is dependent on the availability of L-arginine, the substrate for NOS, and on L-glutamate, which stimulates NO synthesis via the NMDA receptor. In this process L-citrulline is formed. A slight but statistically significant elevation of CSF L-citrulline was found

in 15 MSA patients by Kuiper *et al.* (2000) and there were no significant changes in L-arginine levels. The relation between the CSF levels of these amino acids and neuronal NO production is still unclear. Konings *et al.* (1999) measured total glutathione concentrations in the CSF of PD (non-demented or demented), MSA, and AD patients and age-matched controls. No statistically significant differences in the mean total CSF glutathione concentrations were found between groups and dopaminomimetic treatment was not found to have any effect on total CSF glutathione levels. 8-hydroxy-2'-deoxyguanosine (8-OHdG) or 8-hydroxyguanosine (8-OHG), a product of oxidized DNA or RNA, is a good marker of oxidative cellular damage. Kikuchi *et al.* (2002) measured the 8-OHdG/8-OHG levels in the serum and CSF of patients with PD and MSA. Compared to age-matched controls, the mean levels of serum 8-OHdG/8-OHG were significantly higher in PD patients. 8-OHdG/8-OHG levels in CSF were also increased significantly in patients with PD and MSA, however, their relative values were generally much lower than those in the serum.

Since idiopathic chronic autonomic dysfunction may occur as pure autonomic failure (PAF) or in association with MSA, specific studies have been carried out in both these conditions. CSF immunoreactivity to rat locus ceruleus occurred in a significantly greater number of samples from MSA patients compared to control subjects or patients with PAF (Polinsky *et al.*, 1991). Other brain regions infrequently showed immunoreactivity. These findings suggest that degeneration in MSA may release antigen(s) that induce antibodies against locus ceruleus neurons. Further studies are required to determine whether immune abnormalities play a pathogenetic role in MSA (Gahring *et al.*, 1997; Schelhaas *et al.*, 1997).

There are several studies measuring CSF content of biogenic amine metabolites/derivates, thiamine, neuropeptide Y, substance P, or corticotropin-releasing hormone in MSA patients (Gonzalez-Quevedo *et al.*, 1993; Botez *et al.*, 2001; Ichikawa *et al.*, 1986; Orozco *et al.*, 1989; Martignoni *et al.*, 1992; Nutt *et al.*, 1980; Suemaru *et al.*, 1995). Botez *et al.* (2001) measured levels of the dopamine metabolite homovanillic acid (HVA), the serotonin metabolite 5-hydroxyindoleacetic acid (5HIAA) and precursor tryptophan, as well as the noradrenaline metabolite 3-methoxy-4-hydroxyphenylethylene glycol (MHPG) and thiamine in the CSF of patients with OPCA (among others), as compared with sex- and age-matched control subjects. CSF HVA, MHPG and thiamine values were markedly lower than those in control patients, whereas CSF 5HIAA values showed only a trend towards lower levels than control subjects.

Neuropharmacological findings

The combination of nigral and striatal degeneration is the core pathology underlying parkinsonism in MSA. The degenerative process affects nigrostriatal dopaminergic transmission at both pre- and post-synaptic sites (Fearnley & Lees, 1991; Kume *et al.*, 1993). Pathologically, the loss of dopaminergic neurons in MSA-P is comparable to that found in PD (Tison *et al.*, 1995a). Only few patients with MSA exhibit a presynaptic pattern with minimal putaminal changes (Tison *et al.*, 1995a; Wenning *et al.*, 1994b; Berciano *et al.*, 2002). There is a close anatomical relationship between nigral and striatal degeneration in MSA-P. Degeneration of pigmented dopaminergic neurons begins and predominantly involves the ventrolateral tier of SNC which in turn projects to the dorsolateral posterior putamen; the latter is the predominant site of striatal degeneration in MSA. Several post-mortem immunohistochemical and autoradiographical, as well as in vivo neuroimaging studies, suggest that both striatal outflow pathways are affected: enkephalin-containing striatal neurons projecting to the external globus pallidus that carry dopamine D2 receptors (indirect pathway) and substance P (SP)-containing cells projecting to internal globus pallidus and substantia nigra pars reticulata (SNR) that carry D1 receptors (direct pathway) (Quik *et al.*, 1979; Cortes *et al.*, 1989; Shinotoh *et al.*, 1991, 1993; Brooks *et al.*, 1992; Churchyard *et al.*, 1993; Vogels *et al.*, 2000; Goto *et al.*, 1989a,c, 1990, 1996; Schelosky *et al.*, 1993; van Royen *et al.*, 1993; Ito *et al.*, 1996).

In accordance with the topographical projection of the putamen onto pallidal segments, the posterolateral portions of the external and internal globus pallidus, and the ventrolateral portion of the substantia nigra are deafferented from striatal projections (Brooks *et al.*, 1992). Churchyard *et al.* (1993), in a postmortem binding study of two MSA brains, found loss of putaminal D2 receptors in both, but loss of D1 receptors in only one case. Because the duration of the disease was shorter and histopathological changes were less severe in the latter case they suggested the possibility that the disease may initially affect striatal cells expressing D2 receptors (indirect pathway), and only subsequently D1 receptor expressing neurons (direct pathway). However, this assumption remains contentious. The evidence considered so far suggests that the pathology of parkinsonism in MSA-P incorporates variable combinations of loss of dopaminergic nigrostriatal transmission, and impairment of both the indirect and direct striatal outflow pathways at the striatal level, with relative preservation of subthalamic nucleus, globus pallidus and thalamus.

Progressive loss of striatal dopamine receptors and striatal output systems might explain levodopa unresponsiveness in most MSA-P patients (Tison *et al.*, 1995a; Ito *et al.*, 1996; Parati *et al.*, 1993; Rajput *et al.*, 1990). Those patients with a good initial response to levodopa would thus have less striatal damage than those with absent or poor initial response. However, there is evidence suggesting that the response to levodopa does not always depend solely on the degree of striatal cell loss (Wenning *et al.*, 1994b). In vivo PET studies by Brooks *et al.* (1992) have also failed to clearly correlate therapeutic response with striatal D2 receptor status. However, reduced D2 binding as assessed by SPECT or PET performed in levodopa-naïve patients with parkinsonism may predict a lack of response to apomorphine, lack of subsequent response to chronic levodopa therapy or a clinical diagnosis of MSA-P (Schelosky *et al.*, 1993; Schwarz *et al.*, 1998). Additional loss of D1 and opiate receptors could also be an important factor underlying dopaminergic unresponsiveness in MSA-P (Shinotoh *et al.*, 1993; Burn *et al.*, 1995), as well as other changes downstream of the striatum itself.

Neurotransmitter release is modulated by presynaptic histamine H(3) receptors located on histaminergic, noradrenergic and other non-histaminergic neurons of the central and peripheral nervous system. Wiedemann *et al.* (2002) reported the determination of the structure of the human histamine H(3) receptor gene (HRH3) and the identification of a missense mutation in a patient with MSA and autonomic failure. The homozygous Ala280Val variation in the third intracellular loop of the histamine H(3) receptor may be related to the etiology of the illness due to altered norepinephrine release.

Overstimulation of α 1B-adrenergic receptors in transgenic mice resulted in autonomic failure and motor impairment due to neuronal multisystem degeneration (Zuscik *et al.*, 2000, 2001). Whether this phenotype represents a useful model of MSA has been debated (Seppi *et al.*, 2001; Perez, 2001).

Molecular biology

α -synuclein is a 140 amino acid protein that is abundantly expressed in the brain and typically enriched at presynaptic terminals (Dickson *et al.*, 1999a; Clayton & George, 1999). α -Synuclein is exclusively expressed in the soluble fraction of the neuronal cytoplasm in normal humans. However, in MSA (oligo-)glial cytoplasmic inclusions, strongly immunoreactive for α -synuclein (Fig. 43.3), are the most distinctive neuropathological feature (Tu *et al.*, 1998), regardless of phenotypical presentation. Formation

of GCIs appears to be the key pathway to selective loss of oligodendroglia and neurons in MSA. The differential distribution of α -synuclein deposits and associated neuronal pathology (SND, OPCA and spinal cord) suggests variability of pathogenetic mechanisms underlying the multifaceted disease process of MSA. α -Synuclein appears to be extensively nitrated in the cytoplasmic aggregates of PD, DLB, and MSA brains suggesting that nitration is involved in the onset and/or progression of these neurodegenerative diseases (Duda *et al.*, 1999). Presumably, tyrosine 125 plays a critical role for alpha-synuclein dimerization under nitrate stress (Takahashi *et al.*, 2002). Protein nitration in Lewy body diseases and MSA cases has a widespread distribution and is not only associated with the alpha-synuclein deposits (Gomez-Tortosa *et al.*, 2002). Moreover, it has been shown that α -synuclein is phosphorylated by tyrosine kinases (Nakamura *et al.*, 2001; Negro *et al.*, 2002; Ellis *et al.*, 2001), and that some of these tyrosine kinases may play an antineurodegenerative role by phosphorylating α -synuclein, thereby preventing its aggregation (Negro *et al.*, 2002). The amino-terminal half of NAC (Non-A β Component of AD amyloid), as well as stretches of nine and more amino acid residues derived from this part, is able to fibrillate and to seed fibrillation of full-length α -synuclein (Uversky & Fink, 2002). It has been shown that β - and γ -synucleins may inhibit the fibrillation of α -synuclein (Uversky *et al.*, 2002, Hashimoto *et al.*, 2001). Accumulation of α -synuclein may require additional proteins as pathologic chaperones (Tu *et al.*, 1998). If chaperones are involved, their nature is likely to be unique to MSA, because the morphology and array of immunoreactive components in GCIs and NCIs differ from those characterizing Lewy bodies (Spillantini *et al.*, 1998). Engleender *et al.* (1999) identified an α -synuclein-associated novel protein named synphilin-1, and reported that co-transfection of both α -synuclein and synphilin-1 in mammalian cells yielded eosinophilic cytoplasmic inclusions resembling LB. More recently, it was shown that synphilin-1 immunoreactivity is present in Lewy bodies as well as in GCIs (Wakabayashi *et al.*, 2000, 2002). Various neuronal and glial inclusions in neurodegenerative disorders other than LB disease and MSA were synphilin-1 negative. Therefore, abnormal accumulation of synphilin-1 appears to be specific for brain lesions in which α -synuclein is a major component (Wakabayashi *et al.*, 2002). Whether the α -synuclein aggregation is induced by some other factor(s), or whether it is the primary trigger of MSA pathology is unknown. Impairment in the ability of oligodendrocytes to degrade α -synuclein which they may normally produce at low levels may also promote abnormal subcellular aggregation in MSA (Tu *et al.*, 1998). Alternatively, selective

upregulation in the expression of α -synuclein in glial cells could occur in response to certain pathologic conditions (Arima *et al.*, 1998). However, expression levels of α -synuclein mRNA in MSA brains are similar to those of control subjects (Ozawa *et al.*, 2001). These results suggest that the transcriptional regulation of the α -synuclein gene is unlikely to be affected in MSA.

Pathogenesis/mechanism of disease

Recent findings support an important role for glial cells and inflammatory reactions in many neurodegenerative diseases including PD, DLB and MSA (Hirsch *et al.*, 1998; Togo *et al.*, 2001; Vila *et al.*, 2001). Neuronal survival is critically dependent on glial function, which can exert both neuroprotective and neurotoxic influences. Glial cells are a primary target of cytokines and are activated in response to many cytokines, including tumor necrosis factor (TNF)- α (Allan & Rothwell, 2001). This activation can trigger further release of cytokines that might enhance or suppress local inflammatory responses and neuronal survival. These cytokines may also participate in neurodegeneration either indirectly by activating other glial cells or directly by inducing apoptosis (Boka *et al.*, 1994; Hunot *et al.*, 1999; Mogi *et al.*, 1994). Several studies indicated that TNF- α is toxic for dopaminergic neurons in vitro (McGuire *et al.*, 2001) and in vivo (Aloe & Fiore, 1997), thus supporting the potential involvement of this pro-inflammatory cytokine in the neurodegenerative processes in PD and other α -synucleinopathies. However, the relationship between intracellular α -synuclein positive inclusions and the proinflammatory response in α -synucleinopathies remains obscure. The activation of microglial cells may be the final common pathway, contributing both to demyelination and neuronal removal, irrespective of the mode of cell death. PK 11195 selectively binds to benzodiazepine sites on activated microglia. ^{11}C PK 11195 positron emission tomography has demonstrated activated microglia in vivo in the putamen, pallidum, substantia nigra, and pontine region in four patients with MSA (Gerhard *et al.*, 2000).

Trophic factors have been studied in a number of neurodegenerative diseases, both for their potential pathogenetic role and also for their possible therapeutic benefit. Neurotrophic factors such as nerve growth factor (NGF), glial derived neurotrophic factor (GDNF), brain-derived neurotrophic factor (BDNF), basic fibroblast growth factor (bFGF), and platelet derived growth factor (PDGF) have been shown to exert neuroprotective and neuroregenerative effects in various neurodegenerative disorders (Olanow

& Tatton, 1999; Gash *et al.*, 1998; Lindsay *et al.*, 1994). However, until now it is not clear whether neurotrophins may have a direct influence on α -synuclein aggregation and cell death. A study by Stefanis & Cole (2001) suggested that the expression of α -synuclein may be directly regulated by neurotrophic factors such as NGF in neuronal cells, whereas another study did not confirm these findings (Sato & Kuroda, 2001). Further, no correlation was found between synuclein expression and apoptotic death following trophic deprivation (Stefanis *et al.*, 2001). Since neurotrophic factors have a variety of biological effects including modulation of proteasomic function and apoptosis (Yuan & Yankner, 2000), it seems likely that neurotrophins could have a direct effect on the survival of neuronal and glial cells overexpressing α -synuclein. BDNF is abundantly and widely expressed in neurones of the adult mammalian brain. It has a neurotrophic effect on many neuronal types, including nigral dopaminergic and striatal neurones (Murer *et al.*, 2000). BDNF positive neurites have been shown to be more abundant in the striatum of patients with MSA than in the striatum of those with PD and normal controls. The upregulation of BDNF has been interpreted as a protective mechanism against progressive degeneration of the striatal neurones in MSA (Kawamoto *et al.*, 1999). However, it is not clear whether the upregulation has occurred in the major striatal afferents originating in the cortex or in nigral afferents, since the striatal neurones themselves are not BDNF immunoreactive (Murer *et al.*, 2000). White matter astrocytes produce PDGF, which has been shown to act as a survival factor for newly formed oligodendrocytes (Barres *et al.*, 1992). It has been demonstrated that the sensitivity of oligodendrocytes to astrocyte derived PDGF is greatly enhanced by an extracellular matrix glycoprotein, laminin-2 (Frost *et al.*, 1999), which is expressed by Purkinje cell axons (Powell *et al.*, 1998). Laminin-2 also appears to play an important part in the signaling mechanisms that stimulate oligodendrocytes to elaborate the myelin sheath (Buttery & French-Constant, 1999). Neurones/axons generate several isoforms of neuregulins, which are members of a large trophic family all originating from a single gene. Some of the isoforms promote proliferation and survival of oligodendrocytes through their interaction with the erb-B family of receptors, expressed by the oligodendrocytes (Burden & Yarden, 1997). One neuregulin isoform (glial growth factor) promotes proliferation and survival of oligodendrocyte progenitors but inhibits their further differentiation (Canoll *et al.*, 1996, 1999). So far, there have been no reports of alterations in glial growth factors in patients with MSA (Burn & Jaros, 2001). Glial growth factors are derived from both astrocytes and neurones. Other isoforms (acetylcholine receptor-inducing activity protein, neu-

differentiation factors (NDF α , and NDF β)) act as morphogenes for developing oligodendrocytes by promoting the extension and complexity of their processes (Vartanian *et al.*, 1994, 1997; Raabe *et al.*, 1997). In addition to the well-documented effects of neuregulins on glial cells, there is also evidence that neuregulins have direct effects on CNS neurones (Birmingham-McDonogh *et al.*, 1996; Yang *et al.*, 1998; Ozaki *et al.*, 1997). Different groups of neuronal populations appear to use different neuregulin isoforms at successive development of stages of the CNS to support the oligodendrocytes which myelinate their axonal projections. It is conceivable that polymorphisms in certain neuregulin isoforms, which are shared by the suprasegmental motor system, the supraspinal autonomic systems, and their targets, could be a risk factor for MSA and could also underlie the system-bound distribution of the oligodendroglial and neuronal pathology in this disease (Jaros & Burn, 2000).

MSA, as reflected in its current definition, is regarded as a sporadic disease (Wenning *et al.*, 1993) and no confirmed familial cases of MSA have been described yet; notwithstanding, it is conceivable that genetic factors may play a role in the aetiology of the disease. This has, for example, been convincingly demonstrated for PSP (Baker *et al.*, 1999), another disease which, in the vast majority of cases, is a sporadic disease. However, initial screening studies for candidate genes revealed no risk factors (Bandmann *et al.*, 1997; Nicholl *et al.*, 1999; R. Krüger, personal communication). Other recent studies have further looked for polymorphisms or mutations in candidate genes, which may predispose an individual towards developing MSA. The apolipoprotein $\epsilon 4$ allele is not over-represented in MSA when compared with controls, and there have been conflicting reports of the association of a cytochrome P-450-2D6 polymorphism with MSA (Cairns *et al.*, 1997b; Iwahashi *et al.*, 1995; Bandmann *et al.*, 1995). No association was found between MSA and polymorphisms in other genes possibly involved in neurodegenerative diseases (CYP1A1, *N*-acetyltransferase 2, dopamine transporter and glutathione-S-transferase M1) (Nicholl *et al.*, 1999). Furthermore, there is no evidence to support an association between MSA and polymorphisms in the H5 pore region of the human homologue of the weaver mouse gene hiGIRK2, the insulin-like growth factor 1 receptor gene, or the ciliary neurotrophic factor gene (Bandmann *et al.*, 1997). No epidemiological analytical study has yet investigated the relationship between genotype and environment. The pathogenetic role of α -synuclein is still unclear. Inactivation of the α -synuclein gene by homologous recombination did not lead to a severe neurological phenotype (Abeliovich *et al.*, 2000). So, loss of function of the α -synuclein protein is unlikely to account for

its role in neurodegeneration. Mice that lack α -synuclein were found to show increased release of striatal dopamine, indicating that this protein could function as an activity-dependent, negative regulator of neurotransmission in the striatum. While there is strong evidence that α -synuclein participates in the pathogenesis of some types of familial PD (Polymeropoulos *et al.*, 1997; Kruger *et al.*, 1998), no mutations have been found in the entire coding region of the α -synuclein gene in MSA (Ozawa *et al.*, 1999) nor in sporadic forms of PD and DLB (El-Agnaf *et al.*, 1998). However, mutations in the regulatory or intronic regions of the gene have not been ruled out (Burn & Jaros, 2001). Polymorphisms in the α -synuclein gene have been identified in PD (Krüger *et al.*, 1999). They may also increase the risk of developing MSA by promoting α -synuclein protein aggregation. Polymorphisms in codons 1 to 39 of the α -synuclein gene, a domain related to interaction with synphilin-1, or indeed polymorphisms in the synphilin-1 gene itself, or in the genes of other protein-interacting partners of α -synuclein may also need to be considered in the pathogenesis of MSA (Engelender *et al.*, 1999). The number of α -synuclein protein-interacting partners has expanded to include 14-3-3 protein chaperones, protein kinase C, extracellular regulated kinase, and BAD, a Bcl-2 homologue that regulates cell death (Ostrerova *et al.*, 1999). Nevertheless, association studies with genetic polymorphisms for α -synuclein, have so far been negative in MSA (Bandmann *et al.*, 1997; Morris *et al.*, 2000). Gilman *et al.* (1996) have reported a MSA-like phenotype including GCI like (α -synuclein negative) inclusions in one SCA 1 (spinocerebellar ataxia type 1) family. Other SCA mutations (except for SCA-2 (Bösch *et al.*, 2002a)) have not been reported to present with MSA-like features (Schöls *et al.*, 2000; Ranum *et al.*, 1995; Silveira *et al.*, 1996; Leggo *et al.*, 1997; Futamura *et al.*, 1998; Moseley *et al.*, 1998). Conversely, the majority of MSA-C patients do not appear to have expanded SCA1 and SCA3 alleles (Bandmann *et al.*, 1997). MSA-C appears to be a frequent form of sporadic cerebellar ataxia of late onset. 29% of sporadic adult-onset ataxia patients suffer from MSA (Abele *et al.*, 2002). This finding corresponds well to data of a study of sporadic OPCA patients who were followed 3 months to 10 years (Gilman *et al.*, 2000). Within this period, 17 out of 51 patients developed autonomic failure or parkinsonism indicating a diagnosis of MSA. Increased expression of a brain specific protein called ZNF231 in cerebellar neurones has been reported to occur in patients with MSA (Hashida *et al.*, 1998). The gene is located on chromosome 3p21 and encodes a neuronal double zinc finger protein with a nuclear targeting sequence, suggesting that it might function as a transcription regulator. The importance of this finding is as yet uncertain, but it is possible that patients with MSA differ

from unaffected individuals by sequence polymorphisms within, and flanking, the putative functional motifs of the ZNF231 gene.

Clinical picture

Introduction

In a series of 100 cases of clinically probable MSA (Wenning *et al.*, 1994a; Wenning & Quinn, 1997), at the last evaluation, 97% of patients with MSA had autonomic failure, 91% had parkinsonism, 52% had cerebellar features and 61% had pyramidal features. Autonomic failure may be associated with either levodopa unresponsive parkinsonism in 80% of cases (MSA-P subtype) or with cerebellar ataxia in 20% of cases (MSA-C subtype). There is commonly clinical and subclinical evidence of autonomic failure in both MSA variants.

Presenting features

MSA patients may present with parkinsonism that usually responds poorly to levodopa. This has been identified as the most important early clinical discriminator of MSA and PD (Quinn, 1989b; Schwarz *et al.*, 1992; Schelosky *et al.*, 1993; Wenning *et al.*, 2000a), although a subgroup of MSA patients may show a good or, rarely, excellent, but usually short-lived, response to levodopa (Bösch *et al.*, 2002b; Hughes *et al.*, 1992; Parati *et al.*, 1993). Progressive ataxia may also be the presenting feature of MSA (Schulz *et al.*, 1994; Wenning *et al.*, 1997a). A cerebellar presentation of MSA appears to be more common than the parkinsonian variant in Japan compared to Western countries (Watanabe *et al.*, 2002). Autonomic failure with symptomatic orthostatic hypotension and/or urogenital disturbance may accompany the motor disorder in up to 50% of patients at disease onset.

Unusual presentations in pathologically proven cases have included stroke-like episodes evolving into parkinsonism (Lambie *et al.*, 1947), REM sleep disorder (Tison *et al.*, 1995b), pseudo-TIAs in the anterior or posterior circulation (Bannister & Oppenheimer, 1972; Klein *et al.*, 1995) as well as limb shaking attacks (Litvan, personal communication).

Features of established disease

Parkinsonism

Bradykinesia, rigidity, postural tremor as well as dysequilibrium and gait unsteadiness characterize parkinsonism associated with MSA. Jerky postural tremor and less

Table 43.3. Frequency (%) of individual clinical features in three series of MSA

Myoclonus	na	31	29

MSA 168 refers to the series of well documented pathologically proven MSA cases reported in the literature (Wenning *et al.*, 1997b) excluding the 35 confirmed cases from the UK Parkinson's Disease Society Brain Bank that constitute MSA 35 (Wenning *et al.*, 1995). MSA 100 refers to the clinical series of 100 cases with probable MSA (Wenning *et al.*, 1994a). na: not available. (Reprinted with permission from Wenning & Quinn, 1997.)

commonly tremor at rest may be superimposed. Frequently, patients exhibit orofacial dystonia associated with a characteristic quivering high-pitched dysarthria. Postural stability is compromised early on, however, recurrent falls at disease onset are unusual in contrast to PSP. The majority of patients with MSA treated fail to show a sustained, long-term response to levodopa.

The clinical data in Table 43.3 are derived from three MSA series (Wenning & Quinn, 1997): 168 well-documented clinicopathological cases of MSA reported in the literature (Wenning *et al.*, 1997b), 100 cases of clinically probable MSA (Wenning *et al.*, 1994a), and 35 cases of pathologically confirmed MSA from the United Kingdom Parkinson's Disease Society Brain Bank (UKPDSBB) (Wenning *et al.*, 1995). The vast majority of patients in the three series (84–100%) developed parkinsonism. Pure MSA-P (parkinsonism without cerebellar signs) represented the single

most common motor subtype ranging from 40% (literature) through 48% (clinical series) to 66% (UKPDSBB series). In contrast, pure MSA-C (cerebellar ataxia without parkinsonism) was absent in the UKPDSBB series, and present in 9% of patients in the clinical series, and in 16% in the literature series. It has been suggested that a symmetrical atremulous picture might distinguish MSA-P from PD (Fearnley & Lees, 1990, Albanese *et al.*, 1995; Colosimo *et al.*, 1995; Gouider-Khouja *et al.*, 1995). However, motor disturbance was asymmetrical in 74% of patients in the clinical series, and unilateral at onset in 47% of literature cases, and in many of the UKPDSBB cases. Also, some sort of tremor was present in 64% to 80% of cases, and tremor present at rest was observed in 29% to 40% of cases. Even so, a classical pill-rolling resting tremor was reported in only 7% to 9% of subjects. Therefore, the differential diagnosis of MSA-P and PD may be exceedingly difficult in the early stages due to a number of overlapping features such as rest tremor or asymmetrical akinesia and rigidity. Furthermore, levodopa induced improvement of parkinsonism may be seen in 30% of MSA-P patients, however, the benefit is transient in most of them. Levodopa-induced dyskinesia affecting orofacial and neck muscles occur in 50% of MSA-P patients, sometimes in the absence of motor benefit (Bösch *et al.*, 2002b; Hughes *et al.*, 1992). In most instances a fully developed clinical picture of MSA-P evolves within 5 years of disease onset, allowing a clinical diagnosis during follow-up (Wenning *et al.*, 2000a).

Dysautonomia

Dysautonomia is characteristic of both MSA subtypes, primarily comprising urogenital and orthostatic dysfunction.

Urinary incontinence (71%) or retention (27%), often early in the course or as presenting symptoms, are frequent (Wenning *et al.*, 1994a/1999c; Beck *et al.*, 1994; Sakakibara *et al.*, 2000a). Disorders of micturition in MSA generally occur more commonly, earlier, and to a more severe degree than in PD (Beck *et al.*, 1994). Urinary retention can be caused or exacerbated by benign prostatic hypertrophy or, in women, by perineal laxity secondary to difficult childbirth or uterine descent. In men, the urological symptoms of pollakiuria, urgency, nocturia and incontinence together with hesitancy and incomplete emptying or chronic retention may simulate those of prostatic outflow obstruction. In a series of patients with probable MSA, 43% of males had undergone futile prostatic or bladder neck surgery before the correct diagnosis was made, although more than half of them had neurological symptoms or signs at the time of the procedure (Beck *et al.*, 1994). Stress incontinence occurred in 57% of the women and of these half had undergone surgery. The results of

surgery were also poor (Beck *et al.*, 1994; Chandiramani *et al.*, 1997). Fecal incontinence was much rarer (2–12%) (Wenning & Quinn, 1997), despite frequent severe denervation of the external anal sphincter, suggesting that the mechanisms of urinary and fecal continence are distinct in MSA.

Early impotence is virtually universal in men with MSA. In a series of 62 MSA patients, impotence occurred in 96% of the men and was the first symptom alone in 37% (Beck *et al.*, 1994). Reduced genital sensitivity with or without impaired libido has been recently reported in the majority of female MSA patients (Oertel *et al.*, 2003). In addition, MSA patients may note increased constipation and hypohydrosis.

Based on Shy and Drager's description (1960), recurrent syncopal attacks are commonly regarded as a typical feature of MSA. However, severe orthostatic hypotension with recurrent (more than three) syncopes was only reported in 15% of subjects whereas postural faintness was present, but only to a mild or moderate degree, in up to 53% of cases (Wenning *et al.*, 1994a,c). The analysis of a detailed questionnaire and autonomic function tests in a series of 121 patients with clinically diagnosed MSA showed that urinary symptoms (96%) were more common than orthostatic symptoms (43%) (Sakakibara *et al.*, 2000a) (see Section in Onset). Orthostatic hypotension is frequently associated with impaired or absent reflex tachycardia upon standing. Dopaminergic drugs may provoke or worsen orthostatic hypotension. Recumbent arterial hypertension, mainly due to loss of baroreflexes, may be seen in a few patients with severe cardiovascular autonomic failure (Bannister & Mathias, 1999a).

Cerebellar disorder

The cerebellar disorder comprises gait ataxia, limb kinetic ataxia and scanning dysarthria as well as cerebellar oculomotor disturbances. Cerebellar signs, most commonly manifesting as a wide-based ataxic gait developed in 34–59% of patients (Wenning & Quinn, 1997; Schulz *et al.*, 1994) (see Table 43.3). However, a subgroup of patients presented with narrow-based unsteady gait due to more marked impairment of postural reflexes (Wenning *et al.*, 1997a). Spontaneous and/or gaze-evoked nystagmus, often subtle, was detected in 23–25% of patients (Wenning *et al.*, 1994a, 1997a), and cerebellar scanning dysarthria may occur. The finding of a mixed dysarthria with combinations of hypokinetic, ataxic, and spastic components is consistent with both the overall clinical and the neuropathologic changes in MSA (Kluin *et al.*, 1996, Garratt *et al.*, 1994).

Patients with MSA-C develop additional non-cerebellar symptoms and signs, but before doing so may be indis-

tinguishable from other patients with idiopathic late onset cerebellar ataxia (ILOCA), many of whom have a disease restricted clinically to cerebellar signs and pathologically to degeneration of the cerebellum and olives (Abele *et al.*, 2002, Wenning & Geser, 2003).

Pyramidal signs

Although pyramidal signs may be elicited in up to 61% of MSA patients (Wenning & Quinn, 1997), obvious spastic paraparetic gait or significant pyramidal weakness should cast doubt upon the clinical diagnosis of MSA.

Other clinical features

Besides the poor response to levodopa, and the additional presence of pyramidal or cerebellar signs or autonomic failure as major diagnostic clues, certain other features may either raise suspicion of MSA, or at least suggest that one might not be dealing with PD (Quinn, 1989b). These features (Table 43.4), so called “red flags,” often are early warning signs of MSA (Gouider-Khouja *et al.*, 1995).

Dystonia of orofacial and platysma musculature may either be present spontaneously or it may emerge in 30% of levodopa treated patients, sometimes resulting in a characteristic facial distortion particularly, but not exclusively, in MSA-P patients reminiscent of risus sardonicus of cephalic tetanus (Fig. 43.4) (Hughes *et al.*, 1992; Wenning *et al.*, 1996b, 2003a; Bösch *et al.*, 2002b).

Subacute *Pisa syndrome*, a form of severe axial dystonia, has been reported in MSA (Kan, 1978; Colosimo, 1998). However, Pisa syndrome is a non-specific feature of parkinsonism and it may also emerge in patients with otherwise classical PD.

A frequent and characteristic feature suggesting MSA is the development of a *disproportionate antecollis* (Langston, 1936; Neumann, 1977; Caplan, 1984; Quinn, 1989a; Rivest *et al.*, 1990; Bösch *et al.*, 2002b) hampering feeding, communication and vision. The pathophysiological basis remains uncertain. Botulinum toxin injections into sternocleidomastoid muscles are usually unrewarding and worsen dysphagia (Thobois *et al.*, 2001).

Other manifestations of focal dystonia are less common, but may include *hand dystonia*, *torticollis*, and *dystonic toe movements*. Levodopa exposure may worsen dystonic movements in the absence of antiparkinsonian benefit (Bösch *et al.*, 2002b).

Tremulous myoclonic jerks, usually affecting the fingers, of small amplitude, and often stretch-sensitive, occur in a number of patients with MSA, but are otherwise rare in nondemented parkinsonian patients (Quinn, 1989b; Salazar *et al.*, 2000).

Table 43.4. “Red flags”: Warning features of MSA*

Motor Red Flags	Definition
Orofacial dystonia	Atypical spontaneous or L-Dopa induced dystonia predominantly affecting orofacial muscles, occasionally resembling risus sardonius of cephalic tetanus.
Pisa syndrome	Subacute axial dystonia with a severe tonic lateral flexion of the trunk, head, and neck (contracted and hypertrophic paravertebral muscles may be present).
Disproportionate antecollis	Chin-on-chest, neck can only with difficulty be passively and forcibly extended to its normal position. Despite severe chronic neck flexion, flexion elsewhere is minor.
Jerky tremor	Irregular (jerky) postural or action tremor of the hands and/or fingers.
Dysarthria	Atypical quivering, irregular, severely hypophonic or slurring high-pitched dysarthria, which tends to develop earlier, be more severe and be associated with more marked dysphagia compared with PD.
Non-motor Red Flags	
Abnormal respiration	Nocturnal (harsh or strained, high pitched inspiratory sounds) or diurnal inspiratory stridor, involuntary deep inspiratory sighs/gasps, sleep apnoea (arrest of breathing for ≥ 10 s), and excessive snoring (increase from premorbid level, or newly arising).
REM sleep behaviour disorder	Intermittent loss of muscle atonia and appearance of elaborate motor activity (striking out with arms in sleep often with talking/shouting) associated with dream mentation.
Cold hands/feet	Coldness and color change (purple/blue) of extremities not due to drugs with blanching on pressure and poor circulatory return.
Raynaud's phenomenon	Painful “white finger,” which may be provoked by ergot drugs.
Emotional incontinence	Crying inappropriately without sadness or laughing inappropriately without mirth.

* Excluding cardinal diagnostic features of MSA such as orthostatic hypotension, urinary incontinence/retention, levodopa unresponsive parkinsonism, cerebellar (ataxia) and pyramidal signs. Also excluding non-specific features suggesting atypical parkinsonism such as rapid progression or early instability and falls. (Reprinted with permission from John Wiley: Wenning & Geser, 2003b.)

Fig. 43.4 Risus Sardonius (RS) of a patient with MSA-P showing hypomimia, asymmetric orofacial dystonia and cervical dystonia affecting the platysma. (Reprinted with permission from John Wiley: Wenning *et al.*, 2003a.)

Speech impairment develops in virtually all MSA patients and is probably largely related to laryngeal dysfunction (Garratt *et al.*, 1994). It tends to be dominated by hypophonic monotony or a scanning quality according to clinical subtype (Kluin *et al.*, 1996). As well as the low volume

monotony of parkinsonism, a quivering, irregular, severely hypophonic or slurring *dysarthria* is “often so characteristic that the diagnosis can be suggested by listening to the patient on the telephone” (Caplan, 1984). Dysarthria tends to develop earlier, be more severe and be associated with more marked dysphagia in MSA compared to PD (Müller *et al.*, 2001).

MSA patients are prone to sleep-related breathing disorders, often resulting in nighttime oxygen desaturation (Wenning & Quinn, 1997). *Nighttime respiratory stridor*, commonly attributed to vocal cord paralysis (Williams *et al.*, 1979; Hughes *et al.*, 1998) but perhaps reflecting dystonia of the vocal cords (Merlo *et al.*, 2002) is also a helpful diagnostic pointer. Nocturnal stridor has been considered a poor prognostic feature. Analysis of survival curves of 30 patients with follow-up information showed a significantly shorter survival from the sleep evaluation, but not from disease onset, for patients with stridor compared with those without (Silber & Levine, 2000). Inspiratory stridor was documented in 9–34% (Wenning & Quinn, 1997) of patients and occurred at any time point in the disease process. In fact, several cases have presented acutely with laryngeal palsy requiring tracheostomy (Kew *et al.*, 1990) or nasotracheal intubation (Flugel *et al.*, 1984). Tracheostomy in later disease stages may be more controversial. In contrast, stridor is very uncommon in PD.

Fig. 43.5 RBD (striking out with arms in sleep often with sleep talking/shouting and recall of frightening dreams if awakened).

MSA patients also often show disrupted sleep with rapid eye movement (REM) phase alterations and may present with isolated *REM behavior disorder (RBD)* (Tison *et al.*, 1995b; Plazzi *et al.*, 1997) (Fig. 43.5). Sleep disorders are more common in patients with MSA than in those with PD after the same duration of the disease, reflecting the more diffuse underlying pathological process in MSA (Ghorayeb *et al.*, 2002c).

Patient with MSA often have cold, dusky, violaceous hands, with poor circulatory return after blanching by pressure. Changes in skin color or temperature were easily detected by Klein *et al.* (1997), and suggest a defect in neurovascular control of distal extremities. This “*cold hand sign*” is another clinical “red flag” that helps to raise the suspicion of MSA.

In MSA a large proportion report cold sensitivity or *Raynaud's phenomenon* (Santens *et al.*, 1996), with initial pallor followed by cyanosis and in some the later onset of redness, affecting both hands and feet (Mallipeddi & Mathias 1998).

Pseudobulbar crying/laughing spells may be evident in some patients; more commonly this frequent phenomenon may only be elicited by direct questioning (Quinn, 1994).

Core characteristics of the disease

The extrapyramidal features appear similar to those in PD, including bradykinesia with rigidity, postural instability, hypokinetic speech, and occasionally tremor, usually with a poor or unsustained response to chronic levodopa therapy. The signs of cerebellar dysfunction include disorders of extraocular movements, ataxic speech, and ataxia of limb movements and gait resulting in postural instability and frequent falls. Autonomic insufficiency results in orthostatic hypotension, urinary retention or incontinence, and impotence, often accompanied by constipation and decreased sweating. Extrapyramidal, cerebellar and autonomic features often occur in combination in MSA, but in some patients one or two features may predominate.

Clinical variants and their frequency

The clinical diagnosis of MSA is fraught with difficulty and there are no pathognomonic features to discriminate the common (80% of cases) parkinsonian variant (MSA-P) from PD. In a clinicopathologic study (Litvan *et al.*, 1997),

Table 43.5. Clinical diagnostic criteria for multiple system atrophy (Quinn, 1994)

SND type (predominantly parkinsonism)		OPCA type (predominantly cerebellar)
Sporadic adult onset non/poorly levodopa responsive parkinsonism ^a	Possible	Sporadic adult-onset cerebellar syndrome with parkinsonism
Above ^b , plus severe symptomatic autonomic failure ^c or cerebellar signs or pyramidal signs or pathological sphincter electromyogram	Probable	Sporadic adult-onset cerebellar syndrome ^a (with or without parkinsonism or pyramidal signs) plus severe symptomatic autonomic failure ^c or pathological sphincter electromyogram
P/m confirmed	Definite	P/m confirmed

^a Without DSM III dementia, generalized tendon areflexia, prominent supranuclear palsy for downgaze or other identifiable cause.

^b Moderate or good, but often waning, response to levodopa may occur, in which case multiple atypical features need to be present.

^c Postural syncope or presyncope and/or urinary incontinence or retention not due to other causes.

Sporadic: no other case of MSA among first- or second-degree relatives allowable.

Adult onset: onset age 30 years or above. (Reprinted with permission from Quinn, 1994.)

primary neurologists (who followed up the patients clinically) identified only 25% of MSA patients at the first visit (42 months after disease onset). Even at last neurological follow-up (74 months after disease onset), half of the patients were misdiagnosed and the correct diagnosis in the other half was established on average 4 years after disease onset. Mean rater sensitivity for movement disorder specialists was higher but still suboptimal at the first (56%) and last (69%) visit.

Consistent with this observation, most of the MSA patients identified in the epidemiological survey by Schrag *et al.* (1999) were only diagnosed during the study, suggesting that MSA is poorly recognized in clinical practice and is commonly mistaken for PD due to a number of overlapping features (Wenning *et al.*, 2000a). In a more recent study, the clinical diagnosis of MSA maintained until death by neurologists was incorrect in 8 (14%) of 59 cases and application of either Quinn or consensus criteria improved the clinical diagnosis of MSA at first, but not at last visit (Osaki *et al.*, 2002). In an earlier clinicopathological study, 12 of 35 MSA cases remained misdiagnosed as PD until death (Wenning *et al.*, 1995). MSA may be also confused with PSP (Wenning *et al.*, 2000a; Litvan *et al.*, 1996), and other atypical parkinsonian disorders.

In a review of the clinical and pathological diagnoses of 143 cases of parkinsonism the diagnostic accuracy for PD, MSA and PSP was higher than most previous prospective clinicopathological series and studies using the retrospective application of clinical diagnostic criteria (Hughes *et al.*, 2002). The positive predictive value of a clinical diagnosis of MSA was 85.7% (30 out of 35), and the sensitivity was 88.2% (30 out of 34). This study implies that neurologists with particular expertise in the field of movement disorders may be using a method of pattern recognition for

diagnosis which goes beyond that inherent in any formal set of diagnostic criteria.

Clinical diagnostic criteria for MSA were proposed by Quinn (1989b) and later slightly modified (Quinn, 1994). According to this schema, patients are classified as either SND or OPCA type MSA depending on the predominance of parkinsonism or cerebellar ataxia (Table 43.5). There are three levels of diagnostic probability: possible, probable and definite. Patients with sporadic adult-onset (> 30 years) poorly levodopa-responsive parkinsonism fulfil criteria for *possible* SND. The presence of other atypical features such as severe autonomic failure, cerebellar or pyramidal signs or a pathological sphincter EMG is required for a diagnosis of *probable* SND. Patients with sporadic late-onset predominant cerebellar ataxia with additional mild parkinsonism or pyramidal signs are considered *possible* OPCA type MSA. This may result in confusion since some patients with possible OPCA may also qualify for probable SND provided predominant cerebellar ataxia is accompanied by parkinsonian features. A diagnosis of *probable* OPCA type MSA requires the additional presence of severe autonomic failure or a pathological sphincter EMG. A definite diagnosis rests on neuropathological confirmation. Predominant SND or OPCA type presentations may be distinguished from pure types on the basis of associated cerebellar (predominant SND) or parkinsonian features (predominant OPCA). Since some degree of autonomic failure is present in almost all SND and OPCA type MSA patients (Wenning *et al.*, 1994a; Magalhães *et al.*, 1995) a further "autonomic" subtype (SDS) was not considered useful (Quinn *et al.*, 1995).

A number of exclusion criteria were also proposed: onset should be age 30 years or more, and in order to exclude inherited adult-onset ataxias there should be no family history of MSA. However, the chance occurrence of PD in

Table 43.6. Clinical domains, features and criteria used in the diagnosis of MSA according to Gilman *et al.* (1999)*

I. Autonomic and urinary dysfunction

A. Autonomic and urinary features

1. Orthostatic hypotension (by 20 mmHg systolic or 10 mmHg diastolic)
2. Urinary incontinence or incomplete bladder emptying

B. Criterion for autonomic failure or urinary dysfunction in MSA
Orthostatic fall in blood pressure (by 30 mmHg systolic or 15 mmHg diastolic) or urinary incontinence (persistent, involuntary partial or total bladder emptying, accompanied by erectile dysfunction in men) or both

II. Parkinsonism

A. Parkinsonian features

1. Bradykinesia (slowness of voluntary movement with progressive reduction in speed and amplitude during repetitive actions)
2. Rigidity
3. Postural instability (not caused by primary visual, vestibular, cerebellar, or proprioceptive dysfunction)
4. Tremor (postural, resting or both)

B. Criterion for Parkinsonism in MSA
Bradykinesia plus at least one of items 2 to 4

III. Cerebellar dysfunction

A. Cerebellar features

1. Gait ataxia (wide-based stance with steps of irregular length and direction)
2. Ataxic dysarthria
3. Limb ataxia
4. Sustained gaze-evoked nystagmus

B. Criterion for cerebellar dysfunction in MSA
Gait ataxia plus at least one of items 2 to 4

IV. Corticospinal tract dysfunction

A. Corticospinal tract features

1. Extensor plantar responses with hyperreflexia

B. Corticospinal tract dysfunction in MSA: no corticospinal tract features are used in defining the diagnosis of MSA

* A feature (A) is a characteristic of the disease and a criterion (B) is a defining feature or composite of features required for diagnosis. Reproduced with kind permission from Gilman *et al.* (1999).

relatives is allowable. Although some limitation of upgaze and convergence can occur in both MSA and in PD, a prominent downgaze palsy with marked slowing of voluntary saccades is an exclusion criterion for a clinical diagnosis of MSA. Further exclusion criteria include dementia, optic atrophy, pigmentary retinopathy, and generalized tendon areflexia. So far, sensitivity and specificity of the Quinn criteria have never been prospectively determined. Two retrospective validation studies demonstrated

Table 43.7. Diagnostic categories of MSA according to Gilman *et al.* (1999)*

I. Possible MSA
One criterion plus two features from separate other domains. When the criterion is parkinsonism, a poor levodopa response qualifies as one feature (hence only one additional feature is required).

II. Probable MSA
Criterion for autonomic failure/urinary dysfunction plus poorly levodopa-responsive parkinsonism or cerebellar dysfunction.

III. Definite MSA
Pathologically confirmed by the presence of a high density of glial cytoplasmic inclusions in association with a combination of degenerative changes in the nigrostriatal and olivopontocerebellar pathways.

* The features and criteria for each clinical domain are shown in Table 43.6.

Reproduced with kind permission from Gilman *et al.* (1999).

suboptimal diagnostic accuracy (Litvan *et al.*, 1998; Osaki *et al.*, 2002).

In April 1998 an International Consensus Conference was convened to develop optimized criteria for a clinical diagnosis of MSA (Gilman *et al.*, 1998, 1999). The Gilman criteria are now widely used for a clinical diagnosis of MSA. These criteria specify three diagnostic categories of increasing certainty: possible, probable and definite (Table 43.7). The diagnosis of possible and probable MSA are based on the presence of clinical features listed in Table 43.6. In addition, exclusion criteria have to be considered (Table 43.8). A definite diagnosis requires a typical neuropathological lesion pattern as well as deposition of α -synuclein-positive glial cytoplasmic inclusions (Dickson *et al.*, 1999a). A recent retrospective evaluation of the Gilman criteria showed excellent positive predictive values for both possible and probable MSA, however, sensitivity for probable MSA was poor (Osaki *et al.*, 2002). Whether the Gilman criteria will improve recognition of MSA patients especially in early disease stages needs to be investigated by prospective surveys with neuropathological confirmation in as many cases as possible.

Time course of the disease

MSA usually manifests in middle age, affects both sexes, and progresses relentlessly with a mean survival of 6–9 years (Ben-Shlomo *et al.*, 1997; Wenning *et al.*, 1994a, 1997b).

Table 43.8. Exclusion criteria for the diagnosis of MSA according to Gilman *et al.* (1999)**I. History**

Symptomatic onset under 30 years of age
 Family history of a similar disorder
 Systemic disease or other identifiable causes for features listed in Table 43.6
 Hallucinations unrelated to medication

II. Physical examination

DSM IV criteria for dementia
 Prominent slowing of vertical saccades or vertical supranuclear gaze palsy^a
 Evidence of focal cortical dysfunction such as aphasia, alien limb syndrome and parietal dysfunction

III. Laboratory investigation

Metabolic, molecular genetic and imaging evidence of an alternative cause of features listed in Table 43.6

^a In practice, MSA is most frequently confused with PD or PSP (PSP) (Litvan *et al.*, 1997). Mild limitation of upward gaze alone is non-specific, whereas a prominent (>50%) limitation of upward gaze or any limitation of downward gaze suggests PSP (Litvan *et al.*, 1996). Before the onset of vertical gaze limitation, a clinically obvious slowing of voluntary vertical saccades is usually easily detectable in PSP and assists in the early differentiation of these two disorders (Litvan *et al.*, 1996). Reproduced with kind permission from Gilman *et al.* (1999).

Onset

MSA is a disease that commonly causes clinical symptoms beginning in the sixth decade, although occasionally symptoms commence as early as the fourth decade (Sima *et al.*, 1993). In a series of 100 cases of MSA reported by Wenning *et al.* (1994a), the median age of onset was 53 and the range was 33 to 76 years. In a meta-analysis of 433 cases, mean age of onset was 54.2 years (range 31 to 78) (Ben Shlomo *et al.*, 1997). Latency to onset, but not duration, of symptomatic orthostatic hypotension or urinary incontinence differentiates PD from other parkinsonian syndromes, particularly MSA. Wenning *et al.* (1999c) found significant group differences for latency, but not duration, of symptomatic orthostatic hypotension and urinary incontinence: latencies to onset of either feature were short in patients with MSA, intermediate in patients with DLB, CBD, and PSP, and long in those with PD. Symptomatic orthostatic hypotension occurring within the first year after disease onset predicted MSA in 75% of cases; early urinary incontinence was less predictive for MSA (56%). It is likely that urinary dysfunction is more common

and often an earlier manifestation than orthostatic hypotension in patients with MSA, although subclinical cardiovascular abnormalities appear in the early stage of the disease (Sakakibara *et al.*, 2000a). The responsible sites seem to be central and peripheral for both dysfunctions.

Latencies to onset of falls were short in PSP patients, intermediate in MSA, DLB, and CBD, and long in PD (Wenning *et al.*, 1999a). Recurrent falls occurring within the first year after disease onset predicted PSP in 68% of the patients. Conversely, latency to onset, but not duration, of recurrent falls differentiates PD from other parkinsonian disorders.

Progression

MSA is a chronically progressive disease characterized by the gradual onset of neurological symptoms and accumulation of disability reflecting involvement of the systems initially unaffected. Thus, patients who present initially with extrapyramidal features commonly progress to develop autonomic disturbances, cerebellar disorders, or both. Conversely, patients who begin with symptoms of cerebellar dysfunction often progress to develop extrapyramidal or autonomic disorders, or both. Patients whose symptoms initially are autonomic may later develop cerebellar, extrapyramidal or both types of disorders.

The progression to different H & Y stages was evaluated in 81 pathologically confirmed patients with parkinsonism. Patients with PD showed significantly longer latencies to each H&Y stage than patients with an atypical parkinsonian disorder (APD). In fact, development of a H&Y-III within 1 year of motor onset accurately predicted an APD. However, the progression to each H&Y stage was unhelpful in distinguishing the APDs from each other. Once patients with PD and APD became wheelchair-bound, both had equally short survival times (Müller *et al.*, 2000).

In a more recent study (Watanabe *et al.*, 2002), median intervals from onset to aid-requiring walking, confinement to a wheelchair, a bedridden state and death were 3, 5, 8 and 9 years, respectively. Patients manifesting combined motor and autonomic involvement within 3 years of onset had a significantly increased risk of not only developing advanced disease stage but also shorter survival. MSA-P patients had more rapid functional deterioration than MSA-C patients, but showed similar survival.

Prognosis

MSA is a progressive disorder associated with a shortened lifespan, with death occurring on average within about

10 years of symptom onset. In one clinical study, the median survival from onset of symptoms was 9.5 years (Wenning *et al.*, 1994a), and in another 7.5 years (Testa *et al.*, 1996), whereas more recently, Tison *et al.* (2000b) showed a mean disease duration of 6.8 years. Similar average survivals were reported in two autopsy-verified series of MSA patients, 8.7 years in one (Wenning *et al.*, 1995) and 8.0 years in another (Hughes *et al.*, 1992). Schulz *et al.* (1994) found among 32 cases a median survival time after onset of motor symptoms of 4 years in SND and 9.1 years in OPCA. In a meta-analysis of 433 cases of pathologically proven MSA over a 100-year period survival showed a secular trend from a median duration of 4.9 years for publications between 1887 and 1970 to 6.8 years between 1991 and 1994 (Ben-Shlomo *et al.*, 1997). Older age of onset was associated with shorter survival; the hazard ratio for patients with onset after 60 years was 1.8 compared with patients between 31 and 49 years. Cerebellar features were associated with marginally increased survival. These results demonstrate the poor prognosis for patients with MSA but may be biased toward the worst cases.

Epidemiology

Determining the incidence and prevalence of MSA is difficult, as only a few epidemiologic studies have been reported. Estimates of the prevalence of MSA (per 100 000 in the population) in five studies were 1.9 (Tison *et al.*, 2000b), 2.3 (Wermuth *et al.*, 1997), 4.4 (Schrag *et al.*, 1999), 4.9 (Chio *et al.*, 1998) and 310 (in individuals older than 65 years) (Trenkwalder *et al.*, 1995). The annual incidence of MSA was estimated to be about 0.6 cases per 100 000 persons or 3.0/100 000 people over the age of 50 years (Bower *et al.*, 1997). Analytical epidemiology of MSA is even poorer: a case-control study in North America showed an increased risk of MSA associated with occupational exposure to organic solvents, plastic monomers and additives, pesticides and metals (Nee *et al.*, 1991). Another multicenter case-control study in Europe (Vanacore *et al.*, in press), showed a significantly higher risk of developing MSA in subjects having worked in agriculture. Smoking habits seem to be less frequent in MSA cases (as in PD cases) than in healthy controls. The fact that the inverse association with smoking found previously in PD is shared by MSA but not by PSP lends epidemiologic support to the notion that different smoking habits are associated with different groups of neurodegenerative disease (Vanacore *et al.*, 2000).

Investigations

Introduction

The clinical diagnosis of MSA rests largely on history and physical examination. Additional investigations are particularly helpful in excluding differential diagnoses, however, they may also support a presumptive clinical diagnosis. MSA-P patients are usually misdiagnosed as PD early in their disease. Regular follow-up is therefore required to detect development of atypical features suggestive of MSA.

Autonomic function tests

Autonomic function tests are a mandatory part of the diagnostic process and clinical follow-up in patients with MSA. Findings of severe autonomic failure early in the course of the disease make the diagnosis of MSA more likely, although the specificity in comparison to other neurodegenerative disorders is unknown in a single patient. Pathological results of autonomic function tests may account for a considerable number of symptoms in MSA patients and should prompt specific therapeutic steps to improve quality of life and prevent secondary complications like ascending urinary infections or injuries due to hypotension induced falls.

Cardiovascular function

A history of postural faintness or other evidence of orthostatic hypotension, e.g. neck ache on rising in the morning or posturally related changes of visual perception, should be sought in all patients in whom MSA is suspected. After taking a comprehensive history, testing of cardiovascular function should be performed according to consensus recommendations (Consensus statement on the definition of orthostatic hypotension, pure autonomic failure, and multiple system atrophy, 1996; Braune *et al.*, 1999a). A drop in systolic blood pressure (BP) of 20 mm Hg or more, or in diastolic BP of 10 mm Hg or more, compared with baseline within a standing time of 3 minutes is defined as orthostatic hypotension (Consensus statement on the definition of orthostatic hypotension, pure autonomic failure, and multiple system atrophy, 1996) and must lead to more specific assessment. This is based on continuous non-invasive measurement of blood pressure and heart rate during tilt table testing (Bannister & Mathias, 1999b; Braune *et al.*, 1996a, b). Although abnormal cardiovascular test results may provide evidence of sympathetic and/or

parasympathetic failure, they do not differentiate autonomic failure associated with PD vs. MSA (Riley & Chelimsky, 2003).

In MSA, cardiovascular dysregulation appears to be caused by central rather than peripheral autonomic failure. During supine rest norepinephrine (noradrenaline) levels (representing postganglionic sympathetic efferent activity) are normal (Ziegler *et al.*, 1977; Polinsky *et al.*, 1981), and there is no denervation hypersensitivity, which indicates a lack of increased expression of adrenergic receptors on peripheral neurons (Polinsky *et al.*, 1981). Uptake of the norepinephrine analogue meta-iodobenzylguanidine is normal in postganglionic cardiac neurons (Braune *et al.*, 1999b; Orimo *et al.*, 1999; Takatsu *et al.*, 2000; Taki *et al.*, 2000) (see Section on functional imaging) and the response to tilt is impaired with little increase in noradrenaline. In contrast, mainly postganglionic sympathetic dysfunction is thought to account for autonomic failure associated with PD. In keeping with this assumption, both basal and tilted noradrenaline levels are low.

Neuroendocrine testing

In vivo studies in MSA, which involved testing of the endocrine component of the central autonomic nervous systems (the hypothalamopituitary axis) with a variety of challenge procedures, provided evidence of impaired humoral responses of the anterior and the posterior part of the pituitary gland with impaired secretion of adrenocorticotrophic hormone (ACTH) (Polinsky *et al.*, 1987), growth hormone (Kimber *et al.*, 1997), and vasopressin/ADH (Kaufmann *et al.*, 1992), respectively. Although these observations can be made in virtually all patients in an advanced stage of the disease, their prevalence during the early course of MSA is unknown.

There is an ongoing debate about the diagnostic value of the growth-hormone response to clonidine (CGH-test), a neuropharmacological assessment of central adrenoceptor function, in PD and MSA. Clonidine is a centrally active alpha 2-adrenoceptor agonist which lowers blood pressure predominantly by reducing CNS sympathetic outflow. In an early study, there was no increase in GH levels after clonidine in patients with MSA compared to those with PD or pure autonomic failure (Zoukos *et al.*, 1993). Kimber *et al.* (1997) confirmed a normal serum GH increase in response to clonidine in 14 PD patients (without autonomic failure) and in 19 patients with pure autonomic failure, whereas there was no GH rise in 31 patients with MSA. However, these findings have been challenged subsequently (Clarke *et al.*, 1999; Tranchant *et al.*, 2000; Strijks *et al.*, 2002). After clonidine administration, GH rose in PSP subjects and controls, unlike MSA subjects (Kimber *et al.*, 2000). In

PSP subjects, responses to both physiological and pharmacological tests provided evidence against widespread autonomic dysfunction; this differed markedly from MSA subjects. Stimulation of GH release with GH releasing hormone plus arginine (GHRH-Arg) rather than clonidine may differentiate MSA from IPD and ILOCA (Pellecchia *et al.*, 2001), but this hypothesis would need to be confirmed by further investigations. In normal man, clonidine reduces arginine-vasopressin (AVP) secretion, probably by presynaptic inhibition of noradrenergic neuron terminals in the supraoptic nucleus. A lesion of noradrenergic pathways in animals abolishes this response to clonidine. At postmortem in MSA there is marked loss of hypothalamic noradrenergic innervation. Following clonidine there was a significantly greater fall of AVP levels in controls than MSA suggesting that there is an abnormal AVP response to clonidine in MSA, which probably represents loss of functional noradrenergic innervation of the supraoptic nucleus (Kimber *et al.*, 1999a). More studies in well-defined patient cohorts are needed before clonidine challenge tests can be recommended as helpful diagnostic tests in patients with suspected MSA.

Hypothalamic dopaminergic pathways are involved in the regulation of growth hormone and prolactin release from the anterior pituitary. Neuroendocrine studies in patients with MSA, in whom there is a reported loss of hypothalamic dopamine, are few and contradictory. In patients with MSA, the GHRH and GH responses to levodopa were preserved and were similar to responses in age-matched control subjects in a study by Kimber *et al.* (1999b). In contrast, there was impaired dopaminergic suppression of prolactin secretion. In MSA patients this may represent a selective dysfunction, rather than generalized loss, of tubero-infundibular dopaminergic neurons.

Bladder function

Assessment of bladder function is mandatory in MSA and usually provides evidence of involvement of the autonomic nervous system already at an early stage of the disease. Following a careful history regarding frequency of voiding, difficulties in initiating or suppressing voiding and the presence and degree of urinary incontinence, a standard urine analysis should exclude an infection. Postvoid residual volume needs to be determined sonographically or via catheterization to initiate intermittent self catheterization (ISC) in due course. In some patients only cystometry can discriminate between hypocontractile detrusor function and a hyperreflexic sphincter-detrusor dyssynergy.

The nature of bladder dysfunction is different in MSA and PD. Although frequency and urgency are common in both

disorders, marked urge or stress incontinence with continuous leakage is not a feature of PD apart from very advanced cases. Urodynamic studies show a characteristic pattern of abnormality in MSA patients (Kirby *et al.*, 1986). In the early stages there is often detrusor hyperreflexia, often with bladder neck incompetence due to abnormal urethral sphincter function, which result in early frequency and urgency followed by urge incontinence. Later on, the ability to initiate a voluntary micturition reflex and the strength of the hyperreflexic detrusor contractions diminish, and the bladder may become atonic, accounting for increasing postmicturition residual urine volumes.

The detrusor hyperreflexia may result from a disturbance of the pontine micturition centre (Beck *et al.*, 1994; Wenning *et al.*, 1996c). Alternatively, degeneration of substantia nigra and other regions of the basal ganglia that are important in the control of micturition, may contribute to urological symptoms. The atonic bladder in advanced MSA has been related to the progressive degeneration of the intermediolateral columns of the thoracolumbar spinal cord (Beck *et al.*, 1994); however, this remains speculative.

Sexual function

Sexual dysfunction is a frequent and early symptom of MSA, particularly in male patients. Since male MSA patients frequently develop erectile failure in their forties, and therefore experience substantial impairment of their sexual performance, expert urological advice should be sought for further investigation and implementation of appropriate therapeutic intervention. The pathophysiology of impotence in MSA is unclear; however, it is likely to include central autonomic disturbance, and more rarely, peripheral factors such as venous leakage.

Thermoregulation

Abnormal sudomotor function, sympathetic skin response, impaired heat tolerance and skin temperature regulation have been described in MSA (Cohen *et al.*, 1987; Sandroni *et al.*, 1991; Kihara *et al.*, 1991; Santens *et al.*, 1996; Klein *et al.*, 1997) (see Section on other clinical features).

The thermoregulatory sweat test (TST) as a test of preganglionic sympathetic function detects sweating by a color change of an indicator after thermal stimulation, whereas the quantitative sudomotor axon reflex test (QSART) measures an axon reflex mediated by the postganglionic sympathetic sudomotor axon following stimulation of sweat glands with acetylcholine. In MSA, using TST and QSART, both pre- and postganglionic sympathetic failure has been reported (Kihara *et al.*, 1991).

Specialized autonomic units may offer tests of thermoregulatory sweating to search for evidence of central

autonomic failure. However, the sensitivity and specificity of these tests in MSA is unknown and they require specialist experience and equipment.

The pathogenesis of anhidrosis associated with MSA remains unclear. This symptom may be entirely the result of central autonomic dysfunction, or due to (additional) postganglionic sympathetic dysfunction. The latter proposal is supported by tests using direct cholinergic stimulation of peripheral parasympathetic nerves (Baser *et al.*, 1991; Cohen *et al.*, 1987; Sandroni *et al.*, 1991).

Gastrointestinal function

Gastrointestinal motility in MSA has not been investigated in detail, and a single study from Stocchi and colleagues (2000) comparing anorectal function in MSA and PD demonstrated that most patients in both groups showed an abnormal straining pattern, decreased anal tone, or both dysfunctions. The authors suggested that, although bowel and anorectal dysfunctions do not differentiate MSA from PD, both abnormalities occur earlier and develop faster in MSA than in PD. In another study, in seven patients with MSA, pancreatic polypeptide response to insulin-induced hypoglycemia was impaired, indicating involvement of parasympathetic-mediated gastrointestinal function (Polinsky *et al.*, 1982).

Imaging

Magnetic resonance imaging (MRI)

MRI scanning of patients with MSA often, but not always, reveals atrophy of cerebellar vermis and, less marked, of cerebellar hemispheres (Schrag *et al.*, 2000). There is also evidence of shrinkage of pons as well as middle cerebellar peduncles (Schulz *et al.*, 1994), differentiating MSA-C from cortical cerebellar atrophy (CCA). The pattern of infratentorial atrophy visible on MRI correlates with the pathological process of OPCA affecting cerebellar vermis and hemispheres, middle cerebellar peduncles, pons, and lower brainstem (Klockgether *et al.*, 1990). The MRI changes may be indistinguishable from those of patients with autosomal dominant cerebellar ataxias (Wüllner *et al.*, 1993). MRI measures of basal ganglia pathology in MSA such as width of SNC, lentiform nucleus, head of the caudate, etc. are less well established and naked eye assessments are often unreliable. In advanced cases putaminal atrophy may be detectable and may correlate with severity of extrapyramidal symptoms (Wakai *et al.*, 1994). However, in one study MRI-based two-dimensional basal ganglia morphometry has proved unhelpful in the early differential

Fig. 43.6 T₂-weighted images (0.5 T) in a patient with pathologically proved multiple system atrophy showing infratentorial atrophy and signal change in pons (cross sign, arrow) resembling a hot cross bun (inset) baked for the last Thursday before Easter. Reproduced with kind permission from the BMJ Publishing Group: Schrag *et al.* Clinical usefulness of magnetic resonance imaging in multiple system atrophy. *Journal of Neurology, Neurosurgery and Psychiatry* 1998; 65(1):65–71.

diagnosis of patients with levodopa unresponsive parkinsonism (Albanese *et al.*, 1995). A significant progression of atrophy to under the normal limit was observed in the cerebrum, frontal and temporal lobes, showing the involvement of the cerebral hemisphere, especially the frontal lobe (Konagaya *et al.*, 2002). Abnormalities on MRI may include not only atrophy, but also signal abnormalities on T₂-weighted images within the pontocerebellar system and putamen. Signal hyperintensities sometimes seen within the pons and middle cerebellar peduncles are thought to reflect degeneration of pontocerebellar fibers and therefore, together with marked atrophy in these areas, indicate a major site of pathology in OPCA type MSA (Savoiardo *et al.*, 1990; Schulz *et al.*, 1994). The characteristic infratentorial signal change on T₂-weighted 1.5 tesla MRI (“hot cross bun” sign, Fig. 43.6) may also corroborate the clinical diagnosis of MSA (Schrag *et al.*, 2000). Putaminal hypointensities (Fig. 43.7) in supposedly APD were first reported in 1986 by two groups using a 1.5 tesla magnet and T₂-weighted images (Pastakia *et al.*, 1986; Drayer *et al.*, 1986). This change has subsequently been observed by

Fig. 43.7 Putaminal atrophy, hyperintense rim (arrow), and putaminal hypointensity in comparison with the globus pallidus on T₂ weighted images (1.5 T) in a patient with multiple system atrophy.

Reproduced with kind permission from the BMJ Publishing Group: Schrag *et al.* Clinical usefulness of magnetic resonance imaging in multiple system atrophy. *Journal of Neurology, Neurosurgery and Psychiatry* 1998; 65(1):65–71.

others in cases clinically thought to have MSA (Olanow, 1992; Wakai *et al.*, 1994; Schulz *et al.*, 1994), and in some cases with pathological confirmation (Lang *et al.*, 1994; Schwarz *et al.*, 1996; O'Brien *et al.*, 1990). A lateral to medial as well as posterior to anterior gradient is also well established with the most prominent changes in the posterolateral putamen (Pastakia *et al.*, 1986; Wakai *et al.*, 1994; Lang *et al.*, 1994). This putaminal hypointensity has been proposed as a sensitive and specific abnormality in patients with MSA, and to reflect increased iron deposition. However, similar abnormalities may occur in patients with classical PD (Stern *et al.*, 1989; Schrag *et al.*, 1998) or may represent incidental findings in patients without basal ganglia disorders (unpublished observations). The notion of increased iron deposition has been challenged by Brooks and colleagues (1989) and later by Schwarz and colleagues (1996). Recently it was shown that hypointense putaminal signal changes were more often observed in MSA than in PD patients using T₂*-weighted gradient echo (GE) but

not T₂-weighted fast spin echo images, indicating that T₂-weighted GE sequences are of diagnostic value for patients with parkinsonism (Kraft *et al.*, 2002). Increased putaminal relative to pallidal hypointensities may be seen as well as a slit-like hyperintense band lateral to the putamen (Fig. 43.7) (Schwarz *et al.*, 1996; Konagaya *et al.*, 1993, 1994; Yekhleif *et al.*, 2003). These changes are consistent with a clinical diagnosis of MSA. However, they appear to be non-specific and have also been noted in clinically diagnosed PD and PSP (Schrag *et al.*, 1998, 2000). The pattern consisting of hypointense and hyperintense T₂ changes within the putamen is a highly specific MRI sign of MSA, while hypointensity alone remains a sensitive, but nonspecific sign of MSA (Kraft *et al.*, 1999). The hyperintense signal correlated with the most pronounced reactive microgliosis and astrogliosis or highest iron content in MRI-postmortem studies (Lang *et al.*, 1994, Schwarz *et al.*, 1996). Konagaya *et al.* (1998) reported that, in a case of MSA, the slit hyperintensity at the putaminal margin represented widened intertissue space due to a severe shrinkage and rarefaction of the putamen. However, in spite of these speculations the nature of this abnormal signal intensity remains uncertain.

Diffusion-weighted imaging (DWI) may represent a useful diagnostic tool that can provide additional support for a diagnosis of MSA-P. DWI, even if measured in the slice direction only, is able to discriminate MSA-P and both patients with PD and healthy volunteers on the basis of putaminal rADC (regional apparent diffusion coefficients) values (Fig. 43.8) (Schocke *et al.*, 2002). The increased putaminal rADC values in MSA-P are likely to reflect ongoing striatal degeneration, whereas most neuropathologic studies reveal intact striatum in PD. But, since in PSP compared to PD patients rADCs were also significantly increased in both putamen and globus pallidus (Seppi *et al.*, 2003), increased putaminal rADC values do not discriminate MSA-P from PSP.

Whether magnetic resonance volumetry will contribute to the differential diagnosis of MSA from other parkinsonian disorders remains to be confirmed. Schulz *et al.* (1999) found significant reductions in mean striatal and brainstem volumes in patients with MSA-P, MSA-C, and PSP, whereas patients with MSA-C and MSA-P also showed a reduction in cerebellar volume. Total intracranial volume-normalized magnetic resonance imaging-based volumetric measurements provide a sensitive marker to discriminate typical and atypical parkinsonism. Voxel based morphometry (VBM) confirmed previous region of interest (ROI)-based volumetric studies (Schulz *et al.*, 1999) showing basal ganglia and infratentorial volume loss in MSA-P patients (Brenneis *et al.*, 2003). These data revealed prominent cortical volume loss in MSA-P mainly

Fig. 43.8 Apparent diffusion coefficient (ADC) maps (diffusion gradient switched in slice direction) calculated by fitting over 3 b-values in PD (A), the Parkinson variant of multiple system atrophy (MSA-P) (B), and controls (C). Blue, green, red, and black represent descending regional ADC values. Note the marked difference in putaminal ADC maps between MSA-P (B) and PD (A) as well as controls (C).

Fig. 43.9 VBM detects frontal lobe atrophy in MSA-P. SM1, primary sensorimotor cortex, PMd, dorsal premotor cortex; SMA, supplementary motor area; ACC, anterior cingulate cortex; SFG, Superior frontal gyrus. IMSA-SG (Innsbrucker MSA-Study Group) (unpublished data)

Fig. 43.10 Transverse IBZM SPECT images at the level of the striatum in patients with PD – untreated (A), PD – treated (B), and MSA-P (C). Images B and C show bilateral loss of tracer uptake (IMSA-SG). (From Colosimo *et al.*, 2004. © Elsevier. Reproduced with permission.)

comprising the cortical targets of striatal projections such as the primary sensorimotor, lateral premotor cortices and the prefrontal cortex, but also the insula (Fig. 43.9). These changes are consistent with the established frontal lobe impairment of MSA patients (Robbins *et al.*, 1992).

Proton magnetic resonance spectroscopy (MRS) is a noninvasive method that provides information about the chemical pathology of disorders affecting the central nervous system. The largest peak visible with MRS is derived from *N*-acetylaspartate (NAA), an amino acid contained almost exclusively within neurons and their processes in the adult brain (Urenjak *et al.*, 1993). In general, MRS studies have generated conflicting observations of limited relevance to differential diagnosis. Davie *et al.* (1995) showed reduced NAA/Cr in the putamen in MSA compared with PD and controls. Federico *et al.* (1999) have also shown reduced NAA/Cr and NAA/Cho in MSA compared with controls and reduced NAA/Cr in MSA compared with PD. The King's College group initially found reductions in NAA/Cr and NAA/Cho in MSA compared with controls, but a similar reduction in PD (Ellis *et al.*, 1996). More recently, they

have failed to confirm this finding (Hu *et al.*, 1998). In the only study to use absolute quantitation of metabolite concentrations, NAA was unchanged in MSA patients (Clarke & Lowry, 2000).

Functional imaging

Single-photon emission tomography (SPECT) or Positron emission tomography (PET) studies of patients with MSA-P have demonstrated the combined nigral and striatal pathology using [¹²³I]β-CIT [2β-carboxymethoxy-3β-(4-iodophenyl)tropane] (SPECT) or [¹⁸F]fluorodopa (PET) and a variety of postsynaptic dopamine or opiate receptor ligands such as [¹²³I]iodobenzamide (IBZM) (SPECT) (Fig. 43.10), [¹¹C]raclopride or [¹¹C]diprenorphin (PET).

The Hammersmith Cyclotron Unit, using PET found that putaminal uptake of the presynaptic dopaminergic markers [¹⁸F]fluorodopa and S-[¹¹C]nomifensine (Brooks *et al.*, 1990a, b; Burn *et al.*, 1994) was similarly reduced in MSA and PD; in approximately half the MSA subjects, caudate uptake was also markedly reduced, as opposed to only moderate

reduction in PD. However, discriminant function analysis of striatal [^{18}F]fluorodopa uptake separated MSA and PD patients poorly (Burn *et al.*, 1994). Patients with PD, PSP and MSA share a marked loss of fluorodopa uptake in the putamen; however, uptake in the caudate nucleus differs among the three groups, with patients who have MSA showing uptake rates intermediate between those of patients with PD (normal uptake) and with PSP (markedly reduced uptake) (Brooks *et al.*, 1990a). Measurements of striatal dopamine D2 receptor densities using raclopride and PET failed to differentiate between idiopathic and atypical parkinsonism, demonstrating a similar loss of densities in levodopa treated patients with fluctuating PD, MSA and PSP (Brooks *et al.*, 1992). PET studies using other ligands such as [^{11}C]diprenorphine (non-selective opioid receptor antagonist) (Burn *et al.*, 1995) and [^{18}F]fluorodeoxyglucose (Antonini *et al.*, 1998; de Volder 1989; Eidelberg *et al.*, 1993; Perani *et al.*, 1995) have proved more consistent in detecting striatal degeneration and in distinguishing patients with MSA-P from those with PD, particularly when combined with a dopamine D2 receptor scan (Ghaemi *et al.*, 2002). Widespread functional abnormalities in MSA-C have been demonstrated using [^{18}F]fluorodeoxyglucose and PET (Gilman *et al.*, 1994). Reduced metabolism was most marked in the brainstem and cerebellum, but other areas such as the putamen, caudate nucleus, thalamus and cerebral cortex were also involved, differentiating MSA-C from SCAs. Subclinical evidence of striatal pathology in MSA-C, in the absence of extrapyramidal features, has been demonstrated using the non-selective opioid receptor ligand diprenorphine and PET (Rinne *et al.*, 1995). Striatal opiate receptors are reduced not only in MSA-P (Burn *et al.*, 1995) but also in MSA-C with associated autonomic failure (Rinne *et al.*, 1995) supporting its nosological status as the cerebellar subtype of MSA. In another PET study using [^{18}F]fluorodeoxyglucose in comparison with normal controls, putaminal hypometabolism was absent in sporadic OPCA patients without autonomic failure and extrapyramidal features, but present in those who were classified as OPCA type MSA and therefore had autonomic dysfunction with or without parkinsonian features at the time of examination (Gilman *et al.*, 1994). Differences in cerebellar benzodiazepine receptor binding densities have also been shown in MSA-C, CCA and SCA using [^{11}C]flumazenil and PET (Gilman *et al.*, 1995). Additionally, the poor levodopa response may be related to a deficiency in striatal D1 receptor binding, as shown by PET studies in clinically diagnosed patients with MSA using the ligand [^{11}C]SCH 23390 (Shinotoh *et al.*, 1993). This is a potentially helpful observation that may aid early differentiation of MSA and PD if corroborated by other groups.

SPECT imaging studies of patients with dopa naive parkinsonism have used [^{123}I]iodobenzamide (IBZM) as D2 receptor ligand (Fig. 43.10) (Schwarz *et al.*, 1992; Schelosky *et al.*, 1993). A good response to apomorphine and subsequent benefit from chronic dopaminergic therapy was observed in subjects with normal IBZM binding whereas subjects with reduced binding failed to respond. Some of these patients developed other atypical clinical features suggestive of MSA during follow-up (Schwarz *et al.*, 1993). Other SPECT studies have also revealed significant reductions of striatal IBZM binding in clinically probable MSA subjects compared to PD patients (Brücke *et al.*, 1993; Schulz *et al.*, 1994) or controls (Brücke *et al.*, 1993; van Royen *et al.*, 1993). There has been much debate about the mechanism of levodopa-unresponsiveness in MSA. As well as loss of striatal dopamine binding sites, alterations further downstream probably also contribute (Tison *et al.*, 1995a,b). SPECT evaluation of the dopamine transporter (DAT) using [^{123}I]beta-CIT can easily distinguish patients with essential tremor and patients with "lower body parkinsonism" due to a subcortical vascular encephalopathy. MSA and PSP cannot be separated from PD with this method alone (Brücke *et al.*, 2000). DAT SPECT may be useful in differentiating parkinsonism from controls and D2 SPECT in further differentiating MSA from PD and possibly PSP (Kim *et al.*, 2002). In another DAT SPECT study, striatal [^{123}I]beta-CIT uptake was markedly reduced in both the PD and MSA groups (Varrone *et al.*, 2001). In addition, MSA patients showed more symmetric DAT loss compared with the PD patients, consistent with the more symmetric clinical motor dysfunction observed in MSA. Since [^{123}I]beta-CIT SPECT reliably enables the visualization of the presynaptic dopaminergic lesion in patients with MSA, PSP, and CBD (Pirker *et al.*, 2000), this method was used as a label of DAT to study the progression of presynaptic dopaminergic degeneration in PD and APD by Pirker *et al.* (2002). The results of the sequential [^{123}I]beta-CIT SPECT imaging demonstrate a rapid decline of striatal beta-CIT binding in patients with APD, exceeding the reduction in PD.

Scintigraphic visualisation of postganglionic sympathetic cardiac neurons was found to differentiate patients with MSA from patients with PD (Braune *et al.*, 1999b; Orimo *et al.*, 1999; Takatsu *et al.*, 2000; Taki *et al.*, 2000). Considering all reports published so far standard scintigraphy with [^{123}I]metaiodobenzylguanidine (MIBG), which has been used to detect pheochromocytoma cells for years, was able to correctly allocate each of about 70 patients with MSA versus more than 200 patients with PD, because all patients in the latter group showed a severely reduced cardiac uptake of the radioactive ligand. This method appears to be a highly sensitive and specific tool to discriminate

between MSA and PD already within 2 years of onset of symptoms; however, the test cannot distinguish MSA from other APDs such as PSP (Yoshita, 1998).

Neurophysiology

The external anal or urethral sphincter EMG is a useful investigation in patients with suspected MSA. Due to degeneration of Onuf's nucleus both anal and urethral external sphincter muscles undergo denervation and re-innervation. Abnormality of the striated urethral sphincter EMG in MSA was first shown by Martinelli and Coccagna (1978). Subsequently, Kirby *et al.* (1986) confirmed the presence of polyphasia and abnormal prolongation of individual motor units in MSA, and also examined the potential diagnostic role of sphincter EMG in patients with MSA and PD (Eardley *et al.*, 1989). Sixteen (62%) of 26 patients with probable MSA, and only 1 (8%) of 13 with probable PD had a pathological EMG result (sensitivity 0.62, specificity 0.92). This test also helps to identify patients in whom incontinence may develop or worsen following surgery. Anal sphincter EMG is generally better tolerated, and yields identical results (Beck *et al.*, 1994). At least 80% of patients with MSA EMG of the external anal sphincter reveal signs of neuronal degeneration in Onuf's nucleus with spontaneous activity and increased polyphasia (Pramstaller *et al.*, 1995; Palace *et al.*, 1997; Tison *et al.*, 2000a). However, these findings do not reliably differentiate between MSA and other forms of APD. An abnormal anal sphincter examination was present in five of 12 (41.6%) PSP patients (Valldeoriola *et al.*, 1995). Furthermore, neurogenic changes of external anal sphincter muscle have also been demonstrated in advanced stages of PD by several investigators (Libelius & Johansson, 2000; Giladi *et al.*, 2000). Also chronic constipation, previous pelvic surgery or vaginal deliveries can be confounding factors to induce non-specific abnormalities (Colosimo *et al.*, 2000). In summary, in patients with probable MSA, abnormal sphincter EMG, as compared to control subjects, has been found in the vast majority of patients, including those who, as yet, have no urological or anorectal problems. The prevalence of abnormalities in the early stages of MSA is as yet unclear. Patients with PD as a rule do not show severe sphincter EMG abnormalities in the early stage of the disease, unless other causes for sphincter denervation are present. With such criteria, the sensitivity of the method is, however, low and, indeed, sphincter EMG does not distinguish MSA from PSP (Vodusek, 2001). For these reasons, this examination has not been eventually included in the guidelines suggested by the Consensus Conference (Gilman *et al.*, 1998).

In general, the value of evoked potential studies in the diagnosis of MSA is limited. Magnetic evoked potentials are often, but not always, normal in MSA (Wenning & Smith, 1997; Abbruzzese *et al.*, 1997). Somatosensory, visual, and acoustic evoked potentials may show prolonged latencies in up to 40% of patients, but most patients show no abnormalities of central efferent and afferent neuronal pathways (Abele *et al.*, 2000a; Delalande *et al.*, 1998; Abbruzzese *et al.*, 1997).

Some investigators (Montagna *et al.*, 1983; Cohen *et al.*, 1987) have suggested that both somatic anterior horn cells and peripheral nerves are commonly affected in MSA, and their involvement has therefore been regarded as part of the clinical spectrum of MSA. Abnormalities of nerve conduction studies seem to be more frequent in MSA-P (43%) compared to MSA-C (14%) (Abele *et al.*, 2000b) suggesting that the peripheral nervous system is differentially affected in the motor presentations of this disorder.

On electro-oculography many MSA patients show impaired ocular fixation with increased square wave jerks (Rascol *et al.*, 1991). Saccadic pursuit, gaze paretic down-beating nystagmus (Stell & Bronstein, 1994), and impaired vestibuloocular reflex (VOR) suppression may be detectable indicating the presence of concomitant cerebellar pathology (Rascol *et al.*, 1995). Marked supranuclear vertical palsy, more prominent on down- than upgaze, with slowing of voluntary saccades, was not observed in two large series studied by Wenning *et al.* (1994a and 1995) and helped to distinguish MSA from PSP in patients with APD. However, there are three (2%) pathologically proven MSA cases in the literature with documented impairment of downgaze (Gosset *et al.*, 1983 (cases 1 and 3); Jankovic *et al.*, 1993b). A laboratory-based investigation showed similar mild eye movement deficits in MSA-P and PD patients (Vidailhet *et al.*, 1994), but the authors excluded individuals with cerebellar signs.

Excessive auditory startle responses (ASR) may also help differentiate MSA both from PD and other forms of APD (Kofler *et al.*, 2001). Exaggerated ASR may reflect disinhibition of lower brainstem nuclei due to the degenerative disorder. ASR appear to be more disinhibited in MSA-P than MSA-C, and there is a lack of ASR habituation in MSA-C unlike MSA-P, suggesting involvement of different neural structures in the two MSA-subtypes (Kofler *et al.*, 2003).

Other investigations

In its early stages, MSA-C can be indistinguishable from idiopathic late-onset cerebellar ataxia. Six patients with ILOCA, that later evolved to MSA, had impaired hypoxic

ventilatory response when autonomic failure was present, whereas in patients with unimpaired hypoxic ventilatory response the diagnosis remained ILOCA (Tsuda *et al.*, 2002). The demonstration of impaired hypoxic ventilatory response appears to be a good marker enabling earlier diagnosis of MSA in patients presenting with ILOCA.

Patients with MSA usually retain normal intelligence levels, but abnormalities of neuropsychological function have been described (Meco *et al.*, 1996). In a few studies, a distinctive pattern of cognitive defects was found suggesting normal intelligence but disorders of frontal lobe function (Robbins *et al.*, 1992; Brown *et al.*, 2002). These included difficulties with attentional set shifting when extradimensional shifting was required, impairment in subject-ordered tests of spatial working memory, and deficits in speed of thinking (rather than of accuracy) in the Tower of London task. Another study in patients with MSA-P demonstrated impairment on category and phonemic fluency, frontal behaviors, trail making test A and B, and free recall in the Grober and Buschke test (Pillon *et al.*, 1995). These patients were normal on the revised Wechsler Adult Intelligence Scale verbal scale, Wechsler memory scale, Raven 47 colored progressive matrices, California Verbal Learning Test, Wisconsin Card Sorting Test, and the Stroop interference condition.

Treatment

Autonomic failure

Unfortunately there is no causal therapy of autonomic dysfunction available. Therefore the therapeutic strategy is defined by clinical symptoms and impairment of quality of life in these patients. Due to the progressive course of MSA a regular review of the treatment is mandatory to adjust measures according to clinical needs.

The concept to treat symptoms of orthostatic hypotension is based on the increase of intravascular volume and the reduction of volume shift to lower body parts when changing to upright position. The selection and combination of the following options depend on the severity of symptoms and their practicability in the single patient, but not on the extent of blood pressure drop during tilt test. Non-pharmacological options include sufficient fluid intake, high salt diet, more frequent, but smaller meals per day to reduce postprandial hypotension by spreading the total carbohydrate intake and custom made elastic body garments. During night, head-up tilt increases intravascular volume up to 1 l within a week, which is particularly helpful to improve hypotension early in the morning. This approach

is successful in particular in combination with fludrocortisone, which further supports sodium retention.

The next group of drugs to consider are the sympathomimetics. These include ephedrine (with both direct and indirect effects) which is often valuable in central autonomic disorders such as MSA. With higher doses, side effects include tremulousness, loss of appetite, and urinary retention in men.

Among the large number of vasoactive agents that have been evaluated in MSA only one, the directly acting α -adrenergic agonist midodrine, meets the criteria of evidence based medicine (Jankovic *et al.*, 1993a; Low *et al.*, 1997; Wright *et al.*, 1998). Side effects are usually mild and only rarely lead to discontinuation of treatment because of urinary retention or pruritus, predominantly on the scalp. Another promising drug appears to be the norepinephrine precursor L-threo-dihydroxy-phenylserine (L-threo-DOPS), which has been used in this indication in Japan for years and efficacy of which has now been shown by a recent open, dose-finding trial (Mathias *et al.*, 2001). In case the above mentioned drugs do not produce the desired effects, selective targeting is needed. The somatostatin analogue, octreotide, is often beneficial in postprandial hypotension (Alam *et al.*, 1995), presumably because it inhibits release of vasodilatory gastrointestinal peptides (Raimbach *et al.*, 1989); importantly it does not enhance nocturnal hypertension (Alam *et al.*, 1995).

The vasopressin analogue, desmopressin, which acts on renal tubular vasopressin-2 receptors, reduces nocturnal polyuria and improves morning postural hypotension (Mathias *et al.*, 1986). The peptide erythropoietin may be beneficial in some patients by raising red cell mass, secondarily improving cerebral oxygenation (Perera *et al.*, 1995; Winkler *et al.*, 2001). A broad range of drugs (see above) have been used in the treatment of postural hypotension (Mathias & Kimber, 1999). Unfortunately, the value and side effects of many of these drugs have not been adequately determined in MSA patients using appropriate endpoints.

In the management of neurogenic bladder including residual urine, clean intermittent catheterization three to four times per day is a widely accepted approach to prevent secondary consequences of failure to micturate. It may be necessary to provide the patient with a permanent transcutaneous suprapubic catheter if mechanical obstruction in the urethra or motor symptoms of MSA prevent uncomplicated catheterisation.

Pharmacological options with anti- or pro-cholinergic drugs or α -adrenergic substances are usually not successful to adequately reduce post-void residual volume in MSA, but anticholinergic agents like oxybutynin can improve symptoms of detrusor hyperreflexia or sphincter-detrusor

Table 43.9. Practical management of MSA

A. Pharmacotherapy	
I. For akinesia-rigidity	
• Levodopa up to 800–1000 mg/day, if tolerated (↔)	
• Dopamine agonists as second-line antiparkinsonian drugs (dosing as for PD patients) (↔)	
• Amantadine as third-line drug, 100 mg up to three times daily (↔)	
II. For focal dystonia	
• Botulinum toxin A (↔)	
III. For orthostatic hypotension	
• Head-up tilt of bed at night (↔)	
• Elastic stockings or tights (↔)	
• Increased salt intake (↔)	
• Fludrocortisone 0.1–0.3 mg/day (↔)	
• Ephedrine 15–45 mg t.i.d. (↔)	
• L-threo-DOPS (300 mg b.i.d.) (↔)	
• Midodrine 2.5–10 mg t.i.d. (↑↑)	
IV. For postprandial hypotension	
• Octreotide 25–50 mcg s.c. 30 min before a meal (↔)	
V. For nocturnal polyuria	
• Desmopressin (spray: 10–40 mcg/night or tablet: 100–400 mcg/night) (↔)	
VI. For bladder symptoms	
• Oxybutynin for detrusor hyperreflexia (2.5–5 mg b.i.d.-t.i.d.) (↔)	
• Intermittent self-catheterization for retention or residual volume > 100 ml (↔)	
B. Other therapies	
• Physiotherapy (↔)	
• Speech therapy (↔)	
• Occupational therapy (↔)	
• Percutaneous endoscopic gastrostomy (PEG) (rarely needed in late stage) (↔)	
• Provision of wheelchair (↔)	
• CPAP (↑) (rarely tracheostomy [↔]) for inspiratory stridor	

(Reprinted by permission from John Wiley & Sons Inc.: Wenning & Geser, 2003b.)

dysynergy in the early course of the disease (Beck *et al.*, 1994). Recently, α -adrenergic receptor antagonists (prazosin and moxislyte) have been shown to improve voiding with reduction of residual volumes in MSA patients (Sakakibara *et al.*, 2000b). Urological surgery must be avoided in these patients because postoperative worsening of bladder control is most likely (Beck *et al.*, 1994).

The necessity of a specific treatment for sexual dysfunction needs to be evaluated individually in each MSA patient. Male impotence can be partially circumvented by the use of intracavernosal papaverine, prostaglandin E1 or penile implants (Colosimo & Pezzella, 2002). Preliminary

evidence in PD patients (Zesiewicz *et al.*, 2000) suggests that sildenafil may also be successful in treating erectile failure in MSA: a recent trial confirmed the efficacy of this compound in MSA, but also suggested caution because of the frequent cardiovascular side-effects (Hussain *et al.*, 2001). Erectile failure in MSA may also be improved by oral yohimbine (Beck *et al.*, 1994).

Constipation can be relieved by increasing the intraluminal volume which may be achieved by using macrogol-water solution (Eichhorn & Oertel, 2001).

Inspiratory stridor develops in about 30% of patients. Continuous positive airway pressure (CPAP) may be helpful in some of these patients (Iranzo *et al.*, 2000). In only about 4% a tracheostomy is needed and performed.

Motor disorder

General approach

Because the results of drug treatment for the motor disorder of MSA are generally poor, other therapies are all the more important. Physiotherapy helps maintain mobility and prevent contractures, and speech therapy can improve speech and swallowing and provide communication aids. Dysphagia may require feeding via a nasogastric tube or even percutaneous endoscopic gastrostomy (PEG). Occupational therapy helps to limit the handicap resulting from the patient's disabilities and should include a home visit. Provision of a wheelchair is usually dictated by the liability to falls because of postural instability and gait ataxia but not by akinesia and rigidity *per se*. Psychological support for patients and partners needs to be stressed.

Parkinsonism

Parkinsonism is the predominant motor disorder in MSA and therefore represents a major target for therapeutic intervention. Although less effective than in PD and despite the lack of randomized-controlled trials, levodopa replacement represents the mainstay of antiparkinsonian therapy in MSA. Open-label studies suggest that up to 30–40% of MSA patients may derive benefit from levodopa at least transiently (Parati *et al.*, 1993, Wenning *et al.*, 1994a). Occasionally, a beneficial effect is evident only when seemingly unresponsive patients deteriorate after levodopa withdrawal (Hughes *et al.*, 1992). Pre-existing orthostatic hypotension is often unmasked or exacerbated in levodopa treated MSA patients associated with autonomic failure. In contrast, psychiatric or toxic confusional states appear to be less common than in Parkinson's disease (Wenning *et al.*, 1994a). Results with dopamine agonists have been even more disappointing (Lees, 1999).

Severe psychiatric side effects occurred in a double-blind crossover trial of six patients on lisuride, with nightmares, visual hallucinations and toxic confusional states (Lees & Bannister, 1981). Wenning *et al.* (1994a) reported a response to oral dopamine agonists only in 4 of 41 patients. None of 30 patients receiving bromocriptine improved, but three of ten who received pergolide had some benefit. Twenty-two percent of the levodopa responders had good or excellent response to at least one orally active dopamine agonist in addition. Antiparkinsonian effects were noted in 4 of 26 MSA patients treated with amantadine (Wenning *et al.*, 1994a); however, there was no significant improvement in an open study of nine patients with atypical parkinsonism, including five subjects with MSA (Colosimo *et al.*, 1996).

Blepharospasm as well as limb dystonia, but not antecolitis, may respond well to local injections of botulinum toxin A.

Ablative neurosurgical procedures such as medial pallidotomy fail to improve parkinsonian motor disturbance in MSA (Lang *et al.*, 1997). However, more recently beneficial short-term and long-term effects of bilateral subthalamic nucleus high-frequency stimulation have been reported in four patients with MSA-P (Visser-Vandewalle *et al.*, 2003).

Cerebellar ataxia

There is no effective therapy for the progressive ataxia of MSA-C.

Occasional successes have been reported with cholinergic drugs, amantadine, 5-hydroxytryptophan, isoniazid, baclofen and propranolol; for the large majority of patients these drugs proved to be ineffective.

One intriguing observation is the apparent temporary exacerbation of ataxia by cigarette smoking (Graham & Oppenheimer, 1969; Johnsen & Miller, 1986). Nicotine is known to increase the release of acetylcholine in many areas of the brain and probably also releases noradrenaline, dopamine, 5-hydroxytryptophan and other neurotransmitters. Nicotinic systems may therefore play a role in cerebellar function and trials of nicotinic antagonists such as dihydro-beta-erythroidine might be worthwhile in MSA-C.

Practical therapy

Because of the small number of randomized controlled trials, the practical management of MSA is largely based on empirical evidence (\leftrightarrow) or single randomized studies (\uparrow), except for three randomized controlled studies of mido-

drine ($\uparrow\uparrow$). The present recommendations are summarized in Table 43.9.

Future therapeutic approaches

Two European research initiatives, i.e. the European MSA-Study Group (EMSA-SG) as well as the Neuroprotection and Natural History in Parkinson Plus Syndromes (NNIPPS), are presently conducting multicentre intervention trials in MSA. These trials will radically change our approach to MSA. For the first time, prospective data concerning disease progression will become available allowing us to reliably identify predictors of survival.

The need for prospective natural history studies has led the EMSA-SG to develop the Unified MSA Rating Scale (UMSARS) including a video teaching tape to standardize severity assessments in specialized clinics and research programs (Wenning *et al.*, 2002). This novel scale will also be useful in future multicenter intervention trials.

Furthermore, surrogate markers of the disease process will be identified by the EMSA-SG and NIPPS trials using structural and functional neuroimaging. These markers will allow to plan future phase III intervention trials more effectively.

Research into the etiopathogenesis and neuropathology of MSA is being conducted by EMSA-SG, NNIPPS and North American MSA-Study Group (NAMSA-SG). A number of animal models have become available as testbeds for pre-clinical intervention studies (Wenning *et al.*, 1996a, 1999b, 2000c; Scherfler *et al.*, 2000; Waldner *et al.*, 2001; Fernagut *et al.*, 2002; Ghorayeb *et al.*, 2000, 2002a,b, Kahle *et al.*, 2002). This work will lead to a multitude of neuroprotective candidate agents ready to be tested during the next decade.

Conclusions

During the last 15 years there have been major advances in our understanding of the cellular pathology of MSA. At the same time the first multicentre intervention trials have been launched in Europe. Although therapeutic options are limited at present, there is a real hope for a radical change of our approach to this devastating illness.

Progressive supranuclear palsy

Lawrence I. Golbe

Department of Neurology, Robert Wood Johnson Medical School, New Brunswick, NJ, USA

Introduction

Progressive supranuclear palsy (PSP) is unusual among the neurodegenerative disorders in the variety of neural structures it involves and the complexity of the illness that results. The tau-based neurofibrillary tangles and the associated degeneration affect both neurons and glia. The damage involves systems at every level from cerebral cortex to lumbar spinal cord. It affects dopaminergic, cholinergic and GABAergic systems. Its superficial clinical resemblance to Parkinson's disease (PD) and close pathological resemblance to postencephalitic parkinsonism delayed its definitive clinicopathological description until the early 1960s. (Richardson, 1963; Olszewski, 1963; Steele *et al.*, 1964). Its full-blown, typical clinical appearance is unmistakable, but atypical forms are frequent and multiple conditions can mimic it.

The etiology of PSP is no clearer than that of most other neurodegenerative disorders but the late 1990s have brought important new insights into the molecular defects underlying neurofibrillary tangle formation. Such insights will probably prove the best route to treatment of PSP, as symptomatic palliative treatments have been disappointing.

Clinical summary

Presentation

In its full-blown, typical state, PSP will not be confused with other illnesses. There can be little diagnostic doubt in a patient with a progressive syndrome of gait instability with early falls, neck rigidity with erect posture and bradykinesia, predominantly vertical supranuclear gaze abnormality,

spastic dysarthria, dangerous dysphagia, tonically contracted facies and frontal behavioral abnormalities.

Restriction of vertical gaze with preserved oculocephalic reflexes is the most specific feature of PSP and the source of its name. However, gaze restriction is often absent until the middle of the course and is only rarely the presenting symptom (Table 44.1). Gaze palsy may fail to appear during life in up to half of all autopsy-confirmed cases (Birdi, 2002). Yet many physicians fail to consider the diagnosis of PSP until vertical gaze restriction occurs.

Well over half of all patients with PSP present with gait disturbance, usually with falls in the first year of illness (Birdi, 2002; Golbe, 1988; Maher, 1986; Litvan, 1997a; Wenning, 1999). This may prompt a workup for vestibulopathy, myelopathy, basilar artery ischemia, cardiac syncope or epilepsy. In the minority of cases presenting with gaze palsy, dysarthria or dysphagia, the initial workup may embark on a search for myasthenia gravis, progressive bulbar palsy or local causes of esophageal dysmotility. Cataract extraction may be performed in an attempt to correct the non-refractile visual deficit of unrecognized supranuclear gaze fixation instability.

Cases departing from the typical picture are common. Some patients with PSP have prominent dementia suggestive of Alzheimer's disease (Milberg, 1989). Others have asymmetric apraxia or dystonia suggestive of corticobasal degeneration, and others resemble Parkinson's disease or MSA of the parkinsonian type until late in the illness, when clear vertical supranuclear gaze abnormalities finally appear. Even such findings as moderate asymmetry and mild rest tremor (Rivest, 1990; Gibb, 1989), claimed by earlier authors to virtually exclude PSP, occurred in two of 12 pathologically confirmed cases in a recent series (Collins, 1995). A few patients in the literature have "pure akinesia" without other features of PSP until very late in the course (Mizusawa, 1993; Riley, 1994).

Table 44.1. Actuarially adjusted median interval from initial symptom to onset of disease milestones in PSP (Golbe, 1988)

Milestone	Years
Initial gait difficulty	0.3
Cane or helper needed to walk	3.1
Dysarthria	3.4
Visual symptoms	3.9
Dysphagia	4.4
Confined to bed or wheelchair	8.2
Death	9.7

Atypical clinical features tend to cluster in patients with atypical pathological and molecular features that occur in Alzheimer's disease (Morris, 2002). This suggests that there may be two or more disease entities presently lumped as "PSP."

Rating scale and diagnostic criteria

A clinical disability rating scale, the "PSP Rating Scale," has been devised for use by neurologists (Golbe, 1997; Golbe, 1999). It is available at <http://www.psp.org>.

A set of diagnostic criteria (Golbe, 1988) has been formulated for use in settings that permit detailed examination of patients (Table 44.2). Its specificity is 96% (Litvan, 1996a). Another set (Litvan, 1996a) includes "probable" clinical criteria with the high specificity necessary to a treatment trial and "possible" criteria sufficiently sensitive for use in a prevalence study (Table 44.3).

Differential diagnosis

For a neuropathologist, the principal entities competing with PSP are only corticobasal degeneration (CBD), postencephalitic parkinsonism (PEP) and the Parkinson-dementia complex of Guam (PDC) (Hauw, 1994). The clinician must contend with not only these, but also some cases of PD, CBD, multiple system atrophy (MSA) (principally striatonigral degeneration but also olivopontocerebellar atrophy) (Robbins, 1994), progressive subcortical gliosis (Will, 1988), Creutzfeldt-Jakob disease (Bertoni, 1983), Alzheimer's disease with parkinsonism, diffuse Lewy-body disease (Fearnley, 1991), Pick's disease and the primary pallidal atrophies including dentatorubropallidolusian atrophy (Pahwa, 1993). Lacunar states, the most common non-degenerative PSP mimic, can reproduce virtually the full range of clinical features of PSP (Tanner, 1987; Winikates and Jankovic, 1994; Dubinsky & Jankovic, 1987).

Hydrocephalus can approximate a PSP-like syndrome as well (Curran & Lang, 1994).

In patients under age 50 with a PSP-like picture, especially with a positive family history, frontotemporal dementia related to chromosome 17 (Stanford, 2000) and Niemann-Pick disease type C (Josephs, 2003) are considerations. Whipple's disease that impairs vertical gaze can be mistaken for PSP (Averbuch-Heller, 1999), as can the mitochondrial encephalomyopathies, which are protean in their presentations (Truong, 1990).

Clinical points by which PSP can be differentiated from the most common of these entities appear as Table 44.4. Perhaps the most difficult differentiation of PSP is from MSA of the parkinsonian type, particularly in the absence of specific signs such as downgaze palsy or extensor axial dystonia (Colosimo, 1995).

Clinical evaluation

A thorough clinical examination and history will generally reveal PEP, PDC, myasthenia gravis (as a cause of gaze palsy, dysarthria and dysphagia), mitochondrial myopathy (as a cause of gaze palsy), and bulbar amyotrophic lateral sclerosis. MRI or X-ray computed tomography may reveal mimics such as hydrocephalus (Curran and Lang, 1994), midbrain tumors and a multi-infarct state.

Radiologic evaluation

Positron emission tomography using ^{18}F -fluorodopa distinguished 90% of patients with clinically diagnosed PSP, where the ratio of putaminal to caudate uptake constants is close to unity, from a group with PD, where the ratio is higher (Burn, 1994). Similar results are produced by use of ^{18}F -deoxyglucose (FDG) as a marker of cortical and subcortical metabolic rate (Burn, 1994; Foster, 1988; D'Antona, 1985; Nagahama, 1997) and by comparing caudate and putamen with regard to uptake of a dopamine transporter marker (Ilgin, 1999).

Although ^{18}F -fluorodopa and ^{18}F FDG PET can identify presymptomatic members of families with PSP (Piccini, 1998), the sensitivity and specificity of PET in distinguishing patients with clinically equivocal or early PSP from other conditions has not been assessed. For this reason, PET is not yet considered a standard diagnostic tool in PSP.

MRI (Table 44.5) and CT imaging are non-specific in early PSP. In the moderate to advanced stages, they may reveal thinning of the anteroposterior diameter of the midbrain tectum and tegmentum with atrophy of the colliculi and disproportionate enlargement of the sylvian fissures and posterior third ventricle (Schonfeld, 1987; Drayer, 1986; Savoiardo, 1989; Saitoh, 1987; Yuki, 1990; Stern, 1989). The

Table 44.2. Diagnostic criteria for PSP (proposed by Golbe, 1988)

<i>All four of these:</i> Onset at age 40 or later Progressive course Bradykinesia Supranuclear gaze palsy, <i>per criteria at right</i>	Criteria for Supranuclear Gaze Palsy: <i>Either: both of these:</i> Voluntary downgaze less than 15 degrees (tested by instructing patient to "look down" without presenting a specific target; accept the best result after several attempts).
<i>Plus any three of these five:</i> Dysarthria or dysphagia Neck rigidity (to flexion/extension) greater than limb rigidity Neck in a posture of extension Minimal or absent tremor Frequent falls or gait disturbance early in course	Preserved horizontal oculocephalic reflexes (except in very advanced stages) <i>or all three of these:</i> Slowed downward saccades (defined as slow enough for the examiner to perceive the movement itself) Impaired optokinetic nystagmus with the stimulus moving downward
<i>Without any of these:</i> Early or prominent cerebellar signs Unexplained polyneuropathy Prominent noniatrogenic dysautonomia other than isolated postural hypotension	Poor voluntary suppression of vertical vestibulo-ocular reflex

Table 44.3. Diagnostic criteria for PSP (proposed by Litvan, 1996)

"Possible" PSP	"Probable" PSP
All three of these: 1. Gradually progressive disorder 2. Onset at age 40 or later 3. No evidence for competing diagnostic possibilities Plus either of these: 4. Vertical gaze palsy or 5. Slowing of vertical saccades <i>and</i> prominent postural instability with falls in the first year	All five of these: 1. Gradually progressive disorder 2. Onset at age 40 or later 3. No evidence for competing diagnostic possibilities 4. Vertical gaze palsy 5. Slowing of vertical saccades <i>and</i> prominent postural instability with falls in the first year
<i>Criteria that would exclude PSP from consideration:</i>	
1. Recent encephalitis 2. Alien limb syndrome, cortical sensory defects or temporoparietal atrophy 3. Psychosis unrelated to dopaminergic treatment 4. Important cerebellar signs 5. Important unexplained dysautonomia 6. Severe, asymmetric parkinsonian signs 7. Relevant structural abnormality of basal ganglia on neuroimaging 8. Whipple's disease on CSF PCR, if indicated	

MRI features that are most likely to permit a differentiation of PSP from MSA are the absence (in PSP) of abnormal signal and/or atrophy in the cerebellum, middle cerebellar peduncle, pons and inferior olive. The hyperintense putamenal rim caused by iron deposition also occurs less commonly and later in PSP than MSA (Stern, 1989).

Also of undetermined utility in early, diagnostically equivocal cases is single photon emission computed tomography (SPECT) using markers of cerebral blood flow and/or metabolism. Such studies show bifrontal

hypometabolism in established PSP (Timmons, 1989; Habert, 1991; Neary, 1987). However, SPECT imaging of D2 receptor sites using ¹²³I-iodobenzamide (IBZM) is promising as a means of differentiating PSP, where there is often detectable striatal D2 loss, from PD, where there is not (van Royen, 1993; Schwarz, 1992).

Magnetic resonance spectroscopy (MRS) is starting to show promise as a means of differentiating PSP from PD or other states (Davie, 1997; Abe, 2000; Clarke, 2001). The diagnostic finding is a reduction in the ratio of *N*-acetyl

Table 44.4. Clinical points differentiating PSP from some other parkinsonian disorders

	PSP	PD	MSA (SND)	CBD
Symmetry of deficit	+++	+	+++	–
Axial rigidity	+++	++	++	++
Limb dystonia	+	+	+	+++
Postural instability	+++	++	++	+
Vertical supranuclear gaze restriction	+++	+	++	++
Frontal behavior	+++	+	+	++
Dysautonomia	–	+	++	–
Levodopa response early in course	+	+++	+	–
Levodopa response late in course	–	++	+	–
Asymmetric cortical atrophy on MRI	–	–	–	++

– absent or rare; + occasional, mild or late; ++ usual, moderate; +++ usual, severe or early.

aspartate to creatine in the region of the putamen and/or pallidum. However, as for PET, the ability of this modality to distinguish the conditions during their early, clinically equivocal phases is unproven. The same caveat applies to diffusion-weighted MR imaging, where the apparent diffusion coefficient of the putamen increases in PSP but not in PD (Seppi, 2003).

