The fruit of their labors was an easy-to-use film with exceptional quality and color accuracy that was equally popular with amateur and professional still and movie photographers. Kodachrome's superior dark-storage longevity allowed amateur photographers to preserve family photo albums and home movies for generations. Folk singer Paul Simon wrote about his appreciation of the qualities of the film in his hit song "Kodachrome."

Perhaps more important, the storage longevity has permitted the archiving and preservation of thousands of historic images ranging from color movie footage of World War II events to Steve McCurry's *National Geographic* portrait of Sharbat Gula, the "Afghan Girl." In February, 2000, footage taken by George Jefferies of John F. Kennedy ninety seconds before he was assassinated was found and was still in excellent condition. The Sixth Floor Museum in Dallas, Texas, has this footage on display.

Godowsky and Mannes were first inspired to work on color photography after viewing a disappointing color movie in 1917. Their first goal was to produce a method to make improved commercial color movies. However, the Technicolor Motion Picture Corporation developed Technicolor in 1922, and it was this invention that went on to be widely used by the motion-picture industry.

Peter Carl Goldmark

Hungarian American engineer

Goldmark invented the long-playing phonographic record, which revolutionized recorded sound and dominated the music industry for four decades. He also produced a system for transmitting and receiving color-television images and contributed to the development of audiocassettes and videocassettes.

Born: December 2, 1906; Budapest, Hungary
Died: December 7, 1977; Rye, New York
Primary fields: Communications; electronics and electrical engineering; physics
Primary inventions: Long-playing (LP) record; color television

Early Life

Peter Carl Goldmark was born in Budapest, Hungary, in 1906, the eldest child of Alexander Goldmark and Emma Steiner. His father was a businessman, and his great-uncle, Joseph Goldmark, was a chemist and inventor. Young Peter grew up in a musical household and was influenced by his musical mother and another great-uncle, Karl Goldmark, who was one of Hungary's greatest classical composers. Peter learned the piano and cello as a child, and his interest in music undoubtedly influenced his later work with sound recording. He was also fascinated by machines and science.

After his parents divorced when he was eight years old, Peter and his mother moved to Vienna, where he set up a home laboratory in the bathroom. He built a radio telegraph receiver and developed an interest in contemporary devices that were used for showing motion pictures. During this period, he also applied for his first patent for an invention that allowed an automobile driver to activate a horn with his knee.

In 1925, Goldmark attended the University of Vienna to study physics. A year later, he obtained a primitive televison kit from Scottish engineer John Logie Baird, who is generally credited as being the first person to successfully transmit a television image (in 1925). Goldmark modified and enlarged the small screen, which had been about the size of a postage stamp, and became intensely interested in television electronics.

Peter Carl Goldmark stands next to a storage tower holding hundreds of 78-rpm records while he holds long-playing records (LPs) with the same amount of music. (Time & Life Pictures/Getty Images)

After graduating with a Ph.D. in 1931, Goldmark began working as a television engineer for Pye Radio in Cambridge, England. A few years later, he moved to the United States, and in 1936 he became the chief engineer for the Columbia Broadcasting System (CBS) in New York. He became a U.S. citizen the following year. At CBS, Goldmark was instrumental in developing a television department for the company, and he went on to revolutionize the recording industry with the invention of vinyl phonographic records.

Life's Work

Throughout his career, Goldmark was awarded numerous patents for his inventions. During World War II, he developed electronic jammers that were used by pilots to disrupt enemy radar, and his devices were used during the Allied invasion of Normandy.

During a trip to Montreal in 1940, Goldmark saw a screening of *Gone with the Wind* (1939), one of the first motion pictures filmed in color. He was impressed with the Technicolor format of the movie. At the time, television was in its early stages, and pictures were still broadcast in black and white. Goldmark became determined to develop a method to colorize TV images. Within months, he had developed his field-sequential system, which was demonstrated for the first time in New York in the summer of that year. The method used a rotating disk of three color filters (red, blue, and green), which were placed in front of the camera and synchronized with a similar disc in the TV set. The result was a sharp, colorized image. Unfortunately, Goldmark's method was not compatible with the millions of existing black-and-white televisions and would have required consumers to purchase new TV sets.

The Radio Corporation of America (RCA) also developed a method to transmit color images that was compatible with existing black-and-white TV sets. Although image quality was inferior to Goldmark's, the RCA method was eventually approved by the Federal Communications Commission (FCC) and became the industry standard when color television was introduced in the United States in 1951. Due to the outstanding quality of Goldmark's system, it was still used for medical and educational applications that required closed-circuit television. Years later, Goldmark's lightweight system was used by the National Aeronautics and Space Administration (NASA) to broadcast color images during the Apollo 11 Moon landing.

Goldmark's most important invention originated from his interest in music. During a casual evening at a friend's home in the fall of 1945, his dinner host played a recording of Brahms's Second Piano Concerto. Six records were required to play the fifty-minute piece, and the frequent interruptions to the music by changing and flipping the records irritated Goldmark. These early records spun on a turntable at 78 revolutions per minute (rpm) and relied on a steel needle to trace the record grooves to produce sound. Each time a record was played, however, both the needle and the brittle shellac discs became worn and damaged, making the already poor sound quality even worse. Goldmark immediately began a quest to find a replacement for these discs and improve sound recording technology.

After working on the project for three years, Goldmark produced a record with much thinner microgrooves. He increased the width of the record by several inches (to twelve inches) and slowed the revolution speed to 33⅓ rpm. This increased playing time to over twenty minutes for each side, allowing for most popular classical works to fit on one disc. The new records were made of lightweight vinyl and were virtually indestructible. He also replaced the old steel needles with sapphire, extending the lifetime of the record and needle considerably, and made improvements to the recording microphone to produce a clearer and cleaner sound.

The first long-playing record was demonstrated in 1948 and featured Goldmark playing the cello accompanied by other CBS employees playing other instruments. Although LPs were not an immediate commercial success, the popularity of the Broadway hit musical *South Pacific* (1949) boosted LP sales enormously. Longtime competitor RCA quickly marketed 45 rpm "singles" for individual popular songs, but the LP dominated the music industry for forty years until it was displaced by the compact disc in the 1980's.

During his years at CBS, Goldmark was promoted several times and eventually became president of the CBS Laboratories. While at CBS, he worked on developing a new audio system that could be played in automobiles. Chrysler models (1956-1959) used the system that was called Highway Hi-Fi. It was installed below the car's instrument panel in a shock-proof case and used special seven-inch discs with ultramicrogrooves. Because the devices were prone to malfunction, the concept was not pursued by CBS, which also feared that drivers would spend less time listening to CBS radio stations while driving. The idea eventually led another company (Philips) to develop audiocassettes that used magnetic tape to store sound and cassette decks that could be easily installed in automobiles. Goldmark also aspired to create a system for recording both sound and pictures on tape; his Electronic Video Recording system eventually evolved into the videocassette that was developed by Sony in 1971.

Goldmark left CBS in 1971 to form his own company, Goldmark Communications Corporation, in Stamford, Connecticut. While he continued to be involved in researching new communication technologies (for example, satellites and cable television), he devoted more time to humanitarian issues, promoting education, and using technology to increase peoples' quality of life. In 1977, the same year he was awarded the National Medal of Science by President Jimmy Carter, Goldmark was killed in an automobile accident in Westchester County, New York.

The Long-Playing Record

The vinyl, long-playing (LP) record evolved from an original recording method invented by Thomas Alva Edison, who first recorded sound in 1877. Sounds produce vibrations in the air molecules, which conduct waves to the eardrums, where the vibrations are detected and transmitted via nerves to the brain. To record sounds, a device is needed to capture the air vibrations and convert them into a form that can be stored on a master disc, which can then be copied for duplication and mass production.

Peter Carl Goldmark's LP records contained up to 350 V-shaped grooves per inch. The grooves contained tiny hills and valleys that represented the sound waves recorded on the disc. As a sharp diamond or sapphire needle (or stylus) followed the groove around the record, it produced vibrations that were converted into electrical signals. Since the output signals were very weak, an amplifier was needed to magnify the signal to make the recorded sounds audible. Goldmark's LPs were made of soft, polyvinyl chloride (PVC), which was pressed between two hot molds that contained the original master recording to produce the copy. It took about twenty-five seconds to stamp each record.

Records were protected in a thin cardboard case, or album, which usually featured colorful and detailed artwork on the cover. Long after the popularity of LPs declined, vinyl records were still sought by collectors.

Impact

Goldmark produced more than 150 inventions, many of which had an influence on society and improved the quality of life for humanity. His technology-based communications products were both functional and fun, improving leisure activities. His discoveries in the areas of electronics and communications were especially significant in expanding the entertainment industry and advancing education.

By providing thousands of artists with the means to record their songs, Goldmark's long-playing records became a worldwide industry and popular form of entertainment. Compared to early records, his lightweight, vinyl discs reduced shipping and storage costs, resulting in huge savings for consumers, producers, and retailers. By the 1970's, annual sales of LP records in the United States were over a quarter million. LP records had an enormous impact on the economy, creating many jobs and opportunities for people in the entertainment and arts industries.

From the mid-1950's and beyond, record players or stereos were purchased by millions of families and, together with televison sets, introduced the electronics revolution to consumers around the world.

Charles Goodyear

American chemist and businessman

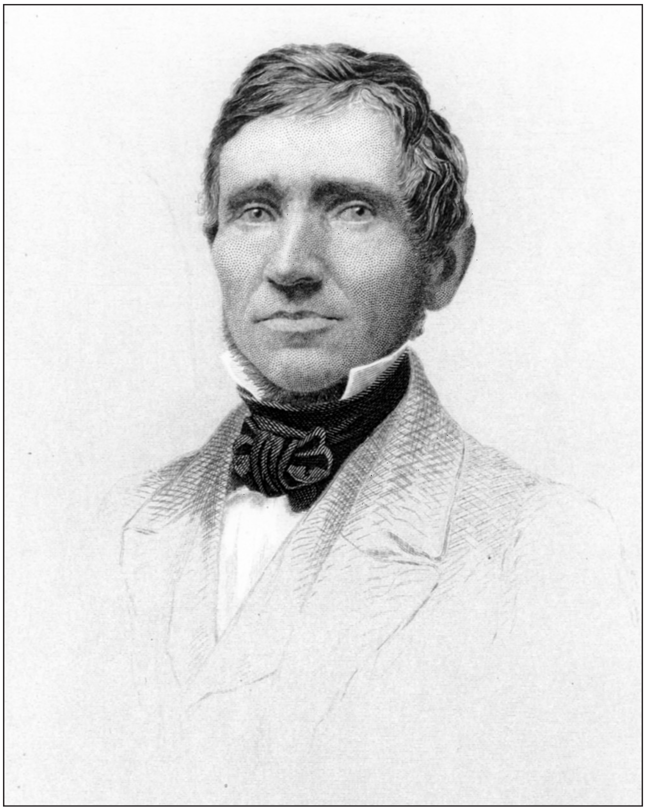
Goodyear's vulcanization process, modified but essentially the same today, transformed rubber from an almost useless, smelly substance that was sticky in summer, hardened and cracked in winter, and soluble in solvents into a versatile, stable, commercial product with hundreds of uses.

Born: December 29, 1800; New Haven, Connecticut
Died: July 1, 1860; New York, New York
Primary fields: Chemistry; manufacturing
Primary invention: Vulcanized rubber

Early Life

Charles Goodyear, the oldest son of Amasa Goodyear and Cynthia Bateman Goodyear, was born in New Haven, Connecticut, on December 29, 1800. His father was an inventor as well as a manufacturer of farm implements and hardware. The family included seven inventors within four generations. The studious and quiet Charles attended school in Naugatuck, Connecticut. In 1817, he was apprenticed to a hardware manufacturer and importer in Philadelphia, Pennsylvania. In 1821, he returned to New Haven to join his father's business. On August 24, 1824, he married Clarissa Beecher, the daughter of a Naugatuck innkeeper. They had nine children.

In 1826, in Philadelphia, the father and son founded the first domestic hardware store in the United States, but because of overextended credit they became bankrupt. For the rest of his life, Goodyear was usually poor and often spent time in debtors' prisons, where he performed most of his experiments on rubber. Often he needed to sell furniture and household items to procure food for his growing family. He became an inventor and was preoccupied with rubber, which he unsuccessfully attempted to use in his inventions. During the period 1830-1834, he was issued six patents on mechanical devices.



Charles Goodyear. (©Smithsonian Institution)

Life's Work

Rubber, obtained from the tree *Hevea brasiliensis*, a member of the Spurge family, is one of the longest-known natural materials. The ancient Egyptians, Ethiopians, and various Asian and African peoples depicted games with bouncing rubber balls in pictures or carvings. Indians of the Amazon basin knew of its properties and uses long before Christopher Columbus (1451-1506) brought it to the attention of Europeans. Spanish historian and navigator Gonzalo Fernández de Oviedo y Valdés (1478-1557) and historian Antonio de Herrera y Tordesillas (1559-1625) described balls used by the Indians. French geographer Charles Marie de La Condamine (1701-1774) brought rubber from the Amazon to Europe.

However, rubber remained a mere novel curiosity. It was used to a small extent to waterproof shoes, boots, and clothing, which were called "mackintoshes," named for Scottish inventor Charles Macintosh (1766-1843). When cold, the rubber hardened and cracked, and when warm, it melted or became sticky. In 1770, English clergyman and chemist Joseph Priestley (1733-1804) called it "rubber" since it could be used to erase pencil marks from paper.

In 1820, English inventor and coach maker Thomas Hancock (1786-1865), who later pirated Goodyear's vulcanization process because Goodyear was denied an English patent, founded the world's first rubber factory. In the summer of 1834, Goodyear visited the Roxbury India Rubber Company's New York City salesroom, where he learned of the problems faced by the new industry. Recognizing rubber's valuable properties—strength, plasticity, durability, electrical nonconductance, and resistance to water—he became intrigued by this peculiar elastomer and devoted the remainder of his life to improving, promoting, and exhibiting it to the detriment of his health and family finances.

Neither a chemist nor scientist, Goodyear used trial-and-error methods, later made famous by Thomas Alva Edison (1847-1931). In 1835, Goodyear received the Mechanics Institute of New York's silver medal for his development of rubber sheeting. Unfortunately, in hot weather the product softened and became sticky. He bought the Eagle India Rubber Company of Woburn, Massachusetts, in 1838 from Nathaniel M. Hayward (1808-1865), who then worked for him. Hayward added small amounts of sulfur to his rubber compounds and exposed them to the sun. He patented this "solarization" process and sold the rights to Goodyear. If he had used a higher degree of heat (which most manufacturers avoided because it caused rubber to melt) rather than sunlight, he, rather than Goodyear, might have discovered vulcanization.

After more than five years of unsuccessful experiments, in January, 1839, Goodyear accidentally put a sample of rubber mixed with sulfur and lead monoxide (litharge) on a hot stove. This chemical reaction of rubber with sulfur at high temperature, which is still poorly understood, converted the sample into a substance that would have versatile commercial product potential. William Brockedon, a friend of both Goodyear and Hancock, suggested that the process be called "vulcanization," for the Roman god of fire and metalworking, a term that Goodyear repeatedly but reluctantly used.

Goodyear immediately applied his new process to

Vulcanized Rubber

Before vulcanization, the only method to seal small gaps between moving machine parts—for example, between a cylinder and piston in a steam engine—was to use leather soaked in oil, which could leak or create extra friction if packed more tightly. Vulcanized rubber could be formed into exact shapes and would comply with moderate to large deformations under pressure and would revert to its original dimensions when the pressure was removed. This property as well as durability and lack of stickiness made it a useful sealing material.

Unvulcanized natural rubber is a polymer made up of long hydrocarbon (carbon and hydrogen) chains, which can move independently toward each other, resulting in an irreversible change of shape. During vulcanization, cross-links are formed between the chains so that they can no longer move independently of each other. Therefore, on application of stress the rubber will be deformed, but on release of stress it reverts to its original shape.

Vulcanization is an irreversible process, and vulcanized rubber is a thermosetting polymer, which does not melt on heating, in contrast to thermoplastic polymers such as unvulcanized rubber, polyethylene or polypropylene, which melt on heating. In vulcanization, the cure agent is usually sulfur, which forms the cross-links, as in Charles Goodyear's original process, but peroxides are sometimes used. Also added are accelerators, such as zinc oxide or stearic acid, which speed up the reaction and decrease the curing time, and retarding agents, which prevent vulcanization from occurring prematurely.

On the rubber molecule, so-called cure sites, usually those with unsaturated (double) carbon-carbon bonds, attract sulfur atoms, which are formed by the breakdown of the naturally occurring six-membered sulfur rings. The length of the sulfur bridges or cross-links, usually between two and eight atoms long, influences the physical properties of the cured rubber. Short cross-links (one or two sulfur atoms) provide excellent resistance to heat, and longer cross-links (six or seven sulfur atoms) provide good dynamic properties—such as flexing movements for the final product needed for the movement of a tire's sidewall—but less resistance to heat. Because the cross-linked polymer possesses strong forces between the chains, it is insoluble, infusible, and thermosetting. The most important vulcanization method employs high temperature (170° Celsius, or 338° Fahrenheit, for passenger tires) and pressure.

The primary problem in recycling discarded tires, the most important of the hundreds of products made of rubber, has been to devulcanize them by delinking the sulfur atoms without losing the rubber's desirable properties. However, recycling processes have failed to yield consistent quality such that the product is unsuitable for use in many products, including tires, and recycled rubber has not been used to replace new or synthetic rubber in significant amounts.

Thanks to Goodyear's revolutionary discovery of vulcanization, this versatile elastomer has become indispensable to a variety of industries and products. The modern world, with its myriad necessities and luxuries, would be unthinkable without natural or synthetic rubber.

---

manufacturing various articles. By 1842, he was manufacturing rubber sheets, and by 1843, when he went bankrupt and was sent to debtors' prison, he was manufacturing other articles. He received a U.S. patent for his vulcanization process on June 14, 1844, and profits and license fees permitted him to pay his creditors.

Because his vulcanization process was so simple, numerous people used it without paying royalties, and Goodyear spent much time contesting as many as sixty patent infringements. The most famous of these, "the great India rubber case," was filed in 1851 against Horace H. Day, probably the most flagrant of the infringers. One of the greatest American business lawsuits of the nineteenth century, the case received widespread press coverage since Goodyear's main attorney was U.S. secretary of state Daniel Webster (1782-1852). Although Goodyear's claim was upheld on September 28, 1852, he spent time in U.S., English, and French debtors' prisons since he spent all his funds on inventions, experiments, and exhibitions.

A dedicated missionary for rubber, Goodyear spent six years in Europe championing its applications. Six weeks before Hancock's English patent was issued (May 30, 1844), Goodyear was issued a French patent (April 16, 1844), the first in any country for vulcanization, but because he had sent several American-made rubber shoes to France before his French patent, he was deprived of all his rights. Emperor Napoleon III (1808-1873) awarded him the Grand Medal of Honor and the Cross of the Legion of Honor. At the time of the second award, Goodyear was in Clichy, the Parisian debtors' prison.

In March, 1853, Goodyear's wife died, and on May 30, 1854, he married Fanny Wardell, an Englishwoman, who bore him three children, only one of whom survived its father. In 1858, Goodyear returned to New Haven, supposedly pawning his wife's jewelry to pay for their passage. On July 1, 1860, he died in New York City, where illness had forced him to rest en route to the funeral of the third daughter of his first marriage, Cynthia. He left behind debts of $200,000-$600,000.

Impact

Rubber technology has advanced since Goodyear's lifetime to the extent that rubber companies are among the world's largest corporations. Most of the world's rubber is used in the manufacture of tires, an application that Goodyear failed to foresee. More than half of rubber tires are now synthetic. In 2000, an unprecedented recall of millions of truck tires for Ford sport utility vehicles and pickup trucks in the United States became front-page news around the world. Goodyear's name is preserved in Goodyear tires and the Goodyear blimp, but neither Charles Goodyear nor any of his family or descendants was connected with the Goodyear Tire and Rubber Company. Its founder, Frank A. Seiberling (1859-1955), named it to honor the founder of an industry indispensable in modern life who was one of the United States' most famous inventors. Goodyear was inducted into the National Inventors Hall of Fame in 1976.

Gordon Gould

American physicist

Gould coined the word "laser" (light amplification by stimulated emission of radiation) to describe his invention. One of the most significant technological advances ever, the laser became an essential tool in research, communications, medicine, military training, aerospace technology, commerce, and manufacturing.

Born: July 17, 1920; New York, New York
Died: September 16, 2005; New York, New York
Also known as: Richard Gordon Gould (full name)
Primary fields: Optics; physics
Primary invention: Laser

Early Life

On July 17, 1920, Richard Gordon Gould (gewld) was born the oldest of three sons in Manhattan, New York. His father, Kenneth Miller Gould, was descended from New England Puritans and was an editor of *Scholastic* magazine. He also wrote *They Got the Blame* (1942), a book about scapegoats in history. Gould's mother, Helen Vaughn Rue Gould, was a descendant of the French pirate Wonny La Rue and was very active in politics.

Gould's mother gave him an Erector Set of toy buildings when he was a child and encouraged him to build things. He would construct objects, take them apart, and then fix them. He and his brothers, David and Geoffrey, enjoyed taking clocks apart and then trying to reassemble them. Gould revered Thomas Alva Edison and dreamed of becoming an inventor.

Gould attended Scarsdale High School in Westchester County, New York. He then entered Union College in Schenectady, New York, where he was a member of Sigma Chi fraternity. Classes with Union College physics professor Frank Studer led to Gould's fascination with optics and the physics of light. In 1941, he received a bachelor of science degree in physics. He then did graduate work in optics and spectroscopy at Yale University and received an M.S. in physics in 1943. After graduating, Gould joined the Manhattan Project, which was focused on developing the atomic bomb. He worked on the separation of uranium isotopes to generate nuclear power. During this time, he met Glen Fulwider, a Marxist and colleague on the Manhattan Project. Gould joined her communist circle of friends. Because of their leftist leanings, Gould and Fulwider were fired from the project in 1945. They married in 1947, but the marriage eventually ended in 1953.

Life's Work

From 1947 to 1954, Gould taught physics at the City College of New York and worked for private engineering companies. In 1949, he enrolled in the graduate physics program at Columbia University, where he studied optics. In November, 1957, Gould conceived of the idea for a device that could shoot out a narrow, intense beam of light that could heat things to an extremely high temperature. He named this device a "laser," an acronym for "light amplification by stimulated emission of radiation." Gould recorded his ideas and sketches in a notebook, which he had notarized on November 13, 1957. However, Gould mistakenly believed that he could not file for a patent for his invention until he had submitted a working model.

He had discussions with physics professor Charles Hard Townes, who in 1953 had invented the maser (microwave amplification by stimulated emission of radiation), the laser's predecessor. They discussed Gould's research on using light to excite thallium atoms, and the idea of an optical version of the maser, which would use optical pumping instead of microwave amplification. The device would thus expand the principles of the maser to the shorter wavelengths of light.

Gould wanted to build the laser in 1958. Lacking the resources to do this, he approached Technical Research Group (TRG), a young Manhattan-based company that did contract work for the Pentagon. In March, 1958, Gould began work at TRG on a project to develop atomic clocks. He convinced TRG to build a laser, and the company sent a proposal to the Air Force Office of Scientific Research and the Army Signal Corps on December 16, 1958. Although TRG received a military contract, Gould could not get a security clearance to be part of the research team because of his association with Marxists in the 1940's.

Gordon Gould, inventor of the laser, in 1977. (AP/Wide World Photos)

On December 15, 1958, Townes and Arthur L. Schawlow, a researcher at Bell Laboratories, published the first scientific paper describing a laser, or optical maser, which would use infrared and/or visible-spectrum light. Gould officially filed an application for a patent in 1959. However, Townes and Schawlow had already filed patent applications for the laser, and Gould's application was denied.

On May 16, 1960, physicist Theodore Harold Maiman of Hughes Research Laboratories in California demonstrated the first working laser, the ruby laser, which produced bursts of red light. He had won the race to build the first working laser. Six months later, Ali Javan and his team demonstrated the first gas laser, the helium-neon laser, which generated a continuous beam of light.

In 1967, Gould became a professor at the Polytechnic Institute of Brooklyn. In 1973, he left teaching to found Optelecom, a firm in Gaithersburg, Maryland, that specialized in fiber-optic communications equipment. In fiber-optic communications, information is transmitted by sending light through an optical fiber. Optelecom was a very lucrative business, and Gould retired in 1985.

Meanwhile, Gould had continued his patent war. He had received laser patents in Belgium in 1962 and in Great Britain in 1964, but his legal battle in the United States lasted three decades. Having lost many appeals, Gould's legal team tried a new strategy: focusing on the optical amplifier, an essential laser part. Consequently, in 1977 he won his first U.S. patent, which was for the optically pumped laser amplifiers. In 1978, the Patent Office Society named him inventor of the year for his laser amplifier. In July, 1979, he was awarded the second patent, which covered laser applications, including welding, drilling, measuring distance, photochemical processes, heating materials, and communication systems. However, court battles continued with companies disputing his patents and refusing to pay royalties.

In 1985, a U.S. district court ruled in favor of Gould's application for the discharge-excited laser patent, and Gould obtained two more patents. In November, 1987, he won the patent for collisionally pumped laser amplifiers, and his patent of May, 1988, covered the optical element inclined at a Brewster's angle. Gould and his assignee, Patlex Corporation, founded in 1979 to handle licensing and enforcement, now held four patents that covered most types of lasers and laser applications. These patents included the lasers used in 80 percent of commercial, medical, and industrial applications.

With the end of litigation in 1988, Gould began receiving royalties. Eighty percent of the proceeds went to cover his court costs, but Gould still eventually made tens of millions of dollars. By this time, lasers had universal applications and a global market, so the patents were worth much more than when Gould had begun the patent war. In recognition of his achievements, Gould was inducted into the National Inventors Hall of Fame in 1991. He died of natural causes on September 16, 2005.

The Laser

Gordon Gould is credited with inventing the laser. He was the first person to envision the powerful laser beam and how to create it. The fundamental idea came from Albert Einstein's description of the relationship between matter and light. In 1916, Einstein proposed the idea that atoms, the basic building blocks of matter, could release excess energy as light, either spontaneously or when stimulated by light.

The laser consists of an optical resonator (laser cavity) between two mirrors, one fully reflecting mirror on one end and a partially reflecting one on the other end so that light can leak out. Light bounces back and forth between the two mirrors and is amplified by a gain medium (such as a crystal or gas) in the resonator. The gain medium is "pumped" by an external energy supply, such as light (optical pumping) or an electric current. The process of light amplification is called stimulated emission. In this process, a photon, the basic unit of electromagnetic energy (or light) excites an atom, which then releases a new photon identical to the incoming photon and going in the same direction. As photons excite more atoms, more photons get amplified. When enough atoms have jumped up into an excited state, then there is a population inversion, and laser light is created. Laser light is monochromatic and its waves are uniform, all going in the same direction and reinforcing each other, resulting in an intense beam.

Gould eventually won patents for the optically pumped and discharge-excited laser amplifiers now used in most industrial, commercial, and medical applications of lasers. Common types of lasers include solid-state lasers, gas lasers, and semiconductor lasers. Solid-state lasers use ion-doped crystals or glasses, pumped with discharge lamps or laser diodes. They include the ruby laser, used in holography and tattoo removal; and the high-power Nd:YAG (crystal) laser used in military range finders, dentistry, eye surgery, and manufacturing. Gas lasers are based on gases typically excited with electrical discharges. Examples include the helium-neon laser, used in bar-code scanning and holography; and the excimer laser, used in laser surgery and ultraviolet lithography. Semiconductor lasers are electrically or optically pumped. They include the most prevalent laser, the AIGaA, which is used in laser pointers, data communications, compact disc players, and optical discs. Another example is the semiconductor laser diode, whose applications include printing, welding, and telecommunications.

Impact

Gould is famous for his invention of the laser, giving the laser its name, and his ultimately successful thirty-year battle to win credit and patents for his invention. His well-documented struggle has continued to cause debate about U.S. patent law and procedures, competition among scientists and laboratories, simultaneous scientific discoveries, scientific awards, and royalties for inventions.

Gould had wanted to be an inventor since he was a child; so while other scientists were theoretical and analytical in their approach, Gould was intuitive and practical. In the race to build the laser, other scientists envisioned a light beam that could travel through air and be used as a research tool. Gould, on the other hand, was the first to conceive of an intense, narrow, and continuous beam of concentrated light that would be powerful enough to cut, drill, and weld. He envisioned a tool that could heat materials to ultra-high temperatures in a split second.

By the time Gould won his patent war, various kinds of lasers had been built that fulfilled his original vision and gave him millions of dollars in royalties. Lasers had become standard tools with widespread applications in medicine, manufacturing, research, communications, and technology. From the simple pointers used by lecturers to the range finders used in space probes, lasers had become ubiquitous. In the twenty-first century, examples of laser applications include cosmetic surgery, supermarket Universal Product Code (UPC) scanners, fiber-optic communication, vision correction, laser printers, compact disc (CD) audio players, CD-ROMs, vision correction, and digital video disc (DVD) technology.

Meredith C. Gourdine

American engineer

Gourdine utilized his electrogasdynamics (EGD) knowledge to design generators to produce electricity from gas. His research and inventions benefited domestic, commercial, and industrial uses with such developments as devices that removed pollutants from air and heat from computer chips.

Born: September 26, 1929; Newark, New Jersey
Died: November 20, 1998; Houston, Texas
Also known as: Meredith Charles Gourdine (full name)
Primary fields: Electronics and electrical engineering; physics
Primary inventions: Electrogasdynamic (EGD) generator; Incineraid; Electradyne paint spray gun

Early Life

Meredith C. Gourdine (gohr-DEEN), was born on September 26, 1929, in Newark, Jersey, to Albert and Charlotte (Carter) Gourdine. He lived with his paternal grandparents in Union, New Jersey, as an infant while his parents sought employment during the Depression. At age five, Gourdine resided in Harlem, New York, where his father became an apartment superintendent. He relocated to Brooklyn, New York, in 1940 when his father began working at the Brooklyn Navy Yard. Gourdine enrolled in Brooklyn Public School no. 67, where a mathematics teacher mentored him, explaining how to solve difficult problems. As a result, Gourdine's examination scores qualified him for admission to the prestigious Brooklyn Technical High School. Gourdine ran track and swam for school teams.

After graduation, Gourdine started classes at Cornell University in Ithaca, New York, in 1948, majoring in engineering physics. Known as "Flash" for his swiftness, he joined the Cornell track team, with the long jump, sprints, and low hurdles as his specialties, and won several Intercollegiate Association of Amateur Athletes of America titles. Gourdine helped Cornell's team achieve second place overall at the 1952 National Collegiate Athletic Association (NCAA) track meet. He competed in the 1952 Olympics in Helsinki, Finland, and was the long jump silver medalist, leaping 24 feet, 8.5 inches.

Prioritizing Olympic training, Gourdine did not concentrate sufficiently on his coursework and no longer qualified for his scholarship. He earned tuition funds assisting a campus research project, but the directing professor was unimpressed by Gourdine's work. Determined to prove his competence, Gourdine learned to balance his varied academic and extracurricular activities. He also participated in Cornell's Naval Reserve Officer Training Program. Gourdine completed a bachelor's degree in 1953. Commissioned as a U.S. Navy officer, he was deployed for two years on an aircraft carrier, gaining practical experiences with electronics. In 1955, he married June Cave. They later divorced, and he wed Carolina Baling. Gourdine had three daughters and one son.

Life's Work

Gourdine, dissatisfied with military work, decided to continue his engineering physics education by pursuing a doctorate. He enrolled in the California Institute of Technology in Pasadena, California, and received a Guggenheim Foundation graduate fellowship. Gourdine also financed his studies with a fellowship from the Ramo-Woolridge Corporation, for which he performed technical work in 1957 and 1958. Influenced by his adviser, Dr. Julian D. Cole, an applied mathematician, Gourdine researched mathematical aspects of magnetic fields and how objects' movement in those fields affected magnetic behavior, writing his dissertation "On Magnetohydrodynamic Flow Over Solids" to receive his Ph.D. in engineering science in 1960.

During his doctoral studies, Gourdine conducted research from 1958 to 1960 at the Jet Propulsion Laboratory in Southern California, where he investigated electrogasdynamics (EGD), the production of electricity from the conversion of kinetic energy in moving, ionized gas. Gourdine experimented with ways to manipulate EGD to create ample amounts of high-voltage electricity needed for industrial machinery and processes in addition to lighting and other basic functions. Frustrated when his supervisors did not appreciate his EGD insights, Gourdine sought a more compatible work environment. Starting in 1960, he directed an aerospace laboratory at Plasmadyne Corporation in Santa Ana, California, where he pursued earlier research he had begun exploring: magnetohydrodynamics as a method to produce power with gas and magnetic fields. Again, he was disappointed with his colleagues' reception of his work.

By 1962, Gourdine returned to New Jersey, where he was the Curtiss-Wright Corporation's chief scientist for aeronautics. During 1964, he invented an EGD channel for gas to move through to interact with electrodes to create charged particles (ions). Gourdine designed the channel's shape to compress ions to intensify forces affecting gases, increasing the amount of power produced. He was unsuccessful in convincing his company or others to develop his EGD generator. Unhappy with corporate restrictions and determined to protect his EGD ideas, Gourdine resigned from his Curtiss-Wright position, and, investing his money and approximately $200,000 in loans from friends, he started Gourdine Systems, Inc., in Livingston, New Jersey.

Gourdine's company, for which he served as president and chairman of the board, provided him autonomy to invent unique devices and technical processes through research and development projects he chose to pursue. His corporation made EGD generators, known as Gourdine Mark I, for school laboratories and licensed the boiler manufacturer Foster Wheeler Corporation to produce industrial EGD generators. In 1966, the U.S. Department of the Interior gave Gourdine $680,500 to create an EGD generator specifically to power a process to extract energy from coal. He filed for his first U.S. patent that year, receiving two EGD-related patents in June, 1969. In his home's basement, Gourdine maintained a laboratory for plasma physics experimentation to develop power supplies.

By 1974, Gourdine decided to cease work at Gourdine Systems and created Energy Innovations, located first in East Orange, New Jersey, then Houston, Texas. Serving as chief executive, Gourdine focused on his inventions. Throughout his career, Gourdine patented approximately seventy inventions with the U.S. and foreign patent offices as inventor or coinventor. His inventions included the Electradyne paint spray gun, which used EGD principles to give paint particles electrical charges, enabling users to coat paint over items of diverse shapes. Gourdine's Incineraid captured pollutants and smoke released from incinerators. Another device

Electrogasdynamic Method and Apparatus

Meredith C. Gourdine utilized his engineering physics knowledge to research electrogasdynamics (EGD), which was the basis for many of his patents. His comprehension of the dynamic behavior of gases and ions enabled him to control them to produce enormous amounts of energy and manipulate particles by using electrical charges. Basic EGD concepts, the conversion of electrically charged flowing gas into energy while undergoing intense pressurization, had been described in scientific literature since the latter eighteenth century. Scientists, however, were unable to achieve conditions necessary to secure the energy potential of EGD with available scientific equipment. By the mid-twentieth century, Gourdine envisioned how he could create a device to place sufficient force on gases to produce energy and began to construct that technology. He designed his generator to exert tremendous pressure on gases moving though a narrow channel containing electrodes.

In the mid-1960's, Gourdine first applied for U.S. patents to document his EGD work and received two patents in June, 1969. Gourdine's initial approved patent, "Electrogasdynamic Method and Apparatus for Detecting the Properties of Particulate Matter Entrained in Gases," described a tubular device he created to evaluate particles in flowing gas. This patent was referenced in other patents for ion and particle sensors from the 1970's through the early twenty-first century. In his next patent, "Gourdine Electrogasdynamic Systems," Gourdine described a channel in which ionized gases were converted to electrical energy when passing through electrodes. Gourdine emphasized that his arrangement of electrodes conducting electrical charges in his generators were more effective than designs other scientists had presented. Several patents, including a 1980 discharge electrode structure and a 2006 electrostatic fluid accelerator, referenced this Gourdine patent.

Gourdine's early EGD patents formed the foundation of his later inventions, often consisting of improvements or design variations. "Electrogasdynamic Systems and Methods," which was approved as a patent in 1971, preceded Gourdine's prolific acquisition of EGD patents. Referring to other inventors' patents for electrostatic and ionization inventions, Gourdine refined his generator channels and source of electrical charges. During the 1970's, he received several patents for EGD coating inventions, mostly for electric forms of industrial painting. He continued that work in the next decade, while also investigating temperature regulation for electronics through the 1990's. Gourdine also applied his EGD methods to acoustic imaging and high-speed printing. He appropriated electrostatic precipitator techniques, inventing systems controlling unwanted particles with electric charges. Gourdine's EGD inventions performed essential roles in technological systems worldwide to provide reliable energy sources for daily electrical needs, to enhance industrial production, and to clean the air.

used electrical charges to remove dust. His focus flow heat sink cooled computer chips.

Gourdine aspired to improve his existing inventions with more research and development and expanded EGD techniques for automobile exhaust purification, salt removal from seawater, refrigeration, and other useful tasks. He licensed his inventions to companies, including Sherwin-Williams, and also arranged for representatives such as the Estey Corporation to produce and distribute technologies by Energy Innovations. Gourdine's corporation generated several million dollars from his patents.

Gourdine published technical articles in such periodicals as the *Journal of Fluid Mechanics* and *Industrial and Engineering Chemistry* and proceedings of conferences he attended sponsored by professional organizations and universities. He also prepared publications printed by the Society of Automotive Engineers, Plasmadyne, and military agencies. Gourdine's final research projects investigated converting thermal and chemical energy to electricity for technological applications, resulting in his last patents, which were issued in 1996.

Gourdine had become diabetic while serving in the Navy. He invented despite retinopathy affecting his eyesight, having a leg removed, and relying on dialysis treatments. By 1986, he was blind. On November 20, 1998, Gourdine, suffering strokes, died in Houston's St. Joseph Hospital.

Impact

Gourdine comprehended aspects of EGD to obtain energy through the conversion of gas into electricity, a complex process that had eluded scientists for several centuries, and achieved significant inventions incorporating that knowledge. His EGD research, which many peers described as pioneering, provided Gourdine and his businesses sizable profits and benefited industrial and commercial users of EGD technologies. Internationally, Gourdine's EGD generators affordably and conveniently created energy without harming the environment, with some inventions decreasing atmospheric pollution by removing contaminants. Officials in New Jersey approved statewide use of Gourdine's Incineraid. His EGD coating devices improved such industrial processes as painting products efficiently and economically. Gourdine's fog-removal system made runways safer and aided airlines by minimizing fog-related disruptions and related costs to compensate passengers. His method appealed to smaller airports, which often could not afford competitors' expensive methods using heat.

Gourdine's work attracted public attention, including from government officials who sought his expertise to shape policies. In 1964, U.S. president Lyndon B. Johnson appointed Gourdine to the federal Advisory Panel on Energy. President Richard M. Nixon selected Gourdine to serve on the President's Task Force on Improving the Prospects of Small Business. Gourdine also provided his insights for the U.S. Army Science Board and New York City Task Force on Air Pollution. Educational institutions valued Gourdine, naming him to the board of trustees at Cornell University and the New Jersey College of Medicine and Dentistry.

Gourdine contributed to advances in physics research by sharing his knowledge of EGD principles with other scientists and engineers. His achievements secured professional recognition. By 1964, Gourdine was an American Institute of Aeronautics and Astronautics associate fellow. An Industrial Research Award recognized the Gourdine Mark I generator. In 1969, Gourdine received honorary degrees from Newark State College and the New Jersey Institute of Technology. He was elected to the National Academy of Engineering in 1991 and inducted into the Engineering and Science Hall of Fame three years later. Gourdine also was selected for the Brooklyn Tech Alumni Hall of Fame in 1998 and the New Jersey Inventors Hall of Fame in 2004.

Bette Nesmith Graham

American typist

At a time when electric typewriters were new and difficult to use, Graham invented a solution used to paint over typing mistakes. The product, later known as Liquid Paper, would ease the job of secretaries worldwide.

Born: March 23, 1924; Dallas, Texas
Died: May 12, 1980; Dallas, Texas
Also known as: Bette Clair McMurray (birth name); Bette Nesmith
Primary field: Business management
Primary invention: Liquid Paper correction fluid

Early Life

Bette Nesmith Graham was born Bette Clair McMurray on March 23, 1924, in Dallas, Texas. She was the first child of Jesse and Christine McMurray. Her sister Yvonne was born two years later. The McMurray family lived in a middle-class community where Bette's father worked in the wholesale automobile industry and her mother was a businesswoman, an artist, and a singer. Christine's capable handling of career and family taught Bette that a woman could both work and raise a family. The influence of family who believed in women's rights and abilities was not limited to her mother. Bette's great-great-grandfather was John Darby, one of the cofounders of Wesleyan College in Macon, Georgia, the first college in the world to grant degrees to women.

As a child, Bette was strong-willed and difficult. She had a number of problems in school and eventually dropped out when she was seventeen years old. She would later earn a GED in place of a high school diploma. When she was eighteen, she married her high school sweetheart, Warren Audrey Nesmith. Nesmith was a National Guard member who, after two months of marriage, was called to serve in World War II following the bombing of Pearl Harbor. Bette found herself pregnant and alone at nineteen years old, and she gave birth to Robert Michael Nesmith on December 30, 1942, in Houston, Texas. When her husband returned from the war, he had changed, and the three-year marriage ended in divorce in 1946. Bette was left to raise Michael (later of Monkees fame) as a single working mother. In 1949, she moved to Dallas.

Life's Work

During the years immediately after her divorce, Bette Graham worked and attended night classes to earn her GED in order to support herself and her child. Though she desired a career in art, it was not a financial possibility, so she turned to secretarial work. Graham's career in Dallas began with a secretarial job at Texas Bank and Trust. By 1951, she had been promoted to executive secretary at the bank. During her time there, Graham started working with new IBM electric typewriters. These typewriters were both a blessing and a curse: Secretaries could type faster because the keys depressed more easily; however, the ink was difficult to erase, so mistakes meant retyping a whole document. Whereas erasers worked on the old-fashioned typewriter ink, the new ink smudged when it was erased. While she was doing holiday artwork on the bank's windows, Graham realized that artists cover errors with paint rather than erasing them. This led her to conclude that paint could cover typing errors as well.

Graham made a mixture of white, water-based tempera paint that she named Mistake Out, which she put in a container and brought to work. Using an artist's detail brush to apply the paint, she was able to cover her typing errors. If the stationery was not white, she simply tinted the paint to match the paper's color. Though her supervisors reportedly never noticed the typing repairs, Graham's secretarial colleagues did. When they eagerly asked to try the miracle solution, she shared.

Increasing interest from other typists inspired Graham to develop her correction fluid into a better product that she could market. By 1956, Graham had organized the Mistake Out Company and was using small appliances (a mixer and blender) in her kitchen laboratory to work out the best mixture. Her laboratory moved twice in these early days: once to the garage and then to a toolshed that she had purchased specifically to house the business. As she began to sell the mixture to more colleagues, she improved it with the help of a high school chemistry teacher and an assistant who had experience working in a paint manufacturing facility. Her son and his friends helped fill orders by filling and labeling bottles. Work was steady during her time away from her job at the bank, but she did not make financial leaps. When she absentmindedly put her new company's name on a business letter for work (she was by then working for IBM), her boss fired her for the error. This turned out to be a blessing, because it gave her time to dedicate herself to her fledgling company, and sales increased.

Within the next eleven years, Graham's life would change both personally and professionally. Advertisement through an article in an office supply magazine generated five hundred orders in 1958. National corporations were starting to notice the product as well, and General Electric placed an order in excess of four hundred bottles. In 1962, Bette met and married Robert Graham, a salesman. Her new husband promptly joined the business, which was selling five thousand bottles per week by 1964. In 1968, she opened her own manufacturing facility and company headquarters, supporting nineteen employees. Her million-dollar company was now producing one million bottles per year. With the growth of the company, a new name, Liquid Paper, was born. By 1970, her company's production had increased to five million bottles per year. In 1975, a new facility was built in Dallas, and production again leapt, to five hundred bottles per minute. Bette Graham now employed two hundred people and marketed the product to dozens of countries. She also divorced her husband that year. In 1979, Gillette Corporation made an offer to purchase Liquid Paper, and Graham sold it for $47.5 million.

Liquid Paper

Before the invention of Liquid Paper by Bette Nesmith Graham, secretaries and other typists were confronted with a predicament: Though the new IBM electric typewriters were faster and easier to use than other models, mistakes made while typing on them often required redoing the work. Older, manual typewriters used ink that erased with a simple pencil eraser, but the new electronic typewriters used carbon ribbons, whose ink smudged when erased.

An artistic ability earned Graham part-time jobs painting holiday scenes on the windows of the bank where she worked. Realizing that artists cover errors with paint rather than erasing them, she concluded that paint could cover typing errors as well. Graham experimented with a water-based tempera paint mixture to fix typos. When the paint worked and her employers did not seem to notice the fix, she began to develop the product. She originally named it "Mistake Out," later renamed "Liquid Paper," and she used it regularly in her job as an executive secretary. The simple idea grew into a business when other secretaries started noticing and asked for their own bottles of correction fluid.

The product eased pressure on secretaries everywhere. They no longer needed to retype documents if they made a simple key error. They could simply paint over the mistake and move on to the next typing job. Hours, paper, and jobs were saved as typists were able to complete jobs in one attempt. Between 1956 and 1975, Graham's business boomed from a household laboratory with a handful of teenage employees filling bottles in the kitchen, garage, and toolshed of her home to a 35,000-square-foot factory that housed two hundred employees, a library, and a child-care facility. In 1979, Graham sold her business for about $48 million. A simple idea, a mixture of white paint and water, had become a multmillion-dollar enterprise.

Impact

Graham's business revolutionized the work of secretaries worldwide. The simple act of painting over a typo instead of retyping a page saved a great amount of time and energy. The growth in popularity of her product also led to large numbers of employment opportunities.

Graham was able to develop her business while maintaining a positive relationship with her son. Understanding the difficulties of being a working mother, she even established an in-house child-care facility in the Dallas facility. She shared her wealth and experiences with her employees and others through family-friendly work environments and charities. Later in her life, she established the Bette Clair McMurray Foundation (1976) and the Gihon Foundation (1978) to offer aid to women in need and to further their efforts in the arts and business. The latter foundation's mission has been to encourage entrepreneurial philanthropy. Graham, a Christian Scientist, retired at age fifty-two to devote herself more fully to her practice.

Elisha Gray

American engineer

Gray was one of several people involved with the invention of the telephone. Because he filed a patent for the telephone on the same day as Alexander Graham Bell, there is no sure way to determine who had precedence and therefore who invented the telephone.

Born: August 2, 1835; Barnesville, Ohio
Died: January 21, 1901; Newtonville, Massachusetts
Primary fields: Communications; electronics and electrical engineering
Primary invention: Telephone

Early Life

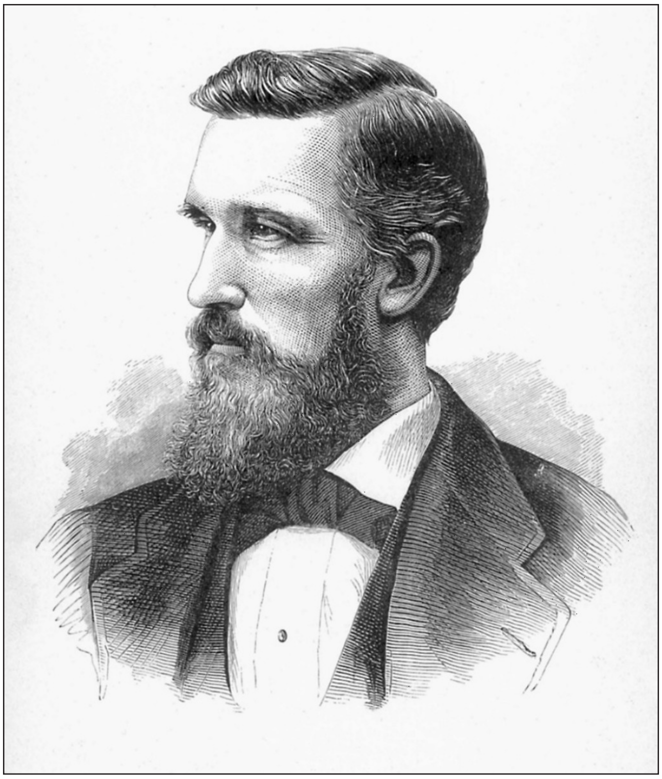
Elisha Gray was not born with a silver spoon in his mouth, nor did he come from a line of engineers or scientists for whom inventing was second nature. He was, in fact, a farm boy who was also employed as a carpenter. Nevertheless, he understood that only through education could he achieve a life of value. Gray was born in Barnesville, Ohio, on August 2, 1835. His parents, David and Christiana Edgerton Gray, had moved there from western Pennsylvania and established a modest farm. Elisha attended grade school until his father died, when he had no alternative but to leave school and assist his widowed mother. Not long thereafter, she remarried to Cozens Smith, a Quaker farmer who lived in East Bethlehem, Pennsylvania, where the family moved.

Gray was apprenticed to a blacksmith, then a carpenter. Unsatisfied with his work, he enrolled in a high school whose principal was L. F. Parker, a recent arrival from Oberlin, Ohio. Gray worked early in the morning and late in the evening at his carpenter's job, attending school in midday. In 1856, he graduated from high school and enrolled in Oberlin College. Although he never graduated from Oberlin, he taught electricity and science there and built laboratory equipment for the science departments.

Life's Work

Gray is most often identified with an invention for which he did not receive a patent—the telephone. That patent was awarded to Alexander Graham Bell. However, there is debate as to who truly invented the device, and to this day there is no way to determine the details of the events of February 14, 1876, when both men filed for their patents. There were many lawsuits regarding the matter, all of which Bell won. (At one time, Gray congratulated Bell on the invention itself, leading some people to conclude that Bell had invented the telephone.) On that February day, Bell filed a patent entitled "Improvements in Telegraphy," while Gray filed a caveat (an abbreviated patent) for a device "for transmitting vocal sounds telegraphically." In all the discussions, arguments, and court battles that took place in the ensuing years, little differentiation was made between the two inventions.

Unlike a patent, which included drawings, description, and claims, a caveat included only drawings and description. The caveat was much less expensive to file and essentially stated that the filer had invented a particular device. If at some later date another similar invention appeared, the filer of the caveat had three months to take further action. At that time, actual dates of invention and practice could be compared. Because the patent and the caveat served essentially the same purpose, the question that arose in the Bell-Gray controversy was who had filed first.