Neuropathology, neurochemistry and their clinical correlates

Neurofibrillary tangles

The filaments composing the NFTs of PSP are unpaired straight filaments 15 to 18 nm in diameter composed of at least six protofilaments 2 to 5 nm in diameter (Powell, 1974; Tellez-Nagel, 1973; Tomonaga, 1977; Montpetit, 1985). A few cortical areas in PSP, or even subcortical nuclei, may display paired helical filaments of the Alzheimer type (Ghatak, 1980; Ikeda, 1994). The tangles themselves, unlike those of AD, tend to be globose rather than flame-shaped.

The immunostaining and ultrastructural properties of the filaments of PSP tangles are nearly identical to those

of CBD (Ikeda, 1994; Mori, 1994). However, the white matter tangles of CBD occur in oligodendroglia rather than in astrocytes, as in most cases of PSP (Wakabayashi *et al.*, 1994; Inagaki, 1994). These are referred to as “tufted astrocytes” (Yamada, 1993). The tau-positive “tufts” and neuropil threads are similar to those in affected neurons. Such astrocytic pathology may be unique to PSP. These changes appear to be primary rather than reactive to degeneration of the astrocytes or other cells (Togo & Dickson, 2002).

Tau protein

Cortical NFTs of PSP appear to be antigenically identical to those of AD, most notably with regard to the presence of abnormally phosphorylated tau protein (Pollock, 1986; Love, 1988; Tabaton, 1988; Yamada, 1993). PSP tau exhibits bands on Western blot of 64 and 69 kD, while AD and Down’s syndrome tau exhibits those two bands plus one of 55 kD (Flament, 1991; Vermersch, 1994).

Anti-tau staining reveals neuropil threads, also known as curly fibers, in the same neurons that include NFTs and in oligodendroglia of white matter tracts connecting affected areas of subcortical gray matter (Probst, 1988; Nelson, 1989;

Iwatsubo, 1994). The NFTs of PSP stain weakly or not at all for ubiquitin (Lennox, 1988).

A mouse model of PSP has recently been described (Lewis, 2000). It expresses one of the mutant forms of tau that causes frontotemporal dementia, but the distribution of lesions is similar to that of human PSP. *Drosophila* models of a generic tauopathy have also been reported (Wittman, 2001; Lewis, 2001). In one of these, intriguingly, adult-onset, selective neurodegeneration with accumulation of abnormal tau occurred without NFTs (Wittman *et al.*, 2001). This and other experimental evidence from many sources suggests that the toxic species is not mature NFTs, but tau in an early stage of aggregation.

Other changes

Grumose degeneration, in which eosinophilic material surrounds degenerating neurons, accompanied by spherical argentophilic components, occurs in a significant minority of cases with PSP, particularly in the cerebellar dentate nucleus (Olszewski, 1963; Arai, 1987). It appears to be composed of abnormally regenerated synaptic terminal material of Purkinje cells.

While amyloid or senile plaques do not occur in PSP, granulovacuolar degeneration, another hallmark of AD, does occur to a mild extent. In addition, swollen, achromatic neurons characteristic of CBD or Pick's disease occur in a few cases of otherwise typical PSP, generally in tegmental and inferior temporal areas (Giaccone, 1988).

Microglial activation, another pathologic change that occurs in some neurodegenerative disorders, has recently been found to be common in PSP (Ishizawa & Dickson, 2001). In the brainstem in PSP, microglial activation does not correlate well with the presence of NFTs. This suggests that neither is the direct cause of the other and that microglia may help produce the neuronal loss of PSP.

Anatomic distribution of degeneration and clinical correlates

Overview

The major areas of primary involvement in PSP are the cerebral cortex, producing cognitive and behavioral changes; the nigrostriatalpallidal area, producing rigidity, bradykinesia and postural instability; the cholinergic pontomesencephalic nuclei area, producing gaze palsies, sleep disturbances and axial motor abnormalities; and the hindbrain area, producing dysarthria and dysphagia (Hauw, 1994).

The daunting complexity of this syndrome may be the principal reason for the continuing resistance of PSP to pathophysiologic understanding and pharmacologic intervention (Table 44.6).

Dopaminergic damage in the nigrostriatal pathway and cholinergic damage in many areas are the most consistent, severe neurotransmitter-related changes in PSP (Jellinger, 1988; Kish, 1985; Ruberg, 1985). GABA-ergic function of the basal ganglia (in striatum and GPi and GPe) is moderately but widely impaired (Levy, 1995). Unlike the case in PD, the peptidergic systems and the mesolimbic and mesocortical dopaminergic systems are intact. Serotonergic receptor sites are reduced in the cortex, but unlike in PD, are normal in basal ganglia (Landwehrmeyer and Palacios, 1994). The loss of adrenoceptors is widespread (Pascual, 1993) reflecting the wide projections of the severely damaged locus ceruleus.

Cerebral cortex

Pathoanatomy

Cortical involvement in PSP differs importantly from that in AD at the gyral, laminar, cytologic, ultrastructural and biochemical levels. Central and cortical atrophy of cerebrum is only mild in PSP (Cordato, 2000). Motor strip (Area 4) and a partly ocular motor association area (Area 39) are the most important of many sites of neocortical pathology (Hauw *et al.*, 1990; Hof, 1992; Braak, 1992). PSP affects the large pyramidal and small neurons of layers V and VI, while AD affects the medium-sized neurons of layers III and V (Bergeron, 1997).

Anatomic and neurochemical changes

The prefrontal areas, which are the most obviously affected by behavioral testing and by measures of cerebral blood flow (Timmons, 1989; Habert, 1991; Neary, 1987; D'Antona, 1985; Noster, 1988; Leenders, 1988; Goffinet, 1989) display relatively little neurofibrillary pathology or neuronal loss in PSP (Verny, 1994; Hauw *et al.*, 1990). This dysfunction may therefore be secondary to subcortical pathology, as in the cholinergic nucleus basalis of Meynert and the cholinergic pedunculopontine nucleus (Tagliavini, 1984; Zweig, 1987; Jellinger, 1988).

Clinical correlates

Behavioral changes were the initial symptom of PSP in 22% of patients in one series (Birdi, 2002) and eventually produce disability in at least 80% (Golbe, 1988; Jankovic & Van der Linden, 1990). Clinical frontal lobe dysfunction in PSP is often the most disabling area of cognitive loss and

Table 44.6. Principal clinicopathological correlates in PSP

can progress rapidly (Soliveri, 2000). Apathy, intellectual slowing and impairment of “executive” functions with little abnormal motor behaviors are the consistent findings (Litvan, 1996b). The executive dysfunction (Pillon, 1995) comprises difficulty with shifting mental set, sorting, problem solving, abstract thinking, motor inhibition and lexical

fluency (Podoll, 1991; Rosser & Hodges, 1994). A brief but formal “Frontal Assessment Battery” is useful for bedside quantification of these deficits (Dubois, 2000).

Apraxia that is milder and less asymmetric than that of CBD is common in PSP (Bergeron, 1997) and can produce diagnostic confusion.

Hippocampus

The hippocampus, a primary site of pathology in AD, is involved in only half of cases of PSP (Agid, 1987). This probably explains the relative preservation of memory in PSP except for memory tasks requiring goal-directed searching, a frontal lobe function (Pillon & Dubois, 1992; Pillon, 1994).

Nigrostriatal system

Distribution of pathology

The most consistent abnormality in PSP is damage to the pigmented neurons of the zona compacta of the substantia nigra (Fearnley & Lees, 1991). However, in PSP, the damage is relatively uniform except for relative sparing of a small, extreme lateral portion, while in PD, both the dorsal and extreme lateral portions are affected little. The dorsal portion projects principally to the caudate, the ventral to the putamen. This probably explains the relative sparing of presynaptic caudate dopamine reuptake in PD and its involvement in PSP, as measured by ¹⁸F-fluorodopa PET (Brooks, 1990; Curran & Lang, 1994). Tissue binding studies have demonstrated little or no loss of postsynaptic dopamine D1 receptors and only mild and inconsistent loss of D2 receptors (Landwehrmeyer & Palacios, 1994; Baron, 1986; Brooks, 1992).

In the striatum, the few neurons lost are mostly cholinergic interneurons (Young, 1985; Villares, 1994; Oyanaki, 1991). However, there is important loss of astrocytes (Ruberg, 1985, Probst 1993). which display the "tufted" appearance described above.

Clinical course

Postural instability is the initial symptom in approximately two-thirds of patients with PSP (Golbe, 1988; Maher & Lees, 1986). Frank falls start a median of 1.8 years into the illness (Bergeron, 1997) and are often unrelated to obstacles or antecedent sensations of imbalance. The initial or only gait abnormality may be severe gait "freezing" or "apraxia" (Matsuo, 1991; Imai, 1993), with no rigidity. In PD, by contrast, gait difficulty or postural instability is a presenting feature in only 11% (Hoehn & Yahr, 1967).

The postural instability is usually the most disabling feature of later PSP. The median intervals from initial symptom are 3.1 years until assistance is required and 8.2 years until wheelchair confinement (Golbe, 1988).

Contrary to widespread impression, rest tremor can occur in PSP, affecting 5–10% of patients, usually early in the course (Masucci, 1989; Jankovic & Van der Linden,

1990). Action or postural tremor occurs in about 25%. The limb rigidity and distal bradykinesia are mild relative to axial rigidity.

Other basal ganglia

Damage to the subthalamic nucleus ranks beside that of the substantia nigra as a constant in PSP and is far more specific to it (Olszewski, 1963). Damage to the GPi in PSP is slightly less constant, but it is sufficient to predict that stereotactic GPi lesions or its inhibition by deep-brain stimulation would be ineffective against PSP despite their efficacy against PD.

The GPi, which is GABA-ergic, projects not only to the thalamus, which is nearly intact in PSP, but also to the cholinergic pedunculopontine nucleus (PPN), which is severely affected (Zweig, 1987; Jellinger, 1988; Morizumi & Hattori, 1992). Experimental lesions of the PPN alone can cause severe postural instability (Masdeu, 1994).

There is also severe depletion of GPe neurons in PSP (Hardman & Halliday, 1999). While most of the thalamus is spared in PSP, there is pathology in the glutamatergic caudal intralaminar nuclei, which regulate caudate and putamen (Henderson, 2000).

Mesencephalic and pontine ocular motor areas

Pathoanatomy

Experimental lesions of the interstitial nucleus of Cajal in monkeys produce extensor rigidity at the neck, postural instability and vertical gaze palsy (Carpenter, 1970). However, in PSP, the last finding could also be caused by the damage to other areas of the rostral midbrain, namely the nucleus of Darkschewitsch, the rostral interstitial nucleus of the medial longitudinal fasciculus, and the mesencephalic reticular formation (Fukushima, 1987; Zweig, 1987; Juncos, 1991; Jellinger & Bancher, 1992). There also appears to be a contribution from the substantia nigra pars reticulata (Halliday, 2000) which projects to the superior colliculus. The ventral tegmental area, red nucleus and locus ceruleus are also involved in PSP (Olszewski *et al.*, 1963) but their specific contributions to the clinical deficits are unclear.

The horizontal gaze palsy that appears eventually in most cases is attributable to degeneration of nuclei of the pontine base (Malessa, 1994). The ocular motor cranial nerve nuclei are perhaps the sole example of cholinergic nuclei to escape important involvement in PSP.

Table 44.7. Clinical ocular motor findings in PSP

Usually precede frank gaze restriction

- Hypometric saccades, particularly downward
- Disordered optokinetic nystagmus, particularly downward
- Slowing of downward saccades (especially when starting at upgaze)
- Square-wave jerks
- Inability to voluntarily suppress the vestibulo-ocular reflex
- Hesitancy (“apraxia”) on command downgaze

Occur in middle stages of illness

- Restriction of range of voluntary downgaze
- Impaired convergence
- Disordered Bell’s phenomenon
- Visual grasping
- Lid retraction with reduced blink rate
- Apraxia of lid opening or closing

Tend to begin in later stages of illness

- Restriction of range of voluntary horizontal gaze
- Loss of oculocephalic reflex
- Disconjugate gaze
- Disabling blepharospasm

Clinical phenomenology

(Table 44.7) Symptomatic eye movement difficulty does not begin until a median of 3.9 years after disease onset, nearly half the clinical course (Golbe, 1988). The loss of range of downgaze, although more specific for PSP, is often exceeded by the loss of upgaze. Voluntary gaze without a specific target (i.e. “look down”) is usually worse than command gaze to a target, which is worse than pursuit, and reflex gaze is by far the least affected.

Signs that can be observed with no specialized apparatus in the examining room and long precede the onset of frank visual symptoms in most patients include delay in saccade initiation, slowing of vertical saccades (Leigh, 2000), saccadic pursuit, breakdown of optokinetic nystagmus in the vertical plane, disordered Bell’s phenomenon, poor convergence and subtle square-wave jerks (SWJs) (Pfaffenbach, 1972; Chu, 1979; Troost & Daroff, 1977). The last finding has close to 100% sensitivity (Troost & Daroff, 1977; Rascol, 1991). In some patients, SWJs are seen only during fixation on a distant light source in the dark. SWJs occur in very few patients with PD, but are sufficiently common in MSA and other cerebellar conditions that they cannot differentiate them from PSP (Rascol, 1977).

The frontal defect impairs the antisaccade task, where the patient is instructed to quickly direct gaze to the examiner’s hand that does *not* wave. An altitudinal visual attentional deficit (Rafal, 1988) arising from damaged tectal centers

may contribute to overloading the fork, poor aim of the urinary stream, poor attention to dress and apathy for the severity of postural instability.

Reflex gaze

From the earliest stages, most patients also suffer loss of the ability to voluntarily suppress the vestibulo-ocular reflex (VOR) (Rascol, 1993). This may be tested by seating the patient in a swivel chair and asking him to extend the arms at the level of the eyes, clasp hands and fixate on one thumb-nail as the examiner slowly rotates the chair and patient *en bloc*. Patients with PSP (and many other basal ganglia disorders) are unable to suppress the optokinetic nystagmus produced by relative movement of the environment.

Eyelid movement

Eyelid movement abnormalities, particularly apraxia of eyelid opening (perhaps better termed “lid levator inhibition” (Lepore & Duvoisin, 1985)) and blepharospasm or a combination of these occurs in about one third of patients and can cause functional blindness (Dehaene, 1984; Jankovic, 1984a; Golbe, 1989). Apraxia of lid closing and the very slow blink rate of PSP, often less than 5/minute, can allow conjunctival drying with annoying exposure keratopathy and reflex lacrimation. The electrical blink reflex is severely impaired, unlike in PD, CBD or MSA (Valls-Solé, 1997), testimony to the profound brainstem pathology in PSP.

Brainstem centers controlling sleep and arousal

The prominent sleep disturbances of PSP are probably explained by damage to the (serotonergic) raphe nuclei, the (cholinergic) pedunculopontine nucleus and others, the (noradrenergic) locus ceruleus and the periaqueductal gray. The most important clinical component is a severe reduction in rapid eye movement (REM) sleep (Aldrich, 1989) with loss of sleep spindles and K-complexes. During the remaining REM-sleep, there are abnormal slow waves and absence of normal sawtooth waves (Leygonie, 1976).

Daytime hypersomnolence, often a disabling problem in PSP, is probably related to damage of dopaminergic systems that maintain wakefulness. There is a fragmentation of sleep/wake periods that culminates at the end stage of PSP in a constant sleep-like state from which the patient can be roused but briefly.

The auditory startle and auditory blink reflexes are absent or severely impaired in PSP despite normal auditory evoked potentials (Tolosa & Zeese, 1979). Startle is mediated via the lower pontine reticular formation, in particular

Table 44.8. Components of dysarthria in PSP and some related conditions

	Hypokinesia	Ataxia	Spasticity
PSP	++	+	+++
PD	+++	–	–
MSA (striatonigral degeneration)	+++	++	+
MSA (olivoponto-cerebellar atrophy)	+	+++	++

the nucleus reticularis pontis caudalis, which degenerates in PSP.

Brainstem centers controlling speech and swallowing

Dysarthria

The dysarthria of PSP is spastic, with a slow rate and a strained, strangled quality. Ataxic components are usually present, creating a combination highly specific for PSP (Kluin, 1993) (Table 44.8). Within 2 years after disease onset, 41% of patients or their families have detected dysarthria. By the fifth year, the figure is 68% (Golbe, 1988).

Dysphagia

Aspiration pneumonia is a major morbidity and mortality risk in advanced PSP (Muller, 2001) but only 18% of patients report symptomatic dysphagia within 2 years after PSP onset and 46% do so by 5 years (Golbe, 1988). In a study using objective criteria, dysphagia occurred in 26 of 27 patients with mean disease duration of 52 months (Litvan, 1997b). While the dysphagia of PSP arises from many levels of the oropharyngeal axis (Leopold, 1997; Sonies, 1992) it emphasizes oral rather than pharyngeal abnormalities, distinguishing it from the dysphagia of PD (Johnston, 1997).

It is common for patients with PSP, but not with PD, to exacerbate the effects of dysphagia by overloading the fork, probably through a combination of poor downgaze, frontal disinhibition, and vertical visual inattention (Rafal & Grimm, 1981). The retrocollis that occurs eventually in some patients with PSP may decrease the ability of the epiglottis to protect the airway.

Spinal and autonomic centers

The spinal cord involvement in PSP principally affects the motor area (lamina IX) and the intermedio-lateral column with minor gray matter tract degeneration (Jellinger

& Bancher, 1992; Sakakibara, 1993; Vitaliani, 2002). There is also severe degeneration of the nucleus of Onuf in the sacral cord (Scaravilli, 2000) and brainstem autonomic nuclei (Rub, 2002). Urinary incontinence occurred in 42% of patients at some point in PSP in one series and started a mean of 3.5 years into the disease course (Gert van Dijk, 1991). Overall, however, PSP produces less dysautonomia than PD (Gert van Dijk, 1991; Skimber, 2000), a point useful in its clinical differentiation from MSA. Anal sphincter EMG reveals denervation caused by loss of Onuf's nucleus in both PSP and MSA, but its sensitivity is low (Vodusek, 2001).

Epidemiology and etiology

Descriptive epidemiology

Onset age

PSP typically begins in the late 50s to mid-60s, one in three cases starting before age 60 (Golbe, 1988). The standard deviation of the onset age is typically between 6 and 7 years, (Golbe, 1988), far less than the 11 years typical for PD. This suggests that the range of etiologies for PSP is narrower than for PD. Age-specific incidence figures are not available.

Survival

Death occurred at an actuarially corrected median of 9.7, 7.0 and 5.9 years in three studies (Maher & Lees, 1986; Golbe, 1988; Testa, 2001). Ten-year survival is approximately 30% (Testa, 2001). Death is usually related to pneumonia and other inevitable complications of immobility, but frank aspiration, head trauma due to falls, and complications of hip fracture are important preventable causes of death in PSP.

Prevalence

The prevalence ratio of previously diagnosed PSP is 1.0–1.4 per 100 000 (Golbe, 1988; Nath, 2001). The overall prevalence, comprised mostly of patients who had not received the diagnosis until researchers with a special interest in PSP examined them, was 6.4 (Schrag, 1999) and 5.0 (Nath, 2001) per 100 000.

Incidence

In Rochester, Minnesota, a study covering the years 1976 to 1990 gave an annual incidence in the population over age 49 of 5.3 per 100 000 per year. (Bower, 1997). Previous figures using indirect methods reached a similar result (Golbe, 1996a). This figure lies very close to that of some

Table 44.9. Approximate incidence rates of PSP and some other neurologic disorders (new cases per 100 000 population per year)

	Incidence Rate
Parkinson's disease	20
ALS	10–20
Guillain–Barré syndrome	10
All muscular dystrophies	7
Polymyositis	5
Tourette syndrome	5
Huntington's disease	5
PSP	3–4
Myasthenia gravis	3–4
Syringomyelia	3
Charcot–Marie–Tooth	2
Wilson's disease	2

better-recognized neurologic conditions such as myasthenia gravis and Huntington's disease (Kurtzke & Kurland, 1973) (Table 44.9).

Sex ratio

Most published series reveal a sex ratio (M:F) of approximately 3:2. The absence of so asymmetric a ratio in other highly referred neurodegenerative disorders is a point against gender-related referral bias as the explanation in PSP and points to an occupational toxin or X-linked mutation as an etiologic factor.

Analytic epidemiology

Two case-control studies from the same New Jersey clinic using clinic and spouse controls, respectively, gave opposite positive results regarding educational attainment of patients (Davis, 1988; Golbe, 1996b). This etiologic clue therefore awaits clarification. Other risk factors implicated in at least one other neurodegenerative disease, including occupation, smoking and head trauma, gave negative results. Attempts to transmit PSP to primates (Brown, 1994) and a search for a prion protein have proven unsuccessful (Jendroska, 1994).

Geographic clusters

Two geographic clusters of PSP-like tauopathies are known. Lytigo-bodig, or the amyotrophic lateral sclerosis–parkinsonism–dementia complex of Guam (PDC), has resisted multiple careful etiologic investigations, but its markedly declining incidence since the westernization of Guam after World War II suggests an environmental cause

(Steele, 2002). The distribution of tau isoforms is similar to that of AD and not PSP (Steele, 2002).

An unusual concentration of a PSP-like tauopathy on the Caribbean island of Guadeloupe is identical to PSP at the level of tau isoforms (Caparros-Lefebvre, 2002). A case-control survey found illness to be associated with consumption of two indigenous plants, soursop and sweetsop (*Annona muricata* and *A. squamosa*), which harbor a number of neurotoxins (Caparros-Lefebvre, 1999). The use of extracts of these plants to produce an animal model and to understand tauopathies in general is starting to be explored (Steele, 2002).

Clinical genetics

A case-control study (Davis, 1988) elicited reports of “Parkinson's disease” among parents, siblings, grandparents, aunts, uncles and first cousins 5.0 times as frequently from patients with PSP as controls. For “Alzheimer's or dementia,” the ratio was 3.6. Another study found that 39% of 23 asymptomatic first-degree relatives of patients with PSP, but none of 23 controls, had abnormal scores on a battery that screens for parkinsonism (Baker & Montgomery, 2001).

Eight reports of families with more than one member with proven PSP usually with autosomal dominant transmission and no purely maternal transmission, offer hope of a clue to the cause of sporadic PSP (Ohara, 1992; Brown, 1993; Gazely & Maguire, 1994; de Yébenes, 1995; Golbe & Dickson, 1995; Tetrud, 1996; Uitti, 1999). It is intriguing that some of these families, including a Spanish family that is by far the largest, include additional members with reports of typical PD or essential tremor (Rojo, 1999; Piccini, 2001). Genetic screening of these families is negative to date.

Nuclear molecular genetics

Tau isoforms

In PSP, the ratio of the two human brain tau isoforms is at least 3:1 in favor of 4-repeat tau (Flament, 1991). Disordered regulation of exon 10 splicing may therefore explain tau aggregation into NFTs in PSP and other tauopathies.

A clue from FTD

Several mutations in and near the 5' splice site downstream of exon 10 have been described in families with hereditary frontotemporal dementia with parkinsonism related to chromosome 17 (FTDP-17), another 4-repeat tauopathy that occasionally resembles PSP clinically (Hutton, 1998; Spillantini, 1998; Stanford 2000). These probably disrupt a stem–loop structure in the RNA transcribed at the

Table 44.10. Frequency of tau haplotypes and genotypes in PSP (Baker, 1999)

		PSP	Controls
N		64	145
Haplotypes	H1	94%	78%
		6%	22%
p			0.00013
Genotypes	H1/H1	88%	63%
	H1/H2	12%	31%
	H2/H2	0	6%
p			0.00098

downstream end of exon 10. This stem-loop regulates splicing of the exon 10 transcript, the inappropriate inclusion of which produces an excess of 4-repeat tau. The cause then, of PSP and other sporadic tauopathies may be dysfunction of the same RNA stem-loop, but from a different cause.

A *tau* allelic variant

A haplotype, "H1," spanning the *tau* gene on chromosome 17q21 is present in approximately 90% of patients with PSP but also in approximately 60% of controls (Conrad, 1997; Baker, 1999; Higgins, 1999; Molinuevo, 2000) (Table 44.10). This suggests that a genetic variation necessary but not sufficient to cause PSP is located in or near *tau*. The precise mutation is not known, but mutations in the *tau* promoter region in linkage disequilibrium with H1 have been described (Ezquerro, 1999; de Silva, 2001).

The occurrence of PSP in sporadic rather than familial fashion must then require an additional exogenous or genetic factor. This caveat is underscored by the observation that corticobasal degeneration shares the haplotype that characterizes PSP (Di Maria, 2000; Houlden, 2001; Pastor *et al.*, 2001), as does PD to a lesser degree (Golbe, 2002). Furthermore, the presence or absence of the H1 haplotype or the H1/H1 genotype has no effect on the age of onset, clinical progression (Morris, 2001; Litvan, 2001a), the anatomical distribution of degeneration or on the biochemical features of the abnormal tau protein (Liu, 2001).

Variants in apo-E that are associated with AD and variants in α -synuclein and synphilin that are associated with PD are absent in PSP (Anouti, 1995; Tabaton, 1995; Morris, 2000).

Mitochondrial or oxidative mechanisms

Skeletal muscle mitochondrial respiratory function is reduced by about 30% in PSP. Evidence for oxidative stress in brain tissue are marked increases in levels of superoxide dismutase 1 and/or 2 activity, malondialdehyde and lipid

peroxidation products specifically in areas that degenerate in PSP (Albers, 1999; Cantuti-Castelvetri, 2000; Swerdlow, 2000).

Evidence that deficiency of Complex I of mitochondrial genetic origin contributes to the cause of typical PSP is provided by the observation of low Complex I activity and mitochondrial dysfunction in cultured neuronal cells in which native mitochondria were replaced by mitochondria from patients with PSP (Swerdlow, 2000; Chirichigno, 2002).

An area of recent inquiry is the role of transglutaminases in PSP (Kim, 2002). Enzymes normally important in stabilizing protein structure, they are aberrantly activated in PSP and other neurodegenerative disorders by oxidative stress. The resulting cross-linking of tau protein could help explain the formation of NFTs or the dysfunction of other proteins and offers a promising site of action for neuroprotective therapy.

Treatment

Pharmacotherapy

As is the case for most other degenerative disorders, neurotransmitter replacement or receptor stimulation in PSP encounters little or none of the success it has with PD (Nieforth & Golbe, 1993; Kompoliti, 1998).

Dopaminergics

In two retrospective, uncontrolled studies, 51% (Jankovic, 1984b) and 38% (Nieforth & Golbe, 1993) of patients responded, most of them minimally. (The placebo response rate in PD drug trials is generally about 30%.) Only the rigidity and bradykinesia, including those components of dysarthria and dysphagia attributable to them, may respond more than would be expected from placebo. The extent and nature of the benefit of levodopa in PSP has not been adequately studied in double-blind fashion, but any benefit is nearly always mild and/or brief. Dopamine receptor agonists give similar benefit or lesser with additional risks (Nieforth & Golbe, 1993; Jankovic, 1983; Weiner, 1999).

Hyperkinetic and behavioral side effects of levodopa are very rare in PSP (Nieforth & Golbe, 1993). This prompts the use of approximately twice the levodopa/carbidopa dosages used for PD with the equivalent degree of parkinsonism.

Cholinergics and anticholinergics

Amantadine, which has anticholinergic, dopaminergic and antiglutamatergic properties, is a close second to levodopa in risk/benefit ratio for PSP (Nieforth & Golbe, 1993). A trial

of amantadine starting at 100 mg daily and increasing to a maximum of 100 mg twice daily is worthwhile for most patients with PSP. It should be tapered and discontinued if symptomatic benefit is not apparent within a month. The typical "pure" anticholinergic agents give little benefit and tend to be poorly tolerated.

Trials of cholinergics have been inspired by the severe and widespread degeneration of acetylcholinergic systems in PSP. The cholinesterase inhibitor physostigmine was reported to improve PET evidence of prefrontal dysfunction, long-term verbal memory, and visuospatial attention, all very slightly (Kertzman, 1990; Litvan, 1989) but a subsequent trial by one of these groups gave negative results, with worsening of gait (Litvan, 1994). Donepezil, a commercially available cholinesterase inhibitor minimally effective in AD, has no benefit against PSP (Litvan, 2001b).

Antidepressants

Amitriptyline improved gait and rigidity in three of four patients in a small double-blind trial (Newman, 1985). In a retrospective series (Nieforth & Golbe, 1993) amitriptyline gave a risk/benefit ratio that was slightly less favorable than those of levodopa and amantadine. Amitriptyline is generally started at 10 mg at bedtime, increasing by that amount each week, given in two divided doses. If 20 mg twice daily proves ineffective, higher dosages are unlikely to do otherwise.

Botulinum toxin

Blepharospasm in PSP usually responds to botulinum A (Piccione, 1997). Torticollis or retrocollis in PSP may also respond, but the occasional occurrence of mild dysphagia after botulinum injection for idiopathic spasmodic torticollis dictates caution in the case of PSP, where slight exacerbation of dysphagia could allow aspiration. Botulinum toxin may also be useful in focal limb dystonia of PSP (Polo & Jabbari, 1994).

Nonpharmacologic therapy

Locomotory aids

The tendency of many patients with PSP to be almost anosognosic for their postural instability requires that the physician and other caregivers encourage the use of a walker early in the course. A heavy rolling model with a low basket into which bricks can be placed as a counterweight against falls often serves well. If falls occur despite the walker, the patient must be strongly encouraged to use a wheelchair and to resist the frequent temptation to arise

from it without help, a tendency that may be related to the frontal motor dysinhibition of PSP.

Gaze and lid pareses

Some patients can overcome the voluntary downgaze palsy that impairs eating by using their remaining pursuit downgaze ability to follow the fork down to the plate. If downgaze palsy or inattention to the lower half of space is present, low-lying obstacles should be removed from the patient's environment. While prisms are not usually useful in correcting the patient's inability to attend to the lower half of space, they may help diplopia related to dysconjugate gaze. The chronic conjunctivitis and reactive lacrimation caused by the low blink rate may be treated by instillation of lubricants.

Physical, speech and swallowing therapy

Physical therapy seems to be of little or no benefit against the postural instability of PSP, but regular exercise has a clear psychological benefit (Sosner, 1993). Similarly, speech therapy is of little benefit, but the speech pathologist may be able to arrange adjunctive means of communication such as electronic typing devices or simple pointing boards if the visual function permits.

Dysphagia in PSP is also unlikely to respond to therapy. However, the family may be instructed in the preparation of foods of proper consistency, using a blender or cornstarch-based thickeners as necessary. A barium swallow radiograph using boluses of varying consistency will guide this advice. The speech pathologist can teach the patient safer swallowing techniques and can monitor the patient for the need for a feeding gastrostomy. Reducing the risk of aspiration may be the most effective means of prolonging the life of a patient with PSP.

Surgical implants

Fetal or porcine nigral cell striatal allografts have not been attempted in PSP, but the advanced state of degeneration of centers downstream from the striatum, contrasting with the situation in PD, suggests that such procedure is unlikely to be of benefit. This prediction is supported by the unfavorable results of a trial of adrenal medullary tissue autografts to striatum (Koller, 1989). A similar rationale predicts that deep brain stimulation would not help PSP.

Patient resources

The Society for Progressive Supranuclear Palsy (www.psp.org) is headquartered in Baltimore and serves North America. The Progressive Supranuclear Palsy

Association (www.pspeur.org) is based in the UK and serves all of Europe. They offer support meetings, lay-language literature and research funding to scientists in all countries. Smaller organizations have recently been founded in other countries.

Corticobasal degeneration

Kailash P. Bhatia and Anthony E. Lang

Sobell Department of Movement Neuroscience, Institute of Neurology, Queen Square, London, UK

Historical review

Dutil (1899) from the Salpêtrière may have been describing a case of corticobasal degeneration (CBD) when reporting a patient said to have the so-called “hemiplegic” form of “parkinsonism in extension,” the latter being the description used by Charcot and his pupils to describe cases of parkinsonism who were atypical because of an extended posture rather than the characteristic flexed posture of paralysis agitans which they recognized. The picture of this patient shows a French woman with a hypomimic face and a rather erect posture with the right arm rigidly flexed at the elbow and perhaps is the first picture of a CBD patient (Goetz, 2000). However, the first clear description was given by Rebeiz, Kolodny, and Richardson (1968), who described three cases with a distinct clinical syndrome characterized by an asymmetric onset of slow, clumsy limb movement, accompanied by rigidity, tremor and dystonia, progressing to impairment of gait, dysarthria and dysphagia, disordered eye movement, and increasing disability. Intellectual function was said to be relatively intact. The illness led to death in 6 to 8 years. The pathological findings were distinctive. There was asymmetric frontal and parietal cortical atrophy, with extensive neuronal loss and gliosis. Some of the cortical pyramidal neurons, mainly in the third and fifth layers, had an unusual swollen hyaline appearance; the cytoplasm did not take up usual stains, except for faint eosinophilia, so such neurons were termed achromatic. No classical Pick bodies, neurofibrillary tangles, senile plaques, or Lewy bodies were found. Such changes were not evident in the hippocampal formation, occipital cortex, inferior or medial temporal cortex. Other findings included loss of pigmented neurons in the substantia nigra, changes in the subthalamic nucleus and in the dentate nucleus, and degeneration of the corticospinal pathways. Rebeiz *et al.* (1968) termed this entity as “corticodentatonigral degeneration with

neuronal achromasia.” Other terms used by different authors to describe the same pathological changes of frontal and parietal lobe atrophy associated with atrophy of the basal ganglia and other subcortical nuclei include corticonigral degeneration with neuronal achromasia (Case Records of the Massachusetts General Hospital, 1985), cortical degeneration with swollen chromatolytic neurons (Clark *et al.*, 1986), corticobasal (CBD) (Gibb *et al.*, 1989; Rinne *et al.*, 1994), cortico-basal ganglionic (Watts *et al.*, 1985) and cortical basal ganglionic (Riley *et al.*, 1990) degeneration (CBGD). Numerous clinical case series based on the characteristic clinical picture have been reported in the literature, few with pathological verification (Rebeiz *et al.*, 1968; Case Records of the Massachusetts General Hospital, 1985; Clark *et al.*, 1986; Gibb *et al.*, 1989; Watts *et al.*, 1985, 1989; Greene *et al.*, 1990; Lippa *et al.*, 1990; Paulus & Selim, 1990; Riley *et al.*, 1990; Rinne *et al.*, 1994; Wenning *et al.*, 1998; Kompolti *et al.*, 1998). Clinical features in the majority of cases reported initially with this pathology were dominated by an asymmetric extrapyramidal and frontal motor disorder with elements of apraxia, rigidity, involuntary movements, dystonia, the alien limb sign, dysarthria, and a supranuclear disorder of eye movement. Some authors have also described this clinical syndrome as progressive apraxic rigidity (Watts *et al.*, 1985; Le Witt *et al.*, 1989).

Most of the earlier reports thus focused on the abnormalities in motor function as that was thought to be the predominant presentation. Initial patient series suggested that this was a distinct clinical-pathological disorder that could be readily differentiated from other “Parkinson-plus” syndromes with which it was classified. However, of late a wider clinical spectrum of this disorder is being recognized, including dementia as the initial or predominant feature (Grimes *et al.*, 1999), as well as progressive aphasia or a behavioral disorder. It has become apparent that the exact

clinical manifestations depend on the topographical distribution of the pathology. Also being recognized is the fact that a variety of different pathological entities may give rise to the same clinical syndrome (Boeve *et al.*, 1999; Bhatia *et al.*, 2000).

In this regard historically the main difficulty related to the pathological overlap with Pick's disease is the severe cortical cell loss with associated gliosis of the subcortical white matter and the large swollen achromatic cells were similar to the findings in Pick's disease. Those who supported the notion that CBD was a separate disorder from Pick's used the basis that argyrophilic inclusions (Pick bodies), typical of Pick's disease, were thought to be uncommon or not found in CBD and that the distribution of atrophy was frontoparietal in CBD in contrast to the frontotemporal lobar atrophy of Pick's disease. Since then, the classification of neurodegenerations on the basis of the dominant accumulated protein and, in the case of disorders characterized by the aggregation of the microtubule-associated protein tau, the specific protein isoforms, has revolutionized our understanding of CBD and its relationship to other neurodegenerations. With advances in molecular pathology (see below) CBD is now known to be a fairly distinct lobar and basal ganglia tauopathy with selective aggregation of four repeat tau protein with characteristic antigenic and ultrastructural characteristics.

Morphological pattern of involvement

Anatomical pathology

The macroscopic pathological findings consist of severe focal cortical atrophy centred on the peri-Rolandic posterior frontal and parietal cortex with lesser involvement of adjacent cortex, and relative sparing of the temporal and occipital regions (Fig. 45.1). Accordingly, the motor and sensory areas of the cerebral cortex are most severely affected, and there is secondary degeneration of the corticospinal tracts. The cortical atrophy tends to be asymmetric, being most marked opposite to the most affected limb. However, in the dementing or aphasic presentation more symmetric and more severe involvement of the frontal and temporal lobes may be present. In the affected cortical regions, the normal cortical architecture is destroyed, the definition of the layers of the cerebral cortex is lost, and there is intense fibrillary gliosis. The white matter beneath the affected cortical areas is atrophic and gliotic. Neuronal degeneration with nerve cell loss and gliosis are present, particularly in the third and fifth pyramidal cell layers of the cortex. Atrophy and cell loss, accompanied by gliosis, is also marked in the lateral two-thirds of the substantia

Fig. 45.1 Frontal atrophy in a case with corticobasal degeneration (courtesy Dr T. Revesz, Institute of Neurology, Queen Square, London).

nigra with loss of pigmented cells (Rebeiz *et al.*, 1968; Gibb *et al.*, 1989). The degeneration also affects the medial third of the subthalamic nucleus, the neostriatum, globus pallidus, the posterolateral thalamus, the red nucleus and other brainstem nuclei. In two of the original cases reported by Rebeiz *et al.* (1968) there was marked atrophy of the dentatorubrothalamic tract; the dentate nucleus was abnormal in these cases but the cerebellar cortex was normal. In subsequent reports, involvement of the cerebellum has been infrequent and the “dentate” component of the original description has been omitted (Case Records of the Massachusetts General Hospital, 1985). Corticospinal tract degeneration has been present in some cases (Rebeiz *et al.*, 1968; Gibb *et al.*, 1989).

Recently it has been shown that the cerebellar Purkinje cells are involved with granular accumulation of tau in about half the cases of CBD studied by Piao *et al.* (2002) using monoclonal antibodies. The spinal cord has not been reported on frequently but in the era prior to the recent advances in molecular pathology was said to have been normal.

A characteristic feature of the degeneration is the presence of large pale neurons to which the term neuronal achromasia was derived (Rebeiz *et al.*, 1968). The affected cortical neurons are medium to large pyramidal cells. They are found most frequently in those cortical regions moderately, rather than severely, affected. They are also found in subcortical and brainstem nuclei including the substantia nigra. These cells, which are indistinguishable from Pick cells, have variously been referred to as ballooned, swollen, chromatolytic-like, or achromatic cells (Gibb *et al.*, 1989) (Fig. 45.2). They are most prominent

Fig. 45.2 Tau-positive intraneuronal inclusions (A), neuropil threads (B) and astrocytic plaque in the posterior frontal cortex in a case with corticobasal degeneration. Ballooned neurons are mainly present in the deeper cortical laminae (D). A, B and C: tau immunohistochemistry (antibody AT8), D: α B-crystallin immunohistochemistry. Bar on A represents 200 μ m on A and 80 μ m on B, C and D. (courtesy Dr T. Revesz, Institute of Neurology, Queen Square, London).

in the third, fifth, and sixth laminae of the cerebral cortex. The swollen achromatic nerve cells are filled with homogenous material which shows faint and variable eosinophilia (Rebeiz *et al.*, 1968) and argyrophilia (Clark *et al.*, 1986). The nucleus is eccentrically located and Nissl substance is not detected within the neurons, distinguishing the degeneration from that seen in central chromatolysis (Rebeiz *et al.*, 1968; Case Records of the Massachusetts General Hospital, 1985). The cytoplasm of such ballooned achromatic neurons stains positively for phosphorylated neurofilaments and beta crystalline, and variably with antibodies to ubiquitin and tau (Gibb *et al.*, 1989; Smith *et al.*, 1992; Dickson, 2000). The presence of ballooned neurons was thought to be characteristic of Pick's disease (hence called Pick cells) and CBD. However, it is clear that these are also (though less commonly) seen in progressive supranuclear palsy (PSP), Alzheimer's disease (AD), frontotemporal dementia and even Creutzfeldt–Jacob disease (CJD). Therefore, it is not the presence of the ballooned neurons alone that is important for the diagnosis. The distribution and the quantity at different sites is crucial, as well as the ultrastructural pattern of the neurofilaments (see below). Lewy bodies, granulovacuolar degeneration, extensive plaque, and neurofibrillary tangle formation have not been features of the cases reported.

Ultrastructurally, as early as 1989 (Watts *et al.*) it had been noted that the the cytoplasm of the swollen pale

neurons was filled with aggregates of 10 nm intermediate filaments. The pathological filamentous inclusions of CBD are now known to be composed primarily of abnormally phosphorylated tau similar to other sporadic and familial neurodegenerative diseases, such as Alzheimer's disease, PSP, Pick's and frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17), collectively referred to as tauopathies. Cortical tau positive neuronal inclusions are found in pyramidal and non-pyramidal neurons and may have a characteristic perinuclear, coiled filamentous appearance. Weakly basophilic nigral neuronal inclusions were first described by Gibb *et al.* (1989), referred to as corticobasal inclusions and were initially thought to be specific for CBD. However, subsequently it has become clear that these inclusions can be morphologically heterogeneous. They vary from slightly fibrillar to frankly filamentous and thus may be indistinguishable from tau-positive neurofibrillary tangles (NFTs) associated with PSP. However, cortical tau positive neuronal inclusions are more common in CBD than PSP, while in the latter disorder the neuronal inclusions are more abundant in the brainstem and deep gray matter. Thus, the distribution of the neuronal (and glial – see below) lesions is important for the pathological differentiation. Feany and Dickson (1995, 1996) and others have also detailed the cytoskeletal abnormalities by immunohistochemical methods looking at the neuropathological overlap between CBD and related conditions, particularly Pick's disease and PSP (see section below on molecular pathology). Apart from the neuronal changes there is glial tau pathology in CBD characterized by two main features, namely astrocytic plaques and coiled bodies which are tau-immunoreactive inclusions in astrocytes and oligodendrocytes in gray and white matter (Komori, 1999; Forman *et al.*, 2002). *Astrocytic plaques* is the term used to describe distinctive annular clusters of thick, short, tau positive deposits within the distal processes of cortical astrocytes (Fig. 45.2). They are thought to be more specific for CBD, than other disorders, such as PSP. These plaques are not associated with beta amyloid. In contrast, *tufted astrocytes* are characteristic of PSP. Astrocytic plaques of CBD also have to be differentiated from thorn-shaped astrocytes, which are not disease specific. The distribution of the abnormal astrocytes is somewhat different. In CBD astrocytic inclusions are more common in cortex than in the deep gray matter or brainstem. Coiled bodies, which are ubiquitin-negative, tau-immunoreactive oligodendroglial inclusions, are also common in the cortical and subcortical regions in CBD. These appear as fine bundles of filaments coiled around a nucleus and extend to the proximal part of the cell process. These inclusions are morphologically and antigenically distinct from the glial cytoplasmic inclusions seen in multiple system atrophy (MSA).

Table 45.1. Neuropathologic criteria for the diagnosis of corticobasal degeneration**Core features**

- Focal cortical neuronal loss
- Substantia nigra neuronal loss
- Cortical and striatal Gallyas/tau-positive neuronal and glial lesions, especially astrocytic plaques and threads, in both white matter and gray matter

Supportive features

- Cortical atrophy, often with superficial spongiosis
- Ballooned neurons, usually numerous in atrophic cortices
- Tau-positive oligodendroglial coiled bodies

Adapted from Dickson *et al.*, 2002.

Thin tau-immunoreactive *threads* of neuronal and glial origin are present throughout the gray and white matter and, although infrequently seen in Pick's disease, are particularly numerous in CBD. Given these nuances, it had been important that pathological diagnosis was made only by those with considerable experience in evaluating these conditions. However, recently validated neuropathologic diagnostic criteria (Dickson *et al.*, 2002, Table 45.1) will be a big help in this regard. These criteria emphasize the presence of tau-immunoreactive lesions in neurons, glia and cell processes. The minimal pathologic features for a diagnosis of CBD are the presence of cortical and striatal tau- (or Gallyas-) positive neuronal and glial lesions, especially astrocytic plaques and thread-like structures in both white matter and gray matter combined with neuronal loss both in focal cortical regions and in the substantia nigra. Although ballooned (achromatic) neurons identical to "Pick cells" were initially believed to be the pathological hallmark of the disorder, they are now considered only a supportive feature in view of rare cases lacking this abnormality but typical in every other way. These criteria provide good differentiation of CBD from other tauopathies with the one important exception being some cases of frontotemporal dementia and parkinsonism linked to specific mutations in chromosome 17. In these cases, additional clinical (particularly a positive family history) or molecular genetic information is required to make an accurate diagnosis.

Molecular pathology

Accumulation of hyperphosphorylated tau, comprising the abnormal filamentous inclusions in neurons and glia, is the characteristic feature of CBD and other tauopathies (Table 45.2). Unique antigenic, biochemical and ultrastructural features help to differentiate these different disorders.

Table 45.2. Conditions characterized by the deposition of tau containing neurofibrillary tangles (tauopathies)

Progressive supranuclear palsy (PSP)
 Corticobasal degeneration (CBD)
 Frontotemporal dementia parkinsonism-chromosome 17 (FTDP-17)
 Postencephalitic parkinsonism (encephalitis lethargica)
 Post-traumatic parkinsonism (including dementia pugilistica)
 Parkinson-dementia complex of Guam
 Alzheimer's disease
 Niemann-Pick type C
 Subacute sclerosing panencephalitis (SSPE)

Adapted from Morris *et al.*, 1999.

The tau gene is located on chromosome 17 and has 13 exons. Six tau isoforms result from variable splicing of exons 2,3 and 10, and these isoforms are variably phosphorylated at specific serine and threonine residues. Three of these isoforms carry the segment specified by exon 10 and four repeats of a microtubule-binding domain called four repeat tau (4R tau). The other three isoforms lack this fourth domain and are hence called three repeat tau (3R tau). Normally 3R and 4R are in equal concentration. Tau isoforms cannot be differentiated by electrophoretic pattern alone and antibodies to exon-specific epitopes help to identify different tau-related neurodegenerative disorders. Differences in morphology and distribution of tau immunoreactivity also have to be taken in consideration when reaching a conclusion.

For example, CBD and PSP have similarity in the electrophoretic pattern of tau both having 68 and 64 kilodalton doublets. However, studies with antibodies to exon 3 tau specific epitopes show that, in contrast to PSP, the CBD inclusions typically lack exon 3 sequences. Also immunoblot studies of CBD and PSP show distinctive patterns of tau fragments suggesting differing intracellular processing of aggregated tau despite identical composition of tau isoforms (Arai *et al.*, 2001). Ultrastructurally, tau in CBD forms paired helical filaments (PHFs). On electron microscopy these have been shown to be less abundant in the double stranded form which separates into the more abundant 15 nm wide, single stranded filaments (Dickson *et al.*, 2000). Straight filaments (15 nm) are also seen in PSP and Pick's disease. However, paired wide twisted ribbons are only seen in Pick's and not in PSP. The tau profile of CBD is also distinct from that seen in AD and chromosome 17 linked dementia (Morris *et al.*, 1999). Thus, CBD is a fairly distinct lobar and basal ganglia tauopathy with selective aggregation of 4R tau, which has characteristic antigenic and ultrastructural characteristics (Feany & Dickson, 1996; Forman *et al.*, 2002).

Another disorder, which can present with dementia personality change, emotional imbalance and has a pathological overlap with CBD and PSP is the recently recognised entity called argyrophilic grain disease (AGD) (Togo *et al.*, 2002). Spindle- or comma-shaped argyrophilic grains in the neuropil of entorhinal cortex, hippocampus, and amygdala characterize AGD. Immunohistochemistry with monoclonal antibodies specific to tau isoforms with four (4R) or three (3R) repeats in the microtubule-binding domain showed immunostaining of grains with 4R, but not 3R, tau antibodies, suggesting that AGD is a 4R tauopathy. The 4R/3R tau ratio is 1 or less for Alzheimer disease controls and more than 1 for AGD, decreasing with increasing neurofibrillary pathology and demonstrating that insoluble tau in AGD is enriched in 4R tau. The frequency of an extended tau haplotype designated H1 (see below) is increased in AGD as it is in the other sporadic 4R tauopathies, progressive supranuclear palsy (PSP) and corticobasal degeneration (CBD). Furthermore, AGD also occurs in PSP and CBD more frequently than in dementia controls, including Alzheimer's disease. These results suggest that AGD, PSP and CBD are all 4R tauopathies and share common pathologic, biochemical, and genetic characteristics (Togo *et al.*, 2002).

Only few neurochemistry studies have been undertaken in CBD. A profound reduction (>90%) in the concentration of dopamine in the substantia nigra, caudate nucleus, and putamen was found in one patient (Riley *et al.*, 1990), corresponding to the degeneration of the substantia nigra and loss of the nigrostriatal pathway.

Pathogenesis/mechanism of disease

The identification of an association between homozygosity for the tau haplotype H1 in PSP led to similar studies in CBD. Di Maria *et al.* (2000) found the same association in cases with a clinical diagnosis of CBD. Houlden *et al.* (2001) in an international collaborative effort also confirmed this association in 57 pathologically confirmed cases (to avoid diagnostic errors). Thus this identical association of the H1 haplotype for both CBD and PSP has led to the notion that abnormalities of the tau gene located on chromosome 17 may be responsible for both CBD and PSP. In this regard it is interesting to note that certain families with FTDP-17 with mutations located in exon 10 of the tau gene or in the 5' exon splice site of exon 10 have been described with a phenotype similar to that of CBD (Dickson *et al.*, 2000). However, the typical sporadic cases of CBD do not have mutations of the tau gene.

Although most cases of CBD are sporadic some familial cases have been described, mostly presenting with a

dementing illness with the diagnosis of CBD being made only on pathology (Mitsuyama *et al.*, 1992; Brown *et al.*, 1996, 1997). For example Brown *et al.* (1996) described a dementing syndrome in multiple members of two families, both with an autosomal dominant inheritance, in which the brain pathological findings in one member from each family showed changes consistent with CBD. Verin *et al.* (1997) reported (in abstract form) two brothers with a probable diagnosis of CBD based on clinical, radiological and metabolic imaging features. Finally there has been a report of monozygotic twins, one of whom (index case) presented with clinical and imaging features of CBD. The other though clinically unaffected, had a positron emission tomography (PET) ¹⁸F fluorodeoxyglucose (FDG) scan showing global hypo metabolism and neuropsychological studies suggestive of left hemispheric dysfunction suggesting presymptomatic CBD (Caselli *et al.*, 1995). There was no mention of tau gene sequencing in any of these reports and it can be debated whether some of these families have CBD or FTDP-17. Nevertheless, these reports and those of the CBD phenotype in some families with FTDP-17 with exon 10 mutations (Bugiani *et al.*, 1999), as well as the H1 haplotype association of CBD and PSP, leads one to reconsider the relationship between these disorders. Indeed, it is being increasingly recognised that CBD may present with a frontal lobe type of dementing illness (see [clinical features](#) below) and some cases of FTDP-17 closely resemble the more classic CBD or PSP phenotype (Bugiani *et al.*, 1999; Lee *et al.*, 2001).

Clinical features

Symptoms begin insidiously in the sixth to eighth decades. In the series by Rinne *et al.* (1994), the youngest age of onset was 40 years, and the eldest 76 years. The condition occurs sporadically and usually there is no family history of a similar disorder. Males and females are probably equally affected although some have wondered about a small female preponderance (Schneider *et al.*, 1994).

The core clinical features are shown in Table 45.3. Although presentation with a dementing process is being recognized of late the most common mode of presentation in the cases reported so far has been that of a slowly evolving motor disorder involving the arm or the leg, particularly the arm. One important source of potential bias for this clinical presentation is that most series (generally lacking neuropathological confirmation) have originated from movement disorders clinics (where these patients present as "atypical parkinsonism") rather than behavioral neurology or dementia clinics (where patients may

present with a variety of cognitive, language or behavioral problems).

One of the most striking findings in the early stages of the illness is the asymmetry of limb involvement. At the onset symptoms may be vague and related to an inexplicable loss of hand function with clumsiness, loss of dexterity of fine finger movement or stiffness. Formal testing at this time may reveal slowness in hand and finger movement, difficulty in using objects or mimicking gestures or producing sequences of movement with the affected hand consistent with an *apraxia* (limb-kinetic or ideomotor). In attempting to perform manual tasks there may be perseveration of one part of the movement. Occasional patients have presented with an akinetic-rigid syndrome, a supranuclear gaze palsy, a pseudobulbar syndrome, and alien limb, a focal movement disorder (e.g. dystonic hand), or a sensory disturbance.

In the series of 36 patients of Rinne *et al.* (1994) five types of initial presentation emerged:

- (i) The most common: a “useless arm,” which was either rigid, dystonic, akinetic and apractic, with or without alien limb behavior, or rigid and jerking with stimulus-sensitive and action myoclonus (20 patients);
- (ii) a gait disorder due to a rigid, apraxic leg with occasional myoclonus or disequilibrium, or both (ten patients);
- (iii) prominent early sensory symptoms, sometimes with severe pain (three patients) and often in combination with clumsiness;
- (iv) an isolated speech disturbance with dysarthria, although this was often associated with limb symptoms (two patients);
- (v) falls and a prominent behavioral disorder (one patient).

Two other large series (Wenning *et al.*, 1998; Kompoliti *et al.*, 1998) and numerous smaller ones or case reports have more or less been in agreement with the motor syndrome as mentioned in the series of Rinne *et al.* (1994). In the series of 14 pathologically proven cases of CBD reported by Wenning *et al.* (1998) the most commonly reported symptom at onset included asymmetric limb clumsiness, with or without rigidity (50%), or tremor (21%). At the first neurological visit, on average 3.0 years after symptom onset, the most often encountered extrapyramidal features included unilateral limb rigidity (79%), bradykinesia (71%), postural imbalance (45%), and unilateral limb dystonia (43%). Ideomotor apraxia (64%), and to a lesser extent cortical dementia (36%), were the most common cortical signs at that stage. During the course of the disease, virtually all patients developed asymmetric or unilateral akinetic rigid

parkinsonism and a gait disorder. Kompoliti *et al.* (1998) reported a series of 147 mostly clinically diagnosed cases of CBD (only 7 with autopsy diagnosis). Based on retrospective chart review, they found parkinsonism as the most common feature (100%) along with higher cortical dysfunction (93%). The [section below](#) details some of the major clinical features.

Once again, it should be emphasized that all of these series (including the Wenning *et al.*, 1998 pathology study) originated from movement disorders clinics and therefore suffer from referral bias with respect to the presenting clinical features.

Apraxia

The major component of the higher-order motor deficit seen in the affected limbs in CBD might best be described as limb-kinetic apraxia, although it may be difficult to ascertain this given that bradykinesia, rigidity and dystonia may coexist. Most patients fail tests for ideomotor apraxia, but they rarely exhibit ideational apraxia (Leiguarda *et al.*, 1994). Ideomotor apraxia is for both transitive and intransitive tasks. CBD patients show impairment in production of meaningless and symbolic gestures and imitation, as well as in using real objects (Spatt *et al.*, 2002). Patients are impaired at using tools, miming tool use and initiating mimes of tool use. Motor performance in the use of tools improves with tactile stimulation (holding the appropriate tool or neutral object) but is not facilitated by visual input, for example being shown a diagram of the tool or the actual tool (Graham *et al.*, 1999). Although ideomotor apraxia can also rarely occur in PSP it is clearly much more severe in CBD (Pharr *et al.*, 2001). Apraxia of the lower limb may present as difficulty walking and may be the presenting complaint. The foot may tend to stick to the floor as walking is initiated or it may drag and cause the patient to trip on uneven surfaces or if attention is diverted. Examination of the affected leg may reveal slowness of rapid alternating movements and difficulty performing sequences of leg movement when lying down. In addition to limb apraxia, it is now recognized that facial apraxia with impairment of tongue and lip movements can also occur fairly frequently in CBD (Rosser & Tyrrel, 1992; Ozsancak *et al.*, 2000). Truncal apraxia has also been recorded (Okuda *et al.*, 2001).

The neural basis of the ideomotor apraxia is uncertain. Jacobs *et al.* (1999) have suggested that the ideomotor apraxia in CBD patients is of the anterior or production type whereby these patients are able to comprehend and discriminate gestures, unlike the posterior type due to involvement of the dominant parietal lobe, which leads to gesture recognition and gesture discriminative deficits. Similarly, using three-dimensional movement analyses to

compare apraxia in a patient with CBD with that seen with a left parietal stroke Merians *et al.* (1999) reported that the CBD patient showed abnormal trajectories when actually manipulating the tool and object. The post-stroke deficits were most pronounced to verbal command with some improvement (although still with overall impairment) on actual tool and object manipulation. However, Spatt *et al.* (2002) felt that, although the main feature is a breakdown of motor programming (anterior involvement), in CBD some patients also have deficits in mechanical problem solving, which has been linked to the parietal lobe. The observation that some CBD patients also have some impairment of semantic memory suggests that the apraxia may be multifactorial (Spatt *et al.*, 2002). In line with this are results of some investigative studies of apraxic CBD patients. Okuda *et al.* (1995) reported that limb kinetic apraxia in CBD arose from involvement of the perirolandic area and constructional apraxia from the opposite parietal lobe on the basis of hypo perfusion of these areas on single photon emission tomography (SPECT) scans. In another study the N20 latency was shown to be significantly prolonged following median nerve stimulation on the more apraxic side, compared with the less apraxic side, suggesting that limb apraxia is partly due to disordered somatosensory processing through the parietal cortex (Okuda *et al.*, 1998). A PET scan study showed hypo metabolism of the anterior cingulate in patients with limb apraxia versus those without apraxia (Peigneux *et al.*, 2001).

Alterations in muscle tone with either *lead-pipe rigidity* or *Gegenhalten* of the affected limbs are a common finding. The affected arm does not swing in the normal manner during walking and tends to flex at the elbow. The hand may progressively adopt a flexed, often fixed, *dystonic posture* with clenching of the fingers into a fist, often closing around the thumb, which is held adducted in the palm. Skin maceration of the palm due to the fingers digging in forcibly is often seen. Pain often accompanies dystonia. Asymmetric limb dystonia was seen in 92% of cases reported by Vanek and Jankovic (2000). Dystonia of the leg was uncommon and dystonia of the head, neck or trunk is almost never seen in CBD (Vanek & Jankovic, 2000). Whether the dystonia in CBD is due to involvement of the striatum, to degeneration of the motor cortex or even parietal cortex is unclear.

In addition to limb apraxia, other frontal lobe motor signs become more evident with progression of the disease. *Gegenhalten* is often present from an early stage, as are *frontal release signs* such as grasp reflexes in the hands and feet, sucking and rooting reflexes. Patients may complain of an inability to release objects from this grasp in addition to the loss of fine motor skills. The *alien limb phenomenon* may be one of the most striking features of the syndrome.

This refers to slow, involuntary, wandering, levitation-like movements of the arm which often are associated with a prominent grasp reflex, forced grasping and groping (Adie & Critchley, 1927), magnetic hand movements (compulsive tactile exploration) (Denny-Brown, 1958) and intermanual conflict. The wandering hand frequently grasps on to parts of the patient's own body, the bedclothes, adjacent furniture or even people next to them, and will not let go. First described in association with tumors of the corpus callosum (Brion & Jedanyk, 1972), alien limb behavior has since been reported in association with infarction of the medial frontal cortex (Goldberg *et al.*, 1981; McNabb *et al.*, 1988; Feinberg *et al.*, 1992; Trojano *et al.*, 1993). The movements are slow and may appear quasi-purposeful; the hand typically rises slowly at the side of the patient who may be unaware of the movement. The unexpected appearance of the patient's hand beside their face gave rise to the term *le signe de la main étrangère* (Brion & Jedanyk, 1972) or alien limb. Limb levitation alone does not constitute true alien limb phenomenon and is often a source of misdiagnosis with other parkinsonism disorders for instance PSP (Barclay *et al.*, 1999; Boeve *et al.*, 2003). This description encompasses both the involuntary active wandering and other behaviors of the affected arm and the patient's lack of awareness or neglect of the limb and the feeling that it is foreign (Doody & Jankovic, 1992). In addition, the apraxic difficulty in using the hand to perform even simple tasks often leads patients to describe the limb as "... not doing what I want it to . . .," or to state that it "... has a mind of its own." Often the patient uses their relatively normal hand to restrain the alien one. Another striking feature of the alien limb is intermanual conflict in which the affected limb reaches across to interfere with the voluntary activities of the contra-lateral normal hand (see Case 2, Rebeiz *et al.*, 1968). Alien leg movements also occur, with the leg rising while the patient is seated. About 40% of CBD patients will develop the alien limb phenomenon (Kumar *et al.*, 1998).

With increasing rigidity, difficulty walking, bradykinesia and facial immobility, the clinical picture becomes one of an *akinetic-rigid syndrome*. Kompoliti *et al.* (1998) in their review of 147 cases (7 autopsy proven) reported that parkinsonism was present in all patients with rigidity being the most common feature (92%), followed by bradykinesia (80%), gait disorder (80%) and tremor (55%). With progression, disequilibrium becomes a common feature in virtually all patients with postural instability and falls. The akinesia and rigidity generally show a poor or unsustained response to dopamine replacement therapy, despite the profound nigrostriatal pathology and the demonstration of dopamine depletion in these structures.

In addition to the asymmetric akinetic-rigid dystonic syndrome there may be *involuntary movements*. Chorea, tremor, and action and stimulus sensitive myoclonus may occur with or without the alien limb movement (mentioned above). Rebeiz *et al.* (1968) (case 2) mention “whenever he moved the hand, it underwent a series of alternating athetoid movements.” Case 3 reported by Gibb *et al.* (1989) noticed that her hand tended to “levitate and the fingers wandered like tentacles.” Tremor and myoclonus interfere with any attempts to use the arm and hand (or leg and foot). The tremor is not the classical rest tremor of Parkinson's disease, but a more jerky irregular tremor most evident in posture or movement. The myoclonus begins at first in the affected limbs. It is typically exquisitely sensitive to cutaneous stimuli and muscle stretch. The precise origin of the reflex myoclonus is uncertain (see below). Seizures are not a feature of the illness and the electroencephalogram does not show epileptic activity.

A *supranuclear gaze palsy* may be an early and prominent sign leading to confusion with PSP. The ocular motor disorder is progressive. It may take the form of a gaze apraxia with difficulty initiating saccades but with preservation of spontaneous reflexive saccades and eye movements elicited by the oculocephalic reflex. Fixation spasm may be evident. Patients may be unable to initiate eye movements to command without using head thrusts or a blink. There also may be marked saccadic hypometria, in both horizontal and vertical directions of gaze, and slowing of voluntary saccadic eye movements (Stell & Bronstein, 1994). Gaze impersistence also has been described. Pursuit eye movements are often saccadic and jerky at an early stage but, with progression of the disease the range of voluntary smooth pursuit becomes restricted and finally all voluntary eye movements may be lost. However, even at these stages it is usually possible to demonstrate that the ocular movement disorder is supranuclear in origin. Vidhaillet *et al.* (1994) have suggested that horizontal saccadic latencies are increased before vertical latencies in CBD (at least in the early stages), unlike PSP where the opposite occurs. There is also decreased saccadic amplitude in the latter, thus helping to differentiate the two conditions. In a longitudinal study it was shown that saccadic velocities are preserved in CBD while PSP patients show decreased saccadic velocity throughout the disease course (Rivaud-Pechoux *et al.*, 2000). The same authors also noted that increased unilateral saccadic latency in CBD occurred ipsilateral to the side with apraxia early on in the course of the illness. Blepharospasm and levator inhibition may produce difficulties in eye opening.

Dysarthria is usually present and becomes increasingly severe, as does dysphagia. Progressive pronunciation dif-

ficulty, loss of speech, and orofacial apraxia may be the presenting features (Lang, 1992) and a primary progressive aphasia as the sole presentation with involvement of the superior temporal gyrus has been recognized (Kertesz *et al.*, 2000).

True weakness is not a feature to begin with, but with the passage of time the limb(s) become useless because of rigidity and apraxia. In addition, *pyramidal signs* appear with hyperreflexia and extensor plantar responses.

Cortical sensory signs with symptoms of numbness or tingling may appear at an early stage. Impaired joint position sense, two point discrimination, graphesthesia and astereognosis with intact primary sensory modalities is typical of cortical sensory loss.

Cognitive changes were believed to be unusual early in the disease; in fact, some reports specifically mentioned that the intellect was generally preserved (Riley *et al.*, 1990; Rinne *et al.*, 1994). Formal psychometric assessment was said to show some impairment on tests sensitive to frontal lobe damage, but this was attributed to performance difficulties due to the profound motor deficits. Cognitive performance in everyday life was usually felt to be unimpaired. However, it was clear even in the early reports, which stressed the motor aspects of CBD, that with the passage of time, memory impairment and dysphasic speech disturbance emerged as the disease progressed. However, there were some reports of focal cortical syndromes with pathological changes similar to those of CBD in which the major symptoms were related to a disturbance of language (i.e. dysphasia) with only subtle motor signs in the limbs (Lippa *et al.*, 1990, 1991; Lang, 1992), and of cases with combinations of dysphasia and limb apraxia (Cases 1, 4, of Sawle *et al.*, 1991). It is only recently that it has been clearly recognised that CBD (proven pathologically) may manifest as a dementing disorder alone or initially with later manifestation of the motor syndrome (Grimes *et al.*, 1999; Bergeron *et al.*, 1998). In one brain bank study involving patients referred by both movement disorders and memory clinics, dementia was the commonest presenting feature (9 of 13) and occurred in all but one of 13 cases over the course of the disease (Grimes *et al.*, 1999). Importantly, the classical movement disorder presentation (a “perceptuomotor” phenotype now often termed the corticobasal syndrome or CBS—see below), encouraging a diagnosis of CBD in life, was present in only 4 of the 13 patients in this study.

CBD can present with severe cognitive deficits with frontal lobe predilection with executive dysfunction, learning difficulties easily compensated for by use of semantic cues for encoding and retrieval, and disorders of dynamic motor execution which include temporal organisation, bimanual coordination, control and inhibition

(Pillon *et al.*, 1995), a pattern different from that typically seen in Alzheimer's disease (AD). However like AD, CBD patients also have prominent deficits on tests of sustained attention/mental control and verbal fluency (Massman *et al.*, 1996). Psychomotor depression is more common and severe in CBD than AD and PSP while apathy is more common in PSP (Litvan *et al.*, 1998).

CBD-like syndromes due to other pathologies

The classical clinical phenotype of CBD has become fairly well established. However, in recent years it has become apparent that a similar clinical picture may turn out to have a different pathological cause (Boeve *et al.*, 1999; Bhatia *et al.*, 2000; Boeve, 2001). PSP is probably the commonest source of this misdiagnosis. For example, there are reports of patients with a diagnosis of PSP proven pathologically, who exhibited a fairly typical CBD phenotype (i.e. CBS) with an asymmetric akinetic-rigid syndrome with dystonia of the affected arm, an alien limb, abnormal eye movement (with normal down gaze), dysarthria and dysphagia, and an impaired gait (Case Records of the Massachusetts General Hospital, 1993; Boeve *et al.*, 1999; Oide *et al.*, 2002). Other patients presenting with a dystonic, alien hand with myoclonus, apraxia, sensory inattention, amnesia, but relatively preserved speech have had the pathology of Alzheimer's disease (Ball *et al.*, 1993; Crystal *et al.*, 1982; Boeve *et al.*, 1999; Bhatia *et al.*, 2000). Also encountered have been patients with a grossly asymmetric rigid dystonic arm, some with alien behavior and myoclonus, attributable to cerebrovascular disease. Furthermore, Pick's disease, FTD with non-specific degeneration, FTDP-17, primary progressive aphasia (all part of the so called "Pick complex"), CJD (Boeve *et al.*, 1999; Kertesz *et al.*, 2000; Ansel *et al.*, 2002), as well as pigmentary sudanophilic leucodystrophy (Bhatia *et al.*, 2000), progressive multifocal leukoencephalopathy, and even a case with Fahr's disease with basal ganglia calcification (Warren *et al.*, 2001) have been reported with a CBD-like clinical picture. Such cases of a CBS due to other pathological causes have been referred to as corticobasal "look-alikes" (Bhatia *et al.*, 2000). It would appear that the constellation of clinical features of CBD can be caused by a variety of pathologies with asymmetric parietofrontocortical (with or without basal ganglia) involvement. An updated review of this heterogeneity from one institution (Boeve *et al.*, 1999) indicated that the underlying pathology in 32 autopsied cases with clinical features of CBD were as follows: CBD, 18; Alzheimer's, 3; Picks disease, 2; PSP, 6; dementia lacking specific histology, 2; Creutzfeldt-Jakob disease, 3. Others have described dementia with Lewy bodies (Horoupian

Table 45.3. Proposed criteria for the diagnosis of the corticobasal syndrome

Core features

Insidious onset and progressive course
No identifiable cause (e.g tumor, infarct)
Cortical dysfunction as reflected by at least one of the following:
Focal or asymmetrical ideomotor apraxia
Alien limb phenomena
Cortical sensory loss
Visual or sensory hemineglect
Constructional apraxia
Focal or asymmetric myoclonus
Apraxia of speech/nonfluent aphasia
Extrapyramidal dysfunction as reflected by one of the following:
Focal or asymmetric appendicular rigidity lacking prominent and sustained l-dopa response
Focal or asymmetrical appendicular dystonia
Supportive investigations
Variable degrees of focal or lateralised cognitive dysfunction, with relative preservation of learning and memory, on neuropsychometric testing
Focal or asymmetric atrophy on CT or MRI imaging, typically in perifrontal cortex
Focal or asymmetric hypoperfusion on SPECT or PET typically maximal in parietofrontal cortex +/- basal ganglia

Adapted from Boeve *et al.*, 2003.

& Wasserstein, 1999) and motor neurone inclusion body dementia (Grimes *et al.*, 1999). Hence Boeve *et al.*, 2003 have recently suggested that the term *corticobasal syndrome* (CBS) be used to characterise the constellation of typical features initially considered the defining characteristics of corticobasal degeneration with the term corticobasal degeneration (CBD) reserved for the histopathological diagnosis. Boeve *et al.*, 2003 have also proposed criteria for the diagnosis of the corticobasal syndrome (Table 45.3).

Of all these disorders the greatest similarities are undoubtedly between PSP and CBD both with regard clinical features and pathology and hence some may question whether these two are distinct disorders or variants of the same pathophysiological process (Boeve *et al.*, 2003). Both have prominent tau pathology with the presence of 4R-tau isoforms and are associated with the H1 tau haplotype and have overlapping clinical features. On the other hand, in support of the notion that these may be distinct clinicopathological entities is a recent report showing distinct patterns of microglial activation and tau pathology in the two disorders (Ishizawa & Dickson 2001). In this regard Lang (2003) has suggested two possible explanations as shown in Fig. 45.3. One possibility is that these are two distinct

nosological entities caused by different factors (environmental/genetic) occurring in individuals with similar genetic predisposition (H1/H1 tau genotype). The second as shown in Fig. 45.3 (B) is that these are distinct phenotypes of the same disorder, occurring in individuals with similar genetic predisposition with differences secondary to differences in genetic background and/or specific differences in the etiologic triggering agent(s) (Lang, 2003). However, the jury is still out on this and further work in this area will be needed to provide the answer to this question.

Epidemiology

It is clear that CBD is a relatively rare neurodegenerative disorder, however the true incidence and prevalence of the disorder remains unknown. It would be true to say that it is the least common of the four parkinsonian disorders which clinicians typically consider in their differential diagnosis of a patient with a neurodegenerative cause of an akinetic rigid syndrome which include Parkinson's disease (PD), multiple system atrophy (MSA), PSP and CBD. In this regard in a recent community based prevalence study of parkinsonian disorders not a single case of CBD was identified vs. rates of 4 and 6/100 000 for MSA and PSP, respectively (Schrag *et al.*, 1999). CBD is estimated to account for 0.9% of parkinsonian cases in a specialized movement disorder clinic compared to PSP which accounts for about 5%. Togasaki and Tanner (2000) have estimated CBD will develop in 4–6% of those with parkinsonism and based on the incidence of Parkinson's disease the estimated incidence rate of CBD would be 0.62–0.92/100 000 per year with a prevalence of 4.9–7.3/100 000 based on a survival rate of 7.9 years. However, this could be an overestimate with regard the motor (akinetic rigid) presentation of the disorder due to referral bias of a specialised movement disorder clinic. On the other hand, it may well be an underestimate since the dementia phenotype of CBD may be more common than is currently appreciated.

Investigations

Routine laboratory studies of blood, urine, and cerebrospinal fluid (CSF) are normal. Riley *et al.* (1990) noted that 4 of their 15 cases had a history of dysimmune diseases, but this has not been a general finding. Heavy metal toxic screens in urine have been negative. Watts *et al.* (1985) described decreased levels of somatostatin in CSF in three cases, but this has not been replicated. Increased total CSF tau protein has been reported in patients with CBD compared with normal controls and total CSF tau is said to be

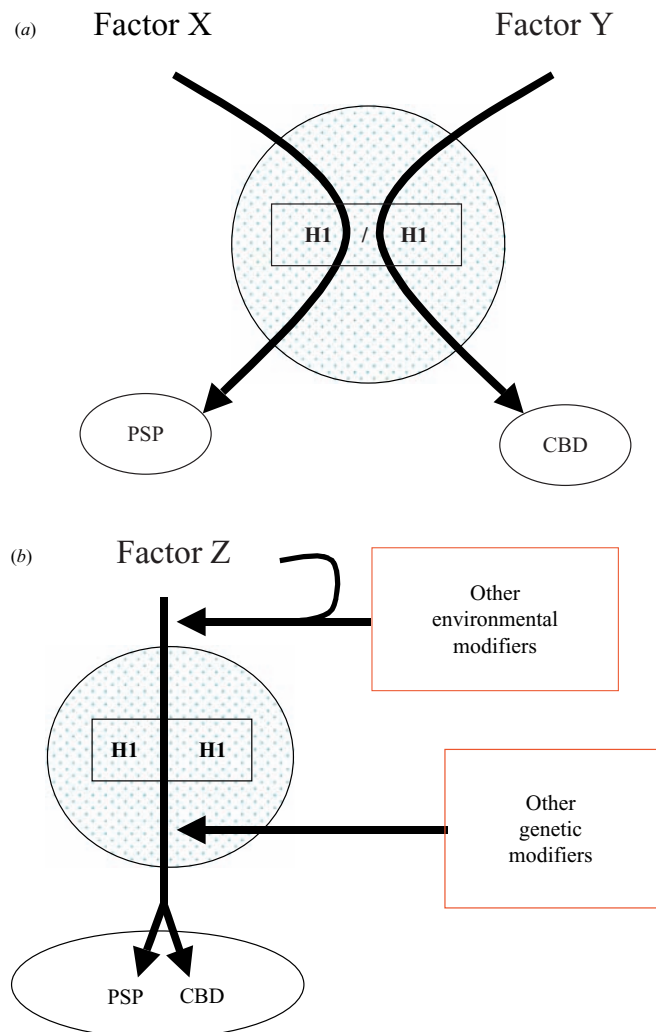

Fig. 45.3 Two possible explanations for the relationship between corticobasal degeneration (CBD) and progressive supranuclear palsy (PSP). (a) Two distinct nosological entities caused by different factors (environmental/genetic) occurring in individuals with similar genetic predisposition (H1/H1 tau genotype). (b) Distinct phenotypes of the same disorder, occurring in individuals with similar genetic predisposition; differences secondary to differences in genetic background and/or specific differences in the etiologic triggering agent(s). (From Lang, 2003 with permission.)

higher in CBD than PSP (Mitani *et al.*, 1998; Urakami *et al.*, 1999, 2001).

Imaging

Computerized tomography (CT) and magnetic resonance imaging (MRI) of the brain will show localized and

asymmetric frontoparietal atrophy in 50–96% of cases (Savoirdo *et al.*, 2000). Atrophy of the middle and posterior part of the corpus callosum has also been described in CBD (Yamauchi *et al.*, 1998). Hyperintense lesions of the primary motor cortex (M1), extending to the midline and possibly supplementary motor area (SMA) have been reported in two CBD cases (Winklemann *et al.*, 1999). Hyperintensity of the atrophic cortex or white matter may be seen particularly with fluid attenuated inversion recovery (FLAIR) sequences and hypointensity of the lentiform nuclei on T₂-weighted images has also been mentioned (Doi *et al.*, 1999; Savoirdo *et al.*, 2000). Atrophy tends to become more severe as the disease progresses. Early minimal cortical atrophy may be detected only by specialised three-dimensional MRI techniques (Caselli *et al.*, 1992). Reduced *N*-acetylaspartate (NAA) to choline (Cho) ratios were observed by MR spectroscopy in the right basal ganglia in one study of patients said to have the Pick complex which included patients with CBD (Kizu *et al.*, 2002). In the same study in patients with CBD low NAA/ creatine (Cr) ratios were also detected in the right perisylvian region. The explanation for the preferential involvement of the right side was not entirely clear.

Positron emission tomography (PET) has shown a typical pattern of an asymmetric reduction in the uptake of ¹⁸F-6-fluorodopa in the striatum (caudate and putamen) and in the medial frontal cortex (Riley *et al.*, 1990; Sawle *et al.*, 1991; Blin *et al.*, 1992). Caudate and putamen are said to be almost equally affected, in contrast to Parkinson's disease where ¹⁸F-6-fluorodopa uptake into putamen is considerably reduced, but that into caudate nucleus is relatively spared. This is consistent with the loss of nigrostriatal projections as predicted by the profound nigral cell loss demonstrated pathologically (Rebeiz *et al.*, 1968; Gibb *et al.*, 1989) and the striatal dopamine depletion in the case reported by Riley *et al.* (1990).

Characteristic patterns of asymmetric cerebral cortical hypo metabolism are seen with the greatest reductions of oxygen metabolism in the superior and posterior temporal, inferior parietal and occipital visual association cortices (Sawle *et al.*, 1991). There is also some reduction of oxygen metabolism in medial frontal regions, especially in those patients exhibiting alien limbs. Significant regional asymmetries in cerebral glucose metabolism also have been found in the thalamus, inferior parietal lobule, and hippocampus (Eidelberg *et al.*, 1991). This picture on FDG-PET can be apparent on simple visual inspection and can be present early on even before the characteristic signs appear to be able to make a diagnosis on clinical grounds (Coulier *et al.*, 2003). Similar asymmetry has been found in regional blood flow using single photon emission computed tomography (SPECT) with significant reduction in the posterior

frontal and parietal cortex, as well as the caudate and thalamus (Markus *et al.*, 1995). These changes were bilateral though more pronounced on the side opposite to the more affected side (Markus *et al.*, 1995). FDG PET studies in cognitively impaired CBD patients compared to PSP patients found that the CBD group had significant hypometabolism in the parietal lobes and suggested that this played a role in the cognitive changes in CBD (Hosaka *et al.*, 2002).

PET studies attempting in vivo imaging of activated microglia. With a ligand [¹¹C]PK11195 are said to show an increased [¹¹C](R) PK11195 signal in the cortex, thalamus and pons contralateral to the more affected side in a few patients with CBD (A. Gerhard and D. Brooks, personal communication). Formal reports of these studies are awaited.

It should be emphasized once again both that the CBS is not specific for the pathology of CBD and the pathology of CBD may present with features other than the classical CBS (i.e., dementia, progressive aphasia, etc.). Therefore, the metabolic or blood flow imaging patterns described above, obtained in clinically diagnosed cases, correlate with a distribution of underlying pathological change (and thus with a clinical phenotype) rather than a specific type of pathology.

Electrophysiology

The electroencephalogram is usually normal initially, but may develop asymmetric slowing, maximal over the hemisphere contralateral to the most affected limbs. Nerve conduction studies and electromyography have not revealed consistent evidence of peripheral nerve involvement, although evidence for a sensorimotor polyneuropathy has been found rarely (Case Records of the Massachusetts General Hospital, 1985). Visual and brainstem-evoked potentials have been normal.

Some authors have drawn attention to the similarity of the focal stimulus sensitive myoclonus to that seen in cortical reflex myoclonus (Riley *et al.*, 1990), although there are several differences (Thompson *et al.*, 1990, 1994). Somatosensory evoked potentials (SEP) may be abnormal (Thompson *et al.*, 1990, 1994). However, unlike classical reflex myoclonus, there is no enlargement of the secondary components of the SEP (P₁–N₂ component), but instead the later parietal components are distorted. Absent or increased latency of N30 SEP frontal component has also been reported in CBD (Monza *et al.*, 2003). There is no cortical discharge preceding myoclonic jerks on back-averaging (Thompson *et al.*, 1990; Monza *et al.*, 2003), although magnetoencephalography does support a cortical origin for the myoclonus (Mima *et al.*, 1998). Median nerve stimulation

in the affected arm often produces abnormal late C waves, corresponding to myoclonic jerks (Thompson *et al.*, 1990; Riley *et al.*, 1990). The latency of the reflex myoclonus following stimulation, of the order of 40 ms (Thompson *et al.*, 1994; Chen *et al.*, 1992), is shorter than the reflex latency of 50–60 ms in typical cortical reflex myoclonus (Obeso *et al.*, 1985). Reduced inhibition following magnetic stimulation of the cortex in CBD has been described (Strafella *et al.*, 1997). Similarly, significantly shortened post-motor-evoked potential (MEP) silent period has been reported in CBD (Lu *et al.*, 1998) supporting the notion that the action myoclonus is a result of pathological motor cortex hyperexcitability, probably due to loss of input from the sensory cortex.

Treatment

Unfortunately, there is no effective treatment for this condition (Kompolti *et al.*, 1998), which is relentlessly progressive and universally fatal. Levodopa and dopamine agonists have little effect, but are tried. Kompolti and colleagues (1998) found that 92% of the 147 cases in their international series had received dopaminergic drugs and a beneficial result was reported in only 24% with levodopa being the most effective. However, the effect if any is marginal and not sustained. Rarely, levodopa-induced dyskinesias may occur even in the absence of clinical benefit. Baclofen and/or an anticholinergic may help the rigidity a little, but they usually produce unwanted side effects. Clonazepam may dampen the myoclonus and dystonia somewhat (Kompolti *et al.*, 1998). Other drugs such as dopamine antagonists, propranolol, dantrolene sodium, anticonvulsants including sodium valproate and serotonin agonists, are generally of no help. Botulinum toxin injections into the rigid limb muscles may be useful. Two recent studies have found that EMG activity recorded at rest and during active and passive flexion/extension movements of the finger and wrist was useful both in distinguishing between muscle contraction and underlying contractures and in determining the dosage of botulinum toxin to be used in those with a dystonic clenched fist. Some benefit could be produced which depended on the severity of the deformity and the degree of contracture (Cordivari *et al.*, 2001; Muller *et al.*, 2002). All patients had significant benefit to pain and the muscle relaxation made it possible to cleanse the palms and reduce palmar infection when present (Cordivari *et al.*, 2001). Stereotaxic thalamotomy in a single case did not help the painful arm dystonia and myoclonus (Riley *et al.*, 1990). Other functional neurosurgical procedures effective in Parkinson's disease (e.g. deep brain stimulation of the subthalamic nucleus) would not be expected

to reduce disability in CBD since the benefit closely correlates with ongoing response to levodopa. The main thrust of management is thus confined to measures to assist mobility and distress. There are important roles for physio- and occupational therapy however, the apraxia often limits the extent to which patients can benefit from these interventions. Ongoing concern for the well being of the caregiver is also a critical component of the management strategy.

Cerebellar degenerations

Approach to the patient with ataxia

Thomas Klockgether

Department of Neurology, University of Bonn, Germany

Definition and classification of ataxia

The term *ataxia* is derived from ancient Greek and literally means absence of order. In modern clinical neurology, ataxia is used to denote disturbances of coordinated muscle activity. Ataxia is caused by disorders of the cerebellum and its afferent or efferent connections. Spinal afferent pathways are often involved in ataxia disorders. Diseases of the peripheral nervous system, such as chronic idiopathic demyelinating polyneuropathy, may also cause ataxia. However, ataxia is rarely the prominent symptom in these disorders.

The afferent and efferent connections of the cerebellar cortex are topographically organized resulting in functional specialization of different parts of the cerebellum. Dysfunction of the lower vermis (vestibulocerebellum) leads to truncal ataxia. Spinocerebellar lesions (upper vermis and anterior parts of hemispheres) are characterized by unsteadiness of gait and stance which are more evident after eye closure (positive Rombergism). The most prominent symptom of neocerebellar damage (cerebellar hemispheres) is ataxia of intended limb movements. Ataxic limb movements are irregular and jerky and tend to overshoot the target (past-pointing). They are often accompanied by rhythmic side-to-side movements as the target is approached (action or intention tremor). Dysarthria characterized by slow and segmented speech with variable intonation and disturbances of ocular movements (broken-up smooth pursuit, saccadic hypermetria, gaze-evoked nystagmus) almost invariably accompany ataxia of gait and limb movements (Diener & Dichgans, 1992; Thach *et al.*, 1992).

Knowledge of the topographical organization of the cerebellum is helpful for the localisation of focal cerebellar disease. However, it is only of limited value in the differential diagnosis of non-focal cerebellar disorders such as cerebellar

degenerations or cerebellar encephalitis, because these disorders are usually associated with a pancerebellar syndrome involving all aspects of ataxia.

Traditionally, classifications of ataxia were based on neuropathological criteria. Thus, Holmes (1907) distinguished between spinocerebellar degeneration, degeneration of the cerebellar cortex, and olivopontocerebellar atrophy. More recently, a clinical classification introduced by Harding (1983) gained wide acceptance. This classification distinguishes between congenital, hereditary and non-hereditary ataxias. Hereditary ataxias are further subdivided into ataxias with autosomal recessive inheritance such as Friedreich's ataxia (FRDA), and ataxias with autosomal dominant inheritance which are now usually named spinocerebellar ataxias (SCA). In recent years, the causative mutations of most hereditary ataxias have been identified allowing a rational classification of hereditary ataxias (Table 46.1). The non-hereditary ataxias comprise diseases with unknown etiology and symptomatic ataxias with a known cause.

Diagnostic approach to the patient with ataxia

Patients with ataxia may cause considerable diagnostic problems because a variety of heterogeneous diseases are associated with a widely uniform clinical picture. The diversity of disorders associated with ataxia may lead clinicians to apply extensive laboratory screening programs to each individual patient with ataxia. Although such an unspecific approach may be required in some patients, many have characteristic clinical features that allow to select and apply appropriate diagnostic tests.

A rational diagnostic approach implies a sequence of three steps. The first step is to distinguish focal and non-focal cerebellar disorders. The second step is to identify

Table 46.1. Classification of ataxia

Hereditary ataxias
Autosomal recessive ataxias
Autosomal dominant ataxias
Spinocerebellar ataxias
Episodic ataxias
Non-hereditary ataxias
Multiple system atrophy, cerebellar type
Sporadic adult-onset ataxia of unknown origin
Symptomatic ataxias
Alcoholic cerebellar degeneration
Ataxias due to other toxic causes
Paraneoplastic cerebellar degeneration
Ataxia due to acquired vitamin deficiency or metabolic disorders
Cerebellar encephalitis (including immune-mediated cerebellar degenerations other than paraneoplastic cerebellar degeneration)
Ataxia due to physical causes

Table 46.2. Ataxia disorders with a highly characteristic clinical phenotype

Disorder	Phenotype	Laboratory test
Friedreich's ataxia (FRDA)	clinical diagnostic criteria (early disease onset, areflexia, dysarthria, posterior columns signs)	intronic GAA expansion of X25/FRDA gene
Ataxia telangiectasia (AT)	early disease onset, telangiectasias, immuno-deficiency	α -fetoprotein hypersensitivity of fibroblasts and lymphocytes to ionizing radiation mutation of ATM gene
Cerebrotendinous xanthomatosis	xanthomas	cholestanol
Spinocerebellar ataxia type 7 (SCA7)	autosomal dominant inheritance, retinal degeneration	CAG expansion of SCA7 gene
Multiple system atrophy (MSA)	autonomic failure	not available

disorders with a highly characteristic clinical phenotype that can be diagnosed on purely clinical grounds and to confirm the suspected diagnosis by a specific laboratory test. After these initial two steps, there is still a considerable number of patients in which the diagnosis remains unclear. The further diagnostic tests in these patients should be

guided by considering the following aspects of the disease: mode of inheritance, age at disease onset, progression rate, accompanying symptoms. Thus, the initial diagnostic program in a young ataxia patient will be different from that in a patient with disease onset in late adulthood. Similarly, patients with rapid disease progression require another approach than patients with stationary or slowly progressive ataxia. Finally, presence of a specific accompanying symptom such as myoclonus will guide the further procedures in a certain direction.

Focal cerebellar disorders

The first step in the diagnosis of ataxia is to distinguish between focal cerebellar disease (tumor, abscess, ischemia, hemorrhage, focal demyelination) and non-focal disorders. In many cases, this distinction is easily made by taking the history and examining the patient. Acute disease onset, headache, vomiting and unilateral symptoms strongly argue in favor of a focal disease. A definite distinction between focal and non-focal cerebellar disorders is achieved by the use of imaging methods. Magnetic resonance imaging (MRI) is preferable to computed tomography (CT) because MRI – in contrast to CT – is capable of imaging the cerebellum and brainstem at different planes, with high resolution and without major artefacts (Wüllner *et al.*, 1993).

Multiple sclerosis is an important differential diagnosis in the work-up of patients with ataxia. Remitting–relapsing course and multifocal involvement will raise suspicion of multiple sclerosis. To definitely establish the diagnosis of multiple sclerosis, MRI studies and cerebrospinal fluid examinations are required.

Ataxia disorders with highly characteristic phenotypes

A number of ataxia disorders have a highly characteristic clinical phenotype that allows to make a diagnosis on purely clinical grounds. In most of these disorders, laboratory tests are available that serve to confirm the suspected clinical diagnosis (Table 46.2). Friedreich's ataxia (FRDA) is an example for this type of disease. The clinical diagnostic criteria for FRDA, as defined by Geoffrey *et al.* (1976) and Harding (1981) include progressive ataxia with early disease onset, areflexia, dysarthria and signs of posterior column dysfunction. These criteria have an almost 100% specificity. It is important to recall that the characteristic phenotypical features that establish a diagnosis of FRDA, although being specific, lack sensitivity. In other words, a considerable number of patients who do not have the typical FRDA phenotype, may nevertheless suffer from FRDA

(Dürr *et al.*, 1996; Filla *et al.*, 1996). Demonstration of an expanded GAA repeat of the frataxin gene will confirm the clinically suspected diagnosis (Campuzani *et al.*, 1996). Table 46.2 gives a list of disorders in which a diagnosis can be made on the basis of a characteristic clinical phenotype. Most of these disorders are hereditary disorders with the notable exception of multiple system atrophy (MSA). MSA is an adult-onset sporadic disorder clinically characterized by various combinations of cerebellar ataxia, parkinsonism, pyramidal signs and autonomic failure (Quinn, 1989). In general, differential diagnosis of adult-onset sporadic ataxia disorders may be difficult and includes a wide variety of hereditary, degenerative and acquired disorders (Abele *et al.*, 2002). Autonomic failure in association with ataxia, however, occurs almost exclusively in MSA (Quinn, 1989; Wenning *et al.*, 1994; Schulz *et al.*, 1994). Demonstration of autonomic failure in a patient with sporadic adult-onset ataxia will thus establish the diagnosis of MSA without the necessity to perform a large battery of diagnostic tests.

Diagnosis in specific clinical situations

Autosomal recessive inheritance

Autosomal recessive inheritance is highly probable if there are more than one affected siblings in one generation while the parents are healthy. In addition, consanguinity of parents is a strong argument for autosomal recessive inheritance. Nevertheless, most autosomal recessive disorders manifest as sporadic diseases from non-consanguineous marriages. Typically, autosomal recessive disorders start in childhood, adolescence or early adulthood. Since acquired ataxia disorders are rare in young people, sporadic ataxia disorders with early disease onset are most often due to autosomal recessive inheritance. Thus, all diagnostic considerations that refer to autosomal recessive disorders also apply for sporadic disorders with early disease onset (see p. 00). Traditionally, early disease onset is defined as onset of symptoms before the age of 25 years (Harding, 1983). Although 25 years may serve as a general cut-off between early and late disease onset, autosomal recessive disorders may occasionally start much later, in some instances even after the age of 50 years (Dürr *et al.*, 1996; Filla *et al.*, 1996; Saviozzi *et al.*, 2002).

Table 46.3 gives a list of autosomal recessive ataxias along with the laboratory tests that allow to establish a definite diagnosis. For FRDA and autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS), genetic tests are established (Campuzano *et al.*, 1996; Mercier *et al.*, 2001). In abetalipoproteinemia, ataxia with isolated

Table 46.3. Laboratory tests in autosomal recessive ataxias

Disorder	Laboratory test
Friedreich's ataxia (FRDA)	intronic GAA expansion of frataxin gene
Ataxia telangiectasia (AT)	α -fetoprotein hypersensitivity of fibroblasts and lymphocytes to ionizing radiation mutation of ATM gene
Autosomal recessive ataxia with oculomotor apraxia (AOA)	albumin (?)
Abetalipoproteinemia	vitamin E lipid electrophoresis
Ataxia with isolated vitamin E deficiency (AVED)	vitamin E
Refsum's disease	phytanic acid
Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS)	sacsin mutations
Cerebrotendinous xanthomatosis	cholestanol
Autosomal recessive spinocerebellar ataxia, non-Friedreich type 1 (SCAR1)	creatine kinase (?) α -fetoprotein (?)
Autosomal recessive ataxia with hearing impairment and optic atrophy	not available
Infantile-onset spinocerebellar ataxia (IOSCA)	not available
Early-onset cerebellar ataxia (EOCA)	not available

vitamin E deficiency (AVED), Refsum's disease and cerebrotendinous xanthomatosis, the affected genes are known, but – due to considerable allelic heterogeneity – the diagnosis still relies on the demonstration of characteristic biochemical abnormalities. In three other recessive ataxias, autosomal recessive non-Friedreich spinocerebellar ataxia type 1 (SCAR1), autosomal recessive ataxia with hearing impairment and optic atrophy (Bomont *et al.*, 2000), and infantile-onset spinocerebellar ataxia (IOSCA) (Lonnqvist *et al.*, 1998), the chromosomal loci are known, but the affected genes and mutations remain unidentified. In these disorders, a definite diagnosis can only be made by a linkage analysis of the family. In two disorders, autosomal recessive ataxia with oculomotor apraxia (AOA) (Moreira *et al.*, 2001; Date *et al.*, 2001) and SCAR1 (Bomont *et al.*, 2000; Nemeth *et al.*, 2000), biochemical abnormalities have been reported (decrease of albumin in AOA; increase of creatine kinase and α -fetoprotein in SCAR1), but it is not known how reliable these tests are.

A particular diagnostic problem are patients with oculomotor apraxia. Oculomotor apraxia denotes a peculiar difficulty to initiate saccades. In contrast to ophthalmoplegia,

Table 46.4. Mutations, genetic tests and clinical phenotypes of spinocerebellar ataxias (SCA)

Disorder	Mutation	Genetic test	Gene product	Clinical phenotype
SCA1	translated CAG repeat expansion	available	ataxin-1	ataxia, pyramidal signs, neuropathy, dysphagia, restless legs syndrome
SCA2	translated CAG repeat expansion	available	ataxin-2	ataxia, slow saccades, neuropathy, restless legs syndrome
SCA3 (Machado-Joseph disease)	translated CAG repeat expansion	available	ataxin-3	ataxia, pyramidal signs, ophthalmoplegia, neuropathy, dystonia, restless legs syndrome
SCA4	unknown	not available	unknown	ataxia, neuropathy
SCA5	unknown	not available	unknown	almost pure cerebellar ataxia
SCA6	translated CAG repeat expansion	available	calcium channel subunit (CACNA1A)	almost pure cerebellar ataxia
SCA7	translated CAG repeat expansion	available	ataxin-7	ataxia, ophthalmoplegia, visual loss
SCA8	untranslated CTG repeat expansion	available	unknown	almost pure cerebellar ataxia
SCA10	intronic ATTCT repeat expansion	available	unknown	ataxia, epilepsy
SCA11	unknown	not available	unknown	almost pure cerebellar ataxia
SCA12	untranslated CAG repeat expansion	available	phosphatase subunit (PP2A-PR55R)	ataxia, tremor
SCA13	unknown	not available	unknown	ataxia, mental retardation
SCA14	unknown	not available	unknown	ataxia, myoclonus
SCA15	unknown	not available	unknown	almost pure cerebellar ataxia
SCA16	unknown	not available	unknown	almost pure cerebellar ataxia
SCA17	translated CAG repeat expansion	available	TATA binding protein	ataxia, dystonia
SCA18	unknown	not available	unknown	ataxia, neuropathy
SCA19	unknown	not available	unknown	ataxia, myoclonus, tremor

eye movements can be completed in the full range when given sufficient time. When patients intend gaze shifts, they often move their head into the desired direction causing a reflexory, tonic drift of the eyes away from the target. The target is then refixated with considerable delay. Oculomotor apraxia may occur as an isolated problem in a congenital disorder named Cogan's syndrome. It also occurs in a number of ataxia disorders, namely AT, AOA and SCA1R. SCA2 patients with slow saccades (Table 46.4) may have similar problems when attempting to shift their gaze (Bürk *et al.*, 1999). Since reliable genetic and biochemical tests for AOA and SCA1R are not established, the diagnosis may remain uncertain in patients with ataxia and oculomotor apraxia in whom AT and SCA2 are excluded.

The diagnosis early-onset cerebellar ataxia (EOCA) should be reserved for ataxia disorders with an onset before the age of 25 years, in which a definite diagnosis cannot be made (Harding, 1981; Klockgether *et al.*, 1991).

Autosomal dominant inheritance

Presence of ataxia in subsequent generations is highly suggestive of autosomal dominant inheritance, provided that all affected family members have the same disease and that the disease is transmitted by both sexes. In cases in which other affected family members are not available for personal examination, it may be difficult to decide whether they really suffer from the same disease or from an unrelated medical problem. In patients with proven or suspected autosomal dominant mode of inheritance, molecular genetic tests for SCA mutations should be performed (Pulst *et al.*, 1996; Kawaguchi *et al.*, 1994; Zhuchenko *et al.*, 1997). Although the various SCA mutations are associated with characteristic clinical phenotypes, there is large clinical overlap between the different mutations (Bürk *et al.*, 1996; Filla *et al.*, 1996; Schöls *et al.*, 1997). Table 46.4 gives an overview of all known SCA mutations, the available genetic tests and the major features of the respective clinical phenotypes. There is large clinical overlap between

the different SCA mutations precluding a definite clinical diagnosis of a particular SCA mutation. The only exception are patients from families with dominant ataxia and retinal degeneration. This clinical phenotype is almost invariably associated with the SCA7 mutation (Giunti *et al.*, 1999). Tests for the most frequent mutations, SCA1, SCA2, SCA3 and SCA6 are offered by many laboratories.

If tests for SCA mutations are negative in a patient with dominant ataxia, dentatorubral-pallidoluysian atrophy (DRPLA) (Koide *et al.*, 1994) or Gerstmann-Sträussler-Scheinker disease (GSS), a dominantly inherited transmissible spongiform encephalopathy (Hsiao *et al.*, 1989), should be considered as a differential diagnosis. Both disorders have a characteristic clinical presentation that allows to distinguish them from SCA mutations in most cases.

In approximately 30 to 40% of all dominant ataxia families, all presently available molecular tests are negative. These families probably suffer from a yet unidentified SCA mutation (Riess *et al.*, 1997; Moseley *et al.*, 1998).

Early-onset sporadic disease

As discussed earlier, most cases of early-onset sporadic ataxia are manifestations of an autosomal recessive disorder. Thus, the diagnostic tests recommended for autosomal recessive ataxias should be also applied to young patients with sporadic ataxia. In rare instances, sporadic ataxia starting in young age may be due to maternal inheritance (mitochondrial disease), X chromosomal inheritance (adrenoleukodystrophy) (Kurihara *et al.*, 1993; Takada *et al.*, 1987; Kusaka & Imai, 1992) or autosomal dominant inheritance (spinocerebellar ataxias, SCA). All these disorders may well start before the age of 25 years. Autosomal dominant ataxia may occur as a sporadic disease if it is due to a novel mutation. In addition, the family history may be uninformative, if parents died before manifestation of the disease, or fatherhood may be false.

Furthermore, early-onset sporadic ataxia may occur as an acquired disease (symptomatic ataxia) without any genetic background. The most frequent type of symptomatic ataxia in young people is cerebellar encephalitis associated with viral infections (Klockgether *et al.*, 1993). Although ataxia due to paraneoplastic cerebellar degeneration typically starts in adulthood, paraneoplastic cerebellar degeneration may affect children with neuroblastoma and young patients with malignant lymphoma. All other types of symptomatic ataxias are infrequent before the age of 25 years.

Adult-onset sporadic disease

The adult-onset sporadic ataxias can be divided into three major groups. The first group comprises the symptomatic

ataxias that are due to identifiable exogenous causes. The second group includes hereditary ataxias presenting as sporadic adult-onset disorders. The third group are non-hereditary degenerative ataxias such as the cerebellar type of MSA.

Symptomatic ataxias

Symptomatic ataxia denotes all types of acquired disease in which a non-genetic cause can be identified. Usually, symptomatic ataxias start after the age of 25 years, although there are some exceptions that I have discussed above. The most frequent cause of symptomatic ataxia are chronic alcoholism (Timmann & Diener, 2000), other toxic causes (anticonvulsant drugs, antineoplastic drugs, lithium salts) (Botez *et al.*, 1988), malignant disease (paraneoplastic cerebellar degeneration) (Dalmau *et al.*, 1999), vitamin deficiency (vitamin B1, B12, E) (Harding *et al.*, 1982; Victor *et al.*, 1971), other metabolic causes (hypothyroidism) (Hammar & Regli, 1975), cerebellar encephalitis (Klockgether *et al.*, 1993; Connolly *et al.*, 1994), Miller Fisher syndrome (Berlit & Rakicky, 1992), immune-mediated cerebellar damage associated with anti-GAD (Abele *et al.*, 1999; Honnorat *et al.*, 2001), antigliadin (Hadjivassiliou *et al.*, 2002), or antithyroid antibodies (Selim & Drachman, 2001) and less frequently heat stroke. In most cases, history and clinical examination give important hints at the cause of symptomatic ataxia. Nevertheless, there are a number of diagnostic tests that are recommended in the work-up of a patient with suspected symptomatic ataxia (Table 46.5).

Genetic causes of sporadic adult-onset ataxia

Although autosomal recessive ataxias usually start before the age of 25 years, there are exceptional cases with much later disease onset. For example, age of onset is beyond 25 years in about 15% of FRDA patients (Dürr *et al.*, 1996; Filla *et al.*, 1996; Klockgether *et al.*, 1993). Since recessive ataxias occur sporadically in the majority of cases, some patients with adult-onset sporadic ataxia will suffer from an autosomal recessive ataxia with late disease onset. In a survey of 112 patients with sporadic adult-onset ataxia, we recently found 5 patients with the FRDA mutation (Abele *et al.*, 2002). Similarly, negative family history does not exclude autosomal dominant ataxia. Family history may be uninformative because an affected parent died before onset of symptoms. Not infrequently, this is the case for SCA6 because the age of onset is relatively late so that affected parents may have died before ataxia became apparent (Matsumura *et al.*, 1997; Schöls *et al.*, 1998). In addition, negative family history may be due to false fatherhood or to novel mutations. In our own study of 112 patients we

Table 46.5. Diagnostic tests in symptomatic ataxias

Disorder	Diagnostic test
Alcoholic cerebellar degeneration	liver enzymes, carbonyl-deficient transferrin, mean corpuscular volume (MCV)
Other toxic causes	serum levels of lithium/anticonvulsant drugs
Paraneoplastic cerebellar degeneration	antineuronal antibodies (anti-Hu, anti-Yo, anti-Ri, anti-TR) repeated search for occult neoplastic disease
Vitamin deficiency	vitamin B1, B12, E vitamin B12 absorption test (Schilling test)
Hypothyroidisms	thyroid hormones
Cerebellar encephalitis	CSF examination serological test for viral infections
Miller Fisher syndrome	CSF examination nerve conduction studies anti-GQ1B antibodies
Other immune-mediated ataxias	anti-GAD, -gliadin, -thyroid antibodies
Heat stroke	not available

Table 46.6. Disorders that may cause ataxia and myoclonus

Disorder	Diagnostic test
Lafora disease(65)	Lafora bodies in skin, muscle and liver biopsy mutation of EPM2A gene
Progressive myoclonus epilepsy of Unverricht-Lundborg type (EPM1)	mutation of cystatin B gene
Myoclonus epilepsy with ragged red fibers (MERRF)	ragged red fibers in muscle biopsy 8344 point mutation of mitochondrial tRNA ^{Lys} gene
Sialidosis type 1	retinal-macular cherry-red spot sialooligosaccharides in urine neuraminidase activity in white blood cells mutation of neuraminidase gene
Neuronal ceroid lipofuscinosis (infantile, late infantile, juvenile, adult forms)(66)	ultrastructural analysis of lymphocytes and skin (eccrine sweat gland epithelial cells) different gene mutations (CLN1-3)
Dentatorubral-pallidoluysian atrophy (DRPLA)	CAG repeat expansion of DRPLA gene
Early-onset cerebellar ataxia with myoclonus (Ramsay Hunt syndrome)	not available

found SCA2 mutations in 1, SCA3 in 2 and SCA6 mutation in 7 patients (Abele *et al.*, 2002).

In our study of 112 patients, the percentage of sporadic ataxia patients with positive genetic tests was 13% (Abele *et al.*, 2002). In other studies, the frequency of positive genetic tests in apparently sporadic ataxia patients ranged from 2% to 22% (Moseley *et al.*, 1998; Matsumura *et al.*, 1997; Schöls *et al.*, 2000; Pujana *et al.*, 1999).