Elisha Gray. (The Granger Collection, New York)

The filing fee for Gray's caveat was entered on the cash blotter hours after Bell's filing fee; this evidence quite logically suggested that Bell was first. However, there were indications that the various filings that day were put in the in-box in sequential order and that the recording of the events was handled hours later. If this was the case, then Gray's application was at the bottom of the in-box (first in, last out) and would mean that Gray preceded Bell. In addition, Gray was slow in taking any action to challenge Bell's patent. This was likely due to opposition by Dr. Samuel S. White, Gray's financial benefactor, to any work on the telephone. In late 1877, Gray applied for a patent for the same invention. This action put him in interference with Bell's patent. The patent examiner held that "while Gray was undoubtedly the first to conceive of and disclose the [variable resistance] invention, as in his caveat of February 14, 1876, his failure to take any action amounting to completion until others had demonstrated the utility of the invention deprives him of the right to have it considered."

Gray's work on the telephone, though by far his most interesting effort, was not his only achievement. He was the recipient of more than seventy patents, most of which dealt with telegraphy. His first invention was a self-adjusting telegraph relay—a device that compensated for the electrical characteristics of different transmission lines. He received a patent for this device in 1867, nine years before the telephone patent controversy. An invention of particular note was the "telautograph," a device that proved to be the predecessor of the fax machine. It was designed to remotely transmit handwriting through telegraph systems. Several patents pertaining to it were awarded to Gray. His effort resulted in the formation of the Gray National Telautograph Company in 1888; the company continued in business as the Telautograph Corporation until 1994, when it merged with a company that manufactured fax machines. Yet another invention was a primitive television system called the "telephote." It used an array of selenium cells focused on a picture. Signals from these cells would be transmitted to a distant station on separate wires, and at the receiving end the signals would open or close a shutter to re-create the image.

Gray's corporate involvements also deserve note. For some years, Gray had been using a small shop in Cleveland for parts and models for his numerous experiments. He was so impressed with the work of the shop that he and his partner Enos Barton bought the company and labeled it Gray and Barton. Much of the work done by the organization was for Western Union, which invested in the manufacturing enterprise in 1872. Gray and Barton's company reorganized as Western Electric Manufacturing Company. In 1881, Western Electric joined the Bell System (named for the aforementioned inventor) after Bell purchased a controlling interest in its stock, and in 1882 Western Electric became Bell's exclusive manufacturer of telephone equipment in the United States. Thus, Elisha Gray became one of the founders of the Bell System's manufacturing facility—Western Electric.

In 1899, Gray moved to Boston, and on January 21, 1901, he died from a heart attack in Newtonville, Massachusetts. He is buried in Chicago's Rosehill Cemetery.

IMPACT

The telephone invented by Gray was based on the variable-resistance principle—a theory that led to practical, commercial development of the invention. By the end of 1880, there were nearly fifty thousand telephones in the United States. These were connected to each other through what are today called "central offices." The first of these central offices, housing a huge switchboard, was established in New Haven, Connecticut, in 1878—two years after the invention of the telephone. These were manual switchboards controlled by operators who connected one telephone to another using a series of plugs and cords. This process was automated in 1891 by an undertaker, Almon Brown Strowger. The telephone network of today is ubiquitous, and it has grown from a wire-line network to a wireless network that carries voice, data, and video. It is able to connect people everywhere and is truly distance-independent.

Just as the telephone invented by Elisha Gray was an immensely important invention, so too was the commercial enterprise that capitalized on it—Western Electric. This company became the manufacturing facility of the largest telecommunications organization in the country—the Bell System.

—*Robert E. Stoffels*

THE TELEPHONE

On February 14, 1876, Elisha Gray filed a caveat with the U.S. Patent Office, the opening paragraphs of which read as follows: "It is the object of my invention to transmit the tones of the human voice through a telegraphic circuit, and reproduce them at the receiving end of the line, so that actual conversations can be carried on by persons at long distances apart." It had been demonstrated previously that if the current in a wire could be made to vary, this variance could be translated into the mechanical vibration of some sort of membrane. This vibration could cause air molecules to vibrate, and this, by definition, is sound.

The question arose, how might one cause a human voice to control the current in a wire? Gray had the solution—one that was much better than that of Alexander Graham Bell. Gray stretched a thin diaphragm across a frame and attached a thin metal rod to the center of the diaphragm. This rod was dipped in a vat of acidulated water. Gray knew that this water was neither an excellent insulator nor an excellent conductor. He determined that if one millimeter of the solution had an electrical resistance of 100 ohms, then two millimeters would have a resistance of 200 ohms. He laid a conducting plate on the bottom of the vat and suspended the rod only a few millimeters from the bottom. The electrical circuit would be connected from a battery, to the rod, through the water, to the metal plate, and then to the long-distance circuit. A speaker, talking directly into the diaphragm, would cause the rod to vibrate up and down; this would cause the resistance to the transmission circuit to vary, and the human voice could be replicated at the distance telephone.

In later years, it was this transmitter that received the most attention. Something practical had to be designed for commercial and residential use. A number of inventors worked on this problem, and the person who was most successful was Thomas Alva Edison. Instead of the vat of acidulated water, Edison used a small capsule of granulated carbon. He had determined that this carbon, when pressed and released by a speaker's voice on the wall of the capsule, would cause the resistance to vary. This carbon transmitter became the standard of the industry and was used until the electronic telephone came into vogue.

Wilson Greatbatch

American medical researcher

Greatbatch developed and campaigned for the use of an implantable heart pacemaker. When he discovered that the power supply was causing pacemakers to fail, he developed a corrosion-free lithium-iodide battery that made the pacemaker a long-term possibility. This combination has saved millions of lives.

Born: September 6, 1919; Buffalo, New York
Primary fields: Electronics and electrical engineering; medicine and medical technology
Primary inventions: Lithium-iodide battery; implantable pacemaker

Early Life

Electricity and electronics always fascinated Wilson Greatbatch. In his early teens, he wound his own coil and built a two-tube shortwave radio, which allowed him to "visit" other places and people. The hobby was a blessing for Greatbatch, who was an only child. He also joined the Boy Scouts and later the Sea Scouts. During the aftermath of the 1938 hurricane that devastated New England, Greatbatch and the other Sea Scouts forwarded messages for twenty-six hours. The Red Cross gave them a citation for their work.

Greatbatch joined the Naval Reserve in 1938, and in 1940 his unit was called up for a year of service, which, however, extended through the end of World War II. He did many jobs during his service time, including operating a radio on a convoy ship, repairing electronic equipment, teaching in a radar school, and flying as a rear gunner in a dive bomber in combat. A third of his squadron perished in combat.

After the war, Greatbatch moved with his new bride, Eleanor, to his hometown of Buffalo, New York. He worked for the New York Telephone Company as an installer-repairman. After a year, he decided to attend Cornell University using his G.I. Bill benefits. Cornell did not have housing for him as a nonresident student, so he solved the problem by buying a nearby plot of land and enrolling as a resident student. He earned a bachelor's degree in electrical engineering from Cornell in 1950 and a master's degree in electrical engineering from the University of Buffalo in 1957. Cornell stressed a wide range of courses, especially in mathematics, physics, and chemistry, which helped prepare him for his career.

Wilson Greatbatch at his workshop in 1997. (AP/Wide World Photos)

Greatbatch worked several jobs to support his wife and three children. He ran the university radio station on weekends. He also built amplifiers that were later used in the Arecibo radio telescope in Puerto Rico. While working at the Psychology Department's Animal Behavior Farm, he met two doctors who explained heart block, a condition in which electrical impulses cannot properly travel through the heart, resulting in irregular heartbeats. Greatbatch thought he could fix this condition with the right equipment. From 1952 to 1953, he worked at the Cornell Aeronautical Laboratory, where he was involved in monitoring the physiology of the monkeys sent into space by the Army. From 1953 to 1957, he was assistant professor at the University of Buffalo School of Electrical Engineering. Greatbatch and his wife finally had five children, four of whom were boys.

Life's Work

While at the University of Buffalo, Greatbatch began to do work for the Chronic Disease Research Institute. One project involved recording heart sounds. While building an oscillator that would produce a constant electrical signal, Greatbatch picked up the wrong size resistor. The device repeatedly produced a short pulse, much like the beating of a heart. Greatbatch remembered his discussions with the doctors at the Animal Behavior Farm and realized that this device could be used to treat heart block, a condition that leads to a slowed heartbeat or to asystole, the absence of a heartbeat.

In 1957, Greatbatch became a division manager at Taber Instrument Corporation in North Tonawonda, New York. In 1958, he approached Dr. William Chardack, chief of surgery at the Veteran's Administration Hospital in Buffalo, about the concept of an implantable pacemaker. At the time, heart block was treated with a large suitcase-size unit outside the body. The treatment was painful and caused skin damage. Chardack's enthusiasm for the pacemaker concept moved Greatbatch to quit his job, and, using his savings of $2,000, he built fifty pacemakers in two years in his barn. The first pacemaker was implanted in a dog in May, 1958. A high school classmate of Greatbatch, Dr. Andrew Gage, joined Greatbatch and Chardack. By April 7, 1960, a human patient had lived with a pacemaker pacing his heart for one continuous year. Ten of the pacemakers went into human patients; the remaining devices were used in animal studies.

The pacemaker as developed by Greatbatch used two transistors and a transformer arranged in the style called a coupled blocking oscillator. It was encapsulated in epoxy resin and attached to electrodes that were attached to the patient's heart myocardium. The pacemaker was li-

The Lithium-Iodide Battery

Many people feel that the development of the lithium battery is more important than the development of the artificial pacemaker, which others had been working on before Wilson Greatbatch invented his device. Early pacemakers used mercuric oxide-zinc batteries, which had serious faults. First, the battery produced a small amount of hydrogen gas, which the body had to absorb. Second, it was necessary to separate the components with a fabricated separator. Third, the battery could not be hermetically sealed, because one of the reactions produced hydrogen gas. Because the battery could not be sealed, the pacemaker could not be sealed. Since the pacemaker was not sealed, the inside was often 100 percent humidity, which was a poor environment for electronic components. Moreover, the battery was capable of sudden failure, and its longevity was only one to five years.

Greatbatch introduced a lithium-iodide battery for the pacemaker in the early 1970's, and it soon became the standard power source in the world's pacemakers. It produces no hydrogen gas and therefore can be hermetically sealed. With a sealed battery, the pacemaker can be sealed, and leakage into the pacemaker is kept to a minimum. In the lithium-iodide battery, there is no fabricated separator that can fail; thus, the three main problems with the mercuric oxide-zinc battery were solved with the lithium-iodide battery.

The lithium-iodide battery produces a high voltage, 2.8 volts. However, because it has a large internal impedance, the maximum current is only one-tenth of a milliamp. That amount of current is too low for most uses, although it is fine for a pacemaker. The lithium is used as the anode. The cathode is a composite of iodine and poly(2-vinylpyridine). Neither solid iodine nor poly(2-vinylpyridine) are conductive. However, when mixed and heated, they form a conducting liquid that can be poured into the cell in which it forms a solid. When the solid touches the lithium anode, it forms a semiconducting layer of crystalline lithium iodide that is one molecule thick. This layer grows as the cell is discharged. The voltage of the battery changes with the thickness of the layer because the layer is resistive. This allows the battery to be tested without having to be removed from the body. The lithium-iodide battery thus allows for long-term use of a pacemaker. It is now the standard battery for pacemakers because of its small size, high voltage, low self-discharge, and reliability.

censed to Medtronic in Minneapolis. The medical world began to accept and use the pacemaker, partly because of the outstanding reputation of Chardack. In the first year, Medtronic made 300 pacemakers. By the year 2000, more than 600,000 were implanted worldwide annually.

In the first ten years of use, the lifetime of the pacemaker was about one and a half to two years. About 80 percent of the failures of the pacemakers were the result of battery failure. The mercury battery, which used mercuric oxide-zinc cells, could not be hermetically sealed because of the hydrogen gas given off by the reaction of the battery. Potassium hydroxide from the battery could leak out and destroy the circuitry, or the battery could fail because of the contaminants that leaked into the battery. Greatbatch replaced the mercury battery with a sealed, corrosion-free, lithium-iodide battery. This made the pacemaker a long-lasting solution to the problem of heart block and other cardiac conditions.

Greatbatch had formed Wilson Greatbatch, Inc., in 1960. This corporation dissolved in 1963, when Mennen-Greatbatch Electronics, Inc., was formed. Mennen-Greatbatch Electronics later sold its patents to Medtronic and dissolved. Wilson Greatbatch, Ltd., was formed in 1964 to sell medical electronic equipment in Eastern European countries. In 1985, Greatbatch Gen-Aid was formed to provide assistance in genetic engineering to the fields of medicine and agriculture. Between 1980 and 2000, Greatbatch worked with John Sanford of Cornell on inhibiting the replication of acquired immunodeficiency syndrome (AIDS) and another viruses in cats. He holds more than 220 patents.

Greatbatch has been generous with his good fortune, donating funds to Houghton College in New York for a graduate program in music and providing free tuition and books for his company's employees and their children should they wish to go to school. He also spends part of his time giving lectures and demonstrations.

Impact

When Chardack was first approached by Greatbatch, Chardack stated that an implantable pacemaker could save ten thousand lives each year. Today there are more than sixty times that number of pacemakers installed worldwide each year. Patients with heart block will often suffer syncope (loss of consciousness), and then can die. The pacemaker maintains normal blood flow and prevents heart block. The pacemaker also treats rapid and irregular heartbeat. An episode of irregular heartbeat can produce such a small flow of blood that immediate death can result.

Not only does the pacemaker save lives, but it also improves quality of life. A person with restricted blood flow is less able to think quickly or have the energy to do all the things that he or she wants to do. With the pacemaker, the heart produces an adequate flow of blood, which produces more energy and the ability to think quickly. People have lived thirty or more years with a pacemaker.

Greatbatch built upon the ideas of other inventors, but his persistence in getting a doctor to implant his pacemaker, first in animals and then in human patients, set him apart from other inventors and made the pacemaker a common treatment for cardiac problems. He also persevered in making a device that was long-lasting. He continually tested components, finally developing a corrosion-free battery that improved the longevity of both his device and the patients using it.

James Gregory

Scottish mathematician and astronomer

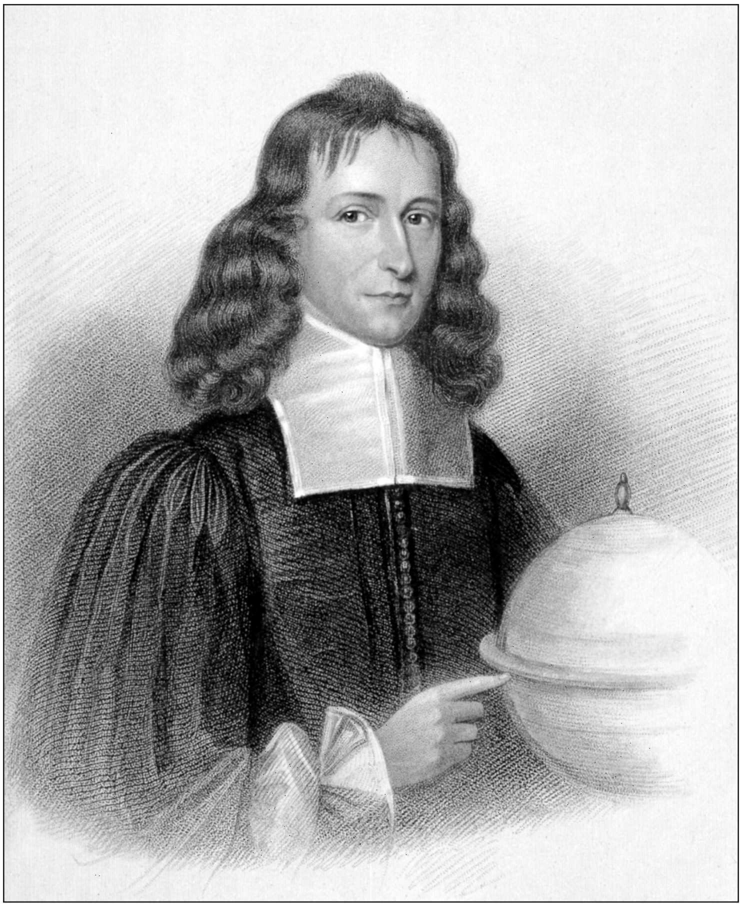
Gregory designed the first practical reflecting telescope. His design remains one of the most important type of optics used in telescopes, especially in large solar telescopes.

Born: November, 1638; Drumoak, Aberdeenshire, Scotland
Died: October, 1675; Edinburgh, Scotland
Also known as: James Gregorie
Primary fields: Astronomy; mathematics; optics
Primary invention: Gregorian telescope

Early Life

James Gregory was born in Drumoak, Scotland, in November of 1638; he was the third child of John Gregory, a pastor, and Janet Anderson. Gregory had two brothers: Alexander, the eldest, and David, who was ten years older than James. His mother introduced him to mathematics at a very young age, teaching him geometry. In 1651, when he was thirteen years old, his father died. His brother David took responsibility for his education and introduced him to Euclid's *Elements*, which James found simple and enjoyable to read. He also attended grammar school and studied in Aberdeen at Marischal College, the school where his father had studied.

Soon, Gregory began to study optics and telescope construction. Encouraged in his investigation by his brother David, he wrote *Optica promota* (1663), in which he described what would become known as the Gregorian telescope. Lacking the skills to construct the telescope, Gregory was unable at the time to proceed past the theoretical stage with his telescope.



James Gregory. (The Granger Collection, New York)

Life's Work

In 1663, Gregory went to London, where he met John Collins, who would become his lifelong friend and adviser. Gregory had moved to London for two reasons: He wanted to publish *Optica promota* (the advance of optics), and he wanted to find someone to construct the telescope described in his book. Several scientists were highly impressed by Gregory's book, including Oxford physicist Robert Hooke, who would build Gregory's telescope some ten years later; Robert Moray, a founding member and president of the Royal Society; and Sir Isaac Newton. Upon the advice of Collins, Gregory contacted a prominent optician named Reive and asked him to construct a parabolic mirror for the telescope. Reive accepted, but his work fell short of Gregory's expectations.

In 1664, Gregory left London and went to Italy, where he spent most of his time at the University of Padua working in mathematics. He concentrated his efforts on using infinite convergent series to find the areas of the circle and the hyperbola. He wrote two books during his stay in Padua. In 1667, he published *Vera circuli et hyperbola quadratura* and in 1668 *Geometriae pars universalis*, which was the first attempt to write a textbook on calculus.

Upon returning to London in the spring of 1668, Gregory sent a copy of *Vera circuli et hyperbola quadratura* to Christiaan Huygens, a highly respected Dutch mathematician, with a letter asking for his opinion on the work. Instead of personally replying to Gregory, Huygens published a highly critical review of the work in which he objected to a number of Gregory's conclusions and also stated that he had already expounded much of the theory for which Gregory was taking the credit. Gregory was severely upset by Huygens's review and subsequently was extremely reticent about his work. He rarely made public the methods that he used in his mathematical investigations.

Although Gregory was disappointed by Huygens's response to his book, his stay in London proved profitable for him. His friend Collins was well informed about the discoveries that were being made in mathematics and shared his knowledge with Gregory. Gregory also renewed acquaintance with his friend Robert Moray and attended the Royal Society's meetings. On June 11, Gregory was elected as a fellow of the prestigious society. He presented several papers to the society, including ones on mechanics, gravitation, and astronomy. He also published *Exercitationes geometricae*, which elucidated his knowledge of sine, cosine, and tangent. The work also served as a rebuttal to Huygens.

It is believed that it was Moray who convinced Charles II to establish the Regius Chair at the University of St. Andrews in order to enable Gregory to continue his mathematical research. Unlike the other professors at St. Andrews, Gregory was not assigned to a college. When he arrived there late in 1668, he was given the Upper Hall of the library as his work area. He gave two lectures each week. The faculty and student body of St. Andrews still adhered to a traditional view of mathematics and were totally uninformed about the latest developments in the discipline; therefore, Gregory's lectures were not well received. Shortly after his arrival at the university, Gregory met Mary Jamesome. They married and had two daughters and a son.

Gregory remained at St. Andrews for six years. During this time, he continued his work in both mathematics and astronomy. He kept abreast of other scholars' work through his correspondence with Collins. Gregory made significant discoveries that he shared with Collins but

The Gregorian Telescope

The Gregorian telescope is an example of a reflecting telescope. This type of telescope uses either a curved mirror or a combination of curved mirrors to reflect light and form an image. In 1616, Italian astronomer Niccolò Zucchi constructed the first reflecting telescope. In 1630, he used it to observe two bands on Jupiter and in 1640 to observe spots on Mars. However, the telescope had serious flaws that made it difficult to use. Zucchi did not succeed in accurately shaping the concave mirror. In addition, he was unable to find a way of viewing an image without blocking the mirror. Consequently, his telescope lacked practicality and did not become popular with astronomers.

In 1663, James Gregory published *Optica promota* (the advance of optics), in which he presented a design for a type of reflecting telescope. Some ten years later, the first Gregorian telescope was actually constructed by Robert Hooke. The telescope proved to be a good instrument for both astronomical and terrestrial observation. However, Sir Isaac Newton also designed a reflecting telescope and actually constructed one in 1668, a few years before the first Gregorian telescope was made. Thus, Gregory is usually credited with designing the first practical reflecting telescope, while Newton is credited with building the first practical reflecting telescope.

The Gregorian telescope uses two concave mirrors, a primary and a secondary mirror. The primary mirror is a concave paraboloid that collects the light and causes it to focus before the secondary mirror, which is a concave ellipsoid. From the secondary mirror, the light is reflected back through a hole in the center of the primary mirror. From there, the image is viewed with an eyepiece at the rear of the primary. The image produced by the telescope is upright. Thus, the Gregorian telescope is very practical for terrestrial observation.

The Gregorian telescope has a distinct advantage over the Newtonian telescope in that its design requires a shorter tube for the same focal length. However, the Cassegrain telescope (named for Laurent Cassegrain) is much more popular today than either the Newtonian or the Gregorian.

Nevertheless, the Gregorian design continues to be used for solar telescopes such as the Solar Optical Telescope on the Hinode satellite. Because the primary mirror creates an actual image before the secondary mirror, a field stop may be placed at this point, preventing light from outside the field of view from reaching the secondary mirror, thus reducing the amount of heat reaching the secondary mirror. In addition, Gregory's design and optics are found in many large telescopes, including the Vatican Advanced Technology Telescope and the Giant Magellan Telescope.

vacillated about publishing. Collins informed him that Newton had come to similar conclusions. Because of his respect for Newton and his desire not to repeat the Huygens incident, Gregory decided to wait for Newton to publish his findings.

Gregory set up his telescope in the Upper Hall of the library, but he tried unsuccessfully to establish an observatory at St. Andrews. The university permitted him to buy some instruments for the observatory but refused to fund the building of the observatory. Having been told that he would have to raise funds to construct it, Gregory traveled back to his home in Aberdeen to secure financial backing.

In 1674, Gregory became part of a collaborative project with his Parisian colleagues. They made simultaneous observations of an eclipse of the Moon. Despite his work, Gregory continued to be victimized by prejudice at St. Andrews. In 1674, he left the institution to take a position at Edinburgh University, where he was the first person to hold the chair in mathematics. There he continued his research in both mathematics and astronomy. He spent a considerable amount of his time attempting to solve quintic equations algebraically. Unfortunately, scarcely one year after going to Edinburgh, Gregory was suddenly stricken and blinded by a stroke while showing the moons of Jupiter to his students. A few days later, he died. He was thirty-six years old. Two lunar features are named after Gregory—the Crater Gregory and the Catena Gregory. His telescope design is known as the Gregorian telescope.

Impact

Because of his reluctance to publish the results of his research, Gregory did not significantly affect the development of the discipline of mathematics during his lifetime. Although he had actually discovered many formulas and solved many problems in mathematics before those credited with their discovery and solutions had done so, Gregory was not recognized for his work simply because he refused to make it known to either the scientific community or the general public. The majority of his investigations and discoveries remained unknown until the 1930's, when a scholar examined his papers, which had been preserved in the library at St. Andrews.

However, his design for a reflecting telescope, which he published in his book *Optica promota*, has been used in the making of telescopes since Robert Hooke, a friend of Gregory and an experimental scientist, constructed the first telescope using Gregory's design in 1673. Gregory's telescope was the standard one used for observations for a century and a half. The Gregorian telescope is still used today.

Alfred J. Gross

Canadian American engineer

Gross developed the concepts and basic workings of many modern electronic devices, including the walkie-talkie and the pager. His visionary work led to the mass communications systems that exist today.

Born: February 22, 1918; Toronto, Ontario, Canada
Died: December 21, 2000; Sun City, Arizona
Also known as: Irving J. Gross
Primary fields: Communications; electronics and electrical engineering
Primary inventions: Walkie-talkie; pager; radio tuner

Early Life

Alfred J. Gross was born in Toronto, Canada, but his family moved to Cleveland, Ohio, when he was an infant. When Gross was nine, his family was traversing Lake Erie on a steamboat when he discovered the ship's radio transmission station as he explored the vessel. The radio operator permitted Gross to observe as he received and transmitted messages to distant stations, and Gross's interest in wireless communication was sparked. He began tinkering with radios while still a young boy, dismantling and assembling them to learn their inner workings. By the time he was twelve, Gross had not only learned all there was to know about radio receivers but also built his first radio transmitter in his parent's basement. Radio was still a new technology, and Gross's transmitter, although homemade from mismatched parts, was one of the earliest and most powerful transmitters in the Cleveland area. As other radio enthusiasts began broadcasting on their own transmitters, amateur radio became more and more regulated. By the time he was sixteen, Gross had obtained an operating license for his transmitter, established a call sign, and joined the growing ranks of ham radio operators.

Two years later, in 1936, Gross enrolled in the electrical engineering program at Cleveland's Case School of Applied Sciences (now part of Case Western Reserve University). He excelled in the technical and theoretical aspects of radio technology and was soon making contributions of his own. Working with state-of-the-art equipment, Gross soon moved beyond his meager homemade radio. Radio sets of the time operated in a low-power setting below 100 megahertz (MHz). Because additional power meant that radio transmission could be heard more clearly at longer distances, Gross began to look for methods of harnessing additional power to radio transmitters. At the same time, he also realized that more power meant more weight, and so radio risked remaining as immobile as his large transmitter at home. Therefore, while searching for additional transmitting power, Gross also sought to make radio more portable.

Life's Work

Gross made his first great technical breakthrough in 1938, when he invented a powerful handheld transceiver using recent breakthroughs in battery technology and new lightweight vacuum tubes. The two-way radio device sent messages clearly because it operated in frequencies in the 200-300 MHz range rather than the usual 100 MHz. These upper ranges of the frequency scale became known as very high frequency (VHF) and ultrahigh frequency (UHF), which were generally allocated to television transmissions. Gross called his device a "walkie-talkie" because the transceiver allowed someone to move around while sending messages without remaining tied to a bulky transmitter.

With World War II raging in Europe, the Office of Strategic Services (OSS, the predecessor to the Central Intelligence Agency), the body responsible for conducting American intelligence operations during the war, took a keen interest in the walkie-talkie. The mobile radio was ideal for use by spies, who needed to be secretive yet able to relay information. Gross was recruited by the OSS to help develop a two-way communications system for the military; the ground unit was code-named "Joan," and the air unit, "Eleanor." Joan, officially the SSTC-502 transceiver, was a small but powerful device that weighed only four pounds and operated at 260 MHz. It permitted intelligence agents to relay information to overhead planes equipped with the Eleanor unit, the SSTR-6 transceiver. The Joan-Eleanor system was the first example of directional transmission. Unlike traditional transmitters, whose signals emanate from the antenna in all directions, the Joan-Eleanor system transmitted the message only upward to the airplane overhead. This allowed only the receiver in the airplane to hear the message; enemy eavesdropping was not possible. An added benefit was that the agent using the Joan device did not have to encode the message and could instead broadcast it in plain language. Encoding and decoding messages took time, but agents broadcasting messages in plain language could get their message across much faster and without any possible misinterpretation by the

Gross's Radio Tuner

The key piece of technology invented by Alfred J. Gross that made his citizens' band (CB) radio possible was his radio-tuning apparatus, which he patented in 1950. Gross's radio tuner was much more efficient than earlier tuners because it compensated for the tighter frequency bands available to CB radios.

Earlier radios required a separate tuning device attached to the radio receiver-transmitter. Because the tuning device was not an integral part of the radio, the mechanism was often unreliable and incapable of adapting if the transmission pattern changed. If an outside influence affected the incoming or outgoing transmission, the operator had to constantly adjust the tuner while trying to relay or receive the message. A change in either the broadcaster or receiver's location, for instance, meant that both parties had to retune their radios. This made radio transmission difficult from a moving vehicle. Gross's tuner, on the other hand, was an integral part of the radio. His "loop tuner" used the incoming electrical impulse of the message to reset the tuner automatically. With this system, someone using a CB radio did not have to constantly tune the radio after he or she set the original frequency. This made the radio much easier to use, especially for operators who had no previous experience. It also made the radio more hands-free: An operator could use a CB radio with one hand, pushing a button to transmit and releasing the button to receive. This made the radio much safer to use in trucks and vehicles that required attention while operating.

The functionality of the automatic tuner made the CB radio a life-saving device. For operators who might be in danger, the CB radio was simple enough for a novice user or someone under duress to use easily. Conversely, rescue personnel could communicate through their CB radios in real time to those who needed their help, a simple act that facilitated emergency assistance. Moreover, because those who needed help and their rescuers were using the same frequency band, communications device, and open airwaves, everyone associated with an emergency call could speak to one another without an intermediary, in contrast to a telephone, which required a coordinating operator and which allowed only one person to speak at a time.

receiver. The Germans were unaware that the Allies possessed a system that could operate in the VHF frequencies, so the Germans lacked a means to locate the Joan transceiver when it was operating. Consequently, OSS agents could use the device with little fear of detection. The government did not declassify the documents relating to the Joan-Eleanor system until 1976.

After World War II, Gross turned his wartime achievements to peacetime purposes. The Federal Communications Commission (FCC), the government agency responsible for managing commercial radio transmission, permitted private transmitters to operate in the VHF and UHF frequencies. The FCC established the Citizens' Radio Service Frequency Band (a "band" is a range of frequencies reserved for a specific purpose) in 1946 for the exclusive use of nonmilitary and nongovernment transmitters. With citizens' band (CB) radio, common Americans could now transmit personal messages on the higher frequencies, ensuring longer-range and clearer transmission than that of the much larger, bulkier, and more expensive transmitters of only a few years earlier. Gross established a company in Cleveland, Gross Electronics, Inc., in 1948 to manufacture transmitters in the citizens' band. Because of his expertise, his company was the first to receive FCC approval. Gross's CB radios soon became the most reliable means to communicate for people in remote areas or in occupations that required constant motion. Farmers came to rely on them, and CB radios soon equipped trucks that crossed the country delivering freight. Law-enforcement and rescue agencies also employed CB radios as an inexpensive and reliable means to serve the public and save lives.

Gross next turned his mind to inventing devices for long-distance, personal communications. In 1949, he demonstrated "remote telephonic signaling" with a pocket-sized wireless device known as the pager. Gross saw it as a life-saving device, capable of summoning help by sending an electronic summons if someone could not speak. Doctors and rescue workers did not like to constantly carry the summons device, so the pager did not immediately become popular. Gross's idea for the mobile telephone was also rebuffed. Gross envisioned the possibility of adapting the Joan-Eleanor system to personal use, proposing a modified walkie-talkie that used a directional antenna like that of the Joan unit. It could broadcast a voice message to a local receiver, which would in turn boost the power of the message and send it to the next receiver. Gross's new phone would be both cordless and mobile, and it was based on the same principle that modern cellular phones use. Unfortunately, Gross could not get anyone to pay attention to the idea. At the time, the Bell Telephone Company had a monopoly on the telephone industry; it was not going to allow its dominance to end because of wireless transmissions, so it discouraged Gross from pursuing the idea.

According to legend, Gross also influenced pop culture. Chester Gould, the creator of the *Dick Tracy* comics, claimed that Gross once showed him a proposed portable radio small enough to fit onto a wristwatch. Gould was so enamored with the possibilities of the device that he asked Gross if he could use it in his comic strip, and from 1946 onward Dick Tracy kept in contact with his fellow police officers through his Gross-inspired wrist radio. Gross continued to tinker with new ideas for the rest of his life until his death in 2000.

Impact

Gross saw the need for modern communications long before anyone else did. Although he invented the walkie-talkie and the pager and pioneered the technology used in cellular and cordless phones, he never profited from these devices. People were not ready for a wireless world in the 1950's, and by the time they were, most of Gross's patents had expired. Today, cellular phones are a multimillion-dollar industry. The ability to securely send wireless data, which started with Gross's walkie-talkie, defines the modern world. Modern business, personal communications, and international transmissions could not exist without secure data links. Cell phones resist eavesdropping, computers exchange data through a wireless modem, and assistance is a push of a button away thanks to Gross's efforts.

Sir William Robert Grove

British physicist

Grove's primary contributions to technological invention were two new kinds of electrical battery—the nitric-acid battery and the gas battery—but he also made a considerable contribution to theoretical science with his work on the "correlation of physical forces" and was a significant agitator for the professionalization of British science.

Born: July 11, 1811; Swansea, Glamorgan, Wales
Died: August 1, 1896; London, England
Primary field: Electronics and electrical engineering
Primary invention: Nitric-acid battery

Early Life

William Robert Grove was the son of John Grove, a magistrate and the deputy lieutenant of Glamorgan, and his wife, Anne (née Bevan). He was educated at home by a series of private tutors before attending Brasenose College, Oxford, in 1829, where he studied classics. He graduated in 1832 and went to London to prepare himself for a legal career, following in his august father's footsteps. He was admitted as a student at Lincoln's Inn on November 11, 1831, and was called to the bar on November 23, 1835.

Grove must have already developed a strong interest in natural philosophy at this time; he joined the Royal Institution in 1835 and was a founding member of the Swansea Literary and Philosophical Society in the same year. On May 27, 1837, he married Emma Maria Powles, the daughter of John Diston Powles of Summit House, Middlesex, a member of the Royal Institution whom he presumably met there. The couple had at least one son, Coleridge, and two daughters, Emily and Anna; the marriage lasted thirty-two years until Emma's death in 1879. Grove had been suffering health problems before the marriage, and the couple went on a long tour of the Continent thereafter; it was then that his interests in natural philosophy came into full flower.

Grove's first scientific publication was a letter to the *Philosophical Magazine* about the construction of electrical batteries, which were then inclined to decay very rapidly. He continued to publish letters on that subject and, while in Paris in 1839, he read a paper to the Académie des Sciences on a new kind of "voltaic pile." This was the first revelation of the nitric-acid battery that was to make his reputation as an inventor; Michael Faraday asked Grove to demonstrate the device at the Royal Institution following his return to England, which he did on March 13, 1840. By the end of the year, he had been elected a fellow of the Royal Society.

The Nitric-Acid Battery

The nitric-acid battery, or Grove cell, employed a zinc electrode suspended in dilute sulfuric acid and a platinum electrode suspended in concentrated nitric acid, separated by a porous ceramic pot. The battery produced a considerably higher voltage than previous models, doubling the voltage of its most powerful rival, the much more expensive Daniell cell. For this reason, the Grove cell became the battery of choice for telegraph systems in Great Britain and the United States from 1840 on and was not universally replaced until 1860, in spite of two serious defects. The first was that the voltage it generated diminished over time; the second was that the nitric acid tended to give off poisonous nitrogen dioxide gas, which could accumulate dangerously in a cramped but busy telegraph office.

The fact that Sir William Robert Grove made his battery freely available rather than patenting it, thus missing out on the payments that other pioneers of commercial telegraphy received—and which, as a lawyer, he would have been better placed than some of his rivals to claim and negotiate—may seem odd, given his subsequent crusade for the professionalization of science. What he wanted, however, was for scientific research to be better rewarded for its own sake, freed from the lottery that restricted success to the discoverers of patentable applications. The fact that the Grove cell became so important as a power source of early electrical technology presumably gave him a good deal of satisfaction, and there is no evidence that he regretted his failure to cash in on it. He would probably have been delighted to know that his gas battery, which had no useful applications at the time, would eventually become highly significant in the twentieth and twenty-first centuries as a nonpolluting fuel cell.

Life's Work

The professionalization of science was in its infancy when Grove became interested in experimental work. While he had to rely on his income as a barrister, Grove had difficulty finding time and money for further investigations. In 1841, however, he was appointed professor of experimental philosophy at the London Institution, founded in 1805 for the express purpose of bringing natural philosophers and businessmen together for the purposes of technological exploitation. His inaugural lecture on January 19, 1842, introduced the concept of the "correlation of physical forces," which suggested that physically active agencies—heat, light, electricity, magnetism, and so on—were mutually convertible and, in essence, merely different forms of the same phenomenon. Grove's theory was a precursor to the theory of conservation of energy that made his scientific reputation.

In 1842, Grove demonstrated another new kind of battery, which he called a gas battery. It worked by combining hydrogen and oxygen to produce steam and an output of electrical energy. It was of little practical value at the time, largely because it was more energy-expensive to produce the hydrogen and oxygen from steam than it was to redeem the energy thus "stored." Analysis of the way in which the water molecule could be dissociated into its component atoms and then recombined was, however, an important step forward in its own right, and Grove's device was directly ancestral to modern fuel cells, which use exactly the same principle and have the now significant advantage of producing no waste gases. The discovery won him the Royal Society's Royal Medal in 1847.

While he was at the London Institution, Grove worked with John Peter Gassiot on photographic chemistry. Grove also became increasingly impatient with the manner in which the Royal Society and other scientific societies were organized, along the amateurish pattern of gentlemen's clubs, and began to rail against rampant "nepotism" and "corruption." In 1843, he published an anonymous article in *Blackwood's Magazine* that was severely critical of the scientific establishment on these grounds. In 1844, he was appointed, somewhat controversially, as vice president of the Royal Institution. In 1846, still in a spirit of reformist zeal, he resigned his professorship at the London Institution because of the meager salary, but his scientific reputation increased as his book *On the*

Correlation of Physical Forces (1846) went through six editions, some of them augmented. He was elected to the council of the Royal Society and proposed to reform it by giving the council power over nominations to the society and limiting the annual number of nominations. The reforms were passed in 1847, prompting numerous resignations, giving Grove and his supporters effective control over the institution's future membership and direction. They formed the Philosophical Club as an inner circle within the broader organization. Although Grove failed in bids to be elected to higher positions within the Royal Society, he continued to use his council membership to further the professionalization of British science.

In the 1850's, Grove became very interested in the problem of electrical conduction in a vacuum, but his return to legal work left him devoid of laboratory facilities and increasingly short of time. In 1853, he became a Queen's Counsel on the South Wales and Chester circuit, appearing in some notable patent law cases regarding the early development of photographic technology. In 1855, he considered applying for the recently vacated chair of chemistry at Oxford University but did not think he could win a contested election. In 1866, he was elected president of the annual meeting of the British Association for the Advancement of Science (BAAS), held that year in Nottingham, and used his presidency to offer public support for the theory of evolution—the first BAAS president to do so. The last third of his address was a careful and cogent summary of all the evidence then available that the evolution of species had occurred in the past and was still occurring, aided by some kind of gradual and ongoing "spontaneous generation." (The idea of mutation was yet to be proposed.)

In 1871, Grove's legal career made further progress when he was appointed as a judge to the Court of Common Pleas; he was knighted the following year. In 1880, he was appointed to the Queen's Bench. He retired as a judge in 1887 and became a member of the Privy Council. He served on a Royal Commission on Patent Law and on the Metropolitan Commission of Sewers; the latter was an important body that supervised the construction of London's sewer system—one of the marvels of Victorian engineering. Grove died at his home on Harley Street in 1896 after a long illness and was buried in Highgate Cemetery. A lunar crater is named in his honor.

Impact

Grove's impact as an inventor and scientist was muted by his opposition to the way in which scientific endeavor in Great Britain was organized and remunerated, and he might have accomplished far more as an electrical experimenter had he not felt compelled to return to legal work in order to support himself and his family in what he considered to be reasonable comfort. He took out no patents, but his nitric-acid battery was widely adopted as a means of electricity generation. His gas battery, though of little practical value at the time, may yet prove even more significant as its direct descendant technology, the fuel cell, takes an increasingly important role in automotive technology in the twenty-first century. He was one of very few men of his own era to regard work as a Queen's Counsel and judge as mere drudgery, undertaken for money, while his heart was in pure and applied science. Historians of science will judge that his heart was in the right place.

OTTO VON GUERICKE
German physicist

A theoretical physicist, Guericke challenged prevailing assumptions about the nature of atmospheric pressure and the properties of a vacuum and in the process invented a working model for the first vacuum pump.

Born: November 20, 1602; Magdeburg, Saxony (now in Germany)
Died: May 11, 1686; Hamburg (now in Germany)
Also known as: Otto Guericke
Primary fields: Mechanical engineering; physics
Primary invention: Vacuum pump

EARLY LIFE

Otto von Guericke (GAY-rih-kuh) was born to wealth in a family whose position in the town of Magdeburg dated back more than three centuries. As was the privilege of the aristocracy, Guericke attended a number of prestigious universities not so much to complete a degree as to investigate wherever his curiosity would lead. Thus, at fifteen, he entered the University of Leipzig to study the humanities (particularly law and philosophy). However, after his father's death when he was eighteen, Guericke returned home, where he continued his education (this time in jurisprudence), first at Helmstedt and then at Jena and eventually at Leiden in the Netherlands. In 1623 in Leiden, he began to study mathematics and engineering. He underwent the traditional grand tour, studying abroad in both France and England. He was drawn particularly to natural philosophy, or the study of the physical universe.

Guericke returned to Magdeburg in 1626 and married. Given his family's stature and his considerable education, Guericke was selected to serve as alderman, and his dedication to public service would continue for nearly five decades. In 1631, following the plundering of Protestant Magdeburg by the forces of the Holy Roman Empire during the Thirty Years' War, Guericke (who lost virtually his entire estate) was imprisoned briefly by the Swedish army before he was allowed to return to Magdeburg. There, drawing on his background in engineering, he directed the rebuilding efforts that included refortifying the city. In time, he began a lucrative business as a master brewer. In 1646, he was elected the revitalized city's burgomeister, the equivalent of mayor, a position he would maintain for more than thirty years. That career in public service extended to numerous important diplomatic assignments. In recognition of that service, Guericke was raised to peerage by Emperor Leopold I in January, 1666. Hence, "von" (connoting his new aristocratic status) was added to his name. As younger politicians sought to curtail his influence, Guericke in 1678 reluctantly gave up public office and two years later moved to Hamburg, where he lived with his son until his death on May 11, 1686.

Otto von Guericke. (Library of Congress)

LIFE'S WORK

It is remarkable that, despite his considerable public life and the demands of his business, Guericke maintained his deep interest in the sciences. His pursuit of a range of investigations across nearly three decades marks him as a prototypical Renaissance figure. His theoretical experiments touched on the fields of mathematics, engineering, electricity, meteorology, astronomy, and, most prominently, physics. Among his more notable experiments was the invention of a kind of rotating sulfur globe that, when friction was applied (Guericke would touch the globe with his hand), would send off sparks and attract and repel a variety of lightweight objects such as feathers, fabric, and paper. Guericke had no idea that the sparks were static electricity, but he and his audience relished the spectacle effects of the demonstration. In addition, Guericke completed important work in astronomical observations, most notably in the prediction of comets.

In the period of his most significant scientific work (1640-1655), Guericke was drawn to questions raised by the Copernican construction of the physical universe, particularly the nature of space itself and the assumption, grounded in the physical sciences since Aristotle, of the impossibility of a vacuum. The notion that "nature abhors a vacuum" (most vehemently argued by French philosopher René Descartes), called *horror vacui*, had led to a long tradition in philosophy that raised popular anxieties over the idea of empty space. Guericke, however, was not convinced: Experiments by Evangelista Torricelli in 1644 and by Blaise Pascal in 1647 indicated that air pressure was in fact a significant and potentially powerful force, that emptiness was hardly empty.

Determined to test the nature of air pressure and to verify the existence of a vacuum, Guericke began working in his backyard with the basic model of a modified water pump. He found that, in trying to evacuate the air from a barrel of water, the air seeped back into the barrel through the porous wood. That began an intense period of modifications and often frustrating results. By 1650 (the exact year is not known), Guericke had designed and built a prototype copper globe and discovered that he could pump out both water and air and create a powerful seal, or vacuum. It was the first working air pump. Besides his mechanical construction, Guericke was the first theoretical physicist to realize the implications of creating a vacuum. Over the next several years, he conducted tests that would verify (among other properties) that, in a vacuum, a flame could not be lit, the ringing of a bell could not be heard, and animal life could not be supported.

Guericke achieved considerable notoriety for a particularly dramatic demonstration of the sheer power of air pressure conducted at the court of Emperor Ferdinand III and the entire imperial diet in 1654 in Regensburg. Asked to demonstrate his air pump, he joined two identical hollow copper hemispheres into a sphere roughly fifteen inches in diameter and sealed it along fitted edges without any locks. Guericke proceeded to pump out the air, producing a vacuum within the sphere. Sixteen powerful horses divided into two teams pulling on either side of the tiny object failed to pull the sphere apart (although "eyewitness" testimony later put the number of horses at

The Vacuum Pump

When Aristotle stated that "nature abhors a vacuum" (*horror vacui*), that empty space tended to pull matter, gas, or liquid to it, he unintentionally justified centuries of increasingly rigid scientific postulations that conceived of a cosmos in which emptiness itself was something of a terror. Otto von Guericke's experiments in creating a vacuum in apparent refutation of that long-held argument rested on his review of two landmark experiments conducted just ten years earlier. In 1644, Evangelista Torricelli (a protégé of Galileo) performed an experiment to explain why well water was harder to draw when the water was below ground level. He used a glass tube of mercury to create an apparent vacuum. Three years later, Blaise Pascal's experiment measured different elevations and suggested that atmospheric pressure changed with altitude, indicating the enormous influence (and weight) of air pressure.

It was Guericke's historic contribution to actually create a vacuum—that is, to design a device (a vacuum pump) capable of removing molecules of gas from a sealed container. As a prototype, Guericke's pump was basic, what is now referred to as a positive displacement pump. One of the two copper hemispheres had a detachable tube that connected to the modified water pump, which had pistons that, when stroked steadily, removed the air from the enclosed sphere. The guiding principle was to use suction via the attached mechanism that, when pumped repeatedly, would actually expand the closed sphere to allow air to flow out of the chamber into a cylinder. As the pump was repeatedly exerted and closed off, given the differential in pressure, the vacuum seal became stronger. A one-way valve closed off the sphere when the air had been significantly removed (it was not an absolute vacuum). Once the evacuation had been completed and the pump detached, the sphere was held together by the tremendous force of air pressure.

At Regensburg, Guericke had two teams of horses harnessed to the tiny sphere (about fifteen inches in diameter), which they failed to pull apart. This dramatic experiment demonstrated the power of atmospheric pressure. His work disproved the long-standing hypothesis of *horror vacui* and laid the foundation for significant work in a variety of fields, including physics, pneumatics, and thermodynamics.

anywhere from thirty to forty-two). The demonstration made quite an impact: The court was amazed by straining horses thwarted by the tiny sphere held together by apparently nothing. Only when Guericke reentered air into the sphere did it come apart, and then it did so by itself without any pull. The demonstration—which Guericke later twice repeated, most notably in 1663 for the court of Friedrich Wilhelm I of Brandenburg (Berlin)—gave Guericke significant celebrity. Today, the hemispheres are known as "Magdeburg hemispheres."

Over the next decade, Guericke completed landmark experiments that defined the physical properties of the vacuum. He extended his interest in air pressure and vacuums to atmospheric experiments in meteorology. He invented the manometer, which measures atmospheric pressure, and significantly improved the design of the barometer as a tool for predicting weather. In the field of magnetism, he demonstrated that electrical attraction works in a vacuum—that a magnet, indeed electrical attraction itself, does not require air.

Impact

Historically, Guericke stands as a formidable Renaissance figure whose consummate interest in the implications of experimental physics was matched by a long and dedicated career of public service. Guericke's fifty-year record as a public servant represents a contribution that puts his work as amateur physicist in significant relief. His overseeing of the reconstruction of the infrastructure of the devastated Magdeburg—including the design and construction of tunnels, bridges, roads, and fortresses—and his participation in numerous delicate diplomatic negotiations and conventions following the Thirty Years' War are particularly notable. It is no surprise that the University of Magdeburg was renamed in his honor or that a heroic statue of him dominates the city's public square even today.

As a theoretical physicist, Guericke, whose work touched on so many different fields, represents the restless curiosity and intellectual energy of science's lost generation, which came between the death of Nicolaus Copernicus and the rise of Sir Isaac Newton—between the threshold era of initial hypotheses that heroically countered centuries of cosmological assumptions about the operations of the physical world and the era that saw the development of the instruments and observational data necessary to define that new cosmos into knowability. As such, Guericke, far more than an aristocratic dilettante dabbling in sciences, left behind a record of rigorous and painstaking experimentation, a spirit of inquiry free of religious or political biases. His most extensive research project into the nature of vacuums, for instance, redefined the conception of space itself and introduced the notion that the apparent emptiness between planets and stars was far more complicated and far more powerful a force than humanity had ever conceived. His research laid the foundation for significant work not only in pneumatics and physics but also in the fields of electricity, medical technology, thermodynamics, refrigeration, and ultimately space exploration.

Johann Gutenberg
German printer

By inventing the printing press, Gutenberg developed an innovative and extremely productive typographical process. In the mid-fifteenth century, his technological innovations—including the mechanical press and metal movable types—changed printing forever.

Born: 1394-1399; Mainz (now in Germany)
Died: Probably February 3, 1468; Mainz
Also known as: Johann Gensfleisch zur Laden zum Gutenberg (full name); Johann Gensfleisch zur Laden (birth name)
Primary field: Printing
Primary invention: Printing press

Early Life

Johann Gutenberg (YOH-hahn GOO-tehn-burg) was born Johann Gensfleisch zur Laden zum Gutenberg to a noble family in Mainz (now in Germany). He was the third son of a silversmith, Friele Gensfleisch, by his second wife, Else Wyrich, a storekeeper's daughter. He was trained in gold and silver work, which would have a great influence on his future invention. In 1411, his father had to exile himself to Strasbourg (now in France), following the revolts of the bourgeois guilds against the patricians in Mainz, and the rest of the family followed in 1428. At this time, perhaps to conceal his status as an exile, Johann changed his paternal surname to Gutenberg.