Sporadic degenerative ataxia disorders

After all known symptomatic and genetic causes have been ruled out a group of sporadic adult-onset ataxia patients remains in whom a sporadic neurodegenerative disease (comparable to sporadic amyotrophic lateral sclerosis or idiopathic Parkinson's disease) is assumed. In 1981, Harding reported a series of 36 patients with sporadic late-onset ataxia of unknown etiology for which she coined the term idiopathic cerebellar ataxia (IDCA) (Harding, 1981). Since then, various genetic and non-genetic causes of late-onset sporadic ataxia have been identified some of which may have been responsible for the disease in Harding's patients. In addition, it has been found that a considerable portion of IDCA patients suffered from MSA (Quinn, 1989; Wenning *et al.*, 1994). In our above mentioned study of 112 adult-onset ataxia patients there was clinical evidence of MSA in 29%, while the disease remained unexplained in 58%. For this latter group, the designations IDCA or alternatively sporadic adult-onset ataxia of unknown origin may be used. Compared with MSA, patients with sporadic adult-onset ataxia of unknown origin have a more favorable prognosis (Abele *et al.*, 2002).

Rapid disease progression

Most types of hereditary and non-hereditary ataxias are characterized by an insidious onset and continuous disease progression within years. Sudden disease onset and rapid progression are suspicious of focal cerebellar disease. Nevertheless, a number of non-focal cerebellar disorders may cause ataxia with subacute onset and rapid deterioration. These disorders include cerebellar encephalitis associated with viral infection (Klockgether *et al.*, 1993), Miller Fisher syndrome (Berlit & Rakicky, 1992), paraneoplastic cerebellar degeneration (Dalmau *et al.*, 1999), transmissible spongiform encephalopathy, Wernicke's encephalopathy (Victor *et al.*, 1971) and vitamin B12 deficiency.

Myoclonus

Myoclonus is associated with progressive ataxia in a number of disorders. Often, myoclonus and ataxia are part of a larger syndrome that is characterized by ataxia,

Table 46.7. Disorders that may cause ataxia and retinal degeneration

Disorder	Ocular disorder	Laboratory test
Abetalipoproteinemia	retinitis pigmentosa (predominantly of posterior fundus)	vitamin E lipid electrophoresis
Refsum's disease	retinitis pigmentosa posterior subcapsular cataracts	phytanic acid
Ataxia with isolated vitamin E deficiency (AVED)	retinitis pigmentosa	vitamin E
Neuronal ceroid lipofuscinosis (infantile, late infantile, juvenile, adult forms)	retinitis pigmentosa	ultrastructural analysis of lymphocytes and skin (eccrine sweat gland epithelial cells) different gene mutations (CLN1–3)
Sialidosis type 1	retinal-macular cherry-red spot	sialooligosaccharides in urine neuraminidase activity in white blood cells mutation of neuraminidase gene
Spinocerebellar ataxia type 7 (SCA7)	macular degeneration	CAG expansion of SCA7 gene
Cockayne syndrome	retinal dystrophy	not available

myoclonus, epilepsy and progressive dementia. This syndrome is known as progressive myoclonus epilepsy (PME) (Berkovic *et al.*, 1993). In patients with ataxia and accompanying myoclonus all known causes of PME should be considered, even if epilepsy and cognitive disturbances are not prominent. Table 46.6 gives a list of disorders that may cause PME along with the appropriate diagnostic tests. According to general experience, there is a substantial number of patients in whom careful diagnostic work-up will not result in a definite diagnosis. In most of these patients, epilepsy and dementia are mild or absent. These patients should be diagnosed as early-onset cerebellar ataxia with myoclonus (Harding, 1983). This descriptive term seems to be more appropriate than the traditional term Ramsay Hunt syndrome (Marseille Consensus Group, 1990).

Retinal degeneration

Symptoms of retinal degeneration include slowly progressive visual loss and poor night vision. Peripheral retinal degeneration causes constriction of visual fields to the extent of gun-barrel vision, while macular degeneration affects central vision and visual acuity. Progressive visual loss in patients with ataxia requires an ophthalmological examination with detailed funduscopy followed by a number of ancillary investigations (fluorescein retinography, electroretinogram). Table 46.7 gives a list of disorders that may cause retinal degeneration in association with progressive ataxia.

Table 46.8. Specific treatment for ataxia disorders

Disorder	Treatment
Friedreich's ataxia (FRDA)	idebenone (?)
Abetalipoproteinemia	vitamin E supplementation
Ataxia with isolated vitamin E deficiency (AVED)	vitamin E supplementation
Refsum's disease	dietary restriction of phytanic acid
Cerebrotendinous xanthomatosis	chenodeoxycholate, simvastatin
Alcoholic cerebellar degeneration	alcohol withdrawal, treatment for alcoholism, vitamin B1
Ataxia due to other toxic causes	withdrawal of toxic compounds
Vitamin deficiency	vitamin supplementation
Hypothyroidisms	thyroid hormone supplementation
Miller Fisher syndrome	i.v. immunoglobulins

Management of ataxia patients

Although a careful diagnostic work-up allows the cause of most ataxia disorders to be identified, rational treatment approaches are not available for all. Nevertheless, there are a number of ataxia disorders for which specific therapies are available (Klockgether *et al.*, 1996). An overview of these therapies is given in Table 46.8.

In many ataxia disorders, only supportive treatment is possible. In general, it is assumed that physiotherapy and speech therapy are helpful in ataxia disorders. The goal should be to maintain the highest possible level of autonomy, to cope with physical disability and to prevent secondary complications. With progression of the disease many patients will require walking aids and a wheelchair.

It has been repeatedly claimed that drugs that increase neurotransmission at central 5-HT receptors temporarily improve cerebellar ataxia (Trouillas *et al.*, 1995). Three recent studies investigated the antiataxic effect of the anxiolytic 5-HT_{1A} receptor agonist buspirone. Results of an open-label study of 20 patients with different forms of degenerative ataxia suggested an antiataxic action of buspirone at a dose of 30–60 mg per day (Lou *et al.*, 1995). Efficacy of buspirone was confirmed in a randomized, placebo-controlled study of 19 patients with ataxia due to cerebellar cortical atrophy (Trouillas *et al.*, 1997). In contrast, another study did not report a favorable effect of buspirone in ataxia (Hassin-Baer *et al.*, 2000). In my own experience, the efficacy of antiataxic drugs is low, and only very few patients really benefit from them.

There are numerous neurological and non-neurological symptoms that may occur in association with certain ataxia disorders. Well-known examples are cardiomyopathy and diabetes mellitus in FRDA and autonomic failure in MSA. These accompanying symptoms require conventional medical and neurological treatment.

Autosomal dominant cerebellar ataxia

Henry L. Paulson

Department of Neurology, University of Iowa Hospitals and Clinics, IA, USA

This review discusses clinical and genetic features of dominantly inherited ataxia. In addition, potential pathogenic mechanisms are discussed with a special focus on the polyglutamine disorders, since most is known about this group of diseases.

Classification of ADCA

Most adult onset hereditary ataxias are dominantly inherited. Harding (1993) clinically divided autosomal dominant cerebellar ataxia (ADCA) into four types, I through IV. Type I ADCA represents cerebellar disease accompanied by brainstem signs. ADCA type II is similar to type I but also includes retinopathy. ADCA type III represents later onset, “pure” cerebellar disease and ADCA type IV represents episodic ataxia.

A newer, favored classification for ADCA reflects the growing number of identified genetic loci, each of which is designated a specific spinocerebellar ataxia or SCA (Table 47.1). As SCAs are mapped to loci, they are assigned numbers – SCA1, SCA2 and so forth, currently up to 21 at the time of this writing. Most SCAs fall within Harding’s ADCA type I classification. There is considerable clinical overlap among the ADCA type I group, even within families. In contrast, the sole genetic cause of ADCA type II appears to be SCA7, the only dominant ataxia routinely accompanied by retinal degeneration. Most patients with SCA6 (and several rarer SCAs for which the gene defects have not been identified) manifest as a pure cerebellar syndrome and thus fall within ADCA III. Finally, ADCA type IV currently consists of two genetically identified forms of episodic ataxia (EA), EA-1 and EA-2, caused by mutations in a potassium and calcium channel respectively. Additional, less well-characterized loci for episodic ataxia also exist.

As we learn more about the clinical, radiographic and pathological features of each genetic form of ataxia, and particularly as we move toward rational therapies based on defined molecular defects, these disorders should be identified by their SCA, not ADCA, designation.

Molecular mechanisms of ADCA

Dynamic repeat expansions cause most adult onset ataxias

Classification of late-onset ataxias was formerly confusing due to their highly variable manifestations. Adding to the confusion was the fact that many late-onset ataxias show anticipation – the trend toward worsening severity in successive generations. Anticipation and disease variability, we now know, are explained by the remarkable genetic defect underlying most late-onset ataxias: dynamic expansions of simple sequence DNA repeats (Cummings & Zoghbi, 2000). In most cases these are triplet repeat expansions, but tetranucleotide, pentanucleotide and dodecanucleotide repeat expansions have also been identified. Figure 47.1 shows a gene schematic illustrating where the nine known ataxia-causing expanded repeats reside in the gene. All but one of these, Friedreich ataxia, are dominantly inherited. As discussed below, precisely how a repeat expansion causes disease differs depending upon at least three factors: what kind of repeat it is, where it resides in the gene, and what the gene’s function is. The single largest category consists of diseases caused by a polyglutamine-encoding CAG repeat.

CAG repeat/polyglutamine ataxias

At least nine diseases are due to a CAG repeat that encodes an expanded polyglutamine tract in the disease protein

Table 47.1. Polyglutamine diseases

Huntington disease
Spinobulbar muscular atrophy (Kennedy disease)
Dentatorubral-pallidoluysian atrophy
Spinocerebellar ataxia type 1
Spinocerebellar ataxia type 2
Machado-Joseph disease/Spinocerebellar ataxia type 3
Spinocerebellar ataxia type 6
Spinocerebellar ataxia type 7
Spinocerebellar ataxia type 17

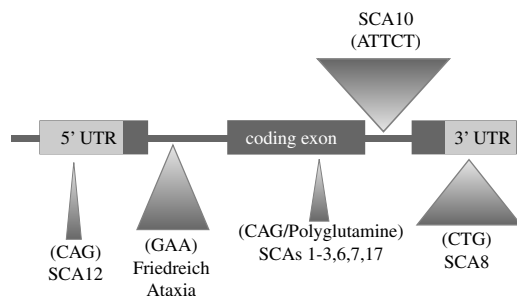

Fig. 47.1 Schematic of a gene indicating the repeat sequence for the known ataxia-causing dynamic repeats and their place of occurrence within the respective disease genes. Range of expansion size is approximated by the width of the triangle. UTR = untranslated regions. Introns and exons are denoted by lines and boxes, respectively.

(Table 47.1). These polyglutamine disorders include at least six dominantly inherited SCAs (types 1, 2, 3, 6, 7 and 17) as well as Huntington's disease (HD), DRPLA and spinobulbar muscular atrophy (SBMA) (Cummings & Zoghbi, 2000). All are progressive neurodegenerative diseases in which the disease protein apparently misfolds, resulting in the formation of abnormal protein inclusions inside neurons. Longer repeats cause more severe and typically earlier onset disease. Polyglutamine expansion thus confers upon the disease protein a novel, dominant neurotoxic property that increases in potency with longer repeats (for review see Taylor *et al.*, 2002; Zoghbi, 2000).

Precisely how expanded polyQ proteins cause neuronal dysfunction and cell death is still not known. Currently, several models of pathogenesis are supported by research: (i) perturbations in protein homeostasis; (ii) dysregulation of gene expression; and (iii) aberrant processing of proteins, leading to the production of toxic fragments of the protein. These are not mutually exclusive hypotheses. Indeed, elements of all three may contribute to disease mechanisms in different polyQ diseases.

Of these three models of pathogenesis, evidence most strongly supports the view that perturbations in protein homeostasis are central to disease. Although the hallmark protein inclusions seen in polyQ diseases may not be directly toxic, they do argue for a fundamental problem in protein folding and clearance. In many cellular and animal models, cellular components that ensure protein quality control have been implicated in polyQ diseases (for review see Bonini, 2002; Muchowski, 2002; Sherman & Goldberg, 2001). For example, heat shock protein molecular chaperones consistently turn up as suppressors of polyQ toxicity in vitro and in vivo. Chaperones capable of suppressing toxicity do so in a manner that alters the solubility of the mutant protein (Bonini, 2002; Chan *et al.*, 2000). One possibility is that suppressor chaperones directly bind abnormal polyglutamine protein and thereby inhibit the formation of toxic monomers, oligomers or protofibrils – which of these species is the actual toxic factor is unknown. The ability to model polyglutamine protein folding in the test tube now allows this to be tested experimentally.

Evidence for dysregulation of gene expression (e.g. Hughes, 2002) has started to build in the past few years. It is still too early, however, to gauge the full significance of these findings. For example, do the observed gene expression changes reflect a primary effect on specific transcription factors, an indirect effect through other cellular pathways, or both? It is clear that at least two polyQ disease proteins normally play central roles in controlling gene expression in the cell. Among the polyQ ataxias, the SCA17 disease protein, TBP, is an essential part of the basal transcription complex. In SCA17, an intrinsic defect in TBP function in transcription may well contribute to pathogenesis. In other polyQ diseases, aberrant protein interactions between the disease protein and various transcription factors or cofactors may disrupt the highly regulated expression of neuronal genes, with deleterious consequences for the neuron.

The toxic fragment hypothesis of polyQ diseases has been studied most extensively in the non-ataxia members of the group: HD, DRPLA and SBMA. For these diseases, a strong, but not foolproof, case can be made that proteolytic cleavage of the disease protein occurs as part of pathogenesis. Much of the work has focused on caspases as the culprit proteases, but recent studies in HD suggest that calpains and aspartic proteases also cleave this disease protein. Data are less well developed and convincing for the six polyQ ataxias. Indeed, in SCA1 there is no evidence that the disease protein ataxin-1 becomes cleaved.

The fact that polyQ diseases are clinically distinct disorders suggests that the individual disease proteins, dissimilar except for their polyQ tract, contribute in unique ways

Fig. 47.2 Disease proteins in the polyglutamine ataxias are shown here as boxes proportionate to their size. Polyglutamine disease proteins differ greatly in size and sequence (here denoted by boxes of various shades of gray). The position of the polyglutamine domain (white box), and the size of the expansion differ for each protein (disease repeat range is shown in parentheses). The protein's function is well established for only two of the ataxia-causing polyglutamine proteins: the SCA17 disease protein, the TATA binding protein, is a critical component of the basal transcription machinery, and the SCA6 protein is an alpha subunit of a voltage-dependent calcium channel. These two also represent the shortest and longest proteins in this group (339 and 2320 amino acids, respectively). In SCA6, the four multi-transmembrane domains are shown (S1–S4).

to pathogenesis in each disease (Fig. 47.2). Even though the diseases likely share a common pathogenesis based on biochemical properties of expanded polyglutamine, the individual proteins almost certainly have divergent functions. Likewise, they probably interact with different, though overlapping, sets of proteins. This suggests that the particular protein context surrounding polyQ dictates many of the disease-specific characteristics of neuronal dysfunction and degeneration in each disease. An extreme case is SCA6, which may differ mechanistically from other polyglutamine diseases based on the fact that the disease protein is a transmembrane, voltage-dependent calcium channel (all other polyQ disease proteins are soluble proteins). In the context of this calcium channel, expanded polyglutamine causes disease with much smaller expansions than are required for the other diseases. Direct changes in ion channel properties may contribute to the cerebellar deficits in this disorder (e.g. Piedras-Renteria *et al.*, 2001).

Researchers have begun to identify compounds and genes that suppress polyQ aggregation and/or toxicity, and the availability of animal models for most polyQ diseases should speed preclinical testing of such genes and compounds. One hopes, of course, that a protective pharmacological therapy for polyQ diseases will arise from such studies. Another direct and simple-minded approach to therapy is based on the premise that, whatever the

pathogenic mechanism may be, the mutant protein is clearly a bad player; eliminating its expression, therefore, would be therapeutically useful. The recent discovery that small interfering RNA (siRNA) can be used to silence target genes with exquisite sequence specificity raises the possibility that this new technology might be harnessed to knock down expression of polyQ disease alleles (Miller *et al.*, 2003; Xia *et al.*, 2002).

Ataxias due to noncoding repeat expansions

At least three dominant ataxias are caused by repeats that are not translated into protein. One of these, SCA8, is a CTG repeat transcribed into RNA in the brain. Similarities between the SCA8 repeat and the two repeats causing myotonic dystrophy suggest that this repeat may act in a dominant manner at the RNA level to alter mRNA processing (Ranum *et al.*, 1994). Transgenic mice containing the SCA8 mutation show abnormalities in central nervous system function and premature death (Moseley *et al.*, 2002). Further studies of this mouse model should help define the molecular mechanisms of SCA8. In SCA10, the mutation is a huge ATTCT repeat, larger than any other repeat expansion described to date (Matsuura *et al.*, 2000). The repeat resides in the ninth intron of the *E46L* gene, which is highly expressed in brain. Here, too, a dominant RNA effect is one of several possibilities for its mechanism of action. A third, much smaller repeat is the CAG expansion in SCA12, residing in the 5' region of the *PPP2R2B* gene (Holmes *et al.*, 1999). This modest expansion has been proposed to alter the expression of the PP2R2B gene product, a regulatory subunit for protein phosphatase 2A. Changes in activity of this phosphatase may have deleterious consequences for neurons, though this is purely speculative.

The spinocerebellar ataxias

SCAs are characterized by progressive ataxia with varying degrees of bulbar dysfunction, ophthalmoparesis, pyramidal and extrapyramidal signs, optic atrophy and dementia. Pathological studies show variable spinocerebellar degeneration even in the same SCA. Three SCAs (SCA2, MJD/SCA3 and SCA6) are the most common, together accounting for approximately half of all affected families worldwide.

As of this writing, at least 19 SCAs have been mapped to chromosomal loci, and the genetic defects have been identified in at least 10 (Table 47.2). Thus far, all but one are dynamic repeat expansions. SCA14 is the sole exception, which is instead caused by point mutations

Table 47.2. Spinocerebellar ataxias

Disease	Locus	Mutation	Associated features
SCA1	6p22.3	CAG/polyQ	ophthalmoparesis, pyramidal and extrapyramidal findings
SCA2	12q24.12	CAG/polyQ	slow saccades, hyporeflexia, dementia
MJD/SCA3	14q32.12	CAG/polyQ	bulging eyes, ophthalmoparesis, spasticity, neuropathy, lingual/facial fasciculations, DOPA-responsive parkinsonism
SCA4	16q22.1	unknown	early areflexia, sensory neuropathy
SCA5	11p11–q11	unknown	milder disease than SCAs1–4
SCA6	19p13.2	CAG/PolyQ	late onset, slow course, often pure cerebellar, gaze-evoked and vertical nystagmus
SCA7	3p14.1	CAG/polyQ	retinal degeneration
SCA8	13q21.33	CTG	bulbar findings, sensory neuropathy
SCA10	22q13	ATTCT	seizures
SCA11	chr15	unknown	mild disease
SCA12	5q32	CAG	tremor, late dementia
SCA13	19q13.3–13.4	unknown	motor dysfunction, mental retardation
SCA14	19q13.4	PKRGC gene	axial myoclonus
SCA15	undetermined	unknown	pure ataxia, mild
SCA16	8q23–24.1	unknown	head tremor
SCA17	6q27	CAG/poly	dementia, dystonia
SCA18	7q31–32	unknown	sensory/motor neuropathy with ataxia
SCA19	1p21–q21	unknown	mild, myoclonus
SCA21	7p21.3–p15.1	unknown	hyporeflexia, akinesia, rigidity

in the PRKCG gene (Chen *et al.*, 2003). As the number keeps climbing, it becomes increasingly clear that different mutations in dissimilar genes can cause a very similar, in some cases indistinguishable, clinical picture of progressive ataxia. Moreover, as is true of other repeat expansion diseases, the phenotype can vary greatly, primarily due to differences in repeat size. Because of this variability and phenotypic overlap, distinguishing the various forms of SCA is difficult on clinical grounds alone. There are, however, clues to be gained from the neurological exam. For instance, the patient with remarkably slowed saccades is most likely to have SCA2; a mild form of disease characterized by truncal ataxia and nystagmus might be SCA6; the presence of retinopathy strongly suggests SCA7; and dementia suggests that SCA2 or SCA17 may be the cause.

Here, features of each of the SCAs identified at the time of this writing will be discussed. Elsewhere in this volume, Klockgether discusses more thoroughly the diagnostic approach to ataxia. For an ataxic patient with slowly progressive disease and a positive family history, commercial testing for SCA mutations is appropriate for at least two reasons. First, a positive test result eliminates the need for other more expensive, less definitive tests. Second, knowledge of the genetic basis can be empowering to the patient and his or her family because an element of uncertainty has been removed. Undergoing genetic testing, however, is a patient's personal decision that should only be made after informed and thorough counseling by a doctor or genetic counselor.

SCA1

The first genetically identified dominant ataxia (Orr *et al.*, 1993), SCA1 is less common than several other SCAs. It is the best understood, however, due to the pioneering research of Drs. Orr, Zoghbi and colleagues (Zoghbi & Orr, 2000). Neuropathological findings include neuronal loss in the brainstem and cerebellum (principally Purkinje cells), and degeneration of spinocerebellar tracts. Atrophy is pronounced in the cerebellar cortex, ventral pons, middle cerebellar peduncles and inferior olives.

SCA1 begins as a gait disorder and evolves to severe four-limb ataxia with dysarthria. Most patients are wheelchair-bound within 15 years of onset. Dysphagia can present early and becomes life threatening. In many patients, early nystagmus and ocular dysmetria progress to ophthalmoparesis. Variable degrees of lower limb amyotrophy, spasticity and choreoathetosis may be seen. Intellect remains largely intact until late stages of disease, when behavioral changes and a frontal lobe-like syndrome may occur. As with other polyQ diseases, SCA1 shows phenotypic variability and anticipation (Ranum *et al.*, 1994).

SCA1 is caused by an expanded CAG repeat in the *SCA1* gene that encodes polyQ in the disease protein, ataxin-1. The SCA1 triplet repeat is 6 to 39 repeats long in normal individuals, with normal repeats greater than 21 being interrupted by 1–4 histidine encoding CAT repeats. In contrast, disease alleles are uninterrupted stretches of 39 to 82 CAG repeats. As with other polyglutamine diseases, longer repeats strongly correlate with earlier onset disease. Mutant ataxin-1, which is an RNA binding protein, is prone to misfold and form inclusions in the nucleus of specific neurons. Nuclear localization, but not inclusion formation, appears to be critical for pathogenesis in SCA1.

SCA2

Initially described in a large Cuban family, SCA2 is one of the most common dominant ataxias, displaying a highly

variable phenotype (Cancel *et al.*, 1997). Most often it is characterized by ataxia, dysarthria, slow saccades, neuropathy and little or no corticospinal or extrapyramidal signs (though parkinsonism has been reported in some cases, Shan *et al.*, 2001). Extremely slow saccades are common but not pathognomonic. Areflexia, facial myokymia and dementia are also fairly common. Radiological and pathological studies usually show olivopontocerebellar atrophy.

Three separate groups identified the *SCA2* disease gene in 1996, confirming that, as many suspected, it is a polyQ disease (Imbert *et al.*, 1996; Pulst *et al.*, 1996; Sanpei *et al.*, 1996). Normal alleles are between 15 and 32 repeats in length, and expanded alleles are ~34 to 77 repeats in length (Geschwind *et al.*, 1997; Imbert *et al.*, 1996; Pulst *et al.*, 1996; Sanpei *et al.*, 1996; Schols *et al.*, 1997). There exists a “zone of reduced penetrance” (32–34 repeats) within which not all individuals develop signs of disease in their lifetime. Compared to most other polyQ diseases, the range of pathogenic alleles in *SCA2* is shifted toward smaller repeats. The disease protein, ataxin-2, is a cytoplasmic protein that is highly conserved in evolution and has predicted RNA binding motifs. The protein is thought to play a role in development and may participate in RNA processing or distribution within neurons.

Machado-Joseph disease/ SCA3

MJD/SCA3 is probably the most common dominantly inherited ataxia in the world (Durr *et al.*, 1996; Maciel *et al.*, 1995; Matilla *et al.*, 1995; Schols *et al.*, 1995). MJD was originally described in families of Portuguese Azorean descent. Soon after the mutation in MJD was identified, scientists discovered that *SCA3*, a dominant ataxia characterized in French and German families, was due to the same mutation. Though the official HUGO designation is MJD, some (including this writer) prefer to call the disease MJD/SCA3.

Most often, MJD/SCA3 begins as a progressive ataxia accompanied by difficulties with eye movements, speech and swallowing. Neuropathological findings include degeneration of cerebellar afferent and efferent pathways, pontine and dentate nuclei, substantia nigra and subthalamic nucleus, globus pallidus, cranial motor nerve nuclei and anterior horn cells. The cerebral cortex, striatum, cerebellar cortex and olivary neurons tend to be spared.

As with other polyglutamine diseases, signs of MJD/SCA3 most frequently appear when patients are in their 30s or 40s, but may begin before age 10 or as late as age 60. The first symptom is usually gait ataxia. Within a few years, many younger patients show signs of progressive supranuclear ophthalmoparesis. Dysarthria, followed by dysphagia and dysphonia, occur. In somewhat less than a third of patients,

lid retraction and decreased blinking lead to characteristic “bulging eyes.” Facial fasciculations are more common in MJD/SCA3 than in most other SCAs. Eventually patients are terminally bedridden, but cognitive functions remain largely intact. MJD/SCA3 progresses over a 15- to 30-year period, resulting in death.

The phenotype can vary markedly even within a family, largely due to differences in repeat size. Younger onset patients, who typically have longer repeats, are more likely to show rigidity and dystonia. This dystonic form has been called Type 1 disease. The more common, adult onset ataxic form has been called Type 2 disease. Later onset patients (after age 40) are more likely to develop milder ataxia accompanied by peripheral neuropathy and motor neuron loss (so called Type 3 disease). In addition, some patients develop parkinsonism responsive to dopamine, referred to by some as Type 4 disease. There is little utility in labeling patients as any particular type, especially since there is no clear demarcation separating the types. The most variable feature of *SCA3* is the degree of peripheral involvement. Some patients will develop hyperreflexia while marked distal amyotrophy with areflexia occurs in others. Sensory disturbances occur frequently.

There are no pathognomonic MRI findings in MJD/SCA3. Abnormalities range from simple enlargement of the fourth ventricle to severe spinopontine atrophy sparing the olives. PET and SPECT have demonstrated decreased glucose metabolism and blood flow in brainstem structures, but the pattern does not reliably distinguish *SCA3* from other SCAs.

In 1994, Kakizuka and colleagues identified the mutation in MJD/SCA3 as a CAG repeat expansion in the *MJD1* gene on chromosome 14 (Srivastava AK *et al.*, 2001). This results in a polyQ expansion in the disease protein, ataxin-3, which recently has been shown to be a ubiquitin binding protein (Chai *et al.*, 2003; Donaldson *et al.*, 2003). The CAG/polyglutamine repeat is 12 to 42 repeats in normal alleles and ~60 to 84 repeats in disease alleles. This gap between normal and disease repeat length is greater for MJD/SCA3 than in any other polyQ disease. Testing for the expanded repeat is highly sensitive and specific, eliminating the need for other more expensive tests. A few individuals have been identified with intermediate size alleles (Taylor *et al.*, 2002; van Alfen N *et al.*, 2001) that are associated with restless leg syndrome and polyneuropathy (van Alfen *et al.*, 2001).

SCA4

In *SCA4*, progressive ataxia is accompanied by a sensory axonal neuropathy and pyramidal tract signs, but eye movements are preserved (e.g. Nagaoka *et al.*, 2000). The genetic defect has not been reported.

SCA5

SCA5 is characterized by pure cerebellar ataxia and dysarthria, with minimal shortening of lifespan. The genetic defect is unknown, but in the large Lincoln kindred maps to chromosome 11.

SCA6

Together with SCA2 and MJD/SCA3, SCA6 is one of the three most common dominant ataxias. In contrast to the other two, SCA6 represents a milder form of disease often manifesting as a “pure” cerebellar ataxia (e.g. Gomez *et al.*, 1997; Ikeuchi *et al.*, 1997). Characteristic features are a slowly progressive gait and limb ataxia, dysarthria, and nystagmus. The typical age at onset is around age 50 but ranges from less than 30 to greater than 70 years of age. Noncerebellar symptoms occur less frequently and may include decreased vibration and position sense and, later in disease, spasticity and hyperreflexia. Disease progresses more slowly than other SCAs, and is usually compatible with a normal lifespan.

In some respects, SCA6 is an exception to the general rules of polyQ disorders. First, the polyglutamine expansion (Zhuchenko *et al.*, 1997) is much smaller than in the other disorders: Normal SCA6 alleles range from 3 to 17 CAG repeats, and disease alleles are expanded to between 21 and 30 repeats. Thus, pathogenic SCA6 alleles fall within a range that, in other polyQ diseases, would represent normal alleles. Second, the disease protein is a membrane protein, a voltage-dependent calcium channel, whereas all other polyglutamine proteins are soluble. And third, there is only modest evidence for protein accumulation in disease tissue. These differences all suggest that the disease mechanism in SCA6 may differ from that in other polyQ diseases. The calcium channel gene responsible for SCA6 (*CACNA1A*) is also the defective gene in episodic ataxia type 2 and familial hemiplegic migraine. In these two diseases, the causative mutations are traditional, non-repeat mutations. This emphasizes the point that clinically distinguishable disorders can arise from different mutations in the same gene.

SCA7

SCA7 is distinguished from other SCAs by the presence of retinal degeneration. In a study of molecularly confirmed SCA7, the mean age at onset of visual failure was 22 years with a range from 1 to 45 years. Decreased visual acuity occurred in 83%, blindness in 28%, optic atrophy in 69% and pigmentary retinopathy in 43% of affected individuals. In most other respects, SCA7 resembles other SCAs characterized by ataxia and brainstem findings.

The defect is an expanded CAG/polyQ repeat in the *SCA7* gene, which encodes a novel protein, ataxin-7 (David *et al.*, 1997; Holmberg *et al.*, 1998). Expanded repeat size is highly variable, ranging from 34 to greater than 200 repeats, whereas normal alleles range from 7 to 17 repeats. Germline repeat instability is a common feature of polyQ diseases but is particularly impressive in SCA7, especially with paternal transmission. In some cases, this leads to massive expansions that cause systemic disease and abnormal brain development in infancy or may manifest even as embryonic lethality.

SCA8

The genetic defect in SCA8 was identified in 1999 by Ranum and colleagues (Koob *et al.*, 1999). It seems to be a trinucleotide repeat disease but, unlike the polyQ disorders, not a disease of protein misfolding. Affected individuals have an unstable CTG repeat expansion in the *SCA8* gene that is transcribed into RNA but not translated into protein. As mentioned earlier, the mechanism of pathogenesis is still unclear. Some individuals with very large SCA8 expansions do *not* develop disease, indicating that SCA8 repeat expansions either are not fully penetrant (which seems most likely) or the actual mutation lies elsewhere in the gene and is in linkage disequilibrium with the expansion (less likely). Commercial testing is available for the SCA8 repeat, but because of this uncertainty test results must be interpreted with caution (Sobrido *et al.*, 2001).

SCA8 clinically resembles most other SCAs: adult onset ataxia with variable brainstem signs. In a study of a seven-generation family, the main clinical symptoms were prominent gait and limb ataxia accompanied by abnormalities of swallowing, speech, and eye movements (Day *et al.*, 2000). In contrast to many other SCAs in which paternal transmission is more prone to result in further expansion of the repeat, there is marked *maternal* bias in SCA8 disease transmission. This may reflect contractions of the expanded repeat during spermatogenesis (Moseley *et al.*, 2000).

SCA10

Described in Mexican families, SCA10 is characterized by prominent cerebellar symptoms and seizures (Grewal *et al.*, 2002; Matsuura *et al.*, 2002). In 2000, Ashizawa and colleagues identified the genetic defect (Matsuura *et al.*, 2000) as a new type of dynamic repeat expansion – an extremely large expansion arising from a *pentanucleotide* (ATTCT) repeat in an intron of the *SCA10* gene, also known as *E46L*. Normally 10–22 ATTCT repeats in length, the repeat becomes grossly expanded in affected individuals, in some cases to several thousand repeats in length.

SCA10 is uncommon outside of families of Mexican descent (Matsuura *et al.*, 2002).

SCA11

This relatively mild form of ataxia, described in two British families, maps to chromosome 15. Mean age of onset is 25 but the disease is compatible with a normal life expectancy.

SCA12

Margolis and colleagues identified a CAG expansion in the 5' untranslated region of the *PPP2R2B* gene that encodes a regulatory subunit for protein phosphatase 2A (Holmes *et al.*, 1999). This CAG repeat expansion segregates with disease in multiple families, suggesting that it is indeed the causative mutation. SCA12 may be more common in India, but is otherwise rare (Srivastava *et al.*, 2001). Age at onset of ataxia ranges from 8 to 55 years, with other symptoms including arm and head tremor, paucity of movements and abnormal eye movements. Dementia can be present in elderly patients.

SCA13

Reported in French families, SCA13 has been linked to chromosome 19 (Herman-Bert *et al.*, 2000). Age at onset is in early childhood with cerebellar symptoms, psychomotor development, mental retardation and slow progression.

SCA14

Initially described in a Japanese family, SCA14 localizes near the SCA13 locus on chromosome 19 (Yamashita *et al.*, 2000). In this family, SCA14 is characterized by prominent ataxia, occasional axial myoclonus and tremor. It is a slowly progressive disease with an age of onset between 10 and 50. As additional families were mapped to the same region (Brkanac *et al.*, 2002), the disease gene was identified this past year. Point mutations were found in the *PRKCG* gene encoding a gamma subunit of protein kinase C (Chen *et al.*, 2003). SCA14, thus, has broken the trend of expanded repeats as the cause of dominant ataxias.

SCA15

This SCA is a mild and late onset "pure" form of disease (Storey *et al.*, 2001) for which the locus has not been reported.

SCA16

This ataxia, which localizes to chromosome 8, can be associated with head tremor (Miyoshi *et al.*, 2001). The genetic defect is unknown.

SCA17

SCA17 is the most recently identified polyQ disease, caused by a glutamine-encoding CAG repeat in the TATA binding protein gene (*TBP* or *TFIID*). SCA17 typically manifests in midlife and the ataxia is accompanied by more dementia and extrapyramidal features (bradykinesia and dystonia) than most SCAs. Neurodegeneration also is more widespread in SCA17 than in most SCAs.

TBP is a critical component of the basal transcription machinery. Because of its polymorphic CAG/glutamine repeat and central role in gene expression, *TBP* had long been viewed as a prime candidate gene in inherited neuropsychiatric diseases. In 1999, Tsuji and colleagues identified a single patient with sporadic ataxia who proved to have a CAG/polyglutamine expansion in the *TBP* gene (Koide *et al.*, 1999). More recently, additional Japanese and European families showed this same expansion, confirming that SCA17 is the newest polyQ disease (e.g. Nakamura *et al.*, 2001).

SCA18

This disorder merges clinical features of hereditary sensory neuropathy and hereditary ataxia and thus has been called autosomal dominant sensory/motor neuropathy with ataxia, or SMNA. SCA18, mapped to chromosome 7q31–q32 in a large Irish American family (Brkanac *et al.*, 2002), shows clinical variability with ataxia, sensory loss, muscle weakness and pyramidal tract signs.

SCA19

This disorder was recently described in a large Dutch family, manifesting as mild cerebellar ataxia with occasional cognitive difficulties and myoclonus (Verbeek *et al.*, 2002). The locus maps to chromosome 1.

SCA21

This dominant ataxia shows variable onset and slow progression in the single large French family in which it has been described (Vuillaume *et al.*, 2002). In this family, hyporeflexia, akinesia and rigidity were seen in some affected persons and anticipation may have occurred, based on age of symptom onset in various generations.

Episodic ataxias

Less common than the SCAs, the episodic ataxias are also a genetically heterogeneous disorders (Baloh *et al.*, 1997). Two forms of dominantly inherited episodic ataxia have been genetically identified. EA-1, due to mutations in the potassium channel gene *KCNA1*, typically causes brief (minutes) episodes of ataxia that may be precipitated by stress or exercise. Myokymia often accompanies this

condition. EA-2, which is due to mutations in the *CACNA1A* gene encoding a calcium channel, typically causes longer bouts of ataxia (hours to days) that also may be precipitated by stress, exercise or fatigue. Acetazolamide can prevent attacks in some patients, particularly those with EA-2. Thus, a trial of this medication should be offered to any patient with episodic ataxia. Two other kindreds with dominantly inherited episodic ataxia do not map to the loci for EA-1 and EA2. A North Carolinian family has been described with periodic vestibular ataxia (Damji *et al.*, 1996), and a Canadian family has been reported with episodic ataxia accompanied by vertigo, tinnitus and interictal myokymia (Steckley *et al.*, 2001). EA-3 and EA-4 are the respective designations, but the genetic loci have not been published as of this writing.

Other dominantly inherited ataxias

Nearly all ADCA represent one of the SCAs describe above. Two other conditions, however, should be considered in the ataxic patient with a dominant family history: the polyQ disorder, dentatorubral pallidolusian atrophy (DRPLA), and the prion disorder Gerstmann–Straussler–Scheinker disease (GSS). Among the polyglutamine diseases, DRPLA most closely resembles HD yet patients often have ataxia as a primary sign (Yabe *et al.*, 2002). Rare in the USA, DRPLA is one of the more common polyglutamine diseases in Japan. GSS is a rare, dominantly inherited disease that most often presents as progressive ataxia and is due to mutations in the prion gene. Mutational screening is not commercially available but can be obtained through research laboratories. Although the 14–3–3 test may help identify sporadic cases of Creutzfeld–Jakob disease, its sensitivity and specificity for familial prion disease is uncertain. Brain biopsy in GSS reveals Kuru amyloid plaques and accumulated prion protein, and western blot analysis of brain lysate demonstrates protease-resistant prion protein.

Friedreich's ataxia and other autosomal recessive ataxias

Hélène Puccio and Michel Koenig

Institut de Génétique et de Biologie Moléculaire et Cellulaire (IGBMC), CNRS/INSERM/Université Louis Pasteur, Hôpitaux Universitaires de Strasbourg, France

Autosomal recessive neurodegenerative ataxias are classified according to the major site of degeneration, which can be the cerebellum or the spinal cord. In the latter case, affection of the posterior columns and of spinocerebellar tracts leads to sensory (proprioceptive) and cerebellar ataxia. A third group of affections recently identified associates cerebellar degeneration and sensorimotor peripheral neuropathy, therefore resulting in sensory and cerebellar ataxia associated with neuromuscular weakness. The first group is dominated by ataxia-telangiectasia (A-T), where cerebellar atrophy is associated with immune deficiency and susceptibility to develop malignancies. Ataxia-telangiectasia and related disorders will be developed in the [following chapter](#). Another member of the first group is spastic ataxia of the Charlevoix–Saguenay region (ARSACS). The second group is dominated by Friedreich's ataxia (FRDA), recognized since the XIXth century. Rare forms of spinal cord ataxias include the inherited vitamin E deficiencies (isolated vitamin E deficiency (AVED) and abetalipoproteinemia (ABL)), Refsum disease (RD), infantile onset spinocerebellar ataxia (IOSCA), and ataxia + blindness + deafness (SCABD). The group of cerebellar atrophy with sensorimotor neuropathy (third group) comprises only very recently identified conditions, such as ataxia + oculomotor apraxia, forms 1 and 2 (AOA1 and AOA2) and spinocerebellar ataxia + neuropathy (SCAN1). All advances on the delineation of the rare forms of recessive ataxias were made thanks to the development of positional cloning strategies based on homozygosity mapping of consanguineous families and on the development of the human genome project.

Friedreich's ataxia

Nicholaus Friedreich (1825–1882) described a familial form of cerebellar ataxia in 1863, clinically different from atax-

ias called “locomotrices” (motor) in 1858 by Duchenne de Boulogne, for the tabès. The clinical entity emerged from the following observations: three sibships including nine patients, presented with balance difficulties in young adulthood, associated with muscular weakness and sensory loss. Scoliosis, foot deformation, and cardiac signs were frequent (Friedreich, 1863a,b). At this time, the loss of tendon reflexes was not mentioned because tendon reflexes were described by Erb only in 1875. Pathologically, the Friedreich cases showed spinocerebellar and posterior column degeneration. The clinical and pathological diagnostic criteria of Friedreich's ataxia were founded on this initial description, until the very recent discovery of the responsible gene and mutation in 1996.

Clinical and pathological features

Epidemiology

Friedreich's ataxia is the most common inherited degenerative ataxia, and accounts for half of the inherited degenerative ataxias, and for three-quarters of those with onset before age 25. FRDA affects 1:50 000 individuals with an estimated prevalence at birth of 1:29 000 due to a GAA expansion carriers frequency of 1 : 85 in the European population (Cossee *et al.*, 1997). Given the high carrier frequency, the finding of a heterozygous expansion in a caucasian patient should lead to the search for a point mutation in the other allele to confirm the involvement of the frataxin gene. The incidence of Friedreich's ataxia is rare in Finland and among black Africans, and the disease is absent in Japan.

Clinical features

Friedreich's ataxia is a progressive and unremitting mixed cerebellar-sensory ataxia with onset usually around puberty, but wide variations are observed, ranging from 2

to 50 years (mean and standard deviation are 15 ± 8 years) (Durr *et al.*, 1996; Filla *et al.*, 1996; Montermini *et al.*, 1997b; Geschwind *et al.*, 1997; Schols *et al.*, 1997; Ragno *et al.*, 1997; Gellera *et al.*, 1997). The presenting symptom is usually gait ataxia (65%) or generalized clumsiness (25%), except for scoliosis and cardiomyopathy, which can be present before the gait ataxia (5% each of cases). Speech and coordination of the upper limbs may be normal in the first five years of the disease. Decreased reflexes in the lower limbs, extensor plantar response, decreased vibration sense at the ankles, axonal neuropathy, and cardiomyopathy constitute the complete clinical picture of Friedreich's ataxia and are present in more than 70% of the Friedreich's ataxia patients. In the majority of the patients the reflexes are decreased in the upper limbs, and there is proximal weakness in the lower limbs. Scoliosis and pes cavus are present in 60% of the patients. Nystagmus is present in less than half of the patients, decreased visual acuity and hypoacusia may be present late in the course of the disease. In contrast, fixation instability, expressed as square waves when registered on ocular movement recording, are a typical finding when cerebellar ataxia is evident. Optic atrophy is a rare finding. Atypical presentation in patients homozygous for the GAA expansion are observed, such as ophthalmoplegia, dystonia, myoclonus (Durr *et al.*, 1996; Schols *et al.*, 1997), ptosis (Schols *et al.*, 1997), chorea (Hanna *et al.*, 1998), seizures, dysmorphia, and mental retardation (Durr *et al.*, 1996). The diagnostic criteria proposed by several studies before the discovery of the gene were revised by Harding to include patients with onset up to 25 years and to take into account incomplete clinical presentations in patients in whom the disease duration was less than 5 years (Harding, 1981).

Cardiomyopathy is a frequent non-neurological finding in FRDA (Pandolfo, 1997). Cardiac involvement is more often observed in patients with earlier age of onset. About 10% of FRDA patients have diabetes mellitus, and an additional 20% have carbohydrate intolerance. A detailed study of glucose and insulin metabolism in FRDA patients revealed a deficiency in arginine-stimulated insulin secretion in all cases, suggesting that beta cells are invariably affected by the primary genetic defect of FRDA (Finocchiaro *et al.*, 1988).

Pathological features

Degeneration of the posterior columns of the spinal cord is the hallmark of the disease (Friedreich, 1863a,b). This is due to an invariable loss of the large primary sensory neurons of the dorsal root ganglia (DRG) (Oppenheimer & Esiri, 1992), resulting in atrophy of the central branches of the corresponding axons causing thinning of the dorsal

roots, particularly at the lumbosacral level, and atrophy of the peripheral branches causing loss of large myelinated fibers from peripheral nerves. The fine unmyelinated fibers are well preserved, and interstitial connective tissue is increased. The motor component of peripheral nerves is well preserved. Atrophy is also observed in the spinocerebellar tracts, the dorsal being more affected than the ventral. Clarke columns, where the spinocerebellar tracts originate, show severe loss of neurons. Therefore, the sensory systems providing information to the brain and cerebellum about the position and speed of body segments, particularly the lower limbs, are severely compromised in FRDA.

Motor neurons in the ventral horns are well preserved, but the corticospinal motor tracts are atrophied, explaining the pyramidal signs. The pattern of atrophy of the corticospinal tracts suggests a "dying back" process (Said *et al.*, 1986). In the brainstem, neuronal loss can be observed in the gracile and cuneate nuclei, where the dorsal column tracts terminate, and in the medial lemnisci, that continue the central sensory pathway after these nuclei (Oppenheimer & Esiri, 1992). Sensory cranial nerves also show myelin pallor and loss of fibers. The cerebellar cortex shows only mild loss of Purkinje cells late in the disease course. This pattern of involvement contrasts with other inherited degenerative ataxias (Riva & Bradac, 1995), in particular with the group of early onset ataxias with retained reflexes (EOCA), where the cerebellum is much more atrophic than the cervical spinal cord. Nevertheless, radiologic evidence of cerebellar atrophy in addition to cervical cord atrophy is observed in several patients. The deep cerebellar nuclei, where cerebellar efferents originate, are severely affected with marked neuronal loss and gliosis in the dentate nucleus (Oppenheimer & Esiri, 1992). As a consequence, the superior cerebellar pedunculi appear markedly atrophic. Other cerebral structures do not appear to be directly involved by the disease, with the exception of a loss of large pyramidal cells in the primary motor areas.

Both the heart and β cells of the pancreas are thought to be primary sites of degeneration in FRDA patients. Enlargement of the heart is the typical finding, with thickening of ventricular walls and/or interventricular septum (Pasternac *et al.*, 1980; Gottdiener *et al.*, 1982) which is best evidenced by echocardiography (Morvan *et al.*, 1992). Connective tissue is increased, with diffuse and focal inflammatory cell infiltration, and intracellular iron deposits in cardiomyocytes are an invariable finding. The pancreas of patients with diabetes mellitus shows a loss of islet cells without sign of autoimmune inflammation (Schoenle *et al.*, 1989).

Molecular pathogenesis

FRDA gene

The human FRDA gene, positionally cloned in 1996, is localised on 9q13 and is composed of seven exons spanning 80 kb of genomic DNA (Campuzano *et al.*, 1996). Northern blot analysis in human and mouse, RNase protection assay and cDNA cloning indicate that the 1.3 kb major transcript is made from five exons (1 to 5a). This transcript encodes a protein of 210 amino acids called frataxin. A very minor alternative transcript contains exon 5b instead of 5a, followed by the noncoding exon 6. The functional significance of this transcript, if any, is still uncertain.

The FRDA gene demonstrates tissue-specific and developmentally controlled expression by northern blot (in human and mouse tissues) and in situ hybridisation (in mouse tissues only) (Campuzano *et al.*, 1996; Jiralerspong *et al.*, 1997; Koutnikova *et al.*, 1997). The expression partially correlates with the main sites of pathology of the disease. DRGs, where the sensory cell bodies are located, are the major sites of expression in the nervous system, from embryonic day 12 until adult life. Deep sensory neuropathy and degeneration of the posterior columns therefore appear as a direct consequence of reduced frataxin level in these structures. Expression in the spinal cord is comparatively much lower, suggesting that degeneration of the spinocerebellar tracts and of the Clarke's columns (containing respectively the axons and the cell bodies of secondary neurons projecting to the cerebellum) might be secondary to degeneration of the DRG neurons. Significant frataxin expression is also observed in the granular layer of the cerebellum. Degeneration of the motor corticospinal (pyramidal) tracts might correlate with frataxin expression in mature cells of the developing forebrain (Jiralerspong *et al.*, 1997), though it was not detected in mouse adult cerebral cortex (Koutnikova *et al.*, 1997). Expression in mouse brain is mostly restricted to the periventricular zone in embryos and to the corresponding ependymal layer in adults (Koutnikova *et al.*, 1997).

The frataxin gene is also expressed in non-neuronal tissues, such as heart and pancreas, which may account for hypertrophic cardiomyopathy and the increased incidence of diabetes observed in FRDA patients (Campuzano *et al.*, 1996; Koutnikova *et al.*, 1997). Frataxin is also prominently expressed in tissues apparently not affected by the disease, such as liver, muscle, thymus and brown fat. All tissues highly expressing frataxin are rich in mitochondria, with brown fat, present in newborns, being particularly rich (Koutnikova *et al.*, 1997). The difference between non-affected and affected tissues may lie in the non-dividing nature of the latter (neurons, cardiocytes and β cells of the

pancreas), implying that cells are not replaced when they die. Also, neurons and cardiocytes have an exclusive aerobic metabolism, making them more sensitive to mitochondrial defect. However, further factors must come into play to explain the specific vulnerability of specific cell types (e.g. the affected sensory system vs. the spared motor system).

FRDA mutations

FRDA is most commonly caused by a large GAA triplet repeat expansion within the first intron of the gene encoding frataxin (Campuzano *et al.*, 1996). Ninety-six per cent of patients are homozygous for GAA trinucleotide repeat expansions while the remaining 4% of cases are compound heterozygotes for a GAA expansion and a point mutation (or a deletion/insertion mutation) within the coding region of the gene (Campuzano *et al.*, 1996; Cossee *et al.*, 1999). Truncating and missense mutations are equally represented, although missense mutations are preferentially found in the second half of the protein, suggesting an important functional domain. In most cases, point mutations are found in clinically typical FRDA patients with few exceptions. The G130V missense mutation always appears associated with an atypical presentation (retained knee reflexes, often brisk, absence of dysarthria, moderate ataxia, spastic gait, and slow progression) (Cossee *et al.*, 1999; Bidichandani *et al.*, 1997; Forrest *et al.*, 1998). The G130V mutation is one of the most frequent frataxin point mutations and arose from a common founder event (Delatycki *et al.*, 1999b). Other missense mutations each represented by a single case (L106S (Campuzano *et al.*, 1996), D122Y (Cossee *et al.*, 1999), R165C and L182F (Forrest *et al.*, 1998)) also seem to be associated with mild presentation.

The clinical equivalence between the GAA intronic expansion and the truncating mutations suggests that the expansion acts by loss of function on frataxin. Indeed, RT-PCR and RNase protection experiments revealed that frataxin mRNA levels are markedly decreased in comparison to controls or unrelated ataxias (Campuzano *et al.*, 1996; Cossee *et al.*, 1997; Bidichandani *et al.*, 1998). RNase protection and in vitro transcription experiments suggest that the expansion acts at the transcriptional level, rather than interfere with the splicing of intron 1 (Bidichandani *et al.*, 1998; Ohshima *et al.*, 1998). Experiments using in vitro and in vivo expression systems revealed that the GAA repeat interferes with transcription in an orientation and length-dependent manner (Bidichandani *et al.*, 1998; Ohshima *et al.*, 1998). The molecular basis for these results was proposed to be the formation of a non-B DNA conformation, probably a triple helical structure. Indeed, Sakamoto *et al.* recently described a novel DNA structure, "sticky DNA," for long tracts of GAA from the frataxin gene (Sakamoto

et al., 1999). Sticky DNA is formed by the association of two purine–purine–pyrimidine (R–R–Y) triple helical structures under the influence of negative supercoiling, thereby inhibiting transcription (Sakamoto *et al.*, 2001). Therefore, the formation of sticky DNA in a FRDA patient would be the mechanism by which the expansion suppresses gene expression, resulting in reduced levels of frataxin.

The normal GAA repeat in the Caucasian population shows two main classes of alleles (Cossee *et al.*, 1997; Epplen *et al.*, 1997; Montermini *et al.*, 1997a). About 80% of alleles have 7–12 GAAs (the most frequent alleles carry nine repeats). A second heterogeneous mode of 16–34 GAAs accounts for 17% of alleles. Heterozygote carriers of expansions >100 GAAs were found at a frequency of 1/85, predicting a disease incidence of about 1/29 000 (Cossee *et al.*, 1997). Haplotype examination strongly suggests that the expanded alleles arise from large normal alleles with the presence of a single or few initial founder events leading to a large normal allele. The fact that very similar haplotypes were found in North African and Yemenite subjects with large normal and expanded alleles suggests the founder event is very old (Cossee *et al.*, 1997).

Clinical–genetic correlation and prognosis

The direct involvement of the GAA expansion as the cause of FRDA is demonstrated by the very significant inverse correlation between the size of the smaller of the two expansions and the age of onset, the severity of the disease and the risk of occurrence of optional signs such as cardiomyopathy, scoliosis and diabetes (Montermini *et al.*, 1997b; Durr *et al.*, 1996; Filla *et al.*, 1996; Isnard *et al.*, 1997; Lamont *et al.*, 1997; Monros *et al.*, 1997). These observations suggest that some frataxin is produced from alleles carrying smaller expansions, in a length dependent manner. This was confirmed using a monoclonal antibody directed against frataxin (Campuzano *et al.*, 1997) and is in agreement with the transcript analyses. The smallest pathological expansions are in the range of 90–110 repeats, and are found in patients with late onset and atypical presentation of the disease (Cossee *et al.*, 1997; Durr *et al.*, 1996) (one exception described (Epplen *et al.*, 1997) is most likely due to the presence of an unstable pre-mutation in one of the parents). As a consequence, the molecular definition of Friedreich's ataxia based on the presence of the GAA expansion mutation is broader than the previous clinically based definition. Patients with small expansions (<400 repeats) often show onset of the symptoms after age 25 or have retained tendon reflexes (Montermini *et al.*, 1997b; Durr *et al.*, 1996; Filla *et al.*, 1996; Lamont *et al.*, 1997; Monros *et al.*, 1997), features previously considered as exclusion criteria (Harding, 1981). Molecular diagnosis

demonstrates that about 12% of cases fulfilling Harding's essential criteria of the disease are negative for GAA expansion (McCabe *et al.*, 2000), while, conversely, one-quarter of patients homozygous for GAA expansion show atypical phenotypes (Berciano *et al.*, 2002). Detection of the expansion mutation thus provides a most useful diagnostic test. The length of expansion has however little value for individual prognosis, given the large scattering of points along the correlation curve.

Frataxin function

Frataxin is a 210 amino acid protein showing no similarity with protein domains of known function. Therefore, the function of frataxin cannot be inferred from its amino acid sequence. The protein, however, shows a striking degree of evolutionary conservation, particularly in a stretch of 27 amino acids encoded by exons 4 and 5a. In the past few years, many studies have addressed the function of frataxin. Although the exact function of frataxin is still controversial, there are currently at least four predominant non-exclusive hypotheses for frataxin's physiological role: roles in (i) mitochondrial iron transport, (ii) iron–sulfur cluster biogenesis (iii) iron binding/sequestration, (iv) response to oxidative stress. In the past year, the most favored hypothesis is that frataxin has an essential role in iron–sulfur cluster biogenesis.

Frataxin mitochondrial localization

A first suggestion that frataxin could be a mitochondrial protein came from phylogenetic studies. Sequence comparisons showed the presence of more distant homologues in gram-negative (γ purple), but not in gram-positive bacteria (Gibson *et al.*, 1996). This suggests that the frataxin gene might be derived from the bacterial precursor of the mitochondrial genome which shares phylogenetic ancestry with gram-negative bacteria, and then underwent transfer to the nuclear genome. Furthermore, computer analysis predicted a mitochondrial targeting signal at the N-terminus of yeast and mouse frataxin, a domain that is absent in the bacterial homologues (Koutnikova *et al.*, 1997). Human and yeast frataxin were directly demonstrated to be mitochondrial proteins by epitope tagging experiments and colocalization with well-established mitochondrial markers (Babcock *et al.*, 1997; Koutnikova *et al.*, 1997; Priller *et al.*, 1997; Wilson & Roof, 1997). Mitochondrial localization of endogenous frataxin was demonstrated using specific monoclonal antibodies. Immunoelectron microscopy results indicate that human frataxin, that has no hydrophobic transmembrane segment, is nevertheless associated with mitochondrial

membranes and crests (Campuzano *et al.*, 1997), while fractionation experiments demonstrate that yeast frataxin behaves like a soluble matrix protein (Branda *et al.*, 1999; Geissler *et al.*, 2000).

The N-terminal mitochondrial targeting sequence of both mammalian and yeast frataxin is proteolytically removed in a two-step cleavage resulting in an 18 kD mature protein (Branda *et al.*, 1999; Campuzano *et al.*, 1997; Koutnikova *et al.*, 1998), whereas the precursors of most mitochondrial matrix proteins are subjected to a single proteolytic event upon import. Both cleavage steps involve the mitochondrial processing peptidase (MPP), a dimeric protease whose β subunit binds to the N-terminus of frataxin (Branda *et al.*, 1999; Koutnikova *et al.*, 1998). MPP first cleaves the precursor to the intermediate form and subsequently converts the intermediate to mature size protein of 18 kD (Cavadini *et al.*, 2000a).

Frataxin and iron homeostasis

Yeast as a model organism proved to be an invaluable system for first insight to unravel frataxin function within the mitochondria. Deletion of the frataxin yeast homologue (YFH1) results in mutant strains that show growth defect on fermentable carbon source, accumulate mitochondrial iron and exhibit a high sensitivity to oxidative stress induced by oxidant agents such as hydrogen peroxide or iron, as well as a reduction in oxidative phosphorylation (Babcock *et al.*, 1997; Foury & Cazzalini, 1997; Koutnikova *et al.*, 1997; Radisky *et al.*, 1999; Wilson & Roof, 1997). In parallel, not only the high affinity iron import system is constitutively turned on in the Δ YFH1 mutants (Babcock *et al.*, 1997; Radisky *et al.*, 1999), but using DNA microarray hybridization analysis, Foury and Talibi found that the expression of all known members of the "iron regulon" was increased in a frataxin-deficient strain (Foury & Talibi, 2001), implying that cells are starved for cytosolic iron. Together, these observations lead to the hypothesis that frataxin is directly involved in iron homeostasis, possibly by mediating iron efflux. Therefore, the direct consequence of frataxin deficiency would be iron accumulation which likely catalyzes the formation of hydroxyl radicals via the Fenton reaction leading to an iron-induced oxidative stress provoking the loss of mitochondrial DNA and iron-sulfur proteins characteristic of the Δ YFH1 yeast (Babcock *et al.*, 1997; Foury & Cazzalini, 1997).

There are multiple evidences that mammalian and yeast frataxins are true orthologues and that human frataxin might also be involved in iron homeostasis. Human frataxin can complement the defect in Δ Yfh1 cells (Cavadini *et al.*, 2000b; Wilson & Roof, 1997), and this complementation is abolished by the introduction of disease-causing missense

mutations within the gene (Cavadini *et al.*, 2000b). Moreover, pathological and clinical studies show that consequences of frataxin reduction are indeed similar in human cells. Iron deposits are consistently observed on autopsy in hearts of FRDA patients (Bradley *et al.*, 2000; Lamarche *et al.*, 1993). Magnetic resonance imaging data indicate that iron also accumulates in the dentate nucleus (Waldvogel *et al.*, 1999), an affected cerebellar structure. Mitochondrial iron content of FRDA fibroblasts, an unaffected cell type in this disease, is minimally increased (Delatycki *et al.*, 1999a). Moreover, an increased serum level of transferrin receptor, the major mediator of iron uptake, has been found in FRDA patients (Wilson *et al.*, 2000) which may indicate an abnormal intracellular distribution of iron. However, a similar increase in patients with other degenerative ataxia was observed (Wilson *et al.*, 2000), suggesting that the elevated transferrin levels is a feature of several degenerative ataxias, rather than specific to FRDA.

Frataxin and the biogenesis of iron-sulfur clusters

A selective deficiency of the respiratory chain complexes I-III and of both mitochondrial and cytosolic aconitases activities in the heart biopsy and autopsy material of patients has been reported (Bradley *et al.*, 2000; Rotig *et al.*, 1997). All the deficient enzymes and complexes contain iron-sulfur (Fe-S) clusters in their active sites. Fe-S proteins are remarkably sensitive to free radicals, and their inactivation further suggests oxidative stress in FRDA affected tissues which could be a consequence of iron accumulation. However, data from FRDA mouse models (see below) demonstrate that the Fe-S protein deficiency occurs prior to iron accumulation (Puccio *et al.*, 2001), suggesting that iron accumulation might not be the primary consequence of frataxin deficiency. We cannot exclude though that deregulation of iron homeostasis without significant iron deposit or accumulation leads to iron-induced oxidative stress.

Is the Fe-S protein deficiency a cause or a consequence of mitochondrial iron accumulation? Studies in the yeast demonstrate that the presence of iron-chelator in the culture media restores normal intramitochondrial iron levels and normal oxidative respiration in Δ Yfh1 yeast cells, while the activity of aconitase is not fully restored (Foury, 1999). These results suggest that the reduction in the activity of the respiratory chain complexes is a consequence of mitochondrial iron accumulation, while the reduced aconitase activity is directly linked in part to frataxin deficiency. Mitochondrial aconitase deficiency therefore does not seem to be a mere consequence of mitochondrial dysfunction. In addition, the inactivation of cytosolic aconitase in FRDA patients (yeasts do not have cytosolic aconitase),

suggests that a general iron–sulfur defect is the underlying mechanism. However, it is possible that the loss of cytosolic aconitase activity observed in FRDA might also reflect a decrease of cytosolic iron content, since cytosolic aconitase loses its Fe–S cluster to acquire iron-responsive element (IRE) binding properties in response to low iron concentration (Kaptain *et al.*, 1991).

It is interesting to note that two other yeast mutants (Δ Atm1 and Δ Ssq1) which specifically accumulate iron in the mitochondria are involved in Fe–S cluster biogenesis. The Atm1 gene encodes a 7 transmembrane ABC ATPase (a putative ABC transporter) which appears to be involved in export of iron-sulfur clusters from the mitochondria (Kispal *et al.*, 1997, 1999). Attempts to identify a direct functional relation between frataxin and Atm1 have failed so far. Interestingly, mutations in ABC7, the human homologue of the Atm1 gene, are responsible for a rare X-linked recessive disease, defined by spinocerebellar ataxia and anemia (Allikmets *et al.*, 1999). The Ssq1 gene, encoding a low abundance mitochondrial heat shock 70 protein (mtHsp70) (Knight *et al.*, 1998), was recently demonstrated to be required for Fe–S cluster assembly in mitochondria, together with the co-chaperone Jac1, a mitochondrial DnaJ homologue (Lutz *et al.*, 2001). Furthermore, the Fe–S cluster assembly into ferredoxin (itself involved in Fe–S assembly) requires frataxin (Lutz *et al.*, 2001). In concordance with these latter results, the phylogenetic distribution of frataxin in 56 available genomes identified an identical phylogenetic distribution with hscA, a paralogue of Ssq1 and hscB, an orthologue of Jac1 (Huynen *et al.*, 2001). Therefore, combining phylogenetic data with experimental and predicted cellular localization data supports the hypothesis that frataxin is directly involved in iron–sulfur cluster assembly. More recently, three independent groups have obtained direct evidence that frataxin promotes Fe–S center synthesis using *in vitro* and *in vivo* experiments. Frataxin was shown to be required but not indispensable for cellular Fe/S protein assembly by directly measuring the *de novo* maturation of several Fe/S proteins in yeast (Muhlenhoff *et al.*, 2002). Furthermore, inhibition of Fe–S cluster biosynthesis by absence of frataxin decreases mitochondrial iron export in the yeast (Chen *et al.*, 2002). All these studies suggest that frataxin is not indispensable for this process, but renders it more efficient.

Frataxin as an iron-storage protein

An attractive hypothesis recently put forward suggests that the function of frataxin is to bind iron and keep it in a soluble and bioavailable form (Adamec *et al.*, 2000). By gel filtration experiments and analytical ultracentrifugation, the authors demonstrated that recombinant purified yeast

frataxin is a soluble monomer that contains no iron, which assembles into a high molecular weight regular spherical multimer sequestering more than 3000 atoms of iron upon titration with increasing concentration of ferrous iron. This function of frataxin is consistent with the role played by frataxin in iron export and would also account for the proposed role in Fe–S cluster assembly. Furthermore, storing uncomplexed iron should prevent iron toxicity, and therefore oxidative damage. Yeast frataxin acts as a ferroxidase in the first oligomerization steps, oxidizing the initial atoms of Fe²⁺ that are incorporated, and then, when more iron gets into the larger complexes, it oxidizes spontaneously (Park *et al.*, 2002). Accordingly, mammalian frataxins, and human frataxin in particular, forms similar complexes, although under different kinetics. Human frataxin is unable to form the ferritin-like particles, but does assemble into higher-order filamentous structures (Cavadini *et al.*, 2002). However, so far, no other group has been able to reproduce the iron binding results for human frataxin.

Analysis of the solution (Musco *et al.*, 2000) and crystal (Dhe-Paganon *et al.*, 2000; Cho *et al.*, 2000) structures of human frataxin and its bacterial Cyay homologue has revealed a compact and globular protein with a novel fold consisting of a five-stranded anti-parallel β sheet packing against a pair of parallel α helices. Frataxin does not have any features resembling known iron-binding sites, and the structure rather suggests that it interacts with a large ligand, probably a protein. However, attempts by different groups to identify the interacting protein have been unsuccessful, possibly because the interaction might be transient. Furthermore, both the crystal and NMR study suggest that human frataxin is not an iron binding protein, under any concentration of iron tested (Dhe-Paganon *et al.*, 2000; Musco *et al.*, 2000). A comparative study using human, yeast and bacterial frataxins selected as representatives of different evolutionary steps, shows that these three proteins preserve their fold but have largely different stability, which is strongly influenced by the presence of cations. Using mutagenesis, the surface involved in iron binding was identified and was shown not to be conserved among the three species. In addition, the high-molecular weight supramolecular structure and the iron binding capability of human frataxin could not be confirmed (Adinolfi *et al.*, 2002).

The different behavior of yeast vs. mammalian frataxin could possibly be explained by the recent discovery of a mitochondrial ferritin in higher eukaryotes (Levi *et al.*, 2001). Although both yeast and mammalian frataxin has the properties for the chaperone activity in Fe/S cluster biosynthesis, an additional iron storage function may have been taken up by the yeast which has no ferritins. Only the chaperone activity in Fe/S cluster biosynthesis would be needed

in higher eukaryotes since they have both cytosolic and mitochondrial ferritins.

Frataxin and oxidative stress

Whether frataxin is directly involved in iron homeostasis or Fe-S cluster biogenesis, the generation of reactive oxygen species plays an important role in the pathogenesis of FRDA. Consistent with this hypothesis, vitamin E deficiency produces a disease very similar to FRDA (see below).

Although the speculation of oxidative stress involvement in FRDA has long been accepted, it is not until very recently that an increased oxidative stress has been demonstrated in individuals with FRDA. Schulz *et al.* reported elevated urinary concentrations of 8-hydroxy-2'-deoxyguanosine (8OH2'dG), a marker of oxidative damage to DNA, in patients with FRDA (Schulz *et al.*, 2000). Similarly, Edmond *et al.* found increased levels of plasma malondialdehyde (MDA), a product of lipid peroxidation (Edmond *et al.*, 2000). More recently, Piemonte *et al.* demonstrated decreased free glutathione concentration in blood of patients with FRDA (Piemonte *et al.*, 2001). Glutathione, the most abundant antioxidant in the cell, can act either as a free radical scavenger or a co-substrate for important enzymes such as glutathione peroxidase and glutathione transferases (Hayes & McLellan, 1999). These studies thus further imply a role of free radical cytotoxicity in the pathophysiology of the disease. In addition, these studies are important because they used readily available fluids, and thus the assays could provide a way to monitor disease status or treatment efficacy.

Therefore, it is unquestionable that oxidative stress plays an important role in the pathogenesis of FRDA. Could frataxin be directly involved in oxidative stress response or is this oxidative stress iron-induced? To address this question, the group of Dr. Rustin devised experimental conditions to endogenously produce superoxides in cells deficient in frataxin (FRDA fibroblasts) by inhibiting the ATP synthase with oligomycin (Chantrel-Groussard *et al.*, 2001). This inhibition normally results in an important superoxide dismutases (SODs) induction, however FRDA cells failed to normally increase SODs activity and iron import and to decrease iron storage capacity, despite parallel loss of membrane bound iron-containing enzyme activity. Similarly, the group of Dr. Pandolfo showed that FRDA fibroblasts exposed to iron, and therefore to iron-induced oxidative stress, failed to normally upregulate the mitochondrial SOD (Jiralerspong *et al.*, 2001). Finally, measurements of SOD enzymes activity in the heart of the conditional mouse models of FRDA (see below) show lower SODs activity than in age-match control mice (Chantrel-Groussard *et al.*, 2001). These observations are consistent

with expression data from DNA chips experiments which show no increase in SOD transcripts in $\Delta Yfh1$ yeast (Foury & Talibi, 2001). Therefore, together, these results suggest that decreased Fe-S biosynthesis impairs early antioxidant defenses resulting in higher cell lethality in response to oxidative stress. The mechanism involved remains to be established, although one can hypothesize that it could be either a Fe-S protein acting as an oxidative damage sensor in the mitochondria or that an abnormal status of mitochondrial iron disturbs the antioxidant response system. However, the primary involvement of superoxide injury is consistent with the pathology of the disease (neurons and cardiomyocytes have limited antioxidant defenses), and the increase in oxidative stress found in FRDA.

Mouse models for FRDA

To further study the mechanism of the disease and to test pharmacological therapy, several mouse models have been generated. Our group generated a classical mouse model by constitutive inactivation of frataxin by homologous recombination (Cossee *et al.*, 2000). Homozygous deletion of frataxin causes embryonic lethality a few days after implantation, demonstrating an important role for frataxin during early development. These results suggest that the milder phenotype in humans is due to residual frataxin expression associated with the expansion mutations. No iron accumulation was observed during embryonic resorption, suggesting that cell death might be due to a mechanism independent of iron accumulation.

To circumvent embryonic lethality, we recently generated in parallel two different conditional knockout models, based on the Cre-lox system, in which frataxin was deleted either specifically in skeletal and cardiac muscle (using a transgenic mouse expressing Cre under the muscle creatine kinase promoter) or predominantly in neuronal tissues (neuron specific enolase promoter) (Puccio *et al.*, 2001). Both models are viable and reproduce some morphological and biochemical features observed in FRDA patients including cardiac hypertrophy without skeletal muscle involvement, large sensory neuron dysfunction without alteration of the small sensory and motor neurons, and deficient activities of complexes I-III of the respiratory chain and of the aconitases. Time course experiments reveal that the Fe-S enzyme deficiencies begin in the initial phase of the pathology, and that intramitochondrial iron accumulation occurs later. In addition, as mentioned above, the SODs are abnormally low in the diseased mouse (Chantrel-Groussard *et al.*, 2001). These mutant mice therefore represent the first mammalian models to evaluate treatment strategies for the human disease.

More recently, the group of Dr. Pandolfo attempted to generate a mouse model by introducing a (GAA)₂₃₀ repeat within the mouse frataxin gene to mirror the chronically reduced levels of frataxin expression found in the human disease (Miranda *et al.*, 2002). Bred with the *Frd*a knockout, the authors obtained animals expressing 25–36% of wild-type frataxin levels, an expression level associated to mildly affected FRDA patients. Unfortunately, these mice did not develop abnormalities of motor coordination, cardiomyopathy, or iron metabolism.

The group of Dr. Chamberlain were able to overcome the embryonic lethality of the *Frd*a knockout by generating a transgenic mouse that contains the entire frataxin gene within a human YAC clone onto the null mouse background (Pook *et al.*, 2001). The human frataxin was expressed in the appropriate tissues at levels comparable to the endogenous mouse frataxin, and was correctly processed and localized to mitochondria. Biochemical analysis of heart tissue demonstrated preservation of mitochondrial respiratory chain function. Therefore, it is possible to envision the generation of a mouse model expressing low levels of frataxin by using a human YAC derived from a patient, thereby having a repeat within the first intron inhibiting the expression of frataxin. It is clearly important to generate a mouse model that molecularly mirrors the human disease in addition to the already existing models.

Therapeutic trials for FRDA

Based on the recent discoveries of the potential function of frataxin, and more specifically on the consequences of frataxin reduction, therapeutic advances can be envisioned. Whether the mitochondrial iron accumulation is a primary or a secondary effect of frataxin deficiency, all data suggest that intracellular iron imbalance and oxidative stress are involved in the pathogenesis of FRDA. This led to initial enthusiasm for iron chelators, such as desferrioxamine, as therapeutic reagents for treating the disease. However, desferrioxamine has a significant side effect profile and its effect on individuals who do not have a generalized iron overload is not well studied. FRDA patients have normal serum iron and ferritin levels (Wilson *et al.*, 1998). Moreover, Rustin *et al.* have experimental evidence suggesting that caution should be taken when using iron chelators as a therapeutic agent since it could displace rather than protect against iron-mediated toxicity (Rustin *et al.*, 1999b).

Since it has been proposed that reducing the load of free radicals will slow the progression of the disease, antioxidants which are usually devoid of side effects can be considered as potential therapeutic reagents. Rustin *et al.*

have shown by in vitro experiments that the antioxidant idebenone, a short chain analogue of coenzyme Q10, protects the membrane respiratory chain enzymes against iron-induced injury without causing a reduction in soluble aconitase activity (Rustin *et al.*, 1999a,b). In addition, the short side chain of idebenone allows it to cross membranes readily (including the blood–brain barrier). Preliminary results on the cardiomyopathy of 40 FRDA patients (Rustin *et al.*, 1999b, 2002) are promising and warrant establishing a larger clinical trial using idebenone. Furthermore, Schulz *et al.* found that 8 weeks of treatment with idebenone decreased the urine levels of 8OH2' dG by 20% (Schulz *et al.*, 2000). Finally, our unpublished results of treatment of the conditional cardiac mouse model show a statistically significant increase in the life span of the animals. Therefore, idebenone appears to have some therapeutic effect, although the neurological consequences need to be evaluated in the long term. On the other hand, treatment of FRDA patients for 6 months with the antioxidants coenzyme Q10 and vitamin E resulted in an increased in the cardiac phosphocreatine to ATP ratios and improved muscle mitochondrial ATP production (Lodi *et al.*, 2001). However, whether FRDA patients will benefit clinically from this bioenergetic improvement needs to be evaluated by appropriate trials in the future.

In conclusion, these findings contribute to the growing body of evidence that treatments aimed to enhance mitochondrial function and reduce toxic radical production are rational and may be a realistic hope for the patients and their families. The next challenge is to resolve the controversial issues as to the function of frataxin to provide solid bases for designing eagerly awaited therapeutic approaches for Friedreich's ataxia.

Other sensory and spinocerebellar ataxias

Ataxia due to isolated vitamin E deficiency (AVED)

The first case of inherited isolated vitamin E deficiency was reported in 1981 by Burck and colleagues (Burck *et al.*, 1981). For 10 years, this entity was considered as extremely rare, until the discovery of an important founding group in North Africa (Ben Hamida *et al.*, 1993a,b; Cavalier *et al.*, 1998). Age of onset is often around 10 years but ranges from 2 to 52 years in exceptional cases. In its classical form, AVED is very similar to Friedreich's ataxia but differs from it by the absence of cardiomyopathy and diabetes and by the presence of head titubation in 28% of cases and of dystonia in an additional 13% of cases (Cavalier *et al.*, 1998). In the absence of supplementation treatment, the

patients will eventually become wheelchair bound after a mean 13 years of disease duration and may develop retinitis pigmentosa (Yokota *et al.*, 1997; Shimohata *et al.*, 1998; Benomar *et al.*, 2002). The pathological study of a single case revealed a severe demyelination of the posterior columns of the spinal cord and a severe atrophy of the sensory nuclei of the medulla, an important loss of cerebellar Purkinje cells and a moderate atrophy of the lateral pyramidal tracts in the spinal cord, and of the dorsal root ganglia and peripheral nerves (Larnaout *et al.*, 1997). Electrophysiologically, the sensory action potentials are altered less and later than in Friedreich's ataxia (Zouari *et al.*, 1998). Another important histological feature was widespread neuronal and muscular lipofuscin accumulation. The lipofuscin deposits were autofluorescent, electron dense, membrane bound and phosphatase acid positive, suggesting a lysosomal origin (Burck *et al.*, 1981; Laplante *et al.*, 1984; Trabert *et al.*, 1989; Stumpf *et al.*, 1987; Yokota *et al.*, 1987). These deposits are thought to represent lipoperoxidation products resulting from the absence of lipophyllic anti-oxidative properties of vitamin E. Indicators of lipid peroxidation (vulnerability of erythrocyte membranes, presence of thiobarbituric acid-reactive substances in blood) are positive (Kohlschutter *et al.*, 1988; Amiel *et al.*, 1995; Schuelke *et al.*, 1999). However, red blood cells morphology is normal and no acanthocytes are present (Burck *et al.*, 1981; Laplante *et al.*, 1984; Stumpf *et al.*, 1987; Harding *et al.*, 1985). Diagnosis of AVED is made by low serum vitamin E levels in absence of fat malabsorption. Serum vitamin E levels are well below the normal range (<2.5 mg/l, often <1 mg/l, with 6 < N < 15 mg/l). Fat malabsorption should be excluded by a normal lipidogram: triglycerides, cholesterol, beta-lipoprotein and other liposoluble vitamins (A,D,K) are normal. Parents and carriers often have vitamin E values at the lower limit of the normal range (Harding *et al.*, 1985; Ben Hamida *et al.*, 1993b).

In normal subjects, vitamin E is absorbed and secreted from the intestine into plasma in chylomicrons. During chylomicron catabolism in the plasma, vitamin E is transferred to circulating lipoprotein particles (IDL, LDL, HDL), which can deliver vitamin E to tissues. The chylomicron remnants are taken up by the liver, which then selects only RRR- α -tocopherol stereoisomer from all the forms of vitamin E for secretion in nascent very low-density lipoproteins (VLDL) (Kayden, 1993). RRR- α -tocopherol represents therefore the almost exclusive form of circulating vitamin E in plasma. Other isomers and stereoisomers are eliminated, presumably through the bile. The specific transfer of vitamin E to nascent VLDL is the work of a liver specific protein, the α -tocopherol transfer protein (α -TTP) (Sato *et al.*, 1991), which is defective in AVED (Ouahchi

et al., 1995; Gotoda *et al.*, 1995). AVED patients absorb vitamin E normally, but their conservation of plasma RRR- α -tocopherol is poor due to impaired secretion of RRR- α -tocopherol in VLDL (Traber *et al.*, 1990, 1993). In the absence of recycling, the entire plasma pool of vitamin E is rapidly eliminated in a little more than a day (Traber *et al.*, 1994). The human α -TTP gene, on chromosome 8q13, is composed of five exons and encodes a 278 amino-acid protein which exhibits structural homologies with the cellular retinaldehyde-binding protein (CRALBP, present only in the retina) and the yeast Sec14 protein, involved in phosphatidylinositol and phosphatidylcholine transfer into membranes (Arita *et al.*, 1995). AVED mutations are scattered throughout all five exons. In Tunisia, AVED is as frequent as Friedreich's ataxia, due to the spreading of the founder mutation 744delA, which is also present in the other North African countries, and in Italy and France. All but one North African AVED patients were found to be homozygous for the 744delA mutation, while the 513insTT mutation is the major mutation across Europe and North America (Cavalier *et al.*, (1998) and unpublished results). The most frequent mutation in Japan is a missense change, H101Q, associated with a very mild phenotype and late onset (Gotoda *et al.*, 1995; Yokota *et al.*, 1997).

There is no limitation or difficulty with the absorption of vitamin E by the intestinal tract in AVED patients. The administration of vitamin E supplements in divided doses daily has resulted in cessation of progression of the neurologic symptoms and signs, and some amelioration of established neurologic abnormalities in a number of patients (Kohlschutter *et al.*, 1988; Martinello *et al.*, 1998). Administration to adults of 800 mg of RRR α -tocopherol given twice daily with meals containing fat, results in plasma α -tocopherol levels that are at or above the normal range (Cavalier *et al.*, 1998). The important number of new cases recently reported indicates that AVED is not so rare, stressing again the importance not to miss the diagnosis in this treatable condition and to institute therapy promptly.

Abetalipoproteinemia (ABL)

The first report of abetalipoproteinemia was published in 1950 by Bassen & Kornzweig from a consanguineous family with two affected children (Bassen & Kornzweig, 1950). In 1958, Jampel and Falls identified in this condition a deficiency in cholesterol and triglycerides associated with a deficiency of plasma lipid transport (Jampel & Falls, 1958), itself causing a deficiency of the lipophyllic vitamins A, K and mostly E. Abetalipoproteinemia presents initially in the neonatal period with gastrointestinal manifestations related to malabsorption of fat, such as vomiting, diarrhea,

and failure to gain weight normally (Kohlschutter, 2000). Endoscopy reveals a yellow discoloration of the duodenum and intestinal mucosa biopsies reveal vacuolization of the cytoplasm of villus cells which are fat-engorged, but otherwise morphologically normal, unlike celiac disease, with which abetalipoproteinemia is frequently confused. The intestinal symptoms tend to diminish with age, reflecting in part a striking aversion of many patients to dietary fat. In the absence of vitamin E supplementation, neurological and visual manifestations progressively appear. The neurological manifestations mimic Friedreich's ataxia, beginning with diminution of the deep tendon reflexes, followed by vibration sense and proprioception loss and finally appearance of an ataxic gait, dysarthria, pes cavus, pes equinovarus and kyphoscoliosis. The characteristic sites of the degenerative process are the large sensory neurons of the dorsal root ganglia and their myelinated axons that enter the spinal cord lateral to the posterior funiculus. The axons degenerate and lead to a secondary demyelination of the posterior columns. As in isolated vitamin E deficiency, muscle biopsy after a long disease duration reveals accumulation of ceroid and lipofuscin pigments. The most prominent ophthalmic abnormality is pigmentary retinal degeneration with involvement of the posterior fundus and loss or attenuation of the pigment epithelium. The presence of lipofuscin pigment in the retina suggests that vitamin E deficiency plays a central role in the retinopathy, although the combined deficiency of *n*-3 type essential fatty acids probably also contribute to its occurrence. Loss of night vision is frequently a presenting symptom and may be related to moderate vitamin A deficiency. Since the early description of abetalipoproteinemia, the abundant presence of abnormal star-shaped erythrocytes, termed acanthocytes, was noted in peripheral blood. The erythrocytes assume the acanthocytic form because of an abnormal composition of their membrane, which itself reflects the abnormal composition of the plasma lipoproteins (Kohlschutter, 2000). Severe anemia is frequent and is the consequence of the malabsorption syndrome.

Patients are virtually free of serum lipoproteins of the b group (chylomicrons, LDL and VLDL, that is all lipoproteins that contain B apolipoproteins), resulting in reduced cholesterol levels (< 500 mg/l), almost undetectable triglyceride levels (< 100 mg/l) and reduced lipophylic vitamins (E, A and K) in the plasma, which when combined with acanthocytosis, establishes the diagnosis of abetalipoproteinemia. This deficiency is due to the inability of intestine and liver cells to secrete B-100 lipoproteins (Wetterau *et al.*, 1992). However, it is not due to mutations in the Apo B gene, but to mutations in the gene encoding the large subunit of the microsomal triglyceride transfer protein (MTP)

(Sharp *et al.*, 1993; Shoulders *et al.*, 1993). The MTP gene, located on chromosome 4q23, is composed of 18 exons and is physiologically expressed in intestinal, liver and cardiac cells. MTP can transfer triglycerides and cholesteryl esters between lipidic vesicles and is thought to promote the acquisition of non polar lipids during or just after completion of translation of apo B, at the luminal aspect of the rough ER (Kane & Havel, 2001). It is likely that Apo-B interacts physically with MTP during the initial lipidation step. In the absence of normal initiation of lipidation of Apo B-100, the latter is degraded by intraluminal protease(s) and transport of plasma lipids is supplemented by apolipoproteins E and A-II.

Treatment involves reduction of dietary fat to prevent steatorrhea and supplementation with vitamin E to prevent progression of the neurological and retinal degenerative disease (Kohlschutter, 2000). A proportion of the ingested fat can be replaced by medium-chain triglycerides, which can be absorbed without the formation of chylomicrons, supplemented with essential fatty acids. Due to the malabsorption and lipoprotein abnormalities that make transfer into the central nervous system extremely difficult, vitamin E supplementation requires the use of large oral doses, up to 150 mg of natural α -tocopherol per kg body weight per day in three divided doses. Repeated evaluation of the vitamin E status is necessary to monitor the effectiveness of the treatment. Supplementation with water-soluble preparation of vitamin A appears also reasonable, but should be carefully monitored due to its toxic effects at high doses.

The primary defect causing Friedreich's ataxia, ataxia with isolated vitamin E deficiency and abetalipoproteinemia shed light on a possible general pathological scheme that would explain the shared sites of degeneration and shared dying-back axonal neuropathy. In Friedreich's ataxia, the disease is thought to result from abnormal Fe-S assembly leading to increased production of free radicals, while in the vitamin E ataxias, the disease appears to be the consequence of reduced neuronal membrane defense against lipid peroxidation and other oxidative stress damage. The effectiveness of idebenone in the therapy of Friedreich's ataxia lends support to the hypothesis that free-radicals are central to the pathology of these and possibly other neurodegenerative diseases.

Refsum disease (RD)

In 1946, Sir Sigvald Refsum described a new neurological entity called hereditary atactic polyneuritis (Refsum, 1946), which was subsequently shown to be due to phytanic acid accumulation (Klenk & Kahlke, 1963).

Refsum disease is defined by the association of retinitis pigmentosa, peripheral polyneuropathy, cerebellar and sensory ataxia, and elevated cerebrospinal fluid proteins in absence of pleocytosis (Gibberd & Wierzbicki, 2000). It usually presents between the ages of 10 and 20 years with retinitis pigmentosa, causing night blindness and restricted peripheral vision that can progress to complete blindness. Anosmia is common. Ataxia develops later, associated with neuropathy. Sensorineural deafness, myopathy and ichthyosis occur in more severe cases. Bony abnormalities may be present, and if they are, they are present early on. The most common abnormality is shortening of the terminal phalanges of the thumb. Asymmetrical shortening of the fourth metatarsal and other long bone abnormalities are also seen. In untreated patients, cardiac arrhythmia and hypertrophic cardiomyopathy may develop.

The clinical biochemical feature is raised plasma phytanic acid more than three times the upper limit of normal (i.e. more than 100 mmol/l). If untreated, phytanic acid accumulates in tissues and may represent up to 5% to 30% of total plasma free fatty acids. Phytanic acid is an isoprenoid fatty acid derived from phytol which is the alcohol anchor moiety of a molecule of chlorophyll. Only bacteria that occur in the digestive tracts of herbivores and fishes can break down chlorophyll to phytol. Hence, in humans, phytanic acid is exclusively of nutritional origin, mostly from dairy products and from fat and meat of ruminant animals and fishes. Long-term diets with food containing no phytanic acid will eventually normalize phytanic acid levels in Refsum patients. Green vegetables and many other products such as pork and poultry contain no phytanic acid. Synthetic phytanic acid free diets also exist. Ataxia, neuropathy, ichthyosis and cardiac arrhythmia are the symptoms that respond best to the lowering of phytanic acid in the blood, while others may be irreversible. Plasmapheresis or lipapheresis may be used initially to achieve efficacy rapidly for the severe cases.

Accumulation of phytanic acid is due to the deficiency of the first step of its degradation, which is an alpha-oxidation that takes place in the peroxisomes. This step yields pristanic acid, which is then degraded by beta-oxidation in the mitochondria. The first step of alpha-oxidation involves an alpha-hydroxylation of phytanoyl-CoA. The cloning of the phytanoyl-CoA hydroxylase (PAHX) gene and the identification of mutations therein allowed demonstration of the role of this enzyme in Refsum disease (Jansen *et al.*, 1997; Mihalik *et al.*, 1997). The most common mutation is an in-frame deletion of 111 bp in the mid region of the gene (135–246del111). However, Refsum disease is genetically heterogeneous and a second locus must exist. Curiously, phytol is also the membrane anchor moiety of vitamin E

and nuclear orphan receptors that bind phytanic acid exist. Whether this may explain some of the clinical similarities between Refsum disease and vitamin E deficiencies is only speculative.

Infantile onset spinocerebellar ataxia (IOSCA)

This form of ataxia, reported in 1985 and 1994 by Kallio and Jauhiainen and by Koskinen and colleagues, respectively (Kallio & Jauhiainen, 1985; Koskinen *et al.*, 1994), was so far found only in patients from Finland (21 patients belonging to 15 nuclear families). The disease manifests close to the age of 1 year as acute or subacute clumsiness, athetoid movements in hands and face, hypotonia and loss of deep tendon reflexes in the legs. Ophthalmoplegia and sensorineural hearing deficit are found by school age, sensory neuropathy (decreased or absent sensory action potentials) and optic atrophy by the age of 10–15 years, and female hypogonadism and epilepsy by the age of 15–20 years. Most patients are nonambulatory by the age of 20. Ten of the 21 patients have had seizures, eight of whom had one or more acute crises that progressed to a therapy-resistant status epilepticus and lasted for 2–4 weeks (Lonnqvist *et al.*, 2000). The fact that three patients never regained consciousness and died in their third decade suggests that lifespan may not be normal. The main pathological features of the disease are sensory axonal neuropathy (with severe loss of especially the large myelinated fibres), and progressive atrophy of the spinal cord, brain stem and eventually cerebellum (Lonnqvist *et al.*, 1998). However, athetosis and epilepsy denote an additional involvement of the cerebrum.

The gene defect of IOSCA has been localised to chromosome 10q24.1 (Nikali *et al.*, 1995). All patients seem to share one founder mutation, as they all bear a common haplotype around the disease gene locus (Nikali *et al.*, 1995). The smallest region of haplotype sharing, defined by a few ancient haplotype recombinations, is 150 kb and contains a single known gene, the paired-box protein 2, PAX2 (Nikali *et al.*, 1997). However, no mutation has been found in the PAX2 gene of IOSCA patients. A disease-causing role for nucleotide changes in non-coding sequences is difficult to assess, particularly since there is no ethnically unrelated patients with linkage at the same locus, which could pinpoint to an independent mutation. The identification of the molecular defect in IOSCA may therefore prove difficult.

Ataxia + blindness + deafness (SCABD)

In 1974, van Bogaert and Martin reported a family with autosomal recessive spinocerebellar ataxia plus optic and

cochleo-vestibular degeneration leading to deafness and blindness (van Bogaert & Martin, 1974). We have reported a similar family, for which we demonstrated linkage to a 17 cM region on chromosome 6p21–23 (Bomont *et al.*, 2000). In our family, an uncle and a niece, both born from consanguineous parents, started with gait ataxia at 3 years of age. The niece had no cranial nerve involvement at age 6 but showed slow responses on electroretinograms at age 14 and had impaired hearing and vision by age 17 years. The uncle was wheelchair bound and almost deaf by age 27 years. Fundus examination revealed bilateral optic atrophy. Common causes of recessive ataxia were excluded, including mitochondrial diseases. The identification of additional families linked to 6p21–23 is needed in order to delineate a precise clinical presentation and progression for this condition.

Cerebellar ataxia + peripheral neuropathy

Ataxia + oculomotor apraxia 1 (AOA1)

The first two cases of ataxia + oculomotor apraxia were reported in 1971 by Inoue *et al.* and were Japanese patients (Inoue *et al.*, 1971). The identification of the gene defective in form 1 revealed that the disease is more frequent in Japan due to the occurrence of two ancient founder mutations, but exists also worldwide, with a major Caucasian founder mutation. In 1988 Aicardi *et al.* collected reports of 14 AOA patients, 6 of them already described in the literature (Aicardi *et al.*, 1988). In 2001, Barbot *et al.* reported 22 Portuguese cases, of which 14 turned out to be defective for the AOA1 gene (Barbot *et al.*, 2001). AOA1 is defined by early onset (between 2 to 5 years of age) cerebellar ataxia, ocular apraxia and areflexia indicative of peripheral axonal neuropathy, which translates later as a clinical motor neuropathy (causing neurogenic distal muscular atrophy). Ocular apraxia is defined as the limitation of ocular movements on command dissociated from movements of pursuit. In the case of AOA1, ocular apraxia would be better defined by saccadic failure or slow (viscous) eye movements and would indicate neuronal lesion in the pons rather than in the motor cortex, as for pure ocular apraxia. The cerebellum is severely atrophic while the brainstem and spinal cord are usually preserved. Dystonia and/or athetosis may be occasionally found. Patients often have borderline intelligence. They may have a normal lifespan, although with severe motor handicap leading to loss of ambulation by age 15 years.

Localization of the defective gene to chromosome 9p13.3 in Portuguese families allowed demonstration that AOA1 is the same disorder as early onset cerebellar ataxia

with hypoalbuminemia (EOCA-HA) (Moreira *et al.*, 2001a), described a few years earlier in Japan (Uekawa *et al.*, 1992). As such, both entities are characterized by reduced serum albumin and elevated cholesterol after a long disease duration (usually 15 years). These biochemical abnormalities (of hepatic and not renal origin) cannot be used for early diagnosis. The FRDA2 locus identified in 9p23-p11 (Christodoulou *et al.*, 2001) is presumably identical with AOA1. Date and colleagues and our group independently identified the AOA1 gene, which encodes for a novel HIT/Zn-finger protein named aprataxin (Date *et al.*, 2001; Moreira *et al.*, 2001b). Proteins containing a histidine triad (HIT) domain are known to have nucleotide polyphosphate hydrolase activity. We have shown in addition that the major isoform of aprataxin (long isoform) encodes an additional domain related to the N-terminal domain of polynucleotide 5' kinase, 3' phosphatase (PNKP) involved in base excision repair (BER) of DNA single strand breaks (SSB). Both this similarity and the nuclear localization prediction of aprataxin suggested that aprataxin might also be involved in SSB repair (Moreira *et al.*, 2001b), a conclusion also supported by the identification of a direct interaction between aprataxin and XRCC1, another component of the SSBR complex (Caldecott, 2003). AOA1 is the most frequent cause of recessive ataxia in Japan, where two founder mutations (689insT and P206L) account for the vast majority of cases (Date *et al.*, 2001; Moreira *et al.*, 2001b). The W279X mutation, found in five out of six Portuguese families (Moreira *et al.*, 2001b), is also widespread and by far the most frequent mutation in the Caucasian population (M.-C. Moreira, personal communication). The missense mutation P206L is associated with a somewhat later onset (around 10 years of age (Date *et al.*, 2001; Moreira *et al.*, 2001b)), and the V263G and K197Q mutations are associated with significantly milder presentations (onset at 25 and 15 years, respectively (Date *et al.*, 2001; Tranchant *et al.*, 2003)). Several DNA repair disorders, such as ataxia-telangiectasia (A-T), xeroderma pigmentosum and Cockayne syndrome, are associated with cerebellar ataxia, neoplasia and/or immunodeficiency (see following chapter). AOA1 shares with A-T early onset cerebellar ataxia and ocular apraxia, but not the extraneurologic features of A-T, suggesting that pathology related to partial BER deficiency might be restricted to postmitotic neuronal tissues. A second disease that rapidly came to support this view is SCAN1.

Spinocerebellar ataxia + neuropathy 1 (SCAN1)

SCAN1 shares with AOA1 the cerebellar atrophy and axonal sensorimotor neuropathy but not ocular apraxia. SCAN1 also shares with AOA1 the borderline low serum

albumin and high cholesterol. The entity was reported in a single multigenerational, consanguineous, family with nine affected (Takashima *et al.*, 2002). Age at onset of the disease ranged from 13 to 15 years in three patients. The disease is linked to chromosome 14q31 and was shown to be due to the H493R mutation in the Tyrosyl-DNA Phosphodiesterase 1 (TDP1) gene (Takashima *et al.*, 2002). TDP1 is an enzyme that repairs stalled covalently bound topoisomerase I-DNA complexes, which lead to single strand breaks during DNA unwinding. H493 is one of the two histidines of TDP1 that act as the nucleophile that attacks the tyrosyl-DNA phosphodiester bond. DNA breaks liberated from the tyrosyl moiety by TDP1 are then repaired by the BER pathway, including intervention of PNKP (see above). It is therefore possible that AOA1 and SCAN1 pathology proceeds from the same biochemical pathway in which aprataxin plays an as yet unidentified role (Caldecott, 2003).

Ataxia + oculomotor apraxia 2 (AOA2)

The first AOA2 family was reported in 1998 by Watanabe and colleagues (Watanabe *et al.*, 1998). The four Japanese patients had cerebellar atrophy, sensory neuropathy but no oculomotor apraxia. Brainstem and spinal cord was preserved. The four patients had moderately elevated alpha-fetoprotein, immunoglobulins and creatine kinase in their blood. The defective gene was localized to 9q34 (Bomont *et al.*, 2000). At the same time, a large Pakistani family with ataxia + oculomotor apraxia was also reported to be linked to 9q34 (Nemeth *et al.*, 2000). The five patients had, however, normal levels of alpha-fetoprotein, immunoglobulins and creatine kinase. We have since then identified eight additional potentially linked families, based on homozygosity of patients born from (remotely) consanguineous parents (unpublished results). Five families had moderately elevated serum alpha-fetoprotein levels and four had oculomotor apraxia. Immunoglobulins and creatine kinase levels were normal and their elevation was presumably fortuitous in the first reported family. Age at onset for all linked families ranged from 14 to 22 years, which is significantly later than for AOA1. It is likely that the majority of the adolescent onset A-T like patients with elevated alpha-fetoprotein levels (Taylor *et al.*, 1994, 1996) do not have hypomorphic ATM mutations but rather AOA2. However, identification of the defective gene is necessary, in order to precisely delineate the clinical features of this entity.

Spastic ataxia of Charlevoix-Saguenay (ARSACS)

More than 300 ARSACS affected individuals are known to live in the Province of Québec, Canada, most of them in the

region of Charlevoix-Saguenay. Molecularly proven cases of ARSACS outside Canada have so far been reported only in Tunisia, but presumably also exist elsewhere. ARSACS was first described by Bouchard and colleagues in 1978 (Bouchard *et al.*, 1978). ARSACS is defined by early and marked degeneration of both the pyramidal tracts of the spinal cord and of the superior cerebellar vermis with subsequent cerebellar hemisphere progressive atrophy (Bouchard *et al.*, 1998). Onset occurs at gait initiation (around 1–2 years). Pyramidal signs dominate the clinical presentation. Spasticity of the lower limbs is the first sign, plantar response is always abnormal, either equivocal or indifferent in youngsters and extensor thereafter. Deep tendon reflexes are increased, often with clonus at the ankles and patellae in early adulthood. Cerebellar signs are sparse at the beginning, but increase slowly from adolescence onwards. They include gait ataxia, dysarthria and nystagmus. The eye signs are most typical of the disease. These early non-progressive signs include saccadic alteration of smooth ocular pursuit and prominent myelinated fibers radiating from the optic disc and embedding part of the retinal blood vessels at fundoscopy (Bouchard *et al.*, 1978, 1998). There is, however, no visual deficit. The abnormal retinal myelinated fibers were not seen in the Tunisian patients (Mrissa *et al.*, 2000). In the mid-20s, motor axonal polyneuropathy appears, resulting in absent ankle jerks. ARSACS patients become wheelchair-bound at a mean age of 41, with a wide range of 17–57 years. The verbal IQ is usually within normal limits, but the handling of visuospatial material is poor and deteriorates with time (Bouchard *et al.*, 1979; Peyronnard *et al.*, 1979). Some patients survive into their 70s, but become bedridden by that time. ARSACS is therefore a very early onset disease with more obvious progression in teenagers and young adults and again subsequent slow progression.

The ARSACS gene was localized to 13q11 in 1999 (Richter *et al.*, 1999) and identified in 2000 (Engert *et al.*, 2000). It is a remarkable intron-less 13 kb long gene encoding for a novel 3829 residue protein named sascin. Sascin contains repeated heat-shock domains, suggesting a role in chaperone mediated protein folding. Ninety-six per cent of the Québec patients are homozygous for the 6594delT founder mutation and the remaining cases (two families) are compound heterozygotes for the founder mutation and a 5254C→T nonsense mutation. Four Tunisian and two Turkish ARSACS families have been identified by linkage analysis (Mrissa *et al.*, 2000; Gucuyener *et al.*, 2001) and all four Tunisian families bear a different mutation (El Euch-Fayache *et al.*, 2003), also different from the Canadian mutations. The diversity of mutations causing ARSACS, including truncating mutations, indicates that ARSACS results from a complete loss of function of

sacsin, a result that was initially unexpected given the high geographic clustering of the cases.

Conclusions

The unravelling of the molecular cause of a growing number of recessive ataxias has revealed that these often rare diseases are the consequences of a large variety of different mechanisms, even involving novel, unsuspected molecular pathways. The functions of the, sometimes novel, proteins encoded by the so far identified defective genes suggest however that the recessive ataxias involving primarily the spinal cord or the cerebellum may proceed from two distinct general pathways. On one hand, Friedreich's ataxia and the vitamin E deficiency ataxias, involving primarily the spinal cord appear to result from increased production of, or lack of protection against, free radical damage, whereas ataxia-telangiectasia, AOA1, SCAN1, as well as MRE11 partial deficiency (see following chapter) appear to result from impaired DNA single or double strand break repair. Further studies on the newly identified proteins defective in recessive ataxias and identification of the, predictably numerous, new genes involved in recessive ataxias when defective should tell whether this trend is a naïve view biased by a small number of observations, or whether it reflects general pathological neurodegenerative mechanisms, which could be amenable to therapy.

Ataxia-telangiectasia (A-T) is an autosomal recessive disorder associated with abnormal function of the nervous, immune and endocrine systems. It was initially described by Syllaba and Henner (1926) and was more completely characterized by Boder and Sedgwick (1958), who also coined the name. The disorder is characterized by a progressive gait and truncal ataxia, immunodeficiency, thymic degeneration, chromosomal instability, predisposition to lymphoreticular malignancies and hypersensitivity to ionizing radiation (for review see Boder, 1985; Gatti *et al.*, 1991; Sedgwick & Boder, 1991; Woods & Taylor, 1992; Gatti, 2002).

Early research into the genetic cause of A-T suggested the presence of as many as four different responsible genes since fusion of fibroblasts from various A-T patients were able to complement one another in radiation sensitivity assays (Jaspers *et al.*, 1988). However, all four groups were subsequently found to have loss-of-function mutations in a single gene, named *ATM* (*ataxia-telangiectasia mutated*), located on chromosome 11q22.3 (Gatti *et al.*, 1988; Savitsky *et al.*, 1995).

The ATM protein is a serine/threonine kinase responsible for maintaining genomic integrity by triggering arrest of the cell cycle, increasing transcription of stress response genes, and repair of double strand breaks in DNA (Shiloh, 2003). Among the many identified substrates are p53, p53BP, MDM2, Chk2, nibrin, Mre11, H2AX, SMC1, Pin2/TRF1, FANCD2, MDC1, and BRCA1. A-T patients express a functionally deficient *ATM* message, with diminished or absent levels of ATM protein (Chun *et al.*, 2003). How mutations in *ATM* result in radiation hypersensitivity or neuronal integrity remains unclear. The function of the ATM protein is addressed in greater detail in Chapter 10.

Neuropathogenesis

The most prominent neuropathologic hallmark of A-T is a marked loss of cerebellar Purkinje and granule neurons. Dendritic arbors of the few remaining Purkinje cells are often abnormal, with abnormal proximal branching of the primary dendrite, reduced secondary and tertiary branching, or both (Fig. 49.1). Shrinkage of the cell soma and “torpedo” formation swelling of the axons are commonly found. Purkinje cell migrational defects are suggested by an increase in the proportion of ectopic cells in the molecular and granule cell layers. However, the majority of Purkinje cells are believed to migrate correctly to the Purkinje cell layer before degenerating. This conclusion is supported by the appropriate positioning of many empty basket cell processes that cradle the Purkinje cell soma only upon its migration into the Purkinje cell layer (Vinters *et al.*, 1985; Gatti *et al.*, 1985). Loss of the granule cells, manifested by thinning of the densely packed granule cell layer, parallels the loss of Purkinje cells. Granule cells synapse upon the Purkinje cell dendritic arbor within the molecular layer, and the loss of either of these cell groups may represent the primary effect of the loss of ATM protein. Reduced numbers of interneurons in the molecular layer and reduced neurons in deep cerebellar nuclei are also observed. Reactive astrocytes and activated microglia have also been observed in the cerebellar white matter, implicating an immune response in the degeneration.

How mutations in *ATM* result in specific neurologic phenotypes remains under investigation. ATM protein recognizes DNA damage probably to signal other proteins that facilitate DNA repair. Consistent with this function, *in situ* hybridization has shown that *ATM* mRNA is confined to subpopulations of cells within highly proliferative zones

Fig. 49.1 Immunohistochemistry on A-T cerebellum shows depletion and dysmorphology of Purkinje cells, with loss of secondary and tertiary arborization. An ectopic Purkinje cell is visible in the centre of the field.

of the brain early in mouse development (Becker-Catania *et al.*, 2000). *ATM* expression is at its peak during embryonic stages during the genesis of early cerebellar and other neuronal precursors. ATM likely has the same critical role of DNA damage surveillance in these proliferating neuroepithelial cells, that later migrate throughout the brain and differentiate into multiple neuronal types. At postnatal times, however, *ATM* expression in the brain is quite low, even in the cerebellar Purkinje and granule cells where neurodegeneration is most prominent. It has yet to be demonstrated that ATM has the same function within postmitotic neurons, but some evidence has suggested that the ATM protein may play a neuroprotective role in tissues undergoing oxidative stress (Barlow *et al.*, 1999).

It is also possible that multiple isoforms of the ATM protein exist. This is suggested by the preponderance of weak splice junctions in the *ATM* gene (Eng *et al.*, 2004). Extensive alternative splicing of large genes, such as *Dscam* (with over 38 000 possible isoforms), has proved important in axonal targeting of olfactory receptor neurons (Hummel *et al.*, 2003). ATM could play a similar role in brain development, in addition to its role as a hierarchical cell signaling kinase.

Mice with targeted knockouts of the *ATM* gene (Barlow *et al.*, 1996; Elson *et al.*, 1996; Xu *et al.*, 1996; Borghesani *et al.*, 2000) exhibit a phenotype that recapitulates many aspects of the human disease, including immune system defects and predisposition to cancer. The cellular phenotype of these mice also includes radiation sensitivity and cell cycle defects. However, the *ATM*^{-/-} (ATM-KO) mice exhibit no obvious neuropathological changes and only mild behavioral disturbances (Barlow *et al.*, 1996; Borghesani *et al.*, 2000; Mount *et al.*, 2004). Atm-KO cerebella display elevated markers of oxidative stress (Barlow *et al.*, 1999;

Quick & Dugan, 2001; Kamsler *et al.*, 2001), increased lysosomes (Barlow *et al.*, 2000) and subtle alteration of synaptic activity (Chiesa *et al.*, 2000), but not the extensive loss of Purkinje cells, thinning of the granule cell layer or gliosis consistently observed in postmortem A-T brain.

Reduced tyrosine hydroxylase and dopamine transporter immunolabeling in the nigrostriatal system of certain Atm-KO mice suggested that the sensorimotor phenotype might be caused by a reduction in dopaminergic transmission (Eilam *et al.*, 1998), an hypothesis consistent with clinical evidence for non-cerebellar extrapyramidal involvement in the human disease (for review see Mount *et al.*, 2002). However, L-DOPA was subsequently found to produce no short-term benefit in clinical trials and neurochemical measurements in behaviorally impaired Atm-KO mice revealed no depletion in catecholamine levels, or turnover in the striatum, ventral mesencephalon, or cerebellum (Mount *et al.*, 2004).