In Strasbourg, Gutenberg taught several arts and worked as a metallurgist. With Hans Riffe, Andreas Dritzehn, and Andreas Heilmann, he set up a company to create mirrors for pilgrims to Aachen, but the business failed. In 1438, Dritzehn died, and his heirs sued to be included in the partnership. The trial documents mention stone polishing, mirror making, and a "new art" that made use of a press, of certain pieces that could be separated and joined, lead forms (probably types), and "materials related to printing." It can be inferred that, as he worked as an engraver, Gutenberg was secretly testing his new art.

Life's Work

Nothing is known of Gutenberg's work between March 12, 1444, when he is last mentioned in the Strasbourg tax registers, and October 17, 1448, when his name reappears in a Mainz document for a small loan he received. What seems certain is that his search for a mechanized system of printing continued. He strove to surmount the technical limitations of printing of his time, which included xylography, a woodblock printing technique that came from China. Given the immense number of characters in the Chinese language, this technique would not be developed in China but in Europe from the fourteenth century on. The twenty-five letters of the Latin alphabet, separately carved in wood, were arranged to form words; thus began the typographic press. The number of prints that could be made was, however, scant, and the finish was irregular. The Dutchman Laurens Coster is said to have printed with movable type as early as 1430,

Johann Gutenberg. (Library of Congress)

The Printing Press

Johann Gutenberg is the inventor of typography—the art of laying out and multiplying texts and images on paper. Taking advantage of the progress made in metallurgy in his time, he set up around 1450 the first printing house in history. It was equipped with a mechanical press, movable type, high-quality paper, and oil-based inks. It had two sections: one for composition, one for printing. Gutenberg devised an innovative typographical five-stage process: punch cutting, matrix fitting, type casting, composing, and printing. The first stage consisted of carving back to front the shape of each letter or symbol on a steel punch. This was then hammered on a small copper piece called a matrix. When the matrix was fixed on a mold's base into which liquid metal was poured, a piece of type was created—a back-to-front, three-dimensional representation of a letter or symbol cast in an alloy of lead, tin, and antimony.

The presses used by Gutenberg and his successors were wooden. The upper part of the press was normally fixed to the ceiling; once the composed type had been locked and inked on the bed of the press, the (usually moist) paper was screwed down against it by means of a movable flat surface, or platen. The press had rails for the printing block to be extracted and to recover its original position. It was a slow and laborious operation: About 250 prints were made each hour, and only one side was printed at a time. Nevertheless, the highly technical process devised by Gutenberg made it (for five centuries) the only printing technique for large print runs. In the course of time, other technical processes—lithography, flexography, engraving, the rotary press, Linotype, offset printing, and modern digital printing—would enhance the performance of this art.

The extraordinary social, artistic, and intellectual impact of the printing press cannot be overstated. Books became valued as objects in themselves; great care was taken with illustrations, typefaces, book covers, and so on. Knowledge became more dynamic, spreading as it had never done before. Periodical publications, propaganda leaflets, pocket editions, and bibliographical collections were born. Public and private libraries increased immensely. People read more and were heard on public affairs. Readers had access to written sources, allowing for personal interpretation of literary texts. A common epistemological framework for all kinds of research became available. The invention of the printing press changed the mentality of human society and marked the beginning of a new age.

but this claim lacks support. Most scholars now credit Gutenberg with inventing the printing press.

Gutenberg, after a number of tests, succeeded in mechanizing the printing process. His workshop brought together the basic components of modern typography: special paper, an oil-based printing ink, a mold with punch-stamped matrices from which movable metal types could be cast, and a new press that he adapted from wine presses. A new typographical process based on composition and printing was thus inaugurated. Typography took immediate advantage of Gutenberg's invention: Manuscript proof corrections were easily done, the number and quality of prints exceeded that of the Middle Ages, uniformity and perdurability in printing were achieved, the graphic possibilities became almost limitless, and prints became cheaper.

However, Gutenberg did not have enough money to set up his printing house. Foreseeing the economic advantages of the invention, the German moneylender Johann Fust became associated with Gutenberg around 1450. Fust first loaned him 800 guilders for the equipment, at an interest rate of 5 percent. Two years later, he promised him 300 guilders more as a share in the invention Gutenberg called "Das Werk der Bücher" (the work of books). Gutenberg set up his first known printing plant in Mainz. Peter Schöffer, Fust's son-in-law and Gutenberg's disciple, joined them in 1452, the year the team's great work began to take shape: the Gutenberg Bible, also called the Mazarin Bible (so called because the first copy described by bibliographers was located in Cardinal Mazarin's library) or the Forty-two-Line Bible (so called because each page has forty-two lines). The work, completed in 1455, is known for its excellent typographic quality and great beauty.

Gutenberg's partnership with Fust and Schöffer did not last. Fust did not wait for the over 150 copies that were being printed to be sold, and he judicially claimed from the inventor some 2,000 guilders. Gutenberg lost in court and was sentenced to give back the still uninvested capital and pay the interest due. In 1455, the partnership was dissolved. Fust and Schöffer kept the printing plant and put the Bible copies on the market in early 1456. In 1457, they published the *Mainzer Psalterium*, the first work to include the printing date and the name of the printers. Gutenberg must have also taken part in this publication before he quit the partnership.

These were times of economic hardship for Gutenberg. Around 1457, he joined one of the many printing houses already established in Mainz, whose manager was the syndic Conrad Homery. Many books were then published in the city; among them were Johannes Balbus's *Catholicon* (1460), the Thirty-six-Line Bible (before 1461), school textbooks, dictionaries, and astronomical calendars in the vernacular. Gutenberg neither dated nor signed any of his books, so it is impossible to determine which ones are his work.

In 1462, Mainz was sacked by the troops of Adolph II of Nassau, archbishop of the city. Like many other printers, Gutenberg suffered heavy financial losses, but he remained in the city. It is said that the archbishop took him into his palace in 1465, made him a knight of the court, and granted him a salary and privileges in gratitude "for the services performed so far and for those he will perform in the future." Gutenberg's financial situation improved considerably, and he continued to print books. He spent the last years of his life between Eltville and Mainz, where he died on February 3, 1468. In 1900, a museum was erected in his native city, where his press and workshop have been re-created.

Impact

That Gutenberg was the real inventor of the printing press is unquestioned today. It was he who devised, equipped, and started the first printing house in history. Between 1450 and 1465, the printing press started to be used for industrial purposes. The disciples of the first typographers taught the new printing technique throughout Europe. Fifty years after Gutenberg's death, presses had been set up in 270 European cities; forty thousand books had been printed by then, amounting to over ten million volumes. In 1476, a Greek grammar was printed in Milan, and in 1488 a Hebrew Bible in Soncino. In Spain, at the request of Cardinal Cisneros, the Complutensian Polyglot Bible was made (1514-1517). The printing press reached America in 1539, when Juan Cromberger brought it to Mexico.

The sixteenth century saw the rise of the great dynasties of printers (the Manutii in Italy, the Estiennes in France, the Plantins and Elzevirs in the Low Countries, for example), precursors of the manufacturing press. State, church, and cultural representatives were soon aware of the advantages conveyed by Gutenberg's typographic art. The Renaissance humanists multiplied the editions of the works of classical antiquity (pocket editions began in 1500 with Aldus Manutius's *Virgilius*) and encouraged the creation of large libraries. The Protestant Reformation made ample use of the printing press, particularly to spread the reading of the Christian source texts in the vernacular. (The German translation of Martin Luther's Bible was printed in 1534.) The printing press was also used for the circulation of propaganda during the political and religious strifes of the sixteenth and seventeenth centuries. The scientists of the modern era used the printing press to relate their ideas and discoveries to a world imbued with the mechanical culture. It took less than a century for the trading bourgeois to set up networks for the diffusion and selling of books, thus favoring the establishment of mercantile associations.

Fritz Haber

German chemist

Haber's research in chemistry paved the way for commercial production of synthetic nitrogen fertilizers, thus enhancing global agricultural productivity. His work was also critical in supplying his native Germany with conventional munitions and chemical weaponry during World War I.

Born: December 9, 1868; Breslau, Silesia, Prussia (now Wrocław, Poland)
Died: January 29, 1934; Basel, Switzerland
Primary fields: Chemistry; military technology and weaponry
Primary inventions: Synthetic fertilizers; Haber process

Early Life

Fritz Haber (HAY-bur) was born on December 9, 1868, in Breslau, Silesia, Prussia (now Wrocław, Poland). The son of Siegfried Haber, a wealthy merchant dealing in dyes and pharmaceuticals, Fritz was a member of an esteemed and well-connected family in his town. His mother, Paula, died in childbirth.

Fritz Haber. (©The Nobel Foundation)

Haber's early schooling took place at the *Volksschule*, or formal school. He then enrolled at the St. Elizabeth classical school in Breslau, where he studied for nine years. Instead of serving as an apprentice, training that would have prepared him for taking over the family business, Haber convinced his father to allow him to attend university. In 1886, at the age of eighteen, Haber entered Berlin's Friedrich-Wilhelms-Universität (now Humboldt University) to study chemistry and physics. From then until 1891, Haber also studied chemistry at the University of Heidelberg and the Technical School at Charlottenburg. Following his university studies, Haber worked in his father's chemical firm. He eventually decided to pursue a career in scientific research.

In 1892, at the age of twenty-four, Haber converted from Judaism to Christianity, presumably to facilitate his academic and professional career. He became fiercely nationalistic; some historians claim he adopted German nationalism as his "religion." In 1894, Haber accepted an assistantship in the Department of Chemical and Fuel Technology at the Technische Hochschule in Karlsruhe, where he worked until 1911. He began as assistant to the professor of chemical technology, Hans Bunte; habilitated as Privatdozent in 1896; and was designated Extraordinarius in 1898. In 1906, Haber was appointed professor of physical chemistry and electrochemistry and director of the institute established at Karlsruhe.

Faculty colleagues Bunte and Carl Engler introduced Haber to the study of petroleum. Haber's subsequent work was strongly influenced by these men. His thesis addressed his experimental studies of the decomposition and combustion of hydrocarbons. In 1911, Haber succeeded Engler as director of the Institute for Physical and Electrochemistry at Berlin-Dahlem.

Life's Work

A group of prominent chemists collaborated to create an elite German institution dedicated to basic and applied research in chemistry. By 1911, the Kaiser Wilhelm Institute for Physical Chemistry and Electrochemistry was inaugurated in Berlin, and Fritz Haber was invited to serve as its first director. The inception of the institute coincided approximately with the start of World War I (August, 1914); as a result, the mission of the institute was abruptly and significantly altered. Haber, being passionately patriotic to Germany, offered his services to the War Ministry. Research into fundamental chemical processes was set aside in favor of research projects of immediate relevance to the war effort. The institute was placed under control of the military.

One of Haber's primary research goals during the war period was to increase the supply of raw materials for the war effort. Of great significance was Haber's work in procuring nitrogen, to be used both for fertilizer manufacturing and for high explosives and other weaponry. Haber overcame the obstacle of supplying nitrogen for both agricultural and wartime needs by inventing a system for synthesis of ammonia from hydrogen and nitrogen using an iron catalyst. The process was subsequently scaled up by Badische Anilin- und Soda-Fabrik (BASF) chemist Carl Bosch, thus giving the title "Haber-Bosch process" (or "Haber process"). Nitric acid was produced from the ammonia and then used as the precursor in a wide array of materials, including inorganic fertilizers. Nitric acid is also a raw material for the production of chemical high explosives and other munitions.

Synthetic Fertilizers

Three elements are required in large quantities for growth of agronomic, vegetable, horticultural, and other crops: potassium (K), phosphorus (P), and nitrogen (N). Extensive deposits of phosphate rock and potash occur worldwide and provide adequate sources of phosphorus and potassium, respectively. A century ago, the largest nitrogen source for fertilizer manufacture occurred in enormous bird guano deposits (saltpeter, $NaNO_3$) located along the coast of Chile. These deposits had accounted for more than 60 percent of the world's supply for most of the nineteenth century. This fertilizer material was, however, rapidly disappearing and had its share of practical drawbacks to its use.

During the period from 1830 to 1930, world population doubled from one to two billion. As population increased, so did demand for agricultural production and concurrent fertilizer use. Worldwide demand for nitrogen-based fertilizers began to exceed the known supply. Furthermore, only a few plants were known to have the capability to directly convert atmospheric nitrogen to so-called fixed nitrogen compounds—that is, those which are directly usable by other biota. In the early twentieth century, three methods were developed to fix nitrogen, either for direct use or to further react to produce fertilizers. The cyanamid process and the electric-arc process were considered to be of little value in making fertilizer. Fritz Haber invented a system for large-scale synthesis of ammonia from hydrogen and nitrogen, both abundant and inexpensive gases, using an iron catalyst. High temperatures (about 500° Celsius), and high pressure (about 3,000 psi) were used to combine the gaseous nitrogen (N_2) and hydrogen (H_2) into ammonia. Haber was assisted by Robert Le Rossignol in designing the laboratory apparatus. Once atmospheric N_2 is "fixed" to ammonia, the ammonia is subsequently oxidized, using the Ostwald process, to make nitrates and nitrites. These compounds are essential for the production of both nitrogenous fertilizer (that is, ammonium nitrate) and high explosives (trinitrotoluene, TNT).

In the 1920's, the first ammonia manufacturing plants based on the Haber-Bosch process went into production in the United States and Europe. The Haber-Bosch process changed the way nitrogen fertilizers are produced and has increased their availability. The process was a critical catalyst for the Green Revolution of the late twentieth century.

Haber went on to develop and encourage the use of chemical weapons and was intimately involved in their deployment, believing that such weapons would bring World War I to a quick conclusion in favor of Germany. Haber, backed by the chemical industry, persuaded Germany's military leadership to stage a battlefield test of a chemical weapon. Haber supervised the initial deployment of chlorine on the western front at Ypres, Belgium, on April 22, 1915. A six-kilometer stretch of the front was exposed to 167 tons of chlorine released from 5,700 gas cylinders. Figures vary; however, between 5,000 and 15,000 Allied troops were killed or wounded that day. The lethality of the chlorine attack at Ypres convinced the German military to adopt chemical warfare. Haber was promoted by an imperial decree to the rank of captain. Haber's efforts in chemical weapons research resulted in the suicide of his first wife, Clara Immerwahr, who was herself a very able chemist. She firmly believed that science should be applied for constructive purposes, not for making weapons of mass destruction.

As World War I continued, Haber's institute developed into a major research laboratory for both development of chemical weapons and methods of protecting against such weapons. For example, colleagues at the Kaiser Wilhelm Institute developed a respiratory filter for a gas mask. After World War I, Haber's institute became the world's leading center of research in physical chemistry, staffed with a distinguished coterie of international scientists. Haber again devoted himself to fundamental research. He conducted studies on insecticide formulations that could be used to control flour moths and other agricultural pests. The hydrogen cyanide-based gas developed by his institute was found to be quite effective. During the late 1920's and early 1930's, this so-called Zyklon B helped to protect the German food supply. This gas, however, would eventually be used in the extermination of millions of innocents condemned to the Nazi death camps of World War II.

Haber's military activities eventually led the Allies to label him as a war criminal. Haber was never convicted for these crimes; however, his direct involvement with development of compounds designed solely for killing posed legitimate problems for his nomination for the Nobel Prize in Chemistry. Use of chemical weapons had been forbidden since the 1899 Hague Convention with Respect to the Laws and Customs of War on Land.

Haber's institute rapidly deteriorated in 1933, when, with the rise of the Nazism and its anti-Semitic policies, he became vilified as the "Jew Haber." Nearly all his staff had to resign, as did Haber, in 1933. He was offered a position at Cambridge, and he left Germany in that year.

For some time, Haber had been suffering from heart disease. Concerned about English winters, he moved to Switzerland. He planned to visit the Daniel Sieff Research Institute in Palestine, but while traveling he suffered a heart attack in Basel and died there in January, 1934, at age sixty-five.

Haber is reported to have died a broken and defeated man. He was cremated, and his ashes, together with those of his wife Clara, were buried in Basel's Hornli Cemetery.

Impact

Haber examined a wide range of projects in physical chemistry and is credited with numerous significant discoveries. His work on the fixation of nitrogen from the air, however, resulted in his award of the Nobel Prize in Chemistry in 1918. It is believed that Germany would have run out of nitrates by early 1916 if it had not been for the discoveries and applications of Haber and his colleagues. Germany's use of the Haber process to make ammonia, and the Ostwald process to convert ammonia into nitric acid and nitrates, were both instrumental in prolonging the war. Germany was no longer dependent on foreign supplies of chemicals to support its agriculture or its progress on the battlefield. Fertilizers and explosives could now be made from readily available natural resources such as air and fossil fuels. Haber's work led to the development of a substantial high-pressure industry and many applications of metallic and other catalysts.

In addition to the Nobel Prize, Haber received many other honors during his lifetime. The Institute for Physical and Electrochemistry at Berlin-Dahlem was renamed the Fritz Haber Institute after his death. On the darker side, Haber is often referred to as the "father of modern chemical warfare." He is said to have viewed gas warfare "as an intellectual challenge," telling industrialist Carl Duisberg that "gas weapons and gas defense turn warfare into chess." His exhaustive efforts in supporting the German war effort altered the relationship among the sciences, the military, and the chemical industry.

Charles Martin Hall

American chemist

Hall discovered an inexpensive method for producing pure, metallic aluminum from its ore using electrolysis. He successfully developed his process into large-scale industrial production and became one of the founders of the Aluminum Company of America (Alcoa).

Born: December 6, 1863; Thompson, Ohio
Died: December 27, 1914; Daytona Beach, Florida
Primary fields: Business management; chemistry
Primary invention: Hall-Héroult electrolytic process for aluminum refining

Early Life

Charles Martin Hall was born in 1863 at the church parsonage in Thompson, Ohio, near Cleveland. In 1873, the family moved to Oberlin so that Hall's older brother and sister could live at home while attending college. Oberlin College was the first institution of higher education in America to admit women as students. Hall was a good student who loved to read. He finished high school in three years and then attended Oberlin Academy for a year of college preparatory courses. He was excited to read about Thomas Alva Edison's invention of the incandescent light bulb. He expressed admiration for George Westinghouse, inventor of the air brake system for trains that had made him a millionaire at age thirty. Hall got permission from his parents to work on chemical experiments in a woodshed behind their house. He obtained glassware, a gasoline stove, various chemicals, and materials to make his own electric batteries. He was a college junior in 1882 when he took his first course in chemistry under Frank Jewett.

Jewett had graduated from Yale University with a Ph.D. in chemistry, followed by a postdoctoral fellowship in Germany before coming to Oberlin. Jewett had obtained some samples of metallic aluminum in Germany that he liked to show to his classes. The ore containing aluminum is very abundant on Earth, but refining it to obtain the pure metal had proved to be extremely difficult. Jewett gave a memorable lecture in which he stated that the person who found an inexpensive process for refining aluminum would make a great contribution to humanity and also would become very wealthy. Hall told a classmate that he wanted to be that person.

Life's Work

From an article in *Scientific American*, Hall had learned that magnesium metal could be refined from its ore by means of electrolysis, so he decided to see if that process would work for aluminum as well. A demonstration of electrolysis frequently done in introductory chemistry classes uses copper sulfate dissolved in water. Two electrodes are partially submerged in the solution and are connected to the positive and negative terminals of a battery. Students can observe how the negative terminal gradually becomes coated with metallic copper because the positive copper ions in the solution are electrically attracted to it.

The most common ore containing aluminum is called bauxite. Its main component is aluminum oxide, which is a combination of aluminum and oxygen atoms. Aluminum oxide, however, is insoluble in water. For electrolysis, it is essential that the material can be dissolved so that the ions can migrate through the fluid to the electrodes. Hall experimented for several months trying to find a chemical solvent for aluminum oxide, but without success. His next idea was to use a very hot mineral bath into which he would stir some finely powdered aluminum oxide, hoping that it would dissolve. He built an insulated oven around his small gasoline burner. A crucible placed into the oven served as the container for various minerals to be tested. Some minerals would not melt in his crude oven, and others that did melt would not dissolve the aluminum oxide. His results were all negative until he tried a mineral called cryolite. To his happy amazement, aluminum oxide dissolved in molten cryolite like sugar in water.

Having found a solvent for aluminum oxide, Hall was ready to try electrolysis. He mounted two electrodes in the crucible inside the oven, with wires coming out to a battery. When the oven was hot and the battery was connected, he observed gas bubbling up at the positive terminal. This was caused by oxygen ions from aluminum oxide combining with carbon from the electrode to form carbon dioxide gas. Hall hoped that aluminum ions would be collected at the other electrode. After running the experiment for several hours, he poured the molten cryolite into an old iron frying pan to let it cool. Then he used a hammer to shatter the cryolite into pieces, among which he found some small pellets of shiny aluminum metal. The date was February 23, 1886, which was important in order to establish priority for his later patent application. His older sister, Julia, and Professor Jewett were his witnesses.

In July of 1886, Hall went to Washington, D.C. to file a patent application, which he entitled "The Process of

Industrial Production of Aluminum from Bauxite Ore

High-grade deposits of bauxite, containing up to 60 percent aluminum oxide, are found most abundantly in Australia, Brazil, and China. Aluminum oxide first has to be extracted from its ore, and then the Hall-Héroult electrolytic process is used to refine the pure metal. Bauxite ore, usually obtained by open-pit (surface) mining, is crushed and washed, and then mixed with caustic soda (sodium hydroxide) at high temperature. The aluminum oxide dissolves while the other components remain as solids and are removed by filtration. Seed crystals are added to precipitate the aluminum oxide. After heating in a kiln to evaporate the water, a white powder of aluminum oxide is left behind.

Electrolytic separation of aluminum metal from its oxide is done in large, steel pots lined with carbon. As in Charles Martin Hall's patented process, molten cryolite acts as the solvent. A carbon rod, inserted into the cryolite from above, is lowered until it comes close to the bottom of the pot. The rod is the positive electrode and the carbon lining of the pot is the negative electrode. Oxygen ions are electrically attracted to the rod, forming carbon dioxide gas, and aluminum ions are attracted to the negative lining, forming molten aluminum metal that sinks to the bottom of the pot. The cryolite is kept hot by resistive heating from the large current flowing between the electrodes, so no external oven is needed. The molten aluminum is siphoned off into a large crucible, from where it is poured into molds to produce solid ingots of metal.

When refined aluminum is removed from a pot, fresh aluminum oxide must be added in order to maintain operation without interruption. Carbon rods gradually wear away due to oxidation and must be replaced periodically. A typical pot operating with 2,000 amperes of direct current will produce about sixteen kilograms (seven pounds) of aluminum per day. At a large refinery, there may be a hundred or more pots operating in a long line. Refineries usually are situated near hydroelectric power plants because electricity constitutes the largest cost in aluminum production.

Reducing Aluminum by Electrolysis." To his surprise, the Patent Office informed him that an application already was pending for the same basic process, filed by Paul Héroult of France in April of that year. According to U.S. law, a patent is issued on the basis of the date of discovery, and since Hall had specific documentation and witnesses for his date of discovery, he was awarded the patent.

Hall next needed to find investors who would finance a start-up company to manufacture and sell aluminum. He demonstrated his apparatus to potential financial backers in Boston, but without success. His breakthrough came when he met Alfred Hunt, a well-established metallurgist in the steel industry in Pittsburgh, Pennsylvania. Hunt and several partners made a commitment for $20,000 and founded the Pittsburgh Reduction Company to set up a pilot plant. To supply electricity for electrolysis, they purchased a Westinghouse electric generator powered by steam, having an output of 2,000 amperes. The pilot plant operated successfully for three years, producing over eighty thousand pounds of aluminum.

Based on the success of the pilot plant, the stockholders voted for a major expansion. They issued new stock for $1 million, with the financier Andrew W. Mellon as a participant. A new facility was built near Niagara Falls, New York, because hydroelectric power had just come online at relatively low cost. In 1907, the Aluminum Company of America (Alcoa) was founded, with Hall as its vice president. Hall died of leukemia in 1914 at the age of fifty-one. Donations to Oberlin College from his will and from earlier gifts totaled over $20 million. The Oberlin Chemistry Department has a display case containing two of the original aluminum pellets from February 23, 1886, popularly called the "crown jewels" of the college.

Impact

Aluminum was unknown to the general public until 1884, when it received widespread national publicity because of its use for the Washington Monument in Washington, D.C. With a height of 550 feet, this was the tallest construction project in the world at the time, and a lightning rod needed to be mounted at the top. The chief engineer decided to use aluminum because it has good electrical conductivity and does not tarnish. At the time, aluminum was considered a semiprecious metal with a cost per ounce equal to that of silver. The Frishmuth Company of Philadelphia was given a contract to make an aluminum pyramid, nine inches high, that would form the cap of the monument. The highly polished pyramid was put on display at Tiffany's jewelry store in New York for people to admire. It was installed in December of 1884, with a copper rod connecting it to the iron scaffold of the elevator shaft leading down to ground.

Hall discovered the electrolytic method for refining aluminum in 1886. Within three years, the small pilot plant in Pittsburgh was producing several thousand pounds per month costing under one dollar per pound. Since that time, aluminum has become the material of choice for a huge number of applications. Aluminum doors, window frames, siding, and gutters are popular in house construction. Aluminum alloys are widely used to manufacture strong beams for large architectural applications. In the aircraft industry, aluminum used for the engine, frame, exterior skin, landing gear, and interior paneling typically makes up 80 percent of a plane's weight. For food packaging, aluminum foil, trays, and billions of beverage cans provide a huge market. In sports equipment, aluminum is used for tennis racquets, skis, baseball bats, canoes, and fishing boats. In automobiles and trucks, aluminum is used for radiators, engine blocks, automatic transmissions, wheels, air conditioners, and body panels, since lighter weight improves the gas mileage. Aluminum wires do not corrode, so they are commonly used for underground electrical cables and for high-voltage cross-country transmission lines. Cooking utensils, appliances for the home, tools, and other consumer goods often are made from aluminum. Except for iron and steel, aluminum has become the most widely used metal in the modern world.

H. Tracy Hall

American physical chemist

Hall invented the experimental method for producing synthetic diamond, which is used for numerous industrial applications, electronics, and the jewelry business. Known as the "father of man-made diamond," Hall was granted nineteen patents that included inventions dealing with high-pressure, high-temperature equipment, as well as various methods for making diamond and other hard chemical compounds.

Born: October 20, 1919; Ogden, Utah
Died: July 25, 2008; Provo, Utah
Also known as: Howard Tracy Hall (full name)
Primary field: Chemistry
Primary invention: Synthetic diamond

Early Life

Howard Tracy Hall, the son of Howard and Florence Tracy Hall, was reared with his four brothers on a farm in Marriott, Utah, a rural town north of Ogden. As a young boy, Hall learned the value of hard work on the family farm and enjoyed roaming the surrounding fields in Marriott. When his family traveled to Ogden to obtain supplies, Hall and his brothers would spend time at the Ogden City Library, where Hall became highly interested in reading about great scientists, particularly Thomas Alva Edison. At the age of nine, Hall decided that sometime in his future he would work as a scientist for Edison's company, General Electric (GE).

In 1939, Hall earned his associate degree in science from Weber College in Ogden. He then attended the University of Utah. There he met Ida-Rose Langford, marrying her in 1941. After completing his B.S. degree in chemistry in 1942, he earned his master's degree from the University of Utah the following year under the direction of G. Victor Beard. Beard was the first scientist to encourage Hall to follow his passion—conducting experiments dealing with diamond synthesis.

From 1944 to 1946, Hall served as a Navy ensign in World War II. After returning to the University of Utah in 1946, Hall, under the tutelage of famed chemist Henry B. Eyring, began thinking more about the theory associated with the conversion of carbon to diamond. He earned his Ph.D. in physical chemistry from the University of Utah in 1948. Two months later, Hall accepted a position as a chemist at the General Electric Research Laboratory in Schenectady, New York, a fulfillment of his childhood dream.

In 1951, GE announced that it would tackle the problem of producing synthetic diamond because of its great value in industrial applications. Volunteers were sought to help with the project, known as Project Superpressure. Hall volunteered and, along with fellow chemist Robert H. Wentorf and a group of physicists led by Herbert M. Strong and Francis P. Bundy, pursued the problem. After thoroughly analyzing a variety of questions related to the chemistry of diamond, Hall decided that the first barrier to overcome was the invention of high-temperature, high-pressure equipment that could convert either graphite or the carbon in carbonates into diamond.

Life's Work

Initial experiments conducted during Project Superpressure used a Carver press, a modified twenty-ton automobile jack. After the research group designed a new, versatile press that would take about two years to build, Hall pursued experimentation using a small bench press and a modified water-operated Watson-Stillman press that leaked water profusely. Although resisted by other scientists in the group who felt that he was intruding into their areas of expertise, Hall continued to develop unique variations of piston-cylinder devices that were formulated by the group but that were not working because of mechanical failure at the junction of the walls and the bottom of the cylinder bore. Hall finally solved the problem by eliminating the cylinder bottom altogether by placing two conical-shaped semi-pistons back-to-back. Internal pressure was confined radially by a belt of prestressed steel bands. Hall was eventually granted a U.S. patent for the high-pressure, high-temperature belt apparatus in 1960. It could generate 120,000 atmospheres of pressure and sustain a temperature of 1,800° Celsius in a working volume of about one-tenth of a cubic centimeter for intervals of several minutes at a time.

Although it was thought that the extreme pressure and temperature conditions available in the belt apparatus were more than sufficient to directly transform graphite into diamond, experiments proved otherwise. Since direct transformation to diamond did not occur, Hall tried hundreds of indirect approaches using various catalysts to speed up the transformation. After numerous failures, GE was considering abandoning the project to produce synthetic diamond.

With only a few days remaining before GE was to scrap Project Superpressure, on December 16, 1954, Hall used his belt apparatus made with a tungsten carbide chamber to run an experiment that used graphite, along with troilite (iron sulfide) to act as a catalyst; a disk made of tantalum was used to conduct electricity into the cell containing the sample. The pressure in the belt apparatus was near 70,000 atmospheres (about one million pounds per square inch) and the temperature was near 1,600° Celsius. Upon breaking open the cell after several hours of run time, Hall observed numerous shiny, octahedral crystals cleaving to the tantalum disk. After regaining his composure, Hall examined the crystals under a microscope and found that they contained structures that looked like natural diamonds. Further analysis showed that the crystals scratched sapphire, burned in oxygen to produce carbon dioxide, and had the density and refractive index of natural diamond. An X-ray diffraction pattern produced a few days later confirmed that the crystals were diamond. During December 17-30, Hall experimented with varying the pressure and temperature to determine the best pressure-temperature range in which diamond would form. On December 31, GE physicist Hugh Woodbury duplicated Hall's results and also produced synthetic diamonds.

Once the achievement of the synthesis of diamond was formally announced by the media on February 15, 1955, Hall was highly sought after, with job offers from numerous high-techology companies. Because of the lack of credit received by Hall from GE for his invention of the apparatus and the method for synthesizing diamond, he accepted a position as a professor of chemistry and director of chemical research at Brigham Young University (BYU) in 1955. At BYU, Hall invented a completely new high-pressure machine for making diamond, known as the tetrahedral press. It contained four anvils (press members) that converged on a tetrahedral volume. He was granted a U.S. patent for the tetrahedral press on December 29, 1959. Hall built and sold tetrahedral presses and invented an improved apparatus, the cubic press, in 1964. The cubic press had six anvils that provided pressure simultaneously onto all the faces of a cube-shaped volume. In 1966, Hall and two other BYU professors, Bill Pope and Duane Horton, formed Megadiamond, a company that manufactured high-pressure equipment and produced synthetic diamond.

In his personal life, Hall was a devoted husband and father. He often said that his greatest accomplishments were his home and family. He was a devoted member of the Church of Jesus Christ of Latter-day Saints, serving as a bishop and in many other positions of responsibility and leadership. During his spare time, he enjoyed farming and growing fruit trees.

Impact

Hall is the epitome of an individual who never gives up no matter what the odds may be. While working at GE, after hundreds of failed experiments, an increasingly impatient management, and intense rivalries and competition among fellow researchers, Hall endured and pursued his dream of making diamond until he succeeded. His inventive genius and perseverance led to his receiving nineteen patents, which included eleven patents for high-pressure, high-temperature apparatuses and five patents for making diamond and diamond composites. Until the late 1990's, every diamond-making press in the world was based on designs invented by Hall.

The first synthetic diamonds produced by Hall and others were very small, but just right for a variety of industrial applications that involved cutting, grinding, and polishing other materials. By 1954, industry was using about 14 million carats of diamond in manufacturing processes, all coming from natural sources. By 1996, industrial diamond usage had risen to more than 505 million carats, with more than 90 percent being produced synthetically using Hall's inventions. Human-made diamonds are used for applications in the aerospace, mining, manufacturing, petroleum, and automotive industries. They can be found in drill bits, masonry saws, cutting tools, and polishing machinery.

As Hall improved his tetrahedral and cubic presses, electronic applications soon emerged, followed by the production of diamonds large enough to be used in the jewelry business, starting in 1970. Industrial diamond in-

Synthetic Diamond

High-pressure, high-temperature presses are needed to squeeze and press carbon into the molecular arrangement of diamonds, as well as into the formation of other hard, crystalline materials, such as cubic boron nitride. H. Tracy Hall's tetrahedral press contained four movable press members, or anvils, while his cubic press contained six press members. Forward and reverse thrusting forces were provided by hydraulic rams. In Hall's presses, a hydraulic ram was connected directly to each movable press member. Hall's belt and cubic press devices have been successfully used in numerous commercial applications, while his tetrahedral press has mainly been employed in experimental, laboratory applications. Hall vastly improved his cubic press by incorporating a guide apparatus to move the press members in a simultaneous, synchronous manner.

The first step in making synthetic diamonds involves putting graphite; a metal solvent, such as tantalum; and a catalyst, such as iron sulfide, into a tungsten carbide or ceramic chamber. The chamber is placed in the center of the press apparatus, where the sample is compressed by engaging the piston press members. The temperature of the sample is increased by passing electrical current through a heating tube into the tantalum. As the conical pistons advance, required pressures of about 55,000 atmospheres (more than 780,000 pounds per square inch) are generated. Temperatures may climb as high as 2,000° Celsius. After several hours, the graphite is converted into diamond, which is chemically identical to natural diamond and exhibits the same fundamental properties.

Synthetic diamonds differ from natural diamonds in those characteristics that depend on the process of manufacture, such as impurities, size, and shape. Synthetic diamonds in highest demand are made in grit sizes (approximately 0.1 millimeter in diameter) and are used for the manufacture of bonded diamond grinding wheels used for shaping and sharpening tungsten carbide tools. Synthetic diamonds are superior to natural diamond for this use because they are single crystals that have many cutting edges. A number of large synthetic diamonds of gem quality have been made by slow growth of diamond from high-purity carbon dissolved in a molten iron-nickel alloy, a process known as chemical vapor deposition (CVD). However, the majority of synthetic diamonds are imitation diamonds made from yttrium-aluminum garnet or strontium titanate.

struments made dental work safer, faster, cheaper, and less painful and allowed eyeglasses to be made in an hour or less. In place of using jackhammers, saws made with synthetic diamond blades became the primary tool used for repairing roads.

In 1970, Hall received the Chemical Pioneers Award from the American Institute of Chemists. Two years later, he was presented the American Chemical Society Award for Creative Invention for being the first scientist to invent a reproducible process for manufacturing synthetic diamond. In 1994, Hall was awarded the Governor's Medal for Science and Technology.

James Hargreaves

English machinist

By inventing the spinning jenny, Hargreaves produced one of the earliest devices that led to the industrialization of the textile industry, and thereby to the Industrial Revolution in the Western world.

Born: January 8, 1720 (baptized); Oswaldtwistle, Lancashire, England
Died: April 22, 1778; Nottingham, England
Also known as: James Hargraves
Primary field: Manufacturing
Primary invention: Spinning jenny

Early Life

Little is known about the early life of James Hargreaves (HAWR-greevz), except that by the 1740's he was working as both a weaver and a carpenter and was for a while employed by Robert Peel, grandfather of the later prime minister of England. Peel was a small-scale manufacturer of textiles, and he employed Hargreaves to help build a machine that could be used to card raw fiber, especially cotton, to prepare the fiber for spinning into thread and weaving into cloth.

Life's Work

Hargreaves's efforts on behalf of Peel led him to develop the spinning jenny, and it is possible that his work on the machine to card raw cotton contributed to his idea. His model is said to have been a spinning wheel that was knocked over by his daughter Jenny but continued to spin, suggesting that a machine in which the action was aligned horizontally instead of vertically as in a spinning wheel inspired his invention. He built several machines in accordance with this conception, the earliest reportedly in 1766, and Peel is thought to have told Hargreaves that if he did not make his idea known, Peel himself would see to it. In response to this argument, Hargreaves is said to have sold several of his jennies to others working in the textile field.

Word soon got out about the new machine, however, and a mob composed of those who drew their livelihood from the old-fashioned spinning wheel looted Hargreaves's home and workshop and then burned them. Hargreaves responded to this assault on his work by switching for a short time to bookkeeping, also for Robert Peel. In 1770, Hargreaves moved from Oldtwistle to Nottingham and there resumed his work on the jenny. At that point, he decided to seek a patent for his invention. Although initially he was granted one, the patent was invalidated when it became known that he had sold early versions of the jenny to others before submitting his application. Hargreaves died in Nottingham in 1778 and appears to have amassed a modest estate prior to his death. Attempts by his widow to resuscitate the patent failed.

The Spinning Jenny

Converting loose fiber to yarn, so that it could be woven in a loom, involved both stretching it out and twisting it, initially using the fingers of the spinner. Hargreaves's invention, building on ideas floating around the textile field at the time, involved using synchronized rollers to replace the twisting fingers of the spinner. The process actually began with carding, which aligned all the fibers in the same direction. Then several strands of fiber were brought together in what was called the roving, which was wound on a spindle. Hargreaves's machine mounted several spindles of roving together and aligned them so that they could pass through two adjacent rollers, which were themselves set in motion. Improved models had the rollers turning in opposite directions, which enhanced the tightness of the yarn, and others replaced the driving wheel (which gave motion to the spindles and rollers) with one that was vertical, rather than the initial horizontal wheel.

The early jennies were made of wood, at least for the frame. The rollers had to be made of metal, however, so that they could be placed immediately next to one another to ensure that as they turned in opposite directions, they would add the desired twist to the yarn. As Hargreaves initially imagined his jenny, it converted the roving to just four strands of yarn. With improvements, the number of spindles rapidly increased, so that output was magnified by much more than the initial factor of four. Nevertheless, in its conception the jenny retained a basic simplicity such that it could be operated even by children, a circumstance that may have led to the employment of children in textile mills, especially in the early nineteenth century.

The earliest output of the jenny made yarn corresponding to the later density of twenty, which meant that it could not be used for the warp thread, the thread that was set up initially on the loom and against which the weft thread would be pushed. Rapid improvements in the quality of the jenny and the upgrading that followed, however, led to the production, by the early nineteenth century, of yarn that was suitable for both the warp and the weft.

Impact

Hargreaves's spinning jenny, and subsequent modifications of it, offered a response to a need. John Kay's invention of the flying shuttle in 1733 had already sped up the weaving process, so that a shortage of yarn soon emerged. The jenny aided in the handicraft production of textile materials that was the prevailing mode at the time. It could be operated by a single individual and was readily transportable, so that it could be set up in the home of the workman. The jenny initially increased by a factor of four the amount of spun yarn that a single workman could produce. A somewhat similar invention by Sir Richard Arkwright, called the spinning or water frame, also spread rapidly around the textile districts of England. Arkwright's machine was bigger, heavier, and required more force to operate, however, so that it was ill-suited to use in the home.

The last half of the eighteenth century, between 1750 and 1800, were years when the world of work was transformed by technological innovation. During this period, the task of spinning yarn from fibers was converted from handwork to machine work, and the spinning jenny was an important step in this process. Because it was really an amplification of the spinning wheel, the jenny had one foot in the old world of craft production and one in the new, foreshadowing how creating textiles in massive quantities would bring into being the industrial world.

Concurrently with the production of new textile machinery was the introduction of the new fiber cotton. Hitherto most European cloth had been made from wool or flax, both of which could be easily produced agriculturally in northern Europe. Cotton cloth, made with fiber from India (a small amount came from Egypt) was a luxury product in the early to mid-eighteenth century. Indeed, some Indian cloths, known as calicoes, had been for some time imported into Europe and worn by the upper classes. As the population expanded in the eighteenth century, however, the need arose for more cotton, especially as the demand grew for underclothing made of cotton cloth. The serendipitous discovery that cotton could be grown in more places, especially the southern region of the United States, and the invention of the cotton gin in 1793 by the American inventor Eli Whitney made possible cotton production on a large scale.

Hargreaves's invention of the spinning jenny was one in a string of new inventions that made the cotton textile industry of Britain the opening phase of the Industrial Revolution. Britain's imports of cotton rose from three metric tons in 1780 to twenty-four metric tons in 1800 and fifty-six in 1810, a growth made possible only as the new textile machinery took over.

Sir John Harington

English author and translator

Known primarily as a literary man in the time of Queen Elizabeth I, Harington perhaps succeeded most practically as the inventor of the flush toilet, which he described in considerable detail in a work published in 1596.

Born: 1561; Kelston, Somerset, England
Died: November 20, 1612; Kelston, Somerset, England
Primary field: Plumbing
Primary invention: Flush toilet

Early Life

Sir John Harington was accorded the advantages of being an early Elizabethan gentleman because his father, John Harington of Stepney, married Etheldreda Malte, a prominent person who was actually a natural child of King Henry VIII. Queen Elizabeth I served as his godmother. He thus was able to obtain an education at Eton and King's College at Cambridge, where he took his degree about 1578. Higher education at that time was based heavily on the acquisition of ancient Greek and Roman culture, but by this time he was exposed to scholars who

And this being well done, and orderly kept, your worst priuie may be as sweet as your best chamber. But to conclude all this in a few wordes, it is but a standing close stoole easilie emptyed.

And by the like reason (other formes and proportions obserued) all other places of your house may be kept sweet.

The design for Sir John Harington's flush toilet, here called "a privie in perfection." (The Granger Collection, New York)

also had a reputation as Renaissance humanists familiar with the work of learned Frenchmen and Italians of the fourteenth through sixteenth centuries.

Harington earned his master's degree in 1581 and then took residence at Lincoln's Inn, where lawyers and prospective lawyers studied and articulated law. In effect, an inn of court such as Lincoln's Inn also served men like Harington who had only an incipient interest in the law but were interested in extending their learning and establishing helpful contacts with educated men. At his father's death in 1582, he separated from Lincoln's Inn. In 1583, he married Mary Rogers, with whom he eventually became the father of eleven children, seven of whom survived him.

Life's Work

Although it may seem curious to associate Harington's invention of the flush toilet with his career as a poet and a translator, humanist scholars at the time actually did literary work that could encompass topics such as social ills, religious intolerance, and other issues seemingly remote from the interests of literary men. One of Harington's interests, cleanliness, he shared with other socially prominent people in a society pervaded by deplorable sanitary conditions. By modern standards, no one in his time washed regularly, garbage and human wastes were routinely emptied into gutters or any handy minor waterway, animals browsed in the streets, and people endured many sorts of environmental pollution. Nevertheless, a gentleman like Harington at least hoped to make his household as sweet smelling as possible. He later displayed his interest in sanitation in his translation of *Regimen sanitatis Salernitanum*, a work from the twelfth or thirteenth century known as "The Medical Poem of Salerno."

A Renaissance humanist characteristically hoped to learn from the people, real and legendary, of classical antiquity. Thus, Harington described his invention of the flush toilet in a work that bore the curious title of *A New Discourse of a Stale Subject, Called the Metamorphosis of Ajax* (1596). Here the word "stale" refers to something that loses freshness or is uninteresting. Humanists also liked to argue that some seemingly uninteresting things might turn out to be interesting after all. Substantively, "stale" can also refer to urine. This play on words, even in a serious discussion, was a common rhetorical device in Harington's time. The reference to Ajax connects the activity of toilet manufacture with the Greek warrior who in the Trojan War was insulted by Odysseus and according to post-Homeric legend went off in a fit of anger to a field in which he slew himself. From the grasses that grew from his blood a young man, needing to wipe himself, took advantage of the grasses. To express his respect to Ajax, he built a fine privy and dedicated it to him. Thus, the English word "jakes" is still used to refer to a privy. The American word "john," named for Harington, refers to a toilet.

In some respects, Harington undercut the seriousness of his invention by writing in a somewhat joking style that doubtless led many readers to undervalue it. Partly, this habit is explained by the fact that Harington enjoyed a reputation as a wag; partly, it was attributable to an attitude toward style found in many Renaissance writers. To take one famous example, Sir Philip Sidney also could assume a jocular style or added bantering details that might deceive an audience unfamiliar with his situation, which was in many respects like Harington's. Both were Elizabethan courtiers, and as such they were supposed to cultivate an attitude that had been described for them by an Italian diplomat named Baldesar Castiglione in his book *Il cortegiano*, published in 1528. Translated into English in 1561, it is usually known today as *The Book of the Courtier*. The courtier must cultivate *sprezzatura*, which can be translated "nonchalance." A literary work should appear to have been done without effort and almost without thought. Sidney wrote an essay that he referred to as a "pitiful defence of poor poetry" and as an "ink-wasting toy of mine." It is actually one of the great works of literary criticism, and Sidney's self-criticisms cannot be taken seriously.

When the work at hand is a manual on how to make a toilet, Harington obviously needed plenty of *sprezzatura*. He would have read *Il cortegiano* in the original Italian, which he understood well, his best-known literary work today being his translation in nearly 33,000 lines of Ludovico Ariosto's famous romance *Orlando furioso*, published five years before Harington's *A New Discourse of a Stale Subject*.

Scholars today know Harington best for works that are today classified as literary. He, like Sidney, wrote an apology (a defense) of poetry as an introduction to his translation of *Orlando furioso*, and a considerable number of his letters and poems have survived. Because he was working in an era dominated by William Shakespeare and many other eminent writers, his writings have largely been ignored.

THE FLUSH TOILET

In his 1596 work *A New Discourse of a Stale Subject, Called the Metamorphosis of Ajax*, Sir John Harington recommended that the flush toilet be installed in such a place that had access to the chimney to take advantage of the wind's capacity to blow off unpleasant odors. He noted that sometimes the operation of the chimney vent failed because of the lack of suitable wind. His invention required the establishment of a cistern, which could be located behind the toilet seat or elsewhere if necessary. Water would be brought from the cistern in a lead pipe controlled by a tap that would "yield water with some pretty strength."

An oval pot of block, stone, or lead, two feet deep, one foot broad, and sixteen inches long (Harington is normally very precise in his measurements) would be placed close to the seat and dressed with pitch or resin to keep the pot from "tainting with the urine." In the lowest part of this vessel there would be fastened a sluice of brass with solder or cement. On this sluice would be an iron stem with a stopper fastened with a strong screw. Harington's practicality is also reflected in his recommending a lock and key to keep children from playing with this device. No air should be allowed to come up except at the sluice, which has the stopper. The water, which could be pumped into this place, could be used more than once but had to be changed when necessary, which he suggested should be at noon or at night, not through any such venting system as exists today.

If constructed carefully, this device would, he said, keep the privy "as sweet as your best chamber." Clearly, a servant would have been necessary to serve the device and perform a task that in later times would be performed by connection to a seepage pit or a sewer. Queen Elizabeth I installed a flush toilet in at least one of her palaces, and Harington made a toilet for himself. Apparently both used their toilets, but there is no record that any others in his time used one.

After the queen's death in 1602, Harington made efforts to win the favor of the court but did not receive the promotion he sought. He became ill in May of 1612 and died in Kelston that November.

Impact

For centuries, Harington's device had no traceable impact. Some people presumably did not share Harington's daintiness about smells; others surely doubted that the advantages of a water-driven system of coping with human wastes justified systematic efforts to bring about this change. The great majority of people lived in small communities or on farms, and such wastes were easily enough disposed of. However, a general unfamiliarity with the literary habits of a man like Harington probably also curtailed the spread of information about his invention.

As a result, the impact of Harington's toilet was very limited until later needs and improvements made it a practical device for people who did not employ servants to assist them in fulfilling their personal needs. Not until the eighteenth century were there any patents for toilets. In the 1770's, several men made contributions. Alexander Cummings developed the S-trap between bowl and trap, Samuel Prosser patented a plunger closet, and Joseph Brahmah devised a valve for the flushing system that worked on a hinge. This was a predecessor to the ballcock that is still often used today.

A series of refinements in the design of the flushing closet from the 1850's to the 1890's made the flush toilet a possession for many householders. The growth of large and densely packed cities in the later nineteenth century made safe and efficient plumbing systems necessary, and increasingly the toilet became a practicable addition to well-appointed households. The toilet that Harington devised did not replace the old privy, and for three centuries it did not become a common feature of life in European or American homes.

John Harrison

English engineer and clockmaker

Harrison developed chronometers that could keep time at sea with sufficient accuracy to make reliable calculations of longitude at any point on the globe. This development revolutionized maritime navigation.

Born: March, 1693; Foulby, Yorkshire, England
Died: March 24, 1776; London, England
Primary fields: Maritime technology; navigation
Primary invention: Sea chronometers

Early Life

John Harrison was born in March, 1693, in the village of Foulby in Yorkshire, England. While he was still a young child, the Harrisons moved to Barrow-on-Humber in Lincolnshire, where John apprenticed with his father to become a carpenter. He married Elizabeth Barrel in 1718, and when she died in 1724 he remarried to Elizabeth Scott. Interested in mechanics from the time he was a teen, Harrison began constructing clocks by 1713.

While carrying out his principal trade, for more than a decade Harrison and his younger brother James worked at perfecting an accurate regulator clock. Their partnership lasted nearly two decades.

Sometime after 1714, Harrison learned that an act of Parliament had established a prize of £20,000 to be awarded to the first person who could develop an accurate method of determining longitude, the east-west position of an object on Earth. This calculation was especially important to ships, which had often missed ports of call or suffered tragedies because they could not determine accurately their location on the open oceans. The act creating the Longitude Prize also established a Board of Longitude to evaluate any proposal or machine submitted by claimants, and it specified terms for the award of any or all of the amount set aside by Parliament. Sometime during the 1720's, Harrison decided to compete for the prize.