Alternatively, the behavioral phenotype of Atm-KO mice could arise as a consequence of changes in the peripheral nervous system. In support of this notion, *Atm* mRNA is expressed at very low levels in the CNS, but at high levels selectively in sensory neurons of the mature dorsal root ganglion (Soares *et al.*, 1998). In the *dystonia musculorum (dt)* mouse, degeneration of the dorsal root ganglion causes an ataxic condition that is due to the loss of spinocerebellar input, rather than to any direct effect on Purkinje cells (Sotelo & Guenet, 1988; Lalonde *et al.*, 1994). Peripheral neuropathy is common in A-T patients, but it appears relatively later than the other more profound motor impairments, and hence likely does not have a primary role.

Molecular genetics

A specific mutation within the *ATM* gene may confer a milder or more severe disease phenotype (McConville *et al.*, 1996; Gilad *et al.*, 1998; Stankovic *et al.*, 1998; Stewart *et al.*, 2001). The large size of the *ATM* gene along with the fact that mutations occur throughout the 62 coding exons of the gene, prevents direct sequencing as a cost-effective approach for A-T diagnosis. The additional problems of false positives that would result from polymorphisms also reduces this feasibility (Concannon & Gatti, 1997; Mitui *et al.*, 2003; Bernstein *et al.*, 2003).

A-T patients who are not from consanguineous families, carry 2 different mutations in the *ATM* gene, one from each parent. Thus, they are “compound” heterozygotes. A large majority of *ATM* mutations are null mutations resulting in undetectable ATM protein levels (Chun *et al.*, 2003; Butch *et al.*, 2004). Despite this, mRNA levels are abundant in

virtually all A-T patients studied to date. Most *ATM* mutations lead to premature termination codons, or mutations that delete portions of the message (Telatar *et al.*, 1996; Teraoka *et al.*, 1999; Mitui *et al.*, 2003). Also included in this group of mutations are those that alter splicing motifs and result in the skipping of certain exons or parts of exons (Eng *et al.*, 2004). More rarely, mutations may result in pseudo-exons, (i.e. insertion of intronic regions into the mRNA). These also result in downstream frameshifts and premature termination codons (McConville *et al.*, 1996; Pagani *et al.*, 2002; Eng *et al.*, 2004).

Missense mutations that change the amino acid sequence account for less than 10% of A-T cases. However, some of these missense mutations may in fact act via exon splice enhancer (ESE) and exon splice silencer (ESS) motifs that alter preRNA splicing (Eng *et al.*, 2004; Coutinho *et al.*, 2004). Thus, the frequency of *ATM* missense mutations is likely to be lower than current estimates.

ATM mutations are mostly detected by serial testing of the DNA and RNA from lymphoblastoid cells (LCL) (Mitui *et al.*, 2003; Coutinho *et al.*, 2004). The large size of *ATM* has made screening for mutations difficult, and several strategies are used by different laboratories. A useful approach is to first identify the *ATM* haplotype using four very informative microsatellite short tandem repeat (STR) markers: S1819, NS22, S2179 and S1818. The alleles for each marker are carefully standardized so that haplotypes are compared to a global database of affected haplotypes from more than 500 A-T patients (Mitui *et al.*, 2003) (see also www.benaroyaresearch.org/bri.investigators/atm.htm). Further identification techniques include ascertaining SNP (single nucleotide polymorphism) haplotypes across the region of the *ATM* gene (Campbell *et al.*, 2003). Once the *ATM* haplotypes have been identified, the mutations most commonly associated with a given haplotype can be checked quickly by single stranded conformational polymorphism (SSCP) (see below). Approximately 30% of all new patients have mutations within previously defined haplotypes, a probability that increases to as high as 95% in certain well-studied ethnic groups, such as Costa Rica, Norway, Spain, Brazil, Poland or Turkey (Telatar *et al.*, 1996, 1998a,b; Mitui *et al.*, 2003; Coutinho *et al.*, 2004) and other genetically isolated populations, such as the Amish, Mennonite, or Moroccan Jews. On the other hand, the percentage of *ATM* mutations that can be identified by this haplotype-shortcut decreases as the genetic heterogeneity of a population increases. For example, the American population typifies a genetically heterogeneous population in which the identification of *ATM* mutations by standardized haplotyping is not particularly efficient (Mitui *et al.*, 2003).

If common *ATM* mutations are not identified by haplotyping, RNA is collected from the patient's LCL, converted to cDNA, and screened first by protein truncation testing (PTT). This gel-based method efficiently identifies the position of truncating mutations (i.e. those leading to premature stop codons) in fragments of approximately 1500 nucleotide length (Telatar *et al.*, 1996). Thus, by studying only eight overlapping fragments, the entire *ATM* transcript (9168 nucleotides) can be screened in a single experiment. Overall, 70% of all *ATM* mutations in A-T patients are detected by this method, although this excludes missense mutations. In contrast, when screening for *ATM* mutations in breast cancer patients, which are primarily of the missense type, PTT is not an efficient method (FitzGerald *et al.*, 1997).

SSCP is a method that detects all types of mutations in fragments of less than 300 nucleotide length. This alternate method is used when a suspected A-T patient does not demonstrate mutations by PTT screening. Screening the *ATM* cDNA with SSCP involves analysis of 34 overlapping fragments. Twenty patients can be screened for 3 fragments on a single gel (Castellvi-Bel *et al.*, 1999). Detection efficiency of SSCP approximates 80%.

Denatured high-performance liquid chromatography (dHPLC) uses genomic DNA and is a more automated screening method, involving capillary gel electrophoresis. However, interpretation of the resulting chromatogram for each segment requires considerable expertise, varies slightly from one apparatus to another, and is difficult to validate for clinical application. The 62 coding exons, and approximately 50 nucleotides of flanking intronic DNA are PCR-amplified and allowed to form heteroduplexes – these would arise if the patient were heterozygous for a mutation in a particular region of the gene (Thorstenson *et al.*, 2001; Bernstein *et al.*, 2003). Inclusion of flanking intronic DNA in each heteroduplex allows for the identification of splice site mutations. In those patients from consanguineous matings (who would be expected to be homozygous for an *ATM* mutation) heteroduplexes cannot form and the mutation cannot be detected by dHPLC unless additional DNA from a normal person is added to the test sample. The efficiency of dHPLC for detecting *ATM* mutations approximates 85% (Bernstein *et al.*, 2003).

When an abnormal pattern is detected by any of the above methods, the suspect region is sequenced to identify the specific genomic mutation. When all these methods are used serially, the detection efficiency approximates 95% for the *ATM* gene (Mitui *et al.*, 2003). The missing 5% reflects the fact that each of these methods depends upon PCR amplification across only exons and the immediately adjacent sequences, leaving large stretches of intron sequences

or the upstream or downstream regulatory regions of the gene unamplified and unstudied. This is primarily because these regions are very large (>90% of the *ATM* gene) and the yield of mutations in these regions is low. Furthermore, limited understanding of these regions of most genes makes it difficult to interpret the functional significance of DNA changes at specific sites. Other missed *ATM* mutations involve large deletion and duplication rearrangements within the *ATM* gene that are masked by the other allele.

Correlating phenotype with specific genotype is in progress, now that both mutations have been identified in a large proportion of patients. To date, only a handful of mutations seem to correlate with phenotypic variations of the classical A-T syndrome, as defined by Boder and Sedgwick (1958). These include: IVS40+1126A>G (McConville *et al.*, 1996) and the 7271T>G (Stankovic *et al.*, 1998; Stewart *et al.*, 2001) mutations. These mutations are associated with slower progression of neurological symptoms, extended life span, and possibly less radiation sensitivity.

Clinical aspects

The onset of unsteadiness and truncal ataxia is generally detected before 3 years of age (Boder & Sedgwick, 1958; Gatti *et al.*, 1991; Gatti, 2002) and head-tilting is sometimes noted as early as 6 months. Ocular motor apraxia, which refers to an incoordination of eye and head movement with shift of gaze in the horizontal axis, generally first appears in early school years (Lewis *et al.*, 1999). Slurred speech is obvious before 5 years. However, the characteristic oculocutaneous telangiectasia are not observed until many of the neurologic symptoms are well established. Most children benefit from the assistance of a wheelchair by the age of 11. In the late teen years, the rate of neurological deterioration appears to slow: whether this is by actual slowing of the underlying pathology or by an increasing ability to cope with the progressive deficits is not clear. Impaired control of head movement and difficulties in swallowing and coughing lead to problems of aspiration, pneumonia, and sinopulmonary infections with non-opportunistic organisms. Whether immunodeficiency adds to the pathogenesis of lung disease is also unclear; pneumonia in older individuals does not appear to correlate with any other laboratory measure of immune function.

Children with A-T have poor articulation of speech, difficulty with handwriting, reading, and mobility, leading to a lifelong dependency for activities of daily living. Mental status is normal in most cases, and in some cases patients have been able to complete a university-level

education. Life expectancy varies, some patients living into the sixth decade. This appears to have changed dramatically over the past 30 years, for unknown reasons. The two main causes of death are malignancy and pneumonia, with another group succumbing to a wide variety of complications. Malignancies, chiefly lymphoreticular, may arise at any age. In many cases pneumonia may be due to chronic aspiration secondary to swallowing dysfunction. A few patients have had fatal reactions to radiation therapy for their malignancies (Gotoff *et al.*, 1967; Gatti, 2002). Because the malignancy sometimes precedes any obvious neurological impairment, it is recommended that a diagnosis of A-T be considered in *all* very young cancer patients before the age when neurodegeneration is prominent, in order to prevent complications of excessive radiation.

Cancer susceptibility

Malignancies in A-T are common, affecting approximately one-third of patients (Swift *et al.*, 1976). Lymphomas and leukemias are the predominate forms of malignancy (Gatti & Good, 1971; Spector *et al.*, 1982; Su & Swift, 2000). Younger children are more likely to develop common acute lymphocytic leukemia, while older children also develop TCL-1 expressing T-prolymphocytic leukemia (formerly called T-CLL) (Chun *et al.*, 2002). Both T-cell and B-cell lymphomas occur. Older patients may also develop non-lymphoid cancers including stomach, breast, basal cell, ovarian, liver, and uterine cancers, as well as melanoma (Su & Swift, 2000). The inherent sensitivity of A-T patients to radiation therapy and chemotherapy has complicated therapy (Gotoff *et al.*, 1967; Gatti, 2002).

Whether heterozygotes for *ATM* mutations demonstrate increased propensities for malignancy is still being investigated. *ATM* heterozygotes may account for about 5% of familial breast cancer (Swift *et al.*, 1991; Gatti *et al.*, 1999), a level greater than the 1–2% that is attributable to mutations in *BRCA1* and *BRCA2* (Chevenix-Trench *et al.*, 2002). *ATM* mutation frequencies vary from 2–16% for various breast cancer cohort studies, with relative risks approximating four times that of the general population. However, estimates of risk are influenced greatly by study designs, age of onset of cancer, and penetrance estimates, and large statistical confidence intervals complicate the interpretation of such results.

The spectra of *ATM* mutations for A-T patients versus unrelated breast cancer patients appears to differ dramatically (Gatti *et al.*, 1999; Concannon 2002). The frequencies of missense and nonsense mutations in breast cancer cohort studies are 15% nonsense and 85% missense,

respectively. In contrast, in A-T patients, approximately 90% of mutations are of the nonsense (null) type, while only about 10% are of the missense type. Furthermore, breast cancer patients in cohorts who are heterozygous for *ATM* mutations do not seem to have any relatives with A-T. Thus, study design biases which types of *ATM* mutations are found. It was hypothesized that heterozygosity for some missense mutations may result in a dominant negative effect (Gatti *et al.*, 1999), i.e. that the presence of mutated *ATM* protein may result in more serious biological consequences than the absence of protein, as is seen with null or nonsense mutations in most A-T patients. Recent studies with *Atm* knock-in mouse models strongly support a dominant negative model (see below). A dominant negative effect on cancer susceptibility is also observed when heterozygous mutations in the *H2AX* gene are introduced into p53^{-/-} (apoptosis-deficient) mice (Bassing *et al.*, 2003).

When missense *Atm* mutations were introduced by knock-in approaches, an increased frequency of tumors in heterozygous (and homozygous) mice was observed (Spring *et al.*, 2002; Concannon, 2002). This was in stark contrast to the absence of tumors in previous studies using mice that were heterozygous for knock-out mutations in the *Atm* gene (Barlow *et al.*, 1996). Thus, dominant negative missense *ATM* mutations may serve to increase susceptibility to cancer in the general population. This is further supported by the mutagenesis experiments of Scott *et al.* (2002).

Taken together, these analyses of *ATM* heterozygosity in cancer cohorts suggest that the carrier frequency in the general population may exceed 5%, as compared with the previous 1% carrier frequency estimate that was based on families with A-T children (Swift *et al.*, 1986). However, carriers of missense *ATM* mutations do not appear to manifest any obvious neurological symptoms.

AT-phenocopy disorders

Several AT-related disorders have been described. However, only *Mre11* deficiency (also called A-T Like Disorder) has ataxia with cerebellar degeneration, is radiosensitive in diagnostic testing, and might be misdiagnosed as A-T (Stewart *et al.*, 1999; Pitts *et al.*, 2001). Because *Mre11* deficiency is very rare, it is difficult to generalize about the clinical picture or cancer risk of homozygotes or heterozygotes. Many of the neurologic features overlap with A-T, although the overall severity in the seven known kindreds resembles a somewhat milder disorder than classic A-T. Telangiectasiae have not been observed.

Since *Mre11* forms a DNA repair complex with *Rad50* and *nibrin*, and is phosphorylated by *ATM* in response

to radiation damage, it is not surprising that the phenotypes of *Mre11* deficiency and A-T overlap. When the *Mre11* gene is knocked-out in mice, the animals die before birth.

Nibrin protein is absent on conventional immunoblot of lysates from patients with Nijmegen Breakage Syndrome (NBS). *Nibrin* is a direct target of *ATM* phosphorylation as well. NBS patients are clinically identified by prominent microcephaly and do not have any of the motor difficulties or ocular telangiectasia that characterize A-T (Hiel *et al.*, 2000). NBS patients manifest both *in vitro* and *in vivo* radiosensitivity (Sun *et al.*, 2002; Bakhshi *et al.*, 2003). All three disorders manifest an increased frequency of translocations involving chromosomes 7 and 14 in peripheral blood lymphocytes. The G1/S checkpoint is also impaired in all. *ATM* protein levels are approximately normal in *Mre11* deficiency and NBS patients. The similarities of cellular phenotypes between A-T, *Mre11* deficiency, and NBS relate these disorders more closely to one another than do their clinical features (Uziel *et al.*, 2003).

The diagnosis of early onset ataxias that are not obviously of a dominant nature must also include two newly defined autosomal recessive ataxias with oculomotor apraxia (AOA1 and AOA2): AOA1 appears to be more common than A-T, NBS, or *Mre11*-deficiency in at least Portugal and Japan (Moreira *et al.*, 2001a). Clinically, the ataxia appears early in childhood and is not associated with telangiectasia or an elevated alpha-fetoprotein. Mutations in the aprataxin (*APTX*) gene on chromosome 9p13 have been identified in these patients. The *APTX* protein is depleted or absent by immunoblotting. Cells from AOA1 patients are not sensitive to ionizing radiation; however, single strand break repair is defective and can be demonstrated by the response to hydrogen peroxide damage. The *APTX* protein colocalizes in nuclei with XRCC1 and poly(ADP-ribose) polymerase (PARP) (Moreira *et al.*, 2001b).

AOA2 is associated with mutations in the *senataxin* gene on chromosome 9q34. These patients have a later onset of ataxia and do not have telangiectasia. Serum alpha-fetoprotein levels are elevated, similar to A-T. Cells from AOA2 patients do not appear to be sensitive to ionizing radiation but again may be defective in single strand break repair. The protein is absent on immunoblots of cell extracts from AOA2 patients. AOA2 has helicase function (Moreira *et al.*, 2004).

Laboratory diagnosis

Three routine tests are immediately available to support a diagnosis of A-T in a young child: 1) serum alpha-fetoprotein

(AFP); 2) karyotyping, with special attention for translocations involving chromosomes 7 and 14; 3) and immune status of B and T cell compartments. The AFP is elevated in more than 95% of A-T patients (Chun *et al.*, 2003). False positives appear to be a diagnostic problem in children under 2 years of age, however, as the AFP descends from very high levels in the fetus at a variable rate during infancy. Serial measurements of AFP can distinguish those with slow descent of normal fetal expression. Elevated AFP is also associated with some malignancies. Karyotyping is seldom normal in A-T cells; however, mitogen-stimulated A-T lymphocytes may have to be harvested slightly later than routine in order to visualize a sufficient number of metaphases for a careful analysis. T cell levels are mildly low in most A-T patients but overlap with the wide range of normal is not uncommon. Gamma/delta T cell levels are usually elevated, probably reflecting a maturation defect in this pathway. B cell levels are normal, or slightly elevated. Serum immunoglobulin levels often reveal marked deficiencies of IgE (80% of patients), IgG2 (80%), and IgA (60%). None of these above parameters changes with age. Patients may develop monoclonal or polyclonal gammopathy, sometimes to the degree that treatment for hyperviscosity is required (Nowak-Wegrzyn *et al.*, 2004).

Radiosensitivity is also characteristic of A-T cells (Taylor *et al.*, 1975) and has been used to confirm the clinical diagnosis. The most commonly used assay is a colony survival assay (CSA) (Huo *et al.*, 1994; Sun *et al.*, 2002). This assay is performed on EBV-transformed lymphoblastoid cells (LCLs) and has a 3 month turnaround time in the laboratory. However, the same LCL can also be used for immunoblotting, to measure ATM protein levels, as well as for testing ATM kinase function and for determining mutations in the *ATM* gene. Virtually all cell lines from A-T patients are radiosensitive (Fig. 49.2). LCLs from patients with a variety of other disorders are also radiosensitive by CSA; of these, only Mre11 deficiency manifests radiosensitivity by CSA and an ataxia of early onset that might be confused with A-T (see below). Conversely, LCLs from patients with Friedreich's ataxia or AOA1 are not radiosensitive (Huo *et al.*, 1994; Gatti, 2002; Sun *et al.*, 2002). Chromosomal breakage studies following in vitro irradiation also demonstrate this radiosensitivity; however, rigorous diagnostic ranges for such testing have not been defined (Woods & Taylor, 1992). Patients with Fanconi anemia are also radiosensitive by CSA (Sun *et al.*, 2002; Nahas *et al.*, 2005); however, these patients characteristically do not manifest ataxia.

Immunoblotting of extracts from normal cells is used to detect ATM protein (Becker-Catania *et al.*, 2000; Chun *et al.*, 2003). If performed on blood, 10–20 million cells are

Fig. 49.2 Radiosensitivity of lymphoblastoid cells from patients with A-T, NBS, Mre11 deficiency, Fanconi anemia (6 complementation groups), as well as normal controls and A-T heterozygotes. Numbers in parenthesis represent the number of patients tested for each disorder. The Colony Survival Assay (CSA) is scored 10 days after irradiation with 1 Gray (Huo *et al.*, 1994; Sun *et al.*, 2002).

needed to obtain reliable results because ATM protein concentrations are normally low. This makes immunoblotting impractical for testing small infants unless a cell line is first established. ATM protein is absent in more than 85% of A-T patients. Very small amounts of ATM protein are seen in the remaining 15% of patients. Controls are also used to ensure equal protein representation within each lane of the gal antibodies to hMre11 can be used for this purpose. Thus, this protocol further serves to screen for patients with Mre11 deficiency (Stewart *et al.*, 1999).

In rare circumstances, an A-T phenotype may present with normal amounts of ATM protein (Stankovic *et al.*, 1998; Stewart *et al.*, 2001). The ATM protein in these cases is functionally defective. This can be demonstrated by assessing ATM kinase activity, wherein Serine or Threonine residues of known ATM substrates are phosphorylated. Either in vivo or in vitro assays of kinase activity can be used (Chun *et al.*, 2003). The most commonly tested ATM substrate is p53, which is phosphorylated by ATM on Serine 15 (Canman *et al.*, 1998; Banin *et al.*, 1998). Studies of >50 A-T patients, with or without detectable ATM protein, have shown that typical A-T cells do not phosphorylate p53, nor alternate substrates like MDM2, SMC1, or nibrin. Patients with some detectable ATM protein, or with some detectable kinase activity, may have slower neurological progression and longer survival (Gilad *et al.*, 1998; Becker-Catania *et al.*, 2000; Saviozzi *et al.*, 2002; Chun *et al.*, 2003).

Differential diagnosis and imaging

A-T is more easily diagnosed in older children once the ataxia, apraxia, telangiectasia, and dysarthria are fully expressed. By this time, the disorder will be clearly progressive and may also be apparent in other sibs, or relatives, indicating a genetic disorder of autosomal recessive pattern. Conversely, early diagnosis is often missed because of the absence of ocular telangiectasia, which is not usually apparent at the time of first concern about impaired balance and motor ability (Cabana *et al.*, 1998). It is in very young patients that laboratory diagnosis is most helpful. Early diagnosis can play a major role in family planning. It can also help to avoid years of costly diagnostic testing.

In very young infants the diagnosis can be easily confused with mild cerebral palsy, acute infectious or episodic ataxia, malignancy, or even with some other rare genetic or mitochondria disorders, such as MERFF or Leigh's Disease (Gatti, 2002). In the United States, A-T is the most common of the known monogenic autosomal recessive ataxic disorders of children before school age; the more common Friedreich's ataxia generally does not begin to manifest until later childhood, adolescence or beyond. Friedreich's ataxia can generally be distinguished from A-T by the early abnormal Romberg sign, hyporeflexia, abnormal Babinski response, and normal control of saccadic eye movements.

Cerebellar atrophy is usually not apparent by MRI in young A-T patients. In a study of MRI changes involving A-T patients of various ages, the pattern of cerebellar atrophy appeared to progress from the lateral hemispheres to the inferior and superior portions (Tavani *et al.*, 2003).

Treatment

Advances in understanding the molecular genetics of A-T have improved understanding of pathogenetic mechanisms and the accuracy and precision of diagnostic testing. Unfortunately, these advances have not yet led to the development of effective neuroprotective, or neurorestorative therapies. Thus, A-T treatment continues to focus upon the supportive care, and in particular the medical management of sinopulmonary infection and dysfunction, immunodeficiency, malignancy and upon rehabilitative efforts in speech and swallowing, nutrition, physical and occupational therapy and the use of adaptive equipment. Occasional patients have expressed improved control of balance, incoordination and dysarthria with hydroxyphenyldil, amantadine (Botez *et al.*, 1996), buspirone (Trouillas *et al.*, 1997) and fluoxetine (Seliger *et al.*,

1989). Clonazepam and gabapentin and other anticonvulsants have been found to help with the cerebellar tremor (Faulkner *et al.*, 2003). Anti-cholinergic compounds can provide some control over drooling, and along with dopaminergic agonists, may also reduce basal ganglia dysfunction. Multiple factors, including significant placebo effects, the pleomorphic nature of movement abnormalities in A-T, tolerance effects of any one medication, rarity of the disorder and individual differences, all undermine the potential for systematic clinical trials of any one agent.

As in essential tremor, botulinum toxin injections to selected muscles have been used to control cerebellar-mediated tremor of the head or limbs. However, the complex and multifactorial nature of the movement abnormalities in A-T inhibits the development of other interventions such as deep brain ablative and stimulation procedures.

Secondary complications of progressive ataxia can include deconditioning/immobility, weight loss or gain, skin breakdown, recurrent pulmonary and urinary tract infections, aspiration, occult respiratory failure, and obstructive sleep apnea, all of which can be life-threatening. Depression in the older patient and involved family members can be encountered, as maturing patients come to realize their physical and social limitations more fully.

Symptomatic treatment can greatly improve the quality of life of these patients and prevent complications that could hasten death. Supportive interventions should always be offered – education about the disease itself, genetic counseling, individual and family counseling, referral to support groups and advocacy groups, and guidance to online resources (e.g. the A-T Children's Project: www.atcp.org).

Treatment is symptom-focused (imbalance/incoordination/dysarthria; cerebellar tremor) and may be monitored with a few, simple, reproducible, and semi-quantitative measures of performance (timing of gait, single-limb balance, hand and foot tapping, completion of a spiral maze or pegboard, reading of a standard paragraph) (Notermans *et al.*, 1994). Self-reporting of functional measures (use of aids to gait, number of falls, success at a keyboard or electronic game or carrying a cup of coffee across a room, need for assistance with dressing or personal care or eating, difficulty being understood) can also be reliable indicators (D'Ambrosio *et al.*, 1987). The use of clinical rating scales sensitive and specific for the most important features of A-T along with other objective, sensitive measure may be invaluable for future clinical trials (Crawford *et al.*, 2000).

Controlled trials of disease-modifying therapy in A-T have not yet been published. Presumed mechanisms of

pathophysiology resulting from increased oxidative stress (Barzilai *et al.*, 2002) have examined antioxidant/free radical scavengers in vitro and in vivo. However, the treatment regimens in these studies do not demonstrate improvement in the neurologic features of any of the inherited ataxias (vitamin E (Marcelain *et al.*, 2002), alpha-lipoic acid (Gatei *et al.*, 2001), *N*-acetylcysteine (Edwards *et al.*, 2002), selenium (Jauslin *et al.*, 2002), idebenone/coenzyme Q10 (Artuch *et al.*, 2002)). The effects of timing in treatment initiation and dosing are unknown. Furthermore, few of these agents cross the blood–brain barrier effectively. Although many antioxidant therapies are safely tolerated, patients trying high-dose antioxidant therapies should be monitored for potential hematologic or hepatic side effects. Recently, the laboratory use of aminoglycosides to increase intracellular ATM levels (400- to 800-fold) and correct ATM function has been reported (Lai *et al.*, 2004), suggesting that the identification of mutations in AT patients may become relevant to therapy.

Motor neuron diseases

An approach to the patient with motor neuron dysfunction

Matthew J. Parton and P. Nigel Leigh

Department of Neurology, The Institute of Psychiatry and Guy's, King's and St Thomas' School of Medicine, London, UK

Introduction

Anatomically, motor system dysfunction is defined as a derangement – either alone or in combination – of the pyramidal neurons of the corticospinal tract (upper motor neurons – UMN), brainstem motor nerve nuclei or spinal cord anterior horn cells (lower motor neurons – LMN). Both UMN and LMN lesions will cause muscle weakness, but other clinical features allow the two to be differentiated (a pyramidal pattern of weakness, spasticity and brisk reflexes follow UMN damage, whereas wasting, fasciculations and reduced or absent reflexes reflect LMN involvement).

A range of neurological conditions may cause a selective motor syndrome. Other illnesses will lead to such dysfunction, together with involvement of other body systems. Alternatively, some conditions will mimic a pure motor disorder but result from a non-selective disease process. These various diseases differ in their etiology, prognosis and management. It is therefore essential to evaluate patients presenting with motor neuron dysfunction carefully, and to make a firm diagnosis as early as possible. With early diagnosis, it is easier to organize effective care, and to keep the patient informed of likely developments in his or her condition.

In this chapter we will discuss the assessment of patients presenting with motor dysfunction and how this allows an accurate diagnosis to be made. We will also introduce and briefly review the principal disorders.

Clinical evaluation

History

The site that was first affected should be determined, as should the precise nature of the original symptom. Patients

usually report a problem with function – difficulty with speech or walking, or with using tools or cutlery – and, at root, these earliest symptoms reflect muscle weakness. In those patients with long-standing problems, the history may reveal that symptoms began in childhood or early adulthood. Such individuals may have had difficulty competing in sports at school, or in passing medical examinations for military service or employment. It should be ascertained whether the original problem has progressed – and over what time – and if other sites of the body have become affected. Questioning may reveal whether the UMN or LMN is involved, for example, if there are symptoms of stiffness or jerking (reflecting spasticity) or loss of muscle bulk or fasciculations (indicating LMN damage). It is important to know if pelvic sphincter or sexual function is impaired. Direct questioning should seek evidence of involvement of other neurological systems (cognitive, sensory or cerebellar). Systemic symptoms such as malaise, weight loss and pain must be evaluated. Finally, a detailed family history should be taken, and a family tree with first- and second- degree relatives drawn. In summary, the history should assess with clarity and precision the nature of the first symptoms, their progression and functional consequences, and should seek evidence to identify or exclude other neurological and systemic disorders. The history serves therefore to propose a hypothesis about the pathological anatomy of the patient's complaint, as well as to place it in the complete medical, social and psychological context of the individual and his or her family.

Examination

A thorough neurological examination and assessment of other body systems will demarcate the sites affected and indicate other possible diagnoses. Attention should be directed as to whether the UMN, LMN or both are involved,

Table 50.1a. Signs associated with upper motor neuron damage

Sign	Comment
Emotional lability (tendency to laugh or cry inappropriately)	As observed during consultation; by reaction to emotionally charged questions
Brisk pout reflex	Tapping upper lip
Brisk facial reflexes	Tapping facial muscles at angle of mouth induces twitch of lower facial muscles
Brisk jaw jerk	Tapping slightly opened jaw causes masseter reflex
Spasticity of tongue	Stiffness and slowing of rapid tongue movements (often best demonstrated by asking patient to repeat lingual phonemes, e.g. “la la la . . .”)
Spasticity of limbs	Very variable in ALS/MND
Brisk tendon reflexes in limbs:	Sometimes difficult to determine if <i>pathologically</i> brisk
• Finger jerks	Usually (but not always) a sign of UMN damage
• Positive Hoffman sign	Almost always pathologically significant
• Brisk and crossed thigh adductor jerks	Almost always pathologically significant
• Positive Babinski sign	Present in ~60% of cases of ALS/MND at some time in the disease

Table 50.1b. Signs associated with lower motor neuron damage

Sign	Comment
Fasciculation	Limbs must be warm and relaxed; fasciculations confined to calves are often innocent
Muscle wasting	Look for characteristic distribution of non-motor neuron disorders (e.g. inclusion body myositis)
Depressed or absent reflexes	LMN form of ALS/MND accounts for ~15% of all cases

and if any other neurological or medical abnormalities are present (see Tables 50.1a and 50.1b). The examination will add to that information already gained from the history, and so clinical evaluation alone will allow the construction of a differential diagnosis. Tables 50.2 and 50.3 list the principal conditions that cause motor neuron dysfunction.

Investigation

Certain investigations are required in order to arrive at a firm diagnosis (Table 50.4). In particular, electrophysi-

ological investigation of motor syndromes is mandatory. Electromyogram (EMG) examination is directed at finding evidence of LMN damage in both clinically affected and unaffected muscles, and excluding other pathologies (such as a myopathy). Nerve conduction studies should also be undertaken to determine if there is neuropathy with or without motor nerve conduction block. Additionally, and particularly when either LMN signs are cranial to UMN involvement or when sensory symptoms complicate the presentation, MRI scanning is indicated to rule out compression or infiltration of the brainstem, spinal cord or nerve roots. T₂-weighted MRI of the brain may occasionally demonstrate increased signal along the corticospinal tracts, but this finding is non-specific (Goodin *et al.*, 1988; Ellis *et al.*, 1999). Creatine kinase may be raised up to 3–4 times normal.

For several motor syndromes – notably amyotrophic lateral sclerosis/motor neuron disease (ALS/MND) – no specific test exists. Therefore, a diagnosis must be established on clinical grounds and supported by appropriate investigations that also exclude other conditions. Research criteria for the diagnosis of ALS/MND have been adopted (World Federation of Neurology Research Group on Neuromuscular Diseases, 1994; World Federation of Neurology Research Group on Motor Neuron Diseases, 1998). The clinical and electrophysiological details are summarized in Tables 50.5 and 50.6.

In certain situations, additional investigation may be required. Muscle biopsy can be helpful when EMG changes are either equivocal or suggestive of a myopathic process. Inclusion body myositis in particular should be considered. DNA analysis will identify Kennedy’s disease and anti-ganglioside (anti-GM1) antibody testing aids the diagnosis of multifocal motor neuropathy with conduction block (MFMN). Anti-GM1 antibodies and conduction block are often difficult to demonstrate in MFMN, but where there is reasonable suspicion of this potentially treatable disorder, a therapeutic trial of intravenous immunoglobulin (0.4 g/kg body weight daily for 5 days) may be considered. Quantitative myometry and clinical assessment before and after treatment are essential to document any response.

Management of the patient

Even before a diagnosis has been established, attention should focus on the management of the difficulties posed by the patient’s condition. All progressive motor syndromes will cause increased disability over time, with variable loss of limb, bulbar and respiratory muscle function. Care should be tailored to individual needs, but we will briefly review the range of interventions and the

Table 50.2. Differential diagnosis of patients with motor neuron dysfunction

Condition	Comment
Amyotrophic lateral sclerosis (ALS) / motor neuron disease (MND)	ALS is specifically the idiopathic degeneration of both UMN and LMN, whereas progressive muscular atrophy (PMA) and primary lateral sclerosis (PLS) are respectively <i>sustained</i> isolated LMN and UMN syndromes. The term MND is broader and allows for the inclusion of all three patterns of involvement.
Spinal cord pathology (especially cervical myelopathy) or disease of the spinal roots or nerves	Clinical features should differentiate these, but they may co-exist with ALS/MND. Consider MRI if appropriate.
Multiple cerebrovascular accidents	Pure motor syndrome unlikely, consider imaging.
Inclusion body myositis	Preferential involvement of quadriceps and finger flexors. May require muscle biopsy.
Kennedy's disease (X-linked bulbar and spinal muscular atrophy)	LMN syndrome affecting males only. Family history and/or features of androgen resistance (gynaecomastia, testicular atrophy, etc.). Diagnosis by detection of trinucleotide repeat expansion in androgen receptor gene.
Multifocal motor neuropathy (MFMN)	Patchy weakness – proportionally greater than wasting; characteristic immunological and electrophysiological findings. Consider trial of IVIg.
Chronic inflammatory demyelinating neuropathy (CIDP)	Symmetrical signs, often sensory symptoms. Raised CSF protein and prolonged nerve conduction studies. Consider steroids and other immunomodulatory treatments.
Other rare CNS degenerations:	
• Adult onset spinal muscular atrophy	Isolated, usually symmetrical LMN syndrome, slowly progressive
• Progressive supranuclear palsy	Vertical gaze palsy, early falls, extrapyramidal features present
• Multi-system atrophy	Complex presentation – amyotrophy rare
• Cortico-basal degeneration	Presents with features of basal ganglia and cerebral cortex dysfunction, amyotrophy occasionally seen
• Machado–Joseph disease (spinocerebellar atrophy type 3)	Complex multi-system presentation overlaps with ALS/MND; autosomal dominant inheritance – trinucleotide repeat expansion in gene linked to chromosome 14q23
• Dementia–disinhibition–parkinsonian amyotrophy complex (DDPAC)	Mutations found in <i>tau</i> gene (microtubule associated protein – chromosome 17q); amyotrophy rare
• ALS–parkinsonian–dementia complex of Western Pacific	Geographical isolate; cause unknown

management of particular aspects of motor system dysfunction below.

It is now generally agreed that the key to effective care is regular review by a multi-disciplinary team (Table 50.7). This should seek to identify and anticipate an individual's problems as early as possible, so as to avoid crises when the patient and carers become overwhelmed. Coordination of care, which is often provided by many healthcare and social services professionals, is of prime importance.

Imparting the diagnosis

This should be done in private, but with the patient's carer(s) in attendance and with ample time for discussion. An early follow-up appointment should be offered to deal with points raised later, and to introduce members of the multi-disciplinary team. Appropriate information, with contact telephone numbers and relevant internet site addresses, should be made available.

Limb dysfunction – managing physical disability

Physiotherapists and occupational therapists play a key role in providing support and advice on mobility and appropriate aids and appliances. Additional assistance can be obtained from specialised services – regional driving assessment centres, rehabilitation units for provision of environmental control systems (giving control of doors, lighting, television, radio, and so on).

Bulbar dysfunction

Assessment of the patient by a speech therapist is desirable when either speech or swallowing become affected by disease. A variety of aids exist that can improve communication, ranging from simple pointing boards to computerised speech synthesisers. Excess salivation (sialorrhoea) may be embarrassing and inconvenient, while violent yawning can be a problem, occasionally leading to jaw dislocation – standard treatments for bulbar spasticity are shown in Table 50.8.

Table 50.3. Other rare motor neuron disorders

Genetically determined forms of motor neuron disorder

Familial ALS

Brown-Vialetto-Van Laere syndrome (early onset bulbar and spinal ALS with sensorineural deafness)

Fazio-Londe syndrome (infantile progressive bulbar palsy)

Hexosaminidase A deficiency

Hereditary spastic paraplegia (many forms, including ALS2, ALS4)

Spinal muscular atrophy (SMA)

Proximal childhood and later onset forms of SMA (types 1–4), SMN gene related

Distal SMA (various forms)

Adult onset proximal SMA (unrelated to SMN gene mutations)

Juvenile or adult onset laryngeal and distal SMA (Harper Young syndrome)

Hereditary Motor and Sensory Neuropathy (predominantly motor forms)

Algrove syndrome

Apparently sporadic (idiopathic) forms of motor neuron disorder

Distal sporadic focal spinal muscular atrophy ('Hirayama syndrome')

Atypical juvenile onset ALS in South India ('Madras' form of ALS)

Western Pacific and other similar forms of ALS (Guam, Kii peninsula, New Guinea)

Motor neuron degeneration in Guadeloupe PSP-Dementia-ALS syndrome

Motor neuron degeneration in Multiple system atrophy

Motor neuron degeneration in Progressive supranuclear palsy

Motor neuron degeneration in Corticobasal ganglionic degeneration

Acquired forms of motor neuron disorder

HTLV-1 associated myelopathy (HAM)

HIV-associated ALS syndrome

Creutzfeldt-Jacob disease (amyotrophic forms)

Multifocal motor neuropathy

Acute poliomyelitis

Lead, mercury toxicity

Neurolathyrim (due to *lathyrus sativa*, containing β -oxalyl-L-aminoacid, BOAA)

Konzo (due to toxic cyanogenic cassava)

Radiation myelopathy (e.g., cervical and lumbo-sacral radiculopathy)

Post-polio progressive muscular atrophy syndrome

Autoimmune disorders (e.g., Sjögren's disease)

Endocrinopathy (Hyperthyroidism, hyperparathyroidism, hypoglycaemia)

Respiratory care

Motor neuron diseases usually cause death by neuromuscular respiratory failure. Earlier, weakness of the chest wall and diaphragm can cause significant distress. A history of

Table 50.4. Investigations in patients with motor system dysfunction

-
- Neurophysiological tests (seeking evidence of anterior horn cell damage in regions not supplied by the same nerve, root or segment)
 - Serum creatine kinase (often elevated, but seldom $> 4 \times$ normal)
 - Brain and spinal cord MRI
 - DNA analysis – *SOD1* mutation for ALS/MND and the expanded trinucleotide repeat in the androgen receptor gene for Kennedy's disease
 - Anti-GM1 ganglioside antibodies (high titre of IgM suggests MFMN)
 - Muscle biopsy
-

Table 50.5. ALS/MND (World Federation of Neurology Research Group on Motor Neuron Diseases 1998)

Required features:

- Evidence of lower motor neuron (LMN) degeneration by clinical, electrophysiological or neuropathologic examination
 - Evidence of upper motor neuron (UMN) degeneration by clinical examination
 - Evidence of progressive spread of symptoms or signs within a region or to other regions, as determined by history or examination
 - No electrophysiological, pathological or neuroimaging evidence of other disease processes that might explain observed signs
-

specific symptoms should be sought (including exertional dyspnoea, orthopnea, disturbed sleep with possible morning headache – indicating carbon dioxide retention and/or daytime somnolence), as early indications of respiratory compromise, together with appropriate signs. It is our practice to refer patients for consideration of respiratory support by non-invasive positive pressure ventilation (NIPPV). This avoids tracheostomy and has been shown to improve survival, symptoms and quality of life (Pinto *et al.*, 1995; Lyall *et al.*, 2001; Newsom-Davis *et al.*, 2001). Both patients and carers should understand that respiratory support is part of palliative care, and that the underlying disease will progress.

Nutritional support

Even without bulbar weakness, motor neuron dysfunction is often associated with weight loss and malnutrition. We found that 21% of ALS/MND patients were malnourished,

Table 50.6. Electrophysiological diagnostic features of ALS/MND (World Federation of Neurology Research Group on Motor Neuron Diseases, 1998)

-
1. *EMG features of LMN involvement: items a) and b) are required*
 - (a) Evidence of active denervation
 - Fibrillation potentials.
 - Positive sharp waves.
 - (b) Evidence of chronic denervation
 - Large motor unit potentials (increased duration, increased proportion of polyphasic potentials, often increased amplitude).
 - Reduced interference pattern with firing rates > 10 Hz (unless significant UMN component, when firing rate may be < 10 Hz).
 - Unstable motor unit potentials.
 - (c) Fasciculation potentials
 - Characteristic and rarely absent in ALS/MND (especially if of long duration and polyphasic). Occur with normal morphology in normal subjects (benign fasciculations) and with abnormal morphology in other denervation disorders (e.g., motor neuropathies).
 2. *Nerve conduction studies*
 - Required principally to define and exclude other disorders (peripheral nerve, neuromuscular junction and muscle); should generally be normal or near normal.
 3. *Electrophysiological features compatible with UMN involvement include:*
 - Up to 30% increase in central motor conduction time determined by cortical magnetic stimulation.
 - Low firing rates of motor unit potentials on maximal effort.
 4. *Electrophysiological features suggesting disease processes other than ALS/MND include:*
 - Evidence of motor conduction block.
 - Motor conduction velocities lower than 70% of normal, and/or distal motor latencies over 130% of normal.
 - Abnormal sensory nerve conduction studies (may be difficult to elicit due to peripheral neuropathies, advanced age, etc., especially in the lower limbs).
 - F-wave or H-wave latencies more than 130% of normal.
 - Decrements greater than 20% on repetitive stimulation.
 - Somatosensory evoked response latency greater than 120% of normal.
 - Full interference pattern in a clinically weak muscle.
 - Significant abnormalities in autonomic function or electronystagmography.
-

with no difference between bulbar-onset and limb-onset cases (Worwood & Leigh, 1998). In addition to difficulty with eating and swallowing, respiratory failure, depression and infection can contribute to poor nutrition. Management is multi-disciplinary: speech therapists assess swallowing and advise on techniques to ease eating and avoid aspiration; a dietician's review will maximise calorific intake in as easily ingested a form as possible. Despite such intervention, oral intake may well become inadequate and so enteral feeding should be considered. Percutaneous endoscopic gastrostomy (PEG) can improve survival prognosis (Mazzini *et al.*, 1995) and is more successful if it is undertaken before respiratory function deteriorates (Chio *et al.*, 1999). The American Academy of Neurology practice parameters state that PEG should be undertaken before vital capacity falls below 50% of predicted? (Miller *et al.*, 1999). More recently, radiologically inserted gastrostomy (RIG) has been advanced and is perhaps suited to patients with respiratory compromise (Thornton *et al.*, 2002). Gastrostomy placement should therefore be considered

early, but as with ventilation, intervention should be considered in the overall context of the individual's quality of life.

Psychological

Depression and anxiety should be treated appropriately, and not viewed as unavoidable consequences of a progressive disease. Emotional lability is usually associated with pseudobulbar palsy and can be eased with antidepressants – particularly SSRIs (such as citalopram or fluoxetine, see Table 50.8). Carers should be supported as well, and patient support organisations can be of great help in such situations.

Other common symptoms

Cramps are a frequent early symptom and may be bothersome. Spasticity may compromise mobility, but can in fact aid weak legs to support the body. Fasciculations are

- Speech and language therapists
- Dieticians
- Counsellors (for bereavement, family support, etc.)
- Specialist nurses
- Palliative care team
- Relevant medical specialities and support staff (gastroenterology, respiratory medicine)
- Care coordinators
- Neurologists

Table 50.8. Symptom control

Symptom	Treatment
Sialorrhoea	Amitriptyline 25–150 mg o.d. Hyoscine patch (1mg) for three days Glycopyrronium bromide 200 mcg (via gastrostomy) Unilateral parotid gland radiotherapy
Fasciculations	Carbamazepine titrated from 200 mg b.d.
Cramps	Quinine sulphate 200 mg o.n. – 300 mg b.d.
Spasticity	Baclofen 5 mg t.d.s. initially, increasing as required Tizanidine 2 mg o.d. initially, increasing as required
Emotional lability	Amitriptyline 25–150 mg o.d. SSRI e.g. citalopram 20 mg o.d., fluoxetine 20 mg o.d., paroxetine 20 mg o.d.

seldom intrusive and often diminish as the disease progresses. Treatment of these symptoms is also outlined in Table 50.8.

End of life

Palliative care can be important before the terminal stages of disease. Home care teams and day centres may offer respite care, with a parallel set of staff complementing those provided elsewhere. Terminal care often involves alleviating distress from respiratory failure. Benzodiazepines and agents to dry secretions may be helpful and opiates can relieve dyspnoea, anxiety, pain or other distress.

Disease-modifying drugs

At the time of writing, only one drug – riluzole for ALS/MND – has been shown to increase survival and thus gain a therapeutic licence. In clinical trials, 18 months' administration of riluzole prolonged life or time to ventilation by an average of about three months (Bensimon *et al.*, 1994; Lacomblez *et al.*, 1996). Patients usually tolerate the drug well, though some experience problems with fatigue and nausea. However, trials demonstrated no convincing effect on functional deterioration, and no assessment was made of quality of life. With these results (and also its relative expense, at ~£3000 per person per year in the UK), its use was controversial in some countries and it was not licensed in others (e.g. Australia).

Genetic issues

The only proven causes of ALS/MND are genetic. Mutation of the gene encoding the enzyme copper/zinc superoxide dismutase (*SOD1*) has been demonstrated in around one-fifth of patients with a family history and 3% of sporadic cases (Rosen *et al.*, 1993; Shaw *et al.*, 1998). A second gene, *ALS2* or *Alsin*, was identified by linkage studies in 2001, but at present the frequency of mutation is unknown (Hadano *et al.*, 2001; Yang *et al.*, 2001). Genetic counselling of pre-symptomatic relatives is necessary before genetic testing is undertaken. Such individuals should be made aware that in 75–80% of familial cases no causative mutation will be found, and thus a negative test does not exclude inheritance of the disease-causing allele. Other rarer conditions (e.g. Kennedy's disease) have wholly hereditary bases.

Models of inheritance

The genetics of a disease such as amyotrophic lateral sclerosis (ALS) require some flexibility in thinking about familiarity compared with the genetics of isolated cases. About 10% of the time, an individual who develops ALS also has first-degree relatives who have been affected. For the remainder, the disease is said to be sporadic, but detailed investigation of the family tree may occasionally reveal that cousins or other more distant relatives have been affected. ALS can therefore be seen as a disease with an inheritance pattern that lies on a continuum from sporadic disease, to familial clustering to clear Mendelian familiarity. For simplicity we have maintained the conventional separation of familial and sporadic disease, but as will become obvious, this distinction is largely artificial.

Familial ALS and the first descriptions

The concepts of genetics were coming into being at about the same time as the earliest descriptions of motor neuron diseases. Mendel presented his classic paper in 1865 (Mendel, 1865) in which he described his famous sweet pea hybridization experiments. He did not use the term gene or genetic to describe the heritable units but called them “formative elements.” Cambridge Professor of Biology William Bateson coined the term “genetics” (from the Greek “to generate”) in 1905 when applying for a university chair in a letter to the Cambridge zoologist, Adam Sedgwick. He wrote, “Such a word is badly wanted and if it were desirable to coin one, Genetics might do.” He was not successful in his application for the chair. The term was first used at a public conference in 1906 (Bateson, 1906), and in 1908 Bateson was finally appointed to the first Chair of Genetics at Cambridge. While it might seem obvious to us now that genes are carried on particles called chromo-

somes, this was not necessarily a widely held view, even by those who strongly supported Mendel, such as Bateson, who believed they were carried as waves or vibrations. This was seen as a reasonable explanation for how such heritable factors could affect the entire body.

In about 10% of cases, amyotrophic lateral sclerosis is inherited as an autosomal dominant trait with age-dependent penetrance of about 96% by the age of 70. About 20% of such families have mutations in the gene for copper/zinc superoxide dismutase, SOD1 (Rosen *et al.*, 1993; Siddique *et al.*, 1991). Although in general, familial ALS is dominant, it is not uncommon for cousins or more distant relatives to be affected. This pattern of familial clustering may be explained by a single gene with very low penetrance, or by more than one locus contributing to disease susceptibility. Either of these explanations could also explain sporadic disease.

Although Charcot first described ALS in 1869 (Charcot & Joffroy, 1869), a familial case of motor neuron disease had been described by the French physician Aran in 1850, in his classic paper describing progressive muscular atrophy. He reported the case of a seaman who had developed cramps in the upper limbs, with subsequent wasting that spread to involve all limbs. The patient had a sister and two maternal uncles with a similar condition.

Aran’s 1850 report portrayed an individual with lower motor neuron degeneration. Because predominant lower motor neuron involvement is often the pattern in SOD1-mediated familial ALS, it is possible that this individual, although reported as having progressive muscular atrophy, in fact had SOD1-mediated familial ALS. His pedigree would be consistent with autosomal dominant inheritance with variable penetrance, concepts and language that did not yet exist.

Pedigrees with familial ALS comprise the most informative group for gene-hunting experiments. The usual

Table 51.1. Familial ALS loci

Familial ALS type	Locus	Gene	Inheritance	Pattern	Mutations	Found in sporadic disease?	References
ALS1	21q	SOD1	AD	Classical	> 105	yes	(Siddique <i>et al.</i> , 1991; Rosen <i>et al.</i> , 1993)

Classification of familial ALS, loci, known genes, phenotype and number of mutations reported to date. AD = autosomal dominant, AR = autosomal recessive, UMN = upper motor neuron predominant, FTD = frontotemporal dementia.

method for gene-hunting in familial diseases is the linkage study. This is a technique based on the discovery by Bateson that some heritable characters tend to be transmitted together and comprise a linkage group. The statistical foundations to utilize this for gene-hunting were developed by Morton in 1955 (Morton, 1955) and constitute the basis of the LOD score method. The ideal pedigree for a linkage study is of at least three generations, as this provides sufficient information on the recombination events to generate a LOD score. This means that it is difficult to perform in a disease such as familial ALS; by the time the diagnosis is established in mid-life in patients, parents may no longer be alive, and children are not yet at the age of risk. Despite these limitations, several successful linkage studies have been performed in ALS, leading to the initial discovery of SOD1 mutations as well as several other loci.

Linked genetic loci in familial ALS

The first locus to be linked to familial ALS was on chromosome 22q21.2, later found to be the location of the SOD1 gene (Rosen *et al.*, 1993; Siddique *et al.*, 1991). This has catalyzed a variety of new lines of investigation in ALS, including the establishment of transgenic mouse and in vitro models of the disease, and has provided insight into the molecular pathogenesis of ALS, as discussed in detail below. Table 51.1 provides a summary of loci and genes to date.

A rare autosomal recessive form of slowly progressive, juvenile-onset predominantly upper motor neuron ALS was described in consanguineous families from Tunisia. Of

the three phenotypic groups, one has been linked to chromosome 2q33 and another to 15q15 (Hentati *et al.*, 1994, 1998). As reviewed below, the chromosome 2q-linked families are now known to have mutations in a novel gene coding for a G-protein known as alsin (Hadano *et al.*, 2001; Yang *et al.*, 2001). Although the initial description of these families included a pedigree with a lower motor neuron component, no other pedigree has amyotrophy, and subsequent mutations have been found in pedigrees with various phenotypes of hereditary spastic paraparesis or primary lateral sclerosis (Eymard-Pierre *et al.*, 2002; Devon *et al.*, 2003). Nevertheless, even though it is not strictly speaking an ALS gene, we will discuss the ALS2 gene and its protein in more detail below.

Typical ALS has also been linked to chromosome 20 and to chromosome 18q (Hand *et al.*, 2002; Sapp *et al.*, 2003). Juvenile ALS with very long survival (tens of years) has been linked to 9q34 in a single large pedigree (Chance *et al.*, 1998).

Predominantly lower motor neuron ALS with tremor has recently been mapped to chromosome 20, and a missense mutation identified in the VAPB gene, involved in vesicle trafficking (Nishimura *et al.*, 2004a).

A US family with typical ALS has been linked to the chromosome X centromeric region in a single brief report presented at a conference (Siddique *et al.*, 1998a).

Recently, four families, three with typical ALS and one with ALS and frontotemporal dementia, were linked to the same region of chromosome 16 (Ruddy *et al.*, 2003; Sapp *et al.*, 2003; Abalkhail *et al.*, 2003). The inheritance of the disease in the typical families was autosomal dominant

with high penetrance, but the family with frontotemporal dementia showed a markedly reduced penetrance. It may seem surprising that a family with ALS may also have individuals affected by frontotemporal dementia, but this is not unusual. The relationship between ALS and frontotemporal dementia is intriguing both pathologically and clinically. ALS with frontotemporal dementia has been linked to chromosome 9q21-q22 (Hosler *et al.*, 2000). A form of parkinsonism with dementia and amyotrophy has been linked to chromosome 17q and subsequently shown to be due to mutations in the gene for microtubule-associated protein tau (for review see (Rosso & van Swieten, 2002)).

Cytosolic Cu/Zn superoxide dismutase (SOD1)

SOD1 is a five-exon gene on the short arm of chromosome 21 that codes for a free radical scavenging enzyme, copper/zinc superoxide dismutase. Mutations in this gene are the only proven cause of typical Charcot ALS. More than 100 mutations have now been described, and rather than tending to cluster in a particular part of the gene, they are scattered throughout the coding region (Andersen *et al.*, 2003). The active site of the enzyme is coded for by exon 3 and this has the fewest reported mutations, suggesting that it is the least tolerant to variation.

The most frequent SOD1 variant worldwide is the D90A mutation, predominant in Scandinavia. In northern Sweden this mutation is present as a clinical silent polymorphism with upwards of 5% of the normal population carrying a copy; indeed, the presence of this variant was first detected by an abnormal pattern of migration of the SOD1 protein in 1968 (Beckman, 1973). In contrast, in southern Sweden, Europe and North America this mutation is rare. In the USA, the A4V variant is the most frequent, accounting for about 60% of SOD1-associated cases. Worldwide, the most common mutations are this A4V substitution and the mutation I113T. Two of these three variants, D90A and I113T, have very low penetrance, implying a low negative evolutionary selection pressure. This could account for their relative abundance in the ALS population. A4V is an aggressive variant, but it is likely that a founder effect in the US population accounts for the high frequency. The low penetrance variants are less likely to generate pedigrees that look suitable for linkage analysis, and it is possible that if these were the only mutations of SOD1 in existence, this cause of ALS would not yet have been found.

Although SOD1 mutations typically cause an autosomal dominant high penetrance ALS, the situation is not straightforward; as noted, some mutations have low penetrance. There is also evidence for a dose effect of mutant SOD1 protein in initiating motor neuron cell death.

This is illustrated by consideration of the D90A mutation (also discussed in more detail in the section on sporadic disease). In northern Sweden, where the D90A variant is common, this missense change generally does not cause ALS when present in single copy, as one would predict of a seemingly benign polymorphism. In contrast, individuals with two copies develop ascending ALS that progresses very slowly. On the other hand, in individuals from other geographic regions, presumably with distinctly different genetic backgrounds, the same mutation can cause ALS when not present in two copies. This propensity to cause ALS when present in heterozygotes is typical of the dominant mechanism of action of all of the other SOD1 missense mutations. In one family, the situation is confounded by the observation that a heterozygous D90A mutation co-exists in affected individuals with the D96N mutation (Siddique *et al.*, 1998b). Whether the disease is solely a consequence of the D96N mutation or the accumulated effects of mutant proteins from both mutant alleles is not clear. Perhaps the best evidence for a dose relationship of mutant SOD1 protein to the initiation of cell death are reports that, in two cases, unusually aggressive, early onset forms of rapidly paralytic motor neuron disease were seen in individuals homozygous for either N86S (Hayward *et al.*, 1998) and L126S (Kato *et al.*, 2001). In the former, the reported case began in early adolescence and proved lethal within only weeks.

In general, there is a poor correlation between genotype and phenotype for most SOD1 mutations, although for most mutations the number of cases on which to base phenotype studies is small (Cudkowicz *et al.*, 1997; Radunovic & Leigh, 1996). SOD1 mutations are often characterized by a predominantly lower motor neuron pattern of ALS, although in such cases the clinical phenotype is otherwise indistinguishable from non-familial ALS. Extramotor involvement (e.g. paraesthesiae or pain) is sometimes seen with SOD1-mediated ALS; the A89V mutation is associated with a sensory neuropathy (Rezania *et al.*, 2003). Bladder disturbances and autonomic dysfunction have also been reported.

The A4V mutation, which may account for up to 60% of SOD1 mutations in the USA, is associated with a poor prognosis; it is not uncommon for A4V cases to survive no more than 12 months or so. The D90A mutation causing disease in single copy is associated with typical ALS, but homozygous (recessive) D90A has a uniform slowly ascending parietic phenotype. Two other exon 4 variants that also have slow progression are G93C and E100K. Exonic position is not a good marker of prognosis, however; for example D90V and I112T are also exon 4 variants but are associated with aggressive disease, while G37R and G41D

are associated with a slower progression but are not exon 4 mutations. One reasonably consistent pattern is that variants associated with lower limb onset are also associated with slow progression and ascending weakness (for example G41D, H46R, D76V, D90A recessive, and E100K). G37R and L38V are associated with an earlier age at onset of symptoms.

ALS2

A form of juvenile, predominantly upper motor neuron, slowly progressive recessive ALS was described in 17 Tunisian pedigrees in 1990 (Ben Hamida *et al.*, 1990). Three phenotypes were distinguished in the initial paper. Group 1 was characterized by corticospinal signs with weakness with wasting in the upper limbs, beginning in early–mid teen years. Two aspects distinguish this phenotype from the other two classes of recessive JALS in this series. First, although there were subtle bulbar findings, no Group 1 cases demonstrated pseudobulbar affective signs. Second, the weakness showed a proclivity to involve the hands early in the disease course, even within the first decade; moreover, the early hand weakness was sometimes unilateral for several years. This form of JALS has been genetically linked to chromosome 15q15–q22 (Hentati *et al.*, 1998) (and designated ALS5) but there is almost certainly genetic heterogeneity in the Group 1 families. Group 2 cases begin early (first or second decade onset) and are clinically characterized by peroneal atrophy with foot drop and spastic paraplegia (with absent ankle reflexes). EMG studies show denervation in all limbs, with normal nerve conduction velocities. Group 3 was defined by one large, consanguineous pedigree with a rather uniform clinical picture of early onset (less than 10 years), spastic paraplegia and prominent pseudobulbar findings. Denervational atrophy was clinically minimal although electromyography demonstrated dysfunction of lower motor neurons in six of six cases.

Group 3 juvenile ALS cases were genetically linked to chromosome 2q33 (Hentati *et al.*, 1994) (and designated ALS2). Subsequently, other recessive families with a similar phenotype and inheritance were found in Kuwait and Saudi Arabia. None had amyotrophy and it may be that this is a unique feature in the one large Tunisian family. In 2001, it was determined that all of the chromosome 2q33 linked juvenile ALS cases had loss of function mutations in a novel gene predicted to have 34 exons encoding a novel protein designated alsin (Hadano *et al.*, 2001; Yang *et al.*, 2001). The first three linked families had small deletions in this gene, predicting a frameshift and premature stop codon resulting in a truncated alsin protein. This gene is

normally processed into two transcripts, short and long. Both are ubiquitously expressed, in the neurons of the central nervous system and other tissues, although the shorter transcript is the predominant form in the liver. Only the Tunisian deletion affects both the short and the long transcripts, and this was postulated as a cause of the amyotrophy seen uniquely in the Tunisian pedigree. Since then, a further deletion also affecting the shorter transcript but not associated with amyotrophy has been reported suggesting that the amyotrophy has a different cause. In the last 2 years, the ALS2 phenotype has been broadened to include infantile hereditary spastic paraplegia with bulbar involvement and mutations have now also been found in families from Algeria, France, Italy and Pakistan, bringing the number of deletions to eight (Devon *et al.*, 2003; Eymard-Pierre *et al.*, 2002). Full length alsin therefore seems necessary for normal motor neuron function, but it is not clear what phenotype if any, would result from missense mutations that do not alter transcript length. The phenotype is more akin to a juvenile hereditary spastic paraplegia with corticobulbar involvement than typical ALS.

Alsin consists of three guanine exchange factor (GEF) domains: a Ran GEF, Rho GEF and a vacuolar sorting domain motif (VPS9 GEF). Guanine exchange factors are small proteins involved in cycling of GTP/GDP for GTPases and are therefore involved in cell signalling. Alsin also contains a membrane occupation and recognition nexus motif (MORN). From this homology, various functions have been proposed, including organization of vacuolar traffic, control of chromatin condensation and cytoskeletal organization.

It is generally recognized that seemingly sporadic forms of ALS might be secondary to defects in genes whose normal functions are important determinants of motor neuron viability. For example, mutations that are either weakly dominant (such as the I113T SOD1 mutation) or recessive in an outbred population could produce apparently sporadic forms of ALS. Because a recessive gene defect would thus be able to masquerade as a cause of sporadic disease, we have recently screened the ALS2 gene for mutations in sporadic ALS cases with some features (early onset, long survival) mimicking features of ALS2. In this study, the alsin gene was sequenced in twelve individuals with predominantly upper motor neuron, young onset (mean age 29, youngest seven years), slowly progressive ALS (Al-Chalabi *et al.*, 2003a). All except one individual were still alive with median survival of 8 years at time of study. Five single nucleotide polymorphisms were found in the coding region, of which all except one were conservative. The non-conservative variant (1102g>a, V368M) in blade 4 of the regulation of chromatin condensation (RCC1) propeller

had already been described in the original papers and does not appear to increase the risk of ALS. (It should be noted that the sequence numbering in the original papers is different in that one starts at base 1 of the coding sequence and the other starts at base 1 of exon 1). Using a maximum likelihood approach to haplotype analysis, regions of linkage disequilibrium were mapped in the gene. Single nucleotide polymorphisms from these regions were used to look for association with ALS in 300 cases and 300 matched controls. No difference was found, suggesting that variants in the ALS2 gene are not a common cause of typical ALS, nor of predominantly upper motor neuron young onset slowly progressive ALS.

Dynactin

Within the last 2 years, another gene defect has been identified in a motor neuron disorder that is an ALS variant. This is coinherited as a dominant trait in a family whose affected members show a late childhood onset form of predominantly lower motor neuron disease with prominent bulbar features. Because it is transmitted equally from mothers and fathers to either daughters or sons, this phenotype might be described as an autosomal form of Kennedy's spinal muscular atrophy. In 2002, Puls and colleagues reported that this disease is a consequence of dominantly acting mutations in the gene that encodes a form of dynactin (Puls *et al.*, 2003). This observation is of considerable biological importance because dynactin is involved in a complex of proteins that comprise a molecular motor for axonal transport; the implication is that an inherited disorder that closely resembles ALS can arise from perturbations in axonal transport. The plausibility of this hypothesis was strengthened by the near simultaneous report that defects in another motor protein, dynein, underlie an inherited motor neuron disease in two strains of mice ("legs at odd angles" or *loa* and "cramping" or *cra*) (Hafezparast *et al.*, 2003).

ALS4

In 1998, a form of slowly progressive, young onset amyotrophic lateral sclerosis was described in a single 11-generation American family (Chance *et al.*, 1998). The phenotype was of distal limb amyotrophy and pyramidal tract signs with severe loss of motor neurons in the brainstem and spinal cord. Mapping studies localized the genetic region to 9q34 with a LOD score of 18.8 and recently, two other families linked to the same locus have allowed the gene to be identified (Ying-Zhang *et al.*, 2004). The SETX (senataxin) gene is a DNA/RNA helicase also responsible

for autosomal recessive ataxia oculomotor apraxia type 2 (AOA2) (Moreira *et al.*, 2004). While three point mutations have been identified scattered through the gene in ALS4, all the mutations identified in AOA2 have been homozygous null deletions except for one compound heterozygote.

ALS8 and VAPB

A form of ALS in which a slowly progressive, predominantly lower motor neuron weakness is associated with fasciculation, cramps and tremor, was recently mapped to the long arm of chromosome 20, in a four-generation, white, Brazilian family (Nishimura *et al.*, 2004a). This was classified as ALS8, and a missense mutation was subsequently found at a conserved amino acid in the vesicle-trafficking protein, VAPB (166c>t, P56S) (Nishimura *et al.*, 2004b). This segregated with disease, and was also found in six other families, also with Portuguese ancestry, and probably from the same founder. Two of these had late-onset, slowly progressive ALS (ALS8 phenotype), three had late-onset spinal muscular atrophy, and one had members with both aggressive, classical ALS and the less typical ALS8 phenotype. This mutation probably disrupts intracellular membrane transport and secretion, especially of the endoplasmic reticulum and Golgi apparatus.

Sporadic ALS

While there is obviously a major genetic contribution from a single gene locus to the development of ALS in Mendelian pedigrees, the situation is not so clear for families with more than a single affected individual but without a clearly Mendelian transmission pattern. The role of inheritance in the majority of cases that are seemingly sporadic is also not defined. The available epidemiological and molecular evidence is that in these cases, the liability to disease is the result of the action of several genes and environmental factors. In such a model, the individual genetic components of disease susceptibility are heritable, but disease does not develop unless a threshold of liability is exceeded. This is best understood by considering the genetics of a continuous trait that shows heritability in humans, such as height.

The distribution of height in the population is Gaussian, and tall parents tend to have tall children. It seems unlikely that there is a single gene, different alleles of which determine height, since the number of discrete alleles required would be huge, and yet height clearly shows heritability. This was the conundrum that faced geneticists in the early twentieth century and was resolved by Fisher in 1918. If a single gene has two alleles, A and a, then if A increases

height by a factor of half a unit above the mean and the a allele decreases height by half a unit below the mean, then the possible combinations, AA, Aa, aA and aa result in heights that are +1, 0, 0 and -1 units around the mean, respectively. If a further locus with alleles B and b has the same effect then the possible combinations AABB, AABb, etc through to aabb result in heights that range from +2 to -2, again with the extremes being rarer than middle values. A three locus system is in fact sufficient to result in a distribution that is almost Gaussian and with the effect of variation from environmental factors, is truly Gaussian. Thus a simple genetic process can result in continuous variation in the population. What is not so clear is whether such a process could result in a tendency to disease that appears sporadic or only showing occasional familial clustering.

The model most geneticists now use to explain this is the liability threshold model. The tendency (or liability) to develop a particular disease shows a Gaussian distribution and could be described by the multilocus inheritance described above. In this model, disease only manifests at one extreme of the distribution, so that only those individuals with a liability to disease above a particular threshold will develop the condition. Under this model, the tendency to sporadic disease is heritable and in some situations this will result in familial clustering. This model also has the property that individuals normally expected to be at lower risk that do develop disease must carry a greater burden of disease-causing genes. For example, in ALS younger individuals are less at risk, so a young person with sporadic ALS would be expected to carry a higher genetic load. A similar argument could be made for females, since there is a 3:2 ratio of men to women. We can therefore believe that sporadic ALS may have a heritable genetic component in theory, but what is the evidence that this is the case?

Evidence that all ALS has a significant genetic basis

Epidemiological studies

There are a number of epidemiological study designs that can provide evidence of a genetic basis for disease. Unfortunately, to date, few of these have been carried out in ALS. The most basic study is a segregation analysis. In this method, the pedigree of everyone in a defined population (for example, those attending a specialist clinic) is used to look for patterns of inheritance. At its most basic, if 50% of family members develop ALS, this constitutes strong evidence for autosomal dominant inheritance. For recessive inheritance the situation is a little more complex. This is

because families in which both parents are carriers, but who by chance do not produce affected offspring, will be common but unknown to the researcher. A correction for ascertainment bias is therefore needed. There are now various computer programs that will analyze large sets of pedigree data for the most appropriate genetic model or combination of models to explain the data. This simple process has not been performed in ALS but could provide evidence that a mixture of dominant genes of major effect and multiple genes of minor effect do indeed produce the distribution of ALS inheritance patterns we see.

Twin studies, adoption studies and adoptive twin studies have proven difficult to carry out in ALS. This is because ALS is relatively rare, and obtaining sufficient numbers is not always possible. One UK-based twin study identified 77 twin probands in 10 872 death certificates bearing the term "motor neuron disease" (used synonymously with ALS in the UK) (Graham *et al.*, 1997). Of these, 26 were monozygotic and 51 dizygotic. Four of the monozygotic probands were concordant with the co-twin for motor neuron disease, although two came from a family with known familial ALS. Based on these figures, the heritability of ALS was estimated as between 0.38 and 0.85.

Epidemiological evidence of familial clustering is important and is used to estimate lambda S (λ_s), the risk to a sibling compared with the general population risk. For ALS, the lifetime risk can be estimated from published epidemiological studies at between 1 in 250 and 1 in 1000 by the age of 70. For those in a family showing autosomal dominant inheritance, there is a 50% chance of inheriting a disease-causing gene and (presuming high penetrance) there is therefore a 50% chance of developing ALS. To understand the risk to a sibling, we can explore a theoretical situation of two siblings adopted into the same family, one of whom develops ALS. What is the risk to the sibling, given that nothing is known about their biological family? There would be a 10% chance that they have come from a family with autosomal dominant ALS, and if so, the risk to the sibling would be 50%. The overall risk is therefore 10% of 50%, which is 5%. When compared with the population risk of 1 in 1000, this gives us lambda S as 50. This is a high figure but is estimated presuming that autosomal dominant disease has high penetrance and that sporadic disease does not increase the risk to a sibling. However, among the 90% of families without autosomal dominant, high penetrance ALS will be some with low penetrance disease. In addition, if we accept the liability threshold model for sporadic ALS, there will be an increased risk for those with no family history at all. In general, for a trait with a normally distributed liability, the risk to a first-degree relative is approximately the square root of the population risk. (This is a result of the properties

Table 51.2. Sporadic ALS candidates

Gene	Findings	References
SOD1	About 2 to 3% sporadic cases have mutations	(Jones <i>et al.</i> , 1994; Andersen <i>et al.</i> , 1997; Jackson <i>et al.</i> , 1997)
APOE	Multiple studies suggest no increased risk, no modification of age of onset. Possible effect on prognosis and presentation	(Al-Chalabi <i>et al.</i> , 1996; Moulard <i>et al.</i> , 1996; Bachus <i>et al.</i> , 1997; Siddique <i>et al.</i> , 1998b)
CNTF	Negative association studies. Anecdotal studies suggestive of age of onset modification, not shown in case-control study. Homozygous deletion not fully excluded as modifier.	(Takahashi <i>et al.</i> , 1994; Orrell <i>et al.</i> , 1995; Takahashi, 1995; Imura <i>et al.</i> , 1998; Al-Chalabi <i>et al.</i> , 2003b)
ALS2	Variants not a common cause of sporadic ALS	(Al-Chalabi <i>et al.</i> , 2003a)
Mitochondrial SOD	Possible risk factor in small studies	(Dhaliwal & Grewal, 2000; Ro <i>et al.</i> , 2003; Mawrin <i>et al.</i> , 2003)
Dynein heavy chain	No increased risk in small study of 3 exons	(Ahmad-Annur <i>et al.</i> , 2003)
MnSOD	Contradictory results in small studies	(Tomkins <i>et al.</i> , 2001; Van Landeghem <i>et al.</i> , 1999; Parboosingh <i>et al.</i> , 1995; Tomblin <i>et al.</i> , 1998)
SMN1	Abnormal copy number possible risk factor. Deletion not.	(Jackson <i>et al.</i> , 1996; Orrell <i>et al.</i> , 1997; Parboosingh <i>et al.</i> , 1999; Corcia <i>et al.</i> , 2002)
SMN2	Homozygous deletion possible risk factor	(Moulard <i>et al.</i> , 1998; Veldink <i>et al.</i> , 2001)
APEX nuclease	Possible risk factor	(Olkowski, 1998; Tomkins <i>et al.</i> , 2000; Hayward <i>et al.</i> , 1999)
LIF	Single small positive study	(Giess <i>et al.</i> , 2000)
NEFH	Multiple positive studies suggest possible susceptibility factor. About 1% of sporadic cases have tail domain indel mutations.	(Al-Chalabi <i>et al.</i> , 1999; Figlewicz <i>et al.</i> , 1994; Tomkins <i>et al.</i> , 1998)
VEGF	Single large multicenter study strongly suggests promoter region SNP haplotype is a risk factor	(Lambrechts <i>et al.</i> , 2003)

Candidate genes studied as possible modifiers or susceptibility factors in sporadic ALS.

of the normal distribution and the distribution of liability in the mating population.) For sporadic ALS this would therefore be the square root of 1 in 1000, which is about 1 in 30. λ_S is therefore about 30 for sporadic ALS. Under these assumptions therefore, the risk to a first degree relative of someone with ALS is between 30 and 50 times the population risk.

Other more unusual methods are also available to provide evidence for a genetic basis of disease. One such is based on the observation that spermatogenesis in humans results in increasing numbers of meioses with increasing paternal age. Since each meiosis carries a small but significant chance of deleterious mutation, genetic disease should arise *de novo* more frequently in those with older fathers (Crow, 2000). This can be tested by inspection of birth order. Last born children will on average have older fathers than first born children, and the demonstration that ALS more commonly occurs in last born than first born individuals would constitute evidence for a genetic basis for ALS.

Another method is estimation of relatedness by isonymy (Lasker, 1968; 1977). This is based on the patrilineal inheritance of surnames in many societies, so that surname inheritance is analogous to Y-chromosome inheritance. In communities with restricted opportunities for outbreeding there is a tendency for a single surname to dominate,

such as Jones or Richards in Wales, or Chan in parts of China. Thus, a restricted set of surnames can be a marker for a genetic bottleneck. Demonstration of a reduced set of surnames in ALS would constitute evidence for increased inter-relatedness of individuals with ALS and therefore of a genetic cause. This has been tested in the UK, Ireland and Germany and has shown a restricted set of surnames for familial disease but not for sporadic disease (Al-Chalabi, personal observation). This is probably because the underlying assumptions of the test are violated sufficiently frequently to reduce its power significantly.

Although the epidemiological evidence is sparse, it does support the notion that there is a significant genetic component to all ALS including sporadic cases. Linkage studies have demonstrated the genes and loci involved in familial disease, but different methods are required in sporadic disease. Table 51.2 summarizes the studies of possible genetic factors in sporadic ALS to date.

Genetic studies – SOD1

Mutations in SOD1 are found in about 3% of apparently sporadic cases (Jackson *et al.*, 1997; Andersen *et al.*, 1997; Jones *et al.*, 1994). In only one case has this been conclusively shown to be due to new mutation (Alexander *et al.*, 2002); it is likely that, in other cases, carrier parents did

not manifest disease. More than 100 SOD1 mutations exist, which suggests that mutation in this gene has not been an uncommon event in our evolutionary history. On the other hand, more than 2000 cases of sporadic ALS per year worldwide should be directly attributable to SOD1 mutation. Because in general ALS affects people after they have started a family, there is not a large negative selection pressure. If the majority of SOD1-mediated sporadic ALS were due to new mutation, the numbers with ALS should be rising rapidly. Further evidence that SOD1 is not especially prone to new mutation comes from four studies of familial ALS that have shown a single founder for two mutants (D90A (Al-Chalabi *et al.*, 1998) and R115G (Niemann *et al.*, 2004)) and two founders for A4V (one for North American cases (Rosen, 2004) and another for the small families from Sweden and Italy (P. Anderson, pers.comm.)).

Two SOD1 mutations in particular, are frequently associated with sporadic disease, I113T and D90A. New mutation is not the usual cause of sporadic cases having SOD1 mutations, and for these two SOD1 variants at least, the explanation is low penetrance. In parts of Scandinavia, D90A in single copy can be regarded as a normal polymorphism of SOD1 with up to 5% of the population carrying it (Andersen *et al.*, 1995, 1996). Individuals homozygous for D90A develop a characteristic phenotype of ALS that is slowly progressive with predominantly spastic legs. (Similar families have also been found in Canada, France, Germany, Italy, Russia and the USA and there is evidence for such a family in Australia). Outside Scandinavia, some individuals with a single copy of the D90A variant develop ALS, either as a sporadic disease or in the context of familial ALS. Such individuals and families have been found in Belgium, Belorussia France, the UK and the USA. These cases generally have a more typical ALS phenotype. Two international haplotype studies have now shown that all D90A variants are identical-by-descent from a single founder, but individuals with the form needing two copies to develop ALS are a subgroup descended from a single more recent founder. The interpretation of this data has been that the recent founder carried a protective factor tightly linked to SOD1 so that in single copy D90A could not cause ALS, whereas individuals descended from the more distant founder alone did not carry such a factor and D90A is therefore toxic in single copy (Al-Chalabi *et al.*, 1998; Parton *et al.*, 2002). An alternative explanation lies within the liability threshold model. If we postulate that the D90A variant is not very toxic but increases liability to ALS by say 51%, then one copy would not cause disease but two copies would. If an individual carries other genetic factors or is exposed to environmental factors that increase liability to ALS by more than 50%, then ALS will result even though there is a single copy of

D90A. In those with a predominantly genetic cause, the other liability factors would tend to be inherited by other siblings, but only 50% of them by offspring. ALS resulting from single copies of D90A would therefore tend to occur in multiple members of the same generation but not in multiple generations, a situation that is in fact observed.

Genetic studies – candidate gene association studies

Other than examining familial genes in sporadic disease, until recently, the only way of finding genes for sporadic disease was the candidate gene association study. This technique relies on selection of a candidate for being a disease-causing gene based on *a priori* assumptions about disease causation or by analogy from animal models. The gene is then assayed for variants in large numbers of cases and controls and if a particular variant is over-represented among the cases the disease is said to be associated with that variant. Association does not imply causation. If cases are not well matched with controls, the distribution of variants between the groups may vary because there may be differences other than disease status between groups. This is known as population stratification. Nevertheless, this technique has yielded some positive results and has excluded other candidates as being important in disease causation.

One of the earliest candidate genes studied was the heavy neurofilament subunit gene, NEFH. Because neurofilament accumulations are a hallmark of the pathology of ALS, they were an obvious choice. The NEFH subunit has a repetitive motif in the tail domain that is heavily phosphorylated. This region was examined in three studies which between them genotyped about 1000 sporadic cases and 1000 controls (Al-Chalabi *et al.*, 1999; Figlewicz *et al.*, 1994; Tomkins *et al.*, 1998). Variants of the tail domain consisting primarily of whole motif deletions or insertions were found in about 1% of cases and 0.2% of controls (both below the usual age of risk, in their thirties). An NEFH deletion was also found in a familial case of ALS, but unfortunately it has not been possible to determine if the mutation segregates with disease in this family. Another study examined 117 unrelated familial cases without finding mutations (Rooke *et al.*, 1996). This suggests that NEFH deletions are susceptibility factors rather than being sufficient to cause disease alone and are therefore predominantly found in sporadic ALS rather than familial ALS.

In Alzheimer's dementia and many other neurological disorders, the 4 allele of APOE is associated with disease or poor prognosis. In ALS several studies have examined this gene. The first of these showed no association between alleles of APOE and susceptibility, age of onset or disease

duration of ALS (Mui *et al.*, 1995). It was subsequently suggested that the 4 allele was associated with bulbar onset ALS (Al-Chalabi *et al.*, 1996) with a trend towards worse prognosis, but not with susceptibility. This association with bulbar onset was also found in a French study, and in that study the association with survival reached significance. In addition, the converse was true for the 2 allele, which conferred protection (Moulard *et al.*, 1996). These findings were called into doubt by subsequent studies that failed to show any association with bulbar onset (Bachus *et al.*, 1997; Siddique *et al.*, 1998a,b). This was the case, too, in a recent study, that also failed to show association with age at onset, but did show a significantly poorer survival in those with the 4 allele by Kaplan–Meier analysis and the log rank test (Drory *et al.*, 2001). It may be that this finding too would disappear if known prognostic factors were controlled for in a multivariate analysis. Finally, a further study has shown no relationship between APOE genotype and clinical presentation or survival, but did show a relationship between APOE plasma levels and survival (Lacomblez *et al.*, 2002).

While dominant mutations of SOD1 can be found in sporadic ALS, it would be reasonable to expect that a recessive mutation might be even more frequent. As discussed above, a form of recessive, juvenile, slowly progressive, predominantly upper motor neuron ALS was recently mapped to the ALS2 (*alsin*) gene on chromosome 2 (Eymard-Pierre *et al.*, 2002; Hadano *et al.*, 2001; Yang *et al.*, 2001). This was therefore a good candidate for sporadic disease and was sequenced in 12 individuals, chosen for having a predominantly upper motor neuron slowly progressive ALS and with a generally young age of onset (Al-Chalabi *et al.*, 2003a). The youngest individual was seven and the mean age of onset was 29. All except one individual were still alive at the time of the study with a median survival of eight years. Several single nucleotide polymorphisms (SNPs) were found, five of which were in the coding region. All were conservative except one, 1102g>a, V368M, which had already been described. This variation occurs in blade four of the RCC1 propeller domain and does not appear to increase the risk of ALS. A further study of 300 cases and 300 matched controls was performed, testing for association with SNP alleles. No difference in allele frequency was found between groups. These findings suggest that variants of the ALS2 gene do not commonly cause typical ALS, nor a predominantly upper motor neuron, slowly progressive form of the disease.

Occasionally, a surprising candidate gene is suggested by accident. One such was the vascular endothelial growth factor gene, VEGF. Transgenic mice with deletion of the VEGF promoter hypoxia response element were gener-

ated by a research team studying the vascular response to hypoxia. Unexpectedly, these mice developed a slowly progressive motor neuron degeneration, with features suggestive of a chronic motor neuropathy or slow ALS in humans. Examination of SNPs in the equivalent region of human VEGF in more than 1900 individuals has shown an association between homozygosity for haplotype AGG or AAG at positions +2,578, -1,154, -634 and ALS. This confers an increased risk of ALS of 1.8, $P < 0.00004$ (Lambrechts *et al.*, 2003). It is known that hypoxia leads to non-specific neuronal death, but this study shows that motor neurons may be especially vulnerable. There is anecdotal evidence of an increased risk of ALS in airline pilots, and it may be that individuals with this haplotype are at risk in certain occupations. There is also an increased risk of ALS in those who exercise heavily, and this, too, may be related to the response to hypoxia. This finding also has implications for the management of respiratory failure in ALS and suggests that aggressive and early treatment may be prognostically very important.

The ciliary neurotrophic factor gene, CNTF, codes for a 200-amino acid protein that is important in the maintenance and repair of the adult nervous system. Studies in mice have shown that disruption of CNTF or its receptor leads to motor neurodegeneration. In humans there is a null allele of CNTF, generated by a G to A intronic mutation. This results in a new splice site and a shorter protein (Takahashi *et al.*, 1994). Homozygous individuals comprise up to 2.3% of the population, but are not at increased risk of neurodegeneration including ALS (Takahashi *et al.*, 1994; Orrell *et al.*, 1995; Takahashi, 1995; Imura *et al.*, 1998). Reports have suggested that CNTF null alleles may be a risk factor for ALS resulting in younger onset and rapid disease (Giess *et al.*, 1998, 2001, 2002). A study of more than 350 individuals with ALS and 167 controls showed no association of the null allele with ALS, clinical features, age of onset or prognosis (Al-Chalabi *et al.*, 2003b).

Another trophic factor, leukemia inhibitory factor, has been implicated in ALS in a single study of 104 patients and 304 controls. Four patients were found to have a 3400 g > a, V64M mutation which was not found in any controls (Giess *et al.*, 2000) ($P 0.0029$ two-tailed Fisher exact test).

The survival motor neuron gene, SMN, has been studied extensively in ALS because of its role in the etiology of spinal muscular atrophy. SMN is found in a duplicated region on the q arm of chromosome 5. Homozygous deletion of SMN1, the telomeric copy, results in spinal muscular atrophy, but the disease severity is modified by the lower activity centromeric copy, SMN2. No study has identified SMN1 deletion as a risk factor for ALS (Jackson *et al.*, 1996; Orrell *et al.*, 1997; Parboosingh *et al.*, 1999; Moulard *et al.*,

1998) but a single study has demonstrated an increased risk of ALS associated with an abnormal SMN1 copy number (1 or 3 copies). Twenty eight of 167 patients compared with seven of 167 controls had an abnormal copy number giving an odds ratio of 1.85 (p 0.00035) for developing ALS (Corcia *et al.*, 2002). One study demonstrated an association of ALS with SMN 2 deletion (but not SMN1) (Moullard *et al.*, 1998) while another showed that homozygous SMN2 deletion is a prognostic factor in ALS, as it is in spinal muscular atrophy (Veldink *et al.*, 2001).

Oxidative stress can lead to alkylating DNA damage. There is evidence of a reduced capacity for repair of such damage in ALS (Tandan *et al.*, 1987; Kisby *et al.*, 1997). A multifunction enzyme APEX nuclease, also known as APE/Ref-1 has a primary function of apurinic/apyrimidinic endonuclease repair. Three studies have shown rare mutations in sporadic ALS and one suggested that an allele of a common polymorphism D148E was over-represented in ALS (Olkowski, 1998; Tomkins *et al.*, 2000; Hayward *et al.*, 1999).

Mitochondrial SOD and MnSOD have been studied as possible candidates in sporadic ALS because of the involvement of Cu/Zn superoxide dismutase. Investigation of mitochondrial SOD mutation requires special techniques because of heteroplasmy. Mitochondria have their own genome and replicate independently of the Mendelian system used by the autosomes and sex chromosomes. Three studies, all small as a result, have been performed. Two of these suggest that mutation or deletion is commoner in ALS than in controls, and another found such changes equally in cases and controls (Dhaliwal & Grewal, 2000; Ro *et al.*, 2003; Mawrin *et al.*, 2003). The studies of Mn SOD have been small and contradictory (Tomkins *et al.*, 2001; Van Landeghem *et al.*, 1999; Parboosingh *et al.*, 1995; Tomblyn *et al.*, 1998).

Genetic studies – genome-wide association studies

The studies discussed above all suffer from the shortcoming that the disease gene needs to be specified *a priori*. In a linkage study, there is no prior assumption about what the disease gene is. The genome scan generates a LOD score which, if sufficiently high, prompts further investigation by haplotyping, fine mapping and positional cloning. This can be done because the common ancestor for family studies is only a few generations back and there will have been little chance for recombination to disrupt the linkage between disease gene and marker. Markers can therefore be placed up to 14 cM apart meaning that 300–400 markers are sufficient. In addition, only family members need be typed, so typically there will be perhaps a maximum of 100 individuals to genotype. What is needed is a similar process for sporadic disease gene hunting.

Groups of apparently unrelated individuals will always have a common ancestor if we look back far enough. Because of the rapid and recent expansion of humans on earth, the effective population size is thought to be only 10 000 individuals. In other words, the six billion people on earth have the genetic diversity of just 10 000. This means that relationships between genetic markers in the genome have been preserved over larger genetic distances than one might expect. The tendency for genetic markers to be inherited together is known as linkage disequilibrium (to highlight its opposite situation of independent inheritance of two loci, or linkage equilibrium). To perform a genome-wide association study in ALS, markers would need to be spaced far closer than in a linkage study because the common ancestor is more distant and linkage disequilibrium will not extend very far in terms of genetic distance. To maximize the chance that a disease gene will be in linkage disequilibrium with a nearby marker requires that the distance between adjacent markers should be much closer than 1cM and probably tens of kilo-bases at most. This means that over 3000 markers would be needed. To have sufficient power to detect a gene of moderate effect needs at least 300 cases and 300 controls, and ideally far more. This means that using today's technology, at least 1.8 million individual genotypings would be needed, compared with, at most, 40 000 for a typical linkage study. The costs and time required mean that for the time being, this is not feasible and other solutions are needed.

One method that has been explored is DNA pooling. In this technique, the DNA from each case is combined as a single sample, and the same is done for controls. The process is carefully controlled so that each person contributes as near as possible the same number of DNA molecules. Although certain measures need to be taken to control for artefacts, this method does allow the estimation of allele frequencies and potentially reduces the workload to just 6000 genotypings. It can also be used without allele frequency estimation as a screen for relative differences between pools.

Another method that will soon be available is the whole-genome association study based on DNA microarrays. With this technology, the genotyping of for example 100 000 SNPs takes about 3 days. The main problem at present is the cost, but this will improve with time.

Conclusions

The finding of SOD1 gene defects in both familial and sporadic cases, and the clustering of ALS seen in families without clear autosomal dominant inheritance unmistakably argue that the distinction between sporadic and familial

ALS is to some extent artificial. As linkage in more low penetrance families is reported, and as the technology to find multiple genes simultaneously contributing to disease improves, the line between familial and sporadic ALS will blur still further.

In the long term, one anticipates that insights acquired through the study of gene defects that cause or predispose to ALS will facilitate the discovery of new approaches to treating this disease. It is evident, for example, that strategies to inactivate dominantly acting mutant alleles and proteins may ameliorate the associated motor neuron death. While a comprehensive view of such therapeutic directions is beyond the scope of this review, we note that multiple approaches to allele inactivation are formally possible. These include techniques using DNA-protein hybrids to correct missense mutations using site directed somatic cell mutagenesis, discovery of small molecules that inhibit the offending promoter, and strategies such as ribozymes, anti-sense oligonucleotides, and inhibitory RNA (Parekh-Olmedo *et al.*, 2002; Xiang *et al.*, 1997). At this point, two groups have reported successful generation of RNAi to inhibit SOD1, both non-specifically and in a mutant, allele-specific manner (Maxwell *et al.*, 2004; Ding *et al.*, 2003). If such molecules can be delivered to the CNS, it is conceivable that they may be beneficial at least for mutant-SOD1 mediated motor neuron disease.

Current and potential therapeutics

Clare Wood-Allum and Pamela J. Shaw

Academic Neurology Unit, Sheffield University Medical School, UK

Introduction

This chapter will survey the research underpinning current therapeutic candidates for amyotrophic lateral sclerosis (ALS), hereditary spastic paraplegia (HSP), Kennedy's disease (SBMA) and spinal muscular atrophy (SMA). It will also review the evidence base and rationale for the use of riluzole in ALS, the only disease-modifying agent currently licensed for use in any neurodegenerative disease of the motor neuron. In the absence of effective therapies to slow disease progression, the focus of management must be on symptomatic therapies aimed at improving quality of life. Guidelines for the symptomatic management of ALS have been generated by the American Academy of Neurology (Miller *et al.*, 1999b) and a number of systematic reviews of the symptomatic management of ALS are also available from the Cochrane library – symptomatic therapies will not be further discussed here (Annane *et al.*, 2000; Langmore *et al.*, 2003). In recent years, improvements in materials science, bioinformatics and the development of exciting new techniques in molecular biology have brought about a revolution in the way that therapeutic candidates are selected and tested. The likely impact of these new techniques on drug development for disorders of motor neurons will also be discussed.

Disease modifying therapies for amyotrophic lateral sclerosis

Aims of therapy

Motor neurons are post-mitotic cells, which make numerous, complex synaptic connections. They are found in the motor cortex, the brainstem and along the entire length of the spinal cord. Even with encouraging developments

in stem-cell research (Holden, 2002), it is difficult to see how motor neurons from brain to distal lumbar spine can be replaced and remake the complex synaptic connections needed for the reversal of disability – a “cure.” For now, at least, the focus must realistically be on halting or slowing the loss of further motor neurons. Unfortunately, at the time of symptom onset a significant proportion of spinal motor neurons may already have been lost (Sobue *et al.*, 1983). In the absence of reliable early diagnostic markers of the disease, a firm clinical diagnosis can often only be made many months after symptom onset (World Federation of Neurology Research Committee on Motor Neuron Diseases, 1998), by which time even more motor neurons have been lost. Until a firm, early diagnosis can be made, the use of treatments to halt disease progression before significant functional impairment has occurred is unrealistic. Asymptomatic, but at-risk, members of families affected by superoxide dismutase 1-related familial ALS in whom the mutation is known may be an exception to this. At-risk people found to carry the mutant gene in pre-symptomatic genetic testing would, in theory, be excellent candidates for the pre-symptomatic institution of any new disease-halting therapy. At present, the pragmatic, if unsatisfactory, aim of new disease-modifying therapies is to halt or slow disease progression, extending patients' survival without undue compromise to quality of life.

Testing therapies in transgenic mice

The discovery in 1993 that mutations in the gene encoding copper/zinc superoxide dismutase (SOD1) cause 20% of cases of familial ALS (Rosen *et al.*, 1993), led to the development of transgenic mouse models of the disease (Doble & Kennel, 2000). Different transgenic mouse models carry different FALS-causing mutations of the human SOD1

gene in a variety of copy numbers and overproduce the mutant protein to different degrees. Different lines of SOD1 transgenic mice vary phenotypically as a result. All are born neurologically intact, but as adults go on to develop a progressive and fatal motor dysfunction very similar to that seen in human ALS. Mean survival is also dependent upon which SOD1 mutation the mice carry and the number of transgene copies.

SOD1 transgenic mice provide a system in which to investigate ALS pathogenesis and test therapeutic candidates. Unfortunately, several agents shown to have promise in trials in transgenic mice have failed to fulfil this promise when tested in patients (Table 52.2). This has prompted renewed scrutiny of the design of therapeutic trials in animal models and several potential confounding factors have been identified. A study of 2000 high copy number G93A SOD1 transgenic mice revealed differences in survival between male and female mice (Ramesh *et al.*, 2002). Differences in survival were also found between litters of mice. Thanks to the polymerase chain reaction, it is possible to identify presymptomatic transgenic mice and thereby study their entire disease course. It is not possible to identify presymptomatic human patients and is often unrealistic to follow-up trial patients until they die, 3–5 years after symptom onset. Assessment of disease progression in patients therefore tends to start later, occurs at a less well-defined stage of disease and covers a smaller proportion of the total disease course than is the case in transgenic mouse models.

In future, studies involving transgenic mice will need to control for mouse gender and, where possible, littermate controls should be used. Avoidance of these recognized confounding factors may improve the congruency of therapeutic trials in mouse models and patients.

Testing therapies in patients

Conducting clinical trials in ALS is far from straightforward (Turner & Leigh, 2003). Diagnosis is clinical, made late (problematic when testing putative neuroprotective agents) and can be difficult (Davenport *et al.*, 1996). Choosing appropriate endpoints is complicated by the effects upon survival of interventions such as PEG (percutaneous endoscopic gastrostomy) feeding and the initiation of respiratory support (Turner *et al.*, 2002). Measuring disease progression is difficult because of problems in finding reliable measures of bulbar dysfunction and muscle power. In the past these problems have made the interpretation of ALS clinical trials difficult. In recognition of this, a World Federation of Neurology committee met in 1998 to update their guidelines for the design and imple-

Table 52.1. World Federation of Neurology guidelines for trials in ALS: inclusion and exclusion criteria

1. Diagnosis should conform to WFN El Escorial/Airlie diagnostic criteria.
2. Patients with sporadic or familial ALS can be entered depending on the nature of the trial.
3. Entry should be limited to patients between the ages of 18 and 85 years.
4. There should be evidence of progression during a period of six months from onset of symptoms; but not more than 5 years.
5. Patients with significant sensory abnormalities, dementia, other neurologic diseases, uncompensated medical illness, substance abuse or psychiatric illness should be excluded.
6. The patient should not be on concurrent investigational drugs.

mentation of clinical trials in ALS (Miller *et al.*, 1999a). These are also available online at <http://www.wfnals.org/guidelines/1998airlieclintrial/airlie1998.htm>. The guidelines recommend the use of the El Escorial/Airlie House diagnostic criteria (World Federation of Neurology Research Committee on Motor Neuron Diseases, 1998) and define common inclusion and exclusion criteria (Table 52.1). Primary endpoints should include survival or death/permanent continuous ventilation along with change in muscle strength. Importantly, given that the recommendations largely apply to trials of agents designed to prolong life, it was also recommended that quality of life should be included as an outcome measure in all trials. Useful guidance was also supplied about techniques for measuring disease progression, ensuring patient safety and the statistical analysis and disclosure of results. It is hoped that the application of these guidelines will improve the usefulness of future clinical trials of disease-modifying therapies in ALS.

Current and future therapies for ALS

Therapeutic candidates have been generated by chance observations in models of other neurodegenerative diseases, by systematic screening of novel agents and drugs already in use for other conditions in *in vitro* neuroprotection models and by theoretical extrapolation from improvements in the understanding of pathogenetic mechanisms (Table 52.3). Riluzole is the only disease-modifying agent currently licensed for use in ALS and is only modestly effective (Miller *et al.*, 2002). The need for new and more effective agents is pressing and is the focus of intense research activity. In this section we will consider the evidence base underlying the use of riluzole and survey trials of other potential therapies for ALS in models of the disease and in patients.

Table 52.2. Incongruity between therapeutic trials in mouse models and patients

Therapeutic candidate	Results in mouse models	Results in patients
Creatine monohydrate (Klivenyi <i>et al.</i> , 1999, Mazzini <i>et al.</i> , 2001, Groeneveld <i>et al.</i> , 2003)	Extended survival in G93A SOD1 transgenic mice and improved motor performance	No effect on survival No slowing of motor decline
α -tocopherol (Vitamin E) (Gurney <i>et al.</i> , 1996, Desnuelle <i>et al.</i> , 2001)	Delayed disease onset in G93A SOD1 transgenic mice and slowed progression No effect upon survival	Not assessable No effect upon progression No effect upon survival
Brain-derived Neurotrophic Factor (BDNF) (Mitsumoto <i>et al.</i> , 1994b, Ishiyama <i>et al.</i> , 2002, 1999, Ochs <i>et al.</i> , 2000)	Disease slowing in wobbler mice	No effect on disease-slowing or survival
Ciliary Neurotrophic Factor (CNTF) (Miller <i>et al.</i> , 1996, Mitsumoto <i>et al.</i> , 1994a, Mitsumoto <i>et al.</i> , 1994b)	Disease slowing and prolonged survival in pmn mice. Short-term arrest of disease progression in wobbler mice (cotreatment with BDNF)	No effect on functional scores. Survival only a 2° endpoint but no beneficial effect and reduced vs. placebo in one subgroup in one trial
Gabapentin (Gurney <i>et al.</i> , 1996, Miller <i>et al.</i> , 2001a)	Modestly prolonged survival in one of two G93A transgenic mice strains tested	No effect on rate of decline of muscle strength of upper limb muscles in patients

Table 52.3. Theories of pathogenesis and some related therapeutic candidates

Pathogenetic mechanism	Therapy	Therapeutic candidates		
Excitotoxicity	Riluzole	Branched chain amino acids	L-threonine	ONO-2506
Oxidative stress		Vitamin E	Tamoxifen	Selegiline
Neuroprotective/trophic effects		CTNF	BDNF	IGF-1 Xaliproden
Mitochondrial dysfunction		Creatine monohydrate	Coenzyme Q ₁₀	Gingko biloba
Inflammation		Minocycline	COX-2 inhibition	ONO-2506
Apoptosis		Minocycline	Caspase inhibitors	

**Fig. 52.1** Riluzole is a benzothiazole.

Riluzole

Excitotoxicity

Riluzole (Fig. 52.1) acts to inhibit the presynaptic release of the excitatory neurotransmitter glutamate (Doble, 1996). Several lines of evidence suggest that excessive excitatory input to motor neurons, mediated by glutamate, may contribute to motor neuron dysfunction and death

(excitotoxicity) (Shaw & Ince, 1997). Excess glutamate acting at its receptors on motor neurons results in an influx of cations including calcium and over-depolarization of the cell membrane. These changes trigger a cascade of damaging reactions which may, eventually, lead to the death of the motor neuron. In support of this idea is the finding of raised glutamate in the CSF of subsets of ALS patients (Shaw *et al.*, 1995a; Spreux-Varoquaux *et al.*, 2002). The measurement of glutamate in CSF is technically challenging, however, and not all groups have replicated these findings. The excitatory stimulus to motor neurons is terminated by removal of glutamate from the synaptic cleft predominantly by EAAT2, an astrocytic glutamate transporter. Expression of this molecule is reduced in ALS spinal cord (Rothstein *et al.*, 1995, Fray *et al.*, 1998). EAAT2 has also been shown to be a target of oxidative modification by 4-hydroxynonenal (4-HNE), resulting in impaired glutamate transport (Keller *et al.*, 1997). 4HNE is itself

generated as a result of oxidative damage to lipids and is increased in the CSF of ALS patients (Smith *et al.*, 1998). No firmer evidence has yet emerged, however, that excitotoxicity is the primary insult resulting in cell death in ALS.

Mechanism of action

Riluzole (2-amino-6-(trifluoromethoxy)benzothiazole) is a benzothiazole, first developed as an antiepileptic drug. Although the initial rationale for its use in ALS was its inhibition of the presynaptic release of glutamate (Cheramy *et al.*, 1992; Martin *et al.*, 1993), riluzole is believed to exert additional neuroprotective effects through several other mechanisms including the inhibition of glutamate-gated and voltage-gated sodium channels (Ashton *et al.*, 1997; Hubert *et al.*, 1994), and the inhibition of protein kinase C (Noh *et al.*, 2000). It has also been shown to induce expression of neurotrophic factors in cultured mouse astrocytes (Mizuta *et al.*, 2001). It is likely that a combination of these potentially neuroprotective mechanisms underlies the undoubted, if modest, clinical efficacy of riluzole.

Trial data

The use of riluzole in ALS is supported by a small number of largely well-conducted clinical trials. The first, published in 1994 by Bensimon *et al.*, was a prospective, double-blinded, randomized trial of 100 mg riluzole vs placebo (Bensimon *et al.*, 1994). Outpatients aged between 20 and 75 years with a diagnosis of probable or definite ALS were eligible. Excluded were patients with evidence of other disease processes, symptoms >5 years, an FVC <60% predicted, pregnant patients, patients with a tracheostomy and those with renal or hepatic impairment or other life-threatening conditions. The primary endpoints were survival/tracheostomy and rate of change of functional status measured on a four-point scale. The main secondary endpoint was change in muscle power measured by manual power testing using the MRC scale. Analysis was performed on an intention-to-treat basis. After 12 months, 58% of the placebo group were alive compared with 74% of the riluzole-treated group ($P = 0.014$). Of patients in the bulbar-onset subgroup, 35% of the placebo group were alive at 12 months compared to 73% of the riluzole-treated group ($P = 0.014$). In patients in the limb-onset subgroup there was a trend towards increased survival but significance was not reached. At the end of the placebo-controlled period, when the analysis of the data had been completed, survival was still significantly increased in the group as a whole and in the bulbar sub-group (median

follow-up 573d). Deterioration in muscle strength, the chief secondary endpoint, was also significantly slower (33.4% reduction) in patients treated with riluzole ($P = 0.028$).

Lacomblez *et al.* published a second trial in 1996. This was a multi-centre, dose-ranging, randomised, placebo-controlled, double-blinded study of 959 ALS patients (Lacomblez *et al.*, 1996). The primary endpoint was survival without tracheostomy and the secondary outcome was rate of change of a number of functional measures. Patients with clinically probable or definite ALS, of no more than 5 years' duration, aged 18–75, with an FVC of >60% predicted were eligible. Exclusions were identical to the previous trial. Follow-up was for a mean of 18 months and analysis was again done on an intention-to-treat basis. At the end of the study, 50.8% of placebo-treated and 56.8% of patients receiving 100 mg riluzole/d remained alive without tracheostomy (adjusted risk of death 0.65, $P = 0.002$). This corresponded to a decrease in the risk of death or tracheostomy of 35% for patients receiving 100 mg riluzole. Of patients receiving 50 mg and 200 mg of riluzole, 55.3% and 57.8%, respectively, were alive and without tracheostomy at the end of the study. No significant difference in any of the secondary functional measures was found between the groups. This trial included a higher proportion of bulbar-onset patients (295/959 vs 32/155) than did the Bensimon trial and unlike Bensimon, improvement in survival in riluzole-treated patients was significant for both bulbar and limb-onset patient subgroups.

A systematic review of the use of riluzole in ALS has been carried out for Cochrane (Miller *et al.*, 2002). Three reports of randomized trials of riluzole in a total of 1282 patients with ALS were considered; the two trials earlier discussed and a third which included many older patients and many patients with more advanced disease. Together these constituted a total of 876 riluzole-treated patients and 406 placebo-treated patients. A fourth trial performed in Japan (Yanagisawa *et al.*, 1997) also met selection criteria but data on tracheostomy-free survival were not available so it was not included in the analysis.

The third trial was multi-centre, double-blind, parallel group, placebo-controlled, and randomized and was carried out in 168 adult patients with ALS who failed to qualify for the Lacomblez trial on the grounds of age, FVC, or disease duration. Treatment with riluzole 50 mg bd was compared to placebo. The primary outcome measure was survival without tracheostomy or endotracheal intubation. Secondary outcomes included changes in functional scales, muscle strength and respiratory function. The findings of this trial were made available to the Cochrane reviewers but have not been formally published (Meininger

Table 52.4. Conclusions of the Cochrane systematic review of the use of riluzole in ALS (Miller *et al.*, 2002)*Implications for practice*

Riluzole 100 mg daily probably prolonged life by about two months in patients with probable and definite amyotrophic lateral sclerosis with symptoms less than five years, forced vital capacity greater than 60% and age less than 75 years. More studies are needed, especially to determine whether older, more advanced patients with longstanding disease derive the same benefit. Benefits are not apparent to individual patients. The most frequent side effects are nausea and asthenia. Liver function becomes altered and requires monitoring.

Implications for research

Future trials should examine the effect on quality of life and in different subgroups (for example, more severely affected compared with mildly affected patients). Data from all clinical trials should be made available to the scientific community.

et al., 1995). There was no significant difference in percentage mortality at 12 months between riluzole-treated patients and placebo-treated patients, with a relative risk of 0.99 (95% CI 0.79 to 1.25). This lack of difference between the groups was maintained at all time points throughout the trial.

In the Cochrane meta-analysis, the Parmar method was used to compare the results of these 3 trials (Parmar *et al.*, 1998). The primary endpoint was the hazard ratio for percentage mortality at 12 months. When the first two trials were assessed there was evidence for a modest benefit of riluzole 100 mg when compared to placebo ($P = 0.039$, HR 0.80, CI 0.64–0.99). Inclusion of the third trial, however, introduced evidence of heterogeneity – unsurprising given the increased age and severity of disease of patients recruited to this trial. Once this was taken into account, statistical significance was not quite reached ($P = 0.056$, HR 0.84, CI 0.70 – 1.01).

The conclusions of the Cochrane reviewers are given in Table 52.5. One important point raised was that none of the trials considered quality of life. In the dose-ranging study by Lacomblez *et al.*, patients receiving riluzole were found to remain in a combined “mild or moderate health state” for significantly longer than were the placebo-treated patients. There was no significant prolongation by riluzole of time spent in a combined “severe or terminal health state.” It is an important concern that an agent which acts to slow disease progression, may theoretically result in a prolongation of the terminal stages of the disease, when quality of life of patients may be poor. For this reason, one of the recommendations of the WFN consensus guidelines on trial

Table 52.5. American Academy of Neurology guidelines for the use of riluzole (1997)*A. ALS patients for whom class I evidence suggests riluzole may prolong survival includes those who have:*

1. Definite or probable ALS by World Federation of Neurology (WFN) criteria (other causes for progressive muscle atrophy have been excluded),
2. Symptoms present for less than 5 years,
3. FVC >60% predicted,
4. No tracheostomy.

B. ALS patients for whom no class I evidence supports the use of riluzole but expert opinion suggests potential benefit includes those who have:

1. Suspected or possible ALS by WFN criteria,
2. Symptoms present for more than 5 years,
3. FVC <60% predicted,
4. Tracheostomy for prevention of aspiration only (ventilator independent).

C. Expert consensus suggests riluzole is of uncertain benefit in patients with:

1. Tracheostomy required for ventilation,
2. Other incurable life-threatening disorders,
3. Other forms of anterior horn cell disease.

design (Appendix 4), is that that data must be collected on quality of life in all future clinical trials in ALS.

Prescription guidelines for riluzole

Riluzole is currently the only drug licensed in the UK and USA for slowing the progression of ALS. It is an expensive drug. In the UK, the annual cost of riluzole is ~£3700 and the estimated cost of a quality adjusted life year (QALY) is £34 000–£43 500. Use of riluzole in the UK is governed by guidelines recently published by NICE (National Institute for Clinical Excellence, 2001), also available at http://www.nice.org.uk/pdf/RILUZOLE.full_guidance.pdf. Under this guidance riluzole should be prescribed only for patients meeting diagnostic criteria for the ALS variant of motor neuron disease (World Federation of Neurology Research Committee on Motor Neuron Diseases, 1998) and not for progressive muscular atrophy (PMA) or primary lateral sclerosis (PLS). This limitation of riluzole treatment to patients with ALS is at variance with the views of many neurologists who consider PMA, ALS and PLS as artificially demarcated subgroups of a continuous spectrum of disease. Guidelines for the use of riluzole in the USA were published by the American Academy of Neurology in 1997 (<http://www.aan.com>) and are summarized in Table 52.4.

Practicalities of prescribing riluzole

Data from Lacomblez *et al.* indicate that the optimal dose of riluzole is 100 mg/d, usually taken in divided doses of 50 mg (Lacomblez *et al.*, 1996). Doses over 100 mg/d did not further increase survival but did cause more drug-related adverse events. Although largely well-tolerated, recognized side effects include nausea and vomiting, loss of appetite, dizziness, weariness and increases in liver transaminases. The drug is contraindicated in patients with renal and hepatic impairment and also during pregnancy and breast-feeding. If more than one baseline liver function test (LFT) is significantly raised, the drug should not be prescribed. LFTs should be checked monthly for the first 3 months of treatment, 3-monthly for a further 9 months and annually thereafter. Trial data indicate that ~50% of patients will have at least one abnormal LFT at some point, 8% will experience elevations > three times normal and only 2% will experience elevations > five times normal. The drug should be discontinued if transaminase levels rise to five times normal and more frequent blood tests instituted if levels rise to three times normal. Gastrointestinal side effects will often diminish with a dose reduction for a few weeks after which time the full dose can often be reinstated without recurrence. There are only very occasional reports of neutropenia associated with riluzole (Debove *et al.*, 2001) but patients should be warned to report any febrile illness to their doctor in order that a full blood count can be checked. Very recently, a well-documented single case report was published of hypersensitivity pneumonitis seemingly attributable to riluzole (Cassiman *et al.*, 2003) – the possibility of idiosyncratic drug reactions to riluzole should also be borne in mind.

Amino acids

Based on work by Plaitakis (Plaitakis *et al.*, 1980, 1984) which suggested that a deficiency of glutamate dehydrogenase (GDH) might underlie abnormal glutamate metabolism in ALS, several trials of L-leucine, L-valine and L-isoleucine (branched-chain amino acids which serve to activate GDH) were performed in the 1980s and 1990s (Gil & Neau, 1992; Testa *et al.*, 1989; Plaitakis & Sivak, 1992). A Cochrane systematic review has recently been performed of these trials, which concluded that overall no benefit was demonstrated (Parton *et al.*, 2003). L-threonine, an amino acid thought to increase levels of the inhibitory neurotransmitter glycine, has also been investigated in ALS but again, no benefit was shown (Patten & Klein, 1988; Blin *et al.*, 1992; Testa *et al.*, 1992).

Anti-oxidant drugs

Oxygen free radicals such as the superoxide ($O_2^{\bullet-}$) and hydroxyl radical (OH^{\bullet}) and their derivatives are generated as by-products of normal metabolism (Turrens, 1997; Han *et al.*, 2001). An array of anti-oxidants within the cell serves to defend proteins, lipids and DNA from the oxidative damage they would otherwise sustain from reaction with these radicals. These include anti-oxidant enzymes such as catalase, glutathione peroxidases, peroxiredoxins and also free radical scavengers such as vitamins C and E, co-enzyme Q_{10} and others. When the quantity of free radicals generated exceeds the capacity of these anti-oxidant defences to remove them, the cell is said to be under oxidative stress. In this condition, damage to cellular components occurs, which disrupts normal cellular function and may, ultimately, lead to cell death. The discovery that mutations to SOD1 are responsible for some cases of familial ALS increased research interest in oxidative stress as a pathogenic mechanism (Rosen *et al.*, 1993). SOD1 is an important anti-oxidant protein, which acts to convert superoxide to hydrogen peroxide. This species, itself capable of generating the even more reactive hydroxyl radical via the Fenton reaction, is then detoxified by catalase and other peroxidases.

There is good evidence for oxidative stress in ALS (Robberecht & de Jong, 2000). Protein carbonylation is a marker of oxidative damage to proteins. Increases in carbonylated proteins have been found in the spinal cords of patients with ALS (Shaw *et al.*, 1995b), and also in SOD1 transgenic mice (Andrus *et al.*, 1998). At disease onset, G93A mice were shown by Beal's group to have defective functioning of the electron transfer chain and ATP synthesis along with evidence of oxidative damage to mitochondrial proteins (increased brain and spinal cord protein carbonylation) and lipids (increased brain lipid hydroperoxides). These deficiencies were not evident in presymptomatic G93A mice nor in mice expressing normal human SOD1 (Mattiazzi *et al.*, 2002). Superoxide may also react with nitric oxide to generate another free radical, peroxynitrite ($ONOO^{\bullet}$). Peroxynitrite reacts with proteins to form nitrosylated tyrosine residues. An increase in free nitrotyrosines was found by Tohgi *et al.* in the CSF of patients with ALS (Tohgi *et al.*, 1999). Oxidative damage to lipids is reflected in levels of 4-hydroxynonenal. Smith *et al.* found 4-hydroxynonenal to be increased in ALS spinal cord (Smith *et al.*, 1998). There is, additionally, some evidence for a compensatory upregulation of some anti-oxidant enzymes in ALS (Shaw *et al.*, 1997). This and other evidence has led to the investigation of anti-oxidant agents as potential therapeutic agents. A number of clinical trials have been

performed and a Cochrane systematic review has been commissioned to examine the evidence they collectively provide for the efficacy of anti-oxidant treatment (Orrell *et al.*, 2003). It is the practice of many neurologists to co-prescribe vitamins C and E along with riluzole in response to the evidence for oxidative stress in ALS. Convincing evidence for additional benefit has yet to be demonstrated for these, or any other anti-oxidant therapies, however.

Vitamin E

A study in SOD1 transgenic mice showed that whilst levels of vitamin E in homogenized spinal cord and brain increased with age in wild-type mice and those expressing normal human SOD1, there was a depletion of vitamin E in mutant SOD1 transgenic mice (Gurney *et al.*, 1996). Supplementation of the diet of these mice with vitamin E caused both a delay in the onset of symptoms of ALS and slowed its subsequent progression. There was no effect, however, upon survival. Desnuelle *et al.* recently published a randomised placebo-controlled trial of 500 mg of α -tocopherol (vitamin E) in 289 patients with ALS already treated with riluzole (Desnuelle *et al.*, 2001). Additional treatment with α -tocopherol had no effect upon the rate of deterioration (modified Norris score) nor was there any effect upon survival. Patients receiving α -tocopherol were, however, less likely to progress from a mild to a more severe ALS Health State ($P = 0.046$).

N-acetylcysteine

N-acetylcysteine is a membrane-permeant molecule, which within the cell is rapidly converted to cysteine, the rate-limiting precursor of glutathione, a natural intracellular anti-oxidant. Work in cell-culture models of SOD1-related familial ALS suggested that N-acetylcysteine could ameliorate mitochondrial dysfunction observed in the presence of mutant SOD1 (Beretta *et al.*, 2003). Trials of the drug in mouse models of the disease, however, have produced conflicting results (Andreassen *et al.*, 2000; Jaarsma *et al.*, 1998). A randomized, double-blind, placebo-controlled clinical trial of subcutaneous N-acetylcysteine (50 mg/kg) in 110 patients with ALS showed no significant difference in survival or in disease progression between treated and control groups (Louwerse *et al.*, 1995).

Selegiline

Selegiline is a monoamine oxidase B-inhibitor, which increases SOD1 and catalase activity, and probably has additional anti-oxidant properties. A 6-month, double-

blind placebo-controlled study in 133 ALS patients showed no effect on the progression of the disease (Lange *et al.*, 1998). These results support a previous, small and also negative trial of selegiline in ALS (Mitchell *et al.*, 1995).

Tamoxifen

Tamoxifen is an established drug in the treatment of breast cancer. It has recently been found to inhibit protein kinase C (Mandlekar & Kong, 2001), a known effect of riluzole (Noh *et al.*, 2000). Activation of protein kinase C appears to be a critical common pathway in many oxidative insults in neurons; it has therefore been suggested that part of the effectiveness of riluzole may lie in an anti-oxidant action mediated by inhibition of protein kinase C. On the basis of this and unpublished work in mice, a dose-ranging study of tamoxifen in ALS patients is under way in the USA.

Combinations of anti-oxidants

Vyth *et al.* published an observational study of a small group of ALS patients treated at their center over a 5-year period with a variety of anti-oxidant cocktails, which included N-acetylcysteine; vitamins C and E; N-acetylmethionine; and dithiothreitol or its isomer dithioerythritol. Whilst a modest survival benefit appeared to be gained, the methods used in this study were far from ideal and the authors themselves concluded that whilst their cocktails of anti-oxidants appeared safe, they could not be said to prolong survival (Vyth *et al.*, 1996).

Bioenergetic modifiers

There is increasing evidence implicating mitochondrial dysfunction in the pathogenesis of ALS, but it remains to be seen whether this dysfunction is the primary cause of motor neuron death (Wood-Allum & Shaw, 2003). Mitochondria are the chief source of oxygen free radicals within the cell, producing superoxide as an unavoidable byproduct of oxidative phosphorylation. Mitochondrial morphological abnormalities have been demonstrated in several neural and non-neural tissues from patients with ALS (Nakano *et al.*, 1987; Siklos *et al.*, 1996) as well as in transgenic mouse (Kong & Xu, 1998) and cell-culture models of the disease (Menziez *et al.*, 2002). Several studies have shown that the activities of electron transport chain complexes are altered in ALS (Fujita *et al.*, 1996; Borthwick *et al.*, 1999). Reduction in the efficiency with which the electron transport chain operates will affect the adequacy of the mitochondrial membrane potential it supports, the supply of ATP it

is able to generate and will also increase the production of free radicals. Compounds known to support the bioenergetic economy of the cell have therefore become candidates for the treatment of ALS.

Creatine monohydrate

Creatine and phosphocreatine co-exist within the cell. Phosphocreatine acts as a temporal buffer of ATP supply allowing the re-phosphorylation of ADP to ATP at times of high energy demand in a reaction catalyzed by creatine kinase. It also acts as a spatial energy buffer between mitochondria and cytosol (Tarnopolsky & Beal, 2001). Exogenous creatine comes in the form of creatine monohydrate, which has been shown to be both well tolerated and safe when taken as a dietary supplement.

Klivenyi *et al.* administered a dietary supplement of 1% or 2% creatine monohydrate to G93A SOD1 transgenic mice (Klivenyi *et al.*, 1999). A statistically significant, dose-dependent improvement of motor performance and improved survival resulted, along with a reduction of the loss of motor neurons at 120 days when comparison was made with control mice. Mean survival of unsupplemented mice was 143.7 ± 2.3 days compared to 157.2 ± 2.8 days for 1% creatine supplemented mice, and 169.3 ± 4.7 days for 2% supplemented mice representing an extension of survival of 13 days and 26 days, respectively. Riluzole extended survival in this model by 13 days. In unsupplemented G93A SOD1 transgenic mice, there was 95% loss of large ventral horn motor neurons when compared to non-transgenic littermate controls. In G93A SOD1 transgenic mice fed a diet supplemented by 1% creatine this loss of large ventral horn motor neurons did not seem to occur. The increase in levels of 3-nitrotyrosine usually seen in the spinal cords of G93A SOD1 transgenic mice was also not seen in G93A SOD1 transgenic mice whose diet was supplemented with 1% creatine monohydrate.

Preliminary results of a small study of creatine supplementation in 28 patients with clinically probable or definite ALS have been published (Mazzini *et al.*, 2001). Supplementation was high dose (20 g/day) for a week, and lower dose (3 g/day) for 3 and 6 months. The maximal voluntary isometric muscular contraction (MVIC) was measured in 10 muscle groups by dynamometry. MVIC was increased significantly in knee extensors (70% patients) and elbow flexors (53% patients) after 7 days of high dose supplementation. A proportion of patients also showed reduced measures of fatigue in two muscle groups. Longer-term follow-up, however, showed a linear decline in MVIC in all muscle groups. As no untreated group was included in the study, the results do not allow assessment of whether the rate of

decline was slowed by creatine supplementation. Groeneveld *et al.* performed a double-blind, placebo-controlled, sequential clinical trial of creatine monohydrate to assess its effects on survival and disease progression in 175 probable, probable-laboratory-supported or definite ALS patients (Groeneveld *et al.*, 2003). Patients received either creatine monohydrate or placebo 10 g daily. Death, persistent assisted ventilation, or tracheostomy were selected as primary endpoints and the rate of decline of isometric arm muscle strength, forced vital capacity, functional status, and quality of life were included as secondary endpoints. In this trial, creatine did not affect survival (cumulative survival probability of 0.70 in the creatine group vs 0.68 in the placebo group at 12 months, and 0.52 in the creatine group vs 0.47 in the placebo group at 16 months), or the rate of decline of functional measurements.

Coenzyme Q₁₀ (CoQ₁₀)

CoQ₁₀, the electron transport chain electron carrier, signalling molecule and anti-oxidant has been suggested as a potential therapy in mitochondrial disease and a number of neurodegenerative diseases, including ALS, in which mitochondrial dysfunction is believed to play a part (Strong & Pattee, 2000). Oral CoQ₁₀ supplementation from 50 days of age at a dose of 200 mg/day has been carried out in a small group of G93A transgenic mice (Matthews *et al.*, 1998). Supplementation produced a modest but statistically significant increase in survival from a mean of 135 days for unsupplemented mice to a mean of 141 days for mice receiving CoQ₁₀. A study of CoQ₁₀ levels in serum from patients with ALS, however, showed them to be no different from those of controls (Molina *et al.*, 2000). No study on the effect of CoQ₁₀ in patients with ALS has yet been published although small, unpublished pilot studies have been undertaken.

Ginkgo biloba

Ginkgo biloba extract is a mixture of compounds obtained from the plant of the same name, which seems to act to reduce mitochondrial damage by reactive oxygen species. Ferrante *et al.* report a statistically significant prolongation of life, improvement of motor performance and protection against loss of anterior horn cells in male G93A SOD1 transgenic mice whose diet was supplemented with EGb761, a standardized extract of green *Ginkgo biloba* (Ferrante *et al.*, 2001). These beneficial effects were not seen in their female transgenic littermates in whom only a non-statistically significant increase in survival was seen. Both male and female

treated transgenic mice showed a reduction in weight loss. This substance has not yet been evaluated in ALS patients.

Neurotrophic agents

Neurotrophic agents are usually, but not always, recombinant versions of endogenous peptides with positive effects on neuronal development and viability in vitro. Unfortunately, promising trials of several neurotrophic agents in animal models have not been followed by equally positive results in patients. Cardiotrophin-1 (Bordet *et al.*, 2001) and glial-derived neurotrophic factor (Acsadi *et al.*, 2002; Manabe *et al.*, 2003) were found to be neuroprotective in transgenic mouse models of ALS, but no reports have yet been published on the use of these agents in ALS patients.

Ciliary neurotrophic factor (CNTF)

Promising work in vitro (Martinou *et al.*, 1992) and in the treatment of wobbler mice (Mitsumoto *et al.*, 1994b) with CNTF led to trials in ALS patients. No significant difference was found in a variety of functional scores between groups of ALS patients receiving either 15 µg/kg or 30 µg/kg of *sc* CNTF 3 times weekly and those receiving placebo (The ALS CNTF Treatment Study Group, 1996). A second study of over 500 ALS patients compared placebo, 0.5, 2 or 5 µg *sc* CNTF per day. The primary endpoint was a composite score of muscle scores and FVC measured monthly for only 6 months. Survival was included as a secondary endpoint. No significant benefit was demonstrated and the survival of the group receiving 5 µg of CNTF was reduced when compared to placebo (Miller *et al.*, 1996).

Human insulin-like growth factor-I (IGF-1)

IGF-1 is a naturally occurring peptide with neurotrophic effects on motor neurons, neuromuscular junctions and muscle (Lewis *et al.*, 1993). Recombinant human IGF-I has been shown to promote the survival of motor neurons in several experimental models of neuronal injury (Neff *et al.*, 1993) and IGF-1 receptors have been reported to be upregulated in postmortem ALS spinal cord (Caroni, 1993). On this basis, subcutaneous recombinant human IGF-1 has been evaluated in ALS. A recent Cochrane systematic review, however, identified only two randomized, controlled trials of IGF-1 (Mitchell *et al.*, 2002). The US trial indicated that 0.1 mg/kg/d *sc* rhIGF-1 taken for 9 months slowed the rate of progression of ALS measured using the Appel ALS Rating Score (AALSRS) by 26% compared to placebo (Lai *et al.*, 1997). The lower dose of 0.05 mg/kg/d showed

only a trend towards progression slowing which did not reach significance. The European trial also used a dose of 0.1 mg/kg/d and showed only a trend towards disease-slowing, again measured using the AALSRS score (Borasio *et al.*, 1998). Unfortunately the methodology used in both of these trials was deemed to be sufficiently problematic that the Cochrane review's authors (one also the main author of the European trial), felt that a reliable assessment of the efficacy of IGF-1 in ALS could not be made from their results. In particular, neither used survival as an endpoint. It was recommended rather that further trials of rhIGF-1 be carried out and such trials are underway.

Brain-derived neurotrophic factor (BDNF)

As a result of reports of in vitro neurotrophic effects on developing motor neurons, BDNF was tested in the wobbler mouse. Two trials, one of BDNF alone and the other of co-administration of BDNF and CNTF, showed statistically significant slowing of disease progression (Mitsumoto *et al.*, 1994b). A further, more recent, study confirmed the positive effects of BDNF in wobbler mice (Ishiyama *et al.*, 2002). The first randomized, controlled trial in patients compared 25 µg or 100 µg of *sc* recombinant methionyl BDNF with placebo in 1135 ALS patients (The BDNF Study Group, 1999). No significant difference was found in the primary endpoints of survival at 9 months and 6-months % change from baseline FVC. A higher than expected 9-month survival of patients in the trial at 85% may have masked any positive effects of BDNF in this study. Further trials of *sc* BDNF have been carried out but were negative and they remain unpublished. The authors of a small study of the safety and feasibility of intrathecal BDNF concluded that the drug may safely be administered by this route, although there were CNS side-effects at higher doses (Ochs *et al.*, 2000). A further, placebo-controlled, randomized trial of intrathecal BDNF was terminated early because of a higher incidence of adverse events, including death, in the treated group (unpublished).

Xaliproden

This compound is an orally administered agent believed to act at 5HT_{1A} receptors with neurotrophic effects in models of neurodegeneration. A phase II study of this drug has been completed but is yet to report. Buspirone, in established use as an anxiolytic, also has a high affinity for 5HT_{1A} receptors. It is also thought to stimulate endogenous neurotrophins. Trials in transgenic mice and patients are underway.

Viral vector-mediated delivery of neurotrophic factors

In response to concerns that delivery to motor neurons of intact neurotrophic factors administered orally or subcutaneously is poor and that this may underlie the to-date disappointing results of trials in patients, efforts have been made to find innovative ways of more efficiently delivering active drug to motor neurons. The discovery that adeno-associated virus (AAV) injected into skeletal muscle is taken up by motor neuron terminals and moved by retrograde axonal transport up the axon to the nucleus of the motor neuron opened up the possibility of delivering neurotrophic factors to motor neurons by viral vector (Davidson *et al.*, 2000). Kaspar *et al.* injected AAV-IGF-1 or AAV-GDNF into skeletal muscle of G93A SOD1 transgenic mice at 60 days, some 30 days before the usual onset of symptoms. Symptom onset was delayed by a mean of 31 and 16 days respectively and survival increased by a mean of 37 and 11 days respectively. Perhaps more powerfully, AAV-IGF injected at 90 days, when symptoms first begin – more realistically modeling the situation for patients – also prolonged life, albeit to a lesser extent (Kaspar *et al.*, 2003). This approach is clearly promising but there is much work still to be done to assess its feasibility and safety in patients.

Anti-inflammatory agents

Histopathology of the spinal cords of patients with ALS and SOD1 transgenic mice indicates that there is significant gliosis in the grey matter of the spinal cord, suggestive of an inflammatory component to the pathological process. This and much other evidence of inflammation in the spinal cord in ALS, reviewed elsewhere (McGeer & McGeer, 2002), has led to interest in anti-inflammatory drugs as potential therapeutic agents.

Minocycline

Minocycline is a second-generation tetracycline with a proven safety record and good blood-brain penetrance. It has been shown to have neuroprotective effects in a number of models of neurodegeneration; effects which appear to be mediated by an inhibition of transcriptional upregulation and activation of caspases 1 and 3 and inhibition of microglial activation (Fournier *et al.*, 1993). Evidence suggesting that motor neuron death in ALS occurs at least partially via an apoptotic route and that microglial activation may be responsible for the spread between contiguous spinal cord segments which characterizes disease progression, prompted testing of minocycline in models of ALS.

Minocycline protects cultured spinal motor neurons from the toxic effects of CSF from patients with D90A ALS, non-SOD1 familial ALS and sporadic ALS (Tikka *et al.*, 2002). Minocycline also delayed disease onset and extended survival of G93A mice in a dose-dependent fashion (Van Den Bosch *et al.*, 2002). At 120 days of age, minocycline protected mice from the loss of motor neurons and vacuolisation observed in untreated mice. In a second study, Kriz *et al.* randomized late pre-symptomatic G37R SOD1 transgenic mice and non-transgenic littermate controls to a diet supplemented with 1g/kg minocycline or an unsupplemented diet (Kriz *et al.*, 2002). Minocycline slowed loss of motor performance but did not prevent eventual paralysis. The average lifespan of treated G37R mice was ~3 weeks longer than that of untreated mice. Axon-counting at 46 weeks (early symptomatic phase) of the L4 and L5 ventral spinal roots showed that minocycline treatment delayed, but did not prevent, the massive loss of motor axons observed in untreated mice. Immunohistochemistry of spinal cord sections showed attenuation of Mac-2 and p-p38 immunoreactivity, both markers of microglial activation, in minocycline-treated transgenic mice compared with untreated transgenics. These findings were reproduced and extended by Zhu *et al.* (2002) who randomised G93A SOD1 transgenic mice to injections of either 10 mg/kg/d minocycline or saline from 5 weeks of age. Onset of impaired motor performance in minocycline-treated mice was delayed and survival extended. Minocycline is currently in phase III clinical trials in patients with ALS.

Celecoxib

Cyclo-oxygenase 2 (COX2) is a rate-limiting enzyme in the synthesis of prostaglandins, which are mediators of the inflammatory response. Prostaglandins generated by COX2 have been shown to cause astrocytic release of glutamate. In a study of spinal cord homogenates of 11 ALS cases and 27 neurological and healthy controls, Yasojima *et al.* demonstrated that there was an over seven-fold upregulation of COX-2 mRNA in the ALS cases compared to controls ($P < 0.0001$). Western blotting for COX-2 showed upregulation of protein expression by 3.79-fold compared with non-ALS spinal cord (Yasojima *et al.*, 2001). These findings were borne out by a further study by Almer *et al.* who found increases in COX2 mRNA, COX2 protein expression and prostaglandin E2 (a pro-inflammatory COX2 product) in spinal cord homogenates of symptomatic G93A SOD1 transgenic mice when compared to levels in age-matched non-transgenic mice (Almer *et al.*, 2001). Levels of PGE2 were also found to be significantly elevated in postmortem

spinal cord homogenates from ALS patients when compared to controls.

In the light of this evidence of increased expression of COX2 in relevant areas of the CNS in SOD1 transgenic mice and ALS patients, COX2 inhibitors became potential therapeutic candidates. Drachman *et al.* used an in vitro model of excitotoxicity to test the COX2 inhibitor SC236 (Drachman & Rothstein, 2000). Rat organotypic spinal cord cultures challenged with THA, an inhibitor of astroglial glutamate uptake, undergo a gradual loss of motor neurons attributable to an excess of extracellular glutamate. Treatment of these cultures with SC236 significantly reduced the loss of motor neurons. In a second study, G93A mice treated with celecoxib, another selective COX2 inhibitor, had reduced spinal cord PGE₂, delayed onset of weakness and weight loss and a 25% increase in survival compared to controls. Histology of the spinal cords of treated G93A mice showed preservation of motor neurons and a reduction of astrogliosis and activation of microglial activation compared to untreated mice (Drachman *et al.*, 2002).

The Northeast ALS consortium in the USA is currently conducting a multi-centre, double-blinded, randomized, controlled clinical trial of celecoxib in 300 ALS patients.

Immunomodulators

An autoimmune basis for ALS has long been sought and some supportive evidence has been found (Appel *et al.*, 2000). In response to this evidence (and possibly also because neurologists are familiar with their use in other neurological conditions) several immunomodulatory therapies have been tried in ALS. These include IVIG (intravenous pooled donor immunoglobulin) (Meucci *et al.*, 1996), plasmapheresis (Kelemen *et al.*, 1983), interferon- α (Mora *et al.*, 1986) and - β (Westarp *et al.*, 1992), cyclophosphamide \pm steroids (Brown *et al.*, 1986), azathioprine (Werdelin *et al.*, 1990) and levamisole (Olarte and Shafer, 1985). Unfortunately none has been shown to be of benefit.

Pentoxifylline

Pentoxifylline (Trental[®]) is a drug already in use for the symptomatic relief of peripheral vascular disease. It is a phosphodiesterase 4B (PDE4B) inhibitor and also modulates the production of pro- and anti-inflammatory cytokines. PDE4B was identified as a potential therapeutic target for ALS through screening in transgenic mice. Encouraging neuroprotective properties were found in vitro. The drug is currently being tested in ALS patients

as add-on therapy with riluzole in a randomized, double-blind multi-centre, placebo-controlled trial.

ONO-2506

This novel agent is believed to modify astrocytic activation, in addition to upregulating expression at the gene level of astrocytic glutamate transporters. A multi-centre, double-blind placebo-controlled study of ONO-2506 as add-on therapy with riluzole is currently being undertaken in 400 ALS patients drawn from several European centres.

The drug-cocktail approach

In the presence of evidence supportive of several different pathogenetic mechanisms, no one of which can explain all the known facts and in the absence of any one therapeutic agent conferring dramatic benefit in either disease models or in patients, investigators have, rationally, turned their attention to cocktails of possible neuroprotective agents. The hope is that agents acting on complementary molecular pathways which when given alone confer only a modest benefit may produce additional benefits when administered together. On this principle, reports of several therapeutic trials employing combination therapies in mouse models of ALS have recently been published. These include combinations of minocycline, riluzole and nimodipine (Kriz *et al.*, 2003); creatine and riluzole (Snow *et al.*, 2003); creatine and minocycline (Zhang *et al.*, 2003); and creatine and rofecoxib (Klivenyi *et al.*, 2004). Most, but not all, of these trials have reported additional survival benefits from combination therapies, suggesting that this may well be a productive approach to the treatment of patients.

Disease-modifying agents for other motor neuron disorders

Under the guidelines issued by NICE, riluzole may not be prescribed for primary lateral sclerosis or progressive muscular atrophy in the UK, nor does the AAN practice advisory committee (Miller *et al.*, 1999b) recommend its use in these patients in the presence of only uncertain benefit. There are no other disease-modifying agents for hereditary spastic paraplegia, spinal muscular atrophy, or Kennedy's disease in use at present. As pathogenetic mechanisms are clarified, this situation may change but until then only symptomatic therapies are available. Prenatal and pre-implantation diagnosis is possible in some of these disorders (Hedera *et al.*, 2001, Matthijs *et al.*, 1998).

Fig. 52.2 The SMA locus on chromosome 5q13.

SMA

SMA is a progressive disease, in which anterior horn cells degenerate producing a symmetrical and predominantly proximal lower motor neuron weakness and atrophy. The commonest type of SMA is autosomal recessive and is associated with abnormalities of the SMN (survival motor neuron) gene. Three main forms are recognized, the severity of which is inversely related to the amount of SMN protein present in anterior horn cells. The most severe form causes death in infancy, the least severe is compatible with life into adulthood but continues to be slowly progressive and is accompanied by considerable disability.

The pathogenetic mechanisms underlying SMA are increasingly well understood, perhaps as a consequence of its largely autosomal recessive etiology, but despite this, very few clinical trials have yet been performed (Merlini *et al.*, 2002). The genes which code for SMN protein form part of a rather complex genetic locus at 5q13 (Fig. 52.2) in which there are two copies of the SMN gene; a telomeric version, *SMN1*, which codes for a full-length SMN protein and a second, more centromeric version, *SMN2*. *SMN2* differs from *SMN1* by only one nucleotide, which acts to alter the activity of a splicing enhancer in exon 7. As a result, mRNA transcripts from *SMN2* frequently lack exons 3, 5 or 7 and very little full-length protein is generated. Loss-of-function mutations to both copies of the *SMN1* gene result in the development of an SMA phenotype. The SMN protein has a role in pre-mRNA splicing, small ribonuclear protein synthesis and the regulation of transcription (Wirth, 2002). The small amount of full-length *SMN2* gene product produced acts to modify disease severity in dose-dependent fashion but cannot completely ameliorate a lack of full length SMN from *SMN1*.

As all SMA patients have at least one copy of *SMN2*, upregulation of this gene has been identified as a therapeutic target. More recently, SR-(serine-arginine-rich)-like splicing factor Htra2-beta 1 has been shown to correct the aberrant splicing of *SMN2*, thereby increasing production of full-length SMN protein (Hofmann *et al.*, 2000). In consequence, upregulation of SR-like splicing factor Htra2-beta 1 has also become a therapeutic goal. Exciting new biotechnologies aimed at manipulating splicing events to increase expression of full-length SMA protein from *SMA2* include the use of targeted peptide-nucleic acid (PNA) mimetics (Cartegni & Krainer, 2003), and bifunctional anti-sense oligonucleotides (Skordis *et al.*, 2003). These techniques, which have been recently reviewed (Khoo *et al.*, 2003), remain at an early stage of development and as in the therapy of ALS, effective delivery of these agents to the motor neuron is far from straightforward. In addition to this practical caveat, there remain concerns that the less specifically targeted of these agents may have widespread, and potentially deleterious, effects on the splicing of genes other than *SMN2*.

A number of different SMA transgenic mouse models have been made in which the single murine *SMN* gene (equivalent to *SMN1*) is knocked out and the phenotype *SMN1* rescued by expression of human *SMN2* in varying amounts (Monani *et al.*, 2000; Hsieh-Li *et al.*, 2000). These mice are being used to test candidate therapeutic agents in SMA.

Sodium butyrate

Chang *et al.* generated lines of immortalized lymphoid cells by transforming lymphocytes obtained from SMA patients with Epstein-Barr virus (Chang *et al.*, 2001). These cells were exposed to candidate drugs and reverse transcriptase PCR performed to establish whether the production of full length *SMN2* mRNA had been increased. Sodium butyrate increased *SMN2* transcription and also increased the inclusion of exon 7 in *SMN2* transcripts, thereby increasing the production of full-length *SMA2* mRNA. A corresponding increase in SMN protein was also seen. Phenylbutyrate has also been reported to increase the in vitro production of SMN protein in cultured fibroblasts obtained from SMA patients (Andreassi *et al.*, 2004). The Chang group went on to expose small numbers of their transgenic SMA II and III mice to sodium butyrate. SMN II mice whose drinking water was supplemented with sodium butyrate for 1–12 weeks lived 4–5 days longer than did untreated mice. The histopathology of the tail muscles of treated SMA II and III mice was much less abnormal than that of untreated SMA mice and immunohistochemistry was used to demonstrate

an increased expression of exon 7-containing SMN protein in a number of tissues of treated mice, including spinal motor neurons. Chang then went on to treat *Smn*^{+/-} *SMN2* intercrossed pregnant mice with sodium butyrate. These mice give birth to types I, II and III SMA pups along with unaffected pups, in varying proportions. Pregnant mice treated with sodium butyrate gave birth to a higher proportion of less severely affected pups than did untreated pregnant mice.

Sodium butyrate and similarly acting drugs have been evaluated for the treatment of the thalassemias and sickle cell anaemia (Sher *et al.*, 1995, Collins *et al.*, 1995) and are relatively well tolerated. A short pilot trial of oral phenylbutyrate has been carried out in 10 SMA II patients (Mercuri *et al.*, 2004). The drug was well tolerated and some improvement in the Hammersmith functional motor scale of patients was observed.

Aclarubicin

A similar approach was adopted by Andreassi *et al.* who used in vitro cell culture models of SMA to screen drugs for the ability to increase the amount of full length *SMN2* mRNA transcribed (Andreassi *et al.*, 2001). Aclarubicin induced incorporation of exon 7 into *SMN2* transcripts in fibroblasts obtained from patients with SMA type I and increased their expression of the SMN protein back to normal levels. Unfortunately, aclarubicin is a chemotherapeutic agent with potentially serious side effects, including cardiomyopathy, which make it a poor candidate for the treatment of children with SMA.

Sodium valproate

Brichta *et al.* (2003) showed that in fibroblast cultures derived from SMA patients, treatment with therapeutic doses of valproic acid could increase the level of full-length *SMN2* mRNA/protein. Brichta *et al.* (2003) showed that, in fibroblast cultures derived from SMA patients, treatment with therapeutic doses of valproic acid could increase the level of full-length *SMN2* mRNA/protein. They attributed this increase to raised levels of Htra2-beta 1 and increased correct splicing of *SMN2* as well as to activation of SMN gene transcription. An increase in SMN protein levels through transcriptional activation was also found in rat organotypic hippocampal brain slices. This work was confirmed by another group in cultured fibroblasts obtained from patients with type I SMA (Sumner *et al.*, 2003). The fact that sodium valproate has been used safely for many years in the treatment of epilepsy, including in children, makes

it a particularly attractive candidate for the treatment of patients with SMA.

Thyrotropin-releasing hormone (TRH)

A small randomized, double-blind 5-week trial of protirelin (a synthetic TRH) vs placebo was carried out in six SMA patients and three controls by Tzeng *et al.* (2000). Protirelin or placebo was delivered intravenously at a dose of 0.1 mg/kg (in 50 ml of normal saline) for a total of 29 days. Dynamometry improved modestly in the six treated subjects ($P = 0.02$) but not in control subjects. A further, larger study is needed before the efficacy of TRH in SMA can be assessed.

Gabapentin

A randomized, double-blind, multi-centre trial of gabapentin 1200 mg *tds* vs placebo was recently completed in the USA (Miller *et al.*, 2001b). The drug or placebo was administered to 84 patients with type II or III SMA for 12 months. The primary outcome measure was percentage change in a composite of the strength of elbow flexion and hand grip bilaterally. Secondary outcome measures included FVC, a functional rating scale and a quality of life scale. No significant differences were found in either the primary outcome measure or any of the secondary outcome measures between patients given gabapentin or placebo.

Riluzole

The proven benefits of riluzole to patients with ALS prompted investigators to trial it in SMA mutant mice and in patients. Haddad *et al.* reported an increase in median survival of SMA mutant mice treated with riluzole (Haddad *et al.*, 2003) but a pilot trial in patients was unfortunately cut short for administrative reasons (Russman *et al.*, 2003). This pilot, a phase I trial, was as a result underpowered (only seven children treated with riluzole, three with placebo) and the question of whether riluzole may be helpful in SMA remains unanswered.

Neurotrophic factors

Lesbordes *et al.* injected SMA mice intramuscularly with an adenoviral vector expressing cardiotrophin-1 (CT-1), and found that it improved median survival, delayed onset of motor dysfunction and seemed to be protective against the loss of proximal motor axons and aberrant cytoskeletal organization of motor synaptic terminals (Lesbordes

et al., 2003). The use of an adeno-associated viral vector to carry extra copies of *SMN1* or 2 into motor neurons to increase expression of the SMN protein has not thus far been reported.

Kennedy's disease (X-linked spinobulbar muscular atrophy)

Kennedy's disease is the result of a CAG repeat expansion within exon 1 of the androgen receptor gene on the X chromosome. It is inherited in an X-linked recessive fashion and affects male carriers. Most female carriers are phenotypically normal although raised creatine kinase and abnormalities on electromyography can be seen. In common with other triplet repeat disorders, the expanded region is unstable between generations and anticipation occurs. Affected males develop a progressive proximal weakness accompanied by wasting and fasciculation and dysarthria and may also have gynecomastia, reduced fertility, and testicular atrophy; signs of androgen insensitivity. Onset is usually in the third to fifth decade and the disease may reduce life expectancy. Weakness is the result of the loss of anterior horn cells from spinal cord and brainstem. The expanded CAG repeat in the androgen receptor gene codes for repeated glutamine residues in the translated protein, which give the protein a tendency to form high molecular weight aggregates. These can be seen by immunohistochemistry as androgen-receptor-immunoreactive nuclear inclusions in motor neurons and some other tissues, for example testis. It seems increasingly likely that these protein aggregates may be responsible for the pathogenicity of the mutation but this remains a subject of debate and ongoing research (Gallo, 2001; Wood *et al.*, 2003).

Development of a transgenic mouse model of Kennedy's disease was far from straightforward as the choice of promoter appeared to affect the neurological phenotype. Abel *et al.* described a transgenic mouse generated from a 5' truncated, much expanded (112 CAG repeats) androgen receptor gene driven by a neurofilament light promoter (Abel *et al.*, 2001). Unlike SOD1 transgenic mouse models of ALS, whose phenotype closely mirrors that of the related human disease, these Kennedy's mice did not develop the neurogenic muscle atrophy that characterizes human disease. They did, however, develop a gait disturbance and adult-onset hind-limb weakness and display the neuronal intranuclear inclusions (NII), which characterize triplet repeat disorders. More recently, transgenic mouse models whose disease better resembles human SBMA have been developed. One such model, expressing a full-

length human androgen receptor gene with expanded CAG repeats and controlled by a CMV enhancer and chicken β -actin promoter, exhibits muscle wasting and weakness, markedly worse in males and rescued by castration (Katsuno *et al.*, 2002). The luteinizing hormone-releasing hormone agonist leuprorelin, which acts to reduce testosterone release by the testes, has recently been shown to rescue the phenotype of these mice (Katsuno *et al.*, 2003) raising the possibility of anti-androgen therapy in patients with SBMA. Androgen-receptor antagonists which bind the receptor and allow or even encourage its nuclear translocation exert no such beneficial effect (Takeyama *et al.*, 2002; Katsuno *et al.*, 2003).

The expanded androgen receptor co-localizes in nuclear aggregates with molecular chaperones, 26S proteasome components and ubiquitin. Overexpression of various heat shock proteins (HSPs) in cell-culture models of SBMA reduced androgen receptor aggregation and cell death by an increase in the solubility of the expanded androgen receptor and its degradation by the proteasome (Ishihara *et al.*, 2003; Kobayashi *et al.*, 2000; Bailey *et al.*, 2002). Sobue *et al.* went on to look at the effect of overexpression of chaperones in SBMA transgenic mice by creating dual transgenics. Their dual transgenic SBMA mice also expressed inducible, human HSP70. Overexpression of HSP70 ameliorated the motor phenotype of the mice and also reduced the nuclear accumulation of androgen receptor (Adachi *et al.*, 2003). It is likely that this line of enquiry may identify new therapeutic candidates as well as clarifying the pathogenic mechanism underlying SBMA.

Hereditary spastic paraplegia (HSP)

Hereditary spastic paraplegia is characterized by progressive disability due to lower limb spasticity and weakness. In uncomplicated HSP this may be accompanied by urinary sphincter disturbance and mild impairment of vibration sense in the distal lower limbs. A spastic paraparesis that begins after childhood is usually insidiously progressive. Complicated HSP is defined by the presence of additional features including seizures, dementia, cataracts, extrapyramidal deficits and amyotrophy (Fink, 2002b). HSP is an inherited condition but shows marked genetic heterogeneity. Thus far there are 20 known HSP loci; 10 with autosomal dominant inheritance, 7 with autosomal recessive inheritance and 3 of which are X-linked recessive. These loci are labelled SPG1–21 in order of their discovery. Of these, 10 HSP genes and the proteins they code have been identified: spastin (SPG4), paraplegin (SPG6), atlastin (SPG3A), heat shock protein 60, proteolipid

protein, L1 cell adhesion molecule (Fink, 2002a), spartin (Patel *et al.*, 2002), KIF5A (Reid *et al.*, 2002), (SPG21) maspardin (Simpson *et al.*, 2003), and NIPA1 (Rainier *et al.*, 2003). The multiple genes and diverse functions of the proteins they code make the prospect of a disease-modifying therapy based on the underlying pathophysiology of the disease and applicable to all HSP a remote one. Therapies tailored to particular, genetically defined, HSP variants or which target a common final pathogenic pathway may be a more realistic goal. At present, research efforts are focussed on defining more clearly the molecular basis of the disease and on the development of a transgenic HSP mouse model. Once disease pathogenesis is better understood, therapeutic candidates will surely follow. In the meantime, management of HSP is symptomatic and predominantly involves the use of spasmolytic agents. Prenatal diagnosis is increasingly possible although there are ethical considerations to be taken into account in this condition which may be phenotypically mild and which is not associated with a reduced life expectancy.

Future directions

Earlier diagnosis of ALS

For patients to benefit from newly developed neuroprotective agents at a time when most of their motor neurons are still salvageable, there needs to be earlier, and reliable, diagnosis of ALS. Currently diagnosis is late, clinical and on occasion incorrect (Davenport *et al.*, 1996). A simple diagnostic test which could be performed at the time of first presentation (when patients are unlikely to have disease sufficiently advanced to meet current diagnostic criteria) would allow the earlier institution of neuroprotective therapy. Where to look for such an early diagnostic marker? CSF bathes the motor roots and spinal cord and as such may be expected to reflect the extracellular milieu of motor neurons and their supporting glia. Several biochemical changes have been found in the CSF of ALS patients, reviewed elsewhere (Shaw, 2001), but none, regrettably, is sensitive or specific enough to be of practical use in the early diagnosis of ALS. Attention has recently shifted to changes in the level and post-translational modifications of proteins within CSF. New advances in the separation and subsequent identification of components of complex protein mixtures from biological samples are being applied to this problem, techniques collectively known as proteomics (Banks *et al.*, 2000). The 14–3–3 proteins which contribute to the diagnosis of Creutzfeldt–Jacob disease were discovered using such a proteomic approach (Harrington *et al.*,

1986). It is hoped that ALS-specific protein changes within CSF may be identified using these new proteomic techniques which might provide the basis of the sought-after early diagnostic test.

Clarification of subgroups with differing responses to therapy

It has long been suspected that the generally poor overall response of ALS patients in clinical trials of neuroprotective agents may be due to the masking of a strongly positive response in a subset of patients by a lack of response in the remainder. Subgroups with different responses to a therapy may be identified by the enrolment of adequate numbers of patients with different (and clearly defined) clinical features or “effect modifiers” (e.g. bulbar onset, slowly progressive disease, LMN at onset, UMN at onset) to allow meaningful subgroup analysis (Miller *et al.*, 1999a). Better definition of the response of patient subgroups to therapeutic candidates may allow recognition of the neuroprotective effects of a therapy useful to at least a subset of ALS patients which might otherwise be overlooked.

Candidate approach via clarification of molecular biology

Drug development in motor neuron disorders is hampered by an incomplete understanding of disease pathogenesis. Despite the discovery of SOD1 gene mutations in 20% of cases of familial ALS in 1993, it still remains unclear exactly how mutant SOD1 brings about motor neuron death. It is even less clear what insult underlies the death of motor neurons in the often clinically indistinguishable sporadic form of the disease. The precise pathogenetic mechanisms which underly the dying-back axonopathy of HSP are unknown, as are the molecular pathways which cause lower motor neurons in SMA to die whilst sparing cortical motor neurons. Clarification of these mechanisms at a molecular level will inevitably generate new therapeutic targets and new therapeutic candidates. The relatively recent discovery of a mutation to the gene coding a novel protein called alsin, which causes the childhood onset of a PLS-like syndrome, is one such advance in the field of ALS (Yang *et al.*, 2001; Hadano *et al.*, 2001). Another is the fortuitous finding that mutation of the gene for a protein known as vascular endothelial growth factor (VEGF) in mice results in a motor neuron-like phenotype (Oosthuysen *et al.*, 2001).

High throughput screening approaches

New developments in proteomics and DNA microarray technology have made possible the large-scale screening of therapeutic candidates. Advances in the understanding of disease pathogenesis are first used to identify molecular targets, for example, an increase in the transcription of full-length SMN in SMA. Thousands of candidate drugs can then be screened for the ability to bring about the desired alteration to cellular biochemistry (detected by analysis of changes in gene expression or of protein expression) in *in vitro* models of motor neuron disorders. Successful candidates may then progress to trials in animal models and ultimately in patients. High throughput screening approaches may also be used to generate therapeutic targets. By using microarray technology, the levels of mRNAs coding tens of thousands of proteins can be measured (Luo & Geschwind, 2001). Powerful data analysis and statistics software can then be used to compare such data obtained from wild-type and from transgenic mouse models of a motor neuron disorder. Those mRNAs whose levels differ between disease and non-disease models may then be investigated further. One drug currently being evaluated in ALS patients was selected as a therapeutic candidate on the basis of high-throughput microarray screening for differences in mRNA splicing between transgenic and wild-type ALS mice.

Stem cell therapy

Given the current problems with early diagnosis and the fact that at diagnosis ALS patients have already lost considerable numbers of their motor neurons, consideration of therapies aimed at replacing dead and dying motor neurons is rational. The discovery that there are pluripotent stem cells present in the adult CNS, capable of differentiating into hippocampal, olfactory bulb and neocortical cells, has made this approach seem more achievable although there are still formidable hurdles to be overcome (Nakatomi *et al.*, 2002). Exogenous sources of cells able to differentiate into neurons under consideration for this role include fetal spinal progenitor cells, umbilical cord blood cells, human fibroblasts, fetal brain stem cells, murine neural stem cells and porcine fetal neurons (Holden, 2002). Unlike Parkinson's disease, in which the site of neuronal loss is highly localized to the substantia nigra of the basal ganglia, motor neuronal loss in ALS and indeed in SMA and SBMA occurs over a wide anatomical area. Replacement stem cells therefore need to migrate long distances from cerebral cortex to spinal cord; this ability tends to be lost as cells become more differentiated. Interesting work done on chimeric transgenic/non-transgenic SOD1 mice

(Clement *et al.*, 2003), moreover, indicates that the provision of a healthy neighborhood around motor neurons may be protective even when those motor neurons express mutant SOD1. This work raises the possibility that stem cell therapy might also beneficially be used to supply healthy non-neuronal cells to the spinal cord to support motor neurons.

Rejection remains a concern, although as an immunologically privileged site, this may be a less prominent problem in the CNS than elsewhere in the body. There are also dangers of introducing poorly differentiated cells into an adult CNS. Uncontrolled overgrowth of introduced stem cells may ultimately generate a mass of cells big enough to cause problems of space occupation clinically. Synaptic connections made by newly differentiated neurons settling in the wrong location or even aberrant connections made by correctly located cells may also produce unwanted side effects.

Despite these difficulties, and significant ethical and political barriers to research on stem cells, some progress has nevertheless been made. As part of a systematic evaluation of the characteristics of different embryoid body stem cells, derived from the germ cells of aborted fetuses, Gearhart *et al.* injected laboratory-sprouted intermediate-stage embryonic body stem cells into a rat model of SMA. Some mobility was restored to animals previously paralyzed, offering a tantalising glimpse of the possible therapeutic benefits of stem-cell therapy (Vastag, 2001). This work remains at a very early stage and it remains to be seen whether its early promise is borne out in real benefits for patients with motor neuron disorders.

The hereditary spastic paraplegias

John K. Fink

Department of Neurology, University of Michigan and Geriatric Research Education and Care Center, Ann Arbor Veterans Affairs Medical Center, MI, USA

Introduction and classification

Inherited disorders in which the predominant clinical syndrome is gait disturbance due to lower extremity spastic weakness are referred to collectively as the hereditary spastic paraplegias (HSPs). The various types of HSP are classified clinically according to the mode of inheritance (dominant, recessive, and X-linked); and whether lower extremity spasticity and weakness and often urinary urgency and subtle dorsal column impairment occur alone (“uncomplicated HSP”), or are accompanied by additional neurologic or systemic symptoms for which alternative causes are excluded (“complicated HSP”) (Harding, 1983).

There are at least 20 genetically distinct types of HSP (Table 53.1) including ten dominant, seven recessive, and three X-linked HSP syndromes. Eight of these HSP syndromes are “uncomplicated;” eight of these are “complicated” by the presence of additional neurologic signs; and four of these may present as either “uncomplicated” or “complicated” HSP syndromes. For some of these latter syndromes, both “uncomplicated” and “complicated” HSP phenotypes may coexist even in the same family (Table 53.1).

It is important to recognize that the HSPs are classified clinically, rather than on the basis of subclinical involvement or neuropathologic findings. Certainly, lower extremity spastic weakness may be an important feature of many other disorders, both inherited and apparently sporadic including such diverse disorders as amyotrophic lateral sclerosis, Friedreich’s ataxia (Berciano *et al.*, 2002; Ragno *et al.*, 1977), Machado Joseph disease (spinocerebellar ataxia type 3), Charlevoix–Sanguenay syndrome (Engert *et al.*, 2000), primary lateral sclerosis, and familial Alzheimer’s disease due to presenilin 1 mutation (Brooks *et al.*, 2003; Assini *et al.*, 2003; Tabira *et al.*, 2002).

The HSP group of disorders is distinguished from these and other conditions by the limitation of symptoms to spastic gait and urinary urgency; and by clinical or laboratory evidence (gene analysis) that the condition is inherited. Clearly, the distinctions between HSP and other causes of lower extremity spastic weakness are somewhat arbitrary. For example, HSP is not considered a lower “motor neuron disorder” despite the fact that minor loss of anterior horn cells may occur in “uncomplicated HSP.” This is because HSP is classified on the basis of signs and symptoms and because anterior horn cell loss is variable, subclinical, and below the threshold of electromyographic detection. On the other hand, the “HSP group disorders” includes some conditions with marked upper extremity or lower motor neuron involvement. For example, even though some complicated HSP syndromes (Troyer (SPG20) and Silver (SPG17) syndromes, and those linked to SPG7, SPG9, SPG10, SPG14, and SPG15 loci; Table 53.1) are associated with motor neuronopathy and distal muscle wasting, they are included in the HSP family of disorders because the predominant syndrome remains progressive spastic gait.

Though imperfect and somewhat arbitrary, clinical classification of HSPs is an important tool for identifying homogeneous kindreds for genetic research; and offers some guidance for long-term prognosis. As discussed below, a molecular classification of the HSPs is emerging as HSP genes are discovered.

Clinical signs and symptoms of uncomplicated HSP

Each of the more than 20 known types of HSP represents a separate, genetically distinct disorder. Generalizations can be made only about “uncomplicated” forms of HSP, which are typically so similar that they may not be distinguished

Table 53.1.

Spastic gait (SPG) locus	Chromosome	Gene/Protein: function	HSP syndrome
Autosomal dominant HSP			
SPG4	2p22	SPG4/Spastin: Cytosolic protein, with AAA domain that binds to microtubules	Uncomplicated
SPG13	2q24–34	Heat shock protein 60 (Hsp60), mitochondrial chaperonin (Cpn60)	Uncomplicated
SPG8	8q23–q24		Uncomplicated
SPG9	10q23.3–q24.2		Complicated: spastic paraplegia associated with cataracts and gastroesophageal reflux, and motor neuropathy
SPG17	11q12–q14		Complicated: spastic paraplegia associated with amyotrophy of hand muscles (Silver Syndrome)
SPG10	12q13	Kinesin heavy chain (KIF5A): molecular motor involved in axonal transport	Uncomplicated or complicated by distal atrophy
SPG3A	14q11–q21	SPG3A/atlastin: Predicted to be GTPase similar to dynamins	Uncomplicated
SPG6	15q11.1	NIPA1: neuron specific membrane protein of unknown function	Uncomplicated
SPG12	19q13		Uncomplicated
SPG19	9q33–q34		Uncomplicated
Autosomal recessive HSP			
SPG14	3q27–28		Complicated: spastic paraplegia associated with mental retardation and distal motor neuropathy
SPG5	8q		Uncomplicated
SPG11	15q		Uncomplicated or complicated: variably associated with HSP associated with thin corpus callosum, mental retardation, upper extremity weakness, dysarthria, and nystagmus
SPG7	16q	SPG6/paraplegin: mitochondrial protein	Uncomplicated or complicated: variably associated with mitochondrial abnormalities on skeletal muscle biopsy and dysarthria, dysphagia, optic disc pallor, axonal neuropathy, and evidence of “vascular lesions”, cerebellar atrophy, or cerebral atrophy on cranial MRI
SPG15	14q		Complicated: spastic paraplegia associated with pigmented maculopathy, distal amyotrophy, dysarthria, mental retardation, and further intellectual deterioration.
SPG20	13q	SPG20/spartin: N-terminal region similar to spastin; homologous to proteins involved in the morphology and membrane trafficking of endosomes.	Complicated: spastic paraplegia associated with distal muscle wasting (Troyer syndrome)
	13q14		Childhood onset HSP variably complicated by spastic dysarthria and pseudobulbar signs 59
X-linked HSP			
SPG1	Xq28	L1 cell adhesion molecule (LICAM)	Complicated: associated with mental retardation, and variably, hydrocephalus, aphasia, and adducted thumbs
SPG2	Xq21	Proteolipid protein (PLP): intrinsic myelin protein	Complicated: variably associated with MRI evidence of CNS white matter abnormality
SPG16	Xq11.2		Complicated: associated with motor aphasia, reduced vision, mild mental retardation, and dysfunction of the bowel and bladder

from each other by clinical signs and symptoms. In contrast, various “complicated” types of HSP often have distinctive clinical signs (such as distal muscle wasting or optic atrophy; Table 53.1) that suggest one or more specific types of HSP.

The hallmark of uncomplicated HSP is gait disturbance due to lower extremity spasticity and weakness. Symptoms may be first evident at any age, from infancy through senescence. Early symptoms of leg muscle tightness, particularly at night, and ankle and knee clonus are followed by stumbling and tripping, particularly when ascending stairs, crossing curbs, or walking rapidly. Over time, gait becomes more functionally impaired, with short strides due to limited flexion of the thigh and difficulty fully dorsiflexing the feet; circumduction; and a tendency to maintain the legs partially flexed (knees bent) due to hamstring muscle spasticity. Hyperlordosis is common.

Progressive vs. non-progressive symptoms

When HSP symptoms begin in very early childhood, developmental milestones of rolling over, sitting up, crawling, and standing, typically are not delayed. The first steps of walking may be abnormal because of toe-walking which is persistent. When symptoms begin in late infancy and early childhood, there may be very little worsening even over many years. In contrast, symptoms that begin after adolescence typically progress insidiously over many years. In part, the relative “progressive” nature of later-onset HSP versus the relatively “static” nature of early-onset HSP may reflect both different genetic types of HSP; as well as the ability of the developing nervous system to compensate for slowly progressive neurodegeneration.

Variable severity

The degree of gait impairment in uncomplicated HSP may be quite variable and range from subtle disturbance that is of no functional consequence; to frank spastic diplegia requiring full-time use of a wheel chair. Severity may be quite variable even within a given family in which all subjects have precisely the same HSP gene mutation.

Urinary urgency

This is very common in subjects with HSP. This typically follows gait impairment by at least several years. For some subjects, however, urinary urgency may be an early sign of

HSP. Fecal urgency is less common although may occur. Sexual disturbances are not infrequent in HSP subjects and include erectile dysfunction; and exacerbation of lower extremity clonus and spasm. A systematic investigation of sexual and autonomic symptoms in HSP has not been reported.

Sensory symptoms

Lower extremity paresthesia are reported in many subjects with uncomplicated HSP. Limitation of paresthesia to one limb or dermatome, spinal sensory level, or loss of light touch or pinprick sensation are not features of uncomplicated HSP, however.

Subclinical cognitive disturbance and late-onset dementia

These have been described in some patients with the most common form of dominantly inherited HSP (due to *SPG4* mutations, described below); as well as in some subjects in these families shown to have inherited the mutant *SPG4* allele but whose gait was as-yet unaffected (Heinzlef *et al.*, 1998; Lizcano-Gil *et al.*, 1997; Webb *et al.*, 1998; Byrne *et al.*, 1998; Reid *et al.*, 1999; Tedeschi *et al.*, 1991). The frequency of cognitive impairment in this and other forms of HSP is not known.

Neurologic examination

Neurologic examination of subjects with uncomplicated HSP shows spasticity and weakness in bilateral lower extremities particularly in tibialis anterior, hamstring, and iliopsoas muscles. Pathologic hyperreflexia in the lower extremities and ankle (and often knee clonus) is present in virtually all subjects with uncomplicated HSP except those in which significant contractures limit joint range of motion. Plantar responses are extensor in the vast majority of HSP subjects. Pes cavus is common.

The relative amounts of spasticity versus weakness are variable. Some patients have prominent weakness, particularly involving tibialis anterior, hamstrings, and iliopsoas muscles. For other patients, however, there may be no significant weakness, with gait impairment due largely to lower extremity spasticity. The relative amount of spasticity-versus-weakness influences the choice (and functional benefit) of using spasticity-reducing medication.

Subtle impairment of vibration sensation in the distal lower extremities is very common in HSP although often not an early sign. Impaired vibration sensation in the toes, when present, not associated with peripheral neuropathy, and not attributed to other causes, is a helpful diagnostic sign in distinguishing lower extremity spasticity in HSP from early stages of amyotrophic lateral sclerosis and primary lateral sclerosis (Fink, 2001).

Although upper extremity deep tendon reflexes are often brisk, there is no evidence of upper extremity weakness, spasticity, or impaired dexterity. Finger tapping is normal and there is no pronator drift in uncomplicated HSP.

Muscle bulk is usually preserved in uncomplicated HSP. However, it is not uncommon for subjects to have mildly decreased muscle bulk in their shins. The presence of significant muscle wasting should prompt electrophysiologic analysis and consideration of motor neuron disease or co-existing myopathy or peripheral neuropathy. HSP subjects with lower motor neuron deficits for which no other cause can be identified are classified as having a form of "complicated" HSP. There are a number of such HSP syndromes (Table 53.1) that include significant muscle wasting and evidence of motor neuronopathy. For example, Silver syndrome and Troyer syndrome are, respectively, autosomal dominant and autosomal recessive complicated HSP syndromes in which lower extremity spasticity is associated with distal atrophy in the hands and feet (Cross & McKusick, 1967; Farag *et al.*, 1994; Silver, 1966).

Laboratory, neuroimaging, and neurophysiologic analysis

Analysis of HSP subjects are important in excluding other disorders. Routine laboratory studies including cerebrospinal fluid examinations are normal in subjects with uncomplicated HSP.

Muscle biopsy of some subjects with autosomal recessive HSP due to paraplegin (SPG7) gene mutation have shown ragged red fibers and cytochrome C oxidase deficient fibers (Casari *et al.*, 1998). Muscle biopsy of subjects with autosomal dominant uncomplicated HSP have been normal, however (Hedera *et al.*, 2000).

Magnetic resonance imaging (MRI) of the spinal cord in subjects with uncomplicated HSP may show atrophy particularly in the thoracic region. MRI of the brain in subjects with uncomplicated HSP is normal. Thin corpus callosum may be observed in subjects with autosomal recessive HSP linked to chromosome 15q (Nakamura *et al.*, 1995; Ohnishi *et al.*, 2001). Many of these subjects have mental retardation.

Electromyography (EMG) and nerve conduction studies (NCS) are usually normal in subjects with uncomplicated HSP (McLeod *et al.*, 1993). Note, however, that EMG and NCS may be abnormal in types of complicated HSP that have peripheral neuropathy, motor neuronopathy, or distal muscle wasting.

Somatosensory evoked potentials (SSEP) from the lower extremities may show conduction delay (Pelosi *et al.*, 1991; Pedersen & Trojaborg, 1981). When present, this finding is helpful in distinguishing HSP from primary lateral sclerosis and amyotrophic lateral sclerosis, disorders that do not involve dorsal columns. SSEP from the upper extremities are typically normal in uncomplicated HSP.

Central motor conduction velocity can be measured by cortico-evoked potentials. Typically, cortical evoked potentials recorded from the lower extremities show reduced conduction velocity and amplitude of the evoked potential. Cortical evoked potentials recorded from cervical spinal segments are usually normal or show only mildly reduced conduction velocity (Pelosi *et al.*, 1991; Claus & Jaspert, 1995; Claus *et al.*, 1990; Polo *et al.*, 1993; Schady *et al.*, 1991).

Pathology

Knowledge of HSP's pathology is based on very few autopsies (Schwarz, 1992; Schwarz & Liu, 1956). The pathology of HSP can be characterized predominantly by distal axonopathy affecting the terminal portions of the longest motor and sensory fibers in the central nervous system. Axonal degeneration is maximal in the distal portions of corticospinal tracts; and to a lesser extent, in the distal portions of fasciculus gracilis fibers. Spinocerebellar fibers are involved to a lesser extent. Myelin loss occurs in neurons whose axons are degenerating. Myelin loss in uncomplicated HSP is consistent with the degree of axonal degeneration and is not considered to represent a primary demyelinating process. Dorsal root ganglia, posterior roots and peripheral nerves are normal in uncomplicated HSP (Harding, 1993). Although usually normal, decreased numbers of cortical motor neurons and anterior horn cells have been reported (Harding, 1993; Behan & Maia, 1974).

Treatment

Presently, there is no treatment that prevents HSP in presymptomatic subjects; or retards the rate of progression in affected subjects. Treatment is symptomatic and directed toward reducing muscle spasm, reducing urinary urgency, and improving muscle strength and gait.

Lioresal is helpful in reducing muscle spasticity in HSP subjects. The dosage must be individualized as there is significant interindividual variation in the degree of spasticity. Intrathecal baclofen has benefited individuals with particularly severe spasticity. Additional medical approaches to reduce spasticity include tizanidine, dantrolene, and botulinum injections.

We recommend that HSP subjects undergo daily physical therapy including lower extremity muscle stretching, muscle strengthening, cardiovascular conditioning, and gait training. This recommendation is based not on well-controlled prospective studies but on the nearly unanimous beneficial reports of more than 200 HSP subjects; the importance of maintaining cardiovascular conditioning in subjects with paraplegia; and the potential value of gait training on spinal cord neuroplasticity.

Ankle foot orthotics are often helpful in reducing the tendency to catch the toes and stumble. Generally, however, subjects with significant plantar flexion will require reduction of spasticity with medication and physical therapy prior to using ankle-foot orthotic devices.

Prognosis and genetic counseling

Subjects in whom HSP symptoms begin after adolescence, usually experience gait disturbance that gets slowly worse over many years. As noted previously, many subjects with early childhood onset of HSP symptoms do not appear to worsen even over many years.

It is important to recognize the often significant variation in symptom severity when providing genetic counseling. Age of symptom onset, rate of worsening, and degree of disability may be either uniform or highly variable within a given family in which all subjects share precisely the same HSP gene mutation. Such phenotypic differences are attributed to differences in modifying genes and potentially to environmental factors. Whereas the risk of inheriting or transmitting HSP can be estimated from pedigree analysis (or determined accurately in cases where the HSP gene has been identified), it is usually not possible to determine the age at which symptoms will begin (childhood versus adulthood) and whether symptoms will be severe or not functionally disabling.

Genetic analysis of the HSPs

Twenty different genetic forms of HSP have been defined by their linkage to different genetic loci. HSP loci (and the respective types of HSP) are designated Spastic Gait (SPG) loci 1 through 20 in order of their discovery. Thus far, ten

autosomal dominant, seven autosomal recessive, and three X-linked HSP loci have been discovered (Table 53.1).

Whereas various types of “complicated” HSP can sometimes be recognized by their associated signs (Table 53.1), clinical and neuroimaging parameters can not reliably distinguish one genetic form of “uncomplicated” HSP from another. There are differences in the average age at which symptoms first appear however. Gait disturbance generally begins in childhood for subjects with HSP linked to chromosomes 12 (SPG10), 14 (SPG3), and 19 (SPG12) (for review see Fink & Hedera, 1999); and after age 20 in subjects with autosomal dominant uncomplicated HSP linked to chromosomes 2p (SPG4), 2q (SPG13), 8 (SPG8), and 15 (SPG6). There is significant overlap in the range of ages at which symptoms begin between the various forms of uncomplicated HSP. This limits the accuracy of predicting the genetic type of uncomplicated HSP from the age of symptom onset.

The most common types of autosomal dominant uncomplicated HSP are those linked to chromosome 2p (SPG4/spastin gene) and chromosome 14q (SPG3A/atlastin gene), representing approximately 40% and 10% of such families, respectively (Fink *et al.*, 1996). Each of the other types of autosomal dominant HSP are rare and have been reported in only one to several kindreds.

It is estimated that 50% of autosomal recessive HSP kindreds are linked to the SPG11 locus (Martinez-Murillo *et al.*, 1999; Shibaski *et al.*, 2000) on chromosome 15q13–q15. Each of the other types of autosomal recessive HSP have been described in only a few kindreds.

HSP genes

Nine HSP genes have been identified (Table 53.1). Little is known about the function of most of these proteins because they are novel and have only recently been discovered.

SPG4 gene (spastin protein) mutations are the single most common cause of autosomal dominant uncomplicated HSP. *SPG4* mutations cause approximately 40% of autosomal dominant HSP (Hazan *et al.*, 1999). *SPG4* gene analysis is available commercially (Athena Diagnostics, Boston) and can be used for confirmation of diagnosis and for prenatal diagnosis.

More than 80 *SPG4* mutations have been identified (see Hazan *et al.*, 1999; Hentati *et al.*, 2000; Lindsey *et al.*, 2000; Fonknecten *et al.*, 2000; Svenson *et al.*, 2000; Wang *et al.*, 2002). These are almost always unique to the family in which they are discovered. Most, if not all *SPG4* mutations are considered to be pathogenic through haploinsufficiency (insufficient abundance of sequence-normal spastin) (Hazan *et al.*, 1999; Charvin *et al.*, 2002) rather than through a dominant negative mechanism.

SPG4 is widely expressed (Charvin *et al.*, 2002). The function of *SPG4*'s encoded protein ("spastin") is not known. Spastin contains an ATPase associated with diverse cellular activities (AAA) domain (Hazan *et al.*, 1999), and may interact with microtubules (Azim *et al.*, 2000; Errico *et al.*, 2002). Spastin's intracellular distribution is uncertain as both nuclear (Hazan *et al.*, 1999) and cytoplasmic (Errico *et al.*, 2002) localization have been observed.

SPG3A gene ("atlastin" protein) mutations cause approximately 10% of autosomal dominant HSP (Fink *et al.*, 1996; Zhao *et al.*, 2001). *SPG3* ADHSP typically begins in childhood. One study observed *SPG3A* mutations in 25% of autosomal dominant HSP kindreds in which all affected subjects developed symptoms in childhood (Alvarado *et al.*, 2001).

Atlastin's function and the mechanisms by which atlastin mutations cause HSP are not known. Atlastin contains conserved motifs for GTP binding and hydrolysis (Zhao *et al.*, 2001), and bears structural homology to guanylate binding protein 1 (GBP1), a member of the dynamin family of large GTPases (Zhao *et al.*, 2001). The occurrence of an HSP specific mutation in atlastin's GTPase motif indicates the likely significance of this domain (Muglia *et al.*, 2002).

Mutations in kinesin heavy chain (KIF5A) cause either uncomplicated autosomal dominant HSP; or ADHSP associated with distal muscle atrophy (Pericak-Vance *et al.*, 2002). KIF5A is a molecular motor that participates in the intracellular movement of organelles and macromolecules along microtubules. Disturbance in this axonal transport could cause distal axonal degeneration in this and possibly other forms of HSP (Crosby & Proukakis, 2002).

Mutations in mitochondrial chaperonin 60 (also known as heat shock protein 60) cause uncomplicated ADHSP (Hansen *et al.*, 2002). The mechanisms by which disturbance in this mitochondrial protein cause HSP are not known.

SPG7/araplegin gene mutations cause a rare form of autosomal recessive HSP (De Michele *et al.*, 1998). Subjects with paraplegin mutations exhibit either uncomplicated HSP; or HSP associated with dysarthria, dysphagia, optic disc pallor, axonal neuropathy, and evidence of "vascular lesions," cerebellar atrophy, or cerebral atrophy on cranial MRI.

Like chaperonin 60, paraplegin is a mitochondrial chaperone protein (DeMichele *et al.*, 1998). Muscle biopsy in some (but not all) HSP patients with *SPG7* gene mutations showed ragged-red and cytochrome oxidase negative fibers and abnormal mitochondrial structure typical of mitochondriopathy (DeMichele *et al.*, 1998).

Troyer syndrome, a complicated form of autosomal recessive HSP associated with distal muscle wasting is due to mutations in a novel gene designated Spartin

(Spartin-related autosomal recessive Troyer protein) (Patel *et al.*, 2002). Spartin's amino-terminal region is similar to spastin's. Spartin's function is unknown although homology to proteins involved in the endosome morphology and membrane trafficking suggest these possible actions.

Mutations in a novel non-imprinted Prader-Willi/Angleman gene (*NIPAI*) were recently identified as the cause of ADHSP linked to chromosome 15q (Rainier *et al.*, 2003). *NIPAI* is a neuron-specific protein of unknown function. Analysis of *NIPAI*'s predicted secondary structure suggests that it is a membrane protein.

Proteolipid protein (PLP) gene mutations (duplications and point mutations) cause Pelizaeus-Merzbacher disease, an infantile-onset, progressive leukodystrophy; and a slowly progressive form of X-linked HSP (Cambi *et al.*, 1995; Dube *et al.*, 1997). PLP is an integral myelin protein. MRI evidence of CNS leukodystrophy is present in some but not all X-linked HSP patients with PLP mutations.

Neuronal cell adhesion molecule L1 (L1CAM) gene mutations cause a variety of X-linked developmental neurologic disorders including complicated X-linked spastic paraplegia, X-linked hydrocephalus, and X-linked mental retardation aphasia, shuffling gait, and adducted thumbs (MASA) syndrome (Fransen *et al.*, 1996). L1CAM is an integral membrane glycoprotein and a member of immunoglobulin superfamily of cell adhesion molecules that mediate cell-to-cell attachment. L1CAM functions include guidance of neurite outgrowth during development, neuronal cell migration, and neuronal cell survival (Kenwrick *et al.*, 2000).

Conclusions

HSP is a genetically and clinically heterogeneous group of disorders. At least 20 types of HSP have been genetically defined. Although core symptoms of spastic gait are shared with all types of HSP, whether gait disturbance is progressive or static, early or late onset, or associated with muscle wasting, mental retardation, or other neurologic impairments may vary from one genetic type of HSP to another. Furthermore, variation in age of symptom onset and degree of severity within a given family limits the ability to predict accurately the ultimate degree of disability for an individual at risk of developing HSP. A cautious "wait and see" approach is advised.

It is essential to carefully consider the differential diagnosis (for review, see Fink *et al.*, 1996) for subjects with progressive spastic gait, even if there is a strong family history. Alternate disorders (such as multiple sclerosis) or co-existent disorders (such as peripheral neuropathy) may

occur in subjects with strong family history of HSP. Laboratory, neuroimaging, and electrodiagnostic studies are helpful in this regard.

It is perhaps not surprising that as causes of HSP have been discovered, they have proven to be molecularly diverse. The distal ends of extremely long fibers (corticospinal tracts and dorsal column fibers subserving the lower extremities) appear to be quite vulnerable to a number of distinct biochemical disturbances. It will be interesting to learn whether some of these disparate primary biochemical disturbances converge into one or more common pathways.

Over time, the HSPs will be classified by their molecular basis and not simply by mode of inheritance and clinical features. An emerging molecular classification might include a) HSP due to mitochondrial abnormality (including SPG13 due to chaperonin 60 mutation and SPG7 due to paraplegin mutation); b) HSP due to axonal transport abnormality (including SPG10 due to kinesin heavy chain mutation and possibly SPG3A (atlastin mutation) and SPG4 (spastin mutation); c) HSP due to primary myelin disturbance (SPG2 due to PLP mutation); and d) HSP due to embryonic development of corticospinal tract neurons (SPG1 due to LICAM mutation).

Discovery of HSP genes permits laboratory-based diagnoses. Already, commercially available analysis of *SPG4*/spastin and *SPG3A*/atlastin genes will diagnose more than 50% of autosomal dominant HSP. Moreover, discovery and analysis of HSP genes is the primary method for learning the molecular basis of the HSPs, information that is essential for developing treatments for these disabling conditions.

Spinal and bulbar muscular atrophy (Kennedy's disease): a sex-limited, polyglutamine repeat expansion disorder

Patrick S. Thomas, Jr.¹ and Albert R. La Spada²

²Department of Laboratory Medicine, Medicine and Neurology and Center for Neurogenetics and Neurotherapeutics
University of Washington Medical Center, Seattle, WA, USA

Clinical background

In 1968, William Kennedy and co-workers described a slowly progressive neuromuscular disease in male members of two families (Kennedy *et al.*, 1968). The “Kennedy’s disease” syndrome that they reported was most consistent with a spinal muscular atrophy, but exhibited rather unique genetic and clinical features that differentiated it from other well-described motor neuron diseases at that time (Table 54.1). A number of other case reports describing patients with similar findings soon followed, establishing “Kennedy’s disease” as a single specific genetic entity. Further work supported the classification of Kennedy’s disease as a sex-linked form of spinal muscular atrophy that involved the bulbar musculature (Harding *et al.*, 1982; Ringel *et al.*, 1978; Stefanis *et al.*, 1975). Because of the bulbar involvement, the disorder also came to be known as spinal and bulbar muscular atrophy, and “SBMA” was selected as its official genetic designation. While much has been learned about the pathogenesis and molecular basis of SBMA in the last 35 years, the original description provided by Dr. Kennedy and his colleagues remains an accurate clinical and laboratory vignette of what we now know as Kennedy’s disease or SBMA.

SBMA is a slowly progressive motor neuronopathy that shows an X-linked pattern of inheritance, fully affecting only males. Dysfunction followed by gradual loss of motor neurons occurs in the anterior horn of the spinal cord and in the bulbar nuclei of the brainstem, while upper motor neurons are spared. Most SBMA patients display proximal girdle muscle weakness with striking fasciculations of the tongue or chin. Chin and tongue twitching is a particularly common finding in SBMA, whereas it is not often seen in other motor neuron diseases (Harding *et al.*, 1982). Onset of SBMA in affected individuals usually occurs in the fourth or fifth decade of life, although earlier onset has been reported

(Antonini *et al.*, 2000). Even in the earliest occurrences of the disease, the first signs are seen in late puberty or early adulthood (Andrew *et al.*, 1997) – there are no cases of SBMA presenting in infants or children. Early symptoms include shoulder and pelvic girdle muscle weakness, which may present as problems lifting objects and walking. Most patients report muscle cramps, many times occurring as early as 15–25 years before complaints of muscle weakness (Harding *et al.*, 1982). In most cases, the condition of SBMA patients worsens over a period of 10–30 years. One-third of patients require a wheel chair about 20 years after symptom onset. Proximal muscle weakness is typically accompanied by a much milder distal muscle weakness. SBMA patients seldom have sensory complaints, as sensory involvement is minimal and often only revealed by physical exam or electrodiagnostic testing (Antonini *et al.*, 2000; Ferrante & Wilbourn, 1997; Harding *et al.*, 1982; Ringel *et al.*, 1978). As the disease progresses, bulbar muscles can become affected, leading to dysarthria and dysphagia. Although the bulbar weakness does not prevent the patient from acquiring adequate nutrition, it does cause significant morbidity as it places the patient at risk for asphyxiation and aspiration pneumonia. These complications are the only causes of mortality directly related to motor neuron degeneration in Kennedy’s disease, and occur in no more than 10% of affected patients. Thus, despite the disability incurred by their disease, the majority of SBMA patients can expect to have a normal life-span. On physical exam, SBMA patients will demonstrate signs typical of lower motor neuron pathology – namely muscle weakness, flaccidity, and atrophy. This pathology is apparent in the proximal muscles, but is sometimes noted in the distal muscles as well (Fig. 54.1). No signs of upper motor neuron disease, such as hyperreflexia or spasticity, are evident, although cramping and tremor may be elicited upon strength testing and intention movement, respectively (Arbizu *et al.*, 1983;

Fig. 54.1 Patient with SBMA. Note the atrophy of the proximal upper limb musculature and the presence of gynecomastia.

Harding *et al.*, 1982; Stefanis *et al.*, 1975). Deep tendon reflexes are either decreased or absent, depending on where the patient is in the progression of his disease. Examination of patient sensation is initially unremarkable, although decreased distal sensation on provocative testing emerges as the disease progresses. This sensory impairment, however, usually remains subclinical.

A prominent feature of Kennedy's disease / SBMA that permits its clinical differentiation from other spinal muscular atrophies and predicted its molecular delineation is the presence of striking androgen insensitivity in affected patients (Arbizu *et al.*, 1983). Most SBMA patients will display obvious gynecomastia (Fig. 54.1), and this finding is

Table 54.1. Findings in Kennedy's disease/spinal and bulbar muscular atrophy

Neurological

Prominent signs of lower motor neuron disease in spinal cord and brainstem

Muscle weakness and muscle atrophy (proximal > distal)

Hypo-reflexia

Fasciculations

Late bulbar involvement (dysphagia and dysarthria)

Minimal signs of sensory tract involvement

Decreased sensation on physical exam seen occasionally

Reduced to absent sensory nerve action potentials

Absence of upper motor neuron disease findings

No spasticity or hyper-reflexia

Endocrinological

Prominent signs of androgen insensitivity

Gynecomastia

Testicular atrophy

Reduced fertility

Genetic

X-linked inheritance pattern

Sex-limited penetrance with only males fully affected

Racial/population group distribution

Caucasians and Asians (never reported in Africans or

Aborigines)

1/50 000–1/100 000 males are affected in most population groups

Highest prevalence is among Japanese due to founder effect

Laboratory

Bio-markers

Moderate elevations of creatine phosphokinase (CPK)

often the initial presentation of the disease in post-pubertal teenagers who are yet to develop neuromuscular signs. Decreased testicular size and reduced fertility accompany the gynecomastia, although there is considerable variability in this triad of findings in affected patients. Despite the prominence of these findings in certain patients, no SBMA patients have failed to fully develop normal male genitalia, either externally or internally. Indeed, SBMA patients generally have normal sexual function, though some report impotence in the later stages of the disease, difficulty conceiving children, and an inability to grow thick facial hair. Thus, a thorough evaluation of male patients with onset of lower motor neuron findings demands that the clinician take a complete history and perform a full examination to document the possible coexistence of androgen insensitivity. This is extremely important as SBMA can be confused with disorders such as amyotrophic lateral sclerosis (ALS), autosomal spinal muscular atrophy type IV, spinocerebellar ataxia type 3, Friedrich's ataxia, adult-onset Tay–Sachs

disease, or even the adrenomyeloneuropathy variant of adrenoleukodystrophy. ALS is most often confused with SBMA – so much so that one series found that as many as 5% of SBMA cases are misdiagnosed as ALS (Parboosingh *et al.*, 1997).

Neuropathology studies of SBMA demonstrate marked reduction in the number of anterior horn cells at all levels of the spinal cord (Amato *et al.*, 1993; Kennedy *et al.*, 1968; Ogata *et al.*, 1994). Bulbar motor neuron loss is also evident, and even dorsal root ganglia can be decreased in size and number in elderly patients at autopsy (Olney *et al.*, 1991; Sobue *et al.*, 1981). The pathology of SBMA seems to be restricted to the neurons themselves, as there is no evidence of concomitant white matter disease or corticospinal tract involvement. Muscle biopsies from several studies are consistent with denervation atrophy, although an element of myopathy can not be excluded and may be suggested by moderate elevations in serum creatine phosphokinase (CPK). Electrodiagnostic studies including electromyography (EMG) and nerve conduction velocity (NCV) testing reveal findings suggestive of denervation atrophy (Ferrante & Wilbourn, 1997; Guidetti *et al.*, 1996; Olney *et al.*, 1991). Specifically, EMGs are remarkable for large amplitude, long duration motor unit action potentials, typical of chronic denervation with reinnervation. NCVs are typically slow in all nerves, and sensory synaptic nerve action potentials (SNAPs) are reduced or absent. However, as noted above, this lack of SNAPs does not usually produce symptoms. While electrodiagnostic studies may assist in the diagnosis of SBMA, the discovery of a specific molecular defect in SBMA has made electrodiagnostic testing no longer necessary, except in atypical cases.

Other available clinical laboratory tests are of marginal utility in supporting the diagnosis of SBMA. Endocrinology tests for luteinizing hormone, follicle stimulating hormone, and testosterone yield normal results for most SBMA patients. However, serum CPK is elevated in the majority of SBMA patients at levels that exceed what one would expect for a pure motor neuronopathy. Finally, while many workers have considered the possibility that SBMA patients are at increased risk for type II diabetes mellitus, there is no clear evidence to date that the prevalence of diabetes or impaired glucose tolerance is any higher in SBMA patients than in the general population.

Genetics and molecular biology

SBMA fully affects only men, but does so rarely with a prevalence of less than 1/50 000 males (Tanaka *et al.*, 1996). The disease is observed in individuals of Caucasian and

Asian racial background, but never in Africans or Aborigines. Almost all Caucasian population groups are affected, as patients of English, Irish, Belgian, Danish, Dutch, French, Italian, Finnish, German, Greek, Polish, Spanish, Swiss, Moroccan, and Turkish ancestry have been ascertained. Chinese, Japanese, Korean, and Vietnamese cases have been reported, suggesting that various Asian population groups exhibit SBMA. Of all population groups, the Japanese have the highest prevalence of SBMA by far, and this appears due to a founder effect (Tanaka *et al.*, 1996). A founder effect has also been reported in the Scandinavian population (Lund *et al.*, 2000), but is not present across other Caucasian or Asian population groups.

The X-linked inheritance pattern of SBMA allowed researchers to focus their efforts upon the X chromosome in the search for the causal SBMA gene defect and thereby take what was then called a “reverse genetics” (now positional cloning) approach to identifying the cause of this disorder. Linkage analysis of SBMA families permitted localization of the SBMA gene to the proximal long arm of the X chromosome (Fischbeck *et al.*, 1986). At around the same time, the gene for the androgen receptor (AR) was cloned and mapped to Xq11-12, an overlapping region of the X chromosome (Brown *et al.*, 1989; Lubahn *et al.*, 1988). Given the signs of the androgen insensitivity in SBMA patients and the localization of the AR gene and SBMA defect to overlapping regions of the X chromosome, the AR gene emerged as a candidate gene for SBMA. Sequencing of the AR gene in SBMA patients yielded no differences in its amino acid composition, except for an alteration in the length of a normally highly polymorphic glutamine tract in the amino-terminal region (La Spada *et al.*, 1991). The basis of this polymorphism is a CAG trinucleotide repeat in the first exon of the AR gene, and analysis of affected SBMA patients and obligate carriers indicated that expansions of the CAG tract were present in all SBMA patients or carriers (Fig. 54.2). This finding of a CAG trinucleotide repeat expansion as the cause of a human genetic disease was the first one of its kind, and occurred at the same time that another inherited disorder, the fragile X syndrome of mental retardation, was shown to be due to (what would turn out to be) a non-coding CGG repeat expansion (Verkerk *et al.*, 1991). In the case of SBMA, normal individuals possess anywhere from 5 to 36 CAG repeats in their AR genes, while affected SBMA patients and carriers have 38 to 70 CAG repeats. It is important to note that CAG repeat expansion is the only mutational cause of SBMA identified to date – thus, all SBMA affected males show a CAG repeat expansion. At the same time, the mutation appears fully penetrant – thus, no male individuals who are clinically normal have ever been shown to possess a CAG repeat expansion in their AR gene.

Fig. 54.2 CAG repeat expansion in the first exon of the androgen receptor (AR) gene is the cause of SBMA. The AR gene is composed of eight exons. A polymorphic CAG repeat that encodes the amino acid glutamine resides in the first exon. CAG repeat size ranges are shown for both normal individuals and for SBMA patients / carriers.

Fig. 54.3 The androgen receptor protein contains a number of functional domains. I = polyglutamine tract; II = activation function domain; III = polyproline tract; IV = polyglycine tract; V = DNA-binding (zinc finger motif) domain; VI = bipartite nuclear localization signal; and VII = ligand-binding domain.

One unique feature displayed by the CAG repeat expansion mutations seen in SBMA patients and carriers is genetic instability. When a SBMA repeat allele is transmitted from parent to offspring, it often changes in size (Biancalana *et al.*, 1992; La Spada *et al.*, 1992). The likelihood of repeat length change and of repeat expansion is significantly greater when the sex of the transmitting parent is male. This repeat instability occurs rarely in alleles of normal size (Zhang *et al.*, 1994). The genetic instability of expanded CAG repeats has yielded a wide range of allele sizes in the SBMA patient population, and a genotype-phenotype correlation of SBMA disease severity with CAG repeat length found a significant relationship between allele size and certain clinical landmarks in SBMA patients (Doyu *et al.*, 1992; La Spada *et al.*, 1992). In particular, age of onset of clinical symptoms and age of onset of difficulty climbing stairs were shown to inversely correlate with the size of the expanded CAG repeats – thus, the longer the CAG repeat expansion, the earlier the age of onset of each of these events in SBMA patients. While a significant correlation was found, it was not very strong, leading to the conclusion that other factors – genetic, environmental, or random – account for the variability in disease natural history in most SBMA patients. The tendency of CAG repeats to expand, however, is an important feature of related trinucleotide repeat diseases (see below), and is now known to

account for the phenomenon of anticipation (Harper *et al.*, 1992), which may be defined as worsening clinical severity in successive generations of a family pedigree segregating an inherited disorder.

The AR gene encodes a protein that is a well-known and well-studied member of the steroid/thyroid receptor superfamily, with a domain structure that typifies that protein family (O'Malley, 1990). The AR gene spans ~ 150 kb, contains 8 exons, and has an ORF that codes for a 919 amino acid protein. AR has a number of functionally important domains (Fig. 54.3), including a DNA binding domain, comprised by amino acids 556–616 and composed of two zinc finger motifs. There is a bipartite nuclear localization signal at residues 617–633 (Zhou *et al.*, 1994). AR also has a ligand-binding domain at amino acid position 666–919, the carboxy-terminal one-third of the protein. These three domains are highly conserved across a wide range of mammalian and avian species (Thornton & Kelley, 1998). The large amino-terminal region, on the other hand, is mostly a poorly conserved region possessing few recognizable domains with one notable exception. Since the amino-terminal region is required for the transcription activation function of AR, a so-called “activation function” (AF) domain is contained within this portion of the protein. In addition, there are three poly-amino acid tracts. The polyglutamine tract, which expands to

cause SBMA, begins at amino acid 58, and has an average length of about 21 amino acids in humans (Edwards *et al.*, 1992). The glutamine tract motif is commonly seen in transcription factors and has been shown to be important for transcription activation function. Thus, the large amino-terminal region of AR is believed to be involved in mediating transactivation via protein–protein interactions with other transcription cofactors and coregulators. AR's transactivation function is modulated by ligand binding. Unliganded AR is normally located in the cytoplasm and sequestered by heat shock proteins and chaperones (Caplan *et al.*, 1995). Upon binding to its ligands, testosterone or 5-dihydrotestosterone, AR undergoes a conformational change, dissociates from the heat shock protein / chaperone complex, and translocates to the nucleus. There it forms a complex with co-activators and other components of the transcriptional machinery, and this complex binds to specific promoter DNA sequences known as androgen response elements (ARE's), thereby producing androgen-responsive gene expression (Gelman, 2002). Ligand binding yields a functional AR by causing an intramolecular interaction between the C-terminal and N-terminal domains, which then permits an intermolecular interaction to occur in the nucleus, resulting in an AR homodimer. Dimerization of AR is required for its transcriptional function (Langley *et al.*, 1995).

Polyglutamine expansion: a common cause of neurodegeneration

About two years after a polyglutamine expansion was found to be the cause of SBMA, an international team of researchers from multiple institutions reported that Huntington's disease (HD) is caused by the identical type of mutation – a polyglutamine expansion (Huntington's disease CRG, 1993). Over the last decade, a number of other inherited neurodegenerative disorders were found to be caused by polyglutamine expansions. In addition to SBMA and HD, dentatorubral-pallidoluysian atrophy (DRPLA) and six types of spinocerebellar ataxia (namely, SCA1, 2, 3, 6, 7, and 17) are now all known to be due to polyglutamine tract expansions within their respective proteins (Nakamura *et al.*, 2001; Zoghbi & Orr, 2000). The CAG / polyglutamine repeat diseases thus form a distinct category of neurodegenerative disorders sharing the common feature of having an unstable CAG trinucleotide repeat encoding an elongated run of glutamines as their mutational basis. For most of these diseases, a strong correlation between polyglutamine repeat length and disease severity exists, and vertical transmission of larger repeat expansions

produces childhood onset cases, a phenomenon known as anticipation (Harper *et al.*, 1992). A number of lines of evidence support the conclusion that the polyglutamine tract expansion is a gain-of-function mutation that imparts a novel activity or action to the mutant proteins within which they reside. Importantly, studies have shown that the mutant proteins are transcribed and translated (Zoghbi & Orr, 2000), and expression of the polyglutamine expansion at the protein level appears necessary for production of the full phenotype (Goldberg *et al.*, 1996). Further evidence for gain-of-function comes from the observation that loss-of-function of the different disease proteins does not cause the expected phenotypes. Among the best examples of this are SBMA and HD, which have human examples of disease protein loss of expression for their respective genes. Deletion of the AR gene (that causes SBMA) results in complete androgen insensitivity or testicular feminization, a phenotype not characterized by neuromuscular disease (Brown *et al.*, 1988). Loss of the tip of the short arm of chromosome 4 yields Wolf-Hirschhorn syndrome in humans, a multi-system disorder, but one not noted for striatal degeneration (Wilson *et al.*, 1981). To corroborate that loss-of-function does not equate with disease phenotype, certain groups have knocked out the various polyglutamine disease genes in mice, and have not reproduced the same phenotype (Duyao *et al.*, 1995; Matilla *et al.*, 1998; Nasir *et al.*, 1995; Zeitlin *et al.*, 1995). (However, as we will discuss below, a role for loss-of-function as a contributory factor in disease pathogenesis is now supported by recent findings.)

Molecular basis of polyglutamine neurotoxicity

A discussion on how gain-of-function of the polyglutamine-expanded AR leads to motor neuron pathology in SBMA requires that we consider the results of work done on all the polyglutamine diseases. Much of the earlier work on polyglutamine neurotoxicity focused upon how an expanded polyglutamine tract could be neurotoxic. Max Perutz hypothesized that expanded polyglutamine tracts would form novel structures, and he demonstrated that elongated runs of glutamine can form beta-pleated sheets by folding back on themselves (the so-called “polar zipper”) and, once in this conformation, could bind with other proteins with unusually high affinities and form aggregates (Perutz *et al.*, 1994). The notion of an altered conformation as the crux of polyglutamine neurotoxicity was further advanced by the production of an antibody (1C2) that specifically recognized polyglutamine expansions (Trottier *et al.*, 1995). Once in an abnormal conformation, the expanded polyglutamine tracts were

then found to be resistant to turnover and degradation by the ubiquitin-proteasome system (Bence *et al.*, 2001; Sherman & Goldberg, 2001), suggesting that they would accumulate and thereby be able to interfere with cellular processes.

A key turning point in the polyglutamine disease field came when Gillian Bates' group identified aggregates of proteins in the nuclei of neurons from the brains of a transgenic mouse model of HD, and Hank Paulson's group detected such intraneuronal nuclear inclusions (NIs) in the brains of patients with SCA3 (Davies *et al.*, 1997; Paulson *et al.*, 1997). These findings led to the "aggregate" hypothesis of polyglutamine neurodegeneration that postulates that the aggregates themselves are the toxic moiety giving rise to neuronal dysfunction, degeneration, and cell death in the polyglutamine repeat diseases. Subsequent studies of a SCA1 mouse model and an HD primary striatal neuron model disconnected aggregate formation from neurodegeneration, arguing that the aggregates are not the key cause of cellular pathology in the polyglutamine diseases (Klement *et al.*, 1998; Saudou *et al.*, 1998). Further studies in the SCA1 mouse model showed that crossing onto a ubiquitin-protein ligase null background prevented aggregate formation but worsened the disease phenotype of SCA1 transgenic mice, suggesting that aggregation could very well be a protective mechanism in the polyglutamine diseases (Cummings *et al.*, 1999). While the pathway by which expanded polyglutamine tracts cause neurotoxicity remains unresolved, all of these studies have established that polyglutamine expansions are intrinsically toxic. Perhaps the best illustration of this is that expression of an expanded polyglutamine tract alone, out of context of the protein within which it normally resides, is sufficient to cause neurotoxicity in a wide range of model organisms (i.e. yeast, fruitflies, worms, and mice) (Hughes *et al.*, 2001; Marsh *et al.*, 2000; Ordway *et al.*, 1997; Sipione & Cattaneo, 2001). Most striking among these studies was the insertion of a polyglutamine expansion into the hypoxanthine phosphoribosyltransferase (HPRT) gene in mouse embryonic stem cells, yielding a mouse that developed a neurodegenerative phenotype with characteristic NIs due to production of a chimeric HPRT protein with an ~ 150 glutamine repeat tract (Ordway *et al.*, 1997).

Given that all expanded polyglutamine tracts are toxic based upon their ability to form abnormal structures and adopt aberrant non-degradable conformations, the question arises: Why do the polyglutamine diseases differ in their clinical phenotypes? While one might think that the explanation would simply be different patterns of expression of the various disease genes, this is not at all the case. Most of the polyglutamine disease gene products

show overlapping expression throughout the central nervous system. For example, the mutant huntingtin protein (that causes HD) is expressed highly in cerebellum, while a number of the mutant ataxin proteins (that cause the SCAs) are highly expressed in the basal ganglia. Nonetheless, classic HD patients are not ataxic, and typical SCA patients do not display choreiform movements. Thus, a key question in the polyglutamine field is how is the common pathological property of polyglutamine expansion modulated to produce selective patterns of cell-type specific neurodegeneration in the different diseases? Much of the work performed over the last decade suggests that it is the amino acid context of the protein within which the polyglutamine expansion resides that determines the pattern of pathology. Amino acid context is responsible for specifying disease pattern based upon its role in regulating protein-protein interaction. In the case of huntingtin, a long list of interacting proteins has been compiled (Jones, 1999; Kalchman *et al.*, 1997; Li *et al.*, 1995). For SCA7, it appears that the retinal degeneration phenotype is a reflection of a specific interaction with a protein known as the cone-rod homeobox protein (CRX) (La Spada *et al.*, 2001). For SCA1, interaction with leucine-rich acidic nuclear protein (LANP) or polyglutamine binding protein 1 (PQBP-1) may explain the pattern of pathology seen in this disorder (Matilla *et al.*, 1997; Okazawa *et al.*, 2002). In each case, it is the expression pattern of the interacting protein that mirrors the pattern of at-risk neuron cell populations and thus accounts for the cell-type specificity, if this model is correct.

Molecular basis of motor neuron degeneration in SBMA

With this background in mind, we will now consider how the polyglutamine-expanded AR produces a lower motor neuron disease phenotype in patients with SBMA. As noted above, many lines of evidence support the conclusion that all polyglutamine-expanded proteins adopt an abnormal conformation and that this misfolding is the initial event in the pathogenic cascade. This also appears to be the case for the polyglutamine-expanded AR in SBMA, as immunohistochemical studies of SBMA patients material have shown that AR-containing aggregates are present in the nuclei of neurons destined to degenerate (Li *et al.*, 1998a,b). However, in addition to detecting NIs in the remaining anterior horn cells of the spinal cord in SBMA patients, these studies also found NIs in a wide range of other nervous system tissues and non-neuronal organs (Li *et al.*, 1998a). NIs occur in CNS tissues not affected in SBMA (such as cerebellum and cortex), as well as in skin, testes, kidney,

heart and glia. While this pattern of NI formation suggests that NIs form in all tissues where AR is expressed, no NIs are found in muscle, a tissue where high-level AR expression occurs. As no studies of NI distribution have been carried out in presymptomatic or early symptomatic SBMA patients, the presence of NIs throughout the body in SBMA may be a late stage event preceded by more localized NI formation OR may be a general feature of this disorder. In one mouse model of SBMA, pure polyglutamine expansions of 239 residues were placed under the regulatory control of a promoter fragment from the human AR gene and yielded a non-specific neurological phenotype with NIs identified in a wide range of neural and non-neural tissues (Adachi *et al.*, 2001). It would thus appear that high-level or long-term expression of polyglutamine expansion products is capable of producing NIs in a variety of cell types – even those that are not pathologically affected in the disease of interest.

One feature of SBMA that makes it unique among the polyglutamine repeat diseases is its X-linked inheritance, as all of the other polyglutamine expansion mutations show autosomal dominant inheritance. Although SBMA differs from the rest of the polyglutamine diseases in this way, the polyglutamine expansion in AR acts as a dominant, gain-of-function mutation. Despite the dominant action of the AR mutation in SBMA, female carriers seldom show appreciable findings, and to date, there have been no examples of severely affected female patients who lost mobility and ended up wheelchair-bound. In most X-linked diseases, occasional females are seriously affected due to unfavorable lyonization when random inactivation of the X chromosome bearing the normal gene in the relevant cell lineage occurs. This does not appear to happen in SBMA. Rather, female SBMA carriers seldom have symptoms, and instead are “protected,” suggesting that SBMA shows sex-limited inheritance. Why is it then that female SBMA carriers are protected if the AR polyglutamine mutation is dominant in action? Although non-random X-inactivation due to selection against the X chromosome bearing the mutant AR in precursor cells could explain this, a much more attractive hypothesis has been that females are protected by virtue of the fact that their serum testosterone levels are much lower than what is seen in males. As noted above, translocation of AR from the cytoplasm and into the nucleus is strongly favored by ligand binding (Zhou *et al.*, 1994). Confirmation of this hypothesis as the basis of sex-limited inheritance in SBMA was recently achieved by developing a mouse model of AR polyglutamine neurotoxicity using the entire AR protein. In this study, male mice and female mice widely expressed full-length AR protein containing 97 glutamines, but only the males developed the

full neurological phenotype, as is seen in SBMA (Katsuno *et al.*, 2002). Moreover, when male mice were castrated, they no longer developed neuromuscular disease, and, when female mice received testosterone injections, they became symptomatic. Similar results showing the importance of androgen binding in modulating subcellular localization and producing neurotoxicity were also generated in an elegant *Drosophila* model of AR polyglutamine disease (Takeyama *et al.*, 2002). Independent corroboration of the “androgen-dependent” nature of the SBMA gene mutation also comes from a clinical study of a woman homozygous for CAG / polyglutamine repeat expansion in her AR gene (Schmidt *et al.*, 2002). Despite having two mutant AR genes with disease-causing CAG repeat expansions, she was basically unaffected in middle age, supporting the conclusion that appreciable testosterone levels are required for phenotypic expression. Thus, the dual findings of prominent NIs in SBMA patient material and the dependence of the SBMA disease phenotype upon androgen binding to the mutant AR support a model in which nuclear localization of polyglutamine-expanded AR is required for neurotoxicity (Fig. 54.4). Such a model appears to apply to most, but not all, of the polyglutamine repeat diseases (Huynh *et al.*, 2000; Ishikawa *et al.*, 1999).

Another feature of androgen receptor biology that appears important for its toxicity in SBMA is proteolytic processing (Fig. 54.4). The immunohistochemical studies of SBMA patient material described above also were notable for their observation that NIs failed to label with antibodies directed against the middle portion or carboxy-terminal region of AR, suggesting that the NIs contained only amino-terminal truncation products of AR (Li *et al.*, 1998a). Cell culture models have shown that amino-terminal truncation products are considerably more toxic than their full-length counterparts (Brooks *et al.*, 1997; Merry *et al.*, 1998). Furthermore, amino-terminal truncated versions of AR with 112 glutamines have been used to derive mouse models of SBMA by directing expression throughout the CNS with heterologous promoters (Abel *et al.*, 2001). Such mouse models have recapitulated certain features of the SBMA phenotype (such as prominent motor dysfunction and NIs), but have lacked other features (namely, gender difference and motor neuron degeneration). The rationale for using truncated versions of the AR for cellular and organismal studies is biologically based. In addition to the evidence for amino-terminal truncations in patient material, numerous cell culture studies have detected amino-terminal truncations of the polyglutamine-expanded AR (Butler *et al.*, 1998; Ellerby *et al.*, 1999; Kobayashi *et al.*, 1998; Merry *et al.*, 1998). Furthermore, such amino-terminal truncations are observed in mouse models and *Drosophila*

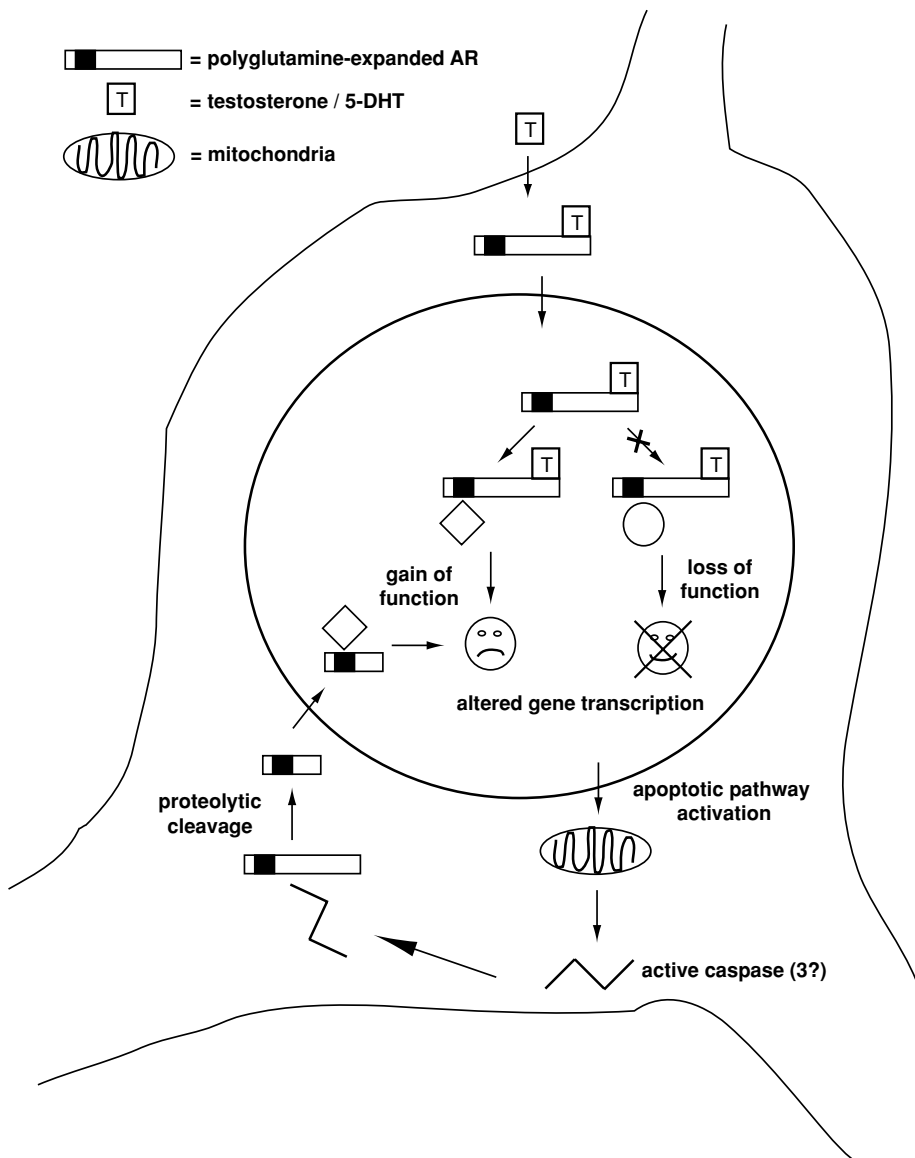

Fig. 54.4 Model for androgen receptor (AR) polyglutamine neurotoxicity in SBMA motor neurons. The polyglutamine-expanded AR is present in the cytosol, and upon ligand-binding to testosterone (T), the ligand-receptor complex translocates into the nucleus. Once in the nucleus, ligand-bound full-length polyglutamine-expanded AR may interact inappropriately with certain transcription factors and/or complexes (symbolized as a diamond), owing to its altered conformation. These aberrant and/or novel interactions represent the gain-of-function pathway of action of the mutant AR, and yield changes in gene expression that are detrimental to the neuron. Transcription interference with CBP-mediated gene expression may be one example of such aberrant interaction. At the same time, ligand-bound AR would be expected to normally interact with transcription factors and co-regulators (shown as a circle) to promote androgen-responsive gene transcription that is trophic in nature. However, the polyglutamine-expanded AR may no longer be able to perform such normal androgen-responsive transcription activation, resulting in the loss of expression of gene products important for cellular survival and homeostasis. Thus, the polyglutamine-expanded AR protein may produce altered gene transcription effects that reflect a combination of gain-of-function and loss-of-function events. These gene expression alterations likely place the neuron under stress, culminating in activation of apoptotic pathways, a process that typically involves depolarization of the outer mitochondrial membrane and yields active caspases. The polyglutamine-expanded AR has been shown to be a substrate for active caspases (such as caspase-3), and caspase cleavage may yield a proteolytic fragment(s) of the mutant AR. (The proteolytic processing is shown to occur in the cytosol, but it may take place in the nucleus and could involve a different protease.) An amino-terminal truncated version of the polyglutamine-expanded AR ends up accumulating in the nucleus where it can potently interfere with normal gene transcription, again through aberrant, perhaps now more avid, interactions with transcription factors and co-regulators (shown as a diamond). This results in further transcription dysregulation and accelerates the process of neuronal dysfunction. Ultimately, the neuronal dysfunction becomes so severe that the motor neuron begins to show degenerative changes that eventually so impair the cell that recovery is no longer possible, so the neuron dies.

models of SBMA that utilize the full-length AR cDNA in their respective expression constructs (Katsuno *et al.*, 2002; Takeyama *et al.*, 2002). The *Drosophila* study is particularly noteworthy in this regard, as it reported the production of an amino-terminal truncation fragment only when AR with 52 glutamines translocated to the nucleus upon treatment with the androgen 5-dihydrotestosterone (Takeyama *et al.*, 2002). Much of the work on AR proteolytic cleavage has focused upon the ability of AR to be cleaved by caspase-3, one of the executioner enzymes of the programmed cell death pathway (Kobayashi *et al.*, 1998; Wellington *et al.*, 1998). After demonstrating that AR is a substrate for caspase-3, one group established that the site of cleavage is at the aspartic acid residue at position 146 and went on to show that mutation of this cleavage site abolished mutant AR's ability to produce cellular toxicity and apoptotic cell death in vitro (Ellerby *et al.*, 1999). Despite these advances, the relationship between proteolytic cleavage, caspase activation, programmed cell death pathways, and AR polyglutamine neurotoxicity in SBMA remains unclear (Fig. 54.4).