After a decade of experimentation, in 1730 Harrison published a lengthy treatise describing his method for crafting a "sea clock" for use in calculating longitude by comparing the local time to the time at a fixed point of departure. While the method made sense theoretically, few thought it possible to construct a device that would keep accurate time under the harsh conditions at sea. Harrison disagreed. He proposed an innovative design that reduced fluctuations due to friction, compensated for changes in temperature, and adjusted for fluctuations in the speed at which a clock might run when first wound or when in need of rewinding. Confident in his ability, in 1730 he applied to the Longitude Board for funds to construct his first sea clock. Some members were immediately interested, and they obtained financial support for him. Harrison spent the next five years building a machine that he could submit to the trials specified for earning the prize.

Life's Work

Harrison's challenge was significant. He was operating on the principle that longitude could be calculated by comparing the difference between local time and the time at the ship's point of departure. Although local time could be measured at sea using astronomical readings, knowing the time at one's departure point had always been difficult to determine because even the best timepieces lost seconds (sometimes minutes) each day. Errors of seconds or minutes could result in inaccuracies placing a ship many miles from its actual location. Therefore, the design of a clock that could withstand the rigors of sea travel and keep time with sufficient accuracy was key to solving the problems associated with determining longitude.

The first sea clock designed by Harrison with the assistance of his brother, designated H1 by later historians, was a bulky chronometer measuring three feet in height, width, and depth, consisting of various metals and wood. After inspection by members of the Royal Society of London, the country's leading scientific organization, it was given a short sea trial to Lisbon, Portugal, in 1736. The terms of the act of Parliament establishing the prize, however, specified that the device must be proven accurate on a round-trip voyage to the West Indies. In 1737, the full Board of Longitude met to examine H1 and review results from the Lisbon voyage before authorizing the West Indies test. Curiously, rather than submit H1 to the West Indies voyage, Harrison indicated that he wished to construct a new clock for this test, and with the board's financial support he began crafting H2, incorporating improvements of original concepts used to build H1. Two years later, Harrison decided to shelve H2 and begin work on H3. For the next nineteen years, he worked diligently on the project. During this time, he received small sums from the Longitude Board to underwrite his work. Additionally, even though none of Harrison's clocks had yet been tested under the terms established for the award of the Longitude Prize, in 1749 Harrison's accomplishments were celebrated publicly when the Royal Society presented him with the Copley Medal, its highest honor.

While Harrison was working to perfect H3, he was also experimenting with the design of watches. Although there were similarities between the two forms of timepieces, the construction of an accurate watch required even more skill. Harrison manufactured a pocket watch in 1753 and, perhaps encouraged by its accuracy, began constructing a larger one for use at sea. Harrison was now working closely with his son William, who eventually became his spokesperson and public champion. By 1760, Harrison had completed work on H3, which was scheduled to be tested on a voyage to the West Indies, but for some reason Harrison decided to submit to the Longitude Board his new watch, designated H4, for testing. Because he was too old for extended sea travel, Harrison sent William on the voyage to Jamaica, during which the watch proved remarkably accurate. Unfortunately, when the board met in 1762 to review the results, questions arose about testing procedures and Harrison was denied the prize. Instead, over the next several years the board established new criteria Harrison would have to meet in order to claim the £20,000.

Harrison was furious, and he blamed his fate on machinations by certain board members, particularly Nevil

Maskelyne, who in 1762 was working on an alternative method for calculating longitude using lunar charts, and who eventually assumed the influential post of astronomer royal. Maskelyne was not alone in expressing concern about Harrison's work. Many board members were insistent that Harrison turn over all of his timepieces to them and agree to let others reproduce his chronometers so that the board could determine if his solution was practical. Harrison was hesitant to comply with these directives. By 1763, rivals began to emerge to compete for the prize, and he was concerned that his work might be pirated.

A second sea trial of H4 was authorized, and even though Maskelyne was heavily involved in it, the results were sufficiently promising for the board to award Harrison half the prize, indicating that he could qualify for the other half if the watch passed further tests—and if it could be shown that his chronometer was replicable. Harrison was not content with the decision, which he thought was politically motivated. After fighting for years to keep his designs secret, in 1767 he finally acquiesced to the board's demands, turning over his four devices and his technical drawings to them. The board commissioned a rival watchmaker, Larcum Kendall, to construct a duplicate of H4. Further trials of Harrison's watch were held at the Royal Observatory in Greenwich. Harrison was also instructed to make two duplicates, but he delayed that work for a variety of reasons, instead concentrating his efforts on construction of yet another timepiece, H5. By this time, King George III had begun to show a personal interest in Harrison's work, and a test of the H5 was conducted at the king's personal observatory in Richmond outside London.

While they continued wrangling with the Longitude Board, both John and William Harrison mounted a public campaign to gain the remainder of the prize money, lobbying Parliament for redress. In 1773, at the urging of the king, Parliament agreed to award Harrison £8,750—not the full amount he had hoped for, but a sum that clearly indicated the nation's gratitude for his accomplishments. Although Harrison felt only partially vindicated by this grant, he was finally satisfied that he was being recognized as the person who had solved "the longitude problem." He died in 1776 before mass production of maritime chronometers based on his designs would revolutionize shipping throughout the world.

Impact

Harrison's chronometers proved that it was possible to create a device that could keep time at sea with sufficient accuracy to make reliable calculations of longitude at any point on the globe. His combination of specially designed balances, his employment of a bimetallic strip to compensate for expansion of metals at different temperatures, and his development of a mechanism to ensure that time was kept accurately while his chronometers were being rewound were revolutionary ideas that paved the way for the production of chronometers that would allow ships to sail with greater assurance of their position.

Harrison's Sea Clocks

During his lifetime, John Harrison created five timepieces designed to aid in the calculation of longitude at sea. While their external shape and size varied greatly, they shared common characteristics that made them radically different from earlier clocks and watches, largely because their internal mechanisms compensated for a number of technical difficulties that interfered with the ability of a mechanical timekeeper to function regularly. Among these were problems of friction, damage from natural elements (especially changes in temperature), and irregularities caused by the use of a metal spring that must be wound.

By the time Harrison came to design H4, a watch measuring 5.5 inches in diameter, he had managed to find solutions for most of these problems. When developing his larger clocks, he had perfected a system of balances that replaced the conventional pendulum, which had to be maintained in an upright position to work accurately. The new balances permitted the clock to continue to operate accurately regardless of its position, an important innovation since the rocking motion of a ship at sea made it impossible to keep the clock vertical at all times. In creating H4, Harrison transferred this idea to a set of balances that functioned in a similar fashion inside the smaller device. He solved the problem caused by the expansion and contraction of metal parts by developing a bimetallic strip, which helped regulate the movement of the watch. Because the two metals expand and contract at different rates in different temperatures, one counteracts the other; this allowed the watch to keep time accurately despite fluctuations in temperature. Harrison also developed a mechanism for transferring the power of the mainspring, which could fluctuate as it gradually lost tension after being wound, through a secondary spring that was constantly rewound so that it applied a constant force to the movement of the clock's hands.

The first real vindication for Harrison's efforts was accomplished before he died. Captain James Cook departed England in 1772 for a South Seas voyage, taking along the copy of Harrison's chronometer made by Kendall. As Cook reported, that device proved exceptionally valuable for determining longitude and charting the lands visited by him in his three-year cruise. While many improvements were made in the decades following Harrison's death, several devices modeled on his designs were constructed for general use. Not only did these provide a means of calculating a ship's position, but, as Cook had shown on his voyage, they also were instrumental in helping mariners revise charts of the ocean and its land masses, especially islands located at remote places around the world. As a consequence, the work Harrison did in developing his sea clocks paved the way for the expansion of both commercial trade and exploration that occurred during the nineteenth century and beyond.

OLIVER HEAVISIDE

English mathematician, physicist, and electrical engineer

Heaviside invented the distortionless transmission line for telegraph and telephone cables. He also invented operational calculus and vector calculus, using the latter to simplify James Clerk Maxwell's electromagnetic field equations to their modern form.

Born: May 18, 1850; London, England
Died: February 3, 1925; Torquay, Devon, England
Primary fields: Communications; electronics and electrical engineering; mathematics; physics
Primary inventions: Distortionless transmission lines; operational calculus

EARLY LIFE

Oliver Heaviside (HEHV-ee-sid) was born on May 18, 1850, in London, England. His father was Thomas Heaviside, a watercolorist and engraver, and his mother was Rachel Elizabeth West, whose brother-in-law was Sir Charles Wheatstone, coinventor of the telegraph in the 1830's. Oliver was born in the slums of London and suffered from scarlet fever as a child, which left him partially deaf and unable to relate easily with other children. Although he was a good student, he left school at age sixteen to study at home, concentrating for two years on telegraphy, electromagnetism, and the study of German and Danish.

At the age of eighteen, with assistance from his famous uncle, Heaviside began his first and only paid job as a telegraph operator with the Great Northern Telegraph Company, beginning in Denmark in 1868. Three years later, he was transferred by the company back to England at its office dealing with overseas traffic in Newcastle upon Tyne, where he became a chief operator. During his six years of employment, he published two papers on electric circuits and telegraphy (in 1872 and 1873), which interested the Scottish physicist James Clerk Maxwell enough to mention them in the second edition of his *Treatise on Electricity and Magnetism* (1873).

Heaviside became so fascinated with Maxwell's treatise that he gave up his job in 1874 at the age of twenty-four and returned to his parents' home in London to devote himself full-time to studying it and learning the requisite advanced mathematics. During this time, he grew increasingly deaf and reclusive, remaining single all of his life. After several years, he had mastered Maxwell's electromagnetic theory and its associated mathematics before setting it aside to develop his own ideas, including the invention of new forms of mathematics to recast Maxwell's equations in their modern vector form.

Life's Work

Oliver Heaviside began his research in 1880 on the skin effect in telegraph transmission lines that increased the resistance near the center of the lines with increasing frequency and concentrated the current flow near the surface, or "skin," of the conductors. In 1880, he patented the coaxial cable as a way to transmit high-frequency signals more efficiently. He was able to apply Maxwell's equations to the skin-effect problem and solved them for conductors of any shape, showing how the current was distributed and how resistance increased with frequency because of eddy currents induced by the changing magnetism caused by rapidly alternating current. He published this work in 1885 in a paper on "Electromagnetic Induction and its Propagation" in *The Electrician*.

In the course of his electrical research, Heaviside began to adapt complex numbers to the theory of electric circuits. In this work, he introduced the Heaviside step function to aid in mathematical modeling of circuits. He also independently formulated vector analysis along lines similar to the work of Josiah Willard Gibbs in the United States, and he invented an operational form of calculus for solving linear differential equations by transforming them into algebraic equations. His mathematical work led to controversy because he did not apply rigorous methods to the derivation of his results, viewing them as pragmatic and experimental. Nevertheless, this work became the basis for much of electrical engineering in the twentieth century and provided the key to his success in reformulating Maxwell's equations in a simpler form and obtaining solutions from them.

In 1884, Heaviside applied his new ideas of vector analysis to electromagnetic theory. Maxwell's original equations linking electric and magnetic fields were extremely cumbersome, requiring twenty equations in twenty variables representing the sources and spatial components of the fields. With the use of vector notation and the vector calculus operators he had invented, Heaviside reduced Maxwell's equations to just four elegant vector equations in two variables, emphasizing the basic symmetries between electric and magnetic fields. Two of these equations derive from Gauss's law and describe the source and structure of electric and magnetic

Distortionless Transmission Lines

Although Oliver Heaviside began his career as a telegraph operator, he spent much of his time thinking about the theory of telegraph circuits and cables. His earliest papers of 1872 and 1873, before his retirement in 1874, already reveal his ingenuity on these topics. His second paper introduced his duplex telegraph invention, which allowed telegraph signals to be sent both ways on a telegraph cable at the same time without interfering with each other, eliminating the need for two separate cables. The key to this invention was the application of his uncle's invention of the Wheatstone bridge to telegraph cables, which he used at both ends of the line. By properly arranging the resistances of the bridge circuits and the connecting telegraph cable, he could assure that the receivers placed in the bridge would be isolated from the sending signals.

A general transmission-line theory was developed by Lord Kelvin in 1855, using a diffusion model for the current in a submarine cable, including the effects of resistance and capacitance. Kelvin's model correctly predicted the poor performance of the first trans-Atlantic submarine cable, completed in 1858, which could transmit only about one-tenth of a word per minute and operated for just one month before technical mistakes led to its demise. A second improved cable was completed in 1866, but still was limited to about eight words per minute. This problem led to considerable distortion in telephone messages when they began to be used in the 1880's. Heaviside began to analyze this problem after deriving his telegrapher's equations in 1885 from James Clerk Maxwell's equations.

The telegrapher's equations generalized Kelvin's equation with the inclusion of inductance, thus going beyond mere diffusion effects and accounting for the kind of wave propagation involved at the higher frequencies of telephone signals. After a careful analysis, Heaviside published the conditions for distortion-free signaling in 1887 and showed that adding the right amount of inductance along the transmission line would reduce and equalize the attenuation of currents at all frequencies. Unfortunately, his suggestion of adding induction coils along the line was rejected by William Preece, engineer in chief of the British General Post Office. Thus, the development of trans-Atlantic telephony was delayed for nearly twenty years until Heaviside's ideas were revived in 1904 by Michael Pupin and AT&T.

fields. The other two equations generalize Ampere's current law and Faraday's voltage law to show how changing electric fields produce magnetic fields and changing magnetic fields produce electric fields. For several years, these vector forms of Maxwell's equations were called the Heaviside-Hertz equations because Heinrich Hertz was the first to apply them in his discovery of radio waves.

In 1885, Heaviside applied Maxwell's equations to electrical transmission lines to obtain the modern form of the telegrapher's equations. He applied these equations to the trans-Atlantic submarine telegraph cable, which suffered from distortion problems. In 1887, he recommended that induction coils be added to telephone and telegraph lines to correct this distortion. Unfortunately, his ideas were ignored for political reasons but were eventually adopted by the American Telephone and Telegraph Company (AT&T) based on a patent given to Michael Pupin in 1904. When AT&T later offered to purchase Heaviside's rights, he refused the money for lack of full recognition even though he had very little income. In 1891, he was elected as a fellow of the Royal Society.

In the 1890's, Heaviside became interested in the problem of the age of Earth, which had been calculated to be about 100 million years by Lord Kelvin some thirty years earlier by assuming uniform thermal conductivity in the cooling of the planet. This notion proved to be a great challenge to Charles Darwin, whose theory of evolution required several billion years. In 1894, Heaviside used his operational calculus to repeat Kelvin's calculation, but making the assumption of a change in thermal conductivity near the surface of Earth corresponding to its crust. This calculation led to a much older age of Earth, which could be on the order of billions of years depending on a range of values for the heat constants.

At the age of forty-seven, after his parents had died, Heaviside began living by himself for the first time in his life. Friends arranged for him to receive a civil list pension of 120 pounds per year as a government-recognized authority. In 1897, he left London and moved to a house in Newton Abbott a few miles from Paignton, Devon, in the southwest corner of England, with an elderly lady as a servant. One of his last scientific contributions was an explanation for Guglielmo Marconi's success in transmitting radio waves across the Atlantic Ocean over the curvature of Earth. In 1902, Heaviside proposed the existence of a charged layer in the upper atmosphere, now known as the Kennelly-Heaviside layer of the ionosphere, which transmits radio waves by reflection between it and Earth's surface. In 1908, he moved to Torquay in Devon, where he lived his last years as a virtual hermit.

Impact

The main impact of Heaviside's work came from the mathematical techniques he invented and their applications in electromagnetic theory. He used these techniques to simplify Maxwell's electromagnetic equations and applied them to a wide range of transmission-line problems. His independent invention of vector analysis, including the divergence and curl operators of vector calculus, made it possible to reduce the twenty equations of Maxwell's electromagnetic field theory to their modern form of just four compact and symmetric equations. It was this form of Maxwell's equations that led Heinrich Hertz to his 1887 discovery of radio waves. Heaviside's invention of operational calculus, similar to the method of Laplace transforms that largely replaced it after 1937, led him to many important solutions of Maxwell's equations. These mathematical techniques have had wide applications in many areas of engineering and physics since their invention.

Heaviside's work is especially important for his innovations in electrical engineering, including the complex-number analysis of electric circuits and the invention of the telegrapher's equation. He introduced much of the modern terminology of alternating-current circuit analysis, including such terms as conductance, permeability, inductance, impedance, admittance, reactance, and reluctance. His derivation of the telegrapher's equation to analyze transmission lines led him to recommend adding induction coils, which made it possible to have distortion-free transmission over long-distance cables for a wide range of frequencies as required in modern telephone communications. One of his final contributions was the publication of his three-volume *Electromagnetic Theory* (1950), summarizing and extending much of his life's work.

Hermann von Helmholtz

German physicist and physician

Helmholtz invented the ophthalmoscope for seeing into the interior of the eye and the ophthalmometer for measuring the curvature of the eyeball. He made major contributions to the physiology of seeing and hearing and established the modern theory of conservation of energy.

Born: August 31, 1821; Potsdam, Prussia (now in Germany)
Died: September 8, 1894; Charlottenburg, Berlin, Germany
Also known as: Hermann Ludwig Ferdinand von Helmholtz (full name)
Primary fields: Medicine and medical technology; optics; physics
Primary inventions: Ophthalmoscope; ophthalmometer

Early Life

Hermann von Helmholtz (HUR-mahn fahn HEHLM-hohltz} was born in Potsdam, Prussia (now in Germany) on August 31, 1821, to August Ferdinand Julius Helmholtz and his wife, Caroline Penn. His father was educated in philology and philosophy and became a teacher at Potsdam Gymnasium. Hermann was a sickly child and was kept home until he was seven years old. He amused himself with blocks and taught himself many things about geometry. His health improved when he was seven, and he was sent to Potsdam Gymnasium, where he amazed his teachers by what he had learned while at home.

His father's interest in philosophy, art, and music had a strong influence on Helmholtz, but after an introduction to physics in the *Gymnasium*, he decided he wanted to be a physicist. His father did not have the money to pay for his further education but found an army scholarship that paid for four years of education at a Prussian army medical institute of the University of Berlin in return for eight years of service in the army as a medical officer. At the institute, he studied under Johannes Müller, who was laying the groundwork for the physics of biology, now called biophysics.

After Helmholtz graduated, he spent two years as a surgeon in the Charité Hospital in Berlin but did not enjoy that assignment because of the hopeless cases he encountered. The remainder of his army service was spent in Potsdam, where he found the time to study further and publish several scientific papers, including his groundbreaking work on the conservation of energy.

Life's Work

Helmholtz's first publication was his thesis on the structure of the nervous system in invertebrates. After he graduated and did his required hospital service, he used his evenings and off-duty hours in Potsdam to study the action of muscles and the heat generated by them. He found that as chemical energy was translated into mechanical work and heat, the total energy within the system remained constant. Although Julius von Meyer and James Joule had made similar observations, Helmholtz's mathematical approach clarified the subject for the first time. His publication on conservation of energy in 1847 established his reputation as a first-rate scientist.

The Ophthalmoscope and Ophthalmometer

The two great inventions of Hermann von Helmholtz are the ophthalmoscope for seeing into the internal structure of the eye and the ophthalmometer for measuring the curvature of the cornea. Together these have become primary tools of ophthalmologists and optometrists.

In 1850, Helmholtz built the first ophthalmoscope to illustrate the physiology of the eye for his students. It was a crude device consisting of a light source and microscope glass slides mounted on a handle at 45° to the eye and observer. The idea was to shine the light into the eye, where it would be reflected by the retina. Helmholtz knew that the light would follow the same path out as going in, so he reflected the outgoing light by 90° to his eye. Present-day ophthalmoscopes are more complex and often consist of a battery-operated light source and a concave mirror that focuses the light into the eye. The physician views the interior of the eye with lenses of different powers through a small aperture in the mirror.

Helmholtz invented the ophthalmometer in 1855 to measure the accommodation of the living eye to different focal distances. The ophthalmometer measures the reflection of objects in the convex surface of the cornea. These measurements determine, among other things, whether the cornea focuses on the lens or in front or behind it. If the focal point is not on the lens, the person is either nearsighted or farsighted. The amount and direction of astigmatism can also be measured by the degree to which the reflected image is displaced from the center of the front surface of the eye.

In his research, Helmholtz invented many other devices for the quantitative measure of the physiology of the eye and ear and the ability to perceive light and sound. As in all of his studies, his primary objective was to understand the fundamental mechanisms by which the eye and ear work.

Because of his obvious scientific talents, Helmholtz was released early from the army so he could take up an academic appointment as assistant at the Anatomical Museum and lecturer in the Academy of Fine Arts in Berlin. Within a year, he moved to the University of Königsberg, where he was appointed assistant professor and director of the Physiological Institute. He had gained worldwide fame with his 1847 paper on conservation of energy, so his rise in academia was spectacular. He spent six years at the University of Königsberg and then three years at the University of Bonn. During this period, his principal scientific work was on the physiology of vision and hearing. He also began his studies on the perception of light and sound.

While teaching at the University of Königsberg in 1850, Helmholtz prepared an experiment for his students to show that the light that enters the eye is partially reflected out, following the same path out as it had going in. He found that he could put his eye in the path of the reflected light and see the internal structure of the eye. He recognized that this would be important to physicians treating problems of the eye, so he publicized his findings, and the ophthalmoscope began to be manufactured. During the years between 1856 and 1867, Helmholtz published his mammoth reference work *Handbuch der physiologischen Optik* (*Handbook of Physiological Optics*). This has remained one of the most important works on the physiology and perception of seeing.

Helmholtz had become unhappy with his position at Bonn because of criticism from traditionalists in the university about his teaching of anatomy. He was teaching a new mechanical and physical approach that the older anatomy professors could not understand. In 1858, he accepted a professorship at the University of Heidelberg with the promise that the university would set up a new physiology institute for him. He did some of his most important work at Heidelberg. In 1863, he compiled his research on sound and published his famous book *Die Lehre von den Tonempfindungen als physiologische Grundlage für die Theorie der Musik* (*On the Sensations of Tone as a Physiological Basis for the Theory of Music*, 1877).

After Helmholtz completed the third volume of *Handbook of Physiological Optics* (1867), his research interests turned from physiology to physics. In 1870, the chair of physics at the University of Berlin became vacant, and Helmholtz, now one of the most famous scientists in the world, was offered the position. After negotiating a high salary and convincing Prussia to build a new physics institute to be under his control, he took up the chair in 1871. After his appointment, Helmholtz became interested in electricity and magnetism, attempting to derive the electrodynamic equations. He was unsuccessful in this, but after James Clerk Maxwell published his famous equations showing that changing electric and magnetic fields produce electromagnetic waves, Helmholtz's student, Heinrich Hertz, showed that these waves were real and measured the wavelength and reflection of the radiation. Helmholtz had many other doctoral students who made important discoveries in physics. Among these students were Albert Michelson, who with Edward Morley cast doubt on the ether theory, and Wilhelm Wien, who studied black-body radiation.

Because of his fame, Helmholtz was asked by different organizations to give popular lectures on science and on his discoveries. These lectures were later collected and published and became an important contribution to the understanding of science by the general public. Helmholtz received many honors during his lifetime, including the addition of the prefix "von" to his family name granted by Kaiser Wilhelm I in 1883. This honor was inheritable and was comparable to a knighthood.

Helmholtz was a "workaholic" and occasionally became ill from overwork. He had never completely recovered from his childhood sicknesses, and most of his life he had occasional migraine headaches and dizzy spells. In 1894, he fell and suffered a concussion from which he never recovered. He died of complications several months after his fall.

Impact

The primary unifying principle that bound together the life and work of Helmholtz was his belief that metaphysical ideas and vitalism were wrong and should be replaced by the laws of mathematics and physics. His philosophy guided his research, and from his earliest work on the conservation of energy to his final studies of electromagnetism and thermodynamics, he showed that nature could be understood in physical terms.

The tools that Helmholtz invented helped to establish the field of ophthalmology and are the main measuring devices for determining problems of vision. In addition, there are other diseases that have consequences for the eyes and that can be recognized by studying the eye. For example, the ophthalmoscope is used to examine retinal blood vessels, from which information can be obtained about high blood pressure and diabetes. The ophthalmometer can measure the ability of the eye to accommodate to situations such as different focal distances and can also measure astigmatism. Before the invention of the ophthalmoscope and the ophthalmometer, there were only limited means to determine the state of health of the eyes and what could be done to improve vision. Simple eyeglasses were available and could be fitted by trial and error, but many other vision problems could not even be recognized. With these two instruments, optometrists could design glasses to correct for defective vision.

From his studies in physiological optics, Helmholtz came up with a theory of three-color vision similar to that of the earlier scheme of Robert Young. This theory is now called the Helmholtz-Young theory of color vision and is important in understanding color blindness. Helmholtz was also interested in how the human ear perceived sounds. As an expert pianist, he wanted to know how pitch and tone were distinguished. He suggested that the inner ear could resonate at certain frequencies, enabling it to differentiate tones, overtones, and timbres—thus enabling the ear to distinguish different instruments playing the same note.

Beulah Louise Henry

American socialite

Henry is noted especially for the large number and the diversity of her inventions. She received forty-nine patents and has been credited with approximately 110 inventions. Her inventions include a vacuum ice cream freezer, a number of children's toys, and improvements to typewriters and sewing machines.

Born: September 28, 1887; Raleigh, North Carolina
Died: February 1973; New York, New York
Also known as: Lady Edison
Primary fields: Business management; household products
Primary inventions: Typewriter devices; children's toys; household devices; parasol improvements; sewing machine improvements

Early Life

Beulah Louise Henry (BYEW-luh LEW-eez HEHN-ree) was a descendant of the Revolutionary War hero Patrick Henry. Her grandfather was William Woods Holden, the governor of North Carolina in the 1860's. She was born in Raleigh, North Carolina, to artistic parents. Her mother was an artist, her father was an art expert, and her brother was a songwriter. As a child, she sketched out her ideas for inventions and made models from household scraps such as tape, soap, hairpins, buttons, and rocks. She lived in Memphis, Tennessee, for part of her youth, and attended college in North Carolina, at Elizabeth College and Queens College in Charlotte. She apparently received a liberal arts education, as she later described herself as having had no technical training.

Henry had synesthesia, a condition in which one type of stimulation evokes the sensation of another. For example, the hearing of a sound produces the visualization of a color or a taste. She said that she had a complete picture of each of her inventions in her mind before she tried to construct it or to describe it to someone hired to construct the invention for her. She felt that her ability to create complex mechanical devices without any technical training was due to the same "inner vision" that allowed her to see color and shape for musical notes.

In 1919, Henry moved to New York City and lived there most of her adult life. She did not marry, and she lived in hotels or hotel apartments all her life. She kept her rooms fairly empty of furnishings in order to allow room for her many models.

Life's Work

Henry's first patent was issued on September 3, 1912, while she was living in Charlotte. It was for an ice cream freezer with a vacuum seal. She was issued two more patents in 1913, while still living in Charlotte. One was for a handbag with interchangeable covers, issued on May 27; the other, issued on November 18, was for a parasol with snap-on covers of various colors that allowed the appearance of the parasol to be altered to match one's outfit. The parasol invention was both a commercial and a financial success for Henry. She earned about $50,000 from the manufacturer, probably Thomas Woodley of Charlotte, who was assigned one-half of the patent (U.S. Patent number 1,079,240). By 1921, Henry had formed the Henry Umbrella and Parasol Company in New York City to manufacture and sell her popular umbrellas and parasols. Her U.S. Patent number 1,492,725, issued May 6, 1924, for improvements to the above parasol was assigned to the Henry Umbrella and Parasol Company. By 1924, she was also president of B. L. Henry Company, her second company.

For the remainder of the 1920's, Henry was awarded numerous patents. Four were awarded in the year 1927 alone. Some were for additional improvements to the parasol. The majority, however, were for toys and household items, a couple of dolls, a floating soap holder made of a sponge that opened up to hold the soap, a hair curler, and several inflatable toys. Some of these patents were assigned partly or wholly to another individual or to a company, presumably to manufacture the items.

Starting in the 1930's, Henry began receiving patents for business machines. She was issued numerous patents for improvements to or devices for use with typewriters. She also received a number of patents for improvements to sewing machines. She continued to receive patents for toys, games, and household items. Several of her patents related to typewriters were for methods of producing multiple copies without carbon paper. This was especially important during World War II, because carbon for carbon paper was in short supply. Other typewriter-related inventions were for improved aligning devices, reduction in typing noise, and a key for use with devices such as a typewriter. In addition to her typewriter en-

Duplication Devices for Typewriters

Beulah Louise Henry received several patents for devices that made multiple copies with a typewriter without the use of carbon paper. Her first patent of this type was issued in 1932, and she received patents for improvements up until 1959. The 1932 patent was for a "Duplication Device for Typewriting Machines." The invention consisted of several devices to be attached to a standard typewriter, so that the typewriter would then have an additional ribbon and the means to insert three sheets of paper: The first sheet would be behind the first (original) ribbon, the second sheet would be between the two ribbons, and the third sheet would be behind the additional ribbon. When the typist hit a key, the letter image would be placed on the front of the first sheet by the original ribbon, on the back of the second sheet by the second ribbon, and on the front of the third sheet by the second ribbon. The second (middle) sheet was supposed to be of transparent material, so that the typing could be read through it, since the letters would be on the back of the sheet. If only two copies were required, then a protective strip was placed between the front sheet and the second ribbon, so that the second ribbon would not print on the back of the first sheet. All of this was accomplished through a rather complicated set of mechanisms attached to the typewriter, so that the two or three sheets could be inserted properly with respect to the ribbons, and so that all three sheets would advance together properly.

The second patent, also issued in 1932, but applied for nearly two years after the first, was for an improved mechanism allowing the second ribbon to be swung out of the way in order to type on only a single sheet. The next improvement in a 1936 patent was for a separate, self-contained attachment, which could be removed when not required. It also allowed for more than three copies to be made. A 1937 patent was for an improved attachment that made insertion and removal of the sheets of paper easier. It also allowed for easier inactivation of the system to type single sheets or envelopes. Patents in 1953, 1954, and 1959 were for additional refinements to the multicopy attachment. They made it simpler, easier to use, and capable of making better typed copies.

With the later advent of photocopiers, and now computers, word processors, and printers, the multicopy attachment seems quaint. However, it served a useful purpose when it was invented, especially during World War II, and for decades after.

hancements, Henry was issued several patents related to envelopes, including construction of envelopes and continuously attached envelopes to aid in addressing them. Her improvements to sewing machines included improved devices for stitching and making seams, and a patent for a method of producing a lockstitch with only one thread, eliminating the need for a bobbin.

Henry began inventing toys early in her career. Several of her inventions made toys seem more realistic, such as a doll whose eyes would close or change colors, dolls with limbs that were movable in a variety of ways, a toy cow that could be milked, toy animals that ate, and dolls that talked. Several of her patents were for inflatable toys and for devices and methods of inflating them.

By the 1930's, Henry's prolific inventiveness was recognized, and she was nicknamed "Lady Edison." In addition to her inventing, she had a wide range of interests, including writing, painting, and membership in the Audubon Society, the League for Animals, and the Museum of Natural History.

Henry was hired by a number of companies in the latter part of her career to develop products for them. She is believed to have had more than one hundred inventions over her lifetime. Her last patent was issued on February 24, 1970, for a method of envelope construction. She died in February, 1973, at the age of eighty-five.

IMPACT

Henry was a prolific inventor. She was busy creating new inventions for most of her adult life. Her first patent was granted when she was twenty-four years old, and she was awarded her last patent at age eighty-two. She was one of the first female inventors to make a comfortable living from her inventing. She manufactured and sold some of her inventions through her companies, and some were licensed to other people or companies to manufacture. She had an amazing breadth of inventions, including improvements to parasols, her first commercial success; a wide variety of children's toys and games; household products; and a number of improvements to machines, notably typewriters and sewing machines.

Henry's early invention of a parasol with snap-on covers became widely used. Parasols and umbrellas were popular at that time, and the ability to change the parasol color in accord with one's outfit was well liked. Her inventions that allowed multiple typewritten copies to be made without carbon paper were of significance, given the shortage of carbon during World War II.

Joseph Henry

American physicist

Henry's experiments in electromagnetic induction helped pave the way for the subsequent revolution in electrical technology. He invented the first electric motor and provided the scientific underpinning for Samuel F. B. Morse's telegraph.

Born: December 17, 1797; Albany, New York
Died: May 13, 1878; Washington, D.C.
Primary fields: Acoustical engineering; communications; electronics and electrical engineering; physics
Primary inventions: Electric motor; electromagnetic telegraph

Early Life

Joseph Henry was born to William and Ann Alexander Henry in Albany, New York, in 1797. His father was an alcoholic who had difficulty earning a living, and Henry spent part of his childhood and adolescence with his stepgrandmother and an uncle in Galway, New York, a small farming community approximately thirty-six miles from Albany. It was in the Galway village school where he received his basic education. He returned to Albany in 1814 or 1815 to live with his now widowed mother, who was running a boarding house. In Albany, he had a failed apprenticeship with a silversmith but gained valuable skills that he later used in creating experimental apparatuses. He had some success as an amateur actor and contemplated a career on stage. However, his life turned completely around when he stumbled upon a book belonging to one of this mother's boarders: George Gregory's *Popular Lectures on Experimental Philosophy, Astronomy, and Chemistry* (1808). Henry always dated his interest in science to the reading of that book in about 1816.

Henry became a schoolteacher and from 1819 to 1822 attended the Albany Academy, the only formal education he had beyond the primary grades. Subsequently, he worked as a tutor and as a surveyor before returning to the Albany Academy in 1826 as professor of mathematics and natural philosophy (physics). He left Albany for a professorship at the College of New Jersey (now Princeton University) in 1832.

Life's Work

In 1820, the Danish physicist Hans Christian Ørsted discovered that an electric current produced what later became known as a magnetic field. Researchers throughout Europe began exploring the relationship between electricity and magnetism. One of the leaders in that exploration was Michael Faraday in Great Britain. Unknowingly paralleling Faraday's research was Henry. Henry began his research in electromagnetism around 1827 by modifying existing apparatuses, with the objective of enhancing the phenomena for pedagogical purposes. He wanted to create spectacular results for demonstration purposes in the classroom. His initial fame was based on his ability to make extremely powerful electromagnets. By 1830, his electromagnets were able to support more than thirty-five times their own weight, making them the most powerful in the world. With his apparatuses, he was soon making original discoveries, fitting his research around an extremely demanding teaching schedule of at least seven hours a day. Sorting out priorities between Henry and Faraday has always

Joseph Henry. (National Portrait Gallery, Smithsonian Institution) been a challenge, especially since Henry did not maintain a laboratory record until 1834, but historians now agree that Faraday first published on the induction of an electric current by a changing magnetic field (1831), while Henry was the first to announce the existence of self-induction, the creation of a current in a wire when a circuit is broken (1832).

Although he saw himself as a research scientist, Henry was very aware of the potential applications of his discoveries. Henry's 1831 electromagnetic machine, although just a scientific demonstration, was the first apparatus to produce continuous motion through electromagnetic attraction and repulsion. It had all the essential elements of a direct-current (DC) motor. Although it should be considered the first DC motor, it was not the first step toward a practical invention. As Henry himself argued, the economic reality of the relative cheapness of the fuel for steam engines versus that for electrical engines in the mid-nineteenth century reduced the latter to curiosities. Moreover, Henry's oscillating design was quickly overtaken technologically by rotating motors.

It was a different story for the electromagnetic telegraph. As early as 1831, Henry had constructed a machine that demonstrated that electromagnetism could be used to produce mechanical effects at a distance (the ringing of a bell). By the mid-1830's, he had invented a primitive relay for his machine, an essential element for a commercial telegraph. In all his subsequent clashes with Samuel F. B. Morse over the question of who invented the telegraph, Henry never claimed he invented a commercial telegraph. He also always acknowledged that Morse's version was the best of the era and demonstrated the most superior reduction of principles to practice. What he did maintain was that he was the first to demonstrate the basic principle for the telegraph: how mechanical effects at a distance could be produced by the application of electromagnetism. His discoveries were a necessary element in the process of the invention of the telegraph. Without them, the invention of the telegraph would have been delayed indefinitely.

Initially, Henry and Morse had a cordial relationship that went back to at least 1838. Henry provided encouragement and technical advice to Morse, while Morse reciprocated by lending Henry apparatuses for scientific experiments. The relationship started to deteriorate in the mid-1840's, first because Henry felt Morse was denying him proper credit, and second because Henry testified in patent lawsuits, especially in *Morse v. O'Reilly* (1849). In the lawsuits, Henry challenged Morse's efforts to gain patent rights for all forms of the electromagnetic telegraph.

As one of the best-known scientists in the United States, Henry was selected as the first secretary (director) of the Smithsonian Institution in

THE ELECTROMAGNETIC TELEGRAPH

By the early nineteenth century, researchers were aware of the potential of electromagnetism for use in telecommunications. However, experiments by the Englishman Peter Barlow in 1824 had shown that it was impossible to deflect a needle after sending a current through only two hundred feet of wire, thus making any form of long-distance communication impossible.

Joseph Henry was able to overcome this limitation through three insights. The early form of the electromagnet, invented by William Sturgeon in the mid-1820's, consisted of loosely wrapped bare copper wire around thick iron wire bent into the shape of a horseshoe. Because the wire was not insulated, only a few feet of wire could be wrapped around the iron before short circuits would develop. Henry painstakingly insulated the wire with silk, enabling him to wrap many layers of copper wire on the iron, resulting in a much more powerful electromagnet. His next insight was to replace the long coil of insulated wire with a series of shorter coils. He found that connecting the coils in parallel (which he called a "quantity magnet") enabled great lifting power at a short distance, but connecting the coils in series (which he called an "intensity magnet") produced a small amount of power at a great distance. By 1831, using an intensity magnet, he was able to transmit a current through one and a half miles of wire. His last insight, in 1835, was the development of a relay, using an intensity magnet to control a much larger quantity magnet.

The two different forms of electromagnets and the relay were essential for development of the telegraph. Morse's repeater, which made it possible for signals to travel great distances, was built around a Henry intensity magnet. Morse's recording instrument was dependent upon a Henry quantity magnet. The intensity to quantity relay was adapted by Morse for connecting his local receiving circuit to a long-distance telegraph line. The significance of Henry's insights to Morse's invention are evident by comparing the Morse telegraph before and after Morse was aware of Henry's work. In 1836, the Morse telegraph was able to transmit a signal only forty feet. After incorporating Henry's first two insights, at the advice of his friend Leonard Gale, a chemistry professor, Morse was able to send messages through ten miles of wire.

1846. He remained secretary until his death. He was also a founding member (1863) and president (1868 until his death) of the National Academy of Sciences. By the 1860's, his research interests had shifted from electromagnetism to applied acoustics, especially the transmission of foghorn signals, an outgrowth of his service on the United States Lighthouse Board. He did, however, provide advice and support to Alexander Graham Bell in 1875, at what Bell perceived to be a crucial moment in his efforts to develop the telephone.

By the time of his death, Henry was recognized as one of the country's leading contributors to science, technology, and public service. Analogies were often drawn between Henry and Benjamin Franklin. In 1893, the International Congress of Electricians honored the pioneers in electrical research by attaching their names to fundamental electrical units. Henry's name was attached to the unit of inductance. When, at the end of the nineteenth century, the Library of Congress decided to memorialize sixteen outstanding contributors to human civilization, Henry was selected to be one of the representatives of science, along with Sir Isaac Newton, joining other icons like William Shakespeare, Plato, and Michelangelo.

Impact

Henry's contribution to the most significant invention in communications history in the nineteenth century, the electromagnetic telegraph, is one of the clearest examples of basic scientific research leading to significant technological innovation. His work also serves as an example of the scientist offering up his discoveries so that others might exploit them for technological innovation and financial reward. Using his positions as secretary of the Smithsonian and president of the National Academy of Sciences, Henry, drawing upon his own experience with the telegraph, became the leading spokesperson for the argument that basic research was essential for technological innovation and economic progress. He claimed that most of the significant inventions of the nineteenth century were the result of the application of scientific principles. Because of their contributions, scientists who discovered the fundamental principles were just as worthy of appreciation as the inventors who reduced ideas to practice and created the machine. Basic research was essential to the well-being of American society, not a luxury, and, he argued, should receive public support.

Henry was the first American scientist to make the case that scientific insights led to inventions, a case that was remade by the industrial research laboratories of the early twentieth century and by weapons researchers after World War II.

Hero of Alexandria

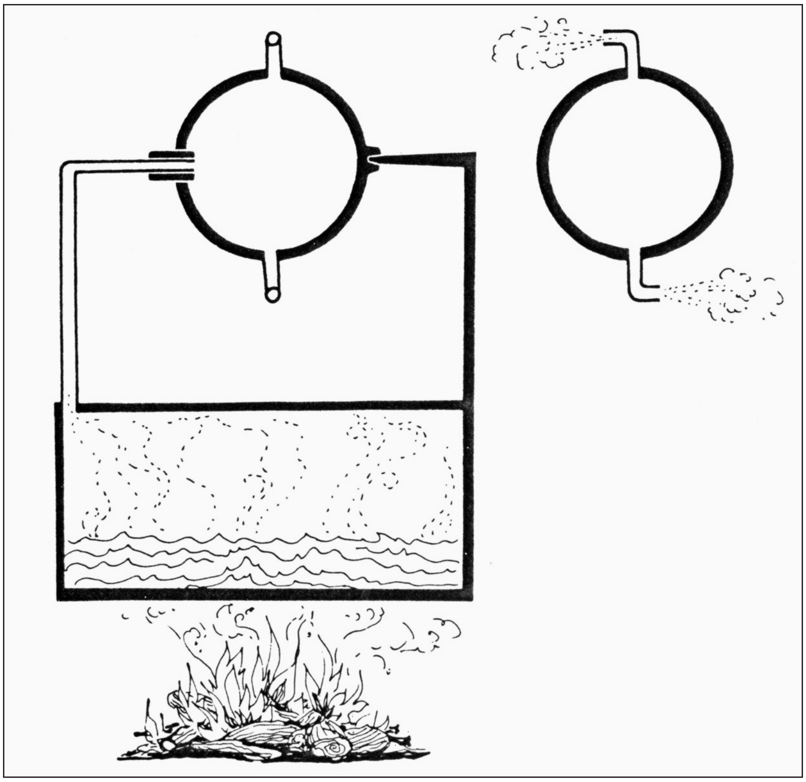
Greek mathematician and engineer

Hero invented, improved, or at least preserved the designs for a variety of devices, including a surveying instrument, a catapult, a coin-operated water dispenser, and automata. His most famous invention was the aeolipile, a forerunner of the steam engine.

Born: Before 62 C.E.; Alexandria, Egypt
Died: c. 100 C.E.; Alexandria, Egypt
Also known as: Heron of Alexandria
Primary fields: Mathematics; mechanical engineering; military technology and weaponry
Primary inventions: Aeolipile; coin-operated water dispenser

Early Life

Virtually no biographical information survives concerning Hero of Alexandria, but some details of his childhood can be reasonably surmised. Given his profession and judging from his voluminous writings, he probably came from at least a moderately wealthy family and received a first-class education. Alexandria, founded by Alexander the Great in 331 B.C.E., had become a thriving center for trade and scholarship under the Ptolemaic dynasty that ruled Egypt from 323 to 30 B.C.E. Though the Romans ruled Egypt in Hero's time, the city of Alexandria remained important both commercially and culturally. The young Hero would presumably have had access to the vast holdings of the Library of Alexandria and may well have attended the lectures of that institution's eminent scholars. In the form of its lighthouse, a hundred-meter-tall structure on the island of Pharos, Alexandria also offered a vivid daily reminder of the wonders that science and technology could achieve. Probably, but not certainly, of Greek descent, Hero was heir to a centuries-old tradition of intellectual curiosity and engineering innovation. In Alexandria, he would have been exposed to an incredibly diverse population of Greeks, Jews, native Egyptians, Romans, and other peoples from the Near East, Africa, and Europe. Perhaps only Rome itself could have offered a more fertile environment for a would-be inventor.



A representation of the aeolipile, an ancient steam engine. (The Granger Collection, New York)

Life's Work

What is known of Hero's work comes almost entirely from his writings. He wrote four works on aspects of mensuration, the science of measuring lengths, areas, and volumes. These works are his *Geometrica*, *Stereometrica*, *De mensuris*, and *Metrica*. Another work on geometry is his *Definitiones*. The works that discuss the construction of devices are the *Pneumatica*, about the use of compressed air, liquids, and steam; *De automatis*, describing the construction of two miniature automatic theaters; *Dioptra*, on a new surveying instrument; *Catoptrica*, which only survives in Latin translation, on mirrors; *Mechanica*, three books surviving only in Arabic translation, on the theory and practice of moving weights; and the *Belopoeica*, on catapults. Only fragments survive of his

Cheiroballistra, which describes another catapult-type weapon. Hero also wrote a volume on water clocks, a commentary on Euclid's *Elements*, and the *Baroulkos*, on a special lifting machine, but these works have not survived. Two later works, the *Geodaesia* and *Liber Geoponicus*, are collections of extracts from his writings.

In his writings, Hero describes a large number of useful, entertaining, and instructive devices, but it is seldom clear which devices he himself invented. In some cases, he merely describes earlier inventions, perhaps with minor improvements of his own. The *Belopoeica*, for example, only describes earlier types of catapults, not contemporary designs. Furthermore, it is sometimes uncertain whether a described device was ever actually built or could have really functioned. Some historians have gone so far as to deny that Hero was an inventor at all, asserting that he merely collected, organized, and published the designs of earlier innovators. However, his nickname, *mechanicus* (machine man), and the practical advice scattered throughout his writings suggest that he was more than just a compiler of information.

Hero was probably an adult by 62 C.E., since his *Dioptra* describes a lunar eclipse that occurred on March 13 of that year. It is unclear when Hero died, but a series of tantalizing references in late first and early second century sources may reflect his activities. Suetonius, the imperial biographer, mentions that the emperor Nero showed off a new kind of water organ in 68 C.E. This instrument, Paul Keyser has suggested, may have been the work of Hero, who describes a hydraulic organ in the *Pneumatica*. Pliny the Elder, who died in the eruption of Vesuvius in 79 C.E., reports in his encyclopedic *Naturalis Historia* (c. 77 C.E.) that a new type of wine press had recently been invented. This too may be the work of Hero, since he describes an innovative screw press design in his *Mechanica*. In his biography of Vespasian, Suetonius reports that the emperor rewarded an unnamed engineer for inventing a device designed to move heavy columns. If, as has been suggested, this is a reference to Hero, who shows considerable interest in such devices, then he was still active in the 70's. It is also likely that Hero invented the *cheiroballistra*, the small, torsion-powered arrow shooter he describes in the work of the same name. This weapon seems to appear on Trajan's Column and thus probably saw use in Rome's wars with Dacia in the first decade of the second century.

Hero invented (or at least recorded the designs for) dozens of devices. Among the most important are the aeolipile, the dioptra, various automata, automatic doors, a coin-operated water fountain, a variety of trick containers for water and wine, a wind-powered organ, a machine

The Aeolipile

Among the many inventions of Hero of Alexandria, none have exerted the same amount of fascination as his so-called aeolipile, or "wind ball," which some historians have described as the first steam engine and earliest jet turbine. Hero briefly explains the construction of this device in his *Pneumatica*. The device is quite simple, consisting of two metal chambers, three tubes, and a rod. The first chamber is a hollow hemisphere or covered cauldron and is meant to be filled with water. When this vessel is heated, the water gradually turns to steam and escapes through a tube or pipe leading to a hollow sphere. This pipe and a rod also attached to the cauldron hold up the sphere and are connected to it in such a way that the sphere can pivot around the axis they form. The steam, after entering the sphere, is allowed to escape through two additional L-shaped tubes set opposite one another along its circumference equidistant from the "poles" formed by the rod and tube connecting the sphere and the hemisphere. The exhaust ends of the L-shaped pipes point in opposite directions so that the force of the escaping steam causes the sphere to rotate around its axis. The classicist J. G. Landels, an expert in ancient science and engineering, reported that his own model of the aeolipile reached speeds of 1,500 revolutions per minute.

There continues to be some dispute over the precise significance of Hero's steam engine. Some scholars have essentially dismissed the device as no more than a toy without any practical application. Others have suggested that Hero intended the aeolipile not to do work but to demonstrate fundamental physical principles. This position seems reasonable given that the introduction to the *Pneumatica* explores the nature of air, water, and vacuum in general. Nevertheless, it is remarkable that this device, mentioned in no other ancient text, receives no special comment or explanation from Hero amid the other, more banal inventions described in this work. Another recurring debate concerning the aeolipile asks why Hero or some other ancient inventor did not adapt it for useful work, precipitating an ancient industrial revolution. The answer seems to be that the lack of proper fuel, construction materials, and tools impeded further development. Some have also suggested that the slave-based Roman economy did not place a sufficient premium on labor-saving machines to promote further development of the device.

for cutting female screws, a fire pump, self-regulating oil lamps, and the syringe. The dioptra was a forerunner of the theodolite, used by surveyors to measure horizontal and vertical angles. Hero's dioptra lacked the theodolite's telescope but could be used to excavate a straight tunnel through a hill or mountain from both ends simultaneously or estimate the distance to an inaccessible or dangerous spot such as an enemy's fortifications. The automata Hero describes include a miniature theater that would produce a multiact Greek tragedy complete with sound effects. His automatic doors opened a temple when a worshiper lit a fire on an external altar. The doors would close again when the fire was extinguished. Hero's coin-operated fountain worked in much the same way as the tank of a modern flush toilet. A coin fell through a slot onto a plate attached to a lever. The coin's weight depressed its end of the lever, lifting a plug attached to the other end and allowing water to flow out. Once the coin slipped off the plate, the plug returned to its initial position, stopping the flow of water. The *Pneumatica* describes a number of trick vessels in which one could pour wine and water and then, depending on which air holes were open or blocked, pour out either wine, water, or a mixture. Hero's windmill-powered organ is the only known application of wind power (aside from sailing) to survive from classical antiquity.

Impact

The mere fact that Hero's writings survived him suggests that later Greek and Roman thinkers considered his work to be important. Writing materials and scribes were expensive, so the preservation of Hero's work constituted a significant investment. A lack of sources makes it difficult to assess Hero's impact in antiquity, but Pappus of Alexandria, an early fourth century scholar, suggests that Hero had many followers. To this day, Hero's books remain a vital source for the study of ancient mathematics, engineering, surveying, and natural philosophy because so few other works on these subjects survive.

The impact of Hero's ideas and inventions in later periods is somewhat easier to gauge and seems to have been considerable. Scholars in the Islamic world preserved some of his writings, demonstrating their continued importance. Hero's wind-powered organ may have inspired Islamic engineers to develop the windmill. Many in both the Islamic world and the Byzantine Empire were inspired, directly or indirectly, by the wonderful automata described in the *Pneumatica* and sought to emulate them. Hero was not forgotten in medieval Europe, but interest in him increased dramatically in the Renaissance. In Italy and elsewhere, demand for automata grew. Humanist scholars also took an interest in Hero, particularly his ideas about the vacuum, and translated the *Pneumatica* into Latin, Italian, and German. Leonardo da Vinci, Francis Bacon, and Robert Boyle were all familiar with his writings. Hero's aeolipile even contributed to early efforts to design functional steam engines.