Regardless of what length(s) of AR protein ends up in the nucleus (and when), it does seem likely that key events in SBMA pathogenesis do play out there. Given AR's well-known role as a nuclear transcription factor, much effort has focused upon understanding how the polyglutamine-expanded AR protein (or a fragment thereof) might interfere with normal processes of transcription regulation and gene expression. A number of findings have suggested that polyglutamine-expanded proteins may interact inappropriately with other transcription factors or co-regulators that contain glutamine tracts or glutamine-rich regions. The protein kinase A / cyclic AMP gene expression pathway involves the coordinated interaction of transcription factors and co-factors that converge upon so-called cAMP response elements (CREs) in promoters and activate gene expression (Shaywitz & Greenberg, 1999). Among the components of this transcriptional machinery is CREB-binding protein (CBP), a transcriptional co-regulator with histone acetylase activity. Recruitment of CBP favors histone acetylation that results in chromatin remodeling to an open DNA configuration that is permissive of gene transcription. CBP contains a glutamine stretch, and was initially implicated in the polyglutamine diseases when it was found that polyglutamine-expanded AR could impair CREB-mediated transcription and NIs from HD and SBMA patient material and mouse models contain CBP (McCampbell *et al.*, 2000; Steffan *et al.*, 2000). Subsequent studies, that have been performed in primary cortical neuron and *Drosophila* models, indicated that CBP loss-of-function due to aberrant interaction with polyglutamine-expanded proteins

(such as huntingtin) might underlie polyglutamine neurotoxicity (Nucifora *et al.*, 2001; Steffan *et al.*, 2001). The *Drosophila* work pinpointed CBP's acetylation function as a key potential factor, as degenerating photoreceptor cells poisoned by polyglutamine-expansion tracts could be rescued by feeding the flies drugs known as histone deacetylase inhibitors, thereby supposedly compensating for the acetylation defect (Steffan *et al.*, 2001). While the CBP connection to polyglutamine neurotoxicity and to the mutant AR is provocative and intriguing, the CBP transcription interference model can not account for the cell type specificity seen in the different polyglutamine repeat diseases, as CBP is ubiquitously expressed. In the case of SBMA, however, the basis of cell type specificity may be less complicated as the CNS regions of highest AR expression do parallel the disease phenotype (Sar & Stumpf, 1977), making a primary role for CBP interference in SBMA more feasible (Fig. 54.4).

When considering the hypothesis of transcription dysregulation as the primary event in SBMA molecular pathology, it is important to consider the possibility that polyglutamine expansions within the AR protein could be preventing AR from carrying out its normal function in motor neurons. Indeed, partial loss of AR function in SBMA males is responsible for their well described features of androgen insensitivity. At present, two competing hypotheses (that are not mutually exclusive) have been put forward to explain this partial loss of AR function. Two independent studies have argued that the transactivation competence of AR decreases with increasing glutamine length (Chamberlain *et al.*, 1994; Mhatre *et al.*, 1993). In other words, as the glutamine stretch lengthens, the AR protein is less effective in mediating transcription activation at AREs. It is relevant here to point out that within the normal range of glutamine lengths, strong data have emerged showing that shorter glutamine runs in AR are the most potent activators of transcription (Gerber *et al.*, 1994). This correlation actually underlies many independent epidemiological observations that AR CAG repeat length is a significant factor in modulating the severity and natural history of prostate cancer progression, so that individuals with the shortest glutamine tracts tend to have more aggressive tumors (Giovannucci *et al.*, 1997; Nam *et al.*, 2000; Nelson & Witte, 2002; Stanford *et al.*, 1997). However, other studies of polyglutamine-expanded AR in cell culture models have noted that less AR protein is generated from disease-length alleles (Brooks *et al.*, 1997; Choong *et al.*, 1996). The decrease in AR protein levels could be due to decreased transcription, decreased RNA stability, decreased translational efficiency, or increased protein degradation (or some combination of these!). Thus, the

other possible explanation for partial loss of AR function in SBMA is decreased levels of AR protein. Studies of AR protein levels in scrotal skin fibroblasts from SBMA patients did show decreased AR levels by Scatchard analysis in a subset of cases (Warner *et al.*, 1992), and one recent in vitro study has suggested that this occurs in MN-1 motor neuron-like cells because of increased degradation by the ubiquitin-proteasome pathway (Lieberman *et al.*, 2002).

Although complete loss of AR function does not appear detrimental to motor neurons in patients with testicular feminization (tfm), partial loss of function in the context of polyglutamine neurotoxic insult could render motor neurons more susceptible to degeneration (Fig. 54.4). In support of this theory are numerous studies showing that AR is actually a trophic factor in the CNS and its absence accounts for loss of motor neurons that normally innervate the bulbocavernosus muscles in tfm rats (Breedlove & Arnold, 1980; Breedlove & Arnold, 1981; Forger *et al.*, 1992). Androgen administration can facilitate recovery from nerve transection injury and can rescue the bulbocavernosus-innervating neurons (al-Shamma & Arnold, 1995; Nordeen *et al.*, 1985; Sengelaub & Arnold, 1989; Sengelaub *et al.*, 1989a,b). In the MN-1 motor neuron-like cells, alterations in the expression of androgen-responsive genes are observed in cells expressing polyglutamine-expanded AR (Lieberman *et al.*, 2002). Such changes could tie into pathways relevant to the gain-of-function pathology. In the case of HD, a number of lines of evidence do support a role for loss-of-function in the pathogenesis of striatal degeneration. Huntingtin may function as a transcription factor and drive expression of brain-derived neurotrophic factor in cortical neurons that project to the striatum (Zuccato *et al.*, 2001). Upon polyglutamine expansion, this transcriptional function may be impaired. Even more compelling is the observation that postnatal loss of huntingtin expression from the forebrain of gene-targeted mice produces neurological phenotypes and neurodegenerative changes reminiscent of HD (Dragatsis *et al.*, 2000). Our own work on SBMA has focused upon generating a truly representative model of AR polyglutamine neurotoxicity in mice so that the roles of gain-of-function and loss-of-function may be teased out and their molecular bases determined. To do this, we have taken a transgenic approach using yeast artificial chromosomes (YACs) that contain the entire human AR gene. We have used recombination to derive a human AR YAC containing 100 CAG repeats, and have now generated transgenic mice that carry the entire human AR gene with either 20 CAGs or 100 CAGs (Sopher *et al.*, 2002). The AR YAC CAG100 mice produce the polyglutamine-expanded AR protein and develop a neurological phenotype that closely recapitulates the neuromuscular phenotype of SBMA, as

severe disease is restricted to males and is characterized by denervation atrophy with motor neuron degeneration. To evaluate the role of AR's normal function in contributing to the disease phenotype, we are crossing the AR YAC CAG100 mice onto an AR null background by mating them with tfm carrier females. Ultimately, this work should allow us to assess whether or not AR's normal function modulates the gain-of-function pathway of polyglutamine neurotoxicity in an in vivo setting.

Towards therapy

Given the pace of research in the polyglutamine field and the progress on SBMA, it is now time to consider how one might go about developing and testing therapies for this disorder. A key factor to the success of this endeavor will be the availability of representative mouse models of SBMA motor neuronopathy. Numerous mouse models have been generated, including truncation fragment mice and now full-length polyglutamine-expanded AR mice driven by different heterologous promoters (Abel *et al.*, 2001; Katsuno *et al.*, 2002; McManamny *et al.*, 2002). Together with our own AR YAC CAG100 mouse model (Sopher *et al.*, 2002), it is clear that ample models are now available to move forward with testing of therapy. Based upon the recent results from the Sobue and Kato groups (Katsuno *et al.*, 2002; Takeyama *et al.*, 2002), it appears that androgen ablation could be an effective therapy. While very promising, this therapy incurs substantial unpleasant side effects and likely should only be reserved for severe or end-stage cases. Thus, it would make sense to now test if androgen ablation can reverse significant neurological dysfunction in the mouse models as a prelude to its consideration in people. Another area of focus should be transcriptional dysregulation. As explained above, feeding fruitflies histone deacetylase inhibitors (HDAC Is) prevented polyglutamine neurotoxicity, raising the question of whether such a therapy could be applied to people. In this regard, it is important to note that certain HDAC I's are entering Phase II and Phase III trials for the treatment of certain malignancies and therefore represent very viable options for polyglutamine disease patients. Again, much work needs to be done in mice, but this avenue of therapy should be pursued. Other approaches warranting consideration are those that would enhance the heat shock protein response, an evolutionarily conserved molecular process whereby chaperone proteins are elevated to counter aberrant protein misfolding induced by an increase in temperature (Hartl, 1996). Much data on the polyglutamine diseases indicate that protein misfolding is a key early event and that protection or

rescue is possible by over-expression of heat shock proteins (Hsps) (Cummings *et al.*, 2001; Sherman & Goldberg, 2001; Warrick *et al.*, 1999). Studies of polyglutamine-expanded AR in cell culture have corroborated the protective role of Hsp70 and its co-chaperone Hsp40 in preventing toxicity (Kobayashi *et al.*, 2000). More recently, it has been shown that Hsp70 with Hsp40 can increase the solubility of polyglutamine-expanded AR and enhance its proteasomal degradation (Bailey *et al.*, 2002). At least one drug, geldanamycin, is effective in inducing the heat shock response and has been shown to be effective in treating Parkinson's disease in *Drosophila* (Auluck & Bonini, 2002). Clearly, combinatorial approaches to produce more effective and less toxic derivatives of geldanamycin are now warranted. Many other compounds are also being identified by high throughput drug screens, such as one large multi-institutional endeavor recently sponsored by the National Institute of Neurological Disorders and Stroke (Abbott, 2002). As we look towards therapy, it seems reasonable to be cautiously optimistic since the identification, testing, and development of one or more drugs to treat neurodegenerative disorders such as SBMA are well underway.

Spinal muscular atrophies

Klaus Zerres and Sabine Rudnik-Schöneborn

Institute for Human Genetics, University of Technology, Aachen, Germany

Definition

The term spinal muscular atrophy (SMA) comprises a clinically and genetically heterogeneous group of diseases characterized by degeneration and loss of the anterior horn cells in the spinal cord, and – depending on type and severity – sometimes also in the brainstem nuclei, resulting in muscle weakness and atrophy. The sensory neurons are always clinically spared, and there are no signs of upper motor neuron (pyramidal tract) involvement (Emery, 1971).

The subdivision of the SMAs into separate genetic and clinical entities (Table 55.1) is still controversial unless biochemical or molecular genetic criteria are available to define distinct pathomechanisms. The criteria used are age of onset, severity (progression, age of death), distribution of weakness, the inclusion of additional features, and different modes of inheritance.

Epidemiology

Autosomal recessive proximal SMA is one of the most common inherited diseases leading to death in early infancy. According to a rough estimate, less than 2% of cases with an onset before 10 years of age show a parent-to-child transmission (Emery, 1971). While vertical transmission of childhood-onset proximal SMA is an exception, autosomal dominant transmission can be found in about two-thirds of the adult-onset proximal SMA families (Pearn, 1978a). Assuming an incidence of about 1:10 000 for all types of autosomal recessive SMA, it has been estimated that adult SMA accounts for 8% of all SMA cases, with a prevalence of 0.32 per 100 000 of the population (Pearn, 1978b). Distal SMA accounts for about 10% of all SMAs (Pearn & Hudson, 1979).

Proximal SMA

Clinical picture

The clinical picture of proximal SMA is highly variable, indicating a continuous spectrum with ages of onset from before birth to adulthood rather than clearly separable subgroups (Table 55.2a). A major problem of existing classifications is that the prognosis of SMA patients is often better than stated in the defined subtype (Russman *et al.*, 1992; Zerres & Rudnik-Schöneborn, 1995) so that a “reclassification,” for example, from the severe type I to the intermediate type II or even type III might be necessary if life span exceeds the designated age of death. Therefore, it is more reasonable to define SMA types I–IV by achieved motor functions and age of onset without given limitations for prognostic considerations (Table 55.2b).

The clinical signs of the most severe SMA type, which is also called Werdnig–Hoffmann disease or acute SMA, are evident from birth or soon after with a median age of onset of 1 month (Fig. 55.1). Nearly all patients present by 6 months of age, and in one-third, even abnormal fetal movements are reported. Symptoms are profound hypotonia and generalized weakness. The diaphragm and the extraocular muscles tend to be spared and distinguishes classical SMA from SMA plus forms. A certain percentage of infants show mild joint limitations from birth (limited hip abduction or knee and elbow extension, ulnar deviation of the hands), which is much less severe than in arthrogryposis multiplex congenita. In the final stage the child is practically immobile, has a nasogastric tube for feeding, a bell-shaped chest with paradoxical breathing, and is tachypneic indicating imminent respiratory insufficiency. Life-span is short with death occurring at a median age of 8 months in patients with onset in the first 6 months due to weakness affecting both bulbar and respiratory muscles.

Table 55.1. Classification of spinal muscular atrophies

1.	<i>Proximal SMA (80–90%)</i>
	Infantile and juvenile SMA (SMA I–III) (a.r., a.d.)
	Adult SMA (SMA IV) (a.r., a.d., mostly sporadic)
2.	<i>Non-proximal SMA</i>
2.1	Distal SMA (a.d., a.r., X-linked, sporadic), predominantly of the legs, of the hands or both
	– segmental SMA or benign monomelic amyotrophy (mostly sporadic)
2.2	Scapuloperoneal SMA (a.d., a.r.)
3.	<i>Bulbar palsy</i>
3.1	Progressive bulbar palsy of childhood type Fazio–Londe (a.r.)
	– bulbar palsy with deafness (Brown–Vialeto–van Laere syndrome) (a.r.)
3.2	Adult onset bulbar palsy (a.d.)
4.	<i>Spinobulbar neuronopathy type Kennedy (X.L.)</i>
5.	<i>Variants of SMA</i>
	Variants of infantile SMA
	– diaphragmatic SMA (a.r.)
	– SMA plus pontocerebellar hypoplasia (a.r.)
	– SMA plus arthrogryposis and bone fractures (a.r., X.L.)
	– SMA with myoclonus epilepsy (a.r.)
	Variants of adult SMA
	– distal SMA with vocal cord paralysis (a.d.)
	– (SMA with cardiomyopathy)
	(a.r.: autosomal recessive, a.d.: autosomal dominant, X.L.: X-linked)

According to our studies, only 8% of patients were alive beyond the age of 10 years (Table 55.2b). However, it is important to recognize long-standing disease courses with an early onset of generalized weakness but survival into adulthood (Borkowska *et al.*, 2002). Based on molecular genetic findings, there is now strong evidence that a “congenital” type of infantile SMA exists. Major findings include severe neonatal onset with respiratory insufficiency, congenital contractures, external ophthalmoplegia and facial weakness, and severe peripheral (sensory and motor) nerve involvement (Korinthenberg *et al.*, 1997).

The clinical course of SMA type II (Fig. 55.2a,b) is marked by periods of apparent arrest in the clinical progression. The age of onset and presenting signs may be indistinguishable from SMA type I, although median age of onset is generally later (8 months). The children fail to pass motor milestones because of proximal weakness and hypotonia within the first 18 months of life. For practical purposes, this group is defined by the ability to sit independently, as the children never learn to stand or walk unaided. Hand tremor (polyminimyoelonus) and fasciculations (in 50% of the cases) are characteristic features. Pronounced weakness of trunk muscles in the nonambulatory patients give rise to spine deformities. Contractures develop early

in all major joints as a result of synergist-antagonist imbalance. Fifty percent of the SMA II patients could sit independently after age 14 years (Russman *et al.*, 1996) but sitting function is not a prognostic predictor of life-span (Zerres *et al.*, 1997).

A mild form of childhood and juvenile SMA-type III is known as Kugelberg–Welander disease and shows a wide range of clinical onset from the first year of life until the third decade. Patients with SMA type III learn to walk without support, which distinguishes them from those with SMA type II. For prognostic reasons, this group can be separated into types IIIa and IIIb (Table 55.2a). In SMA type IIIa, onset is in the first 3 years of life, the children have early walking difficulties and often fail to pass further motor milestones. Since many patients are non-ambulatory by school age (50% are confined to a wheelchair 14 years after onset, Table 55.2b), there is a considerable handicap in comparison to those who start with first walking difficulties in youth or adulthood (Zerres & Rudnik-Schöneborn, 1995). In SMA type IIIb, first signs of proximal muscle weakness occur between 3 and 30 years. Life expectancy is not much reduced, the course of the disease is characterized by slow progression with periods of arrest. As in SMA II, tremor of the outstretched arm and limb fasciculations are frequently encountered. Depending on the degree of weakness, spine deformities and contractures are frequent complications, mainly in the chairbound patients. Respiratory insufficiency may become a problem in the older, wheelchairbound SMA III patients, who require assisted ventilation late in the disease course.

Intrafamilial variability of age of onset is more marked in SMA type III than in SMA type I or II. In a series of 13 sibships with SMA type III, 3 showed discordant ages of onset ranging from 5 to 15 years within a family (Rudnik-Schöneborn *et al.*, 1994). Moreover, unaffected relatives harboring identical gene defects like the affected sibs have mostly been observed in SMA III families (Hahnen *et al.*, 1995).

SMA type IV is defined to have an onset after the age of 30 years. The condition is relatively benign with slow clinical progression, and a normal life span can be expected (Zerres & Rudnik-Schöneborn, 1995). While the majority of adult onset patients do not show deletions of the SMN1 gene (Zerres *et al.*, 1995a), there are some patients with SMN1 deletions who are not diagnosed before their 50s or 60s. These patients have a strictly proximal involvement with marked weakness of the pelvic girdle and in particular of the psoas muscle. It is believed that these patients are characterized by a large number of SMN2 gene copies, but clinical variability cannot be explained by the SMN genes alone (see genetics/molecular biology). It has to be stressed that – in contrast to SMA I–III – recurrence of SMA IV within a sibship is an exception.

Table 55.2a. Classification of proximal spinal muscular atrophy according to the International SMA Consortium*

SMA type	Principal synonyms	Definition	Genetics
I	Werdnig–Hoffmann disease	Sitting not achieved	Autosomal recessive (about 95% SMN1 deletions)
II	Acute infantile SMA	Onset usually within the first 6 months	Autosomal recessive (about 95% SMN1 deletions)
	Chronic childhood SMA	Unaided sitting possible, walking not achieved	
III	Arrested Werdnig–Hoffmann disease	Onset usually in the first two years of life Survival > 90% by 10 years	Autosomal recessive (80–90% SMN1 deletions)
	Kugelberg–Welander disease	Walking without aids achieved	
IV	Adult SMA	Juvenile SMA	Rarely autosomal dominant inheritance
		– IIIa: Onset ≤3 years – IIIb: Onset ≥3 years Onset > 30 years	Excess of males Mostly sporadic Autosomal recessive (rare)

* Zerres and Rudnik-Schöneborn (1995); Zerres and Davies (1999).

Table 55.2b. Prognostic considerations in proximal SMA type I–III*

Survival probability in SMA I and II	2	4	10	20	40 years of age (%)
SMA I	32	18	8	0	0
SMA II	100	100	98	77	(no data available)
Probability of being able to walk in SMA III	2	4	10	20	40 years after onset (%)
SMA IIIa	98	95	73	44	34
SMA IIIb	100	100	97	89	67

* Zerres & Rudnik-Schöneborn (1995); Zerres *et al.* (1997).

Diagnostic findings

The clinical and laboratory criteria of proximal SMA (Table 55.3) were defined by the International SMA Consortium (Zerres & Davies, 1999). With the evidence of deletions in the region 5q11.2–13.3, it has become possible to confirm the diagnosis of proximal SMA with localization on chromosome 5 by direct molecular analysis, although the role of the deleted genes is not fully understood by the time of this report. Therefore, the clinical diagnostic criteria are still valid, but, in fact, deletion screening of the SMN gene has become the most important diagnostic tool. Serum creatine kinase activity (sCK) is normal in SMA I and II, and only slightly increased in juvenile onset cases. If the sCK exceeds more than five fold the upper normal limit of normal, a myopathy is more likely. However, in rare instances,

CK can be as high as in muscular dystrophy causing diagnostic difficulties (Rudnik-Schöneborn *et al.*, 1998).

Neurogenic changes can be seen on EMG and in the muscle biopsy specimen. EMG shows abnormal spontaneous activity (fibrillations, positive sharp waves, fasciculations) as a sign of acute denervation in progressive disease courses. Spontaneous activity is therefore uncommon in chronic anterior horn cell disease. Motor unit potentials show an increased mean duration and amplitude upon voluntary contraction, reflecting re-innervation. An increased proportion of motor unit potentials is polyphasic. The interference pattern on increasing effort is reduced due to loss of motor units. However, motor and sensory nerves can reveal a reduced excitability and nerve conduction can be markedly slowed in severe SMA type I (Korinthenberg *et al.*, 1997; Rudnik-Schöneborn *et al.*, 2003). Conduction velocity is reduced by depletion of fast conducting large-diameter nerve fibers. In severe cases, distinction from early onset peripheral neuropathies can be very difficult.

In the muscle biopsy, large group atrophy is typical in severe SMA, while the atrophic groups of both fiber types appear to be smaller in the chronic forms. Histochemical staining gives evidence of fiber type grouping mainly in the more chronic cases as a result of reinnervation processes. In SMA I and II, hypertrophic fibers of type I can be seen distributed among the atrophic fibers. In SMA III and IV the process of re-innervation gets the overhand showing type-grouping, although there is still acute denervation, i.e. small groups of angular-sized atrophic fibers. In accordance with the diagnostic criteria, peripheral nerves are morphologically normal in the vast majority of SMA patients. If axonal

Table 55.3. Diagnostic criteria of proximal spinal muscular atrophy (Zerres & Davies, 1999)

Inclusion criteria	Exclusion criteria
Symmetrical muscle weakness of trunk and limbs	Involvement of extraocular muscles, diaphragm and myocardium*
Proximal muscles > distal	Marked facial weakness* (<i>* exceptions are rare congenital onset cases with external ophthalmoplegia and facial weakness</i>)
Lower limbs > upper limbs	CNS dysfunction
Fasciculations of tongue, tremor of hands	Arthrogryposis (<i>but rarely seen in severe, congenital onset SMA type I</i>)
Neurogenic changes in EMG and muscle biopsy	CK usually < 5 times the upper normal limit
Homozygous absence/mutation of the telomeric SMN gene	Reduction of motor nerve conduction velocities < 70% of lower normal limit or abnormal sensory nerve action potentials in SMA II–III (<i>motor and sensory conduction can be markedly abnormal in SMA I</i>)

degeneration was observed in peripheral motor nerves, this was mainly attributed to a dying forward phenomenon as a consequence of motor neuron degeneration. Meanwhile, there is increasing evidence of axonal degeneration, including reduction of myelinated fibers and dystrophic axons with shrunken and condensed axon structures, also affecting the sensory nerve system (i.e. sural nerve) at least in SMA I patients to a variable extent (Rudnik-Schöneborn *et al.*, 2003). In the spinal cord, patho-anatomic features are gliosis of anterior horns without areas of demyelination. While the posterior roots appear to be normal, distinct demyelination can be seen in the anterior roots. The degenerated ganglion cells are small and pycnotic until an almost complete loss of anterior horn cells occurs. Since it has been reported that, in patients with severe SMA, also other parts of the central nervous system (CNS) underwent degenerative processes, the extent of pathologic abnormalities in SMA still has to be clarified.

Differential diagnosis

The differential diagnosis of acute SMA type I is given with the whole spectrum of the floppy infant syndrome. The clinical picture of the mild SMA type III is often indistinguishable from the muscular dystrophies. In many patients with limb girdle muscular dystrophy, it is now possible to classify the immunohistochemical defect in the muscle. If cardiomyopathy is seen in patients with apparent

SMA, this should prompt lamin A/C analysis and exclusion of emerin deficiency for autosomal dominant and X-linked Emery–Dreifuss muscular dystrophy, respectively. Hexosaminidase A deficiency may rarely produce a clinical picture resembling SMA type III. The most important differential diagnosis of SMA type IV is Kennedy disease and amyotrophic lateral sclerosis (ALS). Alterations of the SMN genes have been demonstrated in patients with sporadic ALS and with slowly progressive spinal muscular atrophy, suggesting that an SMN deficiency can also modify the phenotype of other motor neuron diseases (Veldink *et al.*, 2001). Adult Pompe's disease can be misdiagnosed as SMA. In families with evidence of autosomal dominant inheritance, proximal myotonic myopathy (PROMM) has also to be considered which can display neurogenic changes in the muscle. Postpoliomyelitis muscular atrophy is supposed to be due to the progressive loss of regenerated sprouts and is a potential cause of diagnostic confusion.

Genetics/molecular biology

The proximal SMAs as well as the non-proximal SMAs are genetically heterogeneous; both autosomal recessive and autosomal dominant genes are known to cause childhood- or adult-onset SMA. The majority of cases with proximal SMA is autosomal recessively inherited but at least two autosomal dominantly inherited proximal types exist showing considerable clinical overlap (Rietschel *et al.*, 1992). Considering the incidence of at least 1:10 000 for acute and chronic proximal SMA, the estimated heterozygosity frequency is about 1:50 in the general population. The gene responsible for most families with childhood SMA with autosomal recessive inheritance has been localized to a small region of the long arm of chromosome 5 (5q11.2–q13.3). Both the severe infantile and the chronic childhood forms were found to conform to this single gene locus at 5q (Brzustowicz *et al.*, 1990; Gilliam *et al.*, 1990; Melki *et al.*, 1990a,b). Different genes and microsatellite markers have been identified in the 5q region that can be deleted in SMA patients. These are located in a complex genomic region on 5q13 that contains a large inverted duplication consisting of at least four genes (Fig. 55.3): the survival motor neuron (SMN) gene, the neuronal apoptosis inhibitory protein (NAIP) gene, the basal transcription factor subunit p44 (BTFp44), and H4F5. All genes are present in a telomeric and a centromeric copy and show homozygous deletions in SMA patients. Since deletions of the NAIP, BTFp44 and H4F5 genes can also be detected in the normal population, deletions or mutations of the telomeric copy of the SMN gene (SMN1) are disease specific. Therefore, most research has been concentrated on the SMN1 gene, as it exhibits

Fig. 55.3

homozygous deletions in more than 90% of SMA patients (Lefebvre *et al.*, 1995; Hahnen *et al.*, 1995). Deletions can be detected visibly by SSCA or by restriction digest of PCR products. In the vast majority of patients, exons 7 and 8 are absent, followed by a 5–10% deletion rate of exon 7 only. Moreover, isolated deletion of exon 8 has been detected in rare instances of mild SMA (Gambardella *et al.*, 1998). The proportion of clinically typical SMA patients who do not show an SMN1 deletion does not exceed 5% in severe SMA type I, but increases to 10% to 20% in mild SMA type III (Hahnen *et al.*, 1995). It has been shown that there is a correlation of SMN protein levels and SMA phenotype, with type I patients showing low SMN protein levels in particular in spinal motor neurons (Coovert *et al.*, 1997). Homozygous deletions of SMN2 genes can be detected in about 5% of the normal population and are generally not associated with a phenotype, if at least one SMN1 copy is retained.

Only in a small number of patients (approximately 3–4%) subtle mutations in the SMN gene have been identified (Parsons *et al.*, 1998; Wirth *et al.*, 1999). It is therefore tempting to speculate that other genes might be responsible for the non-deleted cases. Compound heterozygotes can be detected after PCR-based densitometric assessment of SMN-gene copy number, by pulsed field gel electrophoresis or by fluorescence-based carrier testing. More recently, quantitative analysis of SMN gene copy numbers based on real-time fluorescence polymerase chain reaction (PCR) have been developed by using a LightCycler (Feldkötter *et al.*, 2002) and TaqMan technology (Anhuf *et al.*, 2003). These quantitative methods identify patients and relatives who retain only one copy of SMN1, knowledge which can be used for further diagnostic work-up of clinically typical cases and for genetic risk calculation in affected families.

While there are deletions of variable sizes in SMA type I, gene conversion events of SMN1 to SMN2 are responsible for the reduced SMN protein transcription leading to the milder phenotype in SMA type II and III. Several studies have demonstrated chimeric SMN genes with SMN2 exon 7 fused to SMN1 exon 8 and thus increasing the number of SMN2 copies to 3–4 in milder SMA types. It was concluded that SMA I is caused by physical deletions of SMN1, while the mutations in type II and III SMA are replacements of SMN1 by SMN2. The SMN2 copy number is reflected by the copy number of the adjacent multicopy markers C212 and Ag1-CA. The number of SMN2 copies correlates with SMA subtype, age of onset and length of survival, i.e. the clinical phenotype is directed primarily by the level of functional SMN protein. However, it is not possible to predict the individual disease course on the basis of the observed deletion size or gene conversion event, as there is a wide overlap of molecular genetic findings in different SMA types.

The severity of SMA can be modulated by the number of centromeric SMN gene copies (SMN2). SMN 2 is nearly identical with the SMN1 gene except for single nucleotide differences in exon 7 and 8, yet their transcriptional products are not the same. While SMN1 predominantly produces full-length transcripts (90%), SMN2 primarily gives rise to transcripts lacking exon 7 (60%) and minor amounts of full-length transcripts (20–30%). It is believed that the SMN protein produced by the truncated transcripts is unstable and therefore less able to fulfil its role in RNA metabolism and transcription. The only critical difference between SMN1 and SMN2 is a C→T base change in exon 7, which disrupts a putative exonic splicing enhancer (ESE) and causes alternative splicing of SMN2 exon 7 (Lorson *et al.*, 1999).

It is still unclear why loss of SMN results in selective motor neuron loss, as the gene is ubiquitously expressed. This is underlined by the observation of families, primarily published as unlinked to chromosome 5q markers, in whom SMN gene deletions were found not only in the patients but also in their unaffected sibs (Hahnen *et al.*, 1995). The 38 kDa SMN protein is found in both cytoplasm and nucleus where it is localized in structures called “gems.” The SMN protein is involved in critical steps of RNA processing and acts in concert with several other proteins in the regeneration of the snRNPs and other splicing factors in the cytoplasm [for review see Sendtner, 2001; Nicole *et al.*, 2002]. Presently, it is suggested that additional factors are required to cause, or at least modify, an SMA phenotype.

Animal models

The SMN protein is transcribed by the two SMN genes that were generated by a duplication on chromosome 5q around 5 million years ago (Rochette *et al.*, 2001), therefore no natural animal model for infantile SMA exists. Before the SMN gene was discovered, it was hoped to find a human homologue derived from the different mouse models with motor neuron degeneration (for reviews see Privoro & Mitsumoto, 1996; Monani *et al.*, 2000b; Schmalbruch & Haase, 2001). This approach was eventually successful for the identification of the human homologue of the *nmd* mouse (Cox *et al.*, 1998), which turned out to be the IGHMBP2 gene responsible for diaphragmatic SMA. As regards murine *Smn* and *Naip* genes, the number of *Naip* genes is increased but there is only one *Smn* copy. The replacement of murine *Smn* by human *SMN2* genes resulted in transgenic mice corresponding to the human disease model (Monani *et al.*, 2000a; Hsieh-Li *et al.*, 2000; Jablonka *et al.*, 2000). These mice show a reduction of motor neurons in the spinal cord without displaying any pathology in other parts of the CNS or in the dorsal ganglia. However, the morphological alterations in the spinal cord suggest that not the numerical reduction of neurons but the loss of function is important for the pathomechanism. In the transgenic mouse model created by the French group (Frugier *et al.*, 2000) exon 7 of the murine *Smn* gene has been removed on both mouse chromosomes in a tissue specific manner by using the Cre/loxP recombination system. While mice with SMN deficiency restricted to the spinal cord (neuronal mutant) develop an SMA like phenotype, the situation is different in mice where SMN was deficient in the muscle. These muscular mutants developed a severe muscular dystrophy with partial dystrophin deficiency not at all connected with the SMA like phenotype (Cifuentes-Diaz *et al.*, 2001). This sheds a new light on SMN function in different tissues.

Management perspectives

A curative treatment of the different SMAs is not available, and so far no therapy is known that has a positive long-term effect on the disease course (Zerres *et al.*, 1995b).

As a high number of SMN2 copies is able to partly compensate motor neuron loss in transgenic mice, this finding has stimulated the planning of therapeutical trials in SMA with proven SMN deficiency where it is hoped to increase the protein transcription of SMN2, e.g. by specific splice enhancers (Hofmann *et al.*, 2000). Transgenic mice which were fed with sodium butyrate had a longer life-span and a significantly milder phenotype compared with litter mates without treatment (Chang *et al.*, 2001). First clinical trials have been initiated with phenylbutyrate and showed a benefit in a small number of SMA type II patients in an open study design (Mercuri *et al.*, 2004). However, many studies on protein expression, interactions and therapeutic effects in animals are required before a causal treatment of SMA 5q is on the horizon. At present, electrical stimulation cannot be recommended as a therapeutic tool. No drug treatment can be recommended.

Non-proximal SMA

Distal SMA (Table 55.4) accounts for about 10% of all SMA cases (Pearn & Hudgson, 1979), and comprises a group of genetically and clinically heterogeneous disorders, demonstrating a broad spectrum of clinical manifestations. Both autosomal dominant and recessive genes cause childhood- and adult-onset forms, which normally have a chronic and benign course. The early childhood form of distal SMA starts soon after birth with distal hypotonia and wasting and leads to pes planus and sometimes scoliosis within the first years of life. It is rarely dominantly inherited (Adams *et al.*, 1998). Distal SMA is also denoted as distal hereditary motor neuronopathies (HNMs) which are frequently listed among the Charcot–Marie–Tooth diseases. The HMNs are currently classified into types I–VII according to age at onset, mode of inheritance and predominantly involved muscle groups (De Jonghe *et al.*, 1998), but this purely clinical classification will probably not hold when all genes have been identified (Irobi *et al.*, 2004). By 2004 eight autosomal dominant entities have been assigned to genetic loci and six of them identified (Zerres & Rudnik-Schöneborn, 2005). A proportion of the CMT-like patients becomes wheelchair bound in due course and some even develop respiratory insufficiency necessitating artificial ventilation. Apart from exceptional families who fit well into the entities described (Irobi *et al.*, 2004), genetic testing is not available to

Table 55.4. Non-proximal spinal muscular atrophies*

Name	Principal synonyms	Clinical features	Inheritance	Gene defect
Distal SMA	Peroneal muscular atrophy Distal hereditary motor neuronopathy (HMN)	Distal weakness (lower or upper limb predominance) with normal conduction velocities and normal sensory findings. Sometimes pyramidal features Onset birth–adulthood	A.r. (~75%) A.d. (~25%) X-linked (rare)	Eight gene loci and six identified genes. (For details see Irobi <i>et al.</i> , 2004.)
Segmental SMA	Monomelic juvenile SMA type Hirayama Benign monomelic amyotrophy	Asymmetrical involvement confined to upper (lower) extremities Onset 2nd decade, benign course (arrest usually after 2–4 years) Male predominance	Mostly non-genetic Few a.d. cases	Unknown
Distal SMA with myoclonus epilepsy		Myoclonus epilepsy, atactic movements, muscular hypotonia and generalized weakness, normal intelligence Onset mostly in childhood	A.r. A.d.	Unknown
Distal SMA with vocal cord paralysis	Hereditary motor neuronopathy type VII	Progressive distal wasting, hoarseness of voice, no bulbar palsy Onset in adulthood	A.d.	2q14 (a.d.)
Scapulo-peroneal muscular atrophy	Scapulo-peroneal atrophy type Stark–Kaeser (dominant form)	Variable weakness of foot and toe extensors, shoulder girdle and upper arms, rarely with cardiopathy Onset in youth or adulthood	A.d. A.r. (X-linked)	12q23–24 (a.d.)
Spinobulbar neuronopathy	Kennedy disease	Proximal/distal weakness mostly in adulthood, gynecomastia, bulbar palsy, sensory disturbances	X-linked	Xq13.1 (CAG repeat expansion of the androgen receptor gene)
SMA with respiratory distress	Diaphragmatic SMA	Distal SMA with respiratory distress due to diaphragmatic palsy	A.r.	11q13–q21 IGHMBP2 gene

diagnose distal SMA. The genetic defects of most autosomal recessive forms of distal SMAs remain to be determined. A chronic distal SMA with early onset but late diaphragmatic dysfunction has been assigned to the same genetic region on chromosome 11q13 like diaphragmatic SMA (Viollet *et al.*, 2002).

For other entities see Table 55.4 and detailed reviews (Zerres & Rudnik-Schöneborn, 2002; Rudnik-Schöneborn *et al.*, 1996).

Future prospects

While dramatic progress has been made in the disclosure of the molecular mechanisms of infantile SMA with localization on chromosome 5q, little is known about the pathogenesis of other SMAs. The identification of other genes

involved in motor neuron degeneration will help to differentiate entities and will provide further insight into the pathogenetic pathway of motor neuron degeneration. The SMN protein is involved in critical steps of messenger RNA transcription and processing, which indicates that the SMN protein fulfils an important cellular role that is not limited to motor neurons. Hence, it is still unclear while SMN deficiency specifically affects motor neuron function. The recently identified IGHMBP2 gene is believed to have a similar function in the RNA metabolism like SMN, but further studies are needed to confirm this. The knowledge of the genetic defect in SMA 5q is helpful in diagnostics and genetic risk calculation; however, at present its value for causal treatment is limited. As a high number of SMN2 copies might be able to partly compensate motor neuron loss, it is hoped to find pharmaceutically active substances that can increase the protein transcription of SMN2.

Therapeutic strategies include the search for compounds that can upregulate SMN2 gene expression, prevention of exon 7 skipping or stabilization of truncated SMN transcripts. One has to be aware of the fact that any drug treatment will most likely not be able to re-activate motor neurons that are already degenerated. This assumption has major implications for future therapeutic studies in infantile SMA. Hence, non-targeted therapeutics, which can prevent neurodegeneration, or neuron or muscle replacement by pluripotent cells are other therapeutic approaches (Nicole *et al.*, 2002). It can be expected that many studies on protein expression, interactions and therapeutic effects in animals are required before a causal treatment of motor neuron degeneration is on the horizon.

Introduction

Guam, the southernmost of the Marianas, an archipelago consisting of a chain of 15 islands, is the largest island in the western Pacific. The Marianas are part of Micronesia, a group of Pacific islands that, in addition to the Marianas, consists of the Carolines, the Marshalls, and the Gilberts. Guam is a relatively small island measuring approximately 20 miles long and from 4 to 9 miles wide (total area, 212 square miles). Located at 13 degrees north of the equator, Guam is approximately 3500 miles west of Hawaii, 1500 miles south of Tokyo and 1500 east of Manila. Guam was obtained by the United States as a territorial possession in 1898, as part of the settlement of the Spanish–American War. In the early portion of the twentieth century, Guam served as valuable stopping off place for coal-burning steamships needing to take on fresh water and other vital supplies during their long ocean-going voyages. From a military perspective, Guam's strategic central location in the western Pacific was also important and the United States Navy administered the island from 1898 until 1950 (with the exception of the Japanese occupation during World War II). In 1950, the Organic Act of Guam was passed by the US Congress and gave the inhabitants of Guam United States citizenship. This law also gave the inhabitants of Guam the right to elect a local governor and island legislature, and to send a non-voting representative to the US Congress. The people of Guam vote in American presidency elections, serve in the US military and pay Federal taxes (collected federal tax revenues remain on the island for local use).

In 2000, the population of Guam was 154 805, of which 57 297 (37%) identified themselves as Chamorros, 40 729 (26.3%) as Filipinos, 10 592 (%) as Caucasians (mostly migrants from the mainland USA) and 11 094 (7.2%) as other Micronesians. The Chamorros are an indigenous

population who have continuously inhabited Guam since approximately 1500 BC, when they are believed to have originated from the Malay Archipelago. In 1521, the Portuguese explorer Ferdinand Magellan first encountered the Chamorros of Guam when some of his crew landed near the southern village of Umatac. Magellan and his crew were in the process of circumnavigating the world and this apparently represents the first encounter of the inhabitants of Micronesia with western Europeans. Magellan's crew stopped briefly on Guam to take on supplies after their long sojourn across the Pacific. Following leaving Guam, Magellan took his fleet to the Philippines, where he was killed in a violent dispute with local natives.

The presence of a high incidence focus of neurodegenerative disease on Guam was first brought to medical attention in 1945 by Dr. Harry M. Zimmerman, a pathologist who was assigned to Guam by the United States Navy. On December 8, 1941, the day after the Japanese attack on Pearl Harbor, Japanese forces also occupied Guam. For most of World War II, the Japanese military held Guam in a rather brutal occupation. However, in the summer of 1944, United States military forces retook the island from the Japanese. Owing to the island's relatively large size and strategic position, Guam served as a major staging area and supply site for bombing attacks of the major cities of Japan.

In the final year of World War II, large numbers of military personnel to support these operations were assigned to Guam, including Dr. Zimmerman. During his stay on Guam, Zimmerman identified a number of cases of amyotrophic lateral sclerosis among the native population being cared for in the local hospital, summarizing his findings in a report to his naval supervisors in Washington, DC, including the following: "During the past few months there were admitted to the medical wards of the Civilian Hospital 7 or 8 patients with a full-blown clinical picture of amyotrophic lateral sclerosis. This was surprising in view

of the infrequency with which this neurologic disorder is encountered in the States. Two of the patients died during the month of May and the diagnosis was confirmed at autopsy. It is now planned to investigate the hereditary background of all these patients in an effort to throw some light on the factors concerned in the etiology of obscure malady." (Zimmerman, 1945)

Following the end of the war, Zimmerman's message was noted and a group of clinicians and epidemiologists were sent to Guam to investigate the situation further. These investigators confirmed Dr. Zimmerman's observations of a high prevalence of cases of amyotrophic lateral sclerosis among the native Chamorro population (Koerner, 1952; Arnold *et al.*, 1953). Moreover, in performing door-to-door surveys of neurologic disease on the island a second form of neurodegenerative disease was noted to be highly prevalent among the natives, characterized by parkinsonism with accompanying severe dementia. This other disorder was subsequently called parkinsonism–dementia complex of Guam. Remarkably, within this relatively small population, living in the middle of the Western Pacific, large numbers of natives showed clinical manifestations consisting of the key features of the three major age-related neurodegenerative disorders, namely, Parkinson's disease, Alzheimer's disease and amyotrophic lateral sclerosis (ALS). Although progress has been made in characterizing and understanding the focus, the reasons for this unique phenomenon have baffled numerous investigators for over 50 years and Guam remains a rich, yet perplexing opportunity to explore basic etiologic and pathogenetic mechanisms for neurodegeneration, as seen elsewhere in the world.

Clinical features

Amyotrophic lateral sclerosis of Guam (or the Marianas form of ALS)

Experts on the clinical features of ALS have repeatedly indicated that the disease, as it is seen in the inhabitants of Guam, is virtually indistinguishable from the sporadic form of the disease, as encountered elsewhere in the world (Kurland & Mulder, 1954; Kurland *et al.*, 1956). On Guam, the disease typically begins in an insidious fashion with complaints of weakness, clumsiness and/or an unexplained weight loss. Early clinical signs may include muscle weakness, or atrophy accompanied by prominent muscular fasciculations and hyperreflexia. The disease inexorably progresses and within approximately a year prominent muscular atrophy, weakness and a flaccid paralysis are notable. In approximately 10–15% of cases,

spasticity, in the absence of identifiable muscular wasting, is noted early in the course of the illness. In later stages, prominent dysphagia and dysarthria are seen as the level of paralysis proceeds in a classic ascending fashion. As will be discussed below, despite the fact that such patients show a rather widespread and extensive distribution of neurofibrillary tangle (NFT) formation, dementia has been noted clinically in only about 10% of ALS cases seen on Guam. Death is typically the result of aspiration and/or hypostatic pneumonia. Affected individuals generally survive for approximately 2–4 years following initial diagnosis. As with the sporadic disease seen elsewhere in the world, occasional patients are encountered with more rapid progression of the illness while others have been followed with unusually prolonged periods of survival (Uebayashi, 1984; Rogers-Johnson *et al.*, 1986). Those patients with prolonged survival will typically progress in a slower fashion and their disease progression may actually plateau over a period of many years without further deterioration in their neurologic deficits. Indeed, rare individuals with the Guamanian form of ALS, verified neuropathologically at autopsy, have been followed clinically for over 15 years.

Parkinsonism–dementia complex of Guam

Parkinsonism–dementia complex of Guam was first described clinically by Kurland and Mulder and was subsequently defined as a clinicopathologic entity in the seminal papers by Hirano and colleagues (Hirano *et al.*, 1961a, b). Apparently, an earlier account of the disorder had been published in 1936 (Yase *et al.*, 1978). The major features of the disease combine parkinsonism with severe progressive loss of cognitive function. Parkinsonian features include rigidity, bradykinesia and gait disturbance. While a 4–7 Hz pill-rolling at rest "parkinsonian" tremor of the hands may be noted in some patients, it is rarely incapacitating or as prominent a feature as occurs in idiopathic Parkinson's disease. Some patients show an impairment of ocular motility which is reminiscent of patients with progressive supranuclear palsy (Lepore *et al.*, 1988). As the disease progresses, the bradykinesia and rigidity increase in severity and become a major cause of disability.

The dementia accompanying the disorder includes severe memory impairment, disorientation and difficulty with reasoning and simple calculations. In about 30% of cases, the dementia precedes the parkinsonian features which are then encountered somewhat later in the course of the disease (Elizan *et al.*, 1966). Severe personality changes, in the form of agitation, apathy, irritability and occasionally prominent aggressiveness, may be encountered in the illness and are noted somewhere in the disease course in

approximately one third of cases. It is an unremittingly progressive and invariably fatal disorder and typically leads to death within 4–6 years after the initial diagnosis. Although initial therapy with levodopa may produce some modest improvement in the parkinsonian features (Schnur *et al.*, 1971), the Guam patients soon become refractory to its effects.

Marianas dementia

More recent door-to-door surveys of neurologic disease on Guam have identified Chamorro patients suffering from dementia, in the absence of overt accompanying signs of amyotrophy or extrapyramidal features. Such individuals have been mostly women who live in the southern villages of the island and some have shown onset of symptoms in their 60s. A small number of these patients have now been followed longitudinally. Some have gone on to develop parkinsonian features indicative of parkinsonism–dementia complex of Guam. This is not surprising since many years ago Elizan and coworkers noted that 30% of parkinsonism dementia complex present with dementia (Elizan *et al.*, 1966). However, others have shown a course with progressive cognitive loss in the absence of any superimposed parkinsonian signs or motor weakness. We have tentatively referred to this entity as “Marianas dementia,” pending more detailed clinical, neuropsychological and neuropathological characterization. A limited number of autopsies have been performed on such patients and neuropathologic examination and some have revealed the typical changes associated with ALS/parkinsonism–dementia complex (Perl *et al.*, 1994; Galasko *et al.*, 2002). Others have shown changes of Alzheimer’s disease. The cases with ALS/parkinsonism–dementia complex changes suggest that the outbreak of neurodegenerative disease on Guam may also have a form featuring an onset and clinical course consisting of a purely progressive dementing syndrome, in the absence of amyotrophy and/or parkinsonism. This may thus represent an additional clinical profile for this disorder.

Neuropathologic features of ALS/parkinsonism–dementia complex

Grossly visible features

Almost invariably, brain specimens derived from patients with either ALS or parkinsonism–dementia complex show some degree (usually prominent) of generalized cerebral atrophy accompanied by severely dilated lateral ventricles.

The brain weights of severely affected end-stage cases are frequently less than 1000 g and brains that weigh less than 900 g have been observed. In patients with parkinsonism–dementia complex the pigmented nuclei of the brainstem, the substantia nigra and locus coeruleus, are notably pale upon gross inspection. Patients with ALS often show a subtle discoloration of the lateral columns of the spinal cord that is visible with the naked eye. Atrophy of the ventral spinal roots (particularly when compared to the dorsal roots) is also easily recognized.

Microscopic features

Neurofibrillary tangles

The microscopic hallmark of both the Guamanian form of ALS and of parkinsonism–dementia complex is the presence of severe and widespread NFT formation. It was Nathan Malamud who first noted their presence in ALS cases from Guam (Malamud *et al.*, 1961). They were further characterized in the seminal papers of Hirano and colleagues (Malamud *et al.*, 1961; Hirano & Zimmerman, 1962; Hirano *et al.*, 1967a). Severe NFT involvement is typically seen in the hippocampus, entorhinal cortex, amygdala and neocortex. In some cases the CA1 region of the hippocampus can show virtually complete involvement of every pyramidal neuron by NFTs. Such cases are generally accompanied by extensive neuronal loss in the hippocampus and the appearance of many extracellular “ghost” tangles with a prominent reactive glial response.

Curiously, patients with Guamanian ALS may show rather extensive hippocampal NFT formation at autopsy, yet during life had been considered to possess intact cognitive function. Clearly, in the later stages of ALS patients may have severe dysphonia, bordering on aphonia, and this inability to communicate may prevent proper assessment of cognitive function. Nevertheless, such patients appear, within their obvious physical limitations, to be able to follow and carry out commands. Such observations appear to suggest that severe involvement of the CA1 of the hippocampus by NFTs may not be associated with severe cognitive losses, particularly involving recent memory processing, as has been assumed to be operative in cases of Alzheimer’s disease.

Patients demonstrating prominent extrapyramidal features show extensive NFT formation in brainstem regions, including the periaqueductal gray matter, substantia nigra and locus coeruleus. In such regions the NFTs have a globoid appearance reflecting the rounded shape of the soma, as opposed to the flame-shaped configuration seen in pyramidal neurons with NFTs. Cases with particularly

severe NFT formation may display NFTs in the dentate nucleus of the cerebellum, inferior olivary nuclei and anterior horn cells.

Based on immunohistochemical and electron microscopic studies, the NFTs of patients with ALS/parkinsonism–dementia complex are virtually identical to those encountered in cases of Alzheimer's disease seen elsewhere in the world (Hirano *et al.*, 1968; Hirano, 1973; Shankar *et al.*, 1989). Ultrastructural studies have shown that while the NFTs of the Guam cases contain paired-helical filaments, they also commonly show admixed additional straight filaments. The NFTs of the Guam cases react with antibodies directed against abnormally phosphorylated tau protein (Buée-Scherrer *et al.*, 1995a; Buée-Scherrer *et al.*, 1995b), apolipoprotein E (Buée *et al.*, 1996), lactotransferrin (Leveugle *et al.*, 1994), beta-amyloid peptide (Ito *et al.*, 1991) and ubiquitin, all of which parallel findings seen in the NFTs of Alzheimer's disease. Buée-Scherrer and coworkers (Buée-Scherrer *et al.*, 1995a,b) have demonstrated that PHF-tau derived from cases of ALS/parkinsonism–dementia complex are abnormally phosphorylated and have biochemical and immunological properties that are virtually identical to the PHF-tau of Alzheimer's disease. The six isoform pattern of tau is formed in an identical fashion to that seen in cases of Alzheimer's disease. Recent studies have shown that PHF-tau associated with ALS/parkinsonism–dementia complex is phosphorylated at the identical amino acid residues as is Alzheimer's disease-related PHF-tau (Mawal-Dewan *et al.*, 1996).

The pattern of neocortical involvement by NFTs in cases of ALS/parkinsonism–dementia complex differs significantly from what is seen in cases of Alzheimer's disease (Hof *et al.*, 1991). In ALS/parkinsonism–dementia complex, the neocortical NFTs are most densely situated in layers II–III, when compared to the extent of involvement in layer V. This pattern of involvement differs from what is seen in cases of Alzheimer's disease, where NFT formation is more severe in the deeper layer (layer V), when compared to more superficial aspects of the cortex (layers II–III). As a general rule, parkinsonism-dementia complex cases are more severely affected by NFTs than are cases of ALS (Hof *et al.*, 1994). Both ALS and parkinsonism–dementia complex of Guam show relatively severe involvement of the primary motor cortex by NFTs, as opposed to cases of Alzheimer's disease where such involvement is not encountered (Hof & Perl, 2002). The pattern of neocortical NFT formation demonstrated in cases of ALS/parkinsonism–dementia complex is also a characteristic feature of cases of postencephalitic parkinsonism (Hof *et al.*, 1992b), post-traumatic dementia (dementia pugilistica) (Hof *et al.*,

1992a), and progressive supranuclear palsy (Hof *et al.*, 1992c). In ALS/parkinsonism–dementia complex neurons containing the calcium-binding proteins calbindin, calretinin and parvalbumin tend to be spared from involvement in NFT formation (Hof *et al.*, 1994), a finding that is identical to that seen in cases of Alzheimer's disease.

Beta amyloid accumulation in ALS/parkinsonism-dementia Complex of Guam

The classic neuropathologic descriptions of ALS and parkinsonism–dementia complex by Hirano make specific note of the lack of senile plaque formation in these cases, despite the presence of large numbers of NFTs. Subsequently, Guam cases considered to be senile plaque-free based on silver staining methods have been shown to be free of parenchymal amyloid accumulation by more sensitive immunohistochemical methods (Gentleman *et al.*, 1991). More recently, about one third of autopsied cases demonstrate some degree of parenchymal amyloid accumulation. Such cases contain amyloid deposits in the form of diffuse plaques lacking any accompanying dystrophic neuritic changes. Neuritic plaques may be encountered in some cases of ALS/parkinsonism–dementia complex of Guam, however, the density of plaques seen in such cases is typically rather small. Vascular amyloid deposition (conophilic angiopathy) is notably uncommon in Guam-derived brain specimens. When present, such vascular deposits are typically scanty and the explanation for the paucity of vascular involvement remains unclear.

Eosinophilic rod-like inclusions (Hirano bodies)

Hirano's original descriptions of the neuropathologic features of ALS/parkinsonism–dementia complex included reference to eosinophilic rod-like inclusion bodies noted in the CA1 region of the hippocampus. These prominently stained inclusions are encountered immediately adjacent to the pyramidal neurons and had not apparently been previously described. They were initially considered to be unique and specific for the Guam disease but were subsequently noted in relatively small numbers in the hippocampus of some cases of Alzheimer's disease, Pick's disease and Creutzfeldt–Jakob disease. When seen in these settings the number of such inclusions was typically much smaller than is usually encountered in the Guam cases. Rare examples of the rod-like inclusions may also be encountered in the brains of elderly non-demented controls elsewhere in the world (Gibson & Tomlinson, 1977; Hirano, 1994).

The small number of such inclusions is the likely reason that, over the decades, neuropathologists failed to

recognize them. It was only when Hirano encountered numerous eosinophilic rod-like inclusions in the specimens he examined on Guam that they were readily identified and thus characterized. Hirano later showed their unique “herring-bone” ultrastructural appearance. Immunohistochemical studies revealed that they contain actin and actin-associated proteins (Goldman, 1983; Galloway *et al.*, 1987a), tau (Galloway *et al.*, 1987b) and the middle molecular weight neurofilament protein (Schmidt *et al.*, 1989). These eosinophilic rod-like inclusions are now referred to by most neuropathologists as “Hirano bodies” in honor of his contributions in first characterizing this lesion. The Hirano body represents an example of how, through the presence of a high density of lesions, as occurs in Guam ALS/parkinsonism–dementia complex, important insights may be gained in our understanding of Alzheimer’s disease and related conditions.

Granulovacuolar degeneration

Granulovacuolar degeneration is a poorly understood alteration encountered in the hippocampus of cases of Alzheimer’s disease and the normal elderly. This lesion consists of multiple vacuoles, each with a single internal deeply basophilic granule, present within the perikaryal cytoplasm of pyramidal neurons in the boundary zone of the H1 and H2 regions of the hippocampus. In the normal elderly they are seen in relatively small numbers but when present in relatively large numbers, especially in the posterior portion of the hippocampus, they correlate highly with a diagnosis of Alzheimer’s disease (Tomlinson & Kitchener, 1972; Ball & Lo, 1977). Granulovacuolar degeneration is extremely prominent in the hippocampus of cases of ALS/parkinsonism–dementia complex. Although there are no specific quantitative data available, it is our impression that in Guam cases one sees larger numbers of involved neurons and within each involved neuron the number of vacuoles present is greater. The size of the individual granules also appears to be larger.

Lewy bodies and other alpha-synuclein immunoreactive inclusions

Those cases with prominent parkinsonian clinical manifestations may show a severe degree of cell loss in the substantia nigra and locus coeruleus with accompanying gliosis, incontinent neuromelanin pigment and phagocytosed neuromelanin granules within local macrophages. Rare remaining pigmented neurons will typically contain globoid-shaped NFTs. In end-stage cases the extent of nigral degeneration can be so complete that it may be difficult to identify any remaining intact pigmented neurons. Lewy bodies are rarely encountered in cases

of parkinsonism-dementia complex. A large retrospective study of Guam cases reported that approximately 10% showed evidence of Lewy bodies in either the substantia nigra or the locus coeruleus (Rogers-Johnson *et al.*, 1986). Our experience has been quite similar. Whenever nigral or locus coeruleus Lewy bodies are identified in the Guam cases they are usually few in number and other adjacent intact pigmented neurons will show globoid tangles. The Lewy bodies in Guam cases found in these locations react immunohistochemically to ubiquitin and α -synuclein. It is of interest that, despite autopsy examination of the majority of patients from Guam who had suffered from parkinsonian symptoms over a period of over 40 years, examples of Lewy body Parkinson’s disease in Chamorros have been extremely rare. Indeed, the authors are aware of only a single such case being documented at autopsy in a Chamorro native from Guam. The explanation for this absence of what is a relatively common disorder, elsewhere in the world, remains unknown.

We and others have reported evidence of α -synuclein-immunoreactive inclusion bodies occurring in the amygdala of cases of ALS/parkinsonism–dementia complex (Yamazaki *et al.*, 2000; Forman *et al.*, 2002). In our recent report on the findings in a series of 30 Chamorro brain specimens (Forman *et al.*, 2002), 37% of patients with parkinsonism–dementia complex showed evidence of α -synuclein pathology but this was not detected in any Chamorros with ALS or Alzheimer’s disease. Most amygdala α -synuclein aggregates occurred within neurons that also were harboring a NFT. This suggested to us that there was a possible interaction between the two proteins. Other than the presence of parkinsonism–dementia complex, there was no particular clinical manifestation that distinguished the cases with α -synuclein pathology.

Other microscopic features

Neuropil threads, a prominent feature of AD, are rarely encountered in cases of ALS/parkinsonism–dementia complex (Wakayama *et al.*, 1993). On the other hand, similar thread-like structures have been reported in the white matter of the spinal cord, especially in patients who exhibit more prominent amyotrophic features (Umahara *et al.*, 1994).

Using antibodies raised against the protein core of heparin sulfate proteoglycans, severe abnormalities of the cerebral microvasculature were noted in brain specimens of parkinsonism–dementia complex patients (Buée *et al.*, 1994). The pattern of distribution of these vascular lesions suggests a spatial association between the microvascular abnormalities and a high density of NFT formation. Similar lesions have been seen in cases of Alzheimer’s disease

where they were thought to be related to local vascular and/or parenchymal beta-amyloid deposition. The Guam cases, with their absence of amyloid deposition, provide an opportunity to demonstrate that amyloid deposition is not required for the formation of these vascular abnormalities.

In cases of Guamanian ALS there is prominent loss of anterior horn cells, similar to that seen in the disease elsewhere in the world. Surviving anterior horn cells may show a shrunken soma with a pyknotic nucleus, or else the cell may be swollen with perikaryal accumulations of phosphorylated neurofilaments. As in classic ALS, intervening anterior horn cells may possess a normal histologic appearance. In some Guam patients with ALS, the remaining anterior horn cells may display small eosinophilic inclusions in their cytoplasm. These were first described by Bunina (1962) and are frequently referred to as "Bunina bodies." Similar to cases of sporadic ALS seen elsewhere in the world (Mourelatos *et al.*, 1990), Guam ALS cases show fragmentation of the Golgi apparatus (Mourelatos *et al.*, 1994). Upper motor neuron involvement is virtually always present in the Guam cases and results in prominent myelin loss in both the lateral and anterior corticospinal tracts. In contrast to some cases of familial ALS (Hirano *et al.*, 1967b), the posterior columns of the cases of Guam ALS remain intact.

Neuropathologic studies of Chamorros of Guam with intact neurologic function

In 1979, Anderson and co-workers (1979) reported on the extent and distribution of NFT formation encountered in the brains of Chamorros living on Guam who, during life, had shown no evidence of neurological disease. Specifically, this autopsy-based study was conducted on individuals who died between 1968 and 1974 and, based on their clinical histories and autopsy reports, were considered to be free of evidence of dementia, parkinsonism or amyotrophy. Their study showed that a remarkably high percentage of relatively young Chamorro "controls" living on Guam displayed evidence of prominent NFT formation. The authors noted that when extensive NFT occurred, the overall brain distribution approached that described in full-blown diagnosed cases of ALS/parkinsonism–dementia complex. Although not overtly stated in their report, these findings suggest that Chamorros subjects who demonstrated a prominent degree of NFT formation represented unrecognized preclinical cases of ALS/parkinsonism–dementia complex. The implication was that had the subjects identified with these neuropathologic features survived to a more advanced age they would have accumulated a sufficient extent of pathologic damage to attract clinical attention and ultimately a specific neurologic diagnosis.

We had an opportunity to re-examine the microscopic slides used for the Anderson *et al.* study and to compare the extent of NFT formation seen in those specimens to that obtained from a new series of Chamorros without a diagnosis of neurologic disease who had died between 1988 and 1996 (Perl *et al.*, 2003). Both sets of cases were compared to a group of brain specimens derived from age-matched subjects, free of neurologic dysfunction in life, who were autopsied at the Mount Sinai Hospital in New York, thus representing examples of normal aging in a non-Guamanian setting. We were particularly interested to see if neurologically intact Chamorros living on Guam continue to demonstrate prominent NFT formation. Furthermore, we were interested in whether the age at which such neurodegenerative changes became manifested would increase in parallel to that seen in newly diagnosed cases of ALS and PDC.

We found that a sizeable proportion of neurologically intact Guamanian Chamorros in the general population continue to show evidence of extensive NFT formation. There was not an appreciable change in the tendency of the Guamanian Chamorro to develop severe entorhinal and hippocampal NFTs, although the data suggested that it is less frequently seen among those under age 50. Of Guamanian Chamorros between the ages 50 and 64 years, 67% displayed greater than 6 NFTs/mm² in the CA1 region of the hippocampus, a severe rating using the CERAD neuropathology protocol for Alzheimer's disease (Mirra *et al.*, 1991), and 22% had greater than 40 NFTs/mm². Although these patients had not received formal neuropsychological evaluations during life, these findings raise important questions regarding the clinical significance of hippocampal involvement by NFTs, in general.

Studies of this type indicate that the Chamorro population of Guam continues to demonstrate an extent of NFT formation that is unprecedented and far in excess of what has been reported in populations elsewhere in the world. Further, it is clear that whatever is responsible for the remarkable outbreak of neurodegenerative disease on Guam is still demonstrating its effects on the local native population. These findings are well beyond those encountered in association with normal aging and the pattern of NFT formation in the neocortex, substantia nigra and locus coeruleus was not consistent with this interpretation. This was further reinforced by the lack of accompanying beta-amyloid accumulation in the form of senile plaques and vascular amyloid deposition. We believe that the Guam natives we have identified with evidence of prominent NFT formation do represent early stages of ALS/parkinsonism–dementia complex in individuals who have yet to develop a burden of neurodegenerative lesions sufficient to manifest overt neurologic symptomatology, a conclusion that was

shared by Anderson and his coworkers in their 1979 report (Anderson *et al.*, 1979).

Like Alzheimer's disease, ALS/parkinsonism–dementia complex develops slowly and it is to be expected that it would take many years for a sufficient degree of neuropathologic damage to accumulate before there is a sufficient functional impairment for a clinical diagnosis to be entertained. The non-overtly impaired individuals identified by us and by Anderson in all likelihood represent preclinical ALS/parkinsonism–dementia complex patients who have died prematurely of other causes. Had they survived longer we believe these individuals would have gone on to show clinically recognizable features of ALS/parkinsonism–dementia complex. On the other hand, whether they were truly asymptomatic, as Anderson and coworkers suggested, is more difficult to speculate upon. It is more likely that had the individuals harboring these examples of rather severe NFT formation in their brains been carefully evaluated, subtle (and perhaps, not so subtle) functional deficits would have been detected on neuropsychological testing. Nevertheless, it is clear that, despite the extent of pathology documented at autopsy, the clinicians responsible for their medical care and their families were not sufficiently aware of these deficits to seek further neurologic evaluation.

Epidemiology

Over the years, many epidemiologic studies of the extent and distribution of neurologic disease among the inhabitants of Guam and its neighboring islands have been carried out. These studies were initiated in the 1950s and have continued, of and on, until the present day. Earlier studies established that the incidence of ALS on Guam was 50 to 100 times greater than was seen in the continental US and in certain of the small villages in the southern part of Guam, considerably higher rates were noted. A high incidence of the disease was also seen in the next nearest island, Rota, also populated by Chamorros. For the period 1947–1953, the average annual incidence rate of ALS for Chamorros living on Guam was twice as high for men when compared to women (85 and 40 per 100 000, respectively) with a mean age of onset of 44 years in both sexes. ALS accounted for approximately 10% of all deaths on the island, a figure that was 50 times greater than reported for the continental USA. Subsequent studies comparing rates over the period of 1945–1972 indicated a steady decline in the age-adjusted incidence rate for ALS on Guam. These data included rates for men of 67/100 000 population in 1950–1954 to 21/100 000 in 1970–1972 and of 43 and 12/100 000 for women. Finally, in 1980–1982, Garrutto and coworkers

(1985) found the age-adjusted incidence rates of ALS on Guam to be less than 5/100 000 for both men and women.

In 1961, with the identification of parkinsonism–dementia complex of Guam as a distinct clinicopathologic entity, epidemiologic studies were also initiated for this condition. In 1962, Lessel and colleagues (1962) reported a prevalence for parkinsonism–dementia complex of 118/100 000 with a mean age of onset of 50 years and a male/female ratio of 2.5:1. The average annual mortality rate for the condition was 28/100 000 with a median survival of 3.5 years. Based on door-to-door surveys Reed *et al.* (1966) reported the average annual incidence per 100 000 population of parkinsonism–dementia complex to be 33 for men and 6 for women. Again, in 1985, Garrutto *et al.* reported a significant decline in age-adjusted incidence rates for men and women with parkinsonism–dementia complex. Based on these reports it was widely reported that the neurodegenerative diseases on Guam were declining at a rate that suggested that before long the unique opportunity to identify important etiologic clues would be lost which might represent avenues for understanding comparable diseases elsewhere in the world (Stone, 1993). In 1990, with funding from the National Institute on Aging, the Micronesian Health Study Registry, initially directed by Dr. W. C. Wiederholt and now led by Dr. Douglas Galasko, was begun. Data from this registry indicates that parkinsonism–dementia complex is not disappearing and during 1980–1989 there was an average annual incidence of about 10 cases/100 000 population. Of interest is that the age of onset of this disorder had increased to 68.1 years (Wiederholt, 1999; Galasko *et al.*, 2000, 2002).

Other foci of ALS/parkinsonism–dementia complex

In addition to the focus of ALS/parkinsonism–dementia complex identified and extensively studied on Guam, two similar foci of endemic neurodegenerative disease have been reported, namely in the Kii Peninsula of Japan and among the Auyu and Jakai people of the Irian Jaya region of southwestern New Guinea. Kinnosuke Miura, a pupil of Charcot, published the first clinical description of a case of ALS in Japan (Miura, 1902). He subsequently claimed that ALS was more common among the Japanese than was seen in Europe and noted the unusually high incidence of the disease in the Kii Peninsula, a remote area on the southern coast of the Japanese island of Honshu (Miura, 1911). Subsequent studies indicated that the high prevalence of ALS was mostly confined to two isolated districts in the Kii Peninsula, Kozagawa and Hobara (Shiraki & Yase, 1975; Shiraki & Yase, 1991). Surveys indicated the annual incidence of ALS was 15 cases per 100 000 population in Kozagawa and 55 cases per 100 000 in Hobara.

Neuropathologic studies of ALS cases from the Kii Peninsula revealed a pattern of neuropathologic changes that is virtually identical to that seen on Guam (Shiraki & Yase, 1975, 1991). In cases from the Japanese foci, widespread NFT formation in a pattern that parallels closely what is seen in the Guam cases has been documented. Over the past 30 years the number of cases of ALS encountered in the Kii Peninsula has diminished dramatically, similar to what has been seen on Guam. Until recently cases of parkinsonism–dementia complex from the Kii Peninsula had not been reported. However, Kuzuhara and colleagues (Kokubo *et al.*, 2000; Kuzuhara *et al.*, 2001; Itoh *et al.*, 2003) have now described such cases both clinically and at autopsy. These cases have shown neuropathologic features that are virtually identical to those encountered on Guam.

The focus in the Irian Jaya region of southwestern New Guinea was first identified by Gajdusek, who described a high incidence of ALS based on brief clinical observations while passing through this extremely remote and primitive region (Gajdusek, 1963). It should be noted that this was completely separate and not related to the highland region of New Guinea where he had studied kuru among the Fore natives (Gajdusek, 1977). Gajdusek subsequently returned to the area where he had noted the ALS cases and surveyed the population more thoroughly for all forms of neurologic disease (Gajdusek & Salazar, 1980). They reported an average annual incidence of ALS for the period 1974–1980 of 147 per 1 000 000 (almost 150 times greater than is seen in the continental USA). In the same population the incidence of parkinsonism, both with and without dementia, was 79 per 100 000 population. The mean age of onset in the population for ALS and parkinsonism was 33 and 43 years, respectively, both substantially younger than was seen on Guam, even in the immediate post-World War II era. Unfortunately, although the clinical features of these patients appear quite similar to the disorder seen on Guam, no neuropathologic studies have ever been carried out on the cases from this extremely remote region.

Considerations of etiology

Nature vs. nurture

Dating from the earliest observations of Dr. Zimmerman, the inordinately high prevalence of neurodegenerative diseases among the Chamorro population of Guam has offered the promise of providing insights into etiologic factors responsible for the three analogous disorders seen elsewhere in the world, namely, ALS, Parkinson's disease and

Alzheimer's disease. Zimmerman considered Guam to be an example of an island-bound genetic isolate and naturally assumed the focus to be hereditary in nature. However, a number of studies have shown that, if genetic factors are present, and they most certainly are, they are clearly not etiologic in nature and likely serve only as modifying factors related to relative susceptibility to an, as yet, unidentified environmental etiologic agent (or agents).

One of the major pieces of evidence implicating environmental factors in the etiology of the neurodegenerative disorders encountered on Guam has been the appearance of significant numbers of cases of ALS and parkinsonism–dementia complex among Filipino migrants to Guam who have had long-term residence on the island. Since the 1950s to the present time, there has been a sizable migration of individuals born and raised in the Philippines who have moved and settled permanently on Guam. These migrants do not originate from any one village or region in the Philippines and represent a rather broad spectrum of locations within this large and rather diverse nation. These immigrants have almost entirely been male and now make up a community of approximately 40 000 stable residents on Guam. Many of the Filipino migrants have married native Chamorro women and have adopted, more or less, a Guamanian way of life. However, most Filipino migrants do not eat cycad-based products and they do not eat flying foxes (see discussion of environmental agents, below). Among this Filipino migrant community, many cases of ALS have been documented. Reed and Brody first noted such cases (Reed & Brody, 1975) and Garruto *et al.* (1981) further documented nine cases of ALS and two with parkinsonism–dementia complex. Except for three cases of ALS that had developed within 3 years of their arrival on Guam, the onset of disease was at least 13 years after moving to the island. A small number of autopsies have been performed on the Filipino migrant ALS cases and NFTs have been documented in the brain specimens of half of these cases. The extent of NFT involvement was not as dramatic and widespread as is typically encountered in the native Chamorro cases, but this finding clearly separates them from sporadic ALS, as seen elsewhere in the world, since NFTs are not a recognized neuropathologic feature of ALS, especially among relatively young patients. We wonder if, in the Filipino migrant ALS cases reported as being without NFTs, the search for such lesions had been sufficiently thorough to consider them to be truly negative.

Additional cases of ALS continue to be identified among the Filipino migrant community living on Guam. Neuropathologic examination of these cases show motor neuron degeneration accompanied by mild to moderate involvement by NFTs, fitting the distribution pattern of

Guam neurodegeneration. This indicates that they are not merely incidental cases of sporadic ALS among this population but an extension of the outbreak of neurodegeneration among inhabitants of Guam. Importantly, encountering cases of parkinsonism–dementia complex among this Filipino migrant population on Guam further reinforces the concept that long-term residence on the island underlies the cause of the outbreak of neurodegenerative disease. ALS is a disease that has been seen throughout the world, yet parkinsonism–dementia complex is a disorder that has not been encountered outside the three foci of the western Pacific discussed above.

Garruto *et al.* (1981) reported clinical evaluation of a single case of parkinsonism–dementia complex in a Filipino migrant to Guam, however, no autopsy was performed on this individual. We have had the opportunity to examine the brains of two patients with parkinsonism accompanied by dementia occurring in Filipino migrants following more than 25 years of residence on Guam (Purohit *et al.*, 1992). Both cases showed the characteristic neuropathologic features of parkinsonism–dementia complex and were virtually identical to what we commonly encounter in the native Chamorro cases. In both, there was widespread, rather severe NFT formation in the hippocampus, entorhinal cortex and neocortex, in the absence of parenchymal amyloid deposition. The NFTs were predominant in the superficial cortical layers. There was severe loss of pigmented neurons in the substantia nigra and locus coeruleus with globoid forms of NFTs being seen in several remaining neurons in these nuclei. Lewy bodies were not encountered in either the pigmented neurons or the neocortex. An additional autopsy-confirmed case of parkinsonism–dementia complex in a Filipino migrant to Guam was reported by Chen *et al.* (1982). These three autopsy-proven cases represent important evidence that ALS/parkinsonism–dementia complex is not a disorder that is unique to the Chamorro population, but may also be seen in Filipinos who have lived on Guam for many years. Unless there is a hitherto unrecognized focus of ALS/parkinsonism–dementia complex in the Philippine islands, then these findings strongly support the concept that long-term exposure to a putative environmental agent present on Guam is responsible for the epidemic.

Migration studies of the Chamorros of Guam

If there is a putative environmental agent responsible for ALS/parkinsonism–dementia complex of Guam then there must be a considerable period of latency between initial exposure to such an agent and the eventual onset of neurodegenerative disease. The primary evidence for this has

been studies of the large number of Chamorros of Guam who have migrated off the island. In 1950, the inhabitants of Guam were finally granted full American citizenship and from then on were allowed to travel freely and resettle anywhere they wished in the continental United States. This newly gained freedom prompted an extensive outmigration of Guamanian Chamorros to selected locations along the west coast, such as Chula Vista, San Jose and Oakland, California as well as Bremerton, Washington. In 1957, a survey of 165 adult Guamanians who had migrated to California revealed two patients with ALS. Although the sample was small, this was equivalent to a rate for the disease that was equal to what was then present on Guam (Torres *et al.*, 1957). As part of the survey activities, the investigators also learned of five additional cases of ALS among this migrant population who had died prior to the initiation of the survey. A follow-up study in 1966–1967 by Eldridge *et al.* (1969) found that of 321 Guamanians over age 40 who were then living in California, two were suffering from ALS and another two had parkinsonism–dementia complex.

Garruto *et al.* (1980) subsequently attempted to identify all Guamanian Chamorros who had migrated from the island and eventually developed ALS. They found a total of 28 cases (some of whom were included in the two prior published surveys). Of these, 21 cases had developed ALS while living in the continental United States, three had their onset in other countries (Japan, Germany and Korea) and four became ill following returning to Guam but only after long-term residence on the United States mainland. Ten of these cases had undergone postmortem studies and these showed evidence of widespread NFT formation, confirming these to be examples of the Guamanian form of the disease. In Garruto's migration study, the mean age at migration from Guam was 29.4 years (range, 18 to 63 years) with an average number of years living off Guam prior to the onset of disease of 13.6 years (range, 1 to 34 years). The mean age of onset of ALS was 48.8 years which, at that time, was 4 years younger than was being seen among Chamorros who had never left Guam. Some of these cases had developed more than 20 years after migrating from Guam.

Using the above data, Garruto and Yanigihara (1991) estimated that ALS mortality rates for Chamorros living on Guam were three times greater than for Chamorros who had migrated to the west coast, suggesting that outmigration had significantly lowered their subsequent risk of developing the disease. Nevertheless, Chamorros living off Guam still showed a five to tenfold increased risk of developing ALS, when compared to the non-Guamanian population of the mainland United States. In addition, Guamanians migrating to the continental United States were at risk of developing parkinsonism–dementia complex, a disease

that has no direct counterpart in populations elsewhere in the world. Review of all of the migration studies suggests that the enhanced risk of developing ALS/parkinsonism–dementia complex is attained within the first 18 years of life and then may be retained for many decades and may even be life-long. Inherent in such considerations is the concept that whatever putative environmental agent is responsible for the development of ALS/parkinsonism–dementia complex is present on Guam but not available to those of Guamanian descent who live off the island. This assumption may or may not be correct. People tend to bring with them many aspects of their culture, native foods, festivals, etc. and this may represent an opportunity for exposure to potential environmental agents among an outmigrated community. The Guamanians have a strong attachment to their island culture and items such as diet have accompanied them in their travels and continue to be enjoyed whenever available. Further, with the ready availability of air travel, return trips to Guam are common among this migrant community.

Evidence that the putative etiologic agent has long existed on Guam

In the early 1960s when ALS and parkinsonism–dementia complex were first being characterized by researchers visiting the island, the Chamorros referred to the two maladies in their native Chamorro language as “lytico” and “bodig,” respectively. The term “lytico” is said to originate from the Spanish “paralytico,” referring to the progressive paralysis associated with anterior horn cell degeneration in ALS. The origin of the term “bodig” is more obscure but is loosely defined as “slow” or “lazy” and refers to the parkinsonism–dementia form of the disorder. This suggests that this society had been familiar with the disorders for many years. Furthermore, archival death certificate records had been maintained by US Navy personnel since the beginning of the twentieth century and these documents survived the extensive destruction of facilities on Guam during the hostilities of World War II. These meticulously detailed records carefully document virtually every adult death from that era and contain numerous entries with diagnoses of amyotrophic lateral sclerosis as well as other entries with “presenile degeneration of the brain and spinal cord.” Finally, folklore accounts suggest that the disease had been present on Guam from at least as early as the beginning of the nineteenth century. Based on this evidence, it is clear that whatever causes this remarkable outbreak of neurodegenerative diseases had been present on Guam for hundreds of years and preceded the arrival of the myriad aspects of Western industrialized society to the island. Accordingly, a large

number of potential etiologic agents related to the current presence of a highly technologic way of life on Guam (e.g. fast food restaurants, nuclear weapons, synthetic petrochemical toxins, etc.) can be eliminated as possible explanations for this outbreak.

Environmental agents

Infectious organisms

It was parkinsonism–dementia complex, rather than ALS, that raised concerns for a possible postinfectious etiology of the outbreak of neurodegenerative disease on Guam. Parkinsonism–dementia complex patients show many similarities with postencephalitic parkinsonism patients who survived the epidemic of encephalitis lethargica in the early part of the twentieth century. Postencephalitic parkinsonism patients displayed a latency period between the initial episode of encephalitis and the onset of parkinsonian symptoms. This latency could last as long as a decade or more (although 6 months to a year was, by far, more common) (Yahr, 1968). Patients with postencephalitic parkinsonism may show all of the signs and symptoms of idiopathic Parkinson's disease and are said to characteristically demonstrate oculogyric crises. Clinical studies of Guamanian cases of parkinsonism–dementia complex failed to demonstrate oculogyric crises (Elizan *et al.*, 1966), although the significance of this negative clinical observation remains unclear. The neuropathologic features of postencephalitic parkinsonism include several features encountered in parkinsonism–dementia complex of Guam, namely NFTs in remaining neurons of the substantia nigra, in the absence of Lewy bodies and the finding of neocortical NFTs predominating in superficial layers (layer II/III) (Hof *et al.*, 1992b).

Despite these similarities, studies of both serum and postmortem brain tissues have failed to show any consistent evidence of a preceding CNS infection. Archival death certificates through the first half of the twentieth century fail to document any major outbreaks of encephalitis in the community and interviews with knowledgeable elders in the community failed to provide anecdotal accounts of any notable episodes of encephalitis on Guam. Restricted outbreaks of Japanese B encephalitis and mumps did occur on Guam in December, 1947 and April, 1948 but subsequent interviews with patients suffering from ALS/parkinsonism–dementia complex and their families have failed to confirm a prior history of encephalitis in such cases.

Further, Guam is the southernmost of four closely situated islands which are inhabited by significant populations

(i.e. Guam, Rota, Tinian and Saipan). Ongoing traffic between these four islands has always been extensive, as they are close enough to be within direct visual sighting of each other. This proximity would provide a ready means for the sharing of any infectious disease-carrying vectors. The two neighboring islands of Guam and Rota have continued to show a high incidence of ALS/parkinsonism–dementia complex among their inhabitants. However, this is in sharp contrast to the populations living on Tinian and Saipan where such cases have never been documented. It is highly unlikely that an infectious agent could remain restricted to the two southernmost islands and yet never extend to the other two nearby islands.

The possibility that Guam ALS/parkinsonism–dementia complex represents an example of a prion-related disorder has also been considered. Gibbs and Gajdusek (1982) carried out numerous attempts to transmit neurodegenerative disease through intracerebral inoculation of Guam-derived brain tissues into non-human primates and other susceptible species. All such attempts were negative, including other efforts to recover a transmissible agent through inoculation of affected brain specimens into a variety of tissue culture systems. In the face of this extensive amount of negative evidence it is difficult to consider further a possible infectious etiology for the outbreak.

Cycad

In 1964, Dr. Marjory White first suggested the presence of a putative neurotoxin in the cycad seed of the false sago palm, *Cycas circinalis* (Whiting, 1964). Cycad trees are an important indigenous plant of Guam and its fleshy seed has served as a food source for the Chamorros. The seeds do contain a potent hepatotoxin, making them rapidly fatal unless thoroughly washed prior to eating. The seeds must be soaked in many changes of water over a period of a week or more before they may be safely eaten. The natives then dry the washed seeds and grind them into a flour which is used to prepare tortillas, porridge, doughnuts and to thicken soups. Whiting proposed that a neurotoxin might be present in the seeds and be responsible for the onset of neurodegenerative disease. This gave rise to extensive research to find experimental evidence of a neurotoxin in the plant. The results of these toxicologic studies were published in a series of six cycad conferences which were held under the auspices of the National Institutes of Health (Cycads, 1964; Whiting, 1988). The detailed reports from these conferences provide extensive documentation on numerous studies that were carried out in which a wide range of animals (including non-human primates) were

exposed to high doses of either raw cycad seeds obtained on Guam or their purified constituents.

Among the findings of these toxicologic studies was the identification of cycasin (methylmethoxymethanol β -D-glucosidase), a very potent alkylating agent which comprises 2–4%, by weight, of cycad seeds and is a potent carcinogen. Cycasin represents one of the strongest naturally occurring carcinogens and many of the cycad-exposed animals eventually developed a wide variety of cancers mostly involving the lungs, kidneys, and liver. Importantly, despite being exposed to high doses of cycad seed or its derivatives, the wide range of animals failed to show any evidence of neurotoxicity in these experiments. Based on this entirely negative evidence, support for the cycad hypothesis as the etiology of the Guam outbreak of neurodegeneration waned for many years.

However, in 1987, Spencer and colleagues reported clinical observations of extrapyramidal dysfunction and motor weakness in cynomolgus monkeys fed large oral doses of an “unusual” amino acid present in small amounts in the cycad seed, namely β -*N*-methyl-amino-L-alanine (BMAA) (Spencer *et al.*, 1987). BMAA shares chemical similarities with β -*N*-oxalylamino-L-alanine (BOAA), which had been implicated in neural lathyrism, a disease characterized by non-progressive spastic paraparesis. In this experiment, for up to 13 weeks each monkey was fed a large daily dose of BMAA by way of gastric gavage. The BMAA was chemically synthesized by a laboratory chemist and had not been derived from cycad seeds themselves. The monkeys were reported to develop muscular weakness, masked facies and a loss of aggressiveness and the authors suggested this was similar to the clinical features of ALS/parkinsonism–dementia complex in man. However, this experiment has been questioned on a number of grounds. The doses of BMAA were extremely high (100–300 mg BMAA/kg body weight/day). Duncan *et al.* reported that BMAA is present in very small concentrations in raw cycad seed (0.1% or less, by weight) and is readily removed by even brief washing (Duncan *et al.*, 1990; Duncan, 1991). Indeed, they calculated that an adult human would have to ingest approximately 7 kg of highly toxic unwashed raw seed per day to receive a dose that was comparable to that given to the exposed animals. Since the normal practice is to wash the seeds repeatedly before being safely eaten, most of the BMAA would have been readily removed. Accordingly, a comparable dose of washed cycad seeds would require ingestion of approximately 70 kg of cycad flour per day. Additional studies have questioned whether BMAA crosses the blood brain barrier (Duncan *et al.*, 1990, 1991). Duncan and colleagues (1992) also reported the presence of significant levels of zinc, a potential neurotoxin, within

samples of cycad flour provided from Chamorro sources on Guam.

Importantly, despite reporting motor weakness, evidence of actual motor neuron loss was not demonstrated in any of the BMAA-exposed monkeys. Furthermore, neither a striatal dopaminergic deficit (indicative of nigral degeneration) or denervation atrophy (suggesting anterior horn cell pathology) was documented in the exposed animals and it remains unclear why these monkeys displayed any of the reported neurologic signs. In addition, evidence of tau pathology, indicative of NFT formation was not demonstrated. Finally, the experiment, as reported, failed to compare BMAA-fed animals to controls. Spencer and colleagues (Spencer *et al.*, 1993) has subsequently written that “the changes [induced in monkeys fed synthetic BMAA] fall short of a model of the human disease.”

Nevertheless, discussion of BMAA as an etiologic factor has recently reemerged in the literature. In 2002, Cox and Sacks hypothesized that exposure of the native population to putative neurotoxins could have occurred through the local custom of consumption of flying foxes that had existed on Guam but had more recently been hunted to extinction (Cox & Sacks, 2002). The concept proposed was that flying foxes eat cycad seeds and thus could serve as a conduit for unprocessed constituents of the fruit. Banack and Cox (2003) then published data indicating a high concentration of BMAA within three dried skin specimens of Guamanian flying fox that had been preserved in a museum collection for 50 years. BMAA levels were determined by high-performance liquid chromatography (HPLC) of amino acid extracts of the rehydrated samples. Finally, this group has now indicated that cyanobacteria produce relatively small amounts of BMAA but that it is then concentrated first in the cycad tree, where the bacteria grow symbiotically in the root system and then further concentrated in flying foxes who feed on the cycad seed (Cox *et al.*, 2003). The final step would be consumption of the BMAA through the local practice of the Guam native to boil and eat flying foxes. They also report measuring a mean free BMAA level of 6 $\mu\text{g/g}$ in frontal cortex of the brains of six Chamorro patients with ALS/parkinsonism–dementia complex and a mean of 6.6 $\mu\text{g/g}$ of BMAA from 2 of 13 Canadian patients who died of Alzheimer’s disease.

It is difficult to know how to interpret these results or this hypothesis. The authors have not addressed many of the problems that have remained since Spencer and colleagues first announced their results following extensive dosing of monkeys. There is little evidence that BMAA is a neurotoxin, especially a toxin that is specific to motor neurons or neurons of the substantia nigra. Even if small amounts of this “false” amino acid can be detected in brain

tissues of affected patients or in flying foxes, this may have little to do with what causes ALS/parkinsonism–dementia complex of Guam. It certainly does not explain the well-documented examples of the disease among the Filipino migrants to Guam or the inhabitants of the Kii peninsula.

Shaw’s laboratory has recently also pursued possible cycad-related etiologic hypotheses (Khabazian *et al.*, 2002; Wilson *et al.*, 2002; Shaw & Wilson, 2003). They have identified a series of sterol β -D-glycosides from washed cycad flour with potential neurotoxic properties. Feeding male CD-1 mice washed cycad flour, this group has reported evidence of progressive motor and cognitive dysfunction accompanied by rather widespread TUNEL and caspase-3 labeling of neurons as evidence of neurodegeneration. Other studies indicated that β -sitosterol β -D-glycoside represented the most potent toxic metabolite in the flour. Their work continues in the development and characterization of what they feel is an animal model of ALS/parkinsonism–dementia.

Toxic metals

Yase first suggested that neurodegeneration seen on Guam and the Kii peninsula might be related to exposure to potentially neurotoxic metals (Yase, 1972). He noted that manganese and aluminum were present in significant amounts in the soils of Guam and the Kii peninsula. Manganese poisoning is well documented to produce a parkinsonian syndrome, however, this metal produces degeneration of the striatum with sparing of the substantia nigra and pars compacta (Olanow *et al.*, 1994). Aluminum, on the other hand, had been experimentally linked to neurofibrillary degeneration through the induction of tangle-like lesions in rabbits following direct exposure to aluminum-containing compounds (Klatzo *et al.*, 1965; Terry & Pena, 1965).

In 1980, using the techniques of electron probe microanalysis, Perl and Brody first demonstrated evidence of aluminum accumulation in the NFT-bearing neurons of Alzheimer’s disease (Perl & Brody, 1980). Using a similar microprobe approach on unstained tissue sections, Perl and colleagues then showed evidence of dramatic aluminum accumulation in the tangle bearing neurons of patients with ALS and parkinsonism–dementia complex of Guam (Perl *et al.*, 1982). Additional studies indicated that the concentration of aluminum in the tangle-bearing neurons of the Guam cases was approximately ten times greater than that of Alzheimer’s disease (Good & Perl, 1994). Although the association of aluminum and Alzheimer’s disease continues to remain controversial, the finding of excess aluminum in tangles encountered in the Guam cases has now been confirmed in a number of different

laboratories using five different physical methods (Garruto *et al.*, 1984; Linton *et al.*, 1987; Piccardo *et al.*, 1988; Good & Perl, 1993).

The environmental source of these dramatic intraneuronal accumulations of aluminum remains unclear. It had been hypothesized that a deficiency in environmental sources of calcium and magnesium, physiologically essential ionic constituents, could lead to increased aluminum uptake as an alternative dietary source of cations. However, search for evidence of calcium deficiency among Guamanians did not reveal consistent alterations (Steele *et al.*, 1990; Ashkog *et al.*, 1994) and other alternative explanations must be sought. Guam is partially a volcanic island with an aluminum-rich bauxite soil. One study indicates that the soils of Guam contain 42 times the amount of elutable aluminum when compared to two other bauxite islands, namely, Jamaica and Palau (McLachlan *et al.*, 1989). This suggested that Guam soil may contain a great deal more bioavailable aluminum when compared to other volcanic islands. However, a recent evaluation of Guam soil has failed to confirm these soil findings (Miller & Sanzalone, 2003).

Subsequent microprobe studies using laser microprobe mass analysis demonstrated that the NFTs of Guam cases contained accumulations of iron, as well as aluminum, a finding that parallels that obtained using this technique with cases of Alzheimer's disease. Iron and aluminum excess has also been detected in the neuromelanin granules and Lewy bodies of cases of idiopathic Parkinson's disease (Hirsch *et al.*, 1991; Good *et al.*, 1992). Iron, through the Fenton reaction, is a powerful prooxidant and is capable of catalyzing the production of the highly reactive hydroxyl radical from hydrogen peroxide, a byproduct of normal dopamine metabolism. We have suggested (Olanow & Perl, 1994) that the combination of iron and aluminum may place a neuron in a state of oxidative stress because of aluminum's apparent ability to increase iron's capacity to induce lipid peroxidation (Gutteridge *et al.*, 1985). Recent findings of mutations in the Cu/Zn superoxide dismutase gene in cases of familial ALS (Rosen *et al.*, 1993) as well as the production of transgenic models of motor neuron disease through the introduction of such mutations may have relevance to Guam neurodegeneration (Gurney *et al.*, 1994). Cu/Zn superoxide dismutase plays a role in the balancing of the production of oxygen radicals through energy utilization and the body's natural defenses against the potentially damaging effects of such radical production. In some way that is still not yet understood, altering this critical balance may induce progressive neuronal degeneration in the form of similar neurodegenerative disorders. Whether the striking aluminum and iron accumu-

lations identified in target neurons for neurodegeneration in cases of ALS/parkinsonism–dementia complex of Guam are truly etiologic in nature, remains unknown. The source of these deposits and the mechanism by which they occur also remains to be elucidated.

General comments

It is a mistake to dismiss ALS/parkinsonism–dementia complex of Guam as a unique and completely separate disorder that is without implications for relevant diseases seen elsewhere in the world. Guam represents a rich laboratory in which to explore the dual interactions between environmental factors and genetic factors in the induction of the cardinal features of the age-related neurodegenerative disorders. On Guam, the strongest factor appears to be environmental in nature. Through the study of genetically based familial outbreaks of disease, critical insights into underlying hereditary factors can be gained. However, in a unique geographic isolate, such as Guam, environmentally based aspects may more easily be addressed. Despite extensive research over several decades, the mystery of the etiology of the remarkable concentration of neurodegeneration on the island of Guam remains unsolved. Despite this, Guam still remains the richest resource yet to be identified in which to unravel those critical environmental factors of importance to an understanding of both the disorders seen on Guam but also the analogous disorders encountered throughout the world.

Other neurodegenerative diseases

Huntington's disease

Christoph M. Kosinski¹ and Bernhard Landwehrmeyer²

¹Department of Neurology, University Hospital Aachen, Germany

²Department of Neurology, University of Ulm, Germany

Introduction

The description by George Huntington in 1872 of the disease that has subsequently borne his name is remarkable for its clarity and comprehensiveness (Huntington, 1872). It was not the first description of the disorder (see, for instance, Charles Oscar Waters, 1842, and Johan Christian Lund, 1860) (Waters, 1842; Lund, 1860), but it stands out as the first full delineation of the condition as a specific disease entity, quite separate from other forms of chorea. Huntington's paper was given at Middleport, Ohio, and published later in the Philadelphia journal, *The Medical and Surgical Reporter*. One can do no better than quote it here:

The hereditary chorea, as I shall call it, is confined to certain and fortunately a few families, and has been transmitted to them, an heirloom from generations away back in the dim past. It is spoken of by those in whose veins the seeds of the disease are known to exist, with a kind of horror, and not at all alluded to except through dire necessity, when it is mentioned as 'that disorder'. It is attended generally by all the symptoms of common chorea, only in an aggravated degree hardly ever manifesting itself until adult or middle life, and then coming on gradually but surely, increasing by degrees, and often occupying years in its development, until the hapless sufferer is but a quivering wreck of his former self. (...) There are three marked peculiarities in this disease: 1. Its hereditary nature. 2. A tendency to insanity and suicide. 3. Its manifesting itself as a grave disease only in adult life. (...) When either or both the parents have shown manifestations of the disease, and more especially when these manifestations have been of a serious nature, one or more of the offspring almost invariably suffer from the disease, if they live to adult age. But if by any chance these children go through life without it, the thread is broken and the grandchildren and great-grandchildren of the original shakers may rest assured that they are free from the disease. (...) The tendency to insanity, and sometimes that form of insanity which leads to suicide, is marked. I know of several instances of suicide of people suffering from this form of chorea. As the disease progresses the mind becomes more or less

impaired, in many amounting to insanity, while in others mind and body both gradually fail until death relieves them of their sufferings (...). It begins as an ordinary chorea might begin, by the irregular and spasmodic action of certain muscles, as of the face, arms, etc. These movements gradually increase, when muscles hitherto unaffected take on the spasmodic action, until every muscle in the body becomes affected (excepting the involuntary ones), and the poor patient presents a spectacle which is anything but pleasing to witness. (...) They are suffering from chorea to such an extent that they can hardly walk, and would be thought, by a stranger, to be intoxicated. (...) I have never known a recovery or even an amelioration of symptoms in this form of chorea; when once it begins it clings to the bitter end. No treatment seems to be of any avail.

All the cardinal features of Huntington's disease (HD) are recognized in this description: the adult onset, the progressive course and eventually fatal outcome, the choreic movements combined with mental impairment, even the pattern of inheritance; George Huntington's role as a family doctor, following his father and grandfather to give a 78-year total period of observation, gave him an unique perspective to appreciate the hereditary nature and the clinical features of HD.

The recognition of juvenile HD (Hoffmann, 1888) led to the realization that chorea was not the only motor disorder in HD, and that some patients show a predominance of rigidity and hypokinesia ('Westphal variant' (Westphal, 1883)) usually in young adults or children, but occurring in the same families as cases with chorea as the presenting feature.

It was no earlier than the 1920s that there was general agreement that the neuropathological abnormalities in HD were primarily degenerative and atrophic, despite Jelgersma's description in 1908 (Jelgersma, 1908) reporting generalized shrinkage of the HD brain and atrophy of the caudate nucleus (reduced to one-third of its original volume).

HD as a Mendelian disorder

HD displays an autosomal dominant pattern of inheritance: equal sex incidence, equal transmission by both sexes, a 50% proportion of affected offspring born to an affected parent, and lack of transmission by unaffected family members, are all features that are evident from any large HD pedigree. The HD gene was mapped to chromosome 4 in a classic study of RFLP positional cloning using the anonymous G8 marker (Gusella *et al.*, 1983). In 1985, studies of chromosome 4 of Wolf–Hirschhorn syndrome patients allowed to place the HD gene on the short (p) arm of chromosome 4 (Gusella *et al.*, 1985). Ten years after the mapping of the HD gene to chromosome 4, a gene in the critical region, named ‘interesting transcript 15’ (IT15), proved to contain a CAG repeat in its first exon, which was expanded in HD patients (Huntington’s Group, 1993). The CAG expansion appears to vary and expansions of more than 36 CAG repeats are associated with the HD phenotype. There are quite distinct peaks (at 40 and 16 repeats, respectively), but the tails of the two curves approach each other closely. There is a narrow region of overlap, even though few individuals are represented in this borderline region; therefore there is no absolute separation between the normal and the pathological range – a conclusion of practical importance when the information is being used diagnostically. Generally, repeat size is determined by PCR; it should be kept in mind that another (CCG) repeat existed immediately 3’ to the CAG repeat, which was variable in the normal population (7–12 repeats) and could thus confuse the sizing of the CAG repeats close to the borderline of normal and abnormal (Rubinsztein *et al.*, 1993; Barron *et al.*, 1994; Andrew *et al.*, 1994b); most laboratories therefore use primers 3’ to the CCG repeat. There are also reports of a polymorphism at the 3’ end of the CAG repeat usually containing a CAACAG sequence, but in a few people, the CAA codon does not occur and thus primers which overlap with this end of the repeat will fail to amplify. Thus, this rare polymorphism may lead to an erroneous diagnostic result (Gellera *et al.*, 1996). Overall, the CAG expansion can be considered as the mutation accounting for all patients with true HD. Sample mix-up or misclassification are the most common causes for the apparent absence of the mutation (Andrew *et al.*, 1994a).

The CAG repeat expansion is unstable on meiotic transmission; one of the key consequences of genetic instability in HD is that different individuals carrying the mutation will have different degrees of expansion in the CAG repeat sequence. A strong inverse correlation between repeat number and age at onset was demonstrated (Duyao *et al.*, 1993; Andrew *et al.*, 1993; MacMillan *et al.*, 1993; Snell *et al.*, 1993; Zuhlke *et al.*, 1993; Claes *et al.*, 1995). The CAG repeat

length appears to account for 47–73% of the variance in age of onset in studies of various HD populations (Ranen *et al.*, 1995; Brinkman *et al.*, 1997; Rosenblatt *et al.*, 2001), although it was estimated to account for only 7% of this variance in late-onset cases (Goldberg *et al.*, 1993). A range of onset can be established for each specific repeat number (Brinkman *et al.*, 1997). However, it is important to note the considerable variation for each repeat number. For example, with a repeat number of 41 ($n = 98$), onset ranged from 35–75 years, with a cumulative probability of 0.38 by age 50 (95% confidence intervals 0.48–0.26) and 0.88 by age 65 (0.94–0.76). The strength of the correlation was greatest for the largest repeats, which are frequently associated with juvenile onset of disease, and was weakest in the lower part of the abnormal range, corresponding to the vast majority of adult-onset HD cases.

In contrast to the clear relationship between CAG repeat number and age of disease onset, there is little evidence for a similar correlation with rate of disease progression (Kiebertz *et al.*, 1994; Ashizawa *et al.*, 1994; Brandt *et al.*, 1996). In conclusion, the number of repeats in a HD mutation carrier is strongly correlated with age at onset of disease, especially for large repeat expansions; it is also correlated with severity of brain pathology (Penney, Jr. *et al.*, 1997), but not with the development of psychiatric features or rate of decline. In vitro studies are also demonstrating a relationship between CAG repeat number and formation of protein aggregates (Chen *et al.*, 2002).

Most juvenile and early-onset cases of HD are paternally transmitted; in addition, there appeared to be ‘anticipation’, i.e. progressively earlier onset in successive generations, in male-transmitted cases. Until 1993, these observations were unexplained. Although the concept of anticipation in HD is an old one, the disorder for which most evidence existed has been myotonic dystrophy (McComas *et al.*, 1978; Mahadevan *et al.*, 1992). The correlation of age at onset with the extent of the mutational defect, already discussed, was the first important fact, with juvenile and other early-onset cases showing the largest expansions. Next, two-generation data showed clearly that the anticipation seen in individual families was closely paralleled by an increased number of CAG repeats (Huntington’s Group, 1993; Duyao *et al.*, 1993; Andrew *et al.*, 1993). In a series of 254 parent–child pairs with HD (Kremer *et al.*, 1995), expansion was seen in 70% of meioses. Although small increases in repeat number (up to seven repeats) were seen in transmission by both sexes (47.1% of males and 37.8% of females), large increases (more than seven repeats) were seen almost exclusively in the offspring of males (21.0% vs. 0.7% in the offspring of females). The largest increases were particularly likely to occur in individuals who themselves had the largest expansions (Trottier *et al.*, 1994; Ranen *et al.*,

1995), confirming a size-dependent instability. Analysis of single sperm (Leefflang *et al.*, 1995; Chong *et al.*, 1997) gives a clear picture of the distribution of sperm with different repeat numbers generated at male meiosis, confirming a high frequency (>90%) of increased repeat number for alleles in the pathological range. For an intermediate allele carrier (for definition of 'intermediate allele' see above) this figure was still over 50%, with 8% in the clinically significant range. Large series of sporadic cases showed in most clinically typical cases the HD mutation (MacMillan *et al.*, 1993; Davis *et al.*, 1994; Mandich *et al.*, 1996). When parents of such patients were studied, it became clear that while the clinical phenotype of HD might arise *de novo*, the molecular defect did not, with one parent invariably showing an expanded allele, usually in the 30–38 repeat range, but not associated with evidence of clinical disease, even at an advanced age (Goldberg *et al.*, 1993; Myers *et al.*, 1993). In all six cases in the series of Goldberg *et al.* where parental origin could be determined, the father was the one with the intermediate allele. The recognition of intermediate allele carriers has led to an assessment of penetrance of the HD phenotype in this borderline repeat range. A multicentre study (Rubinzstein *et al.*, 1996) re-analysed 178 individuals with a CAG repeat in the 30–39 range in a single laboratory and estimated the penetrance of the HD phenotype at different points in this range. The finding of six clinically normal individuals aged 75 to over 90 in the 36–39 repeat range is a clear indication of incomplete penetrance in this range, while no individuals with 35 repeats or less were found to have HD.

One of the questions that arose from a study of HD and other diseases caused by trinucleotide repeat expansions is the molecular mechanism by which those expansions occurred in the first place; the same mechanism is likely involved in the generation of intermediate alleles and in their expansion into the HD range as well. DNA undergoes a number of processes during which size changes in repeats could possibly occur. These include replication, recombination, transcription, and repair. The best evidence for the mechanism of instability is that the HD transgenic R6/1 models when crossed with *Msh2*^{-/-} mice have no expansion of the HD mutation in germ cells (Kovtun & McMurray, 2001); this almost certainly reflects a loss of gap repair function rather than DNA strand slippage.

Defining the borderline of the normal and abnormal ranges has received considerable attention since it became clear that they were so close as to give the possibility of overlap. Fortunately, the steep curves of both normal and HD distributions, and the wide separation of the peaks, means that results in the borderline range occur rarely (2–3%) of the total, but it is essential that a clear policy is available for anticipating and handling them. Assuming that a

method is used that excludes the CCG repeat, there is now general agreement that a result of 39 repeats or more in a clinically symptomatic individual is likely to indicate HD; no unequivocal results in this range have been reported in the normal population, though penetrance may be less than complete for 39 repeats. Likewise, a result of 34 or less is almost certainly normal in terms of clinical disease, though not in terms of consequences for the next generation. Thus the problem lies with the very small number of patients lying in the 34–38 repeat range, although many diagnostic laboratories have the policy of repeating all in the range 31–39, to allow for any PCR error or difficulty in reading through stutter bands. Rubinzstein *et al.* (1996) have produced a combined analysis of samples and data from different centres falling in this borderline range; out of 178 individuals with a repeat number of 30–40, seven affected had 36 repeats, while six healthy elderly individuals were found with 36–39 repeats. When such an intermediate result is found in a clinically abnormal individual, there are several approaches to resolving uncertainty. First, the test should be repeated, using a second sample if necessary. Second, if a family history of HD exists, then samples from parents should be taken where possible, to determine whether the borderline result has been transmitted from the HD or unaffected side of the family; in a number of cases it has turned out that the smaller allele has come from the affected parent, allowing a confident prediction of normality, whereas if a borderline result is also present in the affected parent and is the allele that has been transmitted, it is more likely to be associated with the disease. If the result is confirmed as being in the equivocal range, its interpretation will depend on the context; thus it will be unlikely to be relevant if the clinical situation is suspected juvenile HD, but more likely to be so if the picture is of mild disease in later life. It is thus clear that molecular analysis is of considerable value in confirming whether what appears to be typical HD is actually this disorder, as well as providing confirmation in cases where either the whole family or one particular individual is atypical. Another consideration, even more important, is the situation where a family history of HD exists, but the symptoms are not typical; in such a situation careful consideration should be given to whether the individual should be handled through a protocol appropriate for presymptomatic testing or indeed whether testing is appropriate at all. If the mutation is detected in such a person (usually at 50% risk), there is no guarantee that its presence is necessarily related to the symptoms that the patient has, and an unwanted and potentially harmful predictive test result may have been generated inadvertently.

Quality control schemes have now been set up Europe-wide (Losekoot *et al.*, 1999). It is clear that there remains

room for improvement since the latter study showed a 1.3% rate of misdiagnosis. In the USA, laboratory guidelines have also been produced (Nance, 1998) giving not only recommended laboratory procedures but also interpretation of the ranges of results, including intermediate alleles.

Three genetic modifiers of the HD gene have been reported, each probably accounting for only a small proportion of the variance in age of onset of HD. A non-coding TAA repeat polymorphism in the 3' UTR of the kainate receptor (GluR6) gene was reported to account for varying amounts of the residual age at onset variation in HD (Pickering *et al.*, 1993; Rubinsztein *et al.*, 1997). *APOE* genotype had a small but significant effect with the $\epsilon 2\epsilon 3$ genotype associated with an earlier onset in males than females (Kehoe *et al.*, 1999). *APOE* genotype is the only robust genetic risk factor associated with late onset AD (Panas *et al.*, 1999), where it does have an influence on age at onset. Yet another genetic variation detected as influencing age of onset in HD is a length polymorphism in a polyglutamine tract encoded in the CA150 gene, a transcription factor of unknown function, which interacts directly with huntingtin (Holbert *et al.*, 2001). A recent 10-cM density genome-wide scan in 629 affected sibling pairs provides suggestive evidence for linkage at 4p16, 6p21–23 and 6q24–26 (Li *et al.*, 2003).

Differential diagnosis

It seems there is a group of rare cases, which may or may not show atypical symptoms, which are not due to an expansion in the HD gene (Vuillaume *et al.*, 2000). Some of these disorders are rare autosomal dominant diseases, which look like HD and some of these have now had genes associated with them. An HD-like disease in a single pedigree was mapped to chromosome 20p12 (Moore *et al.*, 2001), the site of the prion protein PrP gene, and found to segregate with a 192 nucleotide insertion in the PrP gene, encoding eight octapeptide repeats. This disease was called HD-like 1 (HDL1). Margolis *et al.* (2001) reported an HD-like disease (HDL2), with very similar symptoms and pathology to HD, almost certainly associated with an expanded polyglutamine tract, as an antibody which detects only expanded polyglutamine-containing inclusions found such inclusions in postmortem brain from a member of this family. A consanguineous family affected by an autosomal recessive, progressive neurodegenerative HD-like disorder was recently described in Saudi Arabia (Kambouris *et al.*, 2000). The disease manifests at approximately 3–4 years and is characterized by both pyramidal and extrapyramidal abnormalities, including chorea, dystonia, ataxia, gait instability, spasticity, seizures, mutism,

and intellectual impairment. Linkage with a LOD score of 3.03 was initially achieved with a marker at 4p15.3 (Kambouris *et al.*, 2000).

Finally, a late-onset basal ganglia disease first detected in families in the north of England was associated with an insertion in the ferritin light-chain gene and is called neuroferritinopathy (Curtis *et al.*, 2001). Related polyglutamine diseases like DRPLA, SCA3 and SCA17 may mimic HD (Quinn & Schrag, 1998; Bauer *et al.*, 2004). In addition, neurological conditions associated with acanthocytes may resemble HD (Hardie *et al.*, 1991; Danek *et al.*, 2001). Choreo-acanthocytosis, or neuroacanthocytosis, is one of a heterogeneous group of neurological disorders associated with irregular spiny erythrocytes, or acanthocytes, that can be detected in a peripheral blood smear. Among the neurological disorders with acanthocytes, two groups may be distinguished. The first may additionally be characterized by low serum betalipoproteins and includes Bassen Kornzweig disease (abetalipoproteinemia; a recessive disease with vitamin E dependent polyneuropathy and ataxia); a form of hypobetalipoproteinemia (Mars *et al.*, 1969); and the HARP syndrome – hypoprebetalipoproteinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration (Higgins *et al.*, 1992). A second group comprises those with normal serum betalipoproteins and, apart from a few patients with Hallervorden–Spatz-like disease, includes patients with neuromuscular and basal ganglia disease with or without the McLeod bloodgroup phenotype. This latter group is known as chorea-acanthocytosis, neuroacanthocytosis, familial amyotrophic chorea with acanthocytosis, or the Levine–Critchley syndrome (Critchley *et al.*, 1967). Choreo-acanthocytosis is a slowly progressive neurodegenerative disorder that affects the basal ganglia, peripheral nerves, and muscle. In a review of 19 sporadic and familial British cases, as well as 26 cases from the literature, Hardie and co-authors found onset varying between 8 and 62 years, with a mean of about 32.5 years. Of these 45, 8 were reported to have died between 7 and 24 years after onset of the disease (mean 13.9 years) (Hardie *et al.*, 1991). The clinical manifestations may resemble those of HD, and often patients with this disorder have first been diagnosed as having HD. Mild cognitive impairment and psychiatric symptoms may manifest early in the disease. Dementia will develop in most patients, but early in the disease frontal lobe dysfunction dominates. Personality changes, impulsive and distractable behavior, mood disorder, paranoid delusions, and obsessive-compulsive features may necessitate psychiatric help. In contrast to adult patients with HD, epilepsy occurs much more frequently than in the general population, with about half of the reported cases affected. Choreic movements of the limbs and face are present in almost all

cases: they usually start in the legs. Orofacial dyskinesia may lead to tongue and lip biting and offer a strong clue to diagnosis. Orofacial dyskinesia may cause severe problems with speaking and swallowing. Apart from chorea, dystonia, parkinsonism and tics may occur in the course of the disease. Vocalizations and, rarely, coprolalia may resemble that seen in Tourette's disease. CT or MRI studies of the brain may reveal atrophy of the caudate nucleus. In addition, in a number of cases focal symmetrical abnormalities can be demonstrated in various parts of the basal ganglia that consist of hyperintense lesions in T₂-weighted sequences. These lesions can be found in the caudate, putamen, or globus pallidus, where they may resemble the "eye of the tiger" sign in Hallervorden–Spatz disease. The clinical feature that distinguishes neuroacanthocytosis from HD is the presence of neuromuscular abnormalities, consisting of hypo- or areflexia of tendon reflexes and distal amyotrophy. Serum CK activity is elevated in the majority of cases, while nerve conduction studies reveal reduced sensory action potentials in about 50% of cases. In contrast, motor nerve conduction studies are generally uninformative, and electromyography reveals denervation only in a minority of cases (Hardie *et al.*, 1991).

Senile chorea, or chorea of late onset in the elderly person without a family history of other affected individuals may clinically resemble HD or any of the aforementioned disorders (Shinotoh *et al.*, 1994; Garcia Ruiz *et al.*, 1997). Senile chorea, of unknown origin, and late-onset HD may be clinically indistinguishable, requiring CAG repeat length assessment to produce a diagnosis (Garcia Ruiz *et al.*, 1997). The cause of non-HD senile chorea is a clinical diagnostic challenge. All of the non-inherited causes that are discussed in the previous paragraph should be considered.

Huntington's disease – the clinical phenotype

Clinically, Huntington's disease is characterized by a triad of symptoms and signs: (i) a prominent movement disorder (in adult onset patients chorea), (ii) behavioral and emotional alterations and (iii) a cognitive decline.

Onset of symptoms and signs

A consensus exists among clinicians that a clinical diagnosis of Huntington's disease should only be made with certainty in the presence of a motor disorder. Thus, defining the clinical onset of Huntington's disease as the onset of the motor disorder yields a more or less reproducible way to conduct, for example, onset age surveys or genotype-phenotype correlation studies. However, it should be realized that the onset of motor abnormalities is neither a

sensitive measure of disease onset nor a specific and reliable measure since even well-trained motor raters may over-interpret and over-diagnose mild motor abnormalities resulting in poor inter-observer agreement in assessing the presence of motor signs (de Boo *et al.*, 1998). Prior to motor manifestations mood disorders and cognitive deficits disclosed by neuropsychological testing may be present, accompanied or followed by non-specific, minor motor abnormalities (e.g. general restlessness, abnormal eye movements or impaired optokinetic nystagmus, hyper-reflexia, impaired finger tapping or rapid alternating hand movements, etc.) (Penney, Jr. *et al.*, 1990) which eventually evolve into a recognizable extrapyramidal syndrome. In one series of 171 so-called presymptomatic carriers, mutation carriers performed significantly worse than non-carriers on neuropsychological tests such as the digit symbol test, picture arrangement, and arithmetic; mild impairment was noticed on reaction time tasks and various timed movement paradigms (Kirkwood *et al.*, 2000).

The classic phenotype

On neurological examination Huntington's disease is characterized by both extrapyramidal motor abnormalities and an impairment of voluntary movements affecting gait, speech, and swallowing. Chorea is the major motor sign of Huntington's disease, hence the designation "Huntington's chorea". Choreic movements are excessive movements, involuntary, abrupt, irregularly timed, and randomly distributed typically though with some distal (finger and toes) accentuation. Choreic movements are continuously present during waking hours and worsen during stress. Mild and intermittent choreic movements often go unnoticed by patients, while observers tend to describe them as "nervousness." Severity may vary from restlessness, fidgeting movements of the hands, unstable, dance-like gait to a continuous flow of exhausting and severely disabling, violent movements. Chorea is a sign in most patients suffering from Huntington's disease and tends to increase in severity during the first phase (~10 years) of the patients' illness. Muscle tone is typically decreased. However, rigidity and dystonia are often found in patients in advanced stages of Huntington's disease. As the disease advances, the severity of chorea tends to decrease and chorea tends to be replaced by the more disabling bradykinesia, rigidity and dystonia discussed below (Young *et al.*, 1986).

Bradykinesia and rigidity, best known as core features in Parkinson's disease, appear gradually and often dominate the final stages of Huntington's disease (Young *et al.*, 1986; Penney, Jr. *et al.*, 1990). Early in the illness, bradykinesia alone may contribute to impairment in voluntary motor

performance; some patients display a significant decrease in overall daytime motor activity, suggestive of hypokinesia, or paucity of movements (van Vugt *et al.*, 1996). The use of neuroleptic drugs, intended to suppress choreic movements, may aggravate any existing bradykinesia and rigidity.

Dystonia, characterized by slow, abnormal twisting movements and abnormal posturing with increased muscle tone, may become a prominent feature towards the later stages of Huntington's disease (Young *et al.*, 1986). In a recent study of patients who attended a Huntington's disease speciality clinic, the prevalence of dystonia of any severity was found to be 95%, while in seven of 42 patients (17%) the dystonia was severe and constant although most patients did not complain and appeared hardly bothered (Louis *et al.*, 1999). Dystonia is particularly prominent in juvenile onset patients and in patients with late stage disease. The dystonia-predominant adult-onset form of the disease was recently reported to constitute 11.8% of an adult population seen at an HD speciality clinic (Louis *et al.*, 2000). Oculomotor disturbances are among the earliest signs and are present in the vast majority of affected patients (Schubotz *et al.*, 1976; Lasker & Zee, 1997). Saccadic eye movements are primarily disturbed with inability to suppress reflexive glances to suddenly appearing novel stimuli, and delayed initiation of voluntary saccades (Lasker & Zee, 1997). Later in the disease, slowing of saccades may be seen in up to 75% of symptomatic individuals, especially in early-onset cases, affecting vertical more than horizontal movements (Oepen *et al.*, 1981; Beenen *et al.*, 1986; Lasker *et al.*, 1988; Lasker & Zee, 1997). Impaired pursuit with saccadic intrusions, impairment of gaze fixation due to distractibility, slowing of optokinetic nystagmus and inability to suppress blinking during saccades may also occur (Oepen *et al.*, 1981; Beenen *et al.*, 1986; Penney, Jr. *et al.*, 1990; Tian *et al.*, 1991; Lasker & Zee, 1997). Voluntary motor function is impaired early (Folstein *et al.*, 1983; Hefter *et al.*, 1987; Thompson *et al.*, 1988). Patients and their families describe clumsiness in common daily activities. Disturbances in motor speed, fine motor control and gait correlate with disease progression and appear to be better measures of duration of illness than chorea (Folstein *et al.*, 1983). Mechanisms proposed to underly the slowing of voluntary motor activities include impaired internal motor cueing (Thompson *et al.*, 1988; Phillips *et al.*, 1996; Curra *et al.*, 2000), impairment in constructing and refining internal representations of movement (Georgiou *et al.*, 1997), or a reduced ability to process relevant afferent input (Schwarz *et al.*, 2001). Gait disturbances ultimately result in severe disability. Patients experience frequent falls and are ultimately confined to a wheelchair. Neuroleptic treatment that suppresses choreic movements does not improve

the gait disturbance (Koller & Trimble, 1985). Most patients display speech abnormalities and dysphagia most prominently in later stages of Huntington's disease. Choking with aspiration secondary to dysphagia is a common cause of morbidity.

The final years of most Huntington's disease patients are dominated by loss of independence, severe restrictions in functioning and dependence upon others for activities of daily living. During this phase most patients live in nursing homes.

In advanced stages of the disease, speech is often severely dysarthric and may impair communication to a great extent. Swallowing is equally impaired, which requires very careful assistance by the nursing staff during meals, or, alternatively, feeding through a nasogastric tube or a percutaneous endoscopic gastrostomy (PEG) tube. Patients lose independent gait and spend their days in a chair, a wheelchair, or in bed. An increase in muscle tone which often develops in late stages of Huntington's disease may result in secondary joint contractures, while immobility increases the risk of pressure sores. Reflexes tend to be brisk but hyporeflexia is also often seen. However, in patients in whom weight loss is prominent, it may be hard to judge whether lower motor neuron pathology with muscle atrophy is present, or just plain malnourishment.

Weight loss and striking emaciation are features of late-stage Huntington's disease (Kremer & Roos, 1992). This weight loss may occur in conjunction with adequate dietary intake or even increased carbohydrate intake (Sanberg *et al.*, 1981; Farrer, 1985; Morales *et al.*, 1989). Sedentary energy expenditure is higher than in controls in proportion to the severity of the movement disorder. Total free-living energy expenditure is not higher, however, because patients with HD appear to engage in less voluntary physical activity (Pratley *et al.*, 2000). Intriguingly, a relationship has been found between weight at initial examination and rate of progress of the disease (Myers *et al.*, 1991). The leading causes of death in persons with HD are pneumonia (33%) and – reportedly – heart disease (24%) (Haines & Conneally, 1986; Lanska *et al.*, 1988). Pneumonia occurs five times more commonly in Huntington's disease than in controls and is likely to be secondary to the significant dysphagia, which results in choking and aspiration pneumonia.

Assessment of neurological and functional decline

Although clinical deterioration may be well documented in a qualitative way in the patient's file, long-term follow-up studies and the advent of experimental therapeutics made

a more quantitative description of disease progression necessary. Early attempts at measuring progression focused upon the severity of the motor disorder, but investigators soon turned to the assessment of functional status as a relevant, reliable and reproducible indicator of disease progression. The Total Functional Capacity (TFC) scale introduced by Shoulson and Fahn in 1979 (Shoulson & Fahn, 1979; Shoulson, 1981) has been extensively used. This rating scale with a range from 0 (minimal) to 13 (maximal) is simple to score, more or less linear in its downward slope over the early and mid stages of the disease, and correlates strongly with various other clinical parameters of disease progression (Young *et al.*, 1986; Shoulson *et al.*, 1989; Penney, Jr. *et al.*, 1990; Kremer *et al.*, 1999). During early and mid-disease stages the average annual deterioration is about 0.6 to 0.7 points per year, irrespective of age at onset of HD, body weight, gender of affected parent, or history of neuroleptic use (Feigin *et al.*, 1995; Marder *et al.*, 2000). However, decline slows down, in terms of TFC score, in later disease stages (Marder *et al.*, 2000). This phenomenon represents a floor effect of the scale. Apart from quantitative functional capacity assessments, pure motor assessment scales specifically developed for HD are available, e.g. the Quantified Neurological Examination, first described in 1983 (Folstein *et al.*, 1983). This rating instrument has provided the model for the motor section of the UHDRS. In order to provide a comprehensive assessment of the clinical status of a HD patient, the Unified Huntington's Disease Rating Scale (UHDRS) was developed by the US based Huntington Study Group in 1994 (Huntington Study Group, 1996); the UHDRS is widely used for quantifying progression in natural history and interventional studies.

Non-motor signs and symptoms

Although the motor symptoms are most immediately evident, there is little doubt that it is the non-motor symptoms that have great impact on patients' daily lives, and contribute prominently to patients' loss of independence. The cognitive changes in Huntington's disease have traditionally been referred to as a dementia, an appropriate descriptor when used to indicate that changes are (a) progressive and (b) affect more than one area of cognitive function. In the past, the term dementia has carried the notion of a generalized intellectual impairment affecting all aspects of cognition in a diffuse, undifferentiated way. This is not an accurate portrayal of degenerative brain disorders in general; it is particularly inaccurate in the case of HD. People with HD have specific and characteristic cognitive difficulties, with other aspects of cognitive function remaining well preserved. Cognitive

deficits lie particularly in the realm of executive functions, which include the ability to plan, organize and monitor behavior, to show mental flexibility and switch from one way of responding to another (mental set shifting) (Butters *et al.*, 1986; Bylsma *et al.*, 1991). In addition, procedural memory and psychomotor skills are impaired. Primary tools of cognition, such as language, are relatively preserved. In their daily lives, people with Huntington's disease often exhibit poor planning and judgement. They may appear impulsive and show an absence of forethought, their actions being governed by immediate rather than long-term considerations. Actions are disorganized, a feature that contributes to early occupational and domestic inefficiency. People with Huntington's disease have difficulty coping with multiple tasks simultaneously, suggesting difficulty in the allocation and switching of attention. Difficulty with simultaneous tasks may extend to activities such as talking and walking: Huntington's disease patients are often noted to stop walking in order to answer a question, suggesting that overload of attentional resources may contribute to the multiple-task difficulty. People with Huntington's disease show impaired ability to self-monitor and often fail to notice errors that are apparent to others, sometimes creating a false impression of indolence. People with Huntington's disease are often reported by relatives to be inflexible, rigid in their thinking, with difficulty seeing another's point of view. They are poorly adaptable to altered circumstances and may prefer routine. Cognitive functioning declines over the course of the disease. Nevertheless, the rate of decline is variable so that duration of illness *per se* is a relatively poor indicator of cognitive performance (Brandt *et al.*, 1984). Moreover, different domains of cognitive function do not decline in a uniform fashion (Bamford *et al.*, 1995; Snowden *et al.*, 2001). Bamford *et al.* showed most significant and consistent decline over time in psychomotor skills. Snowden *et al.* showed that, over a 1-year period, significant decline could be detected on low level psychomotor tasks, object recall and verbal fluency. By contrast, there was no change in performance even over 3 years on a test of executive function (Wisconsin Card Sorting Test) and egocentric spatial function (Road map test). It is worth emphasizing that HD is slowly progressive and cognitive changes over one year are typically relatively small. Therapeutic trials that seek to slow the natural course of disease will need to evaluate performance over years rather than months in order to demonstrate efficacy.

Psychiatric changes are distressing for patients and carers alike, but many changes are amenable to symptomatic treatment, so that early detection is vital. Behavioral problems in Huntington's disease are, however, complex. The factors underlying patients' altered behavior need to be assessed individually to improve patient care.

Huntington's disease – the neuropathological phenotype

Gross pathology

Macroscopic inspection of the brain of advanced HD patients at autopsy found that HD brains weigh less than brains of age-matched controls with the weight being reduced about 10–20%. Reduction in size occurs in the cerebral hemispheres, the diencephalon, the cerebellum and also the brainstem and the spinal cord (Forno & Norville, 1979). The most striking neuropathological feature is the shrunken appearance of the neostriatum with gross atrophy of the caudate nucleus and putamen with the caudate nucleus reduced to a thin rim of tissue. Reduction in the size of the caudate is accompanied by secondary enlargement of the lateral ventricles. Another notable feature is the reduced amount of white matter under the cortical mantle.

Microscopic pathology

Neostriatum

At the microscopic level, the atrophied neostriatum shows marked neuronal loss and astrogliosis which has been the topic of many quantitative analyses (Bruyn, 1979; Vonsattel *et al.*, 1985; Roos *et al.*, 1985; Myers *et al.*, 1988; Heinsen *et al.*, 1994). Striatal pathology likely underlies involuntary movements (chorea and dystonia), disordered planning, impulsive behaviors, and diminished emotional control as well as some other symptoms of HD (Crossman, 1987; Reiner *et al.*, 1988; Albin *et al.*, 1989). The extent of gross and microscopic striatal pathology provides a basis for dividing the severity of HD pathology into five grades (0 to 4) of increasing pathologic severity, which correlate with clinical progression (Vonsattel *et al.*, 1985; Myers *et al.*, 1988). Grade 0 cases have a strong clinical and familial history suggesting Huntington's disease but no detectable histological neuropathology at autopsy. In grade 1 cases, neuropathological changes can be detected microscopically with as much as 50% depletion of striatal neurons but without visible gross atrophy. In more severe grades (2–4), gross atrophy, neuronal depletion, and gliosis are progressively more pronounced, and pallidal pathology becomes evident. In the most severe grade (4), more than 90% of striatal neurons are lost, and microscopic studies predominantly reveal the remaining astrocytes. There is a dorsal to ventral, anterior to posterior, and medial to lateral progression of neuronal death with the dorsomedial striatum affected earliest and relative sparing of the ventral striatum and nucleus accumbens (Bots & Bruyn, 1981; Vonsattel *et al.*, 1985; Roos *et al.*, 1985).

The Huntington's disease gene, the Huntington's disease protein ("Huntingtin") and the Huntington's disease mutation

The Huntington's disease gene contains 67 exons (Huntington's Group, 1993) and encodes a 350 kDa protein, named huntingtin. The CAG repeat is located within the first exon and is translated into a polyglutamine tract. Huntingtin is ubiquitously expressed not only throughout the brain but also in many other tissues like muscle, liver, or lymphocytes and its expression pattern cannot account for the regional selectivity of neurodegeneration (Li *et al.*, 1993; Landwehrmeyer *et al.*, 1995; Sharp *et al.*, 1995; Schilling *et al.*, 1995). It is of note that, when the gene was cloned, it had no identifying homologies in the databases and to a very large extent this remains true today. Since the cloning of the HD gene, several other genes with expanded CAG repeats have been isolated (for review, see Cummings & Zoghbi, 2000). All lead to neurodegeneration, have similar sizes of disease causing repeats, and contain expanded glutamine tracts in their cognate proteins.

Whereas neurodegeneration occurs in different brain regions in all these CAG repeat disorders, another similarity between these diseases is that the CAG repeat is always located within the coding region of the protein so that the disease-causing proteins share a region with an expanded polyglutamine repeat.

It was Max Perutz who first hypothesized that instability in the chemical properties of polyglutamines might account for a conformational change above a certain threshold length of the polyglutamine stretch which might, in turn, be related to disease occurrence: "*Poly-L-glutamines form pleated sheets of beta-strands held together by hydrogen bonds between their amides. Incorporation of glutamine repeats into a small protein of known structure made it associate irreversibly into oligomers. That association took place during the folding of the protein molecules and led to their becoming firmly interlocked by either strand- or domain-swapping. Thermodynamic considerations suggest that elongation of glutamine repeats beyond a certain length may lead to a phase change from random coils to hydrogen-bonded hairpins*" (Perutz, 1996)." A length-dependent oligomerization of polyglutamines into amyloid-like aggregates was demonstrated in vitro and in vivo shortly afterwards (Scherzinger *et al.*, 1997). The polyglutamine length above which oligomerization takes place is exactly in the range between 30 and 40 repeats which in Huntington's disease and other CAG triplet disorders delineates a normal from a disease gene. For the first time a plausible explanation for this threshold effect could be given.

Further pending questions were whether such polyglutamine oligomers are, in fact, present in Huntington's disease brains and how these might possibly cause neurodegeneration. In fact, amyloid-like aggregates had already been described by Roizin *et al.* in 1979 predominantly in neuronal nuclei when electron microscopy studies were applied to examine brain biopsies from Huntington's disease patients. Without the knowledge about the Huntington's disease gene defect and a possible role of polyglutamine aggregates, however, the significance of this finding could not be acknowledged at that time.

First clear evidence for the development of amyloid-like aggregates in Huntington's disease, which are formed from a polyglutamine containing fragment of the Huntington's disease protein came from the development of Huntington's disease transgenic mice. Gill Bates group was the first who developed a transgenic mouse which expressed only exon 1 of the human Huntington's disease gene with a massively expanded polyglutamine (around 150 repeats) (Mangiarini *et al.*, 1996). This exon 1 was not only sufficient to cause a neurodegenerative disease in mice but also they described as the most prominent neuropathological finding amyloid like aggregates which were ubiquitinated and could be stained with antibodies against N'-terminal huntingtin. Because of their predominant localization in nuclei and absence in glial cells, these aggregates were named "neuronal nuclear inclusions" (NII). Meanwhile polyglutamine containing amyloid-like aggregates which are highly ubiquitinated have also been described in postmortem Huntington's disease brains where they were not only found in neuronal nuclei but also in dystrophic neurites (DiFiglia *et al.*, 1997).

While the presence of polyglutamine containing ubiquitinated aggregates is widely accepted as a key feature of CAG triplet disorders (Davies *et al.*, 1997), it is still disputed what their exact pathophysiological role is and how important their presence is for the process of neuronal degeneration.

From more detailed analyses of NII in Huntington's disease it is known that these aggregates do not contain the entire huntingtin protein but only a N'-terminal fragment including the polyglutamine chain. In a number of Huntington's disease models cleavage of the polyglutamine containing fragment from the rest of the protein can be induced in a length dependent manner by activation of proteinases such as caspases 1 (Wellington *et al.*, 1997). Cleavage seems to be a precondition for the translocation of the polyglutamine containing fragment from the usual cytoplasm localization of the normal huntingtin protein into the nucleus. In turn, blockade of this cleavage process by caspase inhibition can

reduce disease progression in Huntington's disease models.

These experiments not only demonstrate that cleavage of huntingtin is a pathophysiological key step but they also emphasize the importance of nuclear localization of expanded polyglutamine oligomers for disease development. This fact has been supported also by Saudou *et al.* who showed very elegantly in genetically modified cellular models of Huntington's disease that nuclear localization of the expanded polyglutamine is necessary to induce cell death (Saudou *et al.*, 1998). This notion is also supported by studies in which normal cell cultures were exposed to chemically synthesized polyglutamine peptides which were readily taken up by the cells into the cytoplasm. Those polyglutamines only became toxic to the cells when they also contained a nuclear localization signal and did thus enter the nucleus (Yang *et al.*, 2002).

To further elucidate the function of huntingtin and how the expanded polyglutamines may cause cell death yeast two hybrid systems and immunoprecipitation assays were developed to screen for interacting protein partners and abnormal protein interactions. Within this screen a number of transcription factors (Sp1, TAFII130, N-CoR, mSin3, p53, CREB binding protein, Gln-Ala repeat transcriptional activator CA150) were identified which interact with mutant huntingtin in a polyglutamine length dependent manner, i.e. increasing aggregation with expansion of the polyglutamine (Steffan *et al.*, 2000; Holbert *et al.*, 2001; Dunah *et al.*, 2002; Li *et al.*, 2002; Boutell *et al.*, 2004). This is not very surprising since it is well known that many transcription factors contain polyglutamine rich regions themselves. Also a number of transcription factors like CREB binding protein (CBP) and P53 were identified as components of neuronal nuclear inclusions in Huntington's disease (Steffan *et al.*, 2000; Nucifora, Jr. *et al.*, 2001). Cell nuclei were depleted of these transcription factors not only in various disease models but also in HD brain tissue and compensation for CBP loss through CBP overexpression could rescue cells from polyglutamine induced neuronal toxicity in vitro (Steffan *et al.*, 2000; Nucifora, Jr. *et al.*, 2001).

The expected consequence of nuclear transcription factor inactivation through interaction with polyglutamines from mutant huntingtin protein is a change in the transcriptional activity of the affected cell. In fact, early and very specific changes in the mRNA expression pattern were first demonstrated in Huntington's disease transgenic mouse models for various neurotransmitter receptors (Cha *et al.*, 1998, 1999). Meanwhile this concept has been largely expanded through mRNA expression profiling applying microchip array techniques. A characteristic pattern of reduced mRNA expression was found for encoding

components of neurotransmitter systems, proteins involved in calcium homeostasis and also the retinoid signaling pathways. Similar changes were observed in different HD transgenic mouse models which are known to be critical to neuronal function. Time-course studies also revealed that mRNA changes develop in parallel with pathologic and behavioral deterioration in these animals.

Thus transcriptional dysregulation due to interaction of misfolded mutant polyglutamines in cell nuclei with transcription factors is now thought to be a key feature of HD pathology (Cha, 2000). As a consequence, neuronal dysfunction may occur in parallel at many different cell sites which are all in itself essential for cell survival. A number of well described examples which may thus be all understood as rather late events in the cascade of molecular events are glutamate related excitotoxicity, mitochondrial dysfunction and deficits in energy metabolism, as well as induction of the apoptotic signaling pathway (Beal, 1995; Koroshetz *et al.*, 1997; Browne *et al.*, 1999; Schapira, 1999; Cepeda *et al.*, 2001; Zeron *et al.*, 2002; Behrens *et al.*, 2002; Panov *et al.*, 2002; Ross, 2002; Friedlander, 2003; Hickey & Chesselet, 2003). More than 10 years after the gene defect in HD has been identified there is still a number of unsolved problems in our understanding of the molecular disease mechanisms. Examples are the exact function of the normal huntingtin protein and the regional selectivity of neurodegeneration. But it should be emphasized that our current understanding offers entirely new opportunities for therapeutic approaches. A number of these approaches have already been successfully tested in HD transgenic mouse models. Most promising for a therapeutic intervention in Huntington's disease patients are obviously results with drugs which are already approved by the FDA for diseases or which do not need approval since they are understood as natural food supplements. Examples are inhibition of caspase 1 activity with minocycline (Chen *et al.*, 2000); inhibition of nuclear polyglutamine aggregation with the disaccharide trehalose (Tanaka *et al.*, 2004); compensation for loss of CBP dependent transcriptional activity through treatment with the histone deacetylase inhibitors SAHA (suberoylanilide hydroxamic acid) or sodium butyrate (Steffan *et al.*, 2001; Hockly *et al.*, 2003; Ferrante *et al.*, 2004); improvement of mitochondrial energy metabolism through treatment with creatine (Ferrante *et al.*, 2000; Dedeoglu *et al.*, 2003).

First description and historical review

Dentatorubral-pallidoluysian atrophy (DRPLA) was first reported by J. K. Smith in 1958, in a detailed clinical description of a single case (Smith *et al.*, 1958). The disorder is rare in the western hemisphere, but in Japan is approximately as prevalent as Huntington's disease (HD). Like HD, DRPLA is inherited as an autosomal dominant, and shows a wide range of age of onset, with anticipation caused by instability of the triplet repeat expansion (Naito & Oyanagi, 1982; Takahashi *et al.*, 1988; Iizuka *et al.*, 1984; Goto *et al.*, 1982). The triplet repeat expansion mutation which causes DRPLA was identified as part of a program to find genes with triplet repeats as candidates for neuropsychiatric disorders with anticipation (Li *et al.*, 1993; Ross *et al.*, 1993). Two Japanese groups independently used the primers for amplifying the CAG repeat to determine that it is expanded in DRPLA and identify the gene in which this expanded repeat is located, termed atrophin-1 (Koide *et al.*, 1994; Nagafuchi *et al.*, 1994; Margolis *et al.*, 1996). The availability of a genetic test for DRPLA then made it possible to identify other families with DRPLA, some of whom had previously been diagnosed as having HD.

Morphological pattern of pathology

Among the polyglutamine neurodegenerative diseases, the pathology of DRPLA is most similar to that of HD (Ross, 1995). The areas most severely affected are given in the name of the disease. The dentate nucleus of the cerebellum has the greatest degeneration. The red nucleus, the globus pallidus, and the subthalamic nucleus are also significantly affected. The pathology of DRPLA involves neu-

ronal loss and white matter degeneration (Becher *et al.*, 1997b, Yamada *et al.*, 2000). Like the other polyglutamine disorders, DRPLA involves aggregation of the gene protein product, in this case atrophin-1, into inclusion bodies in neuronal nuclei, especially in areas with degeneration, and also in more widespread areas (Becher *et al.*, 1997a, b, 1998; Becher & Ross, 1998). There are no intranuclear inclusions in the cerebellar Purkinje cells. However it appears to be a common feature of many polyglutamine disorders that Purkinje cells are not sites of intranuclear inclusion formation (Koyano *et al.*, 2002). Atrophin-1 protein also accumulates with an apparently diffuse localization within nuclei in widespread areas of the brain, including cerebral cortex, basal ganglia and many brainstem regions (Yamada *et al.*, 2001b).

Biochemical and neuropharmacological models

There has been little work aimed at devising a pharmacological or toxicological model of DRPLA. Biochemical and genetic studies are described below.

Molecular biology

Atrophin-1 encodes a protein of 1184 amino acids (Yazawa *et al.*, 1995; Margolis *et al.*, 1996). Immunohistochemical and immunocytochemical studies have demonstrated that atrophin-1 is localized to the cytoplasm and nucleus of neuronal and non-neuronal cells (Yazawa *et al.*, 1995; Wood *et al.*, 2000b). Atrophin-1 contains an amino-terminal nuclear localization signal (NLS) and a carboxy-terminal nuclear export signal (NES), and has been

hypothesized to shuttle between the cytoplasm and nucleus as part of its normal cellular function (Schilling *et al.*, 1999). Its major cellular function may be that of a general transcriptional co-repressor.

The first suggestion that atrophin-1 may function in transcriptional regulation came as a result of yeast two-hybrid screens with the amino-terminus of the protein (Wood *et al.*, 2000a, b). Atrophin-1 was shown to interact with ETO/MTG8, a known transcriptional co-repressor, and repress transcription of a luciferase reporter gene in cultured cells (Wood *et al.*, 2000b). However, the physiological relevance of reporter gene assays in cultured cells transiently transfected with naked plasmid DNA is often uncertain. It has since been demonstrated that *Drosophila melanogaster* atrophin interacts with the transcription repressor Even-skipped and is necessary for its repressive function in vivo (Zhang *et al.*, 2002a). Both the *Drosophila* and human atrophin proteins repressed expression of a genomic reporter gene in vivo (Zhang *et al.*, 2002b), and the repressive function of *Drosophila* atrophin was shown to be essential for embryonic patterning (Zhang *et al.*, 2002a; Erkner *et al.*, 2002). Hence there is now strong evidence that atrophin-1 does indeed function as a transcriptional co-repressor.

A protein called RERE is one other known nuclear atrophin-1 interacting protein (Yanagisawa *et al.*, 2000). Atrophin-1 and RERE interact through their arginine-glutamic acid dipeptide repeats, and are probably capable of forming homo- and hetero-dimers (Yanagisawa *et al.*, 2000). Yeast two-hybrid screening with the carboxy-terminal portion of atrophin-1 containing the ER repeats pulled out numerous clones of RERE and atrophin-1, all of which contained the respective ER repeats (J. D. Wood, unpublished data). RERE is localized to nuclear promyelocytic leukaemia (PML) oncogenic domains (PODs) and enhances apoptosis (Waerner *et al.*, 2001). Immunohistochemical studies have demonstrated an association of PML protein with nuclear inclusions in DRPLA (Yamada *et al.*, 2001a, b), while atrophin-1 over-expression in cultured cells apparently disassembles PODs (Wood *et al.*, 2000b).

The function of cytoplasmic atrophin-1 is less well understood. Similarly, the factors that regulate its nuclear trafficking are unknown. What clues there are have again come from yeast two-hybrid screens. Atrophin-1 contains five PY motifs and these appear to modulate interactions with two families of WW domain-containing proteins (Wood *et al.*, 1998). MAGI-1 and MAGI-2 (previously referred to as AIP3 and AIP1 respectively) are large membrane-associated guanylate kinases (MAGUKs) with an inverted arrangement of protein-protein interaction domains. (Dobrosotskaya *et al.*, 1997). MAGI proteins appear to be impor-

tant for the assembly of signalling complexes at synapses and tight cell junctions. WWP1, WWP2 and Itch (previously referred to as AIP5, AIP2 and AIP4, respectively) are highly homologous E3 ubiquitin ligase enzymes, which may be involved in atrophin-1 turnover. At least one of these E3s appears capable of ubiquitinating atrophin-1 in a cell transfection based assay (J. D. Wood, unpublished data).

A proline-rich region in atrophin-1 binds to the SH3 domain of the L and S isoforms of the insulin receptor substrate of 53 kDa protein (IRSp53) (Okamura-Oho *et al.*, 1999, 2001). IRSp53 is a substrate for the insulin/IGF-1 receptor tyrosine kinase and may be involved in post-synaptic insulin signaling in the brain (Abbott *et al.*, 1999). A yeast two-hybrid screen with the PDZ domains of MAGI-2 pulled out the S isoform of IRSp53, which has a C-terminal PDZ domain-binding motif (J. D. Wood, unpublished data). This suggests that atrophin-1, MAGI-2 and IRSp53 have the potential to form a trimeric complex in brain. IRSp53 is known to activate actin polymerization and membrane ruffling through interaction with Rac and WAVE (Miki *et al.*, 2000). Atrophin-1 has not been demonstrated to influence actin polymerization.

Pathogenesis

Our understanding of DRPLA pathogenesis has been advanced by cell model and mouse model studies. Cell model studies have indicated that atrophin-1 with an expanded repeat can be directly toxic to cells. Shorter fragments appear to be more toxic than the full-length protein; the possible role of proteolytic processing will be discussed below. In addition, cell model studies have indicated a role for nuclear localization; fragments small enough to diffuse passively into the nucleus are toxic (Igarashi *et al.*, 1998). Furthermore, we have recently shown in studies involving mutations of putative endogenous nuclear export signal and nuclear localization signal that these localization signals are functional, and that deleting the nuclear localization signal substantially decreases toxicity, while deleting the nuclear export signal substantially enhances toxicity (Wood *et al.*, 2000b; Nucifora, Jr. *et al.*, 2003). These studies strongly suggest that, at least in vitro, nuclear localization enhances toxicity. These data, taken together with data indicating that nuclear atrophin-1 leads to alterations of normal nuclear protein such as PML, CBP and Sp1 (Yamada *et al.*, 2001a, b), indicate that abnormalities of nuclear proteins may contribute to atrophin-1 mediated toxicity.

The cell model studies have also shown that atrophin-1 with an expanded polyglutamine repeat will aggregate in

cells (Igarashi *et al.*, 1998; Nucifora, Jr. *et al.*, 2003; Wood *et al.*, 2000b; Toyoshima *et al.*, 2002). However aggregation is not correlated with toxicity, and in cell model studies, there can be toxicity due to expression of mutant atrophin-1, with no aggregates of atrophin-1 visible in the light microscope (Nucifora *et al.*, 2002). These results are also comparable to those for HD, in which toxicity is enhanced by nuclear localization, but not dependent on visible aggregates. Aggregation and formation of an “aggresome” may be part of the cellular response to misfolded proteins (Kopito, 2000; Shimohata *et al.*, 2002).

Mouse model studies have contributed greatly to our understanding of the pathogenesis of DRPLA. Several mouse models have been made (Schilling *et al.*, 1999, 2001; Sato *et al.*, 1999a, b). The transgenic mouse model made in our laboratory has reproduced many of the features of DRPLA. This model was made using the prion promotor to drive atrophin-1 expression throughout the brain (except in cerebellar Purkinje cells) as well as at lower levels in some peripheral tissues. This is a strategy we have also successfully used for modeling HD (Schilling *et al.*, 1999). For DRPLA, the construct encoded full-length atrophin-1 with either a normal polyglutamine repeat or 65 consecutive glutamines, which would yield juvenile onset in human patients. Control transgenic mice were indistinguishable from non-transgenic litter mates. Mice expressing the 65-glutamine protein (at approximately two to three times the level of endogenous atrophin-1) developed a neurological phenotype resembling the human disease including ataxia, tremors, abnormal movements, and in some mice seizures. The movement disorder progressed to early death (Schilling *et al.*, 1999; Andreassen *et al.*, 2001). Neuropathologic examination of these mice revealed both intranuclear inclusions and diffuse-appearing nuclear reactivity for atrophin-1, similar to human postmortem brain material from DRPLA patients.

Western blot analysis of these mice indicated that the full-length atrophin-1 was expressed throughout the brain and was predominantly cytoplasmic. However, when a nuclear fraction was prepared, a substantial amount of a smaller species was visible. This ran at approximately 120 kDa, compared to endogenous of 200–220 kDa for full-length atrophin-1. Comparison to nuclear extracts prepared from 1-month-old and 11-month-old transgenic mice demonstrated that the 120 kDa fragments accumulated with time. Nuclear extracts from human post mortem brain material showed an almost identical-appearing species at about 120 kDa (running as a closely spaced doublet). Thus we believe there is nuclear accumulation of a fragment of mutant atrophin-1, contributing to pathogenesis. This is comparable to the toxic fragment model for Huntington's disease (Ross, 2002).

Proteolytic processing of atrophin-1

A number of lines of evidence suggest that proteolytic cleavage of mutant atrophin-1 modulate its cellular localization and may be critical for pathogenesis (Nucifora, Jr. *et al.*, 2003; Schilling *et al.*, 1999). For both DRPLA and HD, accumulation of nuclear fragments may be critical to the pathogenic mechanism, since truncation and nuclear localization of either of these proteins enhances cellular dysfunction and toxicity (Nucifora, Jr. *et al.*, 2003; Saudou *et al.*, 1998; Peters *et al.*, 1999). The signals that control cellular localization for atrophin-1 are better understood than for huntingtin, so that DRPLA may provide a model for understanding some aspects of the cellular pathogenesis of HD. Conversely, more is known about the proteases involved in cleaving huntingtin *in vivo* than atrophin-1, and some of the proteolytic cleavage events found in DRPLA may differ from HD. The polyglutamine tract lies near the middle of the atrophin-1 protein, while in huntingtin it is found near the N-terminus of the protein. The atrophin-1 protein contains an NLS in the N-terminus (Nucifora, Jr. *et al.*, 2003), while huntingtin does not appear to contain a functional NLS. Both proteins contain a C-terminal NES (Nucifora, Jr. *et al.*, 2003; Le *et al.*, 2003).

Many studies *in vitro* and *in vivo* are consistent with caspase as well as calpain cleavage of huntingtin (Goldberg *et al.*, 1996; Wellington *et al.*, 1998, 2000; Holbert *et al.*, 2001; Gafni & Ellerby, 2002; Kim *et al.*, 2001). In addition, further truncation of Htt may be produced by an unknown aspartyl protease (Lunkes *et al.*, 2002). Huntingtin may be transported into the nucleus via interactions with an NLS-containing shuttle protein. (Alternatively, if cleavage takes place in the cytoplasm, it is conceivable that fragments could diffuse passively into the nucleus.) Unlike HD, in which truncation leads to small N-terminal polyQ containing products, cleavage of atrophin-1 found in mouse models and human postmortem tissue leads to the generation of a large nuclear N-terminal polyQ containing fragment of atrophin-1 containing the NLS (Schilling *et al.*, 1999).

Similar to huntingtin, atrophin-1 can be cleaved by caspases, and caspase cleavage can modulate atrophin-1 cell toxicity *in vitro* (Ellerby *et al.*, 1999; Miyashita *et al.*, 1997, 1998). Cleavage of atrophin-1 by caspases occurs at D109. Cleavage at this site would generate a very short fragment containing the N-terminus, and a longer fragment missing the N-terminus but containing the polyglutamine repeat. However, evidence for these products *in vivo* is lacking. The large N-terminal nuclear 120 kDa fragment present in the DRPLA transgenic mouse model and post-mortem tissue is immunoreactive to an N-terminal atrophin-1 antibody (Nucifora, Jr. *et al.*, 2003) and therefore cannot be caspase-derived. Indeed, the relevant fragment of

atrophin-1 localized in the nucleus is not generated by any of the currently known caspases (Ellerby *et al.*, 1999; Nucifora, Jr. *et al.*, 2003). Further, calpains, which frequently have cleavage sites clustered in the same region of proteins as caspase sites, do not generate the large N-terminal nuclear 120 kDa atrophin-1 product (L. M. Ellerby, unpublished data).

The locations of the NLS and the NES in the atrophin-1 sequence suggest that truncation *in vivo* would delete the NES, with the shuttling of the mutant atrophin-1 fragment into the nucleus by the NLS unopposed by export pathways. Subsequent nuclear accumulation could then enhance cellular toxicity. As discussed above, expression of a mutant atrophin-1 construct, with an N-terminal fragment of similar size to the truncation product found *in vivo*, and lacking the NES, showed enhanced nuclear localization and cell toxicity when compared to the full-length mutant atrophin-1 protein containing the NES (Nucifora *et al.*, 2003). The proteases responsible for generating the large N-terminal nuclear 120 kDa atrophin-1 fragment found *in vivo* are not known, and therefore it will be important to determine the exact cleavage site in the atrophin-1 protein. This will allow studies to be directed at identifying the protease responsible for generating this cleavage product. Whether the *in vitro* studies suggesting the involvement of an aspartyl protease in huntingtin truncation (Lunkes *et al.*, 2002) are relevant to DRPLA proteolysis is currently not known.

Mechanisms of cell death

Based on the evidence described above, we believe that nuclear localization and proteolytic processing of mutant atrophin-1 contribute to cell toxicity. What might be the mechanisms of cell dysfunction and cell death? Disruption of gene transcription is a likely candidate. Studies have shown that mutant atrophin-1 can interfere with gene transcription when assayed in several different ways. Mutant atrophin-1, as well as mutant huntingtin, may interact with the transcription factor CBP (Nucifora, Jr. *et al.*, 2001). This effect may be mediated by a direct interaction between mutant polyglutamine in atrophin-1 and a short polyglutamine stretch normally present in CBP. The hypothesis that abnormal polyglutamine interactions might be relevant for polyglutamine diseases was first put forward by Max Perutz (Perutz, 1994, 1996), and subsequently studied by David Housman's group (Kazantsev *et al.*, 1999; Preisinger *et al.*, 1999). Elegant data have also been provided for interactions of CBP with the androgen receptor, which undergoes polyglutamine expansion in the disease spinal and bulbar muscular atrophy (SBMA) (McC Campbell *et al.*, 2000; McC Campbell & Fischbeck, 2001).

Abnormal phosphorylation of atrophin-1 may contribute to pathogenesis (Okamura-Oho *et al.*, 2003). Modifications by ubiquitination and especially SUMOylation may also be relevant (Terashima *et al.*, 2002; Ueda *et al.*, 2002).

Other mechanisms have been proposed as well, which may be relevant for HD, or DRPLA. Interactions with p53, or interactions with CBP not dependent on direct polyglutamine interactions have also been proposed (Steffan *et al.*, 2000). Other transcriptional mechanisms may be relevant as well. Atrophin-1 has been reported to interfere with transcription mediated via TAFIII130 (Shimohata *et al.*, 2000). Another possible mechanism resulting in transcriptional dysregulation, which has been proposed for HD, and might also be relevant for DRPLA, would involve interference with the interaction between Sp1 and TAFIII130 (Dunah *et al.*, 2002; Jiang *et al.*, 2003). Taken together, there appears to be substantial evidence for disruption of gene transcription as at least one important mechanism for pathogenesis of DRPLA, though the exact molecular interactions are still not completely clear. One puzzle is that, unlike for huntingtin, substantial amounts of full-length atrophin-1 are present in the nucleus normally. The truncation, removing the NES, would presumably just increase levels further. However the mutant protein, especially after truncation, may interact abnormally with proteins in the nucleus, such as CBP or others, and possibly may do so in subcompartments of the nucleus different from normal.

A more difficult question is the identification of the downstream genes whose transcription might be altered. A gene expression array experiment has found changes in expression levels of a substantial number of genes in DRPLA transgenic mice (Luthi-Carter *et al.*, 2002). There is overlap between the genes changed in the DRPLA model and those changed in HD models (Luthi-Carter *et al.*, 2002; Luthi-Carter *et al.*, 2000). Some of these changes may involve genes coding for proteins involved in neuronal signaling. However, which of them, if any, are involved in pathogenesis is still unknown.

Clinical picture

The nature of the clinical presentation depends greatly on the age of onset and the length of the CAG repeat. Cases with adult onset often have a clinical presentation virtually indistinguishable from that of Huntington's diseases. Motor disorders include chorea, dystonia and voluntary movement abnormalities including incoordination and ataxia. Cognitive dysfunction includes features similar to those of HD with slowed thinking, loss of retrieval of information and difficulty in sequencing tasks initially, progressing to

more severe dementia later on. In addition, a variety of emotional features can be present, including affective disorder and psychosis (Adachi *et al.*, 2001; Tsuji, 1999, 2000; Ross *et al.*, 1997b; Smith *et al.*, 1958; Smith *et al.*, 1958; Smith, 1975; Naito & Oyanagi, 1982; Takahashi *et al.*, 1988). Cerebellar ataxia can be prominent (Yabe *et al.*, 2002) head tremor can also be present (Ohizumi *et al.*, 2002). All of these features are progressive. The illness is invariably fatal except in cases with sufficiently late onset in which patients may die of other illnesses (Ross *et al.*, 1997b).

The clinical presentation of patients with early onset associated with large expansions of the CAG repeat is quite different with cognitive deterioration, incoordination, and progressive myoclonic epilepsy, or other forms of epilepsy, being quite prominent, and considerably less chorea, dystonia, or other involuntary movements (Iizuka *et al.*, 1984; Tomoda *et al.*, 1991). In some cases, features similar to those seen in autism may be present (Licht & Lynch, 2002). This is also a progressive fatal form of the illness, and because of the relatively early onset, individuals may die in early adulthood or even in childhood.

Clinical variants

DRPLA has been most carefully studied in Japan, as mentioned above, but has also been described in North America, Europe and China (Ross *et al.*, 1997b; Potter *et al.*, 1995; Warner *et al.*, 1995; Norremolle *et al.*, 1995; Le *et al.*, 2003; Lee *et al.*, 2001; Villani *et al.*, 1998; Nielsen *et al.*, 1996). While there have been some differences observed, the clinical features all seem fairly comparable. In addition, the neuropathological changes are generally similar.

A family with the clinical features of DRPLA was found in the United States prior to the discovery of the DRPLA gene. The syndrome was named the "Haw River syndrome" after the location of the pedigree in North Carolina. The syndrome in this family was subsequently shown to be caused by expansion in the atrophin-1 gene (Burke *et al.*, 1994). We have seen several families who have moved to Baltimore from this part of North Carolina, and likely represent branches of this extended pedigree. These patients and the patients described from North Carolina appear to have fairly characteristic DRPLA.

Time course

As noted above, DRPLA is invariably fatal, except in the cases in which onset is sufficiently late that affected individuals die from competing causes of illness. As has been described for Huntington's disease, there is some clinical

Fig. 58.1 Model for DRPLA pathogenesis. Atrophin-1 normally shuttles in and out of the nucleus, where it has a role in transcriptional regulation. After removal of the NES, it cannot be exported from the nucleus, and accumulates. Abnormal interactions with transcriptional regulators, such as CBP, contribute to toxicity. See text for details.

impression that the progression of the illness is more rapid in individuals with early onset. However, quantitative studies to document this have not yet been performed. The features that appear to be most clearly progressive are the motor disorder and the cognitive disorder. Emotional features, including affective disorder and psychotic features, are more variable, and may present at different points in the course. In patients with juvenile onset, the epilepsy tends to become more severe as the illness progresses, making management difficult.

Epidemiology

The greater prevalence in Japan compared to other regions of the world has an interesting explanation (Deka *et al.*, 1995; Masuda *et al.*, 1995; Watkins *et al.*, 1995; Yanagisawa *et al.*, 1996; Squitieri *et al.*, 1994). In the Japanese population distribution of the atrophin-1 CAG repeat length is slightly longer than in Europe and the United States, and is skewed toward more of the rare alleles at the higher end of the normal range, or, as has been described for HD, intermediate alleles. Some of these alleles toward the high end of the normal range presumably are slightly unstable, and may occasionally expand, establishing new pedigrees with DRPLA. This is the converse of the situation for HD, in which there are fewer alleles at the high end of normal in Japan, and thus fewer pedigrees with HD in Japan compared to Europe and North America.

Investigations

The major diagnostic test is the genetic test for the presence of the expanded repeat in Atrophin-1. While DRPLA is present in all populations, it is relatively rare in

Fig. 58.2 Primary structure of atrophin-1, which contains 1184 amino acids. There is an NLS in the N-terminal region (16–32) of the protein, and an NES in the C-terminal region (1033–1041). The expanding polyglutamine stretch (indicated as (Q)_n) is located at amino acid 484 of atrophin-1 and the caspase consensus site (DSL_D) is at amino acids 106–109. The putative cleavage site that would release the NES is noted.

populations from European ancestry, and in those cases may be tested after a diagnostic test for HD has come back negative. MRI scans or other brain imaging can also help establish the diagnosis. The extent of cerebellar compared to cortical and other brain atrophy is somewhat variable, in part relating to age of onset of the illness. In addition to these changes, diffuse high-intensity signals are often evident in cerebral white matter on T₂-weighted MRI, particularly in adults with fewer than 65 repeats (Koide *et al.*, 1997). High-intensity signals may also be found in the brainstem, globus pallidus and thalamus on T₂-weighted and flare imaging. As in HD, there have been studies suggesting that there is abnormal cellular metabolism in DRPLA, including evidence of abnormal energy metabolism in skeletal muscle (Lodi *et al.*, 2000). Neuropathology continues to be of use in confirming the diagnosis (Yamada *et al.*, 2000, 2002; Ross *et al.*, 1997a; Becher *et al.*, 1997b).

Treatment

As with other polyglutamine neurodegenerative disorders, there are no treatments known which can delay the onset

or slow the progression of the illness. However, studies in mouse models have recently begun to provide some candidate agents. A number of therapeutic studies of HD models have been done recently, based on current understanding of pathogenesis (Ferrante *et al.*, 2002; Feigin & Zgaljardic, 2002; Jankowsky *et al.*, 2002; Tarnopolsky & Beal, 2001; Steffan *et al.*, 2001; McCampbell *et al.*, 2001). Some of these approaches include designing agents to compensate for the hypothesized abnormal gene transcription caused by the polyglutamine expansion or counteract downstream effects of polyglutamine toxicity, such as increases in free radicals or excitotoxicity.

In cell models of DRPLA, it has been reported that cystamine may provide some neuroprotection (Igarashi *et al.*, 1998). Cystamine can be a transglutaminase inhibitor. However it may have other effects, including effects on oxidative metabolism. The dose used in this study was relatively high, so the mechanism is uncertain. However, cystamine is one of the agents being studied for HD and if it is applicable for HD it may well be useful for DRPLA as well.

There has been little systematic therapeutic trial research in DRPLA. A large study in Huntington's disease called the CARE-HD study showed no effect of a glutamate receptor

antagonist, and a possible modest effect of an anti-oxidant, Co-enzyme Q10 (Huntington Study Group, 2001). It is possible that combinations of agents acting via different mechanisms may have the best chance of success (Figs. 58.1, 58.2).

Neuroacanthocytosis syndromes

Alexander Storch

Department of Neurology, Technical University of Dresden, Germany

Acanthocytes (*acanthos* = thorny or spiny in Greek language) are mature red blood cells with multiple protrusions or spicules, often with terminal bulbs, which are irregular in shape, orientation, and distribution. Consequently, acanthocytosis is defined as an increased amount of such misshaped erythrocytes in peripheral blood. Acanthocytes should not be present in the peripheral blood, but in some general and neurological conditions, such as uremia, advanced hepatic disease, post-splenomegaly, advanced malnutrition or spur cell anemia, significant elevations of acanthocyte levels are reported (Brin, 1993; Stevenson & Hardie, 2001). The association of acanthocytosis with neurological syndromes is found in at least three hereditary neurological disorders that are generally referred to as neuroacanthocytosis syndromes (Table 59.1). The first recognized association was that of “malformation of the erythrocyte” in a sporadic case of progressive ataxia and pigmentary retinopathy by Bassen and Kornzweig in 1950 (Bassen & Kornzweig, 1950), but the underlying inherited metabolic abnormality of abetalipoproteinemia with secondary vitamin E deficiency was established years ago. Since then two other fairly distinct syndromes have emerged: the McLeod syndrome and autosomal recessive chorea-acanthocytosis.

Chorea-acanthocytosis (ChAc)

Chorea-acanthocytosis (ChAc; also referred to as Critchley–Levine syndrome; OMIM #200150) is a multisystem degenerative neurological disorder associated with acanthocytosis in the absence of any lipid abnormalities. ChAc was first described in the late 1960s by Estes and co-workers (1967) as well as by Critchley *et al.* (1968) and Levine *et al.* (1968) in two American kindreds with very similar features. ChAc is a very rare disease, but seems

to be particularly common in the Japanese population (Oshima *et al.*, 1985). The mean age of onset is around 32 years, but it can occur between the first and the seventh decade (Hardie *et al.*, 1991; Rampoldi *et al.*, 2001). The clinical symptoms include a hyperkinetic movement disorder, epileptic seizures, psychiatric symptoms and elevated serum creatine kinase. A full spectrum of movement disorders may be observed including tics, dystonia, akinetic-rigid syndrome and, most typical, chorea affecting the limbs (predominantly the legs) that resembles that seen in Huntington's disease (Bohlega *et al.*, 2003; Bostantjopoulou *et al.*, 2000; Hardie *et al.*, 1991; Spitz *et al.*, 1985). The characteristic and sometimes predominant orofacial and lingual movement abnormalities may cause vocalizations, dysarthria, dysphagia with feeding problems and severe orofacial self mutilations (Hardie *et al.*, 1991). Epileptic seizures have been reported in about half of the cases (Hardie *et al.*, 1991; Kazis *et al.*, 1995). Chronic axonal polyneuropathy with secondary demyelination with predominant involvement of the large diameter myelinated fibers in nerve biopsy studies have also been reported (Spencer *et al.*, 1987). Personality and behavioral changes as well as cognitive impairment with dementia in the late stages are common (Danek *et al.*, 2001; Hardie *et al.*, 1991; Kartsounis & Hardie, 1996). Psychiatric symptoms can comprise paranoia, depression, anxiety and emotional instability (Kartsounis & Hardie, 1996). In all cases there are signs of frontal lobe impairment. Biochemical findings include elevated creatine kinase levels in nearly all patients (Hardie *et al.*, 1991) as well as elevated liver enzymes and signs for an intravascular hemolysis in some cases. Serum lipid electrophoresis findings are normal.

Neuroimaging studies using computed tomography and magnetic resonance tomography in ChAc revealed caudate and generalised cerebral atrophy as well as hyperintensive signal changes in T₂-weighted images in the caudate and

Table 59.1. Neuroacanthocytosis syndromes

Syndrome	Gene	Locus	Protein	Inheritance	Reference
Chorea-acanthocytosis (ChAc)	<i>CHAC</i>	9q21	Chorein	autosomal recessive	Rampoldi <i>et al.</i> , 2001; Rubio <i>et al.</i> , 1997; Ueno <i>et al.</i> , 2001

HARP syndrome	<i>PANK2</i>	20p13–p12.3	Pantothenate kinase 2	single case reports	Ching <i>et al.</i> , 2002

putamen in most cases (Hardie *et al.*, 1991; Okamoto *et al.*, 1997; Spitz *et al.*, 1985; Sorrentino *et al.*, 1999; Tanaka *et al.*, 1998). Positron-emission tomography (PET) studies have shown reduced blood flow and oxygen consumption in all brain areas, but particularly in the caudate nucleus, putamen and frontal cortex (Delecluse *et al.*, 1991; Dubinsky *et al.*, 1989; Tanaka *et al.*, 1998). Studies using ¹⁸F-dopa, ¹¹C-raclopride and PET scans demonstrated presynaptic dysfunction only in the posterior putamen, similar to the findings in patients with Parkinson's disease, and a marked reduction of dopamine D2-receptor binding sites in the putamen and caudate nucleus (Brooks *et al.*, 1991). These observations are consistent with neuropathological data (Bird *et al.*, 1978; Hardie *et al.*, 1991; de Yebenes *et al.*, 1988; Rinne *et al.*, 1994). Consistently, in postmortem studies the most consistent neuropathological finding is an extensive neuronal loss and gliosis in the caudate and putamen, pallidum and *substantia nigra* and milder loss in the thalamus (Rinne *et al.*, 1994). The subthalamic nucleus, cerebral cortex, pons and cerebellum seem to be spared (Hardie *et al.*, 1991; Rinne *et al.*, 1994).

In a linkage study in 11 families of different geographical origin the ChAc locus was mapped to chromosome 9q21 (Rubio *et al.*, 1997). Recently two research groups have identified a novel gene mapping in this region (named *CHAC* gene) and found mutations in ChAc patients (Rampoldi *et al.*, 2001; Ueno *et al.*, 2001). The *CHAC* gene is organized in 73 exons over a chromosomal region of 250 kb.

CHAC expression could be detected in all tissues investigated, in particular in those tissues that are mainly affected in ChAc, such as brain, skeletal muscle, liver and erythroid precursors. Seventy-one mutations in the *CHAC* gene have been reported so far in patients with autosomal recessive ChAc (Rampoldi *et al.*, 2001; Ueno *et al.*, 2001; Dobson-Stone *et al.*, 2002) including deletions or insertions leading to frameshifts, splice-site mutations as well as nonsense/missense mutations. All mutations may lead to degradation of the corresponding mRNA through nonsense-mediated mRNA decay or to production of a truncated protein. These results implicate a loss of function as the pathophysiological mechanism making it difficult to establish any genotype–phenotype correlation. Although most cases of ChAc are transmitted as an autosomal recessive trait, some cases with similar clinical features have been reported to be inherited as an autosomal dominant trait (Hardie *et al.*, 1991; Marson *et al.*, 2003; Saiki *et al.*, 2003). Saiki and co-workers reported a single heterozygous mutation in the last nucleotide of exon 57 of the *CHAC* gene in autosomal dominant ChAc, most likely leading to skipping of the exon (Saiki *et al.*, 2003).

The *CHAC* gene product was named chorein (Ueno *et al.*, 2001), but its function is currently unclear. Amino acid sequence analysis does not reveal conserved domains, motifs or identifiable structural features. However, hints for understanding the function of chorein come from functional studies of its homologue in *Dictyostelium* (TipC)

and *Saccharomyces cerevisiae* (Vps13). Both proteins most likely play important roles in proper intracellular trafficking of different proteins between subcellular structures, such as the trans-Golgi network and the pre-vacuolar compartment, corresponding to the late endosome in animal cells (Raymond *et al.*, 1992; Stege *et al.*, 1999; Nakayama, 1997). Thus, chorein might control the cycling of proteins through the trans-Golgi networks and the late endosome, lysosomes and the plasma membrane. However, analysis of the function of the chorein molecule in mammalian cells is warranted to establish its physiological roles as well as the pathophysiological mechanisms leading to ChAc.

Acanthocytosis is observed in all patients with ChAc and is one of the hallmarks of this disorder (Hardie *et al.*, 1991; Brin, 1993; Feinberg *et al.*, 1991), but in some cases it can occur late during the course of the disease (Sorrentino *et al.*, 1999). The percentage of acanthocytes in the blood of ChAc patients is highly variable, usually between 5% and 70%, and does not seem to correlate with the severity of the disease. Furthermore, the percentage of acanthocytes markedly depends on the method by which red blood cell morphology is investigated. Due to experimental artefact and the occurrence of echinocytes, normal levels of acanthocytes in fresh blood samples using standard dry blood smears could be up to 3% in adult peripheral blood (Hardie *et al.*, 1991; Storch *et al.*, 1998; Storch & Schwarz, 2003). However, this method seems to be not efficient enough to detect acanthocytosis in all patients with ChAc (Feinberg *et al.*, 1991; Storch *et al.*, 2003; Storch & Schwarz, 2003). Feinberg and co-workers (1991) introduced a method utilizing the phenomenon that acanthocytes show a dramatic increase in their sensitivity to echinocytic stress of isotonic dilution of the blood sample (Feinberg *et al.*, 1991; Morrow & Andersen, 1986). Using a similar method, Storch and co-workers were able to detect significant acanthocytosis (between 10.5 and 72% of red blood cells) in all genetically confirmed ChAc patients tested (Storch *et al.*, 2003). To date, only two cases have been reported to have typical neurological symptoms of CHAC in the absence of significant acanthocytosis (Malandrini *et al.*, 1993; O'Brien *et al.*, 1990). However, it is not known whether the authors performed sensitive methods to detect acanthocytosis in these cases, such as the method by Feinberg and co-workers (1991). The mechanism of acanthocyte formation in ChAc is not known, but available data suggest that the protein content of the erythrocyte membrane is responsible for the morphological changes (Asano *et al.*, 1985; Clark *et al.*, 1989; Oshima *et al.*, 1985; Sakai *et al.*, 1991; Ueno *et al.*, 1982). It is hypothesized that impaired intracellular trafficking of membrane proteins, such as band 3 protein or furin-like proteases, to the plasma membrane due to the lack of

chorein function leads to reduced membrane fluidity and destabilization of its structure with subsequent acanthocyte formation.

McLeod syndrome

The McLeod syndrome (OMIM #314850), first described in 1961 and named after the proband (Allen *et al.*, 1961), is a rare X-linked recessive abnormality of the Kell blood group system of erythrocyte antigens in which red blood cells have no detectable Kx and all Kell antigens are expressed weakly. It is characterized by choreic movements, myopathy, cardiomyopathy, peripheral neuropathy, elevated creatine kinase levels, permanent hemolysis and acanthocytosis (Danek *et al.*, 1994, 2001; Malandrini *et al.*, 1994; Wimer *et al.*, 1977). These features can be very similar to those seen in ChAc, but severe orofacial dystonia and self-mutilations seem to be rare. However, the neurological phenotype is heterogenous and the incidence of neurological abnormalities in McLeod syndrome is unknown. The mean age of onset is in the fifth decade of life, but it can occur between the second and seventh decade (Danek *et al.*, 2001). The neurological features of genetically confirmed McLeod patients and an extensive genotype-phenotype correlation was reported by Danek and co-workers in 2001 (Danek *et al.*, 2001). Chorea of arms and legs occurs in all patients with McLeod syndrome, whereas dystonia and epileptic seizure are reported only in some patients. Cognitive impairment and psychological disturbances are found in about half of the patients in the late stage of the disease (Danek *et al.*, 1994). Muscle weakness and muscular atrophy as well as cardiomyopathy are reported in two-thirds of the patients. Consistently, muscle biopsy studies showed myopathic changes mainly of type 2 fibers without changes of dystrophin expression (Danek *et al.*, 1990; Carter *et al.*, 1990). Areflexia showing involvement of peripheral nerves is common in McLeod syndrome. Electrophysiological and nerve biopsy studies demonstrated primary axonal degeneration (Danek *et al.*, 2001; Witt *et al.*, 1992). Serum creatine kinase is usually slightly elevated. Female carriers are usually asymptomatic, but can show mild symptoms according to the degree of inactivation of the X chromosome carrying the mutant XK gene.

Neuroimaging studies using computed tomography and magnetic resonance tomography revealed atrophy of the caudate nucleus and hyperintensive signals in T₂-weighted images in the lateral putamen in the majority of patients (Danek *et al.*, 1994; Malandrini *et al.*, 1994). Dopamine D₂-receptor single-photon computed tomography (SPECT) studies showed diffuse reduction in dopamine

D₂-receptor binding in caudate and putamen, suggesting a cell loss in these brain regions (Danek *et al.*, 1994). PET analysis demonstrated absent metabolism in the basal ganglia and hypometabolism in the frontal and parietal cortex (Dotti *et al.*, 2000; Jung *et al.*, 2001).

The McLeod locus was mapped to chromosome Xp21 in 1988 (Bertelson *et al.*, 1988; Ho *et al.*, 1992). Subsequently, Ho and co-workers found mutations in the *XK* gene encoding for Kx in McLeod patients (Ho *et al.*, 1994; Khamlichi *et al.*, 1995). To date, over 20 mutations including deletions, splice-site mutations and missense mutations have been reported (Danek *et al.*, 2001; Dotti *et al.*, 2000; Ho *et al.*, 1994, 1996; Jung *et al.*, 2001). They seem to be distributed throughout the *XK* gene. Since all gene defects lead to a loss of *XK* gene function, there is no relevant genotype–phenotype correlation (Danek *et al.*, 2001). There is one report of McLeod phenotype caused by a *XK* missense mutation (E327K), but without hematologic (that means without acanthocytosis), neuromuscular or cerebral involvement (Jung *et al.*, 2003). So far, a single female patient with complete absence of Kx antigen expression has been reported (Hardie *et al.*, 1991; Ho *et al.*, 1996). Molecular biology and biochemistry studies demonstrate a tight linkage between the Kx and the Kell protein suggesting a disulfide bridge-bounded Kell–Kx–protein complex (Branch *et al.*, 1985; Khamlichi *et al.*, 1995). However, there are controversial results whether this linkage is needed for the localisation of both proteins on the plasma membrane (Branch *et al.*, 1985; Khamlichi *et al.*, 1995; Russo *et al.*, 1994, 1999). The exact functions of the Kell and Kx protein are not completely known. The Kell protein share homology and structural similarities with M13 metalloproteases, a subtype of zinc endopeptidases (Lee *et al.*, 1999). M13 proteases usually activate bioactive peptides by proteolytic cleavage and indeed, the Kell protein preferentially cleaves large endothelin-3 into the active peptide endothelin-3 (Lee *et al.*, 1999). The Kx protein has sequence homology with the CED-8 protein from *C. elegans*, which is mainly involved in the regulation of apoptosis (Stanfield *et al.*, 2000). The Kx and Kell protein are expressed in tissues that are mainly affected in McLeod syndrome, namely brain, skeletal muscle and cardiac muscle (Russo *et al.*, 2000). However, the pathophysiological mechanisms by which the mutations in the *XK* gene lead to the clinical spectrum of the McLeod phenotype are presently unclear.

Acanthocytosis is found in the majority of patients with McLeod syndrome with levels ranging from 3 to 40% (Danek *et al.*, 2001; Wimer *et al.*, 1977). Ultrastructural studies of red blood cell membranes showed a similar result as those found in ChAc erythrocytes suggesting some membrane instability and impaired membrane fluidity (Terada *et al.*,

1999). These changes are most likely due to the lack of both the XK protein and the Kell antigens, which are associated with the membrane cytoskeleton.

Hypolipoproteinemias

Abetalipoproteinemia (OMIM #200100) is an autosomal recessive disorder characterised by fat malabsorption, pigmentary retinal degeneration, progressive ataxia, neuropathy and acanthocytosis (Bassen & Kornzweig, 1950). Age of onset is usually in the first few years of life. Serum lipoproteins containing apolipoprotein B, low-density lipoproteins (LDL) and very low-density lipoproteins (VLDLs), are absent, which leads to severe impairment of both fat absorption and transport from the intestine. This results in very low serum levels of triglycerides, cholesterol and the fat-soluble vitamin E. The clinical spectrum is heterogeneous and includes steatorrhoea and failure to thrive due to fat malabsorption in childhood as well as spinocerebellar degeneration with ataxia, neuropathy and visual loss due to retinal degeneration in young adults. The neurological symptoms are related to the deficiency of vitamin E (Kayden & Traber, 1993) and can indeed be reversed by vitamin E supplementation (Muller *et al.*, 1985). Neuropathological studies demonstrate degeneration of the posterior columns of the spinal cord and spinocerebellar tracts, but the cerebellum seems to be spared (Harding, 1987; Nelson *et al.*, 1981). These pathological changes are similar to those seen in vitamin E deficient mammals. In contrast, the retinal pigmentary degeneration is thought to be caused by combined deficiency of vitamin A and E. Consistently, vitamin A treatment is able to restore retinal function only in the early stages of the disease, but combined treatment with both vitamin A and E has been shown to slow down retinal degeneration in the long run (Bishara *et al.*, 1982).

Abetalipoproteinemia is caused by mutations in the *MTP* gene encoding for the microsomal triglyceride transfer protein (MTP; Sharp *et al.*, 1993; Shoulders *et al.*, 1993). The *MTP* gene is localized on chromosome 4q22–24 and organized in 18 exons (Sharp *et al.*, 1993). It is expressed in enterocytes and hepatocytes and to a lower extent in kidney and cardiac muscle (Wetterau *et al.*, 1992). Over twenty mutations in the *MTP* gene have been reported in abetalipoproteinemia, which seem to be mainly clustered in the middle and C-terminal regions of the protein (Ohashi *et al.*, 2000; Sharp *et al.*, 1993; Shoulders *et al.*, 1993). These reported mutations are single-base insertions or deletions, slicing mutations and nonsense mutations as well as mutations in the non-coding highly conserved promoter region of the *MTP* gene. The MTP protein is involved in the translocation

of apolipoprotein B across the endoplasmic reticulum membrane and its assembly with lipids (Liang & Ginsberg, 2001; Jamil *et al.*, 1998). Thus, the assembly and secretion of apolipoprotein B-containing lipoproteins in hepatocytes is impaired leading to complete absence of these lipoproteins as well as reduction of vitamin E in the serum of abetalipoproteinemia patients.

Familial hypobetalipoproteinemia (OMIM #107730) is a genetically distinct condition, which is an autosomal codominant disorder characterized by extremely low serum levels of apolipoprotein B (Kayden & Traber, 1993; Linton *et al.*, 1993). Homozygotes are clinically indistinguishable from patients with abetalipoproteinemia, but the neurological involvement is usually less severe. As in abetalipoproteinemia, the clinical spectrum is most likely related to intestinal malabsorption of vitamin E and can therefore be prevented by vitamin E supplementation (Harding, 1987; Kayden & Traber, 1993; Linton *et al.*, 1993). Heterozygotes are normally asymptomatic without acanthocytosis, and serum concentrations of triglycerides, LDL cholesterol and VLDLs are all low but detectable.

In most cases, hypobetalipoproteinemia is caused by mutations in the *APOB* gene on chromosome 2p23–24 encoding for apolipoprotein B, the main apolipoprotein of chylomicrons and LDLs (Ross *et al.*, 1988). Since the first description of the gene defect causing hypobetalipoproteinemia by Young and co-workers (1987, 1988), more than 40 different mutations have been reported. Most of these are nonsense or frameshift mutations resulting in the production of truncated forms of apolipoprotein B (Linton *et al.*, 1993; Farese *et al.*, 1992; Ross *et al.*, 1988). Other defects affecting the rate of synthesis or removal of lipoproteins are emerging (Welty *et al.*, 1998; Wu *et al.*, 1999; Yuan *et al.*, 2000).

Significant acanthocytosis of between 50 and 90% of the red blood cells is commonly observed in hypobetalipoproteinemias and is most likely due to altered lipid composition of the plasma membrane. Indeed, biochemical studies in both conditions showed an increase of sphingomyelin levels and the sphingomyelin/lecithin ratio as well as a decrease of linoleic acid content of the erythrocyte membrane (Cooper *et al.*, 1977; Iida *et al.*, 1984). These alterations are known to affect the fluidity of lipid bilayers such as cell membranes.

Other rare neuroacanthocytosis syndromes

Pantothenate kinase-associated neurodegeneration (PKAN; also referred to as Hallervorden–Spatz disease or late infantile neuroaxonal dystrophy; OMIM #234200)

is characterized by a progressive neurodegenerative syndrome including generalized dystonia with predominance of oromandibular muscles, rigidity, choreic and/or athetoid involuntary movements, behavioral changes followed by dementia and retinal pigmental degeneration (Hayflick, 2003). PKAN has been found to be associated with acanthocytosis in several patients (Köhler, 1989; Luckenbach *et al.*, 1983; Malandrini *et al.*, 1996; Orrell *et al.*, 1995; Roth *et al.*, 1971; Swisher *et al.*, 1972). All of these patients had normal serum lipoproteins, but six had pigmentary retinopathy. Zhou and co-workers identified causative deletions, missense and null mutations in the pantothenate kinase gene *PANK2* in patients with classical and atypical Hallervorden–Spatz disease (Zhou *et al.*, 2001). A point mutation (R371X) in the same gene causes the allelic disorder HARP syndrome (hypoprebetalipoproteinemia, acanthocytosis, retinitis pigmentosa and pallidal degeneration; OMIM #607236; Higgins *et al.*, 1992; Orrell *et al.*, 1995; Ching *et al.*, 2002).

Walker *et al.* (2002) reported a kindred with an autosomal-dominant inherited progressive neurodegenerative syndrome including chorea, dementia, parkinsonism and acanthocytosis. Autopsy in one patient revealed inclusion bodies immunoreactive to ubiquitin, polyglutamine repeats and torsinA in several areas of the cerebral cortex. Subsequent molecular genetic analysis identified repeat extensions in the *JPH3/HDL2* gene encoding junctophilin-3 as shown for Huntington's disease-like type 2 (HDL2; Holmes *et al.*, 2001; Walker *et al.*, 2003). Since investigations of red blood cell morphology in other HDL2 families did not show acanthocytosis (Walker *et al.*, 2003), it is currently unclear whether the HDL2 phenotype does not necessarily include acanthocytosis or whether acanthocytosis is a feature independent from HDL2 genotype in the kindred reported by Walker and co-workers (2002).

Wolman's disease is a fatal disorder characterized by the absence of lysosomal acid lipase activity and accumulation of cholesteryl esters and triacylglycerols caused by mutations in the gene encoding for the lysosomal acid lipase (Wolman, 1995). Eto and Kitagawa (1970) described a disorder with features of malabsorption of lipids, vomiting, growth failure, and adrenal calcification. Hypolipoproteinemia and acanthocytosis suggest this is an entity distinct from Wolman's disease, but might be related to the dyslipoproteinemias (OMIM #278100; Eto & Kitagawa, 1970).

Lerche and co-workers recently described one kindred with a novel autosomal dominant neuroacanthocytosis syndrome with exertion-induced paroxysmal dyskinesias and epileptic seizures (Lerche *et al.*, 2000). The onset is during young childhood without relevant progression.

All affected family members had normal neurological examination, normal serum lipoproteins and the McLeod phenotype was absent. The causative gene defect is unknown.

Introduction

Iron is an essential transition metal required for the binding and activation of dioxygen in a series of critical transport and redox reactions. The facile electron chemistry of iron also accounts for the toxicity of this metal and therefore intricate pathways have evolved to allow for the transport, trafficking and compartmentalization of iron within cells (Kaplan, 2002a). These pathways prevent the formation of iron-induced reactive oxygen intermediates that contribute to the pathogenesis of tissue injury in inherited disorders of iron homeostasis such as hemochromatosis with resultant cirrhosis, diabetes and cardiac failure (Lee *et al.*, 2002). Within the central nervous system, iron is required for critical, diverse processes including neurotransmitter biosynthesis, myelin formation and nitric oxide signaling, as well as oxidative phosphorylation essential for sustaining brain energy requirements (Sipe *et al.*, 2002). Despite this critical role of iron in brain function, the molecular and cellular details of iron metabolism within the human central nervous system remain poorly understood.

Iron uptake into the brain is dependent upon plasma transferrin and transferrin receptors localized to the microvasculature. Although both the apical membrane divalent iron transporter DMT1 and the basolateral transporter ferroportin are expressed within the central nervous system, the precise role of these proteins in brain iron homeostasis is currently unknown (Sipe *et al.*, 2002). The intracellular iron binding protein ferritin is abundantly expressed in neurons and glia and presumably serves as the major source of iron storage within these cells. Iron deficiency in the developing human has been clearly established as a causative factor in long-term developmental and cognitive impairment. In contrast, while several prominent neurodegenerative disorders including Alzheimer's

disease and Parkinson's disease have been reported to be associated with excessive iron accumulation in specific brain regions the relationship of this accumulation to the disease pathogenesis is far from clear. The recent molecular characterization of two inherited neurodegenerative disorders with impaired iron metabolism, neuroferritinopathy and aceruloplasminemia, as well as the elucidation of the molecular genetic basis of a third neurodegenerative disease, Hallervorden–Spatz syndrome, with evidence of excess brain iron, has now provided new insights into the pathways of brain iron metabolism and the role of iron accumulation in brain pathology.

Neuroferritinopathy

Neuroferritinopathy is an adult-onset, autosomal dominant neurodegenerative disorder resulting from a mutation in the gene encoding the light chain of the iron storage protein ferritin (Curtis *et al.*, 2001; Crompton *et al.*, 2002). Recognition of this disorder as a unique neurodegenerative disease emerged from careful clinical observations of patients in the Cumbrian Lake District of northwest England. The proband was noted to have bradykinesia and dystonia and was originally considered to have Huntington's disease based upon a strong family history of affected individuals with choreiform movement abnormalities (Crompton *et al.*, 2002). Of note, her cognitive functions were entirely preserved and extensive review of the pedigree revealed chorea, dystonia and Parkinsonian features appearing in multiple family members in the fourth or fifth decade of life in a pattern consistent with autosomal dominant inheritance. Extensive genome linkage analysis eventually localized the affected region to chromosome 19q13.3 and analysis of candidate genes within this region resulted in the detection of a mutation in

exon 4 of the ferritin light chain gene (Curtis *et al.*, 2001). The mutation is a single base pair insertion that alters the reading frame, replacing the carboxyl-terminal 22 amino acids with a novel sequence of 26 amino acids observed only in affected family members. Further analysis of patients from Northern England and France has identified this same mutation in a dozen additional cases. Haplotype analysis suggests that in each case these affected families have arisen from a common distant founder.

As noted above, neuroferritinopathy is a movement disorder that usually presents in the fourth or fifth decade, although some patients have been identified clinically in adolescence. Unlike aceruloplasminemia (see below) there are no systemic signs or symptoms and the abnormalities of the clinical exam are entirely confined to the central nervous system. All patients identified thus far have presented with chorea, dystonia or bradykinesia and the movement disorders are most predominant in the face and upper extremities, often asymmetrical (Crompton *et al.*, 2002). Biochemical analysis of affected patients reveals a reduced serum ferritin concentration (usually <200 µg/dl) but otherwise normal iron parameters and no evidence of anemia or other hematological abnormalities. Neuropathological examination of brain tissue reveals extracellular iron accumulation in the basal ganglia, forebrain and cerebellum with cystic axonal degeneration. Consistent with these observations, magnetic resonance imaging reveals increased T₂ signal in the basal ganglia. Conventional neurological treatments aimed at reducing bradykinesia and choreiform movements have been minimally effective and most patients show rapid progression from onset of symptoms. Trials of iron depletion with chelation and phlebotomy are currently under way with the hope of ameliorating disease progression in affected patients or preventing symptom development in genetically identified presymptomatic individuals.

The molecular pathogenesis of neuronal injury in neuroferritinopathy has not been elucidated but is undoubtedly related to the critical role of ferritin in cellular iron storage (Torti & Torti, 2002). Ferritin is a heteropolymer consisting of both H and L ferritin chains and it seems possible that the acquired change in the L chain carboxyl terminus must interfere with the ability of the polymer to collect, store and release iron under the appropriate physiological signals. As noted above, free iron in the presence of oxygen will catalyze the production of tissue-damaging free radicals and at the present time this is the most likely mechanism for neurodegeneration in affected individuals. While the molecular characterization of this disease clearly reveals the critical role for ferritin in central nervous system iron homeostasis, further work will be needed to define the molecular details

of how this mutation leads to the observed pathological changes. Nevertheless, the striking similarities to both the clinical and pathological findings in patients with aceruloplasminemia, reinforces the concept that this rare disorder will be of fundamental importance in our elucidation of the normal mechanisms of brain iron metabolism and the role of this metal in the pathogenesis of neurodegenerative diseases.

Aceruloplasminemia

Aceruloplasminemia is an autosomal recessive disorder of iron homeostasis due to loss-of-function mutations in the gene encoding ceruloplasmin. Clinical presentation is in adulthood with neurologic features of dystonia, dementia and dysarthria accompanied by diabetes and retinal degeneration. Laboratory findings include microcytic anemia, marked elevation in serum ferritin and absent serum ceruloplasmin ferroxidase activity. Consistent with the neurological features, iron accumulation is observed as a low-intensity signal within the basal ganglia on T₁- and T₂-weighted magnetic resonance imaging and histological studies reveal abundant iron within astrocytes and neurons in these regions (Nittis & Gitlin, 2002). Elucidation of the molecular pathogenesis of this disease has revealed an essential role for ceruloplasmin in iron homeostasis and provided new insights into the mechanisms of brain iron metabolism.

Ceruloplasmin

Ceruloplasmin is a member of the evolutionarily conserved multicopper oxidase enzyme family characterized by three types of spectroscopically distinct copper. This protein functions as a ferroxidase, utilizing the electron chemistry of bound copper ions to couple the oxidation of Fe²⁺ to the reduction of oxygen bound to a trinuclear copper cluster (Calabrese *et al.*, 1989). Ceruloplasmin is synthesized predominantly in hepatocytes where copper is incorporated into the apoprotein late in the secretory pathway prior to secretion of the holoprotein into the plasma (Sato & Gitlin, 1991; Hellman *et al.*, 2002a). The mature holoprotein has a half-life of greater than five days in the plasma and metabolic studies indicate little or no exchange of the bound copper following secretion (Hellman & Gitlin, 2002). While the availability of copper within hepatocytes has no direct effect on the rate of ceruloplasmin synthesis or secretion, impairment of copper incorporation during synthesis results in secretion of an apoceruloplasmin moiety that is rapidly degraded in the plasma and lacks any ferroxidase

Ceruloplasmin

Transferrin

(D) *In situ* hybridization of transferrin mRNA in these same sections revealing transferrin gene expression within oligodendrocytes (arrowhead) but not the astrocytes shown to express ceruloplasmin (arrows). Modified and reproduced with permission (Klomp & Gitlin, 1996).

activity. As a result, any genetic or metabolic condition that impairs copper availability to the hepatocyte secretory pathway, as occurs in Wilson disease and nutritional copper deficiency, will result in a substantial decrease in the concentration of serum ceruloplasmin.

Although hepatocyte synthesis and secretion accounts for the majority of ceruloplasmin detected in the plasma, this protein is also synthesized in other cell types, including macrophages, present in extrahepatic tissues (Klomp *et al.*, 1996). Within the human central nervous system, ceruloplasmin is synthesized by astrocytes in multiple locations including the brain microvasculature, the basal ganglia and Müller glial cells of the retina (Fig. 60.1) (Klomp & Gitlin, 1996). Astrocytes have been shown to synthesize a distinct isoform of ceruloplasmin containing a glycoposphatidylinositol (GPI) membrane anchor arising from an alternative splicing event and accounting for the majority of ceruloplasmin present in the central nervous system (Patel & David, 1997; Patel *et al.*, 2000; Hellman *et al.*, 2002b). Although the precise role of this isoform in brain iron homeostasis is not established, recent studies indicate that GPI-linked ceruloplasmin is directly associated on the astrocyte plasma membrane with the ferrous iron export protein ferroportin suggesting that the coordinated action of these two proteins is essential for Fe^{2+} efflux from these cells (Jeong & David, 2003). This GPI-linked isoform of ceruloplasmin is also detected in the Sertoli cells of the testis, a finding that may indicate a role for membrane anchored ceruloplasmin in the oxidation and mobilization of iron

at the blood–brain and blood–testis barriers (Fortna *et al.*, 1999).

As noted above, multicopper oxidases utilize the facile electron chemistry of bound copper ions to couple substrate oxidation to the four-electron reduction of dioxygen. These enzymes have been characterized from bacteria, fungi, yeast, worms and mammals where the specific substrates include manganese, iron, nitrate, bilirubin, phenols and ascorbate (Hellman & Gitlin, 2002). While ceruloplasmin is capable of oxidizing multiple different substrates in vitro, critical biochemical studies by Frieden showed that serum ceruloplasmin has a ferroxidase activity required to mobilize iron from the liver with subsequent incorporation of ferric iron into apotransferrin (Osaki *et al.*, 1966, 1971). The biological role of ceruloplasmin as a ferroxidase was demonstrated by Cartwright and colleagues in nutritional experiments using pigs. These investigators showed that copper deficiency results in a marked diminution in circulating serum ceruloplasmin in association with iron accumulation in parenchymal tissues and that administration of ceruloplasmin under these circumstances results in the prompt release of tissue iron with subsequent incorporation into circulating transferrin (Lee *et al.*, 1968; Roeser *et al.*, 1970).

Further support for the role of ceruloplasmin as a ferroxidase comes from genetic and functional studies of homologous multicopper oxidases. In *Saccharomyces cerevisiae* high-affinity iron uptake requires the ferroxidase activity of a plasma membrane multicopper oxidase termed Fet 3 with significant amino acid similarity to ceruloplasmin (Askwith *et al.*, 1994). The *sla* mouse, anemic at birth due to impaired iron uptake across the placenta and gastrointestinal tract, contains a deletion in the gene encoding the multicopper oxidase hephaestin (Vulpe *et al.*, 1999). Hephaestin is highly homologous to ceruloplasmin and is believed to be required for the oxidation of ferrous iron prior to transport of this metal across the basolateral surface of the enterocyte. Definitive proof of a physiological role for ceruloplasmin in iron homeostasis came with the elucidation of the molecular defect in patients with aceruloplasminemia (Yoshida *et al.*, 1995; Harris *et al.*, 1995).

Aceruloplasminemia: genetics

In 1987, Miyajima and colleagues reported the case of a 52-year-old woman from Hamamatsu who presented to their clinic with dystonia and dysarthria. Subsequent evaluation revealed the presence of diabetes, peripheral retinal degeneration, significant iron accumulation in the basal ganglia on MRI and a complete absence of serum ceruloplasmin (Miyajima *et al.*, 1987). Careful family studies in this original

case revealed that the absent serum ceruloplasmin was inherited in an autosomal recessive fashion. These findings were subsequently confirmed in a second case report of a similarly affected Japanese family as well as in two brothers from Belfast, Ireland who presented predominantly with signs of dementia (Logan *et al.*, 1994; Morita *et al.*, 1995). Given the proposed role of ceruloplasmin as a plasma ferroxidase, a direct connection was hypothesized between the absence of this protein and the iron accumulation in these patients. This concept was subsequently confirmed by molecular genetic analysis of these three original families, revealing loss-of-function mutations in the ceruloplasmin gene and leading to the characterization of this disorder as aceruloplasminemia (Yoshida *et al.*, 1995; Harris *et al.*, 1995, 1996). Although epidemiological studies in Japan suggest that this is a rare disease with an incidence of 1:500 000 in that country (Miyajima *et al.*, 1999), subsequent studies have now identified 26 distinct mutations in more than 30 affected families from around the world (Fig. 60.2) (Daimon *et al.*, 1995a, Hellman *et al.*, 2000, 2002a,b; Kohno *et al.*, 2000; Miyajima *et al.*, 1999; Okamoto *et al.*, 1996; Takahashi *et al.*, 1996; Yazaki *et al.*, 1998; Yonekawa *et al.*, 1999; Loreal *et al.*, 2002; Bosio *et al.*, 2002; Takeuchi *et al.*, 2002).

As anticipated for a rare disease, almost all mutations detected thus far are private to specific families where there is often a history of consanguinity. The ferroxidase activity of ceruloplasmin is dependent upon the trinuclear copper cluster, the ligands for which are encoded in part by exon 19 and thus each of the mutations identified thus far would be anticipated to result in complete loss-of-function (Fig. 60.2). Consistent with this concept, the clinical phenotype in affected patients shows little variation regardless of the specific mutation, a finding that also suggests minimal overriding influence of other genetic or environmental factors on the clinical outcome. While almost all patients have a complete absence of serum ceruloplasmin, a novel missense mutation at one of the type I copper binding sites (H978Q) has recently been reported to be associated with normal serum concentration of a ceruloplasmin moiety devoid of ferroxidase activity (Takeuchi *et al.*, 2002). This finding has important diagnostic implications, indicating that the presence of a normal serum ceruloplasmin concentration in a patient with otherwise typical clinical features of aceruloplasminemia requires assessment of ceruloplasmin oxidase activity before the diagnosis can be ruled out. While no mutations have been reported in exon 20, the alternative splice region resulting in GPI-linked ceruloplasmin and the predominate expression of this isoform only within the central nervous system suggests that such a mutation could result in the typi-

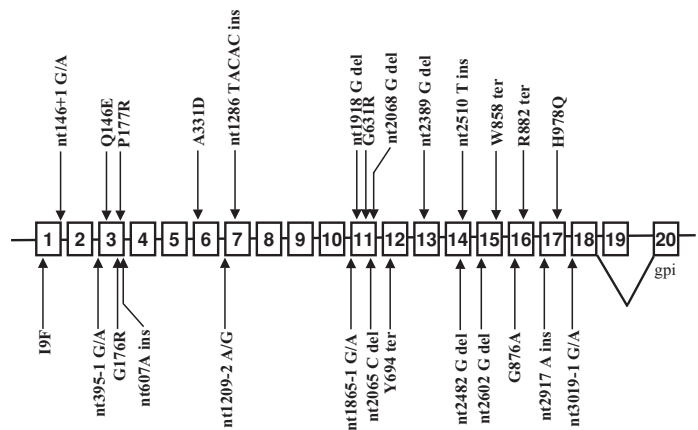

Fig. 60.2 Genetic mutations characterized in patients with aceruloplasminemia or family members. The structure of the human ceruloplasmin gene is shown with 20 exons as previously characterized (Daimon *et al.*, 1995b; Hellman *et al.*, 2002b). Alternative splicing at exon 18 allows for the secreted or GPI-linked ceruloplasmin isoforms as indicated. Mutations indicated are referenced in the text. Modified and reproduced with permission (Nittis & Gitlin, 2002).

cal neurologic features of aceruloplasminemia in a patient with normal serum ceruloplasmin oxidase activity and no evidence of diabetes (Fig. 60.2). Ceruloplasmin is a single copy gene in the human genome; however, the presence of a processed pseudogene on chromosome 8 encoding the carboxyl-terminal 563 amino acids of this protein must be taken into account in the development of strategies for molecular diagnostic testing (Koschinsky *et al.*, 1987).

Aceruloplasminemia: clinical features

Affected individuals present in the fourth or fifth decade of life with neurological signs and symptoms suggestive of basal ganglia disease, including subcortical dementia, dysarthria and dystonia (Gitlin, 1998; Miyajima *et al.*, 2003). These neurologic features are usually rapidly progressive and at the time of diagnosis invariably associated with evidence of brain iron accumulation within the basal ganglia on magnetic resonance imaging (Fig. 60.3). Cerebrospinal fluid analysis reveals no pleocytosis and normal glucose content with elevated protein and iron concentrations (Miyajima *et al.*, 1998). Ophthalmologic examination will usually reveal evidence of peripheral retinal degeneration secondary to iron accumulation and photoreceptor cell loss (Fig. 60.4). At autopsy the cut surface of the brain demonstrates dark pigmentation within the nuclei of the basal ganglia with cavitory degeneration in these regions (Fig. 60.4). Consistent with these findings, biochemical

Fig. 60.3 Histological and radiological analysis of a 52-year-old male with dysarthria, diabetes, elevated serum ferritin, absent serum ceruloplasmin and molecular genetic evidence of homozygosity for a single base pair insertion in exon 14 of the ceruloplasmin gene. (A) Normal liver histology on biopsy with no evidence of cirrhosis or fibrosis. (B) Perl's stain of liver biopsy section reveals marked iron accumulation within hepatocytes (arrowheads) and Kuppfer cells (arrows). (C) Magnetic resonance imaging at the time of diagnosis reveals signal attenuation in the basal ganglia consistent with iron accumulation. Modified and reproduced with permission (Hellman *et al.*, 2000).

Fig. 60.4 Ophthalmoscopic and autopsy findings in aceruloplasminemia. (A) Retinal examination with normal fundus and retinal vessels but peripheral retinal degeneration (arrows). (B) Coronal section of brain from affected patient indicating brown pigmentation of basal ganglia with cavitory degeneration of caudate nucleus and putamen (arrows) and subthalamic nuclei (arrowheads). (C) Histological analysis of putamen reveals regions of neuronal loss (arrows) without gliosis or inflammation. (D) Perl's stain from section of caudate nucleus revealing iron accumulation within microglia (arrowheads) and neurons (arrows). (B) Modified and reproduced with permission (Morita *et al.*, 1995).

studies reveal normal content of copper and zinc but marked elevation in the concentration of iron throughout the brain with the most significant increases (greater than ten-fold) within the basal ganglia (Morita *et al.*, 1995). Histological analysis of the central nervous system at autopsy illustrates areas of neuronal dropout with spongiform degeneration without evidence of gliosis or inflammatory cell infiltrate. Analysis of sections from the basal ganglia by Perl's stain indicates abundant iron accumulation within both glia and neurons with no extracellular metal accumulation (Fig. 60.4). Taken together, these pathological findings are consistent with a primary disorder of iron homeostasis resulting in iron accumulation and subsequent cellular injury and correlate with the signs and symptoms observed in affected patients. In accord with this model of cellular injury, brain tissue from affected patients demonstrates increased lipid peroxidation and impaired fatty acid oxidation (Kaneko *et al.*, 2002; Miyajima *et al.*, 2002).

Although the neurologic features dominate the clinical picture in most patients, all individuals will have evidence of systemic iron overload at the time of diagnosis. In some cases, patients have been initially recognized prior to the onset of neurologic symptoms due to biochemical abnormalities indicating abnormal iron metabolism. These laboratory findings include microcytic anemia, decreased serum iron content and increased serum ferritin concentration, usually greater than 1000 ng/ml (Miyajima *et al.*, 2003; Morita *et al.*, 1995). Liver biopsy samples reveal normal hepatic architecture and histology with no evidence of cirrhosis or fibrosis but invariably demonstrate excess iron accumulation within both hepatocytes and reticuloendothelial cells (Fig. 60.3). Although hepatic iron content is often elevated into the range observed hemochromatosis (>1500 $\mu\text{g}/\text{gram}$ dry weight), individuals with aceruloplasminemia never evidence hepatic dysfunction or cirrhosis, a finding that may reflect the marked accumulation of reticuloendothelial iron that is not observed in hemochromatosis. Aceruloplasminemia also results in insulin-dependent diabetes mellitus and patients will most often have overt diabetes or evidence of abnormal glucose tolerance with elevated hemoglobin A_{1c} at diagnosis. Autopsy examination has revealed significant iron accumulation within the endocrine portion of the pancreas with marked diminution in the β cell population within the islets of Langerhans (Kato *et al.*, 1997; Morita *et al.*, 1995).

The findings of absent serum ceruloplasmin and neurologic features of basal ganglia disease may lead to diagnostic confusion with Wilson disease. In such cases, the finding of half-normal serum ceruloplasmin in the parents or siblings in conjunction with decreased serum iron,

elevated serum ferritin, the presence of diabetes and MRI evidence of brain iron accumulation is useful in establishing the diagnosis of aceruloplasminemia. If patients with aceruloplasminemia are detected with abnormal parameters of iron metabolism prior to the onset of neurologic disease, diagnostic confusion with hemochromatosis may arise (Hellman *et al.*, 2000). In such circumstances the measurement of serum transferrin saturation is often useful as this will be elevated in all cases of hemochromatosis but decreased in aceruloplasminemia. Distinguishing between these conditions is important as phlebotomy, the primary treatment for iron overload in hemochromatosis, is ineffective in aceruloplasminemia and will eventually exacerbate the anemia as such individuals are unable to mobilize reticuloendothelial cell iron stores in response to blood loss. As noted previously, autosomal dominant inheritance of an insertional mutation in the gene encoding ferritin light chain results in a neuroferritinopathy characterized by basal ganglia symptoms and brain iron accumulation similar to that observed in aceruloplasminemia (Crompton *et al.*, 2002). Such patients present at a similar age as those with aceruloplasminemia but are distinguishable by the pattern of inheritance as well as decreased serum ferritin and the lack of diabetes or systemic iron overload. Genetic studies reported thus far have not revealed any evidence of ceruloplasmin gene polymorphisms or heteroallelic mutations influencing the outcome of more common disorders of iron homeostasis (Lee *et al.*, 2002). Although reports have identified neurologic abnormalities in several elderly individuals heterozygous for ceruloplasmin gene mutations, the relationship of this genetic finding to the underlying disease pathology has not been established (Daimon *et al.*, 1999; Miyajima *et al.*, 2001).

Aceruloplasminemia: pathogenesis

The distinct abnormalities of iron homeostasis observed in patients with aceruloplasminemia are most easily understood by considering the cellular physiology of systemic iron metabolism. Only a very small amount of the total iron utilized each day is derived from absorption, the overwhelming portion arising from recycling of heme iron as aging red blood cells are turned over within the reticuloendothelial system (Kaplan, 2002b). Iron recycled in this fashion is released from reticuloendothelial cells in the liver and spleen, bound to plasma transferrin and returned to the bone marrow for erythropoiesis. Ceruloplasmin functions as a critical factor in this cycle by establishing a rate of iron oxidation sufficient for sustaining iron release and uptake by transferrin. The lack of ceruloplasmin ferroxidase activity in patients with aceruloplasminemia results

Fig. 60.5 Plasma iron in wild-type and aceruloplasminemic mice following the administration of iron in the form of heat-damaged red blood cells. Arrow illustrates the time point of administration of human ceruloplasmin to aceruloplasminemic mice (apo or holo) as a single intraperitoneal dose calculated to increase the serum ceruloplasmin concentration by approximately 25%. Modified and reproduced with permission (Harris *et al.*, 1999).

in the slow but consistent accumulation of iron within compartments where this metal is normally made available for release following the turnover of red blood cells. This concept can be readily appreciated by examining the iron cycle in a murine model of aceruloplasminemia (Fig. 60.5). When iron is administered to wild-type mice in the form of heat-damaged red blood cells, these cells are rapidly catabolized within the spleen and the heme-bound iron is released and returned to the plasma. Aceruloplasminemic mice are incapable of raising the serum iron content under these circumstances as the iron remains trapped within the reticuloendothelial system. This defect is directly due to the lack of circulating ceruloplasmin ferroxidase activity as the administration of holo, but not apo, ceruloplasmin to these mice results in the prompt release of this stored iron as reflected by increase in plasma iron content equivalent to that observed in control animals (Harris *et al.*, 1999). Similar observations have been made upon the administration of fresh frozen plasma containing ceruloplasmin to affected patients (Logan *et al.*, 1994; Yonekawa *et al.*, 1999). This impairment in the rate of reticuloendothelial cell iron release results in microcytic anemia in affected patients and illustrates the reason for the ineffectiveness and potential dangers of phlebotomy. The lack of severe anemia in patients with aceruloplasminemia indicates that sufficient iron release can occur to permit some degree of

erythropoiesis, most likely due to alternative sources of ferroxidase activity such as citrate present in the plasma.

As noted above, iron also accumulates within hepatocytes, pancreatic endocrine cells and other systemic tissues in patients with aceruloplasminemia. Under these circumstances, the lack of plasma ferroxidase activity results in increased ferrous (Fe^{2+}) iron within the plasma that is then rapidly taken up from the circulation by hepatocytes and other cell types. This mechanism of iron accumulation has been well documented in atransferrinemia where serum transferrin binding capacity is absent and in hemochromatosis where the binding capacity is exceeded (Craven *et al.*, 1987). Fe^{2+} is transported into cells in a non-transferrin dependent manner by the cation transporter DMT1 that is expressed in most tissues and it is this protein that is most likely responsible for nonreticuloendothelial cell iron accumulation observed in aceruloplasminemia (Andrews, 2002). The mechanism of iron release from most cells, including those of the reticuloendothelial system, involves the basolateral transporter ferroportin (Donovan *et al.*, 2000; Abboud & Haile, 2000; McKie *et al.*, 2000). As noted above, this protein is associated with GPI-linked ceruloplasmin on astrocytes and is believed to function in conjunction with this ferroxidase in the transport of Fe^{2+} into the plasma with subsequent oxidation to Fe^{3+} for incorporation into transferrin (Jeong and David, 2003). Consistent with this model, mutations in the gene encoding ferroportin result in a syndrome of iron overload with increased reticuloendothelial cell iron, decreased transferrin saturation and intolerance to phlebotomy (Montosi *et al.*, 2001; Njajou *et al.*, 2001).

From a clinical perspective, the most striking and important feature of aceruloplasminemia is the accumulation of iron within the central nervous system. Indeed, with the exception of neuroferritinopathy, this is the only disorder of iron homeostasis that results in brain iron accumulation and neurodegeneration (Harris *et al.*, 1998). In contrast to the mechanisms of tissue iron overload in systemic tissues, this accumulation of iron in the central nervous system does not arise from the increased plasma ferrous iron, as brain iron is not increased in other disorders with a similar elevation in ferrous iron such as atransferrinemia and hemochromatosis. Likewise, the absence of plasma ceruloplasmin is not related to the pathogenesis of brain iron accumulation as this protein does not cross the blood-brain barrier. The abundant expression of ceruloplasmin by astrocytes, predominantly as the GPI-linked isoform, taken together with the known function of ceruloplasmin in the systemic circulation suggests that this isoform functions in an analogous fashion in the central nervous system to maintain a sufficient rate of iron release from storage cells with the retina and brain. This model of pathogenesis

implies the presence of a cycle of iron storage and reutilization within the central nervous system that is similar to but distinct from that in the systemic circulation that may be critical in minimizing the effects of systemic iron deficiency on brain function.

The mechanisms of neurodegeneration in aceruloplasminemia have not been defined but presumably are secondary to the slow but consistent accumulation of iron within neurons and glia. The excess glial iron could result in oxidative damage to this cell type with subsequent loss of glial-derived growth factors critical for neuronal survival. Alternatively, neuronal cell injury may result more directly from iron-mediated oxidation or from selective effects of iron deficiency in regions where glial cell iron can not be mobilized for uptake into neurons. A direct role of iron in oxidant-mediated neuronal injury is supported by findings of increased lipid peroxidation in the tissues of affected patients and in brain tissue and cells from a murine model of aceruloplasminemia as well as by studies that demonstrate some amelioration of neurologic symptoms following reduction of brain iron stores with systemic chelation therapy (Miyajima *et al.*, 2002; Miyajima *et al.*, 1997; Patel *et al.*, 2002). Specific mutations that result in impaired ceruloplasmin trafficking with retention of misfolded protein within the endoplasmic reticulum may also contribute to pathology within the central nervous system through conformation-induced cellular injury (Hellman *et al.*, 2002b). Effective therapy aimed at preventing neuronal injury in asymptomatic patients and ameliorating symptoms in those affected must await a more critical understanding of the molecular mechanisms of iron homeostasis within the central nervous system and the precise mechanisms of neurodegeneration in this disorder.