Heinrich Hertz

German physicist and electronic engineer

Hertz invented the first radio transmitter and receiver and used them to discover radio waves and confirm that they are electromagnetic waves that travel at the speed of light. He also discovered the photoelectric effect, in which light produces electricity.

Born: February 22, 1857; Hamburg (now in Germany)
Died: January 1, 1894; Bonn, Germany
Also known as: Heinrich Rudolf Hertz (full name)
Primary fields: Electronics and electrical engineering; physics
Primary inventions: Radio transmitter and receiver

Early Life

Heinrich Rudolf Hertz (HIN-rihk REW-dahlf HURTZ) was born on February 22, 1857, in Hamburg (now in Germany). His father, Gustav Ferdinand Hertz, was Jewish but converted to Christianity and raised his family as Lutherans. He was well known as a lawyer and became a senator in 1887. Heinrich's mother, Anna Elisabeth, was the daughter of a Frankfurt physician, Dr. Pfefferkorn. When Heinrich graduated from the Johanneum Gymnasium (secondary school) in 1875, he was first in his class, having studied Greek, Arabic, and Sanskrit. He was the eldest of four sons and one daughter.

After working for an engineering company in Frankfurt for a year, Hertz left in April of 1876 to enroll in engineering at the Dresden Technical Institute, but he left in September to fulfill a year of mandatory military service with the First Railway Guards Regiment in Berlin. He soon decided that his real interest was in science, and in 1877 he enrolled in physics at the University of Munich. A year later, he transferred to the prestigious Physical Institute at the University of Berlin, where he studied under Gustav Kirchhoff and Hermann von Helmholtz, two of the foremost physicists of the day.

Under the guidance of Helmholtz, Hertz won first prize for his electrical research entitled "Experiments to Determine an Upper Limit to the Kinetic Energy of an Electric Current." In 1880, he obtained his Ph.D. with a thesis on electromagnetic induction in rotating spheres, graduating magna cum laude. He then continued in Berlin for three years as the assistant of Helmholtz, publishing fifteen papers on both electrical and mechanical topics, which included early studies of contact forces associated with two objects under loading.

Life's Work

Heinrich Hertz was an unusual physicist in that he was skilled in both experimental and theoretical physics, both of which he employed during his short career. His first university appointment was in 1883 as a lecturer at the University of Kiel. He remained in contact with Helm-

Heinrich Hertz. (Library of Congress)

The Radio Transmitter and Receiver

The inventions by Heinrich Hertz of the first wireless radio transmitter and receiver were the result of a process of trial and error, followed by systematic experiments to confirm his results. The primary of his induction coil was fitted with an electromechanical vibrator to interrupt the current and produce a pulsed high voltage across the secondary. His antenna oscillator was a dipole consisting of two zinc-covered spheres acting as charge-storing capacitors. Each sphere was connected with a variable length of wire to the terminals of a spark micrometer, which in turn were connected to the secondary of the induction coil. The separation of the spheres could be varied up to 3 meters to support half-wavelength oscillations at resonance, thus producing up to 6-meter wavelengths that were short enough for convenient indoor measurements. The high-voltage pulses charged the spheres until a spark discharged them. About five or six discharges in each pulse produced oscillating currents in the antenna up to 50 megahertz.

At first, Hertz used a loop of wire connected to another spark micrometer as a way of measuring the resonant frequency of the antenna oscillator. When the loop radius was adjusted to resonance, it sparked at the same time as the oscillator. He could then determine their common frequency by calculating the loop frequency. When he found that he could obtain synchronous sparks several meters away, he realized that his antenna oscillator was a wireless transmitter and that he was detecting electromagnetic waves from the transmitter with his variable loop, which was the first radio receiver. He was even able to detect these sparks in an adjacent hallway as the radio waves passed through the walls.

After these inventions, he began a series of experiments in the fall of 1887 to demonstrate that the radiation from his transmitting oscillator corresponded to James Clerk Maxwell's prediction of electromagnetic waves traveling at the finite speed of light. He set up his induction coils and oscillator at one end of a 15-meter lecture hall and covered the opposite wall with a sheet of zinc to reflect the radiation. When he moved his receiving loop and spark gap away from the oscillator, he observed a periodic variation in the strength of sparks, with nodes about 4.8 meters apart, corresponding to a 9.6-meter wavelength in the standing waves produced by the transmitted waves and their reflection. This value was distorted to some extent by the small size of the room relative to the wavelength.

With the radius of the loop at about 35 centimeters, Hertz calculated a resonant frequency of 35.7 million vibrations per second (megahertz), giving a wave speed (frequency × wavelength) of 3.4 × 10 meters per second, about 13 percent more than the measured speed of light. Later corrections by Henri Poincaré showed that the frequency was 50 megahertz and the wavelength was 6 meters, giving a speed of 3 × 108 meters per second, matching the speed of light. These experiments were completed in March of 1888 and published in his paper "On Electromagnetic Waves in Air and Their Reflection," initiating a new era of wireless communication.

holtz, who was one of the first European scientists to seriously study James Clerk Maxwell's 1865 electromagnetic theory and tried to derive Maxwell's field equations using action-at-a-distance assumptions. In Hertz's first paper on electromagnetic theory in 1884, he ignored such assumptions and eliminated the mechanical models that Maxwell had used to justify the theory. He concluded with the modern view that the theory is in essence the equations of Maxwell regardless of how they are derived. In 1872, Maxwell had predicted that oscillating charges should produce electromagnetic waves that travel at the speed of light, but Hertz was unable to test Maxwell's prediction due to the lack of laboratory equipment at Kiel.

In 1885, Hertz accepted a position at the Technische Hochschule in Karlsruhe, which had a well-equipped laboratory. There he met Elizabeth Doll, a professor's daughter, and married her in 1886. They had two daughters, Johanna, born in 1887, and Mathilde, born in 1891. Shortly after arriving in Karlsruhe, Hertz found some large induction coils that could produce a pulsed high voltage and a pair of spark micrometers with brass knobs forming an adjustable spark gap, which he hoped could be used to transmit electromagnetic waves as predicted by Maxwell. With a battery and an interrupter attached to the primary coil, he could obtain a pulsed high voltage across a secondary coil. He then invented a high-frequency oscillating antenna by forming a dipole with two metal spheres about three meters apart connected to the terminals of the secondary coil. He connected one of the spark micrometers between the two terminals, where the wires from the spheres were connected to act as a high-frequency switch.

To measure the frequency in this antenna oscillator, he used a loop of wire with an adjustable length connected to the other spark micrometer. Holding the loop close to the antenna oscillator, Hertz was able to adjust its radius until sparks would form in the gap when the resonant frequency of the loop matched that of the oscillator. He could then calculate the frequency of the loop to determine the corresponding frequency of the oscillator. He published his experiments with this oscillating antenna in 1887 in a paper entitled "On Very Rapid Electric Oscillations."

In the course of these measurements, he noticed that sparks would appear in the loop even when it was moved a few meters away from the antenna, and he realized that he was detecting electromagnetic waves from the antenna. This was in effect the invention of wireless radio, with his antenna oscillator as the first radio transmitter and his loop as the first radio receiver. He then did a series of experiments to show that these were electromagnetic waves, including measurements of frequency and wavelength, the product of which gave the speed of light as predicted by Maxwell. He also showed that these waves were like light in their reflection, refraction, polarization, and diffraction.

In the course of his experiments with what are now called radio waves, Hertz made the unexpected discovery of the photoelectric effect, in which light produces electricity. He first observed that the induced spark in his receiving loop was strengthened, as measured by the spark micrometer, when the light of the larger spark in the oscillator illuminated the induced spark in the loop. He also showed that the spark was enhanced even more when illuminated by ultraviolet light. These results were published in 1887 in his article "On an Effect of Ultra-Violet Light upon the Electric Discharge." After his discovery of radio waves was confirmed by others, Hertz received many invitations from universities and finally moved to the University of Bonn in 1889, where he began a study of cathode rays and wrote a book on mechanics. At Bonn, he had several operations on his head for malignant bones, and on January 1, 1894, he died of blood poisoning at the age of thirty-six.

Impact

The main impact of Hertz's work came from his invention of radio and the associated discoveries of radio waves and the photoelectric effect. Although Hertz was primarily interested in clarifying electromagnetic theory, and never mentioned applications of his work, radio opened up new communication technologies and new extensions of the electromagnetic spectrum. One of the earliest applications of radio waves was by the Italian engineer Guglielmo Marconi after reading papers by Hertz in 1894. Marconi replaced the spark gap between the ends of the dipole antenna with a tube of metal filings called a coherer, which greatly increased the current in the antenna. By 1896, he had succeeded in sending coded messages far enough to warrant a patent, and by 1898 he had transmitted signals from Ireland to Scotland. On December 12, 1901, he sent wireless signals across the Atlantic from England to Newfoundland, using balloons to lift his antennas as high as possible.

The work of Hertz clarified and confirmed electromagnetic theory, leading to both relativity and quantum theory. It opened up a new understanding of the entire spectrum of electromagnetic waves from radio to X rays, all of which travel at the speed of light but differ in frequencies and wavelengths. The absolute value of the speed of light was the basis for Albert Einstein's special theory of relativity, proposed in 1905. The photoelectric effect was studied systematically after Hertz died by his assistant Philipp Lenard, who showed in 1902 that the energy of photoelectrons increases with the frequency of the incident light that produces them. This discovery was used by Einstein in 1905 to confirm and generalize quantum theory, and it is the basis for such devices as digital cameras, in which light signals are changed into electric currents.

Peter Cooper Hewitt

American electrical engineer

Hewitt's invention of the bright and efficient mercury-vapor lamp provided an important component of industrial lighting through the first half of the twentieth century. With little loss of heat energy, the Cooper Hewitt lamp demonstrated the effectiveness of conveying electrical charges through gases and was a precursor to the fluorescent light.

Born: May 5, 1861; New York, New York
Died: August 25, 1921; Paris, France
Primary fields: Aeronautics and aerospace technology; electronics and electrical engineering
Primary inventions: Mercury-vapor lamp; mercury-arc rectifier

Early Life

Peter Cooper Hewitt was born in New York City in 1861. His father was Abram Hewitt, a successful manufacturer, businessman, and from 1886 to 1888, mayor of New York City. His mother was Sarah Amelia Cooper Hewitt. Sarah was the daughter of one of New York City's most famous residents, Peter Cooper, a brilliant inventor in his own right, wealthy industrialist, and philanthropic founder of Cooper Union. Grandfather Cooper taught mechanical skills to Peter and his other grandson Edward. He had a workshop with a lathe, forge, tools, and a steam engine built for the boys, and he hired a mechanic to teach them how to use the implements. When Alexander Graham Bell visited Cooper to explain the workings of his new telephone, Cooper called in Peter and Edward to see the demonstration. The boys returned to their workshop and built a makeshift phone. Strung across the street to a friend's house, it may have been the first house-to-house phone in New York City.

Peter Cooper Hewitt was educated by private tutors, at the Stevens Institute of Technology in Hoboken, New Jersey, and at Columbia University, where he specialized in economics, physics, and chemistry. Recognizing Hewitt's interest and talent for mechanical invention, his grandfather made available to him an old greenhouse as a laboratory for experimentation. Young Hewitt improved machinery in his grandfather's glue factory and invented new models of centrifugal machines and evaporators for use in New York's ubiquitous breweries.

On April 27, 1887, Hewitt married Lucy Bond Work. Given the prominence of the two families, the wedding was considered the social affair of the season, catered by Delmonico's restaurant. A few years later, Hewitt was involved in a well-publicized controversy with the New York police in May, 1890. Hewitt was leaving Madison Square Theatre when he argued with a hansom cab driver. The driver lashed Hewitt with his whip, and Hewitt smashed his cane on the driver's head. A police officer, not knowing Hewitt's prominence, arrested and manhandled him.

Life's Work

Hewitt received three important legacies from his distinguished family. First, he inherited a genius for mechanical invention from his illustrious grandfather and namesake, Peter Cooper. Second, like his grandfather, he followed unorthodox and intuitive methods in developing new technology, relying on experimentation and trial and error rather than theoretical science. Third, he inherited from his father a fortune that allowed him to pursue his scientific interests unhindered.

Working in his laboratory, which eventually occupied five floors in the Madison Square Garden Tower in New York City, Hewitt produced a steady stream of inventions around the turn of the century. Hewitt discovered that if he electrified a quantity of mercury in a vacuum tube, a vapor was formed that could conduct electric currents and produce other extraordinary phenomena. This discovery would become the basis of his life work. In 1898, he produced his most significant invention, the mercury-vapor lamp, also known as the Cooper Hewitt lamp (patented in 1901). It consisted of a quartz or glass tube containing mercury, mercury vapor, and wires connected to an electric current. The tube was sealed vacuum-tight. The contents of the tube conducted electricity to and from the vapor carrying the current. Designed to produce more light and less heat than incandescent lights, Hewitt's mercury-based lamp represented a pioneering effort in employing gases to conduct electrical charges.

Based on his research for the mercury-vapor lamp, Hewitt made other inventions that advanced knowledge of the interaction of electrical charges and gases. Because the light emitted from his lamp was a strange bluish-green color, without red radiation, Hewitt designed a transformer that restored parts of the color spectrum that had been eliminated. He invented the mercury-arc rectifier (also known as a static converter) in 1902. This invention converted alternating electric current into direct current, thus allowing the use of apparatuses designed to work on one kind of current to work on the other kind of current. Hewitt would receive the prestigious Elliott Cresson Medal in 1914 from the Franklin Institute for this important invention. A related invention was Hewitt's electrical interrupter, which could turn off high-tension currents and could make or break a circuit. Hewitt's final invention that grew out of his researches into charged vapors was a wireless telegraph receiver. This invention detected wireless telegraph signals by means of a mercury-vapor tube with an electrode. Hewitt's telegraph receiver increased sensitivity for detecting signals without increasing the possibility of burnout. Engineer, entrepreneur, and industrialist George Westinghouse purchased patent rights to the mercury-vapor lamp from Hewitt. In 1902, Westinghouse provided the capital to launch the Cooper Hewitt Electric Company to develop, manufacture, and market Hewitt's gas-based electrical lamps. Hewitt's productivity in his electrical researches was made possible by his disciplined work habits. He devoted mornings to his business interests and his afternoons and evenings to his scientific experiments. For recreation, he attended the leading social and athletic clubs in New York.

Peter Cooper Hewitt. (Library of Congress)

In the beginning of the twentieth century, Hewitt turned his attention to the engines and modes of transportation characteristic of the new age. As to the automobile, he improved a means of regulating engine speed and assisted his brother, Edward Hewitt, in the manufacture of the Hewitt automobile. As to watercraft, in 1907 he developed a motorboat that employed an eight-cylinder engine to lift the hull on four wing-shaped hydrofoils. With the hull freed from the friction of the water, the boat was able to achieve higher speeds. This motorboat was a precursor of high-speed hydroplanes. As to aircraft, Hewitt made several innovations. He wrote popular articles in 1908 in which he daringly predicted that air travel would one day be inexpensive and widely available. He received a patent in 1915 for an aerostat (balloon) envelope and supporting truss. In 1920, he acquired three patents for a prototype helicopter. Columbia University professor Francis Crocker assisted Hewitt in constructing a model of a machine that could elevate vertically.

Hewitt worked on behalf of American inventors as a member of the board of governors of the Inventors' Guild and as a member of the Naval Advisory Board. For use by the Navy, he designed an aerial torpedo. Columbia University awarded Hewitt an honorary doctorate in 1903, and Rutgers College did likewise in 1916. Hewitt's divorce from his first wife, Lucy, in December, 1918, made a minor sensation in the New York City papers, as they had been a prominent society couple in New York, lavishly entertaining in the Cooper Hewitt mansion on 11 Lexington Avenue in the Gramercy Park neighborhood. Hewitt married Maryon J. Bruguiere on December 21, 1918, only a few days after obtaining the divorce. (It was later revealed that Hewitt's only child, Ann, was born to Bruguiere in Paris in 1914; Ann would be involved in a notorious court case in 1936 over Hewitt's million-dollar estate.) Hewitt died in Paris in 1921.

Impact

Hewitt followed in the footsteps of his famous grandfather and namesake, Peter Cooper, in ingeniously inventing and improving a wide range of devices practical in the commercial world. His four most important inventions—the mercury-vapor lamp, the mercury-arc rectifier, an electrical interrupter, and a wireless receiver—were the result of his study of electric currents in a vacuum tube containing mercury. These devices not only were important industrial instruments but also demonstrated pioneering technological principles. The mercury-vapor lamp showed the effectiveness of employing the motion of electricity through rarefied gases and vapors. Hewitt's success with the lamp helped spur interest in this field of electrical science. His mercury-vapor lamp was also the forerunner of the fluorescent lamp. Hewitt's experiments demonstrated the importance of the rectifying characteristic of electrodes in rarefied gases and led to the invention of his wireless telegraph receiver. His rectifier allowed for direct current to be economically converted from alternating current at its final destination. Acting as a simple transformer, this rectifier was able to replace expensive and heavy rotary converters. Hewitt's research into the nature of moving electricity in a vacuum tube contributed to the development of the vacuum-tube amplifier for radio telephony. Hewitt was also a pioneer in the development of hydroairplanes, high-speed motorboats, and the helicopter.

Coming from a family of inventors and possessed of an independent fortune, Hewitt, nicknamed "the millionaire inventor," was able to fund his own experiments, unaffiliated with any institution. His curiosity and ingenuity produced a variety of inventions, improved by his unorthodox methods and imaginative techniques. As such, Hewitt represents a tradition of independent invention that would become increasingly rare in the twentieth century.

—*Howard Bromberg*

The Cooper Hewitt Mercury-Vapor Lamp

Peter Cooper Hewitt's low-pressure mercury-vapor lamp was designed to address one of the perennial problems of the electric light—the loss of energy through heat. In the first incandescent electric lamps, only about 3 percent of the energy was converted into illumination. The remaining 97 percent was lost, mostly as heat. In the 1890's, Hewitt began experimenting with electrical discharges to solve this problem. Cooper's lamp would demonstrate the ability of gas to conduct an electrical charge. Hewitt built on the work of German scientists Julius Plücher and Heinrich Geissler, who had succeeded in passing electric currents through glass tubes containing tiny amounts of gas. Hewitt experimented with passing electric currents through mercury-filled tubes. In 1898, he succeeded in developing a commercial lamp consisting of an elongated quartz tube containing mercury gas. He patented the lamp in 1901 (U.S. Patent number 889,692).

The lamp was activated by tipping so that the mercury would run from one electrode to the other. The lamp was made of hard borosilicate glass, and the mercury was sealed under high vacuum. With a current of 3.5 amperes, the lamp's total light output was about 6,900 lumens. An electric current from an anode electrode of iron or tungsten to a cathode electrode of mercury vaporized the mercury, emitting an intense but cool light. Because the emitted light was an unattractive bluish-green color, the lamp was not suited for domestic use. However, its greater efficiency in producing light, as much as eight times that of incandescent lamps, made it ideal for industrial purposes, such as in factory lighting, street lamps, and photography studios. The lamp was also helpful in a variety of chemical, therapeutical, and sterilizing operations.

The Cooper Hewitt Electric Company was only moderately successful, however, because of the almost pound of mercury required by each lamp. In addition, many improvements were being made to competing incandescent lamps, such as the use of more efficient tungsten filament. In 1919, the General Electric Company acquired the Cooper Hewitt Electric Company. In 1933, General Electric's Vapor Lamp Department began marketing a much improved high-pressure mercury-vapor lamp that had been developed in Europe and that used only a fraction of the mercury required by the older Cooper Hewitt lamps. General Electric ceased production of the Cooper Hewitt lamp in 1965. Although the lamp itself fell into disuse, it is of historical importance. As the Cooper Hewitt lamp pioneered the use of mercury vapor to create luminescence, it can be seen as the prototype of the modern fluorescent lamp.

William Redington Hewlett

American engineer

Hewlett cofounded the Hewlett-Packard Company, a manufacturer of computer hardware and software and one of Silicon Valley's first start-up companies. Hewlett's audio oscillator was the company's first financially successful product.

Born: May 20, 1913; Ann Arbor, Michigan
Died: January 12, 2001; Palo Alto, California
Primary fields: Computer science; electronics and electrical engineering
Primary invention: Audio oscillator

Early Life

William Redington Hewlett was born in Ann Arbor, Michigan, on May 20, 1913. His father was an influential physician and a faculty member at the University of Michigan. When Hewlett was three years old, his father transferred to Stanford University and the family moved to the San Francisco Bay Area. Hewlett's father died suddenly when Hewlett was twelve, but the family survived the hardship and the boy continued to benefit from the dynamic cultural, scientific, and literary surroundings in the growing San Francisco region.

Hewlett attended Lowell High School in San Francisco, but he did not do well there because he suffered from dyslexia—a language-based learning disorder very poorly understood or accommodated at the time. The dyslexic person has difficulty reading well, sometimes reversing letters as he or she reads or writes. As inconvenient as it is for anyone to master academic subjects with this condition, a number of dyslexics are excellent visual thinkers. Many scientists and inventors have discovered that they can clearly imagine new machines in their minds. This disability can be a surprising asset to the mechanically inclined if their true ability can be recognized early enough. Hewlett was fortunate to have his knack for understanding how things worked brought to the attention of his high school principal, who saw past his poor grades, urged Hewlett to enroll at Stanford, and encouraged the university to accept him.

Life's Work

Hewlett's life work began earlier than most with his entrance in college in 1930. Hewlett was again blessed to have found a mentor in Professor Frederick Terman, one of Stanford's most famous professors, who also had a large role in the development of the computer industry in Silicon Valley. Hewlett also met and became a close personal friend with David Packard—a vital friendship that developed into a synergistic, inventive collaboration and business partnership as they founded the Hewlett-Packard Company. When Hewlett graduated from Stanford in 1934, he went to the Massachusetts Institute of Technology (MIT), where he earned his master's degree in engineering in 1936.

That year, Hewlett returned to California to continue his graduate studies in engineering at Stanford, receiving a master of engineering degree in 1939. Professor Terman again significantly shaped the lives of both Hewlett and Packard by encouraging them to form their own company soon after they graduated. With little founding investment capital, the original headquarters of the Hewlett-Packard Company was in a garage. They also did not have money for a marketing survey to select a proper name for the company, so they decided to name it after themselves and flipped a coin to decide which of their last names would come first. The year 1939 was also important in that Hewlett married Flora Lamson. They eventually raised five children together.

In 1940, Hewlett invented the audio oscillator in his lab at Stanford, and it became the company's first commercial success. Eight of the machines—priced at $71.50 apiece—were sold to Walt Disney's new company to be used to create the 1940 hit film *Fantasia*. Far from being a stage prop for an animated movie, the audio oscillator was a valuable technical tool for physicians, clinical technicians, engineers, geologists, oil explorers, miners, the U.S. military, and others.

Hewlett-Packard founders William Redington Hewlett, left, and David Packard work on electronic counters at their factory. (Time & Life Pictures/Getty Images)

While Hewlett worked virtually his entire life at Hewlett-Packard, he did spend four years as an officer in the Army during World War II. Even then, his work was not far removed from technical engineering work. He first served on the staff of the Army's chief signal officer but was soon elevated to the head of the New Development Division of the War Department's Special Staff. In 1945-1946, he was on the special U.S. team that evaluated Japanese industry in the immediate aftermath of the war.

In 1947, Hewlett returned from the military to become the company's vice president, while Packard served as president. Hewlett moved up to executive vice president in 1957 (the year the company went public) and president in 1964, when Packard became chairman. Hewlett became the chief executive officer (CEO) when Packard served as the deputy secretary of defense in Richard M. Nixon's administration. Whatever the job titles, it is generally acknowledged that Hewlett and Packard worked well together.

Hewlett-Packard did not enter the minicomputer market until 1966. Nonetheless, its first computer, the 2116A, was truly innovative. Nearly all early computers were heat-generating, heat-sensitive, delicate machines requiring large and expensive air conditioning units for the rooms in which they were located. Most also had to be installed on spring-loaded floors to prevent damage from shaking. Hewlett-Packard planned its first computer as an instrumentation computer. As such, the company decided it needed to be as rugged and reliable as the other instruments with which it was to work. As a consequence, Hewlett-Packard is credited with inventing the first "go-anywhere, do-anything" computer. While Hewlett-Packard is most prominently associated with computers, it is important to remember that the company also provided a wide range of technical equipment for manufacturing, testing, measuring, copying, scanning, printing, and calculating.

In 1966, Hewlett and his wife founded the William and Flora Hewlett Foundation, which supports a number of educational and cultural institutions. Flora Hewlett died in 1977, and William married Rosemary Bradford the following year. He died in 2001 at the age of eighty-seven.

Impact

Hewlett had a significant impact not only on the invention and development of computers and their auxiliary products but also on the industry in general. He and Packard are credited with creating a productive corporate work environment in which employees were highly regarded. So famous is this aspect of the Hewlett-Packard corporate ethos that it has earned the sobriquet "The HP Way." Hewlett-Packard was one of Silicon Valley's first start-up companies and one of its most successful. At the time of Hewlett's death, Hewlett-Packard was the thirteenth largest corporation in the United States, with about ninety thousand employees in 120 countries around the globe and annual sales of nearly $50 billion.

—*Richard L. Wilson*

The Audio Oscillator

William Redington Hewlett created the prototype for the audio oscillator as a part of his engineering thesis work at Stanford University in 1938. After graduation in 1939, he refined the device, and it became Hewlett-Packard's first commercially successful invention, the Model 200A. An audio oscillator creates one frequency (pure tone) at a time. As such, it can be used to create or maintain telephones, stereo recording equipment, radios, or other audio equipment.

Hewlett realized that there was a need for a device that combined the stability of a coil-condenser oscillator with the more flexible operation of a beat-frequency type of oscillator. Such a machine would also need to be adjustable, simple in construction, light, and portable. The Model 200A was a completely new kind of oscillator in which the frequency-determinator was a resistance-capacity network. This invention achieved superior performance at a low cost by using a small light bulb in the oscillator circuit to provide negative feedback. The light bulb works with partial current. As the oscillator's signal strength becomes greater or lesser, the light bulb increases its consumption of current to a stronger or weaker degree to eliminate unwanted variations. Thus, the oscillator provides a steady output over its desired operational range.

One of Hewlett-Packard's first customers was the Walt Disney Company, which ordered eight of the machines to test sound equipment for its new Fantasound sound system for the full-length animated film *Fantasia* (1940).

James Hillier

Canadian American physicist

Hillier was a prolific research physicist who, with Albert Prebus, designed and built the first successful high-resolution electron microscope in the Western Hemisphere in 1938.

Born: August 22, 1915; Brantford, Ontario, Canada
Died: January 15, 2007; Princeton, New Jersey
Primary fields: Electronics and electrical engineering; medicine and medical technology; physics
Primary invention: Electron microscope

Early Life

James Hillier was born in Brantford, Ontario, Canada, to James and Ethel (Cooke) Hillier. His father was a mechanical engineer, a fact that may have played a role in the boy's interest in building and designing scientific equipment. As a child, he was interested in ham radio and spotting aircraft in the area. His father bought him a telescope so he could read the numbers on the planes as they flew overhead, and Hillier eventually converted the eyepiece into his first microscope. He expressed an early interest in art, music, and photography and also participated in swimming and boating. He attended high school at the Brantford Collegiate Institute, then completed his education at the University of Toronto, where he received three successive degrees in physics: a B.A. in 1937, an M.A. in 1938, and finally a Ph.D. in 1941.

James Hillier, standing, works with Vladimir Zworykin on an electron microscope, which Hillier invented with Albert Prebus in 1938. (Getty Images)

In 1938, then graduate student Hillier and fellow student Albert Prebus developed a prototype of the electron microscope by adapting the existing work of German scientists. This prototype later became the first commercially successful high-resolution electron microscope. In 1939, Hillier was made a research assistant at the Banting Institute of the University of Toronto Medical School in order to continue the development of the electron microscope. Hillier moved to the United States in 1940, where he was employed by the Radio Corporation of America (RCA) at its electronics research laboratory in Camden, New Jersey. In 1945, he became a U.S. citizen.

Hillier was married on October 24, 1936, to Florence Marjory Bell, daughter of William Wynship Bell in Erindale, Ontario. The couple had two sons: James Robert Hillier and William Wynship Hillier.

Life's Work

During the 1930's, medical science was struggling to understand the role of microbes in human and animal health. Many disease-causing organisms such as bacteria and viruses were too small to be viewed with traditional microscopes, as were human and animal cells. Medical advances were largely dependent on the sophistication of existing and emerging technology. After developing the electron microscope, Hillier took it to RCA, where he continued to make improvements to the device. Within a short time, he had the electron microscope operating near its theoretical limit of efficiency.

In 1940, Hillier designed the first commercial electron microscope to be made available in the United States, and he worked within the medical and biological sciences to develop useful applications of the electron microscope in those fields. Hillier eventually held more than forty patents for devices and processes for improving the fields of electron microscopy, electron diffraction, electron microanalysis, ultrathin sectioning, and virology and bacteriology. Among the most important patents he obtained were those for the electron microscope, the electron microanalyzer, the electron probe analysis employing X-ray spectrography, the method of and means for correcting for distortion in electron lens systems, the method of operating electron guns, the correction device for electron lenses, and the method and apparatus for electronically determining particle size distribution.

In 1942, Hillier was transferred to the RCA Laboratories at the David Sarnoff Research Center in Princeton, New Jersey, where he worked for the majority of his career, barring two brief periods: 1953 to 1954, when he was employed by another firm, and 1955 to 1956, when he was employed as the chief engineer of RCA Industrial Electronics Products in Camden. Having developed the electronmicroscope in its practical form, Hillier sought to introduce the electron microscope into general use as a new and powerful research tool, particularly for the biological and medical sciences as well as for metallurgical research studies. Hillier developed the electron microscope by pursuing engineering improvements in the instrument and developing new techniques for the preparation of biological specimens. During this exploratory and developmental phase, he invented the electron microprobe. In addition to his work on the electron microscope, Hillier also supervised the development of RCA's VideoDisc, a precursor to the digital video disc (DVD).

In 1945, Hillier coauthored *Electron Optics and the Electron Microscope*. During his career, he contributed numerous chapters and articles to scholarly texts, including the *Encyclopedia Britannica*, and more than 150 technical articles published in various professional journals.

In 1960, Hillier was corecipient, with Ernst Ruska of the Technical University in Berlin, of a Lasker Award, conferred jointly by the American Public Health Association for their separate work on the design, construction, and perfection of the electron microscope as an essential tool of modern medical research. In 1967, he was elected to membership in the National Academy of Engineering. Hillier eventually rose to wield corporate responsibility for all of RCA's research, development, and engineering programs. In 1980, Hillier was inducted into the National Inventors Hall of Fame for his development of the electron microscope. On April 17, 1997, he was appointed an Officer of the Order of Canada for this invention.

In keeping with his scientific and academic contributions, Hillier was a fellow of the American Physical Society, the American Association for the Advancement of Science, and the Institute of Electrical and Electronics Engineers. He was a member of the Electron Microscope Society of America (president, 1945), the National Academy of Engineering, and the American Management Association. He died on January 15, 2007, in Princeton.

The Electron Microscope

The first operative electron microscope was built in 1933 by German scientists Ernst Ruska and Max Knoll. Ruska and Knoll's microscope demonstrated all the principles of an electron microscope but could only magnify objects up to four hundred times. Further experiments later produced an electron microscope with resolution superior to a traditional optical microscope. In 1938, James Hillier and Albert Prebus, graduate students at the University of Toronto, created the first practical commercial electron microscope based on the work of Ruska and Knoll.

The electron microscope uses a particle beam of electrons to illuminate a sample and thus create a highly magnified image. Far superior to traditional light microscopes, modern electron microscopes utilize electromagnetic radiation and can magnify objects up to two million times. The electron microscope is capable of greater resolution and magnification because of the electron's wavelength, which is much smaller than that of a photon. The electron microscope controls an electron beam using electrostatic and electromagnetic lenses to form an image by focusing the beam at a specific plane relative to the sample in much the same way that an optical microscope uses glass lenses to focus light on or through a specimen to form an image.

Although modern electron microscopes can magnify objects up to two million times, they are still based upon Ruska's prototype, later perfected by Hillier and Prebus. The electron microscope has become an essential piece of equipment in many hospitals and laboratories around the world. Such microscopes are used to examine biological materials (such as microorganisms and cells) and a variety of large molecules, to detect cancer or tumors in humans and animals, and to examine metals and crystalline structures as well as the characteristics of various surfaces. More recent applications of the electron microscope include its use in inspection and quality assurance in industry, particularly semiconductor device fabrication.

Impact

Hillier and Prebus created the first practical electron microscope in North America based on the previous work of German researchers, who had been able to magnify objects by only four hundred times. Unfortunately, this magnification was within the range of traditional optical microscopes at that time. Hillier and Prebus's electron microscope managed to magnify objects seven thousand times their size by sending a stream of electrons through magnetic coils. This magnification was three times that of optical microscopes.

Hillier dedicated his research to producing a compact microscope that would be both more affordable and more effective for biomedical research than the bulky and expensive prototype. Early efforts at using the electron microscope for medical applications (such as microorganism and blood cell analysis) resulted in the destruction of the specimens by the powerful electron beam. With the help of others, Hillier developed successful methods using protective colloid film to prepare samples, thus allowing bacteria and cells to be viewed and analyzed, and eventually leading to the use of electron microscopy in biopsies.

Later in his career, Hillier helped correct the problem of astigmatism in the lenses used in the electron microscopes, and he worked on the development of a scanning electron microscope that was capable of producing even higher resolution images. Hillier's work on the refinement and application of the electron microscope has had a dramatic effect on the growth of many of the biomedical sciences, including virology, biology, immunology, cytology, and genetics, as well as the geological sciences.

DOROTHY CROWFOOT HODGKIN

English chemist

Hodgkin was an extraordinarily skilled and intuitive X-ray crystallographer who worked out the structure of cholesterol, penicillin, vitamin B_{12}, and insulin. She won the Nobel Prize in Chemistry in 1964.

Born: May 12, 1910; Cairo, Egypt
Died: July 29, 1994; Shipston-on-Stour, Warwickshire, England
Also known as: Dorothy Mary Crowfoot (birth name)
Primary field: Chemistry
Primary invention: X-ray crystallography

EARLY LIFE

Dorothy Crowfoot Hodgkin was born in Cairo, Egypt, on May 12, 1910. Her parents were John Winter Crowfoot, a supervisor of schools and antiquities for the British government, and Grace Mary (Molly) Hood, a self-taught botanist and botanical illustrator. Until she was four years old, she stayed with her parents and only occasionally visited England, but when World War I began, her parents left her in England with her sisters and a nursemaid. Only when the war ended four years later did her mother return to England to stay with her daughters.

Dorothy attended several private schools. When she was ten, she took a class that used a chemistry book that gave directions on how to grow copper sulfate crystals, which she made at home. At the time, chemistry was considered a suitable science for girls and women to study, and some chemistry sets were made especially for them. Dorothy got one and became fascinated with crystals and their regular, three-dimensional shapes.

While staying with her parents in the Sudan when she was thirteen, Dorothy met soil chemist A. F. Joseph, who helped her analyze a crystal she had found. He was so impressed by her that he gave her a surveyor's box and encouraged her to study analytical chemistry. Her mother later gave her a book on X-ray crystallography by William Henry Bragg that became her inspiration for her lifelong career.

Dorothy graduated from high school in 1928. She hoped to attend Oxford University to study chemistry, only to discover that she was not qualified for admittance because she had not studied Latin or a second science. Her mother taught her botany, and she studied Latin on her own and finally passed the entrance exams. Her gender severely restricted her life at Oxford, as there were strict limits on subjects female students could study or what they could attend socially. Here she began her studies of X-ray crystallography in earnest.

Life's Work

In 1932, after her graduation, Hodgkin was unable to find work. A. F. Joseph, the chemist she met in the Sudan when she was thirteen, suggested that she work for John Desmond Bernal at Cambridge University. With a grant for £75 and a gift of £200 from her aunt, Hodgkin was able to work with Bernal for at least one year. One day in 1934, Bernal succeeded in taking the first X ray of a protein crystal. Hodgkin was diagnosed with severe rheumatoid arthritis, which eventually crippled her hands and feet terribly.

In 1936, Summerville College, the women's college at Oxford, offered Hodgkin a teaching position after she finished another year with Bernal. She stayed as a research fellow at Summerville until 1977. In spite of her horrendous laboratory space in the basement of the Oxford University Museum with its antiquated equipment, Hodgkin began studying cholesterol and succeeded in describing its three-dimensional structure.

One of the difficulties in interpreting the X rays was calculating the distribution of the atoms in the crystals. A. L. Patterson, a physicist, developed an intricate set of calculations to do this. Thousands of tedious calculations were needed to figure out the arrangement of atoms in even a simple crystal, so Hodgkin was thrilled when C. A. Beevers and H. Lipson sold her two boxes containing 8,400 strips of paper that were preprinted with trigonometric values that reduced the Patterson equations to simple addition. Hodgkin also found that substituting one element for another in a complex crystal and then comparing the X rays of each gave her additional information about the element's placement. Looking at hundreds of X rays had also helped Hodgkin develop an intuitive sense of what she was observing.

Dorothy married Thomas L. Hodgkin in December, 1937, when she was twenty-seven. They had three children: Luke, Elizabeth, and Toby. Thomas appreciated Dorothy's work and encouraged her to continue. With his help, Dorothy was able to juggle her career and motherhood. A side benefit of having her children was that her arthritis greatly improved while she was pregnant.

At the beginning of World War II, Dorothy Hodgkin began deciphering the structure of penicillin. She believed that knowing its structure would enable its manufacture, as it would be sorely needed to fight infection among the wounded troops. Although penicillin is a small molecule, the molecules can align themselves in many patterns when they crystallize, making X-ray analysis very difficult. Nevertheless, along with her graduate

Dorothy Crowfoot Hodgkin. (©The Nobel Foundation)

X-Ray Crystallography

Before the development of X-ray crystallography, chemists were able to determine what atoms in what ratios made up a complex molecule, but they could not determine the three-dimensional placements of these atoms. X-ray crystallography and Dorothy Crowfoot Hodgkin's contributions to the science made determining complex molecular structures possible.

X rays were discovered in 1895 by Wilhelm Conrad Röntgen, and X-ray crystallography was first used at the beginning of the twentieth century. X rays are directed at a crystal, and the beams are scattered in specific directions by the electrons in the molecules. The scattered beams appear as spots on the X-ray film, making a diffraction pattern. The crystallographer then measures the angles and intensities of the patterns and through a series of calculations can determine the density of the electrons in the crystal. The positions of the atoms can be determined from the positions of the electrons. At first, X-ray crystallography was used to determine the bond types of simple inorganic compounds such as the ionic bonds in table salt and the tetrahedron structure of the carbons in diamonds. It was also used to determine the arrangement of atoms in minerals and metals. Later, the technique was applied to simple inorganic compounds such as hexamine, which contains twenty-two atoms.

The use of X-ray crystallography to solve the structures of complex biological compounds was very much the innovation of Hodgkin. She used Linus Pauling's rules for how atoms form crystals based on their electrical charges and for determining approximate sizes of atoms as a starting point. In large molecules that had one unique atom, she developed a technique to locate the specific atom by a substituting a different atom in the molecule and using the change this made on the X rays to pinpoint the atom's position. She used this technique to determine the position of the cobalt atom that was in a cyanide group in vitamin B_{12}. She replaced the cobalt with an atom of selenium, took X rays of the new crystal, and compared the results with X rays of vitamin B_{12}. Her studies of crystals led to her discovery of the hitherto unknown corrin ring, which proved to be a major contribution to organic chemistry.

Calculations were essential to computing positions of atoms in a molecule. At first, Hodgkin used A. L. Patterson's computations, her Beevers-Lipson paper strips, and maps of electron densities that she drew based on the computations to determine the structures of the compounds, but this was tedious and slow. She was one of the first to recognize the importance of computers, and as computers developed, she was able to exploit their growing power to perform the complex calculations much more rapidly than she could do using the Beevers-Lipson strips. The development of the computer allowed Hodgkin to determine electron densities for increasingly complex biological molecules. Largely because of her pioneering work, X-ray crystallography continues to be an important tool for chemists working on complex molecules.

student Barbara Rogers-Low, Hodgkin worked out the structure. The two performed their mathematical analyses on an early analog computer from International Business Machines (IBM) that was being used during the day to track British cargo ships, but they were allowed to use it at night, giving the keypunchers data in which the atoms of the penicillin molecule were labeled as cargo shipments. As computers improved in the following decades, their use became invaluable to X-ray crystallographers.

As knowledge of her ability as an X-ray crystallographer spread, both Hodgkin's career and laboratory facilities grew. In 1947, she became the third woman to be elected to the Royal Society of London. She moved into a modern laboratory in 1958, and in 1960 the Royal Society procured for her an endowed chair at Oxford, the Wolfson Research Professorship.

In 1948, a representative of a drug company gave Hodgkin some vitamin B_{12} crystals to analyze. It was known that B_{12} combats pernicious anemia, but without its structure the company could not manufacture it in quantity. Six years and twenty-five hundred X rays of the crystal later, Hodgkin had a massive bank of data but could not analyze it with only her Beevers-Lipson strips. A professor from the University of California, Los Angeles, offered her use of his high-speed computer; via telegrams, letters, and phone calls between England and California, the computations were completed and the structure of B_{12} worked out.

In 1964, Hodgkin won the Nobel Prize in Chemistry for her work. For most of her career, Hodgkin had tried to decode the structure of insulin, a huge molecule composed of 777 atoms. Now that computers were sophisticated enough to handle the massive calculations needed to analyze the X rays, Hodgkin decided to have another go at insulin. In 1969, she published its structure.

Throughout her life, Hodgkin had been an advocate for world peace and harmony, and in her later life her political views created problems with her scientific pursuits. In the Cold War years, she helped organize the International Union of Crystallography so that crystallographers worldwide could share information regardless of the country they lived in or their political views. When they tried to meet in the United States, the United States would not admit Eastern Europeans or Soviets into the country. In 1953, Linus Pauling hosted a conference on protein structures in the United States, but the State Department would not grant Hodgkin a visa because of her communist leanings. Her attempts to bring countries together in peace was not all for naught. Margaret Thatcher, the prime minister of Great Britain from 1979 to 1990, was one of her former chemistry students, and in the late 1980's Hodgkin wrote to her suggesting she visit the Soviet Union to improve relations between the Soviets and Great Britain. Thatcher did, and her visit was fruitful.

Hodgkin retired in 1977 to her home in a village north of Oxford. She died in her home on July 29, 1994, at the age of eighty-four.

Impact

Hodgkin's contributions to chemistry are basically twofold. First, her lifelong work in X-ray crystallography created major advancements in the field and proved that the technique could be used successfully on huge molecules such as proteins, hormones, and vitamins. Second, her discoveries of structures of vitamin B_{12}, insulin, and penicillin helped other researchers better explain their functions and allowed for their synthesis in mass quantities.

Robert Burns Woodward at first disagreed with Hodgkin on the structure of penicillin, thinking that it was a tricyclic structure containing a thiazolidine ring, but Hodgkin proved through her X-ray crystallography that it actually contained a beta-lactam ring. Her description of the actual structure allowed Woodward to produce a semisynthetic version of penicillin. After Hodgkin had deciphered the structure of vitamin B_{12}, Woodward began work on synthesizing it. It took eleven years, but finally Woodward succeeded. His work led to the development of the Woodward-Hoffman rules to predict the stereochemistry and symmetry of molecules and led to a Nobel Prize for Woodward.

Hodgkin described the structure of pig insulin, which differs from human insulin by one amino acid. Her description of the structure of the hormone led to a better understanding of how the molecule actually functioned. Her work allowed manufacture of synthetic insulin in the 1980's, although later production of human insulin was made possible by recombinant DNA synthesis.

Richard March Hoe

American mechanic

Hoe was a manufacturer and inventor of printing presses in nineteenth century New York City. His cylinder rotary presses for printing newspapers were so much speedier than the older flatbed models that they have been credited with helping create the modern world of mass-produced journalism.

Born: September 12, 1812; New York, New York
Died: June 7, 1886; Florence, Italy
Primary field: Printing
Primary invention: Rotary printing press

Early Life

Richard March Hoe was born to Robert and Rachel Mead Smith Hoe in New York City in 1812. Richard was their fourth child and oldest son. He attended New York's public schools until he was about twelve, when he went to work in his father's pattern shop. After eighteen months of work, he returned to high school. At the age of eighteen, Hoe began working in his father's factory. Robert Hoe had started a company for printing presses, long and circular saws, and other tools with his brother-in-law Peter Smith in 1805. Robert and Peter manufactured two kinds of presses, the cast-iron "Smith" and the platen "Washington." Both presses operated on a flatbed model in which a roller traveled backward and forward inking the paper. At the time Richard joined the firm, Robert Hoe was experimenting with cylinder presses. Richard inherited his father's mechanical ability and his ingenuity as to both the manufacturing and business aspects of Smith, Hoe & Co.; he also received a thorough education in every aspect of the enterprise. During the 1830's, Richard Hoe served as commander of the New York National Guard unit, the Washington Greys, achieving the rank of colonel, the title by which he would be known throughout his life.

Life's Work

Robert Hoe, in declining health, retired in 1830, leaving management of the factory to Richard and Peter Smith's son Matthew. Richard Hoe immediately set about improving the printing presses along the lines of a cylindrical operation with which his father had begun experimenting. In 1833, he introduced a single-cylinder press, adapted from presses operating in England. This press operated on a flatbed, but Hoe set the type in a fixed cylinder, with impression cylinders that held the sheets of paper and rotated around the type. Hoe also patented a novel method for grinding circular saws, which gained widespread usage.

In 1837, Hoe made further progress in the use of cylinders in his presses, introducing a double small-cylinder press and a single large-cylinder press. These presses were very popular and were used for books, prints, and woodcuts. Nevertheless, the firm was often short on funds and in 1842 went temporarily bankrupt. Hoe's innovations continued, however. In 1844, he developed an adjustable type-high bearer on each side of the press bed, which improved the press's impression control. In the late 1840's, he developed methods for heating ink fountains so as to enhance viscosity, a double rack and sliding pinion drive mechanism, and a sheet delivery system called a flyer. He also patented new devices for toothing and grinding saws.

Hoe continued to experiment on a high-speed press that would satisfy the need for quickly produced newspapers. His great breakthrough came in 1846 with his invention of the four-cylinder rotary press—the "lightning"—making use of a central revolving cylinder with type-beds and four rotating impression cylinders. As each impression cylinder was able to print two thousand sheets an hour, the four-cylinder rotating press was able to print eight thousand sheets in that time. Over the next few years, Hoe continued to improve his rotary press until it could run with ten impression cylinders. The press had become a massive machine, more than twenty feet high and thirty feet long, staffed by a crew of about fifteen workers running the machine and feeding sheets of newsprint. As the ten-cylinder press was able to make twenty thousand paper impressions an hour, it was quickly adopted throughout the world.

Matthew Smith died prematurely in 1841, and Hoe's younger brothers, Robert Hoe II and Peter Smith Hoe, joined R. Hoe & Company under Richard Hoe's leadership. Hoe built a new factory between Broome and Grand Street, taking up an entire New York City block and covering more than four acres of floor space. Hoe was a farsighted employer, establishing a free apprentice school at night for his employees, a mutual relief society for disabled workers, and cooperative stores supplying goods for his employees at reduced prices. With his factory profits, Hoe became wealthy, branching out to Chicago and London. He also continued to improve his presses, introducing a stop-cylinder press for litho-

graphic and letter-press printing and a collecting cylinder, called an accumulator, in 1853. In 1871, making use of a gathering and delivery device invented by his partner Stephen Tucker, Hoe designed a press that printed from a continuous roll, or web, of paper. This press represented a significant advance because it could automatically feed paper and print on both sides. As a result, it was able to print eighteen thousand newspapers an hour. In 1881, the company introduced a triangular former folder.

Throughout his career, Hoe demonstrated that he was capable of combining his mechanical aptitude with shrewd and adroit industrial management. Acquiring the Isaac Adams Press Works in Boston in 1859, he successfully integrated its operation into his New York plant. He utilized the innovations of his partners, such as Tucker, and competitors, such as William Bullock of Philadelphia, who first patented the web press. Hoe's printing presses won two awards at the famous 1876 Centennial Exhibition in Philadelphia. His branches in San Francisco, Chicago, and England thrived, as did his London repair shop. As a magnate and philanthropist, Hoe bought real estate, served as a director of the Magnetic Telegraph Company, and supported the New York House of Refuge.

Hoe had two daughters, Emily (born 1834) and Adeline (1836), with his first wife, Lucy Gilbert. After her death in 1841, he married Mary Say Corbin, with whom he had Anne (1852), Mary (1854), Fannie (1855), and Helen (1858). He named his stately home Brightside, located on fifty-three country acres in what is now the Bronx, and filled it with expensive works of art and fine, rare books. In 1886, on one of his frequent European trips, he died in Florence, Italy. His nephew Robert Hoe, who had worked for him for many years, took over the firm.

IMPACT

In a sense, the history of printing technology is the constant search for speedier printing presses. With mechanical skill and technological ingenuity inherited from his father, Richard Hoe was well suited to advance this search. His father's printing company had already been successful in producing cylinder presses, an important advance over the hand press. Hoe accelerated this development. His cylinder rotary presses reached a speed of twenty times that of his father's presses. Where it formerly took a day to print thirty thousand newspapers, it could now be done in two hours. It soon became apparent that it was more economical to produce mass-circulation newspapers by typesetting a single Hoe lightning press than by running several smaller machines simultaneously. As a result, his presses were adopted throughout the

United States, the English-speaking world, and Europe. Hoe's industrial success was counted as one of the first examples of the United States being able to compete against the industrial might of Britain and France. Over the following decades, R. Hoe & Co. continued to improve its presses, to the great satisfaction of the publishing world. His web perfecting presses of the 1870's were able to print both sides of a page in a single impression.

Richard Hoe was the owner of a factory and was himself one of the chief innovators and inventors in his industrial field. In this way, he resembles other American inventors of the nineteenth century, such as Peter Cooper, Thomas Alva Edison, and Samuel F. B. Morse, who also combined entrepreneurial leadership and mechanical invention to reach industrial and scientific success and great wealth. Whether this combination of business and invention in the nineteenth century was a uniquely American phenomenon—or in the case of Hoe and Cooper, a uniquely New York one—is worth investigating.

With the rise of Jacksonian democracy in the 1830's, the United States entered its golden age of newspapers. The common people were made aware of political developments, social events, and the bustling progress of the industrial world through a proliferation of inexpensively produced and widely circulating newspapers. Great newspaper enterprises were founded by such men as Horace Greeley, Joseph Pulitzer, and William Randolph Hearst. This golden age of journalism, so integral to the growth and democratization of the United States, relied to a large extent on the technological advances in the printing presses of Richard Hoe and his company.

The Hoe Four-Cylinder Rotary Press

Richard March Hoe's four-cylinder rotary press—the "lightning"—represented a revolutionary advance in printing. The earlier cylinder presses, resting on a flatbed, were able to print only one page with each back-and-forth rolling motion. Hoe's breakthrough was replacing the flatbed with a large rotating cylinder against which the paper would roll. He fastened cast-iron typeset around the circumference of the horizontal cylinder and grouped four smaller impression cylinders around the central cylinder. As the impression cylinders rotated around the central cylinder, each was able to impress two thousand sheets an hour. Two inking rollers distributed ink to the large type cylinder. Workers at each end, usually boys, fed the sheets into the impression cylinders; a crew of some ten men worked the machine. The speed of the printing could be accelerated by increasing the speed of the revolving central cylinder and by increasing the number of impression cylinders, which eventually reached ten. Thus the rotating press was able to increase the speed of newspaper printing by about an order of twenty.

After several years of development, Hoe patented his rotary press—also known at the time as the lightning printing press, the Hoe perfecting press, and the cylindrical-bed press—on July 24, 1847 (U.S. Patent number 5,199). It was first installed at the Philadelphia Public Ledger Office in March, 1847. It was by far the most efficient press for printing newspapers in its day and created a sensation. The press was speedily adopted in England; the British Privy Council called the "lightning" the "greatest step" taken in the art of printing. The *New York Sun* ordered a rotary press in 1849 for $20,000 and held a banquet in New York's Astor House to celebrate the occasion. When the *New York Tribune* installed its rotary press in 1850, it was the ninth made by the Hoe company. Soon Hoe was selling six- and ten-cylinder rotaries for about $25,000 a machine. In July, 1861, Hoe's patent for his rotary printing press was renewed for a seven-year term, the patent office concluding that additional millions of dollars would be made from the machine, in addition to the $78,681 already realized. Historian of the printing press James Moran described the rotary press as revolutionizing printing, not only for its speed but also for replacing a skilled printer at the helm with a mechanic or engineer. In this way, the rotary press symbolized the industrial age, when mass mechanical production replaced the work of a craftsman.

The cylinder rotary press remained the industry standard for several decades until the development of a machine that could print a continuous roll, or web, of paper. Even then, Hoe was able to adapt the techniques of his rotary press to the new machine. With the help of Stephen Tucker, R. Hoe & Co. manufactured a web press in 1873 that could print, cut, and deliver eighteen thousand newspapers an hour. In 1875, Tucker patented a rotating folding cylinder that could fold newspapers as soon as they emerged from the press. With these several decades' worth of improvements to Hoe's original four-cylinder press, Hoe's company was manufacturing the first modern newspaper printing presses.

of North Carolina Press, 2007. Describes the burgeoning publishing industry of mid-nineteenth century United States, including the contribution made by Hoe's rotary and web presses.
Comparato, Frank. *Chronicles of Genius and Folly: R. Hoe Company and the Printing Press as a Service to Democracy*. Culver City, Calif.: Labyrnthos, 1979. Includes a preface by Hoe's descendant (great-grandson of Hoe's nephew) and namesake, Richard March Hoe, who worked at the company in the 1960's. Comparato's tome is a sprawling, thousand-page history of printing, U.S. journalism, and R. Hoe & Co. based largely on Stephen Tucker's memoir. Comparato claims that Hoe's rotary press "created a modern world of journalism."
Kaplan, Richard. *Politics and American Press: The Rise of Objectivity, 1865-1920*. Cambridge, England: Cambridge University Press, 2002. Explores the relationships between political parties and partisan journalism. Emphasizes the importance of technological advances such as the Hoe cylindrical press.
Tucker, Stephen. "History of R. Hoe and Company, 1834-1885," *Proceedings of the American Antiquarian Society* 82, pt. 2 (1972): 351-453. Originally written about 1890 by Tucker, Hoe's partner and an outstanding mechanical inventor in his own right. Although this is a general history of the company, Tucker focuses on the projects that he supervised.

Ted Hoff

American engineer

Hoff placed the entire circuitry of a computer's central processing unit (CPU) on a single chip that could be mass-produced by photolithographic methods. His development of the microprocessor made the digital revolution possible.

Born: October 28, 1937; Rochester, New York
Also known as: Marcian Edward Hoff, Jr. (full name)
Primary field: Computer science
Primary invention: Microprocessor

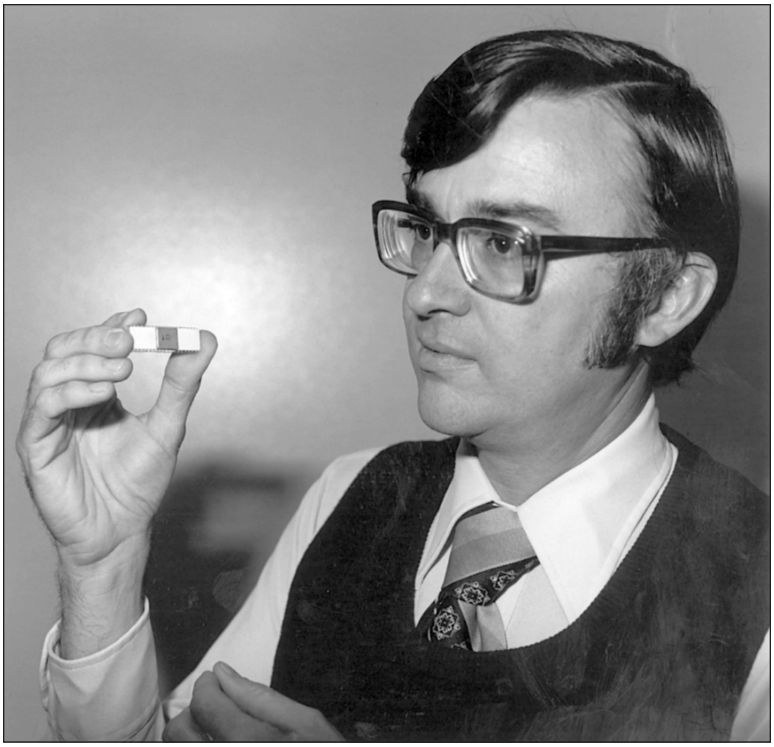
Early Life

Marcian Edward Hoff, Jr., was born in Rochester, New York, on October 28, 1937. His education began in a one-room schoolhouse near the village of North Chili, not far from Rochester. There, a single teacher would instruct the children in all eight grades. In this setting, Hoff was exposed to the work done by older students, and it was relatively easy for him to move to more advanced work even if his classmates were not yet ready.

Hoff's father worked for the General Railway Signal Company, which produced and maintained the signal system that allowed trains to function smoothly. The elder Hoff talked about his work with his son, awakening in him an early fascination with electronics. Hoff's uncle showed him the wonders of chemistry, once pouring two clear liquids together and making them turn bright red. Hoff found the phenomenon so fascinating that he voraciously read everything he could about chemistry, and he took the New York State chemistry examination on the basis of his independent work, scoring very high. However, his uncle warned him that there were few jobs for chemists and that he would be better off studying chemical engineering.

Hoff decided instead to apply his knowledge of chemistry to the newly developed field of semiconductor electronics. At Churchville-Chili Central High School, he maintained an avid interest in electronics and at age fifteen won a $400 scholarship and a trip to Washington, D.C., from the Westinghouse Science Talent Search. In 1954, he entered Rensselaer Polytechnic Institute, one of the oldest technological institutions in the United States. His fellow students would later recall him as a brilliant and inquisitive person, but never one to flaunt his intellect or belittle others. More than once he would finish projects at the last minute but still turn out excellent work. During his summers, he worked with General Railway Signal Company, where his contributions to two different projects led his name to be included on the patent applications.

After he earned his bachelor's degree in 1958, Hoff went to Stanford University for his master's degree and doctorate, specializing in electrical engineering. He continued to do practical work, leading to two more patents in his name. His doctoral dissertation was on neural networks and learning. After earning his Ph.D. in 1962, Hoff spent another six years as a research associate at Stanford.



Ted Hoff holds a microprocessor chip he invented at Intel. (Intel)

LIFE'S WORK

In 1968, Hoff became the twelfth employee at Robert Norton Noyce and Gordon E. Moore's new start-up company, Intel. Noyce was impressed with the practicality of Hoff's academic research and was hoping that Hoff would be able to develop commercial applications for the integrated circuits that Intel was making. At the time, the integrated circuit was relatively simple. Once the processes it would run were burned into its circuitry, it was capable of doing only that one thing. As a result, devices based on integrated circuits required a large number of circuits, one for each process or function. For simple functions such as basic bookkeeping mathematics, mechanical adding machines were still more cost-effective, although they were prone to breakdown as their gears wore down with use.

While working on an assignment for a Japanese calculator company, Hoff began to see the limitations of the integrated circuits. To build a complex, multifunction calculator with hardwired chips would tax the abilities of the entire team at Intel. There were simply too many chips that would have to be designed. If instead it was possible to design a chip that could read programs from memory, execute them, and then remove them when finished, this single chip could do hundreds or even thousands of different functions. It would be easy to create a machine that could do almost any range of functions, limited only by the amount of memory included in the memory chips.

Noyce encouraged Hoff to continue exploring the idea even after the commissioning company showed little interest in it. With the aid of fellow employee Federico Faggin, who designed the actual chips themselves, Hoff developed an entirely new architecture for integrated circuits. This new design took all the circuitry of a computer's central processing unit (CPU) and etched it onto a single piece of silicon. The resultant chip contained 2,300 transistors and had a computing power equal to that of the Electronic Numerical Integrator and Computer (ENIAC), the first general-purpose electronic computer. Moreover, while ENIAC and its ilk required a cabinet the size of a desk to hold all CPU circuitry, Hoff and Faggin's microprocessor chip was hardly bigger than a human thumbnail. Even with the protective ceramic casing and the lead wires for its socket, it was still hardly bigger than a postage stamp.

However, Noyce and Moore knew that the development of the CPU chip, which they called the Intel 4004 (released in 1971), was not an unbeatable coup. Thus, Hoff's team was set to work on a successor chip, the 8008 (introduced in 1972), which contained twice as many transistors and was faster than its predecessor. In 1980, Hoff was made an Intel Fellow, the highest technical position at Intel. However, in 1983 he left Intel to become vice president of corporate research and development at Atari, which had gained its reputation in the arcade game industry and subsequently expanded into console game systems for home use. At the time, Atari was starting to build machines that went beyond gaming to include general-purpose computing functions. However, Atari was already in financial trouble, and a year after Hoff moved, it was sold. Hoff found the new management less than congenial to his interests, so he left to start his own consulting firm, setting up an office and lab in the garage of his Sunnyvale home. He found consulting particularly agreeable because of the freedom it afforded him: He

The Microprocessor

The microprocessor is the key technology of the digital revolution, much as the steam engine was central to the Industrial Revolution. The microprocessor is an outgrowth of the integrated circuit, which in turn was a response to the "tyranny of numbers" that developed as transistors replaced vacuum tubes. Because discrete transistors were so small, it was very difficult to solder all of them into a circuit board properly. If the transistors could all be made together on a single wafer of silicon along with the necessary circuitry to connect them, the only limits to the complexity of a circuit was the ability of chip designers to lay out the masks for the photolithography, the main process used to create microchips.

When Intel was approached by the Japanese corporation Busicom to design the chipset for a new electronic calculator, Ted Hoff saw several ways to simplify the design, combining single-function integrated circuits into more complex ones. Eventually, he was able to reduce the design to three chips, a read-only memory chip in which key functions would be hardwired, a random-access memory (RAM) chip to provide the calculator's working memory, and a central processing unit (CPU) in which actual calculation would be carried out.

Intel chief executive officer Robert Norton Noyce immediately recognized the value of the microprocessor design, but the terms of the agreement by which Intel had undertaken the project assigned all rights to the chips to Busicom. However, Busicom soon ran into financial difficulty, and as a result Intel was able to buy back the rights to what would become the 4004 microchip, the first "computer on a chip," which Intel publicly introduced on November 15, 1971. Even as general production was begun, Hoff and his team were already hard at work designing its successor, the 8008.

Subsequent processors would include the famous X86 family, including the Pentium and the Xeon, as well as Motorola's 68000 and PowerPC chip families. The microprocessor made the personal computer (PC) possible, and microcomputers were designed from the microprocessor chip, generally by young hobbyists such as Apple Computer cofounders Steve Wozniak and Steve Jobs rather than by the corporate interests that built mainframe computers. Only when companies such as Apple Computer proved the market for the microcomputer did International Business Machines (IBM) move into that niche with the 8088-based PC.

The utility of the microprocessor was not limited to general-purpose computing. By the 1990's, microprocessors were increasingly used in runtime applications as microcontrollers, embedded devices that imparted "intelligence" upon ordinary appliances. They enabled many ordinary things to work more efficiently. For instance, embedded controllers could regulate the functions of the engine of an automobile far more accurately than mechanical systems, thus greatly increasing fuel economy. In addition, they made possible such devices as cellular phones, CD and MP3 players, and handheld organizers.

could pick projects of interest to him without having to justify them to corporate management.

In 1986, Hoff decided to return to the corporate fold, becoming vice president and chief technical officer with Teklicon, a company specializing in expert witnesses for patent infringement litigation cases. However, he continued to maintain his home laboratory and to work in his spare time on various projects. Hoff has received a wide variety of honors, including the IEEE Computer Society Pioneer Award, the Rensselaer Polytechnic Institute's Davies Medal, the Stuart Ballantine Medal from the Franklin Institute, and induction into the National Inventors Hall of Fame.

Impact

Hoff's creation of the microprocessor revolutionized the computer industry. For the first time, a single piece of silicon could be a general-purpose programmable computer. The chip's small size and inexpensive manufacture placed computers within the reach of ordinary people for the first time and allowed the integration of computer technology into a wide variety of applications.

JOHN PHILIP HOLLAND
Irish American engineer

Holland was a submarine engineer who developed the USS Holland, *the first submarine to be commissioned by the U.S. Navy. His patents include many advances in submarine engineering, including screw propeller propulsion, steering apparatuses, engines, dive mechanisms, and guns.*

Born: February 29, 1840; Liscannor, County Clare, Ireland
Died: August 12, 1914; Newark, New Jersey
Also known as: Seán Pilib Ó Maolchalann
Primary fields: Military technology and weaponry; naval engineering
Primary invention: Modern submarine

EARLY LIFE

John Philip Holland (HAHL-luhnd) was the second of four sons born to John Holland and Máire Ní Scannláin (Mary Scanlon). His father was a rider for the Coastguard Service, giving young Holland an interest in boats at an early age. When his father and one brother were lost to the 1847 Irish potato famine, his mother moved her remaining family to Limerick. Holland attended the Christian Brothers School in Ennistymon and later the Sexton Street School in Limerick. Two strong influences on Holland were Brother Bernard O'Brien and Brother Dominic Burke. Brother O'Brien, one of his science instructors and an accomplished mechanic, built telescopes that used clockwork mechanisms to track movements of celestial bodies and expanded Holland's interest in mechanics. Brother Burke, a renowned science teacher, researched the use of electricity for underwater propulsion. Burke encouraged Holland's investigations of both submarines and flying machines.

When asked to teach for the Christian Brothers, Holland accepted, joining the Order of the Irish Christian Brothers as Brother Philip. He taught at several schools throughout Ireland. In 1869, while teaching in Dundalk, he developed his first submarine design. In 1872, Holland reached the point where he would have to take his perpetual vows or leave the order. His mother and brother Alfred had already left Ireland for the United States, and Holland decided leave the Christian Brothers behind to follow them, departing Liverpool on May 26, 1873, for Boston, Massachusetts.

LIFE'S WORK

Holland's brother Michael was a member of the Fenian Brotherhood, a group of militant Irish nationalists, and in 1876 he induced Holland to help the Fenians develop a submarine that could be carried aboard a merchant ship, launched with its three-man crew through an underwater door, place an underwater explosive beside a British vessel, and then return to base. Holland built the *Fenian Ram* at the Delamater Iron Works in New York, and it was launched in May, 1881. It was thirty-one feet long and could cruise at nine miles per hour on the surface and seven miles per hour underwater. Much of the mechanisms on the submarine operated using compressed air, including the underwater pneumatic gun. When Holland and the Fenians disagreed over his payment, the Fenians stole the *Fenian Ram* and a sixteen-foot model of the submarine. Holland's relationship with the Fenians abruptly ended with this incident, and twenty years later, Holland sold his design to the British navy.

Following his debacle with the Fenians, Holland took a job as a draftsman with the Pneumatic Gun Company, owned by Army lieutenant Edmund Zalinski. With Zalinski, Holland formed the Nautilus Submarine Boat Company, named for the submarine in the Jules Verne novel *Twenty Thousand Leagues Under the Sea* (1870), which had been an inspiration to Holland. The fifty-foot-long "Zalinski Boat," officially named the *Holland IV*, was built at Fort Lafayette and completed in 1885. It was fitted with a petroleum-powered engine, a periscope, and Zalinski's compressed-air guns. The company planned to sell the boat to France to use in its war in Indochina, but the war ended before the boat's completion. Unfortunately, the wooden hull of the boat was damaged during its launch on September 4.

Holland and Margaret Foley were married in Brooklyn, New York, on January 17, 1887. Their first son, John, Jr., and later a daughter, Mary Josephine, died in infancy, but their three other sons and two daughters survived to adulthood.

In 1888, the U.S. Navy became interested in submarine technology and announced a competition for the design of a submarine that could stay submerged for two hours, withstand pressures to 150 feet, and run at fifteen knots on the surface and eight knots while submerged. Holland won the competition, but no contract was awarded. In 1889, the government reopened the competition, and once again Holland won. This time, the money that was to be awarded to Holland was diverted by a new administration to fund completion of naval ships that were already under construction. Once again, in 1889, the U.S. Navy held a third competition, which again Holland won. On March 3, 1895, the John P. Holland Torpedo Boat Company was given its $200,000 grant to build the submarine *Plunger*. Unfortunately, the money came with interference from Navy technicians who had many impractical specifications; for example, while Holland intended to use a diesel engine in the submarine, the Navy required that he install a steam engine, which produced too much heat and too little power. Their attempt to build the unworkable ship almost bankrupted Holland's company.

While building the *Plunger*, Holland, using private funds, began work on the gasoline-powered *Holland VI*. His new submarine, his own design built to his own standards, was a major improvement and set the stage for the construction of modern submarines. The *Holland VI* had dual-propulsion systems, two separate ballast systems, an improved hydrodynamic shape, and a modern weapons system. Holland offered to trade the ship's design to offset the *Plunger* debts, but the Navy refused, forcing Holland to sell his company. The new owners renamed it the Electric Boat Company. In 1900, the U.S. Navy did finally buy a modified version of the *Holland VI*, commissioned as the USS *Holland*.

Holland designed another submarine, the *Holland VII*,

The *Holland VI*

With a length of 53 feet, 9 inches, a diameter of 10 feet, 3 inches, and a displacement of 74 tons, the *Holland VI* was John Philip Holland's finest submarine design, incorporating many of the mechanisms and components of modern submarines: dual propulsion, ballast systems, hydrodynamic shape, a fixed center of gravity, and modern weapons systems. The concept of having one propulsion system to operate a submarine on the surface and another while underwater had been proposed before, but Holland developed the first practical system. On the *Plunger*, with the requirements the U.S. Navy imposed on its design, Holland had to use steam to propel the submarine on the surface, but the steam engine used up an inordinate amount of space and produced high interior temperatures that were intolerable to the crew. The *Holland VI*, on the other hand, was fitted with a diesel-powered engine that could charge the submarine's electric batteries while operating. When submerged, the submarine used an electric motor powered by batteries. The *Holland VI* could travel one thousand miles on the surface with its diesel engine and thirty miles underwater on battery power.

The *Holland VI* was the first submarine to use a main ballast tank to control its descent and surfacing, and a secondary system to adjust for changing loads and torpedoes. The submarine originally had three ballast tanks: a main tank, an aft ballast tank, and a trimming tank in the bow. When the submarine was overhauled in 1899, two additional trim tanks were installed in the aft section of the submarine. With the *Holland VI*, Holland abandoned his earlier symmetrical ship design for one in which the maximum diameter of the circular superstructure was forward of amidships. He also had his propeller in the centerline of the ship and forward of the rudders, a position that was not adopted by the Navy until the advent of nuclear submarines. Early submarines did not have a fixed center of gravity. With any change of angle of the submarine, the water in the ballast and boiler tanks would slosh in the direction of the lowest end of the vessel, aggravating the angle and making it very difficult to keep the submarine level while underwater. Holland's ballast system included main tanks that were filled completely so the water could not pool at one end or the other. The forward ballast tank was quite small, so allowing water to enter the tank had almost no effect on the longitudinal center of gravity of the submarine.

The *Holland VI* was fitted with a standard torpedo tube, and the Navy supplied two practice torpedoes for the crew to use during the trials of the submarine in 1898. While the *Holland VI*'s stability was touchy even with one man loading the torpedoes, the trials were successful and proved that torpedoes could be successfully launched underwater from a submarine.

in 1904, but was sued by the Electric Boat Company for patent violations and for using the Holland name on his new boat. Discouraged and lacking funds for either litigation or development costs, Holland retired from his submarine research. In his last years, he concentrated on designing a flying machine, but when the Wright brothers successfully flew their aeroplane, Holland gave up this work. He died of pneumonia on August 12, 1914, in the month that World War I began and his designs in naval submarine warfare were first put to use.

IMPACT

Holland has been called the "father of the modern submarine," and rightly so. He was fortunate to live at a time when there was rapid development of mechanization and industrialization. He was quick to see the utility of several of the new inventions and adapted them to his submarines. He used pneumatic power for control operations and to power his guns. He tried to use a steam engine to power a submarine but found that while the engine worked, it generated too much heat and too little power. He finally used diesel power, which was used to power submarines well into the twentieth century, when nuclear-powered submarines were introduced. His propulsion systems, hydrodynamic designs, ballast systems, and weapons systems were all used successfully, and in some cases are still used today.

HERMAN HOLLERITH

American engineer

Hollerith invented tabulating machines using key punches to record data on cards, along with counting, sorting, and recording devices to process the data. After successful use in the 1890 census, his machines proved invaluable to governments and businesses all over the world.

Born: February 29, 1860; Buffalo, New York
Died: November 17, 1929; Washington, D.C.
Primary fields: Business management; industrial technology; mechanical engineering
Primary invention: Census tabulating machine

EARLY LIFE

Herman Hollerith's father fled Germany after the failure of the 1848 revolution and died when his son was seven. Hollerith stubbornly resisted attending public schools and was tutored privately by a Lutheran minister. He entered the City College of New York in 1875, then transferred to the engineering program at the Columbia University School of Mines, graduating with distinction in 1879. When one of his professors became chief special agent of the U.S. Census, he invited nineteen-year-old Hollerith to accompany him to Washington.

Hollerith worked at compiling statistics on manufacturing. On the side, he computed life tables as a favor for John Shaw Billings, director of vital statistics at the Census. Hollerith credited Billings with starting him on the task that would consume the rest of his life by casually saying that there ought to be a machine to carry out the mechanical work of tabulating population and other statistics. Hand-counting the steadily increasing population took so long that there were fears that future counts

Herman Hollerith's tabulating machine, patented in 1889 and used to compile the 1890 census. His machines accomplished in one year what would have taken nearly ten years of hand tabulation. (Getty Images)

might not be completed until after the succeeding one began, rendering the census useless.

In 1882, Hollerith accepted a position at the Massachusetts Institute of Technology teaching mechanical engineering, but he discovered that he disliked teaching and left after one year. During his time in Boston, Hollerith considered various solutions to the problem Billings had posed. Appointed assistant patent examiner at the United States Patent Office in May, 1883, he once again left his position after one year. Hollerith, who always preferred to be in control, then opened an office as an expert consultant on patents. Hollerith's knowledge of patent law and procedures would prove invaluable in his career as an inventor.

Hollerith became engaged in 1885, but his fiancé died of typhus the following year. He would always thereafter be extremely solicitous about his family's health. He married in 1890 and fathered six children; Hollerith's three sons followed him into engineering careers.

Life's Work

Hollerith applied for his first patent for his census machine on September 24, 1884. It was granted on January 8, 1889, along with two other patents describing improvements on his first design. The basic idea was to pass nonconducting paper between electrically charged pins and a metal plate or drum. Electricity flowing through holes in the paper representing coded information activated electromagnetic counters, permitting rapid tabulation of data.

Hollerith first planned to use paper tape but soon decided that tape would make retrieval of single pieces of information a tedious and time-consuming task. Realizing cards could quickly be reread, he settled on cards the size of a dollar bill, which would fit easily available storage boxes. Holes punched on all four sides of the card with a handheld conductor's punch recorded the raw data. When punching cards by hand proved too slow and hard on the operator, Hollerith added a mechanical key punch, modeled after the typewriter; pressing keys punched appropriate holes in the card.

The director of the Census arranged test runs of Hollerith's machine tabulating mortality statistics in Baltimore in 1887, and later in New York City and New Jersey. In direct competition with two other machines, Hollerith's proved clearly superior and was chosen to compile the 1890 census. His invention was estimated to have saved the Census $5 million in labor costs. It completed in three months the simple head count that would have taken over two years by hand. In the next three years, Hollerith's machine produced, for the first time anywhere, a complete analysis of the census data. The Census preferred to rent machines rather than purchase equipment that would stay idle for most of the decade. Hollerith liked the idea: Since he owned the machines, he could prevent anyone from altering his invention. Leasing became the standard way Hollerith placed his machines.

His success with the 1890 census won Hollerith immediate international fame. The Franklin Institute of Philadelphia hailed his machine as the outstanding invention of 1890. Hollerith was invited to speak at the Royal Statistical Society in London in 1894 and International Institute of Statistics in 1895. His machines were used for censuses by Canada, Norway, and Austria in 1891, and subsequently in Russia, France, Germany, and Great Britain.

Hollerith modified his machine to accommodate the needs of an agricultural census and also sought to adapt the tabulators to the world of business, since this would provide a steadier source of income than census work. He custom-made his machines to suit the needs of railroad companies and for use in commercial bookkeeping, management control, and sales and cost analysis. In 1896, Hollerith incorporated his business as the Tabulating Machine Company, holding 502 of 1,000 common shares. To ensure card quality, Hollerith required that customers use only those his company manufactured. Profits from sale of cards exceeded income from machine leases.

In 1911, Hollerith agreed to sell his company to Charles R. Flint, who specialized in combining smaller companies into larger entities. Flint combined the tabulating company with a maker of computing scales and a manufacturer of time clocks into the Computing-Tabulating-Recording Company (CTR). Hollerith received $1,210,500 for his majority stock holdings. However, he was not ready to retire and insisted on a contract as a consultant for ten years at $20,000 per year, granting him a veto on any changes to his machines and stating that he was not to be subject to orders from anyone.

His veto power proved an irritant to Thomas J. Watson when he was hired to run CTR in 1914. Watson wanted to push development of improved tabulators, but despite careful diplomatic handling of Hollerith, sometimes found the stubborn inventor blocking changes needed to match competitors' machines. Watson would be embarrassed after World War II, when it became clear that the semiautonomous German subsidiary Hollerith established in 1910 was run by ardent Nazis who enthusiastically adapted the machines to aid management of the Holocaust. Hollerith retired in 1921. In 1924, Watson renamed Hollerith's company as International Business Machines (IBM).

Hollerith continued to invent after selling his company, mostly designing improvements to his tabulator. His last patent was granted in 1919; at the time of his death, he held thirty-one U.S. patents, as well as patents from eight foreign countries. However, Hollerith never patented his punch card with its clipped corner, since he did not think it was an original idea. In the 1920's, his attention focused on his Georgetown home, his farm, and a series of yachts. Hollerith died of a heart attack eight years after retiring.

Hollerith's Tabulating System

The tabulating machines Herman Hollerith provided the 1890 census had already developed beyond his original idea. His cards provided spaces into which the operator could use Hollerith's key punch to enter forty discrete items. Clipping one corner of the cards prevented their being entered upside down or backward. Once punched, the cards went to the tabulator machine operator, who used a hand-operated press. The upper portion of the press had retractable pins in each position where holes could be punched in the card. Wherever the press found a hole, the pins completed a circuit that moved a dial by one unit. The machine was not limited to counting only forty facts. Hollerith used electrical wiring on the back of the tabulator to connect two or more categories that were registered on separate dials. The first run of the cards produced seventy possible combinations of data.

Hollerith expanded the analytic capacity of his machine by using a sorting box divided into compartments. As the tabulator counted the seventy combinations, operators chose cards with certain characteristics, perhaps race or sex or citizenship, and placed them into the compartments to be run through the machine later. In 1890, the cards were run through the tabulator seven more times to complete the tables of correlations the census director desired. For the 1900 census, Hollerith provided a vertical sorter that automatically dropped the cards into the chosen boxes. The 1900 tabulator also incorporated an adding machine, permitting it to add quantities as well as count units.

In adapting his machine for commercial and industrial use, Hollerith had to change his cards to record numbers, rather than the specific items of information the census required. To do so, he modified his card to use the entire surface, not just the edges. He divided the card into vertical columns, each having the numerals from 0 to 9; groups of columns could be assigned as needed to record relevant numbers. In the New York Central Railroad's case, the first five columns of the card registered weights of shipments; additional columns recorded other data or prices. Hollerith's system could now be adjusted to suit various industrial and commercial enterprises.

Machines were custom-built to suit the needs of the user. Until 1906, the electrical connections needed to correlate data required hand-soldering to process new combinations of data, a time-consuming process. Hollerith automated the changes by providing a plug board, permitting easy switching of the wires, effectively creating a process of physical programming that prefigured electronic programming of computers.

Impact

Hollerith's tabulator made it possible for the U.S. Census to complete future decennial head counts in time for the constitutionally mandated reapportionment of the House of Representatives. Counting by hand could not have kept up with the rapidly increasing American population. As Hollerith improved his machines, it became possible not only to count but also to correlate data. One could now easily determine how many families were headed by two parents, how many children were in each family, and what language they spoke, or any other combination of desired characteristics. The superintendent of the 1890 census boasted that for the first time it had been possible to produce the most complicated tables as easily as the simplest, providing invaluable information for governments, social scientists, and industry.

The improved machines proved particularly useful to managers of the increasingly large and complicated American business enterprises. After the New York Central Railroad used tabulators in 1896 to keep track of freight shipments, railway companies discovered even more ways the machines helped in running day-to-day operations and providing easily retrievable business information. Hollerith's cost-accounting machines transformed the fields of commercial bookkeeping and industrial accounting. Department stores depended upon the machines for sales analysis. Insurance companies used hundreds of thousands of cards to keep track of their policies. Hollerith's machines expanded female employment opportunities, since the devices were as easy to use as a typewriter.

For the first time, business as well as government could process massive amounts of information efficiently, economically, and in time to be of use. Until replaced by computers, for which Hollerith's tabulators were a significant forerunner, his machines would be indispensable for data processing.

Nick Holonyak, Jr.

American electrical engineer and physicist

Holonyak invented the first practical light-emitting diode, the first visible-spectrum semiconductor laser, and the household light-dimmer switch. In 2004, he coinvented the transistor laser.

Born: November 3, 1928; Zeigler, Illinois
Primary fields: Electronics and electrical engineering; physics
Primary inventions: Light-emitting diode (LED); visible-spectrum semiconductor laser; light-dimmer switch; transistor laser

Early Life

Growing up in the southern Illinois coal mining community, Nick Holonyak (HOHL-uhn-yak), Jr., was drawn naturally to anything mechanical or electrical. His parents, Nick (Nickolai) Holonyak and Anna Rosoha, were immigrants from the Carpathian Mountain region of Eastern Europe. The junior Holonyak was born in 1928 in Zeigler, Illinois. Holonyak and his younger sister, Evelyn, were the first in their family to attend school. In 1936, the family moved to Glen Carbon, Illinois.

Because everyone in Holonyak's community made,

Light-Emitting and Laser Diodes

Nick Holonyak, Jr.'s February, 2001, *Scientific American* article, "In Pursuit of the Ultimate Lamp," describes light-emitting diodes (LEDs) and laser diodes. Though both diodes are made of semiconductor materials, they are designed differently to tackle different jobs. Inside the LED is a chip with layers of semiconductor material. One layer has an excess of electrons (N-type) and another layer rests on top with a dearth of electrons, or an excess of positively charged particles called "holes" (P-type). The junction of the N and P layers is the "active" layer. Applying a voltage drives the electrons and holes into the active layer where they meet. As they join, they emit photons, the basic units of light. The atomic structures of the active layer and adjoining materials on each side determine the number of photons produced and their wavelengths (the wavelengths of light determine the colors). In LEDs, the semiconductor material used is a mixture of group III and group V elements of the periodic table.

In laser diodes, the semiconductor material rests between what is essentially a pair of mirrors in the region called the "resonator cavity." When electricity goes through the semiconductor, it gives off photons, which bounce around inside the cavity, exciting nearby electron-hole pairs to release more photons at the same wavelength. The light increases continuously in intensity, with the photons moving together as they oscillate between the two mirrors. If one mirror allows just a bit of light to escape, then some of the photons exit. All at the same wavelength and in phase, these escaping and "coherent" photons produce an extremely narrow column of pure, bright light at a single wavelength. This well-defined beam is a laser, and with proper optics, it can do delicate work such as reading the fine pits on a compact disc or scanning bar codes. The word "laser" is an acronym for "light amplification by stimulated emission of radiation."

In contrast, the light emitted from LEDs is "incoherent." That is, the photons are more widely scattered and are composed of a spread of wavelengths from one area of the spectrum. While the photons an LED produces are not all the same wavelength, they are close enough to be perceived by the eye as being the same color.

Holonyak's first III-V alloy PN junction LED is the prototype for all the high-brightness LEDs made today. Through decades of improving crystal manufacturing techniques, tailoring the properties of the semiconducting layers, and even reshaping the chip itself, researchers have developed bright-light LEDs in every color of the rainbow, including white. In addition to the first red indicator lights, LEDs can be seen everywhere, lighting up traffic lights and signals, message and display boards, automotive brake and headlights, laptop displays, and interior and outdoor spaces, to name a few. During the 2008 Beijing Olympics opening ceremony, the world witnessed a thirteen-hundred-square-meter LED scroll display on the stadium floor upon which performers walked, danced, and drove. The Beijing Water Cube housed 440,000 LEDs embedded throughout its structure.

repaired, and reused whatever they needed, Holonyak became handy with tools and fixing equipment. His godfather's Ford Model T provided a lesson in spark coils and ignition. Holonyak dabbled in making radios with crystal sets, oatmeal boxes, and tuning wires. He turned his dad's carbide lamps into soldering irons. By the time he entered Edwardsville High School, Holonyak was ripe to learn the physics of how and why things worked. His teachers gave him a solid grounding in mathematics.

From 1944 through 1946, Holonyak worked on the Illinois Central Railroad during the summer and on school holidays. Ten hours a day of backbreaking manual labor convinced him that going to college would better enable him to contribute to society. By the time he completed high school, World War II had ended. The University of Illinois at Urbana-Champaign (UIUC) was impacted with soldiers returning from combat. Fortunately, Holonyak was accepted to the university's extension program, for which he paid with his railroad earnings.

He entered UIUC as a sophomore in 1947, a remarkable year in electronics history. Physicist John Bardeen and his colleague Walter H. Brattain, working at Bell Telephone Laboratories (Bell Labs) in New Jersey, had invented the point-contact transistor using the semiconductor germanium. Transistors amplify or switch electrical signals and, together with other semiconductor-based devices, are the fundamental building blocks of solid-state electronics.

Life's Work

By 1951, Holonyak had earned both his bachelor's and master's degrees in electrical engineering and was working toward his doctorate. That same year, Bardeen left Bell Labs and became professor of electrical engineering and of physics at UIUC. Holonyak took Bardeen's atomic physics and semiconductor courses and found him fascinating. In 1952, Holonyak transferred from a lab working on microwave tube problems to Bardeen's semiconductor lab, becoming Bardeen's first graduate student. In addition to forging what would be a lifelong friendship with Bardeen, Holonyak learned as much as he could about the nature of semiconductors, growing crystals, and testing their conductivity. Holonyak felt at home there: Everything in Bardeen's new lab had to be built from scratch, including the benches. An added benefit was learning from other world-renowned scientists who visited Bardeen's lab.

In 1954, Holonyak earned his doctorate in electrical engineering and took a job with Bell Labs in New Jersey. Bell Labs was researching new low-voltage, low-current technology to replace the vacuum tubes and relays in telephone switching systems. Holonyak's supervisor, John L. Moll, was convinced that silicon was a superior elemental semiconductor material to germanium and that it would work better for switching devices. Holonyak was put to work developing silicon-diffused transistors and silicon thyristors. Many of what would become integrated circuit (IC) manufacturing processes, including oxide masking, were developed during this time by Holonyak and other Bell Labs researchers. Holonyak credits Moll with being the first to recognize and promote silicon's future role in electronics.

In 1955, Holonyak married Katherine Jerger, a nursing educator. After a year at Bell Labs, Holonyak joined the U.S. Army Signal Corps, which stationed him in Yokohama, Japan, and worked on classified projects. Upon his discharge in 1957, he moved to the electronic devices lab at General Electric Company (GE) in Syracuse, New York. While there, Holonyak's work on silicon thyristors led him to invent the symmetrical switch, the fundamental silicon device used in household light-dimmer switches.

By 1960, GE scientists were experimenting with gallium arsenide, a III-V semiconductor compound alloy (III and V referring to columns of the periodic table). In July, 1962, Massachusetts Institute of Technology (MIT) scientists reported that their gallium arsenide diode was converting electric current into infrared light. Holonyak wanted to work with visible light and had an idea that a gallium arsenide phosphide (GaAsP) diode could emit red light. He and his technician went to work on making this new crystal from scratch. By October, 1962, Holonyak had succeeded in making the first visible-spectrum diode laser. This time, Bardeen, Holonyak's mentor and by then a Nobel laureate, went to Holonyak's GE lab to see it.

Not only did Holonyak's GaAsP diode produce red laser light, but it also (after more and more phosphorus was added to the gallium arsenide) stopped lasing yet remained a useful light source. Holonyak had invented the red light-emitting diode (LED), the first operating alloy device. He quickly devised a proof that the LED was an "ultimate lamp."

In 1963 and earlier, Bardeen asked Holonyak to consider returning to UIUC as a faculty member. Holonyak accepted the position, as he enjoyed both teaching and being at the forefront of invention. Through numerous discoveries and advancements in laser technology, Holonyak and his UIUC students have continued inventing better lasers. Their work has made lasers practical for myriad applications, including compact disc (CD) and digital video disc (DVD) players, high-frequency cell phone circuits, fiber-optic communications, medical diagnosis, surgery, copy machines, laser printers, and laser television and projectors. In 1993, Holonyak became the John Bardeen Endowed Chair Professor of Electrical and Computer Engineering and Physics, a fitting tribute to both gentlemen. Holonyak has kept all three inventions—the symmetrical switch, first visible laser, and first LED—in a box he calls "the coffin" inside his UIUC office desk.

While having a coffee break in 2003, Holonyak asked his former student and UIUC colleague Milton Feng (inventor of the world's faster transistor) if he had seen any light coming out of his high-speed heterojunction bipolar transistor. Feng told Holonyak he had not, but after a few months and a different detector, Feng did see infrared light shooting out in all directions from his transistor. After modifying the transistor's structure to favor light emission and to intensify it into a laser beam, in 2004 Feng, Holonyak, and their research team demonstrated the transistor laser. At once a new form of transistor and a new form of laser, it marked the first time a single device had taken an electrical input and simultaneously output both an electrical signal and a coherent optical signal. Holonyak told several reporters that Bardeen (1908-1991) would have a big smile to see how far his and Brattain's invention had come in fifty-eight years.

Impact

Holonyak's LED has sparked revolutionary changes in the traditional lighting industry and has become the basis of a global optoelectronics industry worth billions of dollars. In addition, the transistor laser may prove to be one of the most important inventions since the original transistor. Processing information at the speed of light, the transistor laser could lead to faster signal processing, larger capacity seamless communications, and higher performing electrical and optical ICs. "Like the fundamental work that went into creating the point-contact transistor, then the junction transistor, and eventually the LED and the laser—and ultimately led to the booming semiconductor industry—our work is just at the beginning of what could be a new era in computing and communications," said Holonyak and Feng in their February, 2006, *IEEE Spectrum* article, "The Transistor Laser."

The LED is proving to be the best-qualified device to replace Thomas Alva Edison's light bulb. Energy and lighting standards are requiring more efficient light bulbs. The very definition of "green" energy, the LED emits more intense light at much lower power and for decades longer than the incandescent bulb, and it does not contain the harmful mercury found in compact fluorescent bulbs.

Holonyak's legacy is rooted in his more than sixty postdoctorate students who have become entrepreneurs, professors, business leaders, and inventors. Many of Holonyak's former students shared his lessons at Holonyak's October, 2008, eightieth birthday symposium at UIUC's Beckman Institute: Tackle the problems within your reach with hard work and collaboration; build and test, do not just model, your ideas; and even a small group can take on a big problem and really have an impact around the world. Holonyak holds forty-one patents and is the recipient of numerous awards, including the Japan Prize (1995), Russia's Global Energy Prize (2003), Lemelson-MIT Prize (2004), and both the National Medal of Science (1990) and National Medal of Technology and Innovation (2002). He is a 2008 inductee to the National Inventors Hall of Fame.

Robert Hooke

English physicist

Hooke did significant research in most areas of seventeenth century science, including collaborating with Robert Boyle on inventing the first air pump, building a microscope with which he made important discoveries, inventing the universal joint, and investigating planetary motion. He was one of Sir Christopher Wren's two assistants in rebuilding fifty-one city churches after the Great Fire of London in 1666.

Born: July 18, 1635; Freshwater, Isle of Wight, England
Died: March 3, 1703; London, England
Primary fields: Architecture; navigation; physics
Primary inventions: Air pump; spiral spring balance watch; universal joint

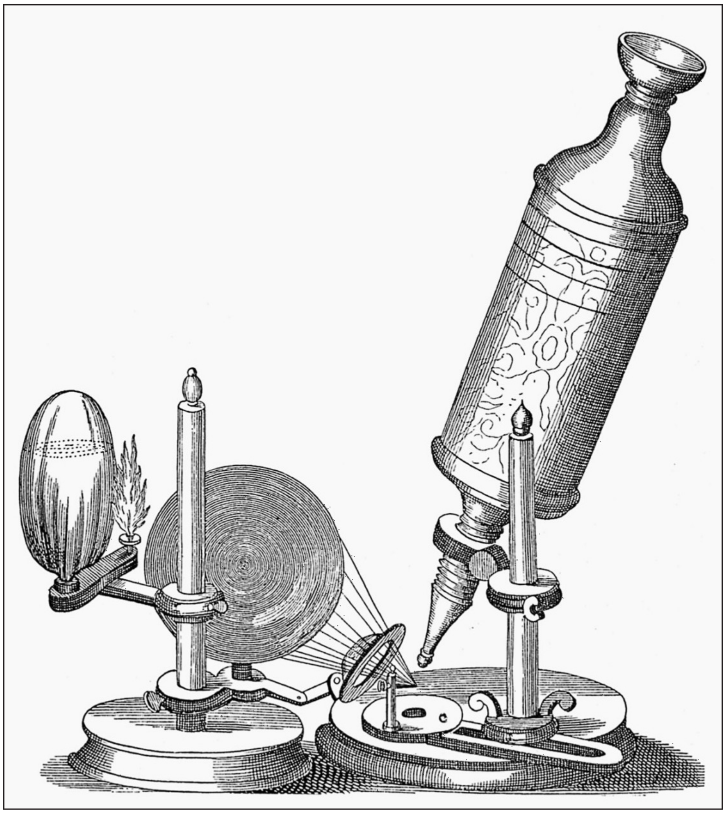
Early Life

Robert Hooke was born on July 18, 1635, in the village of Freshwater on the Isle of Wight, where his father, John Hooke, was the curate of All Saints', the parish church. His mother, Cecilie, née Gyles, was John Hooke's second wife. Robert had two older sisters, Anne and Katherine, and an older brother, John, who left home to become a grocer in Newport. Robert was a weak child, raised on a mild diet and educated at home. He soon evinced extraordinary talents, especially in mechanical pursuits, and imitated the work of the local craftsmen, while cultivating a lifelong interest in clocks and navigation. His skill with the pen and pencil facilitated his later work in microscopy and mechanics, as well as his work as an architect and surveyor.

Hooke's father died in 1648, and he took his £50 inheritance and braved a new life in busy London. He went first to the London suburb of Westminster, where he had planned on assuming an apprenticeship with the Dutch portraitist Peter Lely, but he quickly scrapped this plan and instead enrolled at Westminster School. The headmaster at Westminster, Dr. Richard Busby, was a stern taskmaster, and sixteen of his students became bishops. Hooke stayed in Busby's house from 1649 to 1653, learned to play the organ, studied Euclid, and mastered Latin and Greek. It was at this time that he developed his intense interest in flying. When he was sixteen years old, he became afflicted with a twisted back, a condition that Stephen Inwood speculates may have been a deformity identified in 1921 as Scheuermann's kyphosis, in which the vertebrae become misaligned. Unfortunately, Hooke's forward stoop became worse as he grew older, as is common with kyphosis sufferers.

Life's Work

In 1653, Hooke entered Christ Church, Oxford, as a servitor, a student who earned his keep by working for a rich student. In 1656 or 1657, he was employed by the wealthy scientist Robert Boyle and lived in Boyle's home until at least 1662. Unlike many scientists of his day, Boyle was devoted to the experimental method, and at his urging Hooke devised an air pump in 1658 or 1659. This important invention enabled Boyle to formulate



Robert Hooke's microscope, from a line engraving based on the illustration in his Micrographia *(1665).* (The Granger Collection, New York)

Boyle's law: The volume of a gas, the temperature remaining constant, varies inversely with the pressure sustained by it. Hooke's successful association with Boyle led to his appointment in 1662 as a Royal Society curator of experiments, and in 1664 he moved into rooms at Gresham College in London, where he was installed in 1665 as Gresham Professor of Geometry and lived until his death.

SPIRAL SPRING BALANCE WATCH

Robert Hooke's famous principle of Hooke's law grew out of his work to build a reliable timepiece that would enable sailors to determine longitude at sea. If a ship carried an accurate clock that was set to the time of the port from which it had left, then since the Sun swept across 15° in an hour, when the Sun stood directly overhead at high noon the vessel's longitude could be calculated by simple arithmetic. If, for instance, the ship's clock read 4:00 P.M., its longitude would be 4 × 15° west of its embarkation point. This theory, however, depended on a reliable timepiece, and the great challenge was thus to develop a clock that would still keep accurate time while being tossed around in a rough ocean. Several trials of conventional pendulum clocks were conducted at sea in the early 1660's, but Hooke scorned them as inconsistent.

A breakthrough came in 1674 when Christiaan Huygens announced that he had devised a spiral spring balance, an innovation that would be the basis of Hooke's law. The physical principle was that the energy tensioning a balance spring would equal the energy released by the spring, creating an isochronal action as trustworthy as the pendulum and not dependent on gravity. Huygen's announcement came in two letters read to the Royal Society by Henry Oldenburg, and it spurred Hooke to declare that he had invented the spring-regulated watch in 1658, but his only evidence was a reference to it in the Royal Society register book for 1666. When Hooke learned in 1675 that Huygens had offered Oldenburg the patent on his spring watch, he accused Oldenburg of profiteering from his position as secretary of the Royal Society and of revealing the secret of Hooke's watch to Huygens. Hooke also began collaborating with the skilled instrument maker Thomas Tompion in building a spring watch of his own that would outperform any timepiece that Huygens could produce.

Tompion was a superb craftsman, and by late 1675 he and Hooke had a watch with a spiral balance spring to present to King Charles II boasting the engraved inscription "Robert Hook inven. 1658. T. Tompion fecit 1675." Until 2006, there had been no way of confirming Hooke's claim, but then an auctioneer examining the contents of a home in Hampshire found over five hundred yellowing manuscript pages in a cupboard. This remarkable find proved to be Hooke's notes of the Royal Society meetings from 1661 to 1682, a trove that completed the society's records. In one passage, Hooke reports that in the draft minutes for June 23, 1670, Oldenburg had written: "The curator [Hooke] produced a pocketwatch of a new contrivance devized by himself, which he affirmed should goe as equally as a pendulum, and without stopping, and might be made to goe for 8 days." Sixty years after Hooke's death, the work of the inventor John Harrison led to a chronometer that would give a ship's exact position at sea, an accomplishment that built upon Hooke's spiral spring-governed balance wheel and escapement.

Hooke's early research for the Royal Society included studies in navigation, working on a depth sounder, fixing the freezing point of water at zero degrees, and making a wheel barometer. He dissected a living dog to study its lungs, discovered a dark spot on Jupiter, and described in *Micrographia* (1665) the features he discerned on the Moon. Hooke revealed wondrous discoveries in *Micrographia*, including a patch of blue mold on a leather book, an eruption of blight on a rose leaf, and the tiny compartments in cork for which Hooke coined the word "cells." The book was an astonishing compendium of five years of inspired work, with disquisitions on light, fossils, animal behavior, lunar craters, and a multitude of other topics. Samuel Pepys, the diarist, called *Micrographia* "the most ingenious book that ever I read in my life." Hooke's observations of the development and birth of gnats in a jar of rainwater prompted him to question "whether all those things that we suppose to be bred from corruption and putrifiction, may not be rationally suppos'd to have their origination as natural as these Gnats. . . ."

Hooke was the first to posit the correct role of gravity in creating planetary motion when he read a paper to the Royal Society in May, 1666, "On the Inflection of a Direct Motion into a Curve by a Supervening Attractive Principle." This paper evolved in four years into a theory of universal gravitation, proposing that all bodies, not just the Sun, exerted attraction over bodies orbiting around it. Second, all bodies put into motion would remain in a straight line unless some force deflected them. Finally, the attracting power was stronger near the center of the attracting body and weakened at longer distances. Also in 1666, Hooke calculated the rotation of Mars on its axis within thirty-seven minutes of the time accepted today, developed a clock based on a conical pendulum, and invented a quadrant featuring a screw-controlled adjustment and a reflecting mirror, an advance over previous quadrants but fated to be neglected until John Hadley came up with a similar instrument in 1731.