Hallervorden–Spatz syndrome

Hallervorden–Spatz syndrome is an autosomal recessive disorder due to mutations in the pantothenate kinase 2 gene and associated with marked basal ganglia iron accumulation (Zhou *et al.*, 2001; Hayflick *et al.*, 2003). The disorder encompasses a spectrum of presentations including the classic childhood form with dystonia, dysarthria and rigidity that is progressive and fatal as well as more atypical presentations with the onset of extrapyramidal symptoms later in life and a much less aggressive course. In all cases, iron deposition in the basal ganglia is detectable by magnetic resonance imaging. In the classical form of the disease, signs and symptoms of neurodegeneration usually occur within the first 5 years of life with the predominant features being dysarthria, dystonia, rigidity and

choreoathetosis. Dystonia often presents in the cranial and limb muscles and later progresses to axial involvement. Cognitive decline and retinopathy are also present as the disease progresses and despite some variation in the rate of deterioration most affected individuals are nonambulatory by early in the second decade. In all cases T₂ magnetic resonance imaging will reveal bilateral hyperintensity within an area of hypointense signal in the medial globus pallidus, the so-called “eye of the tiger” pattern. This specific image is highly diagnostic for Hallervorden–Spatz syndrome and appears to result from tissue necrosis and edema within a region of iron accumulation in the basal ganglia.

Molecular genetic analysis in a series of affected patients localized the gene to chromosome 20p13 and identified mutations in a novel pantothenate kinase (*PANK2*), proposed to be a key regulatory enzyme in the pathway of coenzyme A biosynthesis (Zhou *et al.*, 2001). All patients with the classical presentation of the disease analyzed thus far have mutations in the *PANK2* gene. A detailed clinical and molecular analysis of patients with the more atypical presentations noted above found mutations in *PANK2* in a subset of these individuals where speech disorders and psychiatric symptoms predominated (Hayflick *et al.*, 2003). Importantly, regardless of the clinical presentation, this analysis revealed complete correlation between the radiographic findings of the eye-of-the-tiger on magnetic resonance imaging of the brain and the presence of mutations in the *PANK2* gene. This finding is of diagnostic significance to clinicians and suggests a direct relationship between the alterations in pantothenate kinase function and the iron accumulation associated with the radiographic findings. Most patients with an atypical presentation were found to have missense mutations, raising the possibility that the delay in symptoms in such individuals arises from residual kinase activity. This finding raises the important therapeutic possibility that dietary availability of pantothenate as vitamin B₅ may prevent or ameliorate disease onset or neurodegeneration.

In contrast to neuroferritinopathy and aceruloplasminemia, clues to the pathogenesis of iron accumulation in Hallervorden–Spatz syndrome are not directly apparent from the molecular defect. Furthermore, given the very early age of onset with the classical disease compared to that observed in all other known metal storage diseases with tissue injury, and the presence of symptoms in some patients with an atypical presentation and normal brain iron content, arguments for any direct role of iron in the neurodegenerative process remain less persuasive. Nevertheless, pantothenate kinase deficiency is predicted to lead to abnormalities in brain citrate metabolism and it is possible that this metabolite may serve to inap-

propriately sequester iron within affected neurons (Zhou *et al.*, 2001). Obviously further metabolic studies and the development of appropriate animal models will permit a more direct analysis of the role of pantothenate kinase in brain iron metabolism. Despite some similarities of brain iron accumulation to those observed in patients with neuroferritinopathy and aceruloplasminemia, individuals with Hallervorden–Spatz syndrome may be differentiated by presentation in early childhood and the lack of any biochemical evidence of perturbation in systemic iron homeostasis.

Conclusions

Elucidation of the molecular genetic basis of these three neurodegenerative diseases has provided new insight into the function of ferritin and ceruloplasmin in brain iron homeostasis. Future efforts in this area are clearly warranted given the well recognized role of iron in early cognitive development as well as recent studies that implicate brain iron accumulation in the pathogenesis of neurodegeneration observed in Parkinson's, disease and Alzheimer's disease (Andrews, 2000; Kaur *et al.*, 2003). Specific research efforts must now focus on a critical understanding of the role of the basal ganglia in brain iron metabolism as well as the mechanisms underlying the unique susceptibility of this brain region to iron-mediated neurodegeneration. Careful analysis of human genetic diseases of iron metabolism will undoubtedly continue to provide answers and permit new insights into the neurobiology, pathogenesis and treatment of neurodegenerative diseases.

Acknowledgement

We gratefully acknowledge the contributions of our many colleagues around the world who have generously referred patients and shared ideas, including James Kushner, Fernando Perez-Aguilar, Grazia Mancini, Clara Camaschella, Wolfgang Stremmel, Massimo Pandolfo, John Logan and Hiroshi Morita as well as the numerous families and patients who have contributed to this work. Work from the author's laboratory reported in this review was supported in part by National Institute of Health Grant DK 61763.

Introduction

As a trace metal with several critical metabolic roles, copper is present throughout the brain (Warren *et al.*, 1960) and other organs as an essential element needed for maintaining health. This vital mineral enters the body as a dietary component readily absorbed in the small intestine. The body's load of copper is largely stored in the liver and other visceral organs. Systemic organ load of copper is normally regulated by the ability of the biliary system to excrete excess quantities (Frommer, 1974; Gibbs & Walshe, 1980). A failure of the body's mechanisms for eliminating copper is the characteristic feature of an uncommon but distinctive systemic disorder originally termed progressive hepatolenticular degeneration, or Wilson's disease (WD). The latter eponym, now widely used for this disorder, credits the man who discovered much of what we know today and helps to avoid a mistaken notion that excess copper deposition affects only the liver and brain. WD's manifestations throughout the body can be variable from patient to patient, and can include features listed in Table 61.1. In nearly all cases, the liver is a major target of WD. Death from hepatic WD is usually inevitable unless decoppering therapy is instituted early enough. Other systemic manifestations of WD, including its propensity for neurological involvement, can vary greatly among patients. In the pediatric population, hepatic damage is often a presenting feature of the disorder, while neurological impairment becomes increasingly more common with onset in the second or third decades of life.

The pathophysiology of WD is linked to failure in copper transport. Though vital for life in trace amounts, copper in excess quantities is toxic. Normally, ingested copper is excreted into the bile (Cartwright & Wintrobe, 1964). WD arises from an inability to accomplish adequate removal of

copper, leading to massive, toxic tissue deposition (O'Reilly *et al.*, 1971; Frommer, 1974; Gibbs & Walshe, 1980). While the defect in copper excretion in WD is likely a problem of protein complexing, all aspects of WD pathophysiology have not been worked out.

When first described in 1912 by the American–British neurologist Samuel Alexander Kinnier Wilson, WD was not known to have the massive tissue copper deposition that was finally recognized more than 30 years later (Cumings, 1948). Further investigation showed WD to be a direct consequence of the greatly enhanced copper concentrations in tissues. Normally, mechanisms are operative to exclude all but minute quantities of copper from all tissues of the body. In WD, tracer studies with radiolabelled copper have shown that regions correlated to WD symptomatology are at locations where the most of this trace metal has been deposited (Walshe & Potter, 1977). Prior to the development of effective decoppering agents, WD was incurable and progressive to death (Lichtenstein & Gore, 1955). Several treatment options have been devised in the past five decades that can dramatically reverse the natural history of this disease. It is now typical for WD patients to achieve at least a partial reversal of their neurological symptomatology as well as protection against further damage to the liver and other affected organs. The range of treatment options is discussed below, along with the diagnosis and pathophysiology of this disorder. WD is caused by one or more mutations in a copper transporting P-type ATPase called ATP7B, situated on chromosome 13q14.3 (Bull *et al.*, 1993; Yamaguchi *et al.*, 1993; Tanzi *et al.*, 1993). This location differs from the site for the structural gene of ceruloplasmin (CP), a liver-derived copper-binding protein whose serum concentrations are usually decreased in WD. While CP provides a useful screening marker for WD (see below), its deficiency does not appear to be involved in the pathophysiology of WD.

Table 61.1. A Survey of WD systemic manifestations (adapted from LeWitt and Pfeiffer, 2002)

Hematopoietic system: acute hemolytic anemia, Heinz body anemia, thrombocytopenia, splenomegaly (Deiss <i>et al.</i> , 1970; Goldman & Ali, 1991; Prella <i>et al.</i> , 2001)
Bone and connective tissue: Rickets, osteoarthritis, recurrent arthritis, bone fragmentation, chondrocalcinosis, osteoporosis, spinal degeneration, spontaneous fractures, spontaneous rupture of Achilles tendon (Kabra <i>et al.</i> , 1990; Dobyns <i>et al.</i> , 1979; Golding & Walshe, 1977; Feller & Schumacher, 1972; Hu, 1994; Menerey <i>et al.</i> , 1988; Olsen <i>et al.</i> , 1996; Balint & Szebenyi, 2000)
Kidney: Renal lithiasis, hematuria, hypercalcuria, nephrocalcinosis (Laufer <i>et al.</i> , 1992; Hoppe <i>et al.</i> , 1993)
Heart: Cardiomyopathy, left ventricular thickening, extrasystolic beats, supraventricular tachycardia (Hlubocka <i>et al.</i> , 2002)
Brain: Atrophy, necrosis, gliosis, demyelination, central pontine myelinolysis (see below)
Liver: Cirrhosis, acute hepatitis, ascites, cholelithiasis (Wilson, 1912; Goswami <i>et al.</i> , 2001)
Eye: Corneal (Kayser–Fleischer) rings; lens cataract (“star-burst” or “sunflower” appearance) (Heckmann <i>et al.</i> , 2000; Goyal & Tripathi, 2000; Patel & Bozdech, 2001; Deguti <i>et al.</i> , 2002)
Endocrine: Hypoparathyroidism, amenorrhea, diabetes (Erkan <i>et al.</i> , 2002); Pancreatic exocrine impairment (Owen, 1981)
Iron metabolism: Hemosiderosis (Knisely, 2001)
Splenic rupture (Ahmed & Feller, 1996)
Skeletal muscle: Acute rhabdomyolysis (Propst <i>et al.</i> , 1995)
Autonomic nervous system: Peripheral and central dysfunction (Meenakshi-Sundaram <i>et al.</i> , 2002; Bhattacharya <i>et al.</i> , 2002)

Excessive copper deposition exerts damage to brain, liver, and other organs. However, removing the excess quantities of this metal offers some recovery from organ damage and can be lifesaving for the patient with WD. Even with massive copper deposition, reversal of liver and brain damage manifestations is possible if decoppering treatment is instituted early enough. For this reason, the challenge posed by this rare, genetically determined disorder is strong diagnostic suspicion and adequate screening studies (Shale *et al.*, 1987). The protean features of WD include clinical syndromes that can closely mimic other disorders, including several neurological conditions much more benign than WD.

Effective treatment began a half-century ago once there was recognition of massive tissue copper deposition in WD. This finding led to medications for extracting systemic copper, a search that continues. These investigations have been augmented with the discovery of a genetic animal homologue of the human disorder, the Long-Evans Cinnamon rat (Sasaki *et al.*, 1994; Yamaguchi *et al.*, 1994). Several drugs

are now available to prevent intestinal absorption of copper, to enhance its urinary excretion, or to act by additional mechanisms to produce an anticopper effect. By creating a negative systemic copper balance, WD can be arrested from its otherwise inevitable progression. In the best of circumstances, much of the liver damage, neurological impairments, and other systemic features can be reversed if treatment is started early enough. Occasionally, almost complete recovery can be achieved. In general, certain neurological problems tend to persist, such as dystonic postures, dysarthria, and behavioral disturbances (Pellecchia *et al.*, 2003). With instances of rapid progression or hepatic failure, liver transplantation can be life-saving and can lead to recovery of severe neurological manifestations (Suzuki *et al.*, 2003). The range of therapeutic options is described in a later section.

Neurological manifestations of WD

In Western countries, neurological manifestations of WD most commonly appear in the second or third decades of life (Sternlieb *et al.*, 1985; Walshe & Yealland, 1992). In India and probably in other Eastern countries, the disease tends to occur in earlier age groups (Dastur *et al.*, 1968; Bhavé *et al.*, 1994, 1987). In general, neurological involvement tends to develop at a later age than cases of purely hepatic disease. Despite these generalizations, there is great variability reported in the age of onset for WD presenting with neurological impairments (from less than 5 years to greater than 50 (Fitzgerald *et al.*, 1975; Czlonkowska & Rodo, 1981; Ross *et al.*, 1985; Madden *et al.*, 1985; Piloni *et al.*, 2000)). The presenting neurological features of WD are typically one or more types of movement disorder often with an additional type of neurological deficit (Stremmel *et al.*, 1991). Some patients develop predominantly dystonic or Parkinsonian features, while others are affected more with bulbar dysfunction and a coarse, proximal action tremor. This type of tremor can be associated with other cerebellar dysfunction such as ataxic speech. Since this pattern of neurological WD resembles some common manifestations of multiple sclerosis, this category of WD was referred to as “pseudosclerosis” in the nineteenth century literature on WD (Westphal, 1883). In a more recent series, Walshe and Yealland (1992) found one-quarter of their patients had a “pseudosclerotic” syndrome, while Parkinsonian signs affected almost one-half and the remainder presented with primarily choreic or dystonic features.

In the original descriptions of Kinnier Wilson, this disorder presented insidiously with the problems of tremor, dystonia, rigidity, dysarthria, drooling, dysphagia, unsteady

gait, and mental deterioration (Wilson, 1912). The damaged structures Wilson found in the basal ganglia and elsewhere in the brain provided a correlation to the observed neurological deficits. In one series of 44 neurological WD cases, 12 presented primarily with impairments related to basal ganglia damage, 6 had cerebellar dysfunction, and 17 had a combination of these features (Dobyns *et al.*, 1979). The disruption of dopaminergic neurotransmission in striatal structures, as demonstrated in neuroimaging studies, probably contributes to the development of Parkinsonian features, dystonia, and dyskinesia in WD (Barthel *et al.*, 2001). Rarely, WD can be superimposed on another movement disorder such as essential tremor (Quinn *et al.*, 1986). This hereditary disorder can be a potentially confounding diagnostic feature in a family also affected with WD (Nicholl *et al.*, 2001). One of the curious features of WD is the considerable heterogeneity that can be observed among its manifestations in a family with several involved members. WD has a propensity for asymmetrical or focal deficits, despite neuropathological observations that virtually all cases of WD possess bilateral damage to the lenticular nuclei and other structures. As described below, there can also be extensive pathology found beyond the boundaries of the basal ganglia.

Of all the types of movement disorders that can evolve in neurological WD, tremor involving the hand is usually the first (Walshe, 1976, 1986). The tremor can be unilateral or bilateral, intermittent or continuous, or initiated only during specific motor tasks. Other locations for tremor include the head, trunk, or the tongue (Wilson, 1955; Topaloglu *et al.*, 1990). All categories of tremor (rest, postural maintenance, and action) have been observed in WD, sometimes in combination. The action tremor of WD can be similar to cerebellar disease. However, other typical signs of cerebellar dysfunction (such as dysdiadochokinesis, nystagmus, or the Holmes rebound sign) are generally lacking in the WD patient. Many observers have highlighted a characteristic pattern of tremor in WD, a coarse, irregular to-and-fro movement during action. With the arms held forward and flexed at the elbows, this maneuver can bring out a proximal tremor sometimes described as “wing-beating.”

In addition to tremor, another common presentation of neurological WD is motor dysfunction involving the bulbar musculature. Illustrated in Wilson's 1912 report was a dystonic alteration of the lower face, a fixed, “sardonic” smile with retracted lips and opened jaw. One series found bulbar motor impairment to be more common than tremor as an early feature of neurological WD (Starosta-Rubenstein *et al.*, 1987). Typical features of WD include drooling, dysarthria, various focal and segmental features of cranial dystonia, and pharyngeal dysmotility (Gulyas & Salazar-

Grueso, 1988). In addition, patients can exhibit facial grimacing, involuntary closure of the eyes (blepharospasm), and tongue dyskinesia (Liao *et al.*, 1991). With increasing rigidity of the oral musculature, patients can become unable to close their mouth. The sustained rigid states of cranial musculature can also exhibit spasmodic or jerking movements.

A progressive disturbance of speech is characteristic of WD. These problems include indistinct articulation, defective consonant production, “whispering dysphonia” (Parker, 1985), and slowed cadence of speech (Purdon Martin, 1968; Berry *et al.*, 1974). In its most severe form, the outcome can be complete loss of speaking capability (anarthria). The various elements of dysarthria arise from multiple regional disturbances in the control of facial and oropharyngeal musculature.

The varieties of motor impairment in WD sometimes can be difficult to categorize. Clumsiness and slowness of movement can have a major impact on everyday activities such as handwriting. The source of impaired dexterity obvious in most cases of WD (Hermann *et al.*, 2003) could arise from a number of CNS locations. Clinical testing, such as finger tapping (Davis & Goldstein, 1974), can bring out the extent of motor deficit even in early neurological WD. Other changes commonly seen in WD include trunk titubation, altered posture, and a disturbance of gait. Muscle cramping can be experienced (Golding & Walshe, 1977).

One of the challenges posed in the diagnosis of neurological WD is its duplication of other neurological disorders unrelated to excessive copper deposition. For example, some cases of WD have presented with a unilateral or bilateral Parkinsonian syndrome, including resting tremor, cogwheel rigidity, facial masking, bradykinesia, and other typical features. Ataxia has been described as the only clinical manifestation in a chronic case of WD (Madden *et al.*, 1985). These, and other instances, illustrate that clinical varieties of neurological WD can be sufficiently atypical so as to halt the search for this rare but potentially curable disorder. WD can present with neurological features of other disorders of unknown etiology, such as dystonia. Early presentations of WD have included unusual task-specific difficulties, such as inability to maintain a particular head posture, or to protrude the tongue (Purdon Martin, 1968). Many series have shown that sustained, abnormal postures characteristic of dystonia are common in WD. The varieties of dystonia in WD include generalized, segmental, or multifocal patterns, such as bilateral foot dystonia (Svetel *et al.*, 2001).

Why WD can take on such clinical heterogeneity in its presenting features has long been a mystery (Denny-Brown, 1964). For this reason, WD merits a high level of suspicion with respect to any number of categories of movement disorder. Impairment of the extrapyramidal and

cerebellar systems, and bulbar dysfunction are highly typical. Other patterns of neurological damage may be intermingled. Spasticity of the limbs is not a common finding although hyper-reflexia and Babinski signs can be part of the examination. Behavioral manifestations such as pseudobulbar palsy with involuntary crying or laughter can accompany the earliest findings and can persist as a major disability (Mingazzini, 1928). The latter problems, when advanced, can be highly disabling. Certain other types of movement disorders, such as tics and myoclonus, are generally not observed. However, in one case of WD that presented as a tremor disorder, several additional types of motor impairment were reported, including episodic truncal myoclonus, priapism, and seminal ejaculation that occurred several times per day (Nair & Pillai, 1990).

Neurological WD can be picked up on a screening MRI scan even in patients lacking evidence for this disorder on clinical examination. Patients have been described with Kayser–Fleischer rings but without concurrent neurological signs or symptoms of the disease. Kayser–Fleischer rings can be difficult to recognize without magnification, or in patients with dark irises. A formal slit lamp examination by an experienced ophthalmologist is necessary to exclude the possibility of Kayser–Fleischer rings.

Psychiatric and behavioral disorders in WD

Studies of cognition, psychiatric manifestations, and behavior have demonstrated that a range of problems can evolve for patients with WD (Akil *et al.*, 1991). While those without movement disorders or other types of neurological involvement can be spared, patients with basal ganglia lesions or more extensive pathology have shown mild impairments in all realms of cognitive functioning including frontal-executive ability, aspects of memory and visuospatial processing (Seniow *et al.*, 2002). These neuropsychological deficits do not appear to be correlated to the extent of copper toxicity in either symptomatic or asymptomatic WD patients (Rathbun, 1996). Even early in the course some WD patients have shown a decline in memory or other types of cognitive abilities (Knehr & Beam, 1956; Goldstein *et al.*, 1968; Scheinberg & Sternlieb, 1984). Other functions, such as the rate of information processing, may be spared (Littman *et al.*, 1995). With more extensive brain pathology (or concomitant liver failure from hepatic copper deposition), an irreversible dementia can be the outcome. Psychiatric presentations of WD are rare but need to be considered among the “organic” causes of psychosis and mood disorders (Stiller *et al.*, 2002).

Beyond the problems of cognitive functioning, patients with WD can experience a wide range of psychiatric and

behavioral disturbances. The initial presentation of WD can be depression or other psychiatric disturbances (Keller *et al.*, 1999; Medalia & Scheinberg, 1989; Jackson *et al.*, 1994). Although original reports by Wilson minimized these problems, patients commonly have shown problems of anxiety, mood alteration, impulsivity, and other psychiatric disorders. Early on, children and adults with WD can manifest disturbances of school performance, altered personality traits, and behavioral indiscretions. Prominent abnormalities on the MMPI and other evaluations of personality traits may be found (Portala *et al.*, 2001). In the latter study of 25 adult patients, these changes were not related to disease duration, age, or when WD began.

Patients with WD have a substantial incidence of moderate to severe depression and related problems (Portala *et al.*, 2000; Akil & Brewer, 1995). In one study, 17 of 34 patients had received psychiatric treatment for various disorders (including schizophrenia, depression, and anxiety) prior to the diagnosis of WD (Rathbun, 1996). When there is clear brain abnormality on neuroimaging or in the form of a movement disorder, the likelihood of a behavioral disorder is much increased. These include aggressiveness, a low anger threshold, impulsiveness, irritability, self-injurious behaviors, suicidal ideation, sexual preoccupations, and childishness (Denning, 1985). As a result, WD is commonly associated with decline in schoolwork or work performance (Akil & Brewer, 1995), and antisocial or criminal behavior can occur (Kaul & McMahon, 1993). Rare associations with WD include reports of anorexia nervosa (Gwirtsman *et al.*, 1993), hypersomnia (Firneisz *et al.*, 2001) and catatonia (Davis & Borde, 1993).

The range of psychiatric disturbance in WD includes schizophreniform or paranoid features. Sometimes hallucinations or delusional thinking can be prominent (Denning, 1985; Scheinberg *et al.*, 1968). Non-psychotic manifestations include medication-unresponsive depression, mood swings, unexplained lethargy, nightmares, disinhibited behavior (such as inappropriate laughter), or loss of insight (Scheinberg & Sternlieb, 1984; Brewer & Yuzbasiyan-Gurkan, 1992; Hawkes *et al.*, 2001). Disordered sleep is another consequence of neurological WD, as shown by findings of increased nocturnal awakening frequency (Portala *et al.*, 2002).

Epilepsy in WD

As recognized by Kinnier Wilson (1912), epilepsy is an uncommon occurrence in WD whether or not there is other evidence of neurological involvement. Seizures occur at an incidence approximately tenfold greater than in the general population (6.2% in the WD patient group in one large

series) (Denning *et al.*, 1988). They can be focal or major motor in classification, and can occur either early or late in the course of this disorder, especially in the younger patient (Smith & Mattson, 1967; Chu, 1989). In some instances, the first occurrence of convulsions coincided with the start of decoppering treatment.

Copper deposition in the eye in WD

Copper deposition in the periphery of the cornea is characteristic of WD when it involves the CNS (Heckmann *et al.*, 2000; Patel & Bozdech, 2001). Although not recognized by Wilson in his 1912 monograph, these opaque bands of corneal pigmentation were known prior to the recognition of hepatolenticular degeneration. Reports by both Kayser (1902) and by Fleischer (1903, 1912) led to the eponym applied to these distinctive cornea signs of copper deposition. With further study of neurological WD cases, clinicians came to realize that Kayser–Fleischer (KF) rings in the cornea are nearly always present. KF rings can be the initial clinical feature of WD (Liu *et al.*, 2002) and only rarely are absent in otherwise typical cases (Ross *et al.*, 1985; Heckmann & Saffer, 1988; Walshe & Yealland, 1992). In one reported instance, KF rings developed the first time penicillamine was started in a patient with otherwise highly typical neurological WD (Willeit & Kiechl, 1991). KF rings can be confused with other peripheral corneal opacifications, such as arcus senilis. Other disorders, such as cirrhosis and other forms of biliary obstruction, can produce corneal deposits of similar appearance to KF rings (Frommer *et al.*, 1977; Fleming *et al.*, 1977).

KF rings are caused by minute copper-containing granules deposited primarily in Descemet's membrane of the cornea. Due to their copper content, KF rings have a brownish or greenish tint and are readily seen without magnification or special illumination. Most KF rings are uniformly concentric around the cornea. Sometimes there is increased prominence of a KF ring at the upper pole of the cornea, which requires lifting of the eyelid for easy recognition. In exceptional circumstances KF rings can be unilateral (Madden *et al.*, 1985; Innes *et al.*, 1979). The definitive means for detecting (or excluding) KF rings, however, is a careful ophthalmologic slit lamp examination by an ophthalmologist. The slit lamp examination also permits recognition of another characteristic finding in WD, a lens opacification with the appearance of a sunflower (Goyal & Tripathi, 2000). "Sunflower" cataracts, also caused by copper deposition, are a less common finding in WD than the KF ring but have the same significance (Wiebers *et al.*, 1977; Deguti *et al.*, 2002). For both the KF ring and the "sunflower"

cataract, Scheimpflug photography can be used to document the clinical course of corneal and lens opacification (Obara *et al.*, 1995).

In most instances, the KF ring and the "sunflower" cataract arise simultaneously when neurological manifestations of WD begin (Wiebers *et al.*, 1977). Sequential analysis of KF rings has shown that they tend to diminish with continued decoppering therapy (Sussman & Sternlieb, 1969; Esmaeli *et al.*, 1996) or after liver transplantation (Song *et al.*, 1992). With chronic therapy, KF rings can disappear. However, the usual situation is the chronic persistence of KF rings at a reduced level of intensity.

Visual and eye movement disorders in WD

Unique presentations of neurological WD include progressive visual loss (Gow *et al.*, 2001) and oculogyric crises (Lee *et al.*, 1999). Patients with neurological WD may be impaired in their reading abilities early on in the disorder (Hyman & Phuapradit, 1979). The original observations by Wilson (1912) of gaze distractibility and difficulty in visual fixation have been confirmed by others (Lennox & Jones, 1989). Among the reported abnormalities of eye movements are defects of supranuclear accommodation (Klinkele *et al.*, 1980), impaired smooth pursuit, nystagmus, episodic diplopia, slowed saccadic pursuit (Kirkham & Kamin, 1974), impaired convergence (Sternlieb *et al.*, 1985; Walshe & Yealland, 1992) and apraxia of eyelid-opening (Keane, 1988).

Abnormalities of clinical neurophysiology in WD

Though peripheral nerve function is spared in WD, the damage in this disorder to central conduction pathways and neuronal circuitry is associated with neurophysiological changes representing the extent of pathology. WD does not have pathognomonic findings on electroencephalography (EEG) or evoked responses (EPs), though testing can be useful in demonstrating evidence of nervous system involvement or improvement (Chu, 1986). The EEG in WD is non-specifically abnormal, with generalized slowing and sometimes focal abnormalities (Giagheddu *et al.*, 2001). Spectral analysis and topographic mapping can enhance the recognition of slowing or epileptiform activity found in most patients with WD (Chu *et al.*, 1991). Similarly, most WD patients with neurological involvement have evidence for one or more types of prolonged EPs. EPs can serve as a tool for detecting sub-clinical WD affecting the CNS, as emphasized by a study showing abnormal EPs in

almost half of those lacking other evidence of neurological impairment (Grimm *et al.*, 1990). Brainstem auditory and somatosensory EPs may also show changes in response to therapy for WD (Grimm *et al.*, 1992). Abnormalities of pattern-reversal visual evoked responses and flash electroretinograms can undergo improvement with treatment of WD (Satishchandra & Ravishankar, 2000).

Several patterns for delayed conduction of sensory EPs have been demonstrated (Giagheddu *et al.*, 2001) and the general consensus is that EPs can be highly sensitive to brain or spinal cord involvement by WD. However, the several publications on this topic disagree as to the varieties of abnormality in WD. For example, several studies have reported that abnormal visual EPs are common in WD, especially with respect to the P100 waveforms (Aiello *et al.*, 1992; Butinar *et al.*, 1990; Satishchandra & Swamy, 1989). In a comparison of all three types of EP, brainstem auditory and somatosensory pathways were more likely to be delayed than visual EPs (Grimm *et al.*, 1991). Other investigators testing brainstem auditory EPs have shown no abnormality (Butinar *et al.*, 1990). In one report, prolongation of auditory EPs was unrelated to the duration or severity of the disease (Satishchandra & Swamy, 1989). Another series of patients with WD found prolongation of one or more types of EP when severe or moderately severe features of the neurological disorder were present (Grimm *et al.*, 1991). When only mild features of neurological WD were evident, there was an abnormal EP in more than half, and 17% of cases without evidence for neurological features of WD also had one or more EP abnormalities.

In addition to evoked responses, the technique of magnetic stimulation of the motor cortex has been useful for studying damage to central conduction pathways in WD (Perretti *et al.*, 2001). Cortically evoked motor responses can be diminished or absent in subjects with various patterns of neurological WD (Chu, 1990; Meyer *et al.*, 1991a; Berardelli *et al.*, 1990). In one reported case of neurological WD, the abnormal electromyographic response evoked by transcranial magnetic brain stimulation was the only electrophysiological disturbance, and this abnormality reverted to normal with effective decoppering therapy (Meyer *et al.*, 1991b).

Neuropathological changes in WD

Kinnier Wilson's 214-page monograph on the brain's changes in hepatolenticular degeneration provided a wealth of detailed description. The most common target of pathological change is the lenticular nuclei. The cut brain in

WD generally shows cavitory or cystic degeneration, sometimes with massive necrosis in this region (Schulman, 1968; Shiraki, 1968; Dastur & Manghani, 1977). The severity of change in the lenticular nuclei can vary greatly from case to case, but there is usually symmetrical involvement in each affected brain. Atrophy of the caudate nuclei and lateral putamen are typical. The putamen may be tinted brown, red, or yellow from the copper content. In the pallidum, discoloration may be present, but usually this region is spared gross degenerative change.

In about 10% of WD cases, atrophic or degenerative changes extend beyond the lenticular nuclei (Schulman, 1968). There can be cystic or cavitory necrosis in structures such as claustrum, extreme capsule, thalamus, subthalamic nucleus, and red nucleus (Dastur & Manghani, 1977; Owen, 1981; Duchen & Jacobs, 1984). Additionally, the brain in WD can show dilation of the lateral ventricles and generalized atrophy. Atypical patterns of brain involvement in WD include degenerative changes primarily in cerebral cortical gray and white matter (Schulman & Barbeau, 1963; Richter, 1948; Ishino *et al.*, 1972; Miyakawa & Murayama, 1976). In such instances, the greatest extent tends to be most prominent in the superior and middle frontal gyri, or in the temporal and parietal cortex.

The "pseudosclerotic" clinical phenotype of WD appears to have a correlate in some unusual cases (Hedera *et al.*, 2002). Several reports have documented an extensive loss of deep white matter so extensive as to suggest the picture of demyelinating disease (Ishino *et al.*, 1972; Miyakawa & Murayama, 1976; Schulman & Barbeau, 1963). In another variant of WD's cerebral pathology, atrophy in the brainstem and cerebellar folia have been described (Miskolczy, 1932). With cerebellar involvement, atrophy has a predilection for superior vermis and the dentate nucleus (Bielschowsky & Hallervorden, 1931). The appearance of central pontine myelinolysis has been described in otherwise typical cases of WD (Popoff *et al.*, 1965; Seitelberger, 1973; Horoupian *et al.*, 1988; Shiraki, 1968), including one instance in which this picture developed after liver transplantation (Lui *et al.*, 2000).

Microscopic pathological change in WD tends to be more widespread than would be suspected from inspection of the cut brain. Sometimes the deeper layers of cerebral cortex and adjacent white matter are the most affected regions. In the lenticular nuclei and elsewhere, prominent changes include capillary endothelial swelling and proliferation of glia (especially those of the Alzheimer Type II type) (Schulman, 1968; Scheinberg & Sternlieb, 1984). Gliosis is most abundant in the putamen and can also affect globus pallidus and caudate nuclei. Eventually, WD evolves to extensive damage to myelinated fibers in association

with Alzheimer Type II gliosis diffusely throughout cerebral white matter. Among the patterns of pathological involvement in white matter are spongiform changes (Schulman, 1968).

The Alzheimer Type II glia is a distinctive change in WD, though it is not entirely specific to this disorder. However, when Type II glia arise in the context of other forms of chronic liver disease with encephalopathy, they may not be as prominently localized to the lenticular nuclei as in typical WD. Together with Alzheimer Type II glia in most cases of WD is the Opalski cell. These are large, rounded cells with irregularly shaped nuclei and PAS-positive staining for cytoplasmic granules. Opalski cells are most commonly situated in cerebral cortex cells and in the boundaries of lenticular nuclei cavity. The finding of Opalski cells with Alzheimer Type II glia is almost pathognomonic for WD. Alzheimer Type I glia can also be found. Their presence was highly correlated to the extent of reactive astrogliosis, and inversely proportional to the severity of Alzheimer Type II changes in one study (Ma *et al.*, 1988). Opalski cells and both Alzheimer Type I and Type II glia may be involved in a copper detoxification process, since they express the copper binding protein metallothionein (Bertrand *et al.*, 2001).

The degenerative changes in neurons and glia can be prominent throughout the brain. In the cerebellum, pathological change is most prominent to the white matter surrounding the dentate nuclei and to Purkinje cells (Scheinberg & Sternlieb, 1984). Electron microscopy has been used to study cerebral cortex in two cases of WD (Foncin, 1970; Anzil *et al.*, 1974). The findings included typical degenerative changes of neurons, myelin, glia, and axons; there were also Hirano bodies and protoplasmic astrocytes (probably Alzheimer Type II). Degenerative changes in cortical neurons included prominent spheroid bodies. Similar changes have appeared in the lower brainstem sensory nuclei in WD (Jellinger, 1973).

The impact of copper chelation therapy was assessed in a series of eleven WD brains taken from subjects chronically treated with penicillamine (Horoupian *et al.*, 1988). For five of the patients, all neurological features of WD had resolved, while the remaining six patients were markedly improved. Despite continued copper chelation therapy, measurement of brain copper content showed values greatly increased over controls in 8 of the 9 brains studied in this manner. The neuropathological changes of WD were prominent in each of the penicillamine-treated cases in spite of their good neurological outcomes from decoppering therapy. These results are important clues that removing copper systemically does not fully remove abnormally high brain content of copper, nor does it avert either the gross or

microscopic pathology associated with CNS WD. In this study, there was only a weak correlation between the severity of neuropathological change and regional cerebral copper content.

One confounding factor in the analysis of changes produced by WD is the effect of concomitant liver failure. In distinction to neuropathological changes found in WD, hepatic encephalopathy usually is characterized by a pseudodoulegyric pattern of distribution in neuronal loss. Hepatic encephalopathy also tends to lack the necrotic changes in the putamen or frontal gyri as found in neurological WD (Shiraki, 1968).

Making the diagnosis of WD

As important as any diagnostic test for WD is the need for a high index of suspicion for the disorder, given its protean manifestations. Even with the obvious concerns that would accompany the development of CNS involvement, WD can be a late diagnosis for many affected individuals. In a review from the United Kingdom (Walshe & Yealland, 1992), symptoms referable to WD were present for 9 to 40 years (mean, 16 years). At presentation to a physician, only one-third were correctly diagnosed, and the delay in correct diagnosis for the others averaged more than 1 year. Making the best use of diagnostic options requires an understanding of their benefits and limitations. It also is important to remember that WD can arise in the context of other illness or movement disorders (Quinn *et al.*, 1986).

Patients from 4 to 60 years old (but with the highest incidence in the second and third decades of life in Western countries) can present in roughly equal proportions with the hepatic, neurological, and psychiatric forms of WD (Brewer & Yuzbasiyan-Gurkan, 1992; Danks, 1989; Scheinberg & Sternlieb, 1984; Brewer, 2000, 2001, 2003). When WD presents as a hepatic disorder, the clinical picture closely resembles that in other primary forms of liver disease. In such instances, chronic active hepatitis may be the first diagnosis, or if the patient regularly consumes alcoholic beverages, the cirrhosis found may be incorrectly attributed to this behavior rather than to WD. Sometimes, a hepatic presentation of WD can be quite nonspecific, consisting of little more than mild hepatic failure, reduced serum albumin, ascites, and jaundice. In other instances, patients can become acutely and desperately ill with fulminant liver failure. In each of these clinical scenarios, it is incumbent on physicians to consider the possibility of WD to facilitate treatment. Once the diagnosis has been considered, one or more of the following investigations can be used to confirm or exclude the possibility of WD.

The most often used laboratory test for screening for WD is serum CP. Although one of the characteristic features of WD is a reduction in concentration of CP, it is a relatively insensitive and non-specific test, and other tests are better. Approximately 85% of patients with neurological presentations of WD have low CP levels (Brewer & Yuzbasiyan-Gurkan, 1992). However, CP levels cannot be used to confirm or exclude WD. In approximately 80% of all patients with WD, serum CP will be very low, but for 20%, concentrations can be low or midnormal (Brewer & Yuzbasiyan-Gurkan, 1992; Scheinberg & Sternlieb, 1984; Brewer, 2000, 2001, 2003). The use of CP for diagnostic purposes can be especially problematic if the patient also has an inflammatory disorder (i.e. hepatitis) or is receiving oral contraceptives. CP is an acute phase reactant, and even patients with WD can respond to stimuli increasing its production, thereby masking the low concentration they maintain at baseline. Approximately 20% of heterozygotes carrying the gene for WD manifest an intermediate or low CP level despite their freedom from copper pathology in all of their organ systems.

The measurement of urinary copper excretion over 24 hours (especially when conducted on two occasions) is an excellent way to assess whether WD is present (Brewer & Yuzbasiyan-Gurkan, 1992; Brewer, 2000, 2001, 2003). Although there are few biological reasons for false-negative or -positive results to occur, there can be several technical drawbacks to studies of urinary copper excretion. One is a practical matter involving the potential unreliability of collecting urine over 24 hours, or the copper contamination of the specimen from collection materials or other sources. Many laboratories encounter difficulties in conducting an accurate assessment of low copper concentrations in urine. Nevertheless, if conducted reliably, determinations of urinary copper output provide important information regarding the diagnosis of WD. The measurement of serum copper concentration is not a substitute for this test because blood concentrations are highly correlated to serum CP concentrations. Patients who are symptomatic with some form of WD almost always have 24-hour urine copper outputs of more than 100 μg (normal range, 20 to 50 μg). In addition to WD, there are only two known physiological mechanisms for increased urinary copper excretion. One is obstructive liver disease. When liver failure impairs the ability of copper to be excreted into the bile, hepatic copper content tends to increase, and the urinary excretion of copper is enhanced. Thus, when a patient has obstructive liver disease, the reliability of urinary copper excretion declines. Second, during an episode of hepatitis, enough copper may be released by hepatocytes, even in the absence of WD, to elevate urine copper.

Another ambiguity for diagnosing WD can arise in the evaluation of an affected patient's siblings. Each has a 25% chance of carrying two abnormal WD genes, and there is an additional 50% risk of being a heterozygous carrier. Despite their lack of other WD manifestations, heterozygous carriers can have mildly elevated urinary copper excretion with a decrease in serum CP concentration. Rates of copper excretion of 50 to 85 $\mu\text{g}/24\text{ h}$ are not uncommon among WD heterozygotes (Yuzbasiyan-Gurkan *et al.*, 1991). A similar range in copper excretion rates can be encountered in WD homozygotes that are presymptomatic for clinical manifestations. In the experience of one of the authors (G. J. Brewer), the lowest rate in a presymptomatic patient has been 65 $\mu\text{g}/24\text{ h}$. The substantial overlap in 24-hour rates of urinary copper excretion among presymptomatic patients and heterozygous carriers of the gene limits the usefulness of urine copper excretion in differentiating these possibilities.

The "gold standard" for diagnosis continues to be biopsied liver tissue with quantitative assay of copper content. An accurate diagnosis requires certain skills in carrying out the analysis. Histochemical staining for copper is unreliable for diagnostic purposes. The presence of positive findings from copper stains is dependent on the sequestration of copper at high concentrations within hepatic cells. When the distribution of copper is diffuse throughout the cytoplasm, the results of staining for copper can be negative despite a very high tissue copper concentration. In general, the concentration of hepatic copper provides an unequivocal answer as to the possibility of WD (Brewer & Yuzbasiyan-Gurkan, 1992; Brewer, 2000, 2001, 2003). Concentrations of copper in WD exceed 200 $\mu\text{g}/\text{g}$ tissue (dry weight); the normal range is 15–50 $\mu\text{g}/\text{g}$ tissue. Heterozygote carriers can have a mild elevation of hepatic copper, but usually not more than 100 $\mu\text{g}/\text{g}$ tissue. A possible ambiguity can arise in patients with obstructive liver disease because tissue concentrations of hepatic copper can increase to the range encountered in WD.

Radioisotope copper tracer tests have not been particularly reliable for the diagnosis of WD, although they can provide clues to copper handling in WD as compared to controls (Walshe & Potter, 1977; Brewer & Yuzbasiyan-Gurkan, 1992). Although these tests can reveal clear differences between normal and homozygous WD patients in the way that copper is handled, there can be substantial overlap between homozygotes and heterozygotes for the WD gene (Houwen *et al.*, 1989; Brewer & Yuzbasiyan-Gurkan, 1992).

The so-called "penicillamine provocative test" is also not a useful procedure for diagnosing WD. In this test, a dose of penicillamine is given and the urinary copper response

is measured. The test has never been evaluated in terms of differentiating heterozygous carriers from homozygous affected, and there is likely strong overlap. The straightforward basal 24-hour excretion of copper provides more reliable data.

The gene for WD, ATP7B, has been cloned (Bull *et al.*, 1993; Tanzi *et al.*, 1993; Yamaguchi *et al.*, 1993). There are already over 200 known mutations in ATP7B that disable the gene and cause WD (Cox & Roberts). In general, no single mutation, or small group of mutations, predominate as a cause of WD in any population. Hence, mutation screening as a diagnostic tool is not practical at this moment. Once a patient is diagnosed by conventional means, full siblings can be evaluated by haplotype analysis, which involves typing polymorphic markers that are close to the WD locus (Thomas *et al.*, 1995). If markers on both chromosomes match between the affected patient and a sibling, that sibling is affected with WD. If there is a single match, the sibling is a carrier, and if without matches, the sibling is homozygous normal.

There are several cases in the literature describing abnormal copper metabolism coinciding with movement disorders and other types of neurological and systemic abnormalities (Willvonseder *et al.*, 1973; Pall *et al.*, 1987). Whether these are “forme frustes” of WD or represent other types of copper pathophysiology remains to be determined.

Neuroimaging of WD: CT, MRI, PET, and SPECT

In most patients with neurological impairments with WD, one or more abnormalities can be detected by magnetic resonance imaging (MRI) (Aisen *et al.*, 1985; Prayer *et al.*, 1990; Thuomas *et al.*, 1993; Roh *et al.*, 1994; Brugieres *et al.*, 1992; Giagheddu *et al.*, 2001). Computerized tomography using X-ray also shows abnormalities (Nelson *et al.*, 1979; Harik & Post, 1981; Kendall *et al.*, 1981; Williams & Walshe, 1981; Dettori *et al.*, 1984; Chu, 1989), but is probably not as sensitive (Metzer & Angtuaco, 1986). The most common sites for abnormal MRI findings are the basal ganglia structures and the midbrain region (Starosta-Rubinstein *et al.*, 1987; Magalhaes *et al.*, 1994; Hitoshi *et al.*, 1991; Imiya *et al.*, 1992). Especially useful for detecting abnormalities are diffusion MRI (Sener, 1993) and T₂-weighted images, in which patches of increased signal intensity are characteristically found with a central core of decreased signal intensity. Other typical findings of WD are features described as the “face of the panda” sign in the midbrain (Hitoshi *et al.*, 1991) and the “bright claustrum” sign (Sener, 1993). The various abnormalities on MRI sometimes improve or recover completely following decoppering therapy (Alanen *et al.*, 1999;

Stefano Zagami & Boers, 2001). Other neuroimaging techniques useful for demonstrating the regional abnormalities of WD include positron emission tomography with fluorodopa (Snow *et al.*, 1991) and deoxyglucose (Kuwert *et al.*, 1992), and single photon emission computed tomography (SPECT) (Tatsch *et al.*, 1991; Schwarz *et al.*, 1992; Giagheddu *et al.*, 2001; Barthel *et al.*, 2001). SPECT findings in neurological WD have typically shown decreased striatal binding of the tracer, implying diminished dopaminergic projections (Barthel *et al.*, 2001). However, there can be considerable heterogeneity in neurological WD, and despite the presence of akinesia, rigidity, and substantia nigra lesions on MRI, some patients have had normal striatal findings with SPECT using ligands for the dopamine transporter (Huang *et al.*, 2003).

Genetics and pathophysiology of WD

WD is inherited as an autosomal recessive disorder (Bearn, 1960), which means that carriers of the gene never develop the disease. Most evidence supports a conclusion that the gene is fully penetrant, so all homozygotes ultimately should develop the disease sometime during their lifetime. For this reason, each sibling of a newly diagnosed patient has a 25% risk for WD. Because there are several highly effective therapeutic options for WD, it is essential to screen siblings of affected probands to determine whether they also are affected with the disease.

The frequency of WD has been estimated to be approximately 1 per 40 000 births (Scheinberg & Sternlieb, 1984; Brewer, 2001). An attempt to refine this number for the United States led to an estimate of 1 per 55 000 births but with a wide confidence interval (Olivarez *et al.*, 2001). If we use 1 in 40 000 in the United States, this frequency means that the number of homozygotes is 5000 to 6000. Assuming this incidence figure, the carrier frequency can be calculated as approximately 1% of the population. From this estimation, the a priori risks for relatives of an affected patient can be calculated as 1 in 200 for offspring, 1 in 600 for nieces and nephews, and 1 in 800 for first cousins. The actual risk of any individual in such families developing WD is age dependent. Once an individual has passed through the age range of maximal presentation, the odds of remaining free of the disorder increase.

The gene for WD (ATP7B), a copper binding, membrane bound, ATPase shows considerable homology to the gene for Menkes disease, called ATP7A (Vulpe *et al.*, 1993; Chelly *et al.*, 1993; Mercer *et al.*, 1993). The genes show quite dissimilar expression patterns: ATP7B is primarily expressed in the liver, while ATP7A shows a

generally ubiquitous expression pattern (although with little expression in the liver). Because of the large number of mutations, most patients with WD in most populations are compound heterozygotes. This situation hampers attempts at genotype-phenotype correlation. There has been an impression among researchers that complete gene knockouts tend to lead to an expression of liver disease earlier in life, while missense mutations (which might provide some low level of ATP7B protein expression) tend to generate a neurological presentation later in life.

Although clinical manifestations can be widespread throughout the body, the primary defect of copper metabolism clearly is a function of the liver. The normal mechanism for controlling copper balance involves the excretion of excessive copper into the bile (Ravestyn, 1944; Cartwright & Wintrobe, 1964). The failure of this mechanism leads to WD (Bush *et al.*, 1955; Frommer, 1974; O'Reilly *et al.*, 1971; Gibbs & Walshe, 1980). For this reason, hepatic transplantation can cure the underlying copper disorder. ATP7B functions in the hepatic transport of copper into the bile in an as yet undefined manner. When both copies of the gene are disabled, as in WD, excess copper is not excreted, and accumulates in the liver. At some point, the excessive copper cannot be adequately stored and begins to cause liver damage. In some patients, this process probably begins as early as 3 years of age. Later on, excessive circulating copper leads to accumulation in other organs, especially in the brain where centers involved in motor control are particularly susceptible to copper accumulation.

A primary role for the copper-containing serum protein CP in the pathogenesis of WD originally was proposed after the discovery that most patients manifest a low serum concentration (Bearn & Kunkel, 1952; Scheinberg & Gitlin, 1952). Although CP can serve as a marker for the disease, the structural gene for CP is found on chromosome 3, while ATP7B is on chromosome 13. It appears that one of the functions of ATP7B in the liver is to facilitate the acquisition of copper by CP. When both copies of ATP7B are disabled, as in WD, the acquisition of copper by hepatic apoCP is subnormal. Thus, defects in ATP7B produce both inadequate hepatic biliary excretion of copper, and inadequate hepatic secretion of mature, copper containing, CP into the blood, generally leading to a low blood CP level.

The toxicity of copper

All studies indicate that copper is the agent that produces tissue damage in WD. This conclusion is established by the complete correlation between disease manifestations and the presence of excessive amounts of copper in tissue.

Furthermore, the remarkable recovery of patients with WD after copper-removing therapy provides additional proof. It is most likely that copper toxicity is pro-oxidant in nature. The best support for this concept comes from studies of red blood cells that show excess copper producing an increase in oxidant radicals (Hochstein *et al.*, 1980; Metz & Sagone, 1972; Rifkind, 1974). Copper-damaged red blood cells exhibit Heinz bodies, which are markers in red blood cells of oxidative damage to cell membranes (Deiss *et al.*, 1970; Ishmael *et al.*, 1972; Metz, 1969). These cells also show an accelerated loss of reduced glutathione, a molecule that is important for protecting against damage from oxidant stress (Deiss *et al.*, 1970; Mital *et al.*, 1966). In some tissues, the outcome of oxidant damage involves lipid peroxidation (especially membrane peroxidation), whereas in other cells, oxidative damage to other components may be more important (Hochstein *et al.*, 1980; Sokol *et al.*, 1989).

The occurrence of liver damage in WD can be explained by the extremely high concentrations of copper accumulating in this organ. The liver is capable of storing relatively large amounts, primarily by synthesizing metallothionein, which complexes copper for storage. However, copper is not the best stimulus for inducing production of metallothionein. At some level of copper load, hepatic concentrations of this metal may exceed the amount that can be complexed effectively with metallothionein. When this occurs, hepatic cellular damage begins to develop. Ultimately, the progressive damage to the liver results in a lowering of its storage capacity, and the accumulating excess copper reaches the point at which escape into the blood can increase, thereby permitting its deposition in other organs such as the brain.

Why the CNS is such a prominent target for WD involvement is not known. The concentrations of copper that accumulate in the brain are not much greater than those in other organs, nor do the specific regions of the brain tending to be affected (e.g. the basal ganglia) accumulate more copper than other sites (Scheinberg & Sternlieb, 1984; Owen, 1981). The most tenable explanation for the heightened occurrence of copper toxicity is that some sites of the brain have a decreased resistance to the ability of copper to produce oxidant damage. One possibility is that the specific regions most likely to be involved are less capable of inducing metallothionein as a protectant mechanism. Alternatively, it is possible that enzymatic mechanisms for antioxidant protection are diminished regionally. Although the neurotoxicity of copper is not duplicated by excess administration of other metals such as manganese (Pentschew *et al.*, 1963), there are some similarities based on pro-oxidant effects.

Table 61.2. Recommendations for medical therapy of Wilson's disease

Clinical situation	Therapy choices	Comments
<i>Initial treatment</i>		
Hepatic presentation	First: trien and zinc	Best drug or combination not well established
	Second: penicillamine and zinc	
Neurological presentation	First: tetrathiomolybdate	Not generally available yet
	Second: zinc	Slow in action
	Third: trien	May precipitate neurological worsening
<i>Maintenance treatment</i>	First: zinc	Excellent efficacy, no toxicity
	Second: trien	Efficacious but long-term toxicities unknown
	Third: penicillamine	Efficacious but a very toxic drug
<i>Presymptomatic treatment</i>	Same as for maintenance treatment	Same as for maintenance treatment
<i>Pregnancy treatment</i>	First: zinc	Non-teratogenic in animals
	Second: trien	Teratogenic in animals

Treatment of WD

Classifications of the current treatments of WD are given in Table 61.2. The following sections provide greater details.

Initial treatment

The initial treatment of WD must be considered apart from the later strategies because there are objective differences and different therapeutic alternatives. For a patient presenting with liver disease (other than acute fulminant failure), the use of both a chelating agent and zinc can be recommended. At present, the best choice for chelation is trien because this compound is less toxic than penicillamine and appears to be just as effective. The objective for the use of a chelating agent is to mobilize copper rapidly to achieve a large negative copper balance. Administration of zinc provides a major stimulus for the synthesis of hepatic metallothionein, which sequesters copper in the hepatocyte and renders it nontoxic. This combination therapy has proved to be quite successful for the treatment of hepatic disease (Askari *et al.*, 2003). The only difficulty we have encountered has been the induction of proteinuria in a few

patients; when trien is stopped, this problem resolves. We recommend the use of this combination for 4 to 6 months followed by discontinuation of the trien. Zinc maintenance therapy provides long-term protection against recurrence of symptomatic WD.

For the patient presenting with acute fulminant hepatic failure, there is a high risk for a fatal outcome. The only effective means of avoiding progression to death in such circumstances has been through hepatic transplantation (Schilsky *et al.*, 1994). This procedure has become used on a widespread basis. An index has been developed by Nazer and colleagues (1986) to help in the differentiation of patients requiring hepatic transplantation from those who can be salvaged by medical therapy. This prognostic algorithm, which is computed from the prothrombin time and the serum concentrations of bilirubin and serum glutamic-pyruvic transaminase, has proved to be quite useful in decision-making regarding hepatic transplantation (Brewer, 2001). One issue in the use of this prognostic index formula is that bilirubin can be elevated from red blood cell destruction as well as from liver disease. Because hemolysis can be a feature of WD, the bilirubin concentration becomes a less reliable factor in the decision-making process because the elevation is derived from a cause more benign than liver disease.

For patients presenting with acute neurological illness, the situation can be quite precarious. Conventional treatments for chronic management of WD can result in significant and irreversible worsening due to mobilization of hepatic copper that can then enter the brain. The administration of chelators such as penicillamine (and probably trien as well) may cause substantial neurological deterioration. In almost 50 percent of patients, some worsening of neurological signs occurs when such therapy is instituted, and for almost 25 percent of patients, the loss of neurological function will be permanent (Brewer *et al.*, 1987b). We cannot highly recommend the use of zinc in this situation because its effect at achieving a negative copper balance is slow and progression of neurological deficits can occur during its initial use.

Because of the limitations of current therapy with respect to neurological WD, a new type of drug is under development at the University of Michigan. This drug, ammonium tetrathiomolybdate (TM), acts by promoting the complexing of copper to protein, an effect that has two advantages (Bremner *et al.*, 1982; Gooneratne *et al.*, 1981; Mills *et al.*, 1981a,b). When administered with meals, TM blocks absorption of both dietary and endogenously secreted copper, thereby achieving an immediate negative copper balance. When taken between meals, TM is absorbed and reacts with the blood-borne copper to complex with

albumin (Brewer *et al.*, 1991a). This protein-linked copper becomes unavailable for cellular uptake and therefore is not toxic. With TM, it has been possible to decrease progressively the concentration of free copper in the bloodstream (Brewer *et al.*, 1991a). By this means, TM can prevent shifts of copper into the CNS that are the result of chelator therapy. Strategies for the optimal use of TM (Brewer *et al.*, 1991a, 2003) have evolved into a regimen in which the drug is administered four times per day, three doses with meals and one dose at bedtime away from food. This regimen is carried out for 8 weeks, after which a switch to zinc is undertaken as a maintenance therapy. Fifty-five patients have been treated in this manner, and they have recovered with only two instances of neurological deterioration (Brewer *et al.*, 2003), compared to the estimated 50% frequency of worsening with penicillamine (Brewer *et al.*, 1987b).

Maintenance therapy

Experience at the University of Michigan and in the Netherlands suggests that chronic maintenance therapy with zinc can be recommended. The United States Food and Drug Administration has given approval for this indication. Extensive research with zinc has shown it to be fully effective, and it has virtually no toxicity (Brewer *et al.*, 1983, 1987a, 1987c, 1989, 1990, 1991b, 1993a, 1993b, 1994, 1997, 1998, 2001; Hill *et al.*, 1986, 1987; Yuzbasiyan-Gurkan *et al.*, 1989, 1992; Brewer & Yuzbasiyan-Gurkan, 1992; Askari *et al.*, 2003; Hoogenraad *et al.*, 1978, 1979, 1987). Occasionally, patients exhibit mild discomfort related to stomach upset from zinc. This problem usually results from the first morning dose. Therefore, administration of the first dose between breakfast and lunch can lessen the risk of this problem. Studies with zinc have shown that it can bring copper toxicity under control by preventing re-accumulation of hepatic copper in patients previously treated with chelation. With zinc treatment, plasma and urinary copper concentrations are reduced, as can be confirmed by monitoring the results of 24-hour urinary excretion of copper and zinc. Patients receiving adequate therapy with zinc usually excrete at least 2 mg zinc every 24 hours (Brewer *et al.*, 1990, 1998). Incomplete compliance in drug intake will be shown by reduced quantities of zinc excretion. Urinary copper output also can be useful in guiding therapy because in the absence of chelators, urinary output of copper is proportional to the body load of copper. Thus, with adequate zinc therapy, output should be less than 125 µg every 24 hours when measured during maintenance therapy (Brewer *et al.*, 1998). When the urinary output of copper is more than 125 µg every 24 hours

(after a period of adequate control), the most likely conclusion is inadequate compliance in the regular use of zinc.

Treatment of the presymptomatic patient

Because the ideal time for treatment for the disorder is in the presymptomatic phase (during which most of the body's load of copper will be deposited), it is of vital importance to pursue the diagnostic workup to a definitive level, which may include liver biopsy, in each at-risk individual such as a WD patient's sibling. Institution of prophylactic treatment against WD appears to be served adequately by the same strategy for maintenance therapy with zinc. Thirty patients have been treated at the University of Michigan with zinc therapy alone, and results have been excellent (Brewer *et al.*, 1998, and unpublished results).

Treatment of the pregnant patient

During pregnancy, WD can present special management challenges. Both penicillamine and trien are teratogenic in animals (Keen *et al.*, 1982), although zinc is not (Food and Drug Administration, 1973). For this reason, zinc appears to be the drug of choice during pregnancy, and trien can be a second choice. At the University of Michigan, 19 women have been treated through 25 pregnancies using zinc with no significant problems for the mothers and only two fetal abnormalities noted (Brewer *et al.*, 2000). The medical literature on WD indicates that features of this disorder can progress or recur during pregnancy when medication is discontinued; hence, it is important for effective decoppering treatments to be continued.

Disorders of the mitochondrial respiratory chain

Anthony H. V. Schapira

Royal Free and University College Medical School, and Institute of Neurology, University College London, UK

Introduction

Mitochondria are ubiquitous and present in all mammalian cells. They are host to a range of biochemical pathways including oxidative phosphorylation, β -oxidation and the urea cycle. Mitochondria are also important in mediating a variety of intracellular triggers for apoptotic cell death. This chapter will focus on defects of the mitochondrial respiratory chain and specifically those that are related to human diseases; toxin induced mitochondrial defects will be considered elsewhere.

The mitochondrial respiratory chain and oxidative phosphorylation system comprises five multisubunit proteins, which are embedded within the inner mitochondrial membrane. The first four complexes are connected in functional terms by coenzyme Q, and cytochrome c. Electrons are transferred from NADH and FADH₂ and result in the reduction of oxygen to water. This process also involves the shuttling of protons across the inner membrane to the internal membranous space, and this provides the proton motive force for the generation of ATP from ADP by complex V (ATPase).

Complexes I–V comprise approximately 82 different subunits, of which 13 are encoded by mitochondrial DNA. The remainder are encoded by nuclear genes and imported into the mitochondrion often by way of specific targeting sequences and import machinery. Mitochondrial DNA is a 16.5 kb double-stranded circular molecule, which lies in the matrix attached near its D-loop to the inner mitochondrial membrane. Mitochondrial DNA encodes 2 ribosomal RNAs, 22 transfer RNAs and 13 proteins (Table 62.1 and Fig. 62.1). It is dependent upon nuclear enzymes for transcription, translation, replication and repair.

Mitochondrial DNA is inherited virtually exclusively from the female line. There may be some paternal linkage, but this is either not replicated or is diluted beyond

detection. The pattern of inheritance of mitochondrial DNA has been valuable in ethnic and migration studies. Mutations of mitochondrial DNA also result in the phenomenon of maternally inherited diseases. Over 100 different mutations of mitochondrial DNA have now been associated with human pathology. These include micro- and macro- deletions, point mutations and insertions affecting ribosomal or transfer RNA genes or protein coding genes. A quantitative defect of mitochondrial DNA (mitochondrial DNA depletion) has also been identified, although this latter phenomenon is associated with mutations of nuclear genes encoding enzymes responsible for mitochondrial DNA replication. Mitochondrial DNA mutations have a tendency to be heteroplasmic, i.e. to exist concomitantly with wild-type mitochondrial DNA at least within the same cell, and probably within the same mitochondrion. This results in a variation of mutation load between tissues and between affected individuals. There is also a relatively high carrier state associated with mitochondrial DNA mutations.

The clinical expression of disorders related to defects of the mitochondrial respiratory chain is very broad, and may include virtually any system or tissue. Those areas most commonly affected are the brain and muscle, as these tissues are probably the most dependent upon oxidative phosphorylation. Common symptoms include proximal myopathy and external ophthalmoplegia, CNS features may include seizures, dementia, ataxia and deafness, retinitis pigmentosa and diabetes mellitus. The basis to the considerable variation in clinical phenotype, even caused by the same mutation, is thought to be related to the variation in mutation load that may exist between tissues and patients. However, this is likely to be an over-simplification, and there may well be a number of other factors both genetic and environmental that might influence the expression of mitochondrial DNA mutations.

Table 62.1. Respiratory chain components

Complex	Enzyme	Subunits	MtDNA encoded subunits
I	NADH CoQ, reductase	~42	ND1–6, ND4L
II	Succinate dehydrogenase	4	–
III	Ubiquinone cytochrome c reductase	11	Cytocrome b
IV	Cytochrome oxidase	13	COI, COII, COIII
V	ATPase	15	ATPase 6 and 8

The classification of mitochondrial disorders of the respiratory chain is challenging, and none is universally accepted. Much of this difficulty is the result of only an approximate correlation of genotype and phenotype. For instance, mitochondrial DNA deletions most frequently result in chronic progressive external ophthalmoplegia (CPEO) or Kearns–Sayre syndrome (KSS). These same mutations, however, may result in isolated proximal myopathy or encephalopathy or a combination of features that might, for instance, fall within other mitochondrial phenotypes including MELAS (myopathy encephalopathy, lactic acidosis and stroke-like episodes) or isolated syndromes such as cardiomyopathy or diabetes mellitus. Similarly, the A3243G mutation in the transfer RNA for lysine, which is most commonly associated with MELAS, can also result in CPEO, pure myopathy, isolated diabetes, isolated deafness, etc. In view of this complexity, this review has taken a pragmatic approach, and will describe the major mitochondrial phenotypes caused by mutations of mitochondrial DNA. There is a second group of primary respiratory chain disorders caused by mutations of nuclear genes encoding subunits of complexes I–V and, together, these are often referred to as the primary respiratory chain disorders.

CPEO and KSS

CPEO may manifest any time from adolescence to late adulthood, although usually, before the age of 30. Patients develop symmetric or asymmetric, slowly progressive, non-fatiguable ptosis in association with external ophthalmoplegia. Diplopia does occur, but is present only in the minority, given that the ophthalmoplegia is usually symmetrical. There may be an associated pigmentary retinopathy of the salt and pepper type, and/or a proximal myopathy. Additional complications are relatively uncommon, and the great majority of patients are never significantly

disabled, and usually have a normal lifespan. Onset of CPEO in late adulthood is well recorded.

Creatine kinase is usually normal, electromyography may be normal or show some mild non-specific myopathic features. Serum lactate may be elevated at rest, and exercise may induce a significant and sustained increase. Definitive diagnosis requires a muscle biopsy, and this will show the morphological features characteristic of the mitochondrial myopathies. These include the presence of ragged red fibers on the Gomori trichrome stain. This pattern reflects the subsarcolemmal accumulation of mitochondria, often associated with increased lipid and glycogen. The ragged red fibers usually stain negative for cytochrome oxidase, and positive for succinate dehydrogenase (see Fig. 62.2). At the ultrastructural level, the mitochondria are often enlarged with aberrant crystal configuration. The matrix may be vacuolated, and para-crystalline inclusions may be present in the intra-membranous space. Although characteristic of mitochondrial myopathies, these light and electron microscopic findings are not specific. For instance, ragged red, COX negative, SDH positive fibers may be present in inflammatory myopathies. Furthermore, mitochondrial abnormalities accumulate with age, and up to 5% of fibers may be abnormal over the age of 50 (Muller-Hocker, 1990). The combination of ragged red, SDH positive, COX negative fibers is relatively typical of mitochondrial DNA deletions. *In situ* hybridization studies show that the highest percentage of mutant mtDNA is present in these fibers (Hammans *et al.*, 1993; Moraes *et al.*, 1991, 1992; Shoubridge *et al.*, 1990).

The most common mutation found in patients with CPEO is the mitochondrial DNA deletion, being found in 70% of those with CPEO (Holt *et al.*, 1988, 1989; Moraes *et al.*, 1989). The deletions are single, i.e. affecting the same segment of the mtDNA molecule in all tissues, but the proportion of deleted molecules varies from one to another. For instance, it is extremely rare to find the deletions in blood. DNA confirmation is therefore dependent on providing a tissue sample, i.e. skeletal muscle. It appears that the proportion of deleted mitochondrial DNA is stable over time. One particular mtDNA deletion is the 4977 base pair deletion, referred to as the “common deletion,” and spans the region from the ATPase 8 gene to the nd5 gene. This occurs in approximately 30% of patients with CPEO or KSS (see below) (Schon *et al.*, 1989; Mita *et al.*, 1990).

KSS is defined by CPEO and pigmentary retinopathy together with either complete heart block, a cerebrospinal fluid protein level > 1 g/liter and ataxia. Onset is before the age of 20, although later-onset cases may occasionally occur. Furthermore, there may be an associated proximal limb weakness. Taken together with CPEO, ptosis may

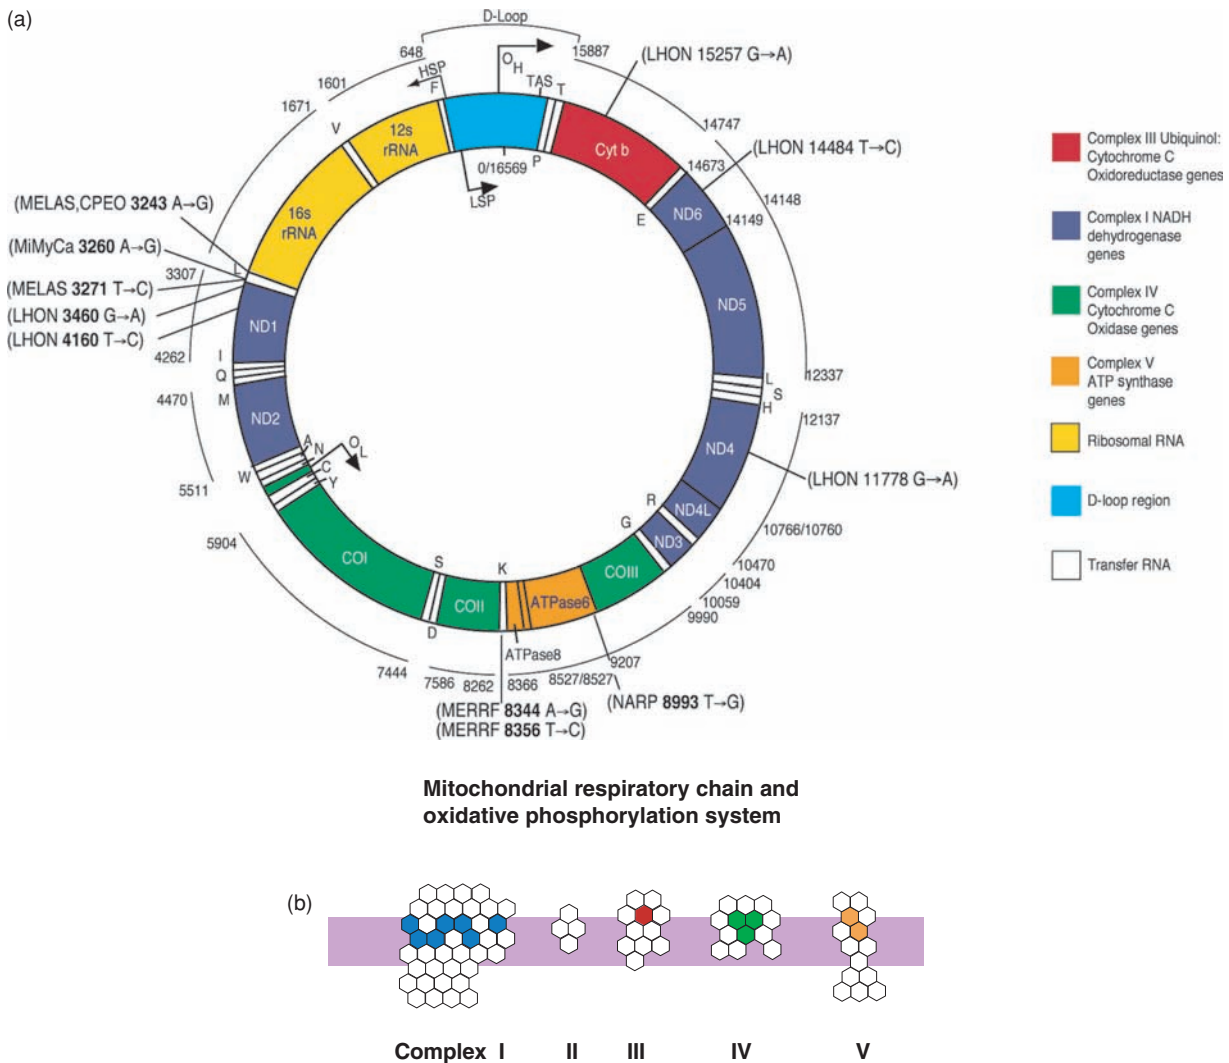

Fig. 62.1 The human mtDNA genome (a). The protein coding genes are colour coded to the subunits in the respiratory chain cartoon (b). The location of some of the more common point mutations are shown in (a).

be asymmetrical in 58% or unilateral in 8%. Dysconjugate eye movements occur in 35% with transient or persistent diplopia in 36%. The ophthalmoplegia may be severe, and in 62% of patients, gaze is limited to less than 10% of normal in any direction (Petty *et al.*, 1986). Mitochondrial DNA deletions are also the most common cause of KSS being found in 80% of patients (Holt *et al.*, 1988, 1989; Moraes *et al.*, 1989). Mitochondrial DNA duplications may also be found, although in low abundance, and may be an intermediate step to deletion (Holt *et al.*, 1997) duplications of mitochondrial DNA are not necessarily pathogenic (Holt *et al.*, 1997; Tang *et al.*, 2000). In both CPEO and KSS, mitochondrial DNA deletions are present in highest proportion in the COX negative ragged red fibers.

The majority of patients with CPEO or KSS have no family history. This is thought to be due to the mitochondrial DNA deletions arising *de novo* in maternal oocytes. Duplicated mtDNA molecules have been identified with a maternal inheritance pattern such as in cases in renal tubular dysfunction ataxia and diabetes mellitus (Rotig *et al.*, 1992), CPEO, myopathy and diabetes mellitus (Dunbar *et al.*, 1993). More often, maternally inherited CPEO is due to a point mutation of mtDNA rather than a rearrangement, e.g. the A3243G mutation in tRNA (Moraes *et al.*, 1993). Several other tRNA mutations have also been associated with maternally inherited CPEO. Muscle biopsies in these patients show the typical CPEO pattern of COX negative fibers, rather

Fig. 62.2(a) Succinate dehydrogenase (SDH) stain of a muscle biopsy showing SDH positive fibers corresponding to ragged red fibers.

Fig. 62.2(b) Cytochrome oxidase negative fibers.

than the usual COX positive fibers associated with tRNA mutations.

CPEO may also exhibit autosomal dominant or recessive inheritance. The first description of autosomal dominant CPEO was in an Italian pedigree with onset in early adulthood of ptosis, dysarthria, dysphasia, facial and proximal limb weakness with cataracts and early death (Servidei *et al.*, 1991). Other pedigrees have been described with additional features such as cardiomyopathy, endocrine abnormalities, ataxia, rhabdomyolysis and peripheral neuropathy (Melberg *et al.*, 1996, 1998). Patients often exhibit lactic acidosis and muscle biopsy shows the usual features of ragged red fibers. At least three chromosomal loci have been identified in autosomal dominant CPEO including chromosome 4 (Kaukonen *et al.*, 1999), and a mutation has

recently been identified in the gene for adenine nucleotide translocator 1 (Kaukonen *et al.*, 2000). The other locus is on chromosome 10 (Li *et al.*, 1999; Suomalainen *et al.*, 1995). There are likely to be additional loci that are not linked to either chromosome 4 or 10. Autosomal dominant CPEO is associated with multiple deletions in the same patient and as in sporadic CPEO and KSS, the deletions are not present in mitotically active cells, e.g. lymphocytes and fibroblasts.

Myopathy encephalopathy lactic acidosis and stroke-like episodes

This phenotype is characterized by growth retardation, focal and generalized seizures and recurrent stroke-like episodes, particularly hemianopia and hemiplegia. Additional features may include diabetes, deafness, dementia, ataxia and myopathy. Pigmentary retinopathy is relatively uncommon. Onset is usually in adolescence, although patients may manifest later, and MELAS remains an important differential diagnosis in patients with stroke under the age of 40. Clinical progression is usual, but at a variable rate. Many patients develop features of migraine with aura and recurrent episodes of lactic acidosis associated with nausea and vomiting. The stroke-like episodes may be transitory or result in permanent neurological deficit. Imaging in patients with MELAS usually reveals low-density areas affecting grey and white matter, which typically do not conform to vascular territories, and most often affect the parietal occipital regions (Pavlikis *et al.*, 1984; Allard *et al.*, 1988). Elevation of CSF lactate is invariable in patients with encephalopathy.

Skeletal muscle morphology in patients with MELAS usually demonstrates ragged red and SDH positive fibers. In contrast to those with mitochondrial DNA deletions, the cytochrome oxidase fibers are usually strongly positive. Histochemical analysis of cerebral vessels also demonstrate strong SDH reactivity suggesting that angiopathy is a significant component of the pathogenesis of MELAS associated strokes (Kuriyama *et al.*, 1984). Basal ganglia calcification is also a common radiological feature of MELAS (Sue *et al.*, 1998). This most commonly affects the globus pallidus but can also include the striatum, thalamus and internal capsules.

Eighty per cent of patients meeting the clinical criteria for MELAS are positive for the A3243G mutation in the tRNA for leucine (Hammans *et al.*, 1991; Goto *et al.*, 1990; Kobayashi *et al.*, 1990). Analysis of the effects of this mutation in cybrids has shown a reduction in global protein synthesis due to abnormalities of aminoacylation and post-transcriptional modifications of the tRNA (Borner

et al., 2000; Chomyn *et al.*, 1991; Helm *et al.*, 1999). There is also evidence that a partially processed polycistronic transcript (RNA19) which is composed of a segment of RNA, the tRNA leucine(UUR) stop signal and ND1 is significantly increased in cybrids (King *et al.*, 1992). This maybe incorporated into ribosomes and interfere with translation (Schon *et al.*, 1992).

Other mutations have been associated with the MELAS phenotype including four different mutations within the tRNA leucine (UUR) gene, and in numerous other tRNAs.

Cybrid analysis using the A3243G mutation showed that this particular base change was recessive in the sense that 5–10% of wild-type mitochondrial DNA was sufficient to compensate biochemically for the mutation; whether these data from cybrids can be translated to the *in vivo* situation is not known.

Myoclonic epilepsy and ragged red fibers (MERRF)

The core features of this syndrome are myoclonus, ataxia and seizures. Patients often manifest with myoclonic epilepsy which may be stimulation sensitive. Additional seizure types may also occur including drop attacks, tonic-clonic seizures and focal seizures (Hammans *et al.*, 1993; Berkovic *et al.*, 1989). The myopathy is usually relatively mild, and involves proximal upper and lower limb weakness. Additional clinical features may include hearing loss, neuropathy, dementia and growth retardation (Silvestri *et al.*, 1993). Some patients have been recoded with ophthalmoplegia, ptosis, optic atrophy, and cervical lipomas (Berkovic *et al.*, 1989; Fukuhara *et al.*, 1980; Truong *et al.*, 1990; Tulinius *et al.*, 1991). The clinical causes are variable, but usually progressive.

The presence of lipomas is an interesting phenomenon in MERRF patients, and as indicated, usually comprises multiple symmetrical cervical lipomas (Larsson *et al.*, 1995). In some patients, this may be the only manifestation of MERRF (Holme *et al.*, 1993). The lipomas comprise brown adipose tissue expressing mitochondrial uncoupling proteins (Vila *et al.*, 2000).

Phenotypic variation as suggested by the above range of clinical features can be substantial even within the same family (Graf *et al.*, 1993). For instance, in one family, some patients presented with Leigh syndrome, others with spinal cerebellar degeneration or a form of motor and sensory neuropathy (Howell *et al.*, 1996).

The electroencephalogram may be abnormal in MERRF patients (So *et al.*, 1989) but the changes are not specific. Plasma and CSF lactate levels may be elevated. Muscle

Fig. 62.2(c) Electron micrograph shows mitochondrial paracrystalline inclusions.

biopsy shows ragged red fibers, which are SDH positive, and COX negative.

The most common mutation detected in MERRF is the A8344G mutation, which is present in 80% of patients (Hammans *et al.*, 1991; Shoffner *et al.*, 1990; Zeviani *et al.*, 1991). The tRNA lysine gene may also harbor other mutations which can result in the MERRF phenotype. Likewise, single base changes in other tRNAs for leucine or serine, may also produce a phenotype with features of MERRF (Moraes *et al.*, 1993; Folgero *et al.*, 1995; Nakamura *et al.*, 1995). The MERRF mutations in cybrids result in reduced protein synthesis of certain protein translation products (Chomyn, 1998; Enriquez *et al.*, 1995; Hao & Moraes, 1996; Masucci *et al.*, 1995). There are some suggestions that the mutant load in the muscle or blood, the age of onset and certain clinical parameters may give some indication for prognosis (Hammans *et al.*, 1993; Shoffner *et al.*, 1991).

Neurogenic muscle weakness ataxia and retinitis pigmentosa (NARP)

The key features of this syndrome are myopathy, peripheral neuropathy, ataxia, seizures, dementia and retinitis pigmentosa (Holt *et al.*, 1990). They may also include migraine

and mental retardation (Tsairis *et al.*, 1973; Ortiz *et al.*, 1993; Fryer *et al.*, 1994; Makela-Bengts *et al.*, 1995; Puddu *et al.*, 1993).

The most common cause of this phenotype is the T8893G mutation in the ATPase 6 gene. This mutation is heteroplasmic and, when present at around 70%, is associated with a NARP phenotype, and when present at >90%, is associated with maternally inherited Leigh syndrome (Holt *et al.*, 1990; Santorelli *et al.*, 1994). T8993C mutation has also been associated with NARP (65), and one patient with Leigh syndrome (Santorelli *et al.*, 1994). The mutations affect the region of ATPase associated with the proton channel and may result in impairment of the electrochemical gradient required to synthesize ATP (Tatuch *et al.*, 1992). Alternatively, the mutations may impair the efficiency of the coupling of proton flow to the rotation of the ATPase subcomplex in the inner membrane (Schon, 2000; Schon *et al.*, 1997).

Ragged red fibers and other morphological abnormalities are usually absent in the muscle biopsies from patients with NARP (Holt *et al.*, 1990). Biochemical analysis may also be normal unless ATPase activity is assessed specifically. Blood levels of citrulline have been found to be low in some patients with NARP and it has been suggested that it is the surrogate marker of this phenotype (Parfait *et al.*, 1999).

Additional phenotypes

Approximately 1–2% of all non-insulin dependent diabetic mellitus is thought to be related to the presence of the A3243G mutation (Kadowaki *et al.*, 1993; Gerbitz *et al.*, 1995), and this may occur as the only clinical manifestation of this mutation in some patients (Gerbitz *et al.*, 1993; Reardon *et al.*, 1992), or be present with associated sensory neural deafness (Kadowaki *et al.*, 1993; van den Ouweland *et al.*, 1992).

Sensory neural hearing loss may occur as an isolated phenomenon with mutations in the tRNA for serine (Guan *et al.*, 1998).

Cardiomyopathy which may be either dilated or hypertrophic has been reported with a number of mitochondrial DNA mutations including rRNA genes (Santorelli *et al.*, 1999). A number of cases have also been described with pure myopathy (Hudgson *et al.*, 1972; Kamieniecka, 1977). These patients usually have fatigue and exercise intolerance (Petty *et al.*, 1986), and some patients with recurrent myoglobinuria and exercise intolerance, have mitochondrial DNA deletions (Ohno *et al.*, 1991; Andreu *et al.*, 1999). Cytochrome oxidase gene mutations have also been associated with myopathy and myoglobinuria (Keightley

et al., 1996). Mutations in mitochondrial DNA COX genes have been associated with a variety of clinical presentations including motor neurone disease (amyotrophic lateral sclerosis), and sideroblastic anemia (Comi *et al.*, 1998; Gattermann *et al.*, 1997).

Leber's hereditary optic neuropathy (LHON)

This is a maternally inherited disorder characterized by acute or subacute bilateral sequential painless visual failure. The mean age of onset is in the early 20s and 90% of patients are affected by age 45; 85% are men. In most cases the visual loss is severe, and permanent, although this is dependent upon the underlying mutation.

Three mitochondrial DNA mutations are considered primary, and all are located within mitochondrial DNA complex I genes. These are the G11778A mutation in ND4, which is found in 50–70% of LHON patients, the G3460A mutation in 15–25%, and the T14484C mutation in ND6. The latter is relatively uncommon, but is associated with visual recovery in 70% (Wallace *et al.*, 1988; Howell *et al.*, 1991; Johns *et al.*, 1992; Mackey & Howell, 1992).

The mutations are detectable in blood, and are usually homoplasmic. There is evidence for a complex I defect in muscle and platelets of patients (Smith *et al.*, 1994; Larsson *et al.*, 1991), and this has been confirmed in cybrid studies. Only 15% of women who carry one of the primary mutations are clinically affected. This initially led to the suggestion of x-linked susceptibility, but no evidence has yet been found to support this (Chalmers *et al.*, 1996). Autoimmune involvement (Smith *et al.*, 1995) or alternatively some influence of nuclear expression have also been suggested to influence disease expression. Furthermore, a number of secondary mitochondrial DNA mutations have also been proposed to influence expression, and may act synergistically with a primary mutation (Howell, 1997).

Some families exhibiting features of LHON may have additional features such as dystonia or striatal degeneration, and these have also been found to be related to mutations in mitochondrial DNA complex I genes (Jun *et al.*, 1994; De Vries *et al.*, 1996), although dystonia has also been seen in some patients with the 3460 and 11778 mutations (Meire *et al.*, 1995; Nikoskelainen *et al.*, 1995; Thobois *et al.*, 1997).

Myo-neuro-gastrointestinal encephalopathy (MNGIE)

The diagnostic criteria for this phenotype include peripheral neuropathy, CPEO and gastrointestinal dysmotility.

Patient's skeletal muscle has the typical morphological features of mitochondrial myopathy. The gastrointestinal disease usually includes nausea, vomiting and diarrhoea. MR imaging may demonstrate a leukodystrophy. The peripheral neuropathy is sensory motor in type (Hirano *et al.*, 1994). The average age of onset is usually in adolescence, and most patients are dead by 40 years (Nishino *et al.*, 2000).

Southern blotting demonstrates multiple mitochondrial DNA deletions and depletion of mitochondrial DNA (Nishino *et al.*, 2000). Inheritance is autosomal recessive and mutations in thymidine phosphorylase have been identified in those patients that map to chromosome 22 (Nishino *et al.*, 1999). Thymidine phosphorylase activity is severely reduced in patients, and plasma thymidine levels are high.

Leigh syndrome

This is a subacute narcotizing encephalomyelopathy (Leigh, 1951). The clinical features are wide, and include psychomotor retardation, respiratory abnormalities, oculomotor disturbance, optic atrophy, seizures and lactic acidosis. Onset is usually in the first few months of life, or during childhood. This syndrome might be caused by a variety of biochemical abnormalities including respiratory chain defects (Di Mauro & De Vivo, 1996; Van Erven *et al.*, 1987; Willems *et al.*, 1977; Van Coster *et al.*, 199), pyruvate dehydrogenase deficiency (Kretzschmar *et al.*, 1987) or biotinidase deficiency (Baumgartner *et al.*, 1989). Respiratory chain defects include those patients with mutations of nuclear genes encoding subunits of complexes I or II (Loeffen *et al.*, 1998; Bourgeron *et al.*, 1995). Deficiency of complex IV in patients with Leigh syndrome may be associated with mutations of the SURF gene which is responsible for assembly and maintenance of complex IV (Tiranti *et al.*, 1998; Zhu *et al.*, 1998). As indicated above, approximately 20% of Leigh syndrome patients have an ATPase 6 mutation with mutant loads 90% or greater. The MELAS or MERF mutations have also been associated with a Leigh syndrome phenotype (Rahman *et al.*, 1996; Koga *et al.*, 1998).

Neurodegenerative diseases

As can be seen from the review of primary mitochondrial disorders noted above, defects of the mitochondrial respiratory chain due to mutations of mitochondrial DNA or mutations of nuclear genes encoding subunits of the respiratory chain or components required for its construc-

tion or maintenance, result in a variety of features that include progressive neurological features. The following section covers mitochondrial involvement in archetypal neurodegenerative diseases:

Parkinson's disease

Since the first report of mitochondrial dysfunction in Parkinson's disease (PD) (Schapira *et al.*, 1989), there has been considerable interest in mitochondrial dysfunction in this disorder. In the CNS the defect appears to be confined to the substantia nigra (Schapira *et al.*, 2000a,b), and there is some indication of a reduction of complex I subunits in dopaminergic neurons of this region (Hattori *et al.*, 1991). Other neurodegenerative disorders simulating Parkinson's disease, such as multiple system atrophy do not have any evidence of respiratory chain defect in the substantia nigra (Gu *et al.*, 1997). However, numerous reports have identified a complex I defect in platelets from a proportion of patients with PD (Schapira, 1994).

On a group-to-group analysis, the substantia nigra defect in PD is approximately 35%, i.e. 65% residual complex I activity. A defect of this level is likely to result in an increase in free radical release and oxidative stress in the nigra. The substantia nigra is already a site of increased iron and dopamine auto-oxidation (Dexter *et al.*, 1989; Hirsch *et al.*, 1991), and there is evidence for a decrease in reduced glutathione and increase in malonaldehyde as indicators of free-radical mediated oxidative stress and damage (Dexter *et al.*, 1994; Alam *et al.*, 1997a,b). The respiratory chain proteins are also susceptible to damage from free radicals, and this therefore has the potential to exacerbate the underlying respiratory chain defect.

The potential relevance of complex I deficiency to Parkinson's disease has been underlined by the fact that environmental toxins that are complex I inhibitors are capable of producing models of Parkinson's disease. The first of these was MPTP produced as a contaminant of a meperidine designer drug (Langston & Ballard, 1984). MPTP is first oxidized to MPP⁺ by monoamine oxidase B which is found in high concentration in glia. MPP⁺ is then taken up by the dopamine transporter and so is concentrated within nigra dopaminergic neurons (Chiba *et al.*, 1985; Javitch & Snyder, 1984). Because of its positive charge, MPP⁺ is further concentrated several hundredfold into mitochondria, where it is an inhibitor of complex I (Ramsay *et al.*, 1986; Nicklas *et al.*, 1985). MPTP also induces increased free radical generation (Rossetti *et al.*, 1988). It is of note that transgenic mice overexpressing SOD1 are resistant to MPTP toxicity (Przedborski *et al.*, 1992). Likewise, MPTP toxicity in primates can be blocked with the neuronal nitric oxide

synthase inhibitor, 7-nitroindazole (Hantraye *et al.*, 1996). A similar effect is seen in mice (Schulz *et al.*, 1995), and in neuronal nitric oxide synthase (nNOS) knockout mice (Przedborski *et al.*, 1996). Infusion of rotenone, another specific inhibitor complex I, induces nigral cell death in rodents together with the production of inclusions similar to Lewy bodies (Betarbet *et al.*, 2000). Further analysis of this model suggests that neurodegeneration is not confined to the substantia nigra, and this model may more resemble, a model of progressive supranuclear palsy (Hoglinger *et al.*, 2003).

There are also overlaps between some of the recently identified causes of familial Parkinson's disease. For instance, alpha synuclein has in some studies been associated with a decrease in mitochondrial function (Elkon *et al.*, 2002). The ubiquitin proteasomal pathway is now considered to be an important area in the pathogenesis of Parkinson's disease. Alpha synuclein is a significant component of Lewy bodies in sporadic Parkinson's disease. Over expression of this protein as well as its expression in mutant form leads to familial autosomal dominant Parkinson's disease (Singleton *et al.*, 2003). Activity of the ubiquitin proteasomal system is dependent upon ATPases, and a decrease in complex I activity impairs function of the system. Furthermore, a decrease in complex I activity results in an increase in proteins damaged by free radicals that are dependent upon the ubiquitin proteasomal system, for metabolism. A concomitant genetically determined defect of the ubiquitin proteasomal system, such as might be caused by parkin mutations, might act synergistically with a complex I defect to impair cell metabolism, and enhance cell death. Alternatively, environmental agents that impair the proteasomal pathway would have a similar effect.

At present, it is not known whether the complex I defect is a consequence of a genetic abnormality or is environmentally induced. If the latter, this could be a consequence of either exogenous or endogenous toxins. Several studies have sequenced mitochondrial DNA in patients with Parkinson's disease, but none has identified a consistent mutation. To some degree, this might be a consequence of the failure to select patients with complex I deficiency, which probably only affects a proportion of Parkinson's disease cases. Cybrid analysis of patients with complex I deficiency has shown that the defect may be transferred from the platelets of patients with Parkinson's disease to cybrid cells. This involves the passage only of mitochondrial DNA from the platelets to the cybrid cells, and therefore indicates that the complex I defect is determined by mitochondrial DNA (Gu *et al.*, 1998; Swerdlow *et al.*, 1996). What is not known is whether the complex I defect alone can induce nigral cell death or whether it is necessary for

this abnormality to be in combination with either another concomitant genetic defect or to work in synergy with an environmental agent.

Huntington's disease

Huntington's disease is an autosomal dominant disorder caused by an abnormal CAG extension in the N-terminal region of the huntingtin gene. This encodes a polyglutamine stretch. Pathology comprises severe atrophy of the caudate, and to a lesser extent the putamen with selective loss of the medium spiny neurons. The function of huntingtin is not known, but it is highly conserved and widely expressed in neural and non-neural tissues (Strong *et al.*, 1993). Cultured cells expressing mutant huntingtin developed intranuclear aggregates (Cooper *et al.*, 1998; Li & Li, 1998; Martindale *et al.*, 1998) including myoblasts from a transgenic mouse model (Orth *et al.*, 2003).

Excitotoxicity is thought to play an important role in the pathogenesis of Huntington's disease. For instance, intrastriatal injections of kainate results in striatal lesions are similar to HD (Beal, 1992; Coyle & Schwarcz, 1976; McGeer & McGeer, 1976). Quinolinic acid also results in lesions similar to HD in association with chorea (Schwarcz *et al.*, 1983; Beal *et al.*, 1986, 1989).

There is evidence of significant mitochondrial dysfunction in HD brain tissue (Mann *et al.*, 1990). This amounts to a 56% decrease in complex II and complex III activity, and a 33% defect in complex IV activity (Gu *et al.*, 1996; Browne *et al.*, 1997). There is also evidence of a defect of aconitase activity which parallels the neuropathology (Tabrizi *et al.*, 1999). Respiratory chain activities were normal in HD cerebellum and fibroblasts (Schapira, 1999). These observations are of interest, in that they parallel the biochemical defect induced by 3-nitropropionic acid (3-NP) which is an irreversible inhibitor of complex II, and infusion of this agent induces lesions that mimic those found in HD (Brouillet *et al.*, 1993; Beal *et al.*, 1993). The 3-NP induced lesions are dependent upon excitotoxicity through glutamatergic input (Weller & Paul, 1993) that is unlikely to be the only mechanism by which this toxin acts (Weller & Paul, 1993).

3-NP induces encephalopathy and coma with dystonia and chorea in human survivors (Ludolph *et al.*, 1991). The CT scans of those exposed to 3-NP show bilateral hypodensities in the putamen and global pallidus (Ludolph *et al.*, 1991). Thus, complex II inhibition can produce a biochemical and pathological picture which mimics HD.

Given that mutant huntingtin is expressed in skeletal muscle, it is of interest that phosphorus magnetic resonance spectroscopy of skeletal muscle in HD patients has

demonstrated a decrease in ATP synthesis, the severity of which is dependent upon the CAG repeat (Lodi *et al.*, 2000). A similar, but milder, defect was present in pre-symptomatic patients in this study. Proton spectroscopy of HD brains has demonstrated increased lactate levels in the occipital cortex in the basal ganglia (Kuwert *et al.*, 1990; Jenkins *et al.*, 1993, 1998), although this has not been found in all studies (Hoang *et al.*, 1998). One study has also shown a decrease in cortical lactate with CoQ10 (Koroshetz *et al.*, 1997).

The mitochondrial defect present in HD brain and muscle extends to the R62 transgenic mouse model of HD, where in the striatum there is evidence of a significant reduction of complex IV and aconitase with a decrease in complex IV in cerebral cortex (Tabrizi *et al.*, 2000). These changes were accompanied by an increase in immunostaining for inducible nitric oxide synthase.

These abnormalities suggest involvement of excitotoxic mechanisms, in particular, the generation of nitric oxide and peroxynitrite. The early defect of complex IV activity is supported by similar findings in HD lymphoblasts (Sawa *et al.*, 1999). This defect might initiate a chain of events resulting in excess free-radical production, complex II/III and aconitase inhibition.

The relevance of these mitochondrial abnormalities to the pathogenesis of HD remains uncertain. Importantly, their relationship to the huntingtin mutation is not known, but the correlation of the mitochondrial defect with the degree of polyglutamine expansion suggests some direct relationship between the two. Creatine supplementation prolongs the survival of the R62 transgenic mouse (Ferrante *et al.*, 2000), although creatine supplementation in HD does not appear to result in benefit at least over a 12-month period (Tabrizi *et al.*, 2003). CoQ10 has also been tried in HD patients and, whilst there was no significant improvement in the clinical features of HD, there was a trend towards benefit (Huntington Study Group, 2001).

Alzheimer's disease

Several groups have found a reduction in complex IV activity in the brain and sometimes in the platelets of patients with Alzheimer's disease (Kish *et al.*, 1992; Parker *et al.*, 1994a,b; Mutisya *et al.*, 1994). Histochemical stains have also shown a decrease in cytochrome oxidase in the dentate gyrus and hippocampus of AD (Simonian & Hyman, 1993), and there is a reduction in the mRNA for subunit II of cytochrome oxidase (Simonian & Hyman, 1993). No mutations of mitochondrial DNA have been identified in AD patients. The cytochrome oxidase defects may be the result of increased oxidative stress in AD (Bonilla *et al.*,

1999), and thus represent a secondary phenomenon. There is also evidence of microglial activation in AD, and this too could contribute to the complex IV defect.

Friedreich's ataxia

Friedreich's ataxia is an autosomal recessive disorder characterized by onset usually at adolescence with progressive limb and gait ataxia, areflexia, peripheral neuropathy and hypertrophic cardiomyopathy in association with skeletal abnormalities (Durr *et al.*, 1996). In over 95% of patients this disease is caused by GAA triplet repeat in intron I of the gene for frataxin (Campuzano *et al.*, 1996). The remaining patients are compound heterozygous with a GAA expansion in one allele and a point mutation in the other (Pook *et al.*, 2000).

The length of the GAA repeat determines the level of residual frataxin (Bidichandani *et al.*, 1998; Wong *et al.*, 1997; Campuzano *et al.*, 1997). The physiological function of frataxin is not known, although it is a mitochondrial protein, likely involved in iron homeostasis, and probably in iron-sulphur protein construction (Lill *et al.*, 1999; Kispal *et al.*, 1999).

The yeast frataxin homologue knockout model of human frataxin deficiency results in mitochondrial abnormalities including impaired respiratory chain function, iron accumulation, decreased mitochondrial DNA levels, and increased oxidative stress. Based upon these observations, severe deficiencies of complexes I, II and III and aconitase were identified in cardiac muscle from FRDA patients (Rotig *et al.*, 1997; Bradley *et al.*, 2001). These enzymes all contain iron-sulphur clusters. The decrease in respiratory chain activities precede iron accumulation in the conditional frataxin knockout transgenic mouse model of FRDA (Puccio *et al.*, 2001), and so it appears likely that failure of construction of these iron-sulphur proteins is an early event, which may then be followed by secondary free-radical mediated damage.

The respiratory chain defect in patients can be detected by phosphorus magnetic resonance spectroscopy in vivo in skeletal muscle. The defect in ATP synthesis (V_{\max}) correlated with the length of the GAA repeat (Lodi *et al.*, 1999, 2001). In addition to evidence for mitochondrial dysfunction, there is also additional evidence of free-radical mediated damage including elevated malondialdehyde levels (Emond *et al.*, 2000), and urine 8-hydroxy-2'-deoxyguanosine levels. Free glutathione is also decreased in blood from FRDA patients (Piemonte *et al.*, 2001). Fibroblast culture from FRDA patients show increased sensitivity to hydrogen peroxide (Wong *et al.*, 1999).

The evidence for mitochondrial dysfunction and free-radical damage in FRDA patients prompted therapeutic intervention with antioxidants such as idebenone and coenzyme Q10 with vitamin E. A variety of markers for disease severity have been used in FRDA including echocardiography (Lodi *et al.*, 2001; Hausse *et al.*, 2002), phosphorus MR spectroscopy (Lodi *et al.*, 2001) and urine 8-hydroxy-2'-deoxyguanosine (Schols *et al.*, 2001).

Idebenone has shown improvement in cardiac hypertrophy as determined by echocardiography, in some, but not all patients (Hausse *et al.*, 2002). This compound failed to improve phosphorus magnetic resonance spectroscopy or echocardiography in another study (Schols *et al.*, 2001). Treatment with a combination of coenzyme Q10, 400 mg a day and vitamin E, 2100 international units a day improved MRS data in heart and skeletal muscle after 6 months (Lodi *et al.*, 2001). Four-year follow-up has shown that this benefit is maintained and is also associated with some clinical improvement (Hart & Schapira, 2004).

Motor neurone disease (amyotrophic lateral sclerosis)

Motor neurone disease (MND) or amyotrophic lateral sclerosis (ALS) is characterized by degeneration of anterior horn cells, spinal cord and motor cortex. Ten per cent of cases are familial and, in 25% of these, there are mutations in the gene encoding cytosolic copper, zinc, superoxide dismutase (Rosen *et al.*, 1993; Cudkowicz *et al.*, 1997). These mutations may produce toxicity by mechanisms involving increased peroxide nitrite formation (Moncada *et al.*, 1989; Crow *et al.*, 1997; Estevez *et al.*, 1999). There is evidence for oxidative stress and damage in ALS tissue including motor cortex (Ferrante *et al.*, 1997; Bowling *et al.*, 1993) and the spinal cord (Shaw *et al.*, 1995) and levels of 8-hydroxy-2'-deoxyguanosine (8OH2'dG) are increased in the cortex, cord (Ferrante *et al.*, 1997; Fitzmaurice *et al.*, 1996) and in urine plasma and CSF (Bogdanov *et al.*, 2000).

Several studies have demonstrated defects of the respiratory chain in tissues from MND patients. For instance, a defect in complex I activity has been found in skeletal muscle (Wiedemann *et al.*, 1998). Reduced cytochrome oxidase activity has been found in anterior horn cells (Borthwick *et al.*, 1999). Multiple mitochondrial DNA mutations have been found in ALS patients (Vielhaber *et al.*, 2000). A mutation in subunit I of complex IV with reduced cytochrome oxidase activity was identified in one patient with MND (Comi *et al.*, 1998).

The transgenic mice with an SOD1 mutation show morphological changes in the mitochondria (Kong & Xu, 1998). Creatine supplementation improves survival in these

animals (Klivenyi *et al.*, 1999), but has not yet been used in patients.

 - α -synuclein association with pathology 190
- tau transgene mutations 222

- tauopathies 188–90, 484, 494, 685
 animal models 505
 experimental therapeutics 189–90
 geographic clusters 672
 inclusions 188
 neurofibrillary tangles 453, 454–5
 pathogenesis 190
 transgenic models 189
- tellurium-based scavengers 27
- tendon stimulation 237–8
- tetracyclines 6
- tetrahydrobiopterin 4
- 1, 2, 3, 4-tetrahydroisoquinolones (TIQ) 210
- tetrodotoxin (TTX) 141
 neuroprotective effects 142
- thalamotomy, Parkinson's disease 617
- thalamus
 dystonia pathogenesis 236
 gray matter intensity 263
 Parkinson's disease 263
 tremor 233–4
- thermoregulation
 amphetamines 209–10
 multiple system atrophy 641
- thermoregulatory sweat test 641
- thiamine, multiple system atrophy 627
- thiobarbituric acid 11
 oxidative stress 598–9
- thiols, hyperactive 27
- thioredoxin 11
- thioredoxin reductases 11
- L-threo-dihydroxy-phenylserine, multiple system atrophy 647
- L-threonine 777
- thyroid peroxidase 7
- thyrotropin-releasing hormone (TRH) 784
- TNFA* gene in Alzheimer's disease 448
- α -tocopherol *see* vitamin E
- α -tocopherol transfer protein (α -TTP) 727
- tolcapone 616
- tonic vibration reflex 237
- topiramate dementia with Lewy bodies 479
- Total Functional Capacity (TFC) scale 853
- TRAAK activation 143
- transcription factors
 huntingtin 855
 neuronal nuclear inclusions 855
- transcription-coupled repair 131–2, 133
 Cockayne's syndrome 133–5
 deficiency 135
- transferrin 880, 882
- transferrin receptors 880
- transforming growth factor α (TGF- α)
 compensatory neurogenesis 352
 striatal dopaminergic neuron recruitment 356
- transglutaminases, progressive supranuclear palsy 673
- transition metal ions 6–7
- transmembrane protein, γ -secretase proteolysis 179
- transmissible spongiform encephalopathy 704
- trauma
 apoptosis 84–5
 multiple sclerosis 85
- traumatic head injury, NAA/Cr ratio 316
- TREK-1 activation 143
- tremor
 essential
 dopamine transporter binding 291
 neurophysiologic tests 230
 metabolic substrates 294
 multiple system atrophy 631–2
 neuroimaging 233–4
 palatal 266
 Parkinson's disease 552, 564
 progressive supranuclear palsy 669
 Wilson's disease 552, 892, 893
- triacylglycerols 875
- tricarboxylic acid (TCA) cycle 33
 dynamics assay 303
 flux 314–15
 glucose metabolism 314
 glycolysis 35
- trichothiodystrophy, defective DNA repair 135
- trien, Wilson's disease 900, 901
- triglycerides
 abetalipoproteinemia 874
 hypobetalipoproteinemia 875
- trkB receptor 97
- Troyer syndrome 797, 799
- tumor necrosis factor α (TNF- α)
 gene in Alzheimer's disease 448
 multiple system atrophy 629
 Parkinson's disease 603
- tumor necrosis factor receptor 1 (TNFR1) 81
 Parkinson's disease 614
- tyrosine
 nitration 23
 oxidant attack 25
- tyrosine phosphatases 23–4
- tyrosyl radical 25
- tyrosyl-DNA phosphodiesterase 1 (TDP1) gene 731
- ubiquinone *see* coenzyme Q₁₀
- ubiquitin 110–11
 aggregates in amyotrophic lateral sclerosis 183
 Alzheimer's disease
 accumulation 121
 anomalous form 121, 122–3
 conjugation 111
 degradation requirement 111
 α -synuclein inclusion bodies 120
- ubiquitin carboxy-terminal hydrolase L1 (UCH-L1)* 120,
 589–90
 mutations 187, 586

- ubiquitin-carrier proteins (E2s) 111
- ubiquitin-conjugating enzymes 112
- ubiquitin–proteasome pathway 86, 108, 110–11, 916
 - aging effects 122
- ubiquitin-protein ligase (E3) 111
 - parkin mutations 120
- unfolded protein response 109
- Unified Huntington's Disease Rating Scale (UHDRS) 853
- upper motor neurons (UMN) 751–2
 - signs associated with damage 752
- urate 8
 - metabolites 12
- urethral sphincter, multiple system atrophy 646
- urinary incontinence, progressive supranuclear palsy 671
- urinary urgency, hereditary spastic paraplegia 796

- L-valine 777
- valproate, frontotemporal lobar degeneration 490
- vascular dementia treatment 462–3
- vascular endothelial growth factors (VEGF) gene 766, 786–7
- ventral intermediate nucleus (VIM) 233–4
- very low density lipoprotein (VLDL) 727
 - abetalipoproteinemia 874
 - hypobetalipoproteinemia 875
- vesicular monoamine transporters (VMAT) 199
 - imaging 292
- vestibulo-ocular reflex, progressive supranuclear palsy 670
- visual disorders
 - progressive disturbance 424–5
 - Wilson's disease 894
- vitamin A
 - abetalipoproteinemia treatment 728
 - deficiency in abetalipoproteinemia 728
- vitamin B₅ 887
- vitamin B₆ 466
- vitamin B₁₂ 466
 - deficiency 704
- vitamin C
 - Alzheimer's disease 455, 463
 - scavenging 25
- vitamin E 6, 8
 - abetalipoproteinemia 874
 - treatment 728
 - Alzheimer's disease 426–7, 455, 463
 - treatment 426, 463–4
 - amyotrophic lateral sclerosis treatment 778
 - ataxia due to isolated vitamin E deficiency treatment 727
 - chylomicrons 727
 - Friedreich's ataxia treatment 726
 - hypobetalipoproteinemia 875
 - inherited deficiencies 719
 - Parkinson's disease 613
 - phytol 729
 - scavenging 25
- volumetry 254
- voxel-based morphometry 254

- Wallerian degeneration 184
 - SOD1 mutant mice 185
- water, well and Parkinson's disease 567, 602
- Wechsler Adult Intelligence Scale (WAIS) 386
- Werdnig–Hoffmann disease 817–18
- Wernicke's encephalopathy 704
- whispering dysphonia, Wilson's disease 892
- white matter
 - changes
 - with age 390–1
 - dementia with Lewy bodies 258
 - degeneration in dentatorubral-pallidoluysian atrophy 861
 - NAA concentration 307
- Wilson's disease 890–901
 - aceruloplasminemia differential diagnosis 884–5
 - affected siblings 897
 - age of onset 891
 - ammonium tetrathiomolybdate 900–1
 - behavioral disorders 893
 - behavioral manifestations 893
 - brain lesions 264
 - brainstem atrophy 895
 - chelating agents 900
 - clinical presentation 891–3, 896
 - cognitive function 893
 - copper
 - absorption prevention 891
 - assay of liver 897
 - availability 882
 - chelation therapy 896
 - elimination failure 890
 - radioisotope copper tracer tests 897
 - copper deposition 890–1, 899
 - eye 894
 - copper urinary excretion 897, 901
 - siblings 897
 - creatine phosphokinase 896–7, 899
 - decoppering therapy 890, 894, 896
 - depression 893
 - diagnosis 892, 896–8
 - dopamine transporter binding 291
 - epilepsy 893–4
 - eye
 - copper deposition 894
 - movement 894
 - frequency 898
 - genetics 898–9
 - hallucinations 893
 - hepatitis 896