The fire that devastated London in 1666 changed Hooke's career, as he was appointed along with two others to the city's Rebuilding Commission and named city surveyor. In the 1670's, he was kept busy with architectural work. He was appointed in 1670 as one of Christopher Wren's assistants in rebuilding fifty-one city churches, and from 1671 to 1679 he was employed in designing and building a new college for the Royal College of Physicians. In this same decade, Hooke worked on the Monument to the Great Fire of London for five years and on the Bethlem Royal Hospital and the grand Montagu House in Bloomsbury, while also struggling to devise a better calculating machine than Gottfried Wilhelm Leibniz's, exhibiting the first practical Gregorian telescope (named for James Gregory), helping design the Greenwich Observatory, and collaborating with Thomas Tompion in the creation of a good spring watch. The spiral spring watch, in fact, was to become the subject of controversy until 2006.

Hooke continued to investigate subjects as diverse as lenses, the mechanical nature of memory, cannabis, fossils, and the changing shape of the Earth. His last recorded contribution to a Royal Society meeting came in June, 1702, nine months before his death apparently of heart and circulatory ailments in March, 1703. He enjoyed a long career in which he left his mark upon most of the branches of natural philosophy current in his day.

Impact

"*Micrographia*, therefore, became one of the formative books of the modern world, and like all influential pieces of writing, was capable of triggering responses on many different levels of understanding." That is Allan Chapman's judgment of Hooke's great book, and Stephen Inwood is equally flattering, noting that extracts were used in many scientific works for the next 150 years. Hooke had many inventions and advancements to his credit—the universal joint, for instance, and the spiral spring watch—but his main legacy was his devotion to the experimental method. He demonstrated that this approach to science (or natural philosophy as it was known) could achieve great insights into the workings of nature and enable the mastery of nature. Many of Hooke's experiments may have seemed laughable to Jonathan Swift in his satire on the Royal Academy in *Gulliver's Travels* (1726), and to King Charles II, who laughed at the comical Hooke and his contraptions. Most insulting was Thomas Shadwell's mean-spirited play *The Virtuoso* (pb. 1676), in which Hooke is satirized as Sir Nicholas Gimcrack.

Nobody sneers at Hooke today. Boyle's law and Hooke's law are firmly embedded in the discipline of physics, Hooke's speculations on fossils and the history of the Earth are no longer dismissed as outlandish, and his architectural successes have long been admired, perhaps none more so than the great monument to the fire. For several decades, Hooke bustled about on multiple projects—quadrants, telescopes, microscopes, watches, universal joints, and sketching the eye of a fly. Allan Chapman was certainly right to dub him "England's Leonardo."

Erna Schneider Hoover

American computer scientist

A pioneer in computer technology and one of the first women in the field, Hoover revolutionized telecommunications by designing a computerized switching system able to process an unprecedented volume of incoming calls.

Born: June 19, 1926; Irvington, New Jersey
Also known as: Erna Schneider (birth name)
Primary fields: Communications; computer science; electronics and electrical engineering
Primary invention: Electronic switching system

Early Life

Erna Schneider was born on June 19, 1926, in Irvington, a metropolitan area in industrial northeastern New Jersey. One of three children, Erna grew up in a happy and supportive home—her father was a dentist and her mother a teacher in the South Orange public school system that Erna attended. Early on, Erna was enthralled by science, in part because of her father’s influence and in part because of her love of the outdoors (particularly the nearby Adirondack Mountains), which gave her an appreciation for the subtle design of ecosystems. Two events in particular shaped the direction of Erna’s education into the sciences: the death of her younger brother at age five from poliomyelitis (then a terrifying illness without a cure) and her subsequent introduction to the work of Marie Curie through a biography she received from a teacher. That biography impressed young Erna by revealing how science solved problems, giving her a practical rather than theoretical sense of science. In addition, the example of Madame Curie encouraged Erna to pursue a career that at the time was dominated by men.

Gifted in the classroom, Erna completed her B.A., graduating Phi Beta Kappa in 1948 from Wellesley College, a prestigious women’s college in Massachusetts. Despite her love of science, her degree was in classical and medieval philosophy and history; she was encouraged to pursue university teaching as a career appropriate to her gender. Within three years, she had completed a doctorate at Yale University in philosophy and foundations of mathematics. For the next two years, she taught logic and philosophy at Swarthmore College outside Philadelphia. However, because she was married (in 1953, she had married physicist Charles Wilson Hoover), she would not be offered a tenure-track appointment. In 1954, at her husband’s encouragement, she applied for a senior research position at Bell Laboratories, a cutting-edge research facility in electronics headquartered in Murray Hill, New Jersey. Within a year, because of her grounding in symbolic logic (key to developing circuit designs), she was assigned to work in Bell Labs’ accelerated training program in computer science.

Life’s Work

Bell Labs was at the forefront of the postwar technology boom made possible by its introduction of transistors, which were used not only in the development of the first-generation computers but also in everyday household items, from toasters to radios. Given Bell Labs’ prominence, it was swamped daily with hundreds of phone calls that had to be handled by its hard-wired, mechanical switching equipment. The demand on the group’s system was immense, and the system regularly froze, overwhelmed by the volume of calls that had to be processed. The system’s switches first counted the digits dialed, then determined where to direct the call, and finally connected the parties. This methodical, time-consuming endeavor was designed to handle perhaps one hundred calls per workday. The results—dropped calls, busy signals, misrouted calls—created havoc. These problems were hardly Bell’s alone; they were significantly multiplied in public telephone networks. In 1954, Bell organized a division research team to look into an electronic switching system (ESS) that would use cutting-edge transistor technology to design the architecture of a system able to handle a high volume of incoming phone calls.

Hoover served on the project’s initial work, in part because of her grounding in logic. Drawing on that discipline with its assumptions of orderly processes and her own profound admiration for the discipline and order of nature, Hoover was determined to create a system capable of directing the incoming data. When in 1957 she was compelled to take maternity leave (to give birth to her second child), she initially resisted. Ironically, however, it was while she was in the hospital recovering from that birth that—inspired by watching the triage practices of orderlies and nurses in the hectic delivery room facility where cases were routinely managed by the staff by assigning priority to critical cases and holding off attention to less pressing ones—Hoover first sketched (literally, on hospital napkins) what would become the basic design of a working ESS. It was, Hoover would recall later, a simple idea: prioritize the thousands of incoming calls, monitor the frequency of incoming calls throughout a standard workday, and adjust the acceptance rate according to high-volume times, thus distributing the calls into a kind of pecking order that would maintain the system without the threat of breakdowns.

Returning to Bell, Hoover spearheaded the project that gathered the initial data, tracked incoming call patterns, and developed reliable traffic reports that enabled Hoover, over the next five years, to design the Stored Program Control, the software with the memory sufficient to engineer the phone system. It was a massive undertaking. The project alone received more than $500 million in research funding from Bell. With computer-assisted technology (transistor circuits and memory-stored control programs), Hoover's ESS would be able to control the distribution of thousands of calls per second by analyzing the importance of the calls (based on exchange numbers), prioritizing them (research departments, for instance, ahead of clerical), and maintaining control of the system with a significant reduction in the number of staff persons assigned to the task. Given the revolutionary design and its potential impact in electronic telecommunications, Bell decided in 1967 to apply for a patent (while Hoover was again on maternity leave for her third, and last, daughter).

Hoover's Feedback Control Monitor for Stored Program Data Processing System was awarded a patent on November 23, 1971, among the earliest patents awarded to computer software. Hoover, by then promoted to research supervisor (the first woman so promoted), had

The Electronic Switching System

Erna Schneider Hoover's patent application for the electronic switching system (ESS) specifically related to stored program data processing machines that routinely routed incoming phone calls. Specifically, her interest was in developing a software program that would assist the processing under conditions of high stress—periods of high-load conditions in which existing systems tended to break down. To monitor traffic flow, Hoover's software program began by determining a base-level functioning flow—that is, a measure of standard occupancy under which the program could maintain sufficient exercise over calls without malfunction. The system used a particular class of work—both input and output—that the processor performed routinely and repetitively under normal conditions and measured the time interval for performing those tasks. That indication of occupancy was in turn used to control the rate at which new work, or new calls, would be taken into the system for processing. Of course, the process of looping back and assessing volume was done at great speeds. Essentially, Hoover's software provided a continual overview of traffic flow, monitoring the frequency of incoming calls during the day and then adjusting the acceptance rate when the system entries exceeded the predetermined limit. The system would in turn temporarily relegate the volume of calls that would stress the system into breakdown into "hoppers," or areas of buffered and protected memory within the system designed specifically for such short-term storage.

From that point, the executive control, the brains of the data processing system, determined the order in which the overload data would be fed back into the system, dividing the data into several classes according to urgency of the tasks. The idea was to route pressing calls first and then move on to less urgent concerns such as billing or ordering. That switching system maintained control of the data flow during the period of high input until the system managed itself back to predetermined functioning time. By measuring machine occupancy continually and in turn controlling the number of new numbers permitted into the network, the software program stayed current and actually reacted to unfolding conditions. The executive control would continuously revisit the system until either the hoppers were emptied or the quota for a single visit was reached. Thus, the system monitored itself, maintaining an even distribution of incoming calls without appreciable delays or dropped calls, preventing the surge in data that regularly compromised manual systems. Hoover's system architecture became the foundation for all computer routing programs for private and public telephone systems, thus ushering in the era of telecommunications.

been reassigned to work on the high-profile, top secret research project investigating radar control programs that would help intercept incoming intercontinental ballistic missiles. Given that Hoover's work was done during some of the most difficult and tense years of the Cold War, she has been credited with creating the necessary bargaining chip for a succession of presidents to negotiate significant weapons treaties. In 1978, in recognition of her achievements, Hoover was promoted to technical department head (again, the first woman to have that title at Bell Labs).

She retired in 1987 to Summit, New Jersey, where, along with her husband, she lived an active retirement enjoying the outdoors. Although her design basically created telecommunications, she lived quietly; she would tell whatever reporters came to her home that her idea was just common sense. In February, 2008, Hoover received long overdue international recognition when the National Inventors Hall of Fame named her among that year's class of inductees.

Impact

In the 1950's, telephoning involved actually talking to an operator who would manually direct a call by plugging a wire into a switchboard. As phone communications exponentially increased during the postwar business boom (most dramatically after transatlantic telephone cables were introduced in 1956), the problem of overloaded, jammed systems became evident. Undeniably, Erna Hoover's insight into how electronics could be applied to adjust the acceptance rate of incoming phone calls revolutionized postwar telecommunications. After Bell Labs introduced the first computer storage system (initially into its own phoning system), within two years the system program and its software were in commercial service for public networks all over the country.

The growth of the system innovation that Hoover first described is difficult to fathom—but within twenty years, just under two thousand such switching systems were managing more than fifty million subscriber lines. Although successive designs of the system have built upon Hoover's initial idea, all business and private phoning systems directly descend from Hoover's insight. Indeed the basic logic of Hoover's design has provided the system architecture for Internet managing of millions of e-mail messages sent every minute.

Far more important than the impact her innovative design had on the evolution of mass communications is Hoover's stature in the social and cultural history of postwar America as a pioneering woman in a field that was the province of men at that time. Her example in how, despite the glass ceiling, a woman can succeed—both in the workplace and at home—by dint of ingenuity and dedication has had a powerful impact on attracting women to the fields of computer science and electrical engineering.

Grace Murray Hopper

American mathematician and computer scientist

Hopper was a U.S. naval officer who eventually rose to the rank of rear admiral. She is best known for her work on the development of COBOL as a computer programming language. She also created a large variety of computer software that was innovative in terms of the problems addressed.

Born: December 9, 1906; New York, New York
Died: January 1, 1992; Arlington, Virginia
Also known as: Grace Brewster Murray (birth name)
Primary fields: Computer science; electronics and electrical engineering
Primary invention: COBOL programming language

Early Life

Grace Brewster Murray was the eldest of three children born to Walter Fletcher Murray, an insurance broker, and Mary Campbell Van Horne Murray of New York City. Her family was fairly well off, and she spent her childhood summers at the family cottage on Lake Wentworth in Wolfeboro, New Hampshire. Her father encouraged her not to follow the traditional roles that women typically followed at that time. From her surveyor grandfather, John Van Horne, she learned about angles and curves, which may have led to her interest in a mathematics career, although she credited her mother's interest in the subject as being the main influence. Murray received her bachelor's degree in mathematics and physics from Vassar College in 1928, graduating Phi Beta Kappa, and earned a master's degree in mathematics from Yale University in 1930. In 1934, she became the first woman to receive a doctorate in mathematics from Yale. Her dissertation was titled "New Types of Irreducibility Criteria" and was written under the tutelage of famed algebraist Øystein Ore.

Murray married Vincent Foster Hopper in 1930, when she was twenty-three years old. Hopper was an honors graduate of Princeton University and later earned a doctorate in literature at Columbia University. The couple separated in the early 1940's and were divorced in 1945. He died shortly afterward in the final days of World War II. They had no children.

Grace Hopper served as a faculty member at Vassar College from 1931 to 1943, at which time she joined the U.S. Navy's Bureau of Ordnance at Harvard University as a mathematical officer, working under Howard Aiken. Her great-grandfather Alexander Russell had been a rear admiral, and she had always been interested in the Navy. At the age of thirty-seven, she was initially considered too old for the Navy, but her specialty in mathematics was crucial, and the Navy relented and accepted her. There was also a problem with her weight: At 105 pounds, she was sixteen pounds underweight for her height of five feet, six inches. However, she was granted a waiver. Because of her educational background, she was sent to Midshipman's School and graduated at the top of her class in 1944, becoming a lieutenant (junior grade).

Her first job was as one of the initial programmers on the Navy's Mark I—the first large-scale digital computer. The Mark I was fifty-one feet long, eight feet tall, and eight feet wide and was considered a marvel of modern science. It contained five hundred miles of electrical wire and over 750,000 parts. The computer was used to calculate aiming angles for guns in various types of

Grace Murray Hopper. (Naval Historical Center) weather to determine the flight path of artillery shells. Hopper and her assistants had to keep the computer running twenty-four hours a day during the war. In 1946, much of her wartime knowledge was incorporated into a book that she coauthored with James Conant—*A Manual of Operation for the Automatic Sequence Controlled Calculator*.

LIFE'S WORK

Following the war, Hopper was released from active duty, but she remained in the Naval Reserve. She joined the Harvard faculty at the Computation Laboratory, where she continued her work on the Mark II and Mark III. From 1949 to 1967, she worked as a mathematician for Eckert-Mauchly Computer Corporation, which was later acquired by Sperry Rand Corporation. From 1967 through September of 1986, she was on active duty with the Navy. She was promoted to commodore in 1983 at the age of seventy-six. When she retired from the Navy as a rear admiral in 1986, Hopper was the oldest-serving officer at that time and the first female admiral in the history of the Navy. Late in her career, at the age of eighty, she joined Digital Equipment Corporation, where she worked from 1986 to 1988.

At Sperry Rand, Hopper had the opportunity to work on the Universal Automatic Computer, better known as UNIVAC, which operated one thousand times faster than the Navy's old Mark I. The UNIVAC was the first commercial electronic computer. It used vacuum tubes instead of the electromechanical relay switches of the Mark calculating machines. In 1952, she invented the compiler, an intermediate program that translated English-language instructions into computer language. She also was the first to use now standard computer tools such as subroutines, formula translation, code optimization, and symbolic manipulation.

Hopper is best known for creating the computer programming language known as Common Business Oriented Language (COBOL). COBOL was the first language that allowed a programmer to talk to a computer with words rather than with numbers. Before COBOL, computer programs were written either in assembly code or some type of machine code. Hopper felt that programmers should be able to communicate with computers in English.

Hopper is also known for popularizing the term "bug" to describe a computer glitch. Today, correcting problems in computer software is known as "debugging." Hopper used the term "bug" when she traced an error in the Mark II to a real bug—a moth trapped in a relay switch. The moth was removed and taped to a computer log book. Initially, "bug" referred to problems with hardware, but in the 1950's Hopper extended the meaning of "debug" to include fixing software programming errors.

Most of Hopper's inventions dealt with software. Her innovative ideas included computer programs to track the life cycle of crop-eating locusts, a weather computer, software to manage water reserves, and programs to track wave motions at the bottom of the ocean. In 1966, she was promoted to commander in the Naval Reserve, but she had reached the legal limit of twenty years' service and was forced to retire. However, within six months, the Navy decided that it needed her back to work

COBOL: A COMPUTER PROGRAMMING LANGUAGE

Grace Murray Hopper is best known for creating the Common Business Oriented Language (COBOL), a programming language that permitted programmers to communicate with computers by means of the English language rather than through numbers. Hopper attributed the idea for COBOL to her difficulty in balancing her checkbook. Early computers were programmed using a machine code that used numbers. Hopper had learned to add, subtract, multiply, and divide using a numbering system to the base eight, known as the octal system, which used digits 0 through 7. Unfortunately, Hopper became so adept at using the base-eight system that she inadvertently used it when she added and subtracted in her checkbook. Thus, her checkbook did not balance because she was not using the decimal system.

To alleviate the problem of programmers having to use the octal system, she suggested that the Universal Automatic Computer (UNIVAC), the first commercial electronic computer, be programmed to understand English commands. Initially ridiculed by other programmers, Hopper developed the B-0 compiler, later known as FLOW-MATIC, which by 1956 had enabled the UNIVAC to understand twenty English-like phrases. By 1959, this compiler had led to the first standardized universal computer language—COBOL. COBOL was used to retrieve accounting, billing, and payroll data, and the program was easy to use. Hopper then created the manuals to enable others to learn COBOL and to program their own computers. Nicknamed the "Grandmother of COBOL" and "Amazing Grace," Hopper was recalled to active duty in the Navy in 1967 to continue her work on COBOL.

on COBOL. In 1967, at the age of sixty, she returned to active duty. Her new job was to combine versions of COBOL into a USA Standard COBOL.

In her later years, Hopper was a venerable figure, nicknamed "Amazing Grace" for her accomplishments and her ability to motivate audiences. During her career, she was granted more than thirty-seven honorary degrees, including ones from the University of Pennsylvania, Long Island University, and the Newark College of Engineering. Other honors included her selection for the 1969 "man of the year" award (she was the initial recipient of this award) from the Data Processing Management Association. In 1991, she was awarded the nation's first National Medal of Technology by President George H. W. Bush. In 1994, more than two years after her death, she was inducted into the National Women's Hall of Fame. The Navy later launched an Aegis-guided missile destroyer named for her, the USS *Hopper*. Hopper died in 1992 and was buried in Arlington National Cemetery with full military honors.

Impact

Hopper's scientific achievements made her a legend in computer circles internationally. She began as one of the first programmers on the Navy's Mark I computer and progressed to become the first programmer on the first commercial computer, the UNIVAC. Her work with language compilers made computer programming easier. Following her introduction of COBOL, she published more than fifty articles on software and programming languages. Her innovative ideas for the use of computers inspired others to use computers creatively. As a naval officer, and later at Digital Equipment Corporation, she traveled throughout the world speaking to thousands about the future of computers. She was honored on television shows such as *60 Minutes* and was the subject of documentaries. Hopper's work essentially allowed noncomputer specialists to work directly with computers. Computers were made accessible to the average businessperson; in turn, businesses were more successful because of the wide availability of computer technology, which led to economic growth throughout the world.

John Alexander Hopps

Canadian electrical engineer

A pioneer in biomedical engineering, Hopps first experimented with applying electrical current to a failing heartbeat, laying the foundation for the artificial pacemaker that revolutionized heart care and improved the quality of life for millions of heart patients.

Born: 1919; Winnipeg, Manitoba, Canada
Died: November 24, 1998; Ottawa, Ontario, Canada
Also known as: Jack Hopps
Primary fields: Electronics and electrical engineering; medicine and medical technology
Primary invention: Artificial pacemaker

Early Life

John Alexander Hopps was born in 1919 in Winnipeg, Manitoba, in west-central Canada. Little is known about Hopps's childhood. With typical modesty, even after he had achieved considerable celebrity as the father of the artificial pacemaker, Hopps preferred to maintain a low profile and keep his personal life just that. He would speak of an idyllic childhood growing up amid the comforts of a middle-class life—Winnipeg at the time was considered one of Canada's most developed urban areas despite being in a largely agricultural province and decidedly distant from the cultural and political centers of Canada. Hopps was a precocious child and evinced early on a proclivity for mathematics. Ironically, given his eventual international reputation, Hopps never considered medicine; rather, he pursued his first love: engineering. He relished the idea of how engineering, drawing on disciplines ranging from mathematics to architecture, represented the most pragmatic application of human ingenuity. He was particularly drawn to the possibilities of electricity and how directing the energy of currents promised unlimited applications. He graduated with a degree in electrical engineering from the University of Manitoba in 1941.

Immediately, Hopps headed west, accepting that year a position at the prestigious National Research Council (NRC) in Ottawa, then (as now) among the preeminent research facilities in the world, promoting a wide range of scientific, medical, and industrial research projects. He was placed in the Radio and Electrical Engineering Division. Initially, Hopps was assigned work on the problem of improving the efficiency of the pasteurization of beer using microwave rewarming. The research environment suited Hopps: As he had little patience with theoretical work, he was drawn to the assumption that engineering was particularly suited to problem-solving and to the work of trial and error as a strategy for tackling a specific problem. He quickly distinguished himself. In 1949, his division chief recommended that Hopps transfer to Toronto's Banting Institute, where a team of medical researchers was developing pioneering applications of radio-frequency rewarming on cardiac care. Specifically, Hopps joined a research team headed by Dr. Wilfred G. Bigelow and his assistant Dr. John C. Callaghan that was investigating hypothermia, cooling the body to an extreme temperature as a technique for regulating heartbeat during experimental open-heart surgical procedures.

Life's Work

Dr. Bigelow's investigation into induced hypothermia was decidedly unconventional and widely considered risky. During late 1949, however, the research team had successfully lowered a dog's body temperature to nearly 20° Fahrenheit. The resulting slowdown in the heartbeat interrupted the normal circulation and made possible an open-chest heart procedure. Problems arose, however, when procedures were attempted to revive the heart and return it to its normative rhythm. At the time, medical science had two ways to restimulate a stopped heart: a shot of adrenalin administered directly into the heart and/or a heart massage done manually by attending physicians.

During an otherwise routine experimental procedure on a dog, its heart (perfectly healthy otherwise) unexpectedly stopped. Bigelow, more out of desperation than anything else, applied an electrical probe he happened to be holding in his hand at the time directly to the sinoatrial node. The heart, to his surprise, immediately contracted after the poke. Electrical stimulation, gently applied at measured intervals, quickly returned the dog's heartbeat to a regular rhythm without damaging any of the heart's essential muscles or nerves. The idea intrigued the team; it was at this point that the researchers sought the help of Hopps, an electrical engineer with a specific background in temperature-control experiments. They outlined their proposal: to use electrical stimulation to regulate heartbeat. This could potentially solve the problem with reviving postoperative canines and in turn clear the way for exploring the potential of open-heart surgical proce-

The Artificial Pacemaker

The heart's rhythmic beat is actually an electrical impulse generated by a signal that starts in a cluster of highly developed cells of the right atrium. That signal generates the heartbeat at a specific rate, although that rate can be affected by emotional duress or short- or long-term physical impairment. With an artificial pacemaker, generated electricity is used to sustain a heartbeat when the heart's natural conduction system fails to function properly. By contemporary standards—that is, the battery-powered implantable pacemaker—John Alexander Hopps's external pacemaker can seem crude and, given the considerable pain it inflicted on its patients and its susceptibility to electrocuting the patient, even dangerous. It is best appreciated, however, for its daring, as a breakthrough step, a historic juncture when engineering and medicine cooperated to produce a device whose theoretical foundation was far more important than the device itself. It was in use for less than five years before biomedical engineering addressed the problems Hopps's design posed. Medical researchers had long theorized that electrical current could regulate the beating of a damaged heart and maintain a healthy and consistent heartbeat, but they lacked the engineering grounding to create even a prototype device.

The electrical current in Hopps's machine was created and sustained by a vacuum tube, the same technology that made possible the incandescent light bulb and later radio and then early television broadcasting. The device had a foot pedal control switch that allowed surgeons to control the flow of electricity while they would position the actual electrodes manually during open chest surgery. During postoperative care, the device monitored heart rate and instantaneously administered an electric charge should an irregularity be registered. Thus, the generator was kept near the patient and worked off a standard AC wall socket (thus exposing the unit to the danger of fire). The device was not designed to provide long-term regulation but rather to assist in maintaining a consistent heartbeat during emergency procedures or during short-term postoperative maintenance. Patients hooked up to the external pacemaker for any period of time during their postoperative recovery were limited in their mobility (only as far as the cord reached) and under considerable discomfort. Hopps designed the device to achieve transcutaneous pacing, or external pacing. The device delivered gentle pulses of electricity directly to the patient's chest through wires sticking in the body to stimulate the heart to contract. If the patient was conscious, the current, although moderate, was considerably painful—that discomfort significantly enhanced by the wires in the chest. Records from the initial two years indicate that some patients, anxious over the pain, opted not to have the device used. Nevertheless, as a threshold device, Hopps's external pacemaker provided biomedical engineers critical data for developing more efficient devices once transistor technology and batteries were available.

dures. The ensuing project, headed by Hopps, was a landmark moment in twentieth century medicine, the first cooperative venture of the fields of medicine and engineering, the birth of the field of what came to be called biomedical engineering.

Hopps understood the ambitious goal: externally apply an electrical stimulation to the heart that would duplicate the body's normal contraction, thus not damaging the heart as cardiac massage so often did. Also, unlike the quick jolt of adrenalin, the constant application of a steady (and low) voltage would avoid muscle and nerve damage and would ensure long-term stability rather than a quick fix. The application of the electrical current, in turn, not only could control the pulse rate but also could be used in emergencies to restart a stopped heart.

Work on the project was swift and efficient—Hopps drawing not only on his own practical sense of problem-solving but also on the significant resources of both the NRC and the Banting Institute. Initially, Hopps recognized that any successful prototype would need an electrode capable of administering the nanosecond pulses of current needed for such delicate work. He designed the first catheter electrode designed specifically for cardiac resuscitation and stimulation. The catheter electrode would be introduced through the right external jugular vein, and an accompanying electrical generator would maintain the circuit. The Hopps Pacemaker-Defibrillator was first tested in 1950, effectively the world's first artificial pacemaker. Hopps's pacemaker was boxlike, roughly 30 centimeters long and several centimeters high and wide. It was powered by a standard 60-hertz household current and delivered up to 220 volts. It was tested successfully on several canines before it was introduced into patient care. Given its size, its use was restricted to operating room procedures and postoperative care. By 1957, however, the model had been sized down sufficiently to be implanted into the chest, and the era of the portable pacemaker was underway.

Hopps returned to his position at the NRC until his retirement in 1979. During that time, in addition to further developing the pacemaker, he directed important research into devices to assist the blind, to help support and even correct muscular abnormalities in the disabled, and to use ultrasound as a noninvasive diagnostic tool. More to the point, given his international celebrity as the pacemaker became a foundation of cardiac care, Hopps became a tireless proponent of the new field of biomedical engineering, founding the Canadian Medical and Biological Engineering Society and serving on numerous international boards and commissions that encouraged the new field. He championed a variety of community causes in the Toronto area well after his retirement, most notably crusades to improve medical care for children and health-style changes to improve cardiac care among the elderly. Fittingly, in 1984, Hopps himself received a pacemaker, and another later in 1997. After his death in 1998, he was hailed throughout Canada for his visionary contributions to both medicine and engineering.

Impact

Hopps's acumen in solving the problem of electrical heart stimulation is widely credited for revolutionizing cardiac care and improving the quality of life for millions of heart patients, but there is more to Hopps's impact. It is difficult for a contemporary audience to appreciate the magnitude of Hopps's initial experimental prototype as an ethical issue—indeed, the moral implications raised by his pacemaker would become a central issue in the emerging field of biomedical engineering. Although such moral dilemmas never distracted Hopps, who saw the regulation of a heartbeat as a problem that electrical engineering could solve, they are part of his invention's legacy. Indeed, applying electrical stimulation to a faltering heart had been tried before—but its success had been overshadowed by fears of public outrage. In 1926, an Australian doctor, later identified as Mark C. Lidwell, had used a 16-volt electric current to stimulate the stopped heart of a stillborn in cardiac arrest. The procedure had worked, but fears of religious objections to doctors playing God kept the incident in hospital files until the mid-1960's, only after Hopps's work had made this kind of procedure routine.

In addition to raising thorny questions over interfering with the "natural" course of life, Hopps's pacemaker provides a significant example of how medical technology evolves at a remarkable pace. Because Hopps's first working model depended on vacuum tubes, it appears cumbersome to a contemporary audience. However, once Hopps had demonstrated the regulatory power of an electrical current applied directly to the heart as a way to stimulate rhythmic beating, engineers across the globe worked quickly to make the device portable, first as an external model that strapped to the chest but ultimately as the familiar battery-driven device inserted directly into the heart. The evolution of the pacemaker is a landmark case in the cooperation of engineering and medicine, a groundbreaking confluence that has led to major advances in areas as diverse as brain surgery, eye care, pulmonary treatment, and nerve damage repair.

Godfrey Newbold Hounsfield

English electrical engineer

Hounsfield researched, designed, and built the first computerized axial tomography (CAT) scanner, which uses X rays to obtain three-dimensional images of the internal organs of the body. The CAT scan, a noninvasive procedure, revolutionized diagnostic medicine, allowing doctors to locate tumors and other diseased tissues in the body.

Born: August 28, 1919; Newark-on-Trent, Nottinghamshire, England
Died: August 12, 2004; Kingston upon Thames, England
Primary fields: Electronics and electrical engineering; medicine and medical technology
Primary invention: Computerized axial tomography scanner

Early Life

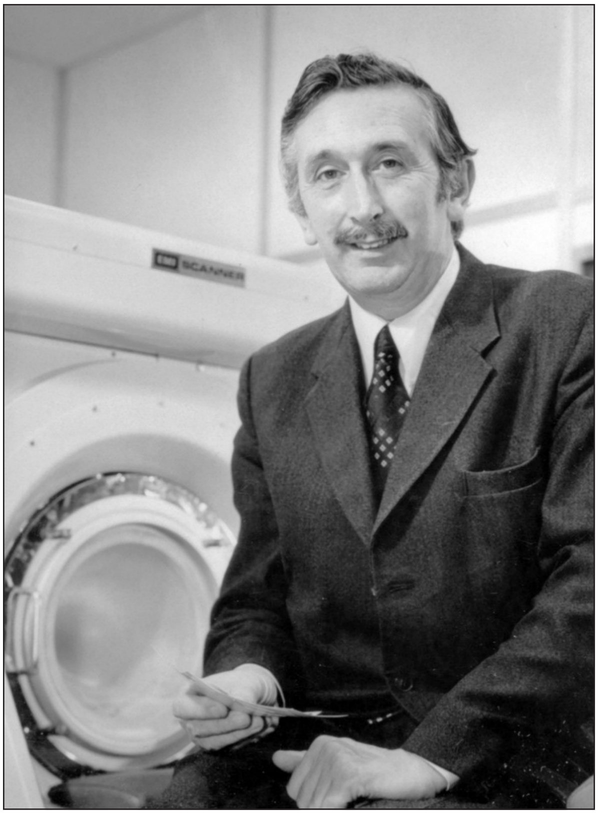
Godfrey Newbold Hounsfield (HOWNZ-feeld) was born in Newark-on-Trent in Nottinghamshire, England, in 1919. His early life was spent on his parents' farm, where he was fascinated by the farm machinery and electricity. Hounsfield learned at an early age how the machines worked and taught himself the fundamentals of electronics. He built electrical recording machines and radio sets, and he tried to fly off haystacks with a home-built glider. Some of his experiments were dangerous. He almost blew himself up while experimenting with water-filled tar barrels and acetylene to see how high they could be propelled by water jets.

Hounsfield had little interest in grammar school and, except for courses in science and mathematics, did not do well. After grammar school, he attended a vocational college and graduated with a degree in radio communication in 1938. He was interested in aviation, and at the outbreak of World War II he volunteered for the Royal Air Force (RAF). There he studied and later taught radar technology at the RAF's Cranwell Radar School. After being discharged from the RAF at the end of the war, he was given a grant to study at the Faraday House Electrical Engineering College, where he graduated in 1951 with a degree in electrical and mechanical engineering. That year, he obtained a position as an engineer at Electrical and Musical Industries (EMI).

Life's Work

At that time, EMI was primarily involved in sound recordings and selling records. The company had become very rich by publishing the Beatles' recordings and was looking to expand its business into other fields. Hounsfield's initial research was on radar and guided weapons, but his interest quickly turned to computers. He worked on memory systems, including core stores and tape decks. He was soon made a team leader and in 1958 helped design the first all-transistorized computer built in England, the EMIDEC 1100. At that time, transistors were very slow compared to vacuum tubes. Hounsfield was able to increase the speed of the transistors to that of vacuum tubes by driving the transistors with magnetic cores.

After these successes, Hounsfield was transferred to EMI's Central Research Laboratories, where he could pursue his own projects. His first project was to design and build a thin-film memory for computers that would hold one million words—a very difficult technical task. After considerable research, EMI decided that the project was not commercially feasible and told Hounsfield to



Godfrey Newbold Hounsfield with his computerized axial tomography (CAT) scanner. (©The Nobel Foundation)

Computerized Axial Tomography

In 1967, Godfrey Newbold Hounsfield conceived the idea for a machine that could create detailed images of the internal structures of the body by taking X rays at various angles. He realized that if X rays were taken perpendicular to each other, a cross section of the examined object could be obtained. If the X-ray beam was collimated and moved around the axis of the body with the X-ray detector opposite, the maximum information about that slice of the body could be collected. Further, by moving the body through the beam as the slices were recorded, the maximum data about the interior of the body could be obtained. The cross-sectional X-ray images could then be assembled by a computer to present a three-dimensional view more detailed than an individual two-dimensional X ray.

Hounsfield invented a density scale, now called the Hounsfield scale, to change signals from the detector into numbers that could be manipulated by the computer. The Hounsfield scale uses Hounsfield units (HU) and ranges from –1000 HU (air) to 0 HU (water) to +1000 HU (bone). The computer takes the numbers from the X-ray detector and solves a series of equations to reassemble the slices and to obtain an image of the interior of the body. The first computers were very slow, and producing a scan of the head took hours. Now, with much faster computers, a high-resolution scan of the entire human body can be obtained within minutes.

Hounsfield's computed tomography (CT), or computerized axial tomography (CAT), scanner was first used on a living patient in the fall of 1971. CAT scanners have since changed the world of medical imaging and now make it possible to measure accurately the position, size, and density of an object within the human body. It is an indispensable tool for localizing a cancer prior to surgery or radiation therapy. Although the procedure is expensive and has a higher radiation dose than an individual X ray, it has helped save thousands of lives.

think about some other research that he would like to do. He chose pattern recognition.

Hounsfield suggested that if one had various pieces of a pattern, it might be possible to reconstruct the image with a computer. He first put together a matrix of numbers representing an object and then scanned these numbers in slices. By connecting the slices together with a computer program, he was able to reconstitute the image. This worked very well, and he saw that by using a collimated beam of X rays and imaging a body in slices around its axis, he could put the slices together with a computer and obtain an image much superior to a conventional X ray.

Because Hounsfield worked for a commercial company, he had not been exposed to the academic literature and did not know of other work that had been done on X-ray computed tomography. Several years earlier, Allan M. Cormack, a South African physicist, had worked out the method of taking many X-ray images from different directions and putting the data together mathematically to form a much better picture than that obtained with conventional X rays. Unfortunately, computers at that time were not capable of handling such data, so it was not possible for Cormack to build a workable model.

Hounsfield's first prototype scanner was built on a lathe bed and took 160 parallel readings through 180 angles. The output was stored in a computer memory and then analyzed using an algebraic reconstruction technique that Hounsfield had worked out. His first tests were made on a preserved human brain and then a fresh cow brain from a butcher shop. The system worked well from the very beginning. After his first successes, he requested a grant from the Department of Health and Human Services to help develop the scanner. This money allowed him to perfect the instrument, and the first computerized axial tomography (CAT) brain scanner was installed in Atkinson Morley's Hospital in London. On October 1, 1971, doctors performed the first CAT scan of a living patient. This trial detected a cystic brain tumor in the patient.

In 1975, Hounsfield built a whole-body scanner and continued to develop the technology for the remainder of his career at EMI. Later, he was also involved in research into nuclear magnetic resonance (NMR) imaging. He retired in 1984 but continued as a consultant for several more years. He lectured in various countries but never felt comfortable speaking in public.

Hounsfield was a lifelong bachelor who lived modestly. He was a shy man, and his main interests were work-related. He lived a solitary life and liked to ski and take long walks in the mountains. He loved music, particularly jazz, and taught himself to play the piano. Though he had wealth and fame, Hounsfield spent little upon himself and never had a permanent residence until the mid-1970's.

Many honors and awards were accorded Hounsfield during his lifetime. He was made fellow of the Royal Society in 1975, and in 1976 was made a Commander of the Order of the British Empire (CBE). In 1979, he received the Nobel Prize in Physiology or Medicine together with

Dr. Allan Cormack for “developing computer assisted tomography.” Hounsfield was knighted by Queen Elizabeth II in 1981.

Upon his death in 2004, Hounsfield’s primary bequests were to his family members. After these bequests, he left the remainder of his money to the British Institute of Radiology to set up an annual Godfrey Hounsfield Lecture.

Impact

The invention of the CAT scanner by Hounsfield was the first major advance in medical imaging since Wilhelm Conrad Röntgen’s discovery of X rays. An X ray is a two-dimensional picture that is most useful in observing dense objects such as bones. However, it is not sensitive enough to resolve tissues with different densities within the body and cannot distinguish between two organs that lay one above the other. Hounsfield’s CAT scanner produced clearer images of soft tissues. After EMI built the first commercial CAT scanner and sold a few of the models to hospitals in England, the utility of the device became obvious.

The first CAT scanners could only scan small volumes and were designed to look for lesions or nodules in the brain that could not be seen by conventional X rays. The CAT scanners were bulky and expensive, but as transistors and integrated circuits became available, the scanners could be used for more than brain scans. Improvements were made to the X-ray detectors to improve the resolution. With more collimated X-ray sources and faster computers, scans can now be made in minutes.

By the year 2000, there were about seven thousand CAT scanners in use in the United States. The scanner is the instrument of choice for cancer diagnostics. Some researchers have claimed that there has been an overuse of CAT scans in the United States, unnecessarily exposing patients to radiation, which may increase their cancer risk.

Elias Howe

American machinist

In addition to being the first American inventor to build a workable sewing machine and have it successfully patented, Howe combined with other sewing machine manufacturers to minimize lawsuits and maximize profits by sharing patents for fees to avoid mutually destructive competition.

Born: July 9, 1819; Spencer, Massachusetts
Died: October 3, 1867; Brooklyn, New York
Also known as: Elias Howe, Jr. (full name)
Primary fields: Household products; manufacturing
Primary invention: Sewing machine

Early Life

Elias Howe, Jr., was one of eight children born to a poor farmer, Elias Howe, Sr., and his wife, Polly Bemis Howe. Among the Howe family, two of Howe’s father’s brothers were inventors. Elias, Sr., himself ran a gristmill and cut lumber, in addition to farming, to support his family. When Elias, Jr., was six, he worked along with his brothers and sisters sewing wires on cards by hand at home. This piecework, for a local cotton mill, brought in some extra money to help the family. His other work as a boy included repairs to his parents’ farmhouse. He showed great patience and determination in his painstaking tasks, often repairing the farm machinery—work he enjoyed. The young boy's life, however, was not all work. Regarded as easygoing and companionable, he had several good friends. He attended school during the winter but spent the other seasons at work on the farm.

By the time Howe was twelve, his father realized that he could no longer feed and clothe him, so he was hired out to work on a neighbor's farm. This arrangement lasted for about one year but had to end when Howe's frailties interfered with his heavy chores. The youngster had been born small and frail, and he never had the endurance and strength necessary for hard labor, a fact with which he had to contend all of his life. He was also congenitally lame.

In 1835, Howe moved to Lowell, Massachusetts, where he found work repairing cotton-mill machinery. Although he was still a young man, he was admired for his advanced skill with machinery. However, the economic panic in 1837 forced the cotton mills in Lowell to close, and young Howe lost his job.

Howe next moved to Cambridge, Massachusetts, where he roomed with a cousin and worked as a foreman for a hemp-carding company; this job was boring and fatiguing, so Howe stayed for only part of a year. His next position was a fortunate one for him. He worked as a repairman for Ari Davis of Boston, a skilled watchmaker, who also made precision instruments for seamen and for the scientists at Harvard University. Davis's shop attracted many inventors, and it was here that Howe got the idea to invent a sewing machine. One day in 1839, he heard the loud-voiced Davis tell a customer who was struggling to invent a knitting machine that the invention of a sewing machine would make a man rich.

Elias Howe. (Library of Congress)

On March 3, 1841, Howe married Elizabeth J. Ames of Boston. In a few years, the couple had three children to support. To help her husband, Mrs. Howe did hand-sewing for her neighbors. Many evenings, Howe watched her sew, pondering how a sewing machine would work. In part from his fascination with machinery and in part from his desire to escape poverty and support his family, Howe became obsessed with the idea of inventing a sewing machine.

Life's Work

Howe quit his job at Davis's shop and moved into the attic of Elias Howe, Sr.'s house—now in Cambridge. There in 1843, working diligently, Howe was beginning to put together his first version of a sewing machine when a fire destroyed the house. A friend, George Fisher, took an interest in Howe's invention and generously funded him five hundred dollars for the equipment he needed; Fisher also boarded the Howes in his home.

From 1844 to 1845 (especially during the winter months), Howe worked at a feverish pace to complete a functioning sewing machine. He used no blueprints or sketches but worked from a mental design; he also used the trial-and-error method of putting his ideas into moving parts, often discarding pieces of the machine that had not worked to his satisfaction. One of his most serious challenges was the designing of the proper needle for his sewing machine; needles with holes at the head (as women use in hand sewing) did not work on the machine. Finally, Howe had a dream in which men were threatening to kill him with spears; he noticed that all the spears had holes near their points—this was his solution. Howe's machine sewed perfectly when he used such needles.

By April of 1845, Howe and his business partner Fisher had a machine that they could present to the public. A demonstration was held at the Quincy Hall Clothing Manufactory, where Howe, operating his machine, sewed at least five times faster than the best women hand-sewers. The stitching produced by Howe's machine was also neater and stronger than that done by hand.

Howe's sewing machine did not impress Boston's clothiers as a useful item for them to purchase. A few factors affected the marketing of Howe's invention to American industry. First, it was expensive—about three hundred dollars. Second, the hand-sewers would have to be retrained to work by machine, and their employers feared that they would refuse (the workers knew that the sewing machines would soon take most of their jobs). Finally, the clothiers already had cheap labor in their women workers, so they saw no need to buy machinery to do the sewing. Howe was also at a disadvantage in that the United States did not yet have a strong communication network. If news of his machine had reached major clothing firms in New York City, he may have found buyers for his invention.

When Howe realized that there were no eager buyers for his machine in the United States, he sent his brother Amasa Howe to London, England, to try to market it there. The British industries were more organized than the American ones at this time and were also more acquainted with manufacture by machine. In October of 1846, Amasa Howe sold his brother's sewing machine to William Thomas of London for £250. Thomas was a maker of corsets, shoes, and umbrellas, and he was also a dishonest man. He obtained a British patent for the Howe machine in his own name, rather than in Howe's as he had promised. Thomas also made a verbal agreement with Amasa to pay Elias a royalty on each sewing machine Thomas sold—an agreement that he ignored.

Howe's profits from the first sale of his invention quickly went to pay his debts. He found himself in poverty again and so accepted an offer from Thomas (still seemingly a fair man) to move to London and build for him a stronger sewing machine (presumably to sew leather for shoes). Howe and his family moved to a poor section of London, and he worked for Thomas for fifteen dollars a week. At the end of eight months, Howe had created the desired machine, and Thomas, not too graciously, ordered Howe to work as a repairman in his factory. Howe felt insulted and left.

The year 1848 was an especially difficult one for Howe. First, he had to be separated from his family. Un-

The Rise of the Sewing Machine

In 1846, Elias Howe was awarded the first U.S. patent, number 4,750, for a functional sewing machine using a lockstitch design. The first patent connected to mechanical sewing had been issued in 1755 in England to the German inventor Charles Weisenthal for a needle that was designed for a machine. However, the patent was for the needle, not a machine—and the machine designed to use the needle may, in fact, not have existed. Many other inventors attempted to design a mechanical sewing device, but their machines were neither functional nor successful.

In 1830, a sewing machine was designed and manufactured by a French tailor, Barthélemy Thimonnier, to mass-produce uniforms for the French Army, but rioting tailors destroyed the machines. His design merely mechanized the hand-sewing operation, as it used one thread only and a hooked needle that made the same chain stitch used with embroidery.

In 1834, New Yorker Walter Hunt contributed a great improvement when he used a lockstitch. He never patented his method, however, because he thought that his invention might cause unemployment. When, twelve years later, Howe independently patented his sewing machine for "a process that used thread from two different sources," the device was on its way to becoming the modern sewing machine.

Howe's machine had a needle with a straight eye-point and transverse shuttle. The needle was pushed through the cloth and created a loop on the other side; a shuttle on a track then slipped the second thread through the loop, creating what is called the lockstitch. The technique proved highly successful, but Howe had problems defending his patent and marketing his invention.

Sewing machines did not enter mass production until the 1850's, when Isaac Singer built the first commercially successful machine. Singer "borrowed" Howe's lockstitch mechanism and became the largest manufacturer of sewing machines. In Singer's sewing machine, the needle moved up and down rather than the sideways, and power was provided by the operator, using a foot treadle. Previous machines were all hand-cranked. However, because Singer used Howe's lockstitch process and a needle similar to that employed in Howe's design, Howe sued Singer for patent infringement, and he won his case in 1854.

Allen Wilson developed the rotary hook shuttle. Ultimately, a design that incorporated the work of Howe, Singer, and Wilson was patented, and by 1860 more than 110,000 sewing machines were produced in the United States alone. Today, modern sewing machines span an enormous variety, for both in-home use and, even more important, for industrial purposes. However, Elias Howe's basic lockstitch operation remains unchanged.

able to support them, he sent them home to the United States, while he remained in England to build another sewing machine with the financial help of Charles Inglis, a relatively poor man himself. When this machine was finished, Howe sold it cheaply and also pawned his American patent papers on his first sewing machine (along with a working model), in order to buy ship passage back to the United States.

Howe landed in New York, where he found employment as a mechanic at a good wage, but he had held this job for only a few weeks when tragedy struck. His wife, having battled consumption for two years, was dying. Elias Howe, Sr., sent his son money to travel home to see Elizabeth before she died; his brother-in-law lent him a suit to wear to her funeral. Howe also learned that the few household goods he owned had been lost in a shipwreck on their passage from England. His father and neighbors helped him through this crisis, taking care of his children.

Ironically, at about this time, Howe learned of several American copies of his sewing machine, produced with total disregard to his U.S. patent. However, Howe remained persistent, patenting his first sewing machine on September 10, 1846, even though he had to mortgage his father's farm for the money that he needed to travel to Washington, D.C., to receive that patent.

Howe's legal patent made a considerable difference in the outcome of his life's work. He now elicited the aid of George Bliss, who had bought the 50-percent business interest in Howe's invention from George Fisher. Bliss and Howe employed the lawyers necessary to wage long court suits against the makers of American sewing machines. Howe wished to win a royalty from these manufacturers for each sewing machine they had sold in the United States; as the patented inventor of the machine, he had this right.

One of Howe's opponents in court proved to be a determined man himself. Isaac Merrit Singer, wishing to retain the fortune he was making from selling Singer sewing machines, hired help to refute Howe's claim that he was the rightful inventor. Singer located Walter Hunt of New York State, who had built a model of a sewing machine earlier than had Howe. Singer lost his case, however, when it was shown in court that Hunt's rebuilt machine did not work and that Hunt had never patented it.

Howe, after battling in court from 1849 to 1854, was victorious and, instantly, a rich man. All of his American competitors who were manufacturing and selling machines had to pay royalties to him. Soon, his income was about four thousand dollars a week. However, Howe was a generous man, sharing his new wealth with the friends and relatives who had helped him in his years of struggle. His one deep regret was that his wife had died before he gained his fortune. The humorous and fun-loving aspects of Howe's personality had left him at her tragic death.

Howe was, however, left with his dedication, which he used to good advantage in his remaining years. In 1865, in Bridgeport, Connecticut, he built a large, modern plant for the manufacture of sewing machines (later managed by his brother Amasa). Howe became a prominent and respected citizen of Bridgeport. When he volunteered to serve as a private in the Union Army during the Civil War (despite his age and infirmities) many young Bridgeport men were moved by his example and volunteered as well. Howe generously outfitted the entire Connecticut Seventeenth Regiment Volunteers, which he helped to organize; he even provided horses for the officers and paid the men when their army wages were delayed. Howe served in a Union Army camp near Baltimore, Maryland, but was forced to leave when his chronic frailty made it impossible for him to continue his duties as the camp's postmaster.

While visiting at his daughter's home in Brooklyn, New York, in 1867, Howe contracted Bright's disease; he never recovered and died October 3, 1867. The large factory he had built in Bridgeport, Connecticut, passed on to his son, who managed it until a fire leveled it on July 26, 1883. In the following year, the city of Bridgeport, in gratitude, erected a statue of Elias Howe, Jr., in their Seaside Park. He stands, hat in one hand and cane in the other, overlooking Long Island Sound. His face is large and solid, with a prominent nose, soft eyes, and firmly set lips—the face of a determined Yankee inventor.

Impact

With his invention of the sewing machine, Howe made a contribution to American industry that profoundly affected Americans' lives. The hand-sewn garments that women laboriously made for their families were replaced by mass-produced clothing that sold at affordable prices. Howe's invention also moved the making of many clothing items, including shoes, out of cottage industries and tailor shops and into manufacturing plants. The sewing machine became a reasonably priced, convenient piece of equipment that was also found in a large number of homes; there sewing became a creative task, rather than a painstaking necessity.

Howe also played an important role in another area of American industrial development. He, along with several successful sewing machine manufacturers, held a conference in Albany, New York, in 1856, with the purpose of avoiding further lawsuits. These manufacturers, known as the Combination, became the first American industrial group to form a patent pool; they shared one another's machine designs and improvements for a reasonable fee, rather than remaining rivals.

Howe's inventiveness, perseverance, and mechanical skill won for him many well-deserved honors in foreign nations, including a gold medal at the famed Paris Exhibition of 1867. His genius and Yankee know-how gained for this once poverty-stricken American the acclaim of a grateful nation and a grateful world.

Bays, Carter. *The Encyclopedia of Early American and Antique Sewing Machines: Identification and Values*. 3d ed. New York: Collector Books, 2006. Aside from information on early sewing machines, this encyclopedia includes abundant colored photographs.

Burlingame, Roger. *March of the Iron Men: A Social History of Union Through Invention*. New York: Charles Scribner's Sons, 1938. A fascinating book, well researched and well organized. As an interpreter of social history, Burlingame has strong opinions, which he defends admirably. Outstanding bibliography, chronology chart, and illustrations. Good at showing inventors' motives, including Howe's.

Chamberlain, John. *The Enterprising Americans: A Business History of the United States*. New York: Harper & Row, 1963. Originally a series in *Fortune* magazine on famous American businesspeople. Includes an extensive and helpful bibliography. Emphasis is on the wit and ingenuity of some Yankee inventors, including Howe. A lively and engaging style throughout. A good book for the high school student.

Gies, Joseph, and Frances Gies. *The Ingenious Yankees*. New York: Thomas Y. Crowell, 1976. The authors focus on how Yankee inventors helped transform an agricultural country into a powerful technological nation. Offers clarity of exposition in an interesting narrative format. A biographical sketch of Howe is included, as well as an extensive bibliography.

Iles, George. *Leading American Inventors*. New York: Henry Holt, 1912. Iles offers a careful analysis of Howe's personality, focusing on the characteristics that caused Howe's success. Iles brings his subject to life for the reader. Some of the details of Howe's life covered here are not found elsewhere; a portrait of him is included.

Parton, James. *History of the Sewing Machine*. Ann Arbor: University of Michigan Library, Scholarly Publishing Office, 2005. Provides a history of the manufacture and repair of nautical and philosophical apparatus kept by Ari Davis.

Poole, Lynn, and Gray Poole. *Men Who Pioneered Inventions*. New York: Dodd, Mead, 1969. A book suitable for a young person, from the Makers of Our Modern World series. Less factual information in its chapter on Howe than in the other books listed here. The Pooles describe how the sewing machine affected American life.

Thompson, Holland. *The Age of Invention: A Chronicle of Mechanical Conquest*. New Haven, Conn.: Yale University Press, 1921. One volume in a series devoted to American life, history, and progress. It has an ample bibliography, as well as photographs and illustrations. Vivid descriptive passages of Howe at work (slightly fictionalized) are provided in a narrative account of his life and work. Also details the mechanics of Howe's sewing machine.

Wilson, Mitchell. *American Science and Invention: A Pictorial History*. New York: Simon & Schuster, 1954. A large volume that relies on period illustrations and photographs to describe the course of American invention. Concise and accurate on Howe's life as well as his inventing. Good descriptions of how his machine operated. Also interesting is a discussion of Howe's character and his mechanical skills.

HUANGDI

Chinese military leader and agriculturist

Although shrouded in mythology and controversial as to his historical veracity, Huangdi is credited with many technological and cultural achievements, including the invention of boats, the horse-drawn chariot, ceramics, military armor, Daoist religious rituals, and the agricultural calendar allowing regular planting cycles and crop rotation. He also wrote important treatises on medicine and political theory. If his books are accepted as authentic, Huangdi is one of the earliest authors in known history.

Born: c. 2704 B.C.E.; China
Died: c. 2600 B.C.E.; China
Also known as: Shen Yen Huang-ti *or* Huang-ti (Wade-Giles); Yellow Emperor
Primary fields: Agriculture; medicine and medical technology; military technology and weaponry
Primary invention: Horse-drawn chariot

EARLY LIFE

Huangdi (huh-wong-dee) is regarded as a patriarch of China, a founding father of an ancient civilization. Moreover, many Han Chinese regard Huangdi as a direct ancestor and worship him as a god. Scholars of Chinese history agree that there is almost no reliable biographical information about Huangdi that can be separated from the mythology. The earliest dynasty of China verified by archaeological evidence is the Shang (1765-1122 B.C.E.), about one thousand years after Huangdi's reign. Whether Huangdi is a historical person or a mythological accretion of early accomplishments, his innovations and inventions tell the story of the earliest Chinese civilization. So pervasive is the reputation of Huangdi that Chinese history might cite the year 1911 C.E. as the year of a nationalist revolution led by Sun Yat-sen, the first year of the Republic of China, or the 4,609th year of the "Yellow Emperor," Huangdi. Huangdi earned the name "Yellow Emperor" because he is associated with the Yellow River (or the Huang He) and earth, which is the yellow element according to ancient Chinese cosmology.

Huangdi is believed to have come from the central heartland of the Yellow River basin. Nothing is known of his family background, but some historians regard Huangdi as the third of the first five Chinese sovereigns. The Age of the Five Rulers, or Legendary period, is thought to have lasted for six hundred years in the middle of the third millennium B.C.E. According to legend, when the early ruler Shennong died, his court official Ch'ih Yu led a rebellion of the southern barbarians, which was put down by Huangdi. Huangdi successfully suppressed the rebellious tribes and incorporated the new regions to the south beyond the Chang (Yangtze) River into the Chinese Empire. He also extended the reach of China to include regions in the eastern province on the Pacific, to the north, and to the western frontier zone including deserts and mountains. He married as his primary wife Leizu, who was the daughter of a local feudal lord. In the tradition of ancient China, Huangdi undoubtedly kept many subsidiary wives who worked in the silkworm industry.

Huangdi's role in religion adds to his cultural importance. Huangdi is regarded as a founder of Daoism who lived centuries before Laozi (Lao Tzu), the traditional "old master" and scribe of the sixth century B.C.E. text the *Dao De Ching*. Daoist practitioners regard Huangdi as the first master who directed the teachings of Laozi, ascended to immortality, and attained the status of patriarch of the nation.

LIFE'S WORK

Huangdi's accomplishments are so numerous as to include many basic ingredients of civilization. Scholars regard his inventions as possibly attributed to an amorphous "grandfather" of China. Scribes during the much later Warring States period of the Zhou Dynasty might have invented Huangdi to record traditional creation stories and myths in a human form. Early Chinese historians might have created the Age of the Five Rulers in order to give their history prestige, longevity, and continuity in the way Roman historians might have invented their early Etruscan monarchs.

Whether historical or mythological, Huangdi is responsible for much of the material culture of Bronze Age China. For example, he is said to have perfected bows and arrows, military armor, and armed boats. Huangdi is thought to have unified the heartland of ancient China, defeating competing tribes to stabilize the region politically. He is credited with clearing swampland and cutting back forests in order to make room for the domestication of animals such as pigs, cows, horses, and goats. Huangdi is also thought to have invented the wheeled cart for transport of farm products and the chariot for war.

In the realm of religion and philosophy, he is said to have received instruction from three female Daoist "immortals" who informed him about the practice of yoga as a curative physiological and religious ritual that would ensure a long life and fertility. In the annals of legend, Huangdi himself achieved Daoist immortality and ascended to heaven on the back of a dragon accompanied by his courtly ministers and seventy female servants.

Some of Huangdi's most astounding contributions to civilization are found in the field of medicine. Huangdi is credited with the invention of acupuncture and the scientific study of human anatomy and physiology. European techniques of healing reached China in the seventeenth century C.E. through Jesuit missionaries, but the early Christian travelers discovered a much older tradition of Chinese traditional healing and acupuncture described in *Huangdi neijing*. Though it is impossible to prove definitive authorship, Huangdi might have written the first treatise on health and sickness and one of the oldest known books in the world. In fact, some scholars attribute the invention of writing to Huangdi for the express purpose of recording his medical knowledge. The *Huangdi neijing* is the foundation of traditional Chinese medicine. Huangdi's book consists of anatomical and physiological charts, methods of diagnosis, description of diseases, therapeutic methods, acupuncture methods, and moxibustion charts (which depict needle placement sites). The book contains illustrations of internal organs such as the kidneys, the liver, the digestion system, as well as the blood vessels and circulatory system.

Huangdi, the "Yellow Emperor." (The Granger Collection, New York)

Huangdi is also credited with one of the earliest treatises on the fundamental Chinese concepts of yin and yang. Huangdi describes yin and yang as the basis for the order of the universe and the foundation of health. Balance and harmony depend on keeping the forces of yin and yang in healthy proportions. In each field of endeavor and human attempt to shape the environment, yin and yang can be seen not as opposed forces but as intertwined tendencies. Yin is thought to be the "female principle," associated with darkness, soft shapes, moist earth, cool water, and the Moon. Yang is the "male principle," associated with items that are light, hard, dry, warm, and the Sun. In Huangdi's theory of health, the human body is divided into the lower, middle, and upper regions. Each of these is in turn subdivided into three sectors containing elements of heaven, earth, and humanity. Each subdivision was held by Huangdi to be composed of one part yin and one part yang; thus Huangdi saw the human body as totally in harmony with three parts of each principle. Treatment of certain diseases depended largely on the location within a particular region of yin and yang, so knowledge of the anatomical structure was essential. For example, the "absolute" and "lesser" versions of yin and yang were said to control the liver, gall bladder, heart, small intestine, spleen, and stomach.

Impact

If regarded as a historical person, Huangdi had a profound impact on ancient China and invented most of the material culture as well as the most influential theories of politics and medicine. If Huangdi is viewed as mythological, his accomplishments are still valuable because they testify to the high level of civilization attained in China during the third millennium B.C.E. While the Greeks and Europeans were living in primitive circumstances, the Chinese of 2600 B.C.E. had invented the building blocks of civilizations: wheeled carts, pottery, and a dependable agricultural calendar. The Chinese had invented writing and started to record their theories of human health, religion, and politics in books attributed to Huangdi.

—*Jonathan Thorndike*

The Horse-Drawn Chariot

According to legend, Huangdi is credited with the invention of the horse-drawn chariot, which might have enabled him to transport soldiers and to stage offensive maneuvers against the rebellious southern barbarians in the early years of his reign. However, archaeologists speculate that the chariot actually entered China from the ancient Near East or Mesopotamia during the much later Shang and Western Zhou periods or around 1200 B.C.E., approximately the same time as the legendary fall of Troy. The archaeological evidence for the development of the chariot in China is quite good, and the theory that it was imported from the Near East is based on the similarities of archaeological finds in both locations.

Whether or not this invention can be attributed to Huangdi is less important than the impact the chariot had on military technique and battle strategy. The military supremacy of the chariot against foot soldiers was based on its speed and maneuverability. Troops could be dispatched quickly from cities to areas of need, and information could travel more quickly back and forth from the front line to the commanding officers or kings. These early Chinese chariots were similar to their Near Eastern brethren in design, consisting of a chariot box, axle and wheels, and harnessing mechanism. The lightness of the chariot was its prime innovation when contrasted with lumbering ox-drawn wagons for carrying farm goods and supplies. The chariot box was rectangular and enclosed by a railing that rose to a height of approximately 45 centimeters (17.7 inches). It was open in the rear, allowing for quick entry and exit. The light design allowed for two or three riders between two wheels made with six to eight spokes and connected to a central spine, or yoke. The single wheel axle could be moved toward the horses to balance out the weight of the soldiers and provide some shock absorption, especially for rough terrain. The chariot would remain the prime advantage in military technology in the ancient world until the introduction by the classical Greeks of the hoplite (heavily armed warrior) and the phalanx combat strategy in the fifth century B.C.E.

David Edward Hughes

British musician and physicist

Hughes's invention of an improved carbon microphone was an important step in the development of the telephone. He also invented a printer that could be used with a telegraph, and the induction balance, used to detect metals.

Born: May 16, 1831; London, England
Died: January 22, 1900; London, England
Primary fields: Communications; electronics and electrical engineering
Primary inventions: Loose-contact carbon microphone; induction balance; printing telegraph

Early Life

David Edward Hughes was born into a family of talented musicians in London, England, though he grew up and began his career in the United States. He and his three siblings were all considered child prodigies, and they performed concerts with their father throughout England. The children were encouraged to develop their skills on different instruments; Hughes played piano, harp, violin, and concertina, and he composed music for all four. The family emigrated to the United States when Hughes was nine, arriving in New York City on October 8, 1840. They performed in New England, Canada, the West Indies, and once at the White House before buying a farm in Virginia and settling there. While only nineteen years old, Hughes was named a professor of music at St. Joseph's College, a school for women in Bardstown, Kentucky, thanks to the support of his piano teacher.

In addition to his interest in music, Hughes was fascinated by the physical sciences and by philosophy. With equipment that he built from common objects, and with little mathematical training, he conducted experiments with electricity and with various ways of sending and receiving signals. When he was twenty years old, he was named chair of the Natural Science Department at the college.

Life's Work

In 1855, at the age of twenty-four, Hughes obtained his first patent, for a telegraph instrument that printed messages. The invention was something of an accident: He had been trying to create a machine that could transcribe musical notation as music was played, and his first keyboard was adapted from a piano. Each key corresponded to a letter of the alphabet, and so a person operating the Hughes printer could, in effect, type a message and have it printed out in words—not in dashes and dots, as in the Morse telegraph system—at the receiving end. Hughes sold the North American rights to a group that became the Western Union Telegraph Company, achieving his first commercial success. His machine became a popular replacement for the Morse system in the United States. Hughes returned to England to try to sell his system to the Electric Telegraph Company there, but the company preferred the Morse system. He moved next to Paris, where the French government agreed to give his system a yearlong trial. The trial was such a success that Napoleon III named Hughes a Chevalier of the Legion of Honor, and his system of telegraphy was quickly adopted throughout the Continent. While in Paris, Hughes met Anna Chadburn, an artist from New Hampshire. Together they moved to London in 1877 and married. Thanks to Anna, Hughes's notes and papers were saved after his death. The couple had no children.

Hughes had made enough money from the printing telegraph that he could devote his time to experimentation without needing to earn an income. Still, he preferred to work with common items, including nails, jam pots, cigar boxes, and scraps of wire as he experimented. His experiments in electricity and magnetism led to several scientific papers, which he presented before the Royal Society in London, and he was eventually named a fellow of that group. In 1886, he became the president of the Institution of Electrical Engineers in London.

With the invention of the telephone in 1875, Hughes joined the legion of professional and amateur scientists working to improve the device and make it commercially viable. He built his own telephone at home according to the prevailing designs; when he repaired a loose connection and lost a sound, he realized that a loose contact was actually preferable for transmitting electromagnetic signals. Putting granules of carbon in loose contact with two plates, he invented the loose-contact carbon microphone. On May 8, 1878, Hughes demonstrated to an astonished Royal Society that his microphone could amplify a whisper so that it could be heard through a room. He made a public announcement on June 9 of that year, inviting others to refine his work. He refused to file a patent, so that the work of other innovators would not be limited.

As part of his experimentation with sound and electromagnetism, Hughes invented the induction balance. It consisted of two coils connected to a battery and a telephone; when one of the coils was disturbed by the presence of a conducting metal object, the induction balance produced sound. Hughes used the device as a tool for producing and amplifying sound as he developed the carbon microphone, but the induction balance later became useful in producing metal detectors.

Not all of Hughes's findings were accepted by fellow scientists. When he began work on the telephone, he was curious to see how far he could send a signal. On February 20, 1880, he demonstrated to the Royal Society a device that sent and received radio waves. His conclusions were dismissed by the group, which declared that it was simple induction, not radio waves, that caused Hughes's signals. Hughes decided not to pursue this project further, and he never published his findings. Decades later, other scientists duplicated his work and developed the wireless telegraph.

Hughes died in London on January 22, 1900. He had lived simply all his life, leaving behind a large fortune,

The Carbon Microphone

After Alexander Graham Bell's first electromagnetic telephone transmission in 1875, the rush to develop a better telephone system was dramatic and contentious, and popular histories credit at least three different men with the invention of its important carbon microphone. Emile Berliner claimed to have invented it in 1876, and he sold his patent to the American Bell Telephone Company. Thomas Alva Edison filed a competing patent claim in 1878, and British and American courts ultimately supported Edison. Still, many sources, including the venerable *Encyclopedia Britannica*, credit Hughes with the invention.

The earliest device used a carbon ball between two metal plates to convert sound energy to electrical energy. As sound waves hit the outer plate, or diaphragm, they changed the pressure on it, which in turn changed the pressure on the carbon, causing the electrical resistance between the plates to change. Edison's telephone system passed an electrical current through the device and exploited the resulting changes in the current. Edison's and Berliner's microphones, which indeed predate Hughes's, are also known as "carbon-button transmitters." Hughes's improved version is the loose-contact carbon microphone. Hughes proved the importance of having a loose contact rather than a tight one between the two surfaces. He also tested various materials to determine which was best for creating resistance, concluding that loose grains of carbon produced the best sound quality. To distinguish his transmitter from Edison's, he brought back a disused term and called his instrument a "microphone." Hughes did not seek a patent for his invention. His microphone became the standard, and he, Edison, and others continued to work separately on improvements to the carbon microphone.

The carbon microphone solved the major problem of the telephone up to that time: weak sound. Although several inventors worked on applying Hughes's principles to Bell's telephone, it was again Edison who secured and defended the patent. Because of its ability to amplify sound, Hughes's loose-contact carbon microphone made possible the modern telephone, the hearing aid, the AM radio, and public-address systems. It continued to be the best device for amplifying sound until the 1920's, when the vacuum tube, which was superior in many ways but which required more power and so also required heavy batteries, began gradually to replace it in uses for which easy portability was not important. Nonetheless, the carbon microphone remained cheaper and easier to transport. It was used in telephone systems until the 1980's, while newer devices, including the transistor, replaced the carbon microphone in hearing aids and radios. Carbon microphones were still in use in the twenty-first century, however, in communications systems where higher-voltage systems would present a hazard, such as in mining or in the chemical industry, and as a backup for certain military communications systems. The telephone, made possible by the invention of the carbon microphone, is one of the most important means of communication throughout the world.

most of which he bequeathed to the Royal Society, the Paris Academy of Science, the Institution of Electrical Engineers, and four area hospitals.

Impact

In his time, Hughes was one of the most famous scientists in Europe, although he never received much recognition or praise from his native England. He was awarded several important awards for his work, including a Grand Gold Medal at the Paris Exhibition in 1867, the Royal Society Gold Medal in 1885, and the Albert Medal from the Royal Society of Arts in 1896. He was knighted or awarded medals from the governments of Austria, Bavaria, Belgium, France, Italy, Russia, Spain, Switzerland, and Turkey. In spite of his fame and his wealth, however, he remained known for his humility and generosity. He refused to take out a patent on his carbon microphone, believing that the invention should belong to the world—and the world profited from it. Similarly, he is now acknowledged as the first person to send and receive radio waves, but he declined to take credit or demand payment when Guglielmo Marconi built on his work in developing the wireless telegraph, leaving it for later generations of science historians to credit him for his important contributions to telegraphy.

It is no exaggeration to say that Hughes's inventions, especially in communications, changed the world. His printing telegraph quickly became the standard in Europe. The telegraph in turn made it possible for trains to run efficiently over great distances, for businesses to make decisions quickly based on a rapid flow of information, and for ordinary people to receive important news quickly and inexpensively. It was the only means of sending messages quickly over a long distance until 1877, when the telephone began to replace it. The telegraph did not immediately cease to be useful, however. The Western Union Telegraph Company, which used the Hughes printer until the 1930's, sent its last telegraph in 2006. Hughes also made important contributions to the development of the telephone, which, until the rise of personal computers and the Internet, was the most important means of communication worldwide. Finally, Hughes's induction balance led to the development of the metal detector, which has been used by militaries and hobbyists to locate missing objects and is still used in airport security systems.

Miller Reese Hutchison

American engineer

Hutchison utilized his engineering expertise to invent numerous devices, notably hearing aids and innovations with communication, transportation, and military applications, and to influence Thomas Alva Edison's policies while serving as the chief engineer of that inventor's laboratory.

Born: August 6, 1876; Montrose, Alabama
Died: February 16, 1944; New York, New York
Primary field: Electronics and electrical engineering
Primary inventions: Acousticon; Klaxon horn

Early Life

Miller Reese Hutchison (MIHL-ur REES HUHT-chih-suhn) was born on August 6, 1876, in Montrose, Alabama, a community on the east side of Mobile Bay. His father, William Peter Hutchison, worked as a broker in Mobile. Hutchison's mother, Tracie Elizabeth (Magruder) Hutchison, was the daughter of affluent landowners who lived near Tuskegee, Alabama. Hutchison grew up in a house near the Hutchison Hotel, which his paternal grandmother had developed as a resort.

When he was seven years old, Hutchison began attending private school in Mobile. Intrigued by electrical and mechanical processes, he explored area machine shops, powerhouses, and foundries, gaining experience with technological devices, comprehending how they functioned and appreciating their practical applications. At home, Hutchison attempted to make batteries, accidentally creating acid holes in carpets. By 1889, Hutchison enrolled in Marion Military Institute, then took classes at Spring Hill College and the University Military Institute at Mobile. At the age of fifteen, he envisioned his first invention—a device to protect communication wires from electrical storms. He filed for a patent on May 25, 1895.

During 1895, Hutchison moved to Auburn to take electrical and mechanical engineering and machine design courses at the Alabama Agricultural and Mechanical College (now Auburn University). Faculty and administrators at that school encouraged innovation, establishing laboratories for electrical and engineering work. Hutchison was surrounded by progressive scientists and engineers who conducted early X-ray experimentation and applied electricity to such industrial uses as ginning cotton. Hutchison constantly contemplated ideas for new inventions. He received a U.S. patent for his first invention on November 12, 1895.

During academic breaks, Hutchison worked in Mobile machine shops. In 1896, he built an electrical X-ray device at the Mobile Light and Railway powerhouse. Hutchison hosted X-ray demonstrations, showing audiences bones in his hands and feet. He considered becoming a surgeon but decided that he preferred being an inventor. A member of the class of 1897, Hutchison left college without graduating in order to focus on engineering endeavors.

Life's Work

In summer of 1897, Hutchison initially visited Thomas Alva Edison's laboratory. During the Spanish-American War, Hutchison secured employment with the U.S. Light House Service as an electrical engineer in charge of the Seventh and Eight Districts, placing cables and mines to impede enemy submarines from entering Gulf Coast ports from Key West, Florida, to Galveston, Texas. He then resumed electronic work in his Mobile laboratory and attended classes at the local Alabama Medical College to study physiological aspects of hearing and ear anatomy to improve his hearing aid inventions. In 1902, he received a patent for the first electrical hearing aid, which he called the Acousticon.

Hutchison moved to New York City, where he established a laboratory and married Martha Jackman Pomeroy. They had four sons. Beginning in 1904, Hutchison applied his engineering knowledge as a consultant for New York City businesses. He devoted his days to financial work and invented at night. That year, St. Louis Exposition officials designated Hutchison as honorary commissioner of the Department of Electricity for that fair, presenting him with two medals.

By 1906, Hutchison envisioned his most lucrative invention, the Klaxon horn. While driving in Newark, New Jersey, Hutchison pushed his automobile's horn when a pedestrian ran onto the road. He realized that a horn's sound should be loud, not pleasant. Hutchison filed an application for his electric horn design in 1906, receiving a U.S. patent three years later. By 1912, General Motors had equipped its stock, over 150,000 vehicles, with Hutchison's horn, providing Hutchison over $40,000 in royalties. Hutchison gave Edison a Klaxon horn. Edison admired Hutchison's excitement for invention and his energetic personality, and the inventors formed a professional friendship, while investigating methods to strengthen storage batteries and strategies to sell them.

By 1908, Hutchison had invented an electronic tachometer to calculate a ship's velocity. He described that invention to Admiral George Dewey, President Theodore Roosevelt, and significant naval officers. The charismatic Hutchison convinced both U.S. and foreign naval officials to outfit submarines with Edison's batteries, which he stressed extended underwater range possibilities. As an Edison Storage Battery Company representative, Hutchison received commissions on battery sales.

In 1911, Edison chose a man named Donald Bliss as his Engineering and Experimental Department laboratory's chief engineer. Although skilled technically, Bliss lacked administrative capabilities. In April of that year, Edison privately invited Hutchison, whom he called "Hutch," to conduct business and research at that West Orange, New Jersey, laboratory and act unofficially as his chief engineer and spokesperson for Thomas A. Edison, Inc. (TAE), stating that Hutchison should be ready to take control if Edison's health failed or if he died.

When Edison needed money to maintain the laboratory, Hutchison loaned him $50,000. Hutchison drove Edison to meetings and sporting events, and they often debated topics all night. Hutchison met Edison's business associates, including J. P. Morgan, Jr. During meetings, Hutchison relayed messages in Morse code to Edison by touching Edison's leg or wrist. In 1912, Edison formally named Hutchison as chief engineer to oversee that laboratory. In addition to managing laboratory conditions, equipment, and personnel, Hutchison offered advice to adjust Edison's kinetophone, which did not perform well because of film and sound losing synchronicity. He served on the Naval Consulting Board, which Edison chaired and which was established to seek inventions useful for military applications, designating that work as his occupation on his World War I draft application.

Hutchison quit the Edison Storage Battery Company on New Year's Day, 1917, and established the Hutchison Company to concentrate on selling Edison batteries internationally as the only distributor of that technology. He resigned his TAE position in July, 1918, because of pressure from Stephen B. Mambert, a TAE executive, who claimed that some government officials preferred direct transactions with TAE, not Hutchison, to purchase Edison's products. The aging Thomas Edison

The Acousticon

A hometown friend's deafness inspired Miller Reese Hutchison to design a battery-powered hearing aid in the mid-1890's. Hutchison wanted to assist Lyman Gould to hear, hoping that his mute friend could speak after he heard sounds. Hutchison designed his hearing aids based on his knowledge that most hearing loss occurred because of auditory nerve problems or inflexible bones in ears that hindered hearing and speaking. Hutchison's device, incorporating an earpiece and transmitter, helped Gould hear several words Hutchison said to him, but Gould remained silent, content with being able to hear.

Hutchison refined his hearing aid, with intentions of marketing it, and named it the Acousticon, which he displayed to audiences in various forms as he altered its design. He focused on extending battery life to power his hearing aid and on reducing the size of the device, which began as a large wooden box containing the aid's components. Because the Acousticon performed the functions of the middle ear, its basic structure included a microphone, which collected sound waves that then vibrated on a diaphragm for amplification and transmission to earphones.

In November, 1901, Hutchison first filed for a hearing aid patent, which was issued the next year. He was the first inventor to create and market an electric hearing aid. His Akouphone Manufacturing Company in New York produced and distributed several hundred thousand Acousticons in the United States and Europe. Hutchison traveled to Paris and London in 1902 to demonstrate his hearing aid to scientists and royals, including Queen Alexandra, who was deaf, at Buckingham Palace. She presented Hutchison a gold medal honoring his inventiveness. In 1904, Thomas Alva Edison's wife purchased an Acousticon for Edison, who was partially deaf. Although Edison noted flaws in the Acousticon, he also praised it for helping him to hear a music concert.

The Acousticon's success motivated Hutchison to invent related devices, including the Massacon for physicians to massage ear drums with repetitive sounds that vibrated from a diaphragm and hit the middle ear. The Hutchison Acoustic Company first manufactured and sold Massacons in late 1902. This invention was referenced almost one century later in U.S. Patent number 5,788,656, an "Electronic Stimulation System for Treating Tinnitus Disorders" (1998), invented by Alfonso Di Mino. By May, 1905, Hutchison had received a patent for a device and procedure to test for deafness, evaluating hearing ability in order to select effective hearing aids.

Later inventors incorporated some of Hutchison's concepts to use battery-powered stimuli in smaller hearing devices worn externally or cochlear implants surgically placed inside ears.

did not defend his friend, and Hutchison sold his distribution rights to TAE.

After leaving TAE, Hutchison initially considered World War I military technological needs. He continued inventing and securing patents in the 1920's and 1930's. In 1921, he demonstrated a supercannon from his Woolworth Building laboratory, emphasizing that weapon's potential three-hundred-mile range. He also created a compound to reduce carbon monoxide in fuel exhaust. After his son, Harold, died in an April, 1928, airplane crash, Hutchison developed the motor-vita for enhanced aircraft performance. He experimented with that invention in his personal plane. Hutchison also devised a film-processing technique to clarify sounds in motion pictures, recording as many as twelve thousand sound vibrations per second.

Hutchison wrote articles for periodicals, including *Proceedings of the Institute of Radio Engineers*, and two booklets, *A Series of Twelve Non-technical Letters on the Edison Storage Battery* (1912) and *The Submarine Boat Type of Edison Storage Battery* (1915). In 1944, he died at the New York Athletic Club, where he resided during retirement.

Impact

Hutchison's attitude regarding invention, embracing all aspects, from designing and revising inventions to marketing and selling them, contributed to his successes. His willingness to promote his innovations assured profits, which financed his continued inventive pursuits and secured respect from Edison and many industrial and political leaders. Hutchison sold several hundred thousand horns and hearing aids, which improved the quality of life for many people. Industries adopted elements of these inventions as standards for later versions of horns installed in vehicles or basic hearing aid designs.

Perhaps Hutchison's most significant achievement as an inventor was how he affected Edison. For almost one decade, Hutchison's close proximity to Edison enabled him to shape laboratory and business decisions more than TAE executives. Because of his association with Edison, Hutchison expanded his contacts with military and political leaders, voicing concerns about technology used in warfare and inventions that could strengthen U.S. defenses.

Many inventors valued Hutchison's insights regarding innovations, incorporating fundamental ideas and technology he devised into their inventions. Several inventors' patents referenced some of Hutchison's patents soon after his inventions became public. References to Hutchison's patented inventions appeared in patents throughout the twentieth century and into the early twenty-first century, indicating the sustained awareness of Hutchison's work over a century since his first inventions were created. Recognizing Hutchison's influence on modern inventors, the Edison National Historic Site's archive preserves Hutchison's diary and correspondence he wrote while employed by Edison.

Scientific groups in the United States and Europe honored Hutchison with awards. When he returned to his alma mater at Auburn in June, 1913, to donate a wireless station, his gift initiated the first wireless telegraphy course taught in the region. In recognition of Hutchison's professional achievements, that college granted him an electrical engineering degree. His legacy continues in Auburn's pioneering wireless engineering program, which develops innovations for twenty-first century telecommunications advancements worldwide.

Christiaan Huygens

Dutch mathematician, astronomer, and physicist

Huygens developed new lens-grinding techniques with which he created more accurate telescopes; invented the most accurate timekeeper to date, the pendulum clock; and proposed a wave theory of light.

Born: April 14, 1629; The Hague, United Provinces (now in the Netherlands)
Died: July 8, 1695; The Hague, United Provinces (now in the Netherlands)
Primary fields: Astronomy; mathematics; optics; physics
Primary inventions: Pendulum clock; lens-grinding techniques

Early Life

Christiaan Huygens (KRIHS-teeahn HOY-gehns) was the second son of Suzanna van Baerle and Constantijn Huygens, the important Dutch poet and statesman who, from an early age, encouraged his son's academic interests by hiring specialized tutors, including the mathematician Jan Jansz de Jonge Stampioen. In 1645, Christiaan matriculated in law at the University of Leiden, where he also studied mathematics under Franz van Schooten as part of the well-rounded general studies curriculum considered necessary for the pursuit of a law degree. After two years at Leiden, he transferred to the newly founded College of Orange in Breda, where he completed his degree in 1649. Through an introduction from his father, he entered into correspondence with the Parisian mathematician Marin Mersenne, who first introduced the young Huygens to the problems of pendular motion by asking him to calculate the pendulum's center of oscillation. Huygens also traveled abroad, where he joined international scientific and mathematical social circles. By 1651, he had published his first mathematical paper on the ancient geometric problem of quadratures (calculating the area of a curve). After publishing a few more mathematical papers, in 1655 he befriended Ismael Boulliau and other astronomers in Paris. It was also in this decade that he contributed to van Schooten's 1659 annotated translation of René Descartes' *Géométrie* (1637), corresponded with its author, and, with Blaise Pascal's encouragement, himself published the first book on prob-

Christiaan Huygens. (Library of Congress)

The Pendulum Clock

The pendulum clock revolutionized timekeeping in Western Europe by making it much more precise: Instead of accuracy within about fifteen minutes per day, clocks became accurate within about fifteen seconds per day. Although the rudimentary idea of the pendulum clock may be credited to Galileo as early as 1637, it was Christiaan Huygens, working independently, who developed the functional models that would change the way clocks were generally made.

Since the invention of the mechanical clock in the thirteenth century, before Huygens all clocks used a verge escapement to regulate their rate. Pallets attached to one end of the verge were pushed by the teeth of the last wheel of the going train. The other end of the verge was attached to a balance wheel, or foliot. The action of the teeth and pallets rotated the balance wheel in one direction and then in the other, and this motion slowed down and regulated the going train. However, verge escapements were not very accurate because the oscillation period was faster with heavier weights or a tighter spring.

Huygens's great discovery was to use the pendulum as a regulating device. Instead of pallets attached to the verge, the pendulum's shaft regularly hit a crutch attached to the balance wheel, thereby forcing the clock's going train to follow its beat. In order to make this possible, Huygens turned the clock's mechanism 90° so that the balance wheel oscillated vertically. The pendulum itself was repeatedly nudged into motion by the force exerted by weights on the clock's going train, its swing being regulated by a small movable weight. The pendulum shaft was attached to the back of the clock to keep the pendulum as free as possible from interference. As the period of a pendulum swinging freely according to a circular path varies according to the magnitude of its swing, the arc of the pendulum itself was guided by curved metal "cheeks" placed on either side of the suspension cord, effectively shortening the length of that cord and causing its bob to swing according a noncircular, cycloidal motion. As the pendulum swung upward around the cheeks, it swung faster—just the right amount faster so that if one began the pendulum's swing at any point on the curve, the force of gravity would carry it to the bottom at the same time, a property called isochronism. Huygens had quickly understood that circular pendulums were not isochronous unless they were of very small amplitude so that the difference in curvature was negligible. Later pendulum clocks would be refined by anchor and other sorts of escapements that removed the need for the cycloidal cheeks by sufficiently limiting the pendulum's arc.

ability theory, *De ratiociniis in ludo aleae* (1657). Although Huygens did not yet hold a research position, his career choice in the areas of mathematics and physics was made by this time, and he was about to enter the most productive period of his life.

Life's Work

Huygens gravitated toward subjects in which his mathematical studies were associated with physical realities and real-world needs. His friendship with astronomers and his interest in dioptrics inspired by Descartes led him to improve the telescope by developing, with his older brother Constantijn, new methods and a new machine for grinding lenses that diminished aberration. With these lenses, he made an improved telescope, discovered Saturn's moon Titan (1655), and solved the mystery of Saturn's true shape (1656), correctly observing that the planet was surrounded by flat rings set at an angle to its axis.

Meanwhile, he had turned to the problem of determining longitude at sea, for which more accurate timekeepers were needed. He devised a new type of clock, regulated by a pendulum. The clock's design was worked out empirically in 1656 and patented in 1657. On June 16, 1657, the Dutch government granted Salomon Coster the exclusive "privilege" of making Huygens-designed pendulum clocks. Many existing clocks were also converted to operate with pendulums. After Coster's sudden death in 1659, French and English clockmakers copied Huygens's design, as Huygens had not been successful in gaining a patent in those countries.

In the last months of 1659—the period in which he formulated his greatest mathematical discoveries—Huygens focused on the problem of gravitational acceleration, recognizing that it was mathematically equivalent to centrifugal force. This insight led him to a theoretical justification for his clock's design that would form the nucleus of his most important book, the *Horologium oscillatorium* (1673).

By 1663, Huygens's fame had spread to England, where he was elected fellow of the Royal Society. Over the next decade, he worked on problems of collision and impact and attempted to adapt pendulum clocks for use on ships. Mounting pairs of sea clocks on the same frame led to his discovery of the property of coupled oscillation, since the pendulums tended to oscillate in exactly opposite directions. His explanation for this phenomenon as due to tiny movements in the frame ultimately led to the abandonment of his sea clock experiments organized by London's Royal Society, for it became clear that such clocks would be affected by a ship's movements. Huygens would later (1675) invent a balance spring clock (for which Robert Hooke also claimed priority), but his concern about the effects of humidity on its accuracy prevented him from intensely pursuing its use at sea.

In 1666, Huygens accepted Louis XIV's invitation to help found the French Academy of Sciences and moved to France. Although he had intended to prove his clock's maritime utility before publishing a detailed theoretical account, the *Horologium oscillatorium* went to press in 1673 with a dedication to the French king, probably for political reasons, as France was then at war with his native Holland. This treatise offered proofs of the relationship between the length of the pendulum and its period, of the center of oscillation of simple and compound pendulums, and further demonstrated that the bob of an isochronous pendulum follows a cycloid path and that a cycloid is its own evolute. Huygens concluded with a short disquisition on conical pendulums and centrifugal force. One of the last important examples of geometrical physics—physics that relies on word proofs involving geometrical figures and relations between physical quantities expressed as proportions—Huygens's style of analysis would soon be supplanted by mathematical physics, which uses equations of differential calculus invented by Isaac Newton and Gottfried Wilhelm Leibniz (with whom he was in regular contact). The book's diminished influence despite its important discoveries was partly due to its geometrical argumentation and infinitesimal analysis and partly due to its publication long after Huygens's initial discoveries.

The 1670's also produced research in physical optics: Huygens devised a wave, or pulse, theory of light and Huygens' principle (all points of a wavefront of light generate new wavelets in all directions), which he used to explain reflection and refraction. Although drafted by 1678, his *Traité de la Lumière* was not published until 1690. After he returned to The Hague in 1681 to recover from an illness, Huygens studied the problems of spherical and chromatic aberration, grinding lenses of great focal distance and creating aerial telescopes—telescopes that did not use tubes but rather a very long cord to line up the lenses. Because of the political climate, Huygens did not return to Paris, thereafter making his home in Holland, where he continued to study mathematics and optics and to tinker with clocks. On a final trip to England in 1689, he met Newton, who had recently published his *Principia* (1687). By early 1695, Huygens had finished a manuscript of his *Cosmotheoros* (1698), in which he posited life on other planets. Later that year, he died, leaving his papers to the University of Leiden.

Impact

Huygens's three main areas of inquiry and invention—telescope lenses, pendular mechanics, and physical optics—produced a variety of profound effects on scientific knowledge and contemporary society. Huygens's recognition of Saturn's rings not only gave scientists a more accurate picture of the solar system but also opened up a line of inquiry regarding the nature of those rings that is still being pursued today. His aerial telescopes constituted a first step toward creating the much stronger telescopes needed for precise astronomic observation (for which internal mirrors would eventually be substituted for distance between the lenses). The pendulum clock's far superior accuracy was not only fundamental to astronomical observation and scientific experimentation but also offered society a clock that was, for the first time, more accurate than a sundial, therefore encouraging the eventual adoption of mean time and equal hours as opposed to Sun time and unequal hours. The mathematical foundation for his cycloid pendulum and his proof that its evolute was also a cycloid led to further inquiries in differential geometry regarding the nature of other curves and their evolutes. Finally, although Huygens's wave theory of light was quickly challenged by Newton's particle theory, by the 1800's it was returning to favor when further studies by Augustin-Jean Fresnel and others supported his view. Eventually, both the wave and particle theories were brought together and broadened to cover all electromagnetic phenomena in what is called the wave-particle duality, a fundamental component of modern quantum mechanics.

Ida H. Hyde

German American physiologist and zoologist

Hyde invented the microelectrode, an instrument small enough to be injected into a single cell. She received no recognition for her work during her lifetime.

Born: September 8, 1857; Davenport, Iowa
Died: August 22, 1945; Berkeley, California
Also known as: Ida Henrietta Hyde (full name)
Primary field: Medicine and medical technology
Primary invention: Microelectrode

Early Life

Ida Henrietta Hyde (I-dah Hehn-ree-EH-tah HID) was one of four children born to German immigrants Babette Loewenthal, a businesswoman, and Meyer Heidenheimer, a merchant. The Heidenheimers changed their family name to Hyde when they arrived in the United States. Mr. Hyde abandoned the family when Ida was still a child. Her mother supported them by doing mending and cleaning work. As a businesswoman, Mrs. Hyde was able to gradually develop her work into a fairly successful small business.

Sometime before 1870, the family moved to Chicago, but shortly thereafter the Great Chicago Fire destroyed their home and displaced their customers. Ida Hyde took an apprenticeship at a hatmaking factory and worked there for seven years to help support the family and to fund her brother's education. One day, she happened to pick up a discarded biology book from a packing crate. It was Alexander von Humboldt's *Views of Nature* (1850; *Ansichten der Natur*, 1808). At her brother's graduation ceremony from the University of Illinois, she met female students and had the idea that perhaps she could also be a student. Neither her mother nor her brother approved of her taking classes, but she was determined and in 1881 easily passed the entrance examination. She walked to school and saved her unspent car fare to pay college tuition for night classes at the university. When her brother became ill in 1882, she suspended her classes to care for him at home, where she stayed for six more years, teaching first in Elmhurst, a suburb of Chicago, and then in the Chicago public system, where she instructed seven- and eight-year-olds. During the summer of 1882, she attended Summer School of Natural History in Martha's Vineyard. During these years, she compiled a systemwide science curriculum for the Chicago public schools.

Life's Work

In 1888, Hyde enrolled at Cornell University and in three years completed a bachelor of arts in biological science. As part of her studies, she carried out an outstanding undergraduate research project on mammalian heart structure that was reported in the *American Naturalist* in 1891. During the summer, she worked for Woods Hole Marine Laboratory Corporation in Maine—the first woman to do so—where she analyzed octopus embryos, jellyfish development, and the respiration of grasshoppers, horseshoe crabs, skates, amphibians, and mammals. In 1892, she lectured on the anatomy and embryology of Scyphomedusae, the class of sea animals composed of jellyfish and other gelatinous organisms.

Impressed with her work in this area, Professor Alexander Goette invited Hyde to conduct further research at the University of Strasbourg in France. Goette was so impressed that he offered her reports to the academic committee in lieu of a doctoral dissertation. However, solely on the basis of her gender, the academic staff rejected her petition to take final exams. Goette then recommended that she apply at the University of Heidelberg in Germany.

The university accepted her, but again she had to overcome obstacles. Dr. Wilhelm Kühne, a noted researcher who coined the word "enzyme," refused to allow her in lectures and laboratories. (Reportedly, he had said that he would never allow "skirts" in his classes.) However, when a colleague asked him whether, if at the end of the course she could pass the examination, he would grant her the degree, he jokingly replied that he would. For six semesters, Hyde had to study physiology independent of the classroom and of hands-on laboratory projects, relying only on Kühne's assistants' notes and lab sketches. Finally, a four-hour oral examination by Kühne's academic committee proved her worthiness. The summa cum laude degree, the highest honors, could not go to a woman, so Kühne invented a new phrase: "multa cum laude superavit" (she overcame with much praise).

The Microelectrode

Even as a teenager and young adult, Ida H. Hyde had been interested in scientific research. As an undergraduate student at Cornell University in 1891, she published her first research paper, "Notes on the Hearts of Certain Mammals." At Woods Hole Marine Laboratory Corporation, she analyzed octopus embryos, jellyfish development, and the respiration of grasshoppers, horseshoe crabs, skates, amphibians, and mammals. While at the University of Kansas, she continued her study of the response of the cardiovascular system to stress. Toward the end of her time at the university, by chance she observed that electrolytes in high concentrations affect processes of cell division, and this led her to note minute differences in electrical potential within cells.

During the years 1918-1919, Hyde worked on single-celled organisms and the eggs of sea urchins. However, in order to understand how nerve and muscle cells work, she needed to be able to stimulate individual cells electrically or chemically and to record the resulting changes in the very small electric current that the cell produces. Hyde needed to be able to stimulate the cell by injecting an electric current and at the same time record the changes that took place. There were instruments that did this, but none of them were small enough to fit into a single cell, so she constructed an instrument called the microelectrode, which had a diameter small enough for her purpose. Using this instrument, Hyde was able to prove that a previously held principle, the "all-or-nothing" principle concerning contractile cells, did not always hold true. She was able to show that a certain single-celled organism did not follow the pattern, thus disproving the all-or-nothing principle.

Although Hyde's invention was reported in 1921, Georg Ettisch and Tibor Péterfi, apparently unaware of it, manufactured an electrode that was essentially the same as Hyde's. It was again reinvented twenty years later by Judith Graham and Ralph W. Gerard of the University of Chicago, apparently with no knowledge of Hyde's earlier work. In the 1950's, Gerard was nominated for a Nobel Prize for developing still another version of the microelectrode. Science historian G. Kass-Simon has praised Hyde's invention as the "most useful and powerful tool in electrophysiology. Its invention revolutionized neurophysiology."

In 1896, Hyde completed the Ph.D. at Heidelberg, the first woman to receive one for this type of work, opening the way for other women to do the same. Kühne recommended her for a position in a research program at the Naples Marine Biological Laboratory in Italy, where she studied the nature and function of salivary glands. Years later, Hyde convinced a group of university women to fund a permanent visiting professorship for women at the Naples Marine Biological Laboratory. She was a life member of this organization and its secretary from 1897 to 1900.

In 1898, Hyde joined the staff at the University of Kansas. In 1903, the school created a separate physiology department with Hyde as its head. There she developed a new curriculum and wrote two textbooks: *Outlines of Experimental Physiology* (1905) and *Laboratory Outlines of Physiology* (1910). She continued to write articles on developing embryos and microtechniques of cell study. As a result, in 1902 she was the first woman elected to the all-male American Physiological Society. She was the only woman until 1913 whose original contributions were considered to meet the society standards for membership.

During her time in Kansas, Hyde again experienced gender discrimination. She pressed repeatedly for a salary that was equal to her male colleagues'. She added restroom facilities for women in the science building, she agitated and got women janitors hired by the university, and she started a drive to hire female corrections' officers in the city of Lawrence. She promoted educational opportunities for women by helping to establish the Sarah Robinson Research Table at Woods Hole.

Hyde taught classes on hygiene, public health, human reproduction, and sexually transmitted diseases. However, to avoid shocking her class, she read lines of poetry to refer to human and animal reproduction and relied on nude Greek and Roman statues rather than more detailed drawings of the human body. She educated Kansans on promiscuous sex and disease, taught classroom lessons on gonorrhea and syphilis for factory women, and teamed with medical doctors to prevent spinal meningitis and tuberculosis. She wanted to test schoolchildren for these diseases, but conservative opposition forced the university chancellor, Francis Strong, to withdraw his support, saying that "compulsory medicine" was not acceptable. In 1918, Governor Arthur Capper named Hyde chair of the Kansas Women's Committee on Health, Sanitation and National Defense. At the same time, President Woodrow Wilson selected her to chair the U.S. Women's Commission on Health and Sanitation.

In 1922-1923, Hyde took a last trip to Europe. She died on August 22, 1945, from a cerebral hemorrhage at her home in Berkeley, California. Her diaries are at the American Association of University Women (AAUW) archives in Washington, D.C. Information can also be found at the University of Kansas archives.

Impact

Hyde was the first woman to conduct research at the Woods Hole Marine Laboratory Corporation in Maine, and she was the first woman to attain a doctoral degree in physiology from the University of Heidelberg. She was the first female head of a Department of Physiology at the University of Kansas. Her most impressive accomplishment, for which she received no credit during her lifetime, was the invention of the microelectrode. Devices that added chemicals to a cell or recorded its current had been created earlier, but Hyde in 1920 was the first to make a tool that could do both at once and that was small enough to stimulate a single cell.

Hyde paved the way for other female scientists. With her own money, she funded scholarships at Cornell University, established the Ida H. Hyde Scholarship for the Biological Sciences at the University of Kansas, and endowed the Ida H. Hyde Woman's International Fellowship of the American Association of University Women with $25,000. She also gave $2,000 to the University of Kansas to fund a scholarship for female graduates in biology. She not only taught, conducted research, and wrote textbooks but also was interested in public health, teaching classes for the general public. She realized, before it was popular, the importance of testing schoolchildren for contagious diseases.

Sumio Iijima

Japanese physicist

Iijima's 1991 observation of multiwalled carbon nanotubes and his 1993 discovery of single-walled carbon nanotubes sparked intense research into these ultramicroscopic carbon needles, whose great strength and unique electrical behavior make them potential building blocks for far-reaching nanotechnological applications.

Born: May 2, 1939; Saitama Prefecture, Japan
Primary field: Physics
Primary invention: Single-walled carbon nanotubes

Early Life

Sumio Iijima (soo-mee-oh ee-ee-jee-mah) was born on May 2, 1939, in Saitama Prefecture in Japan, to the north of Tokyo. His father, Fukumatsu, and his mother, Take, brought up the boy in what was still a rural environment. Iijima loved mountain climbing so much that he focused less on his studies, even though chemistry and physics were favorite high school subjects. At age nineteen, in 1958, Iijima surprisingly failed the all-important national university entrance exams.

For the first time, Iijima took his studies seriously, and he prepared to retake the entrance exams the following year. In 1959, he passed and was admitted to the College of Electro-Communications in Chōfu, a city within greater Tokyo; his alma mater later became a university. After graduating with a bachelor of science degree in 1963, Iijima began graduate studies at Tohoku University in Sendai, northeastern Japan, which enjoyed an excellent reputation for technical studies. Even though his interest was originally in chemistry, Iijima was placed in the high-resolution electron microscopy laboratory and quickly earned a reputation as a very gifted microscopist.

At Tohoku University, Iijima earned his master of science degree in physics in 1965 and his doctorate in solid-state physics in 1968. On March 10, 1968, at age twenty-eight, Iijima married Aida Nobuko. The couple had two children, daughter Masako and son Arihiro.

Life's Work

At first, Iijima stayed at Tohoku University as a research associate. In 1970, he joined the high-resolution transmission electron microscopy (HRTEM) team of Professor John Cowley at Arizona State University (ASU) in Tempe as a visiting research associate. Iijima quickly developed a new technique for producing high-resolution electron micrographs of crystals. In 1971, he became the first scientist whose micrographs showed the atomic structure of certain crystals.

At ASU's Center for Solid State Science, which brought together microscopists from many disciplines, Iijima became known as the best microscopist. He was the first to capture microscopic images that showed the location of atomic defects within a crystal. His colleagues praised him for his unprecedented skill in sensing exactly where to aim the HRTEM instrument. He took the most promising pictures of what later became known as nanomaterials, ultrasmall pieces of matter impossible to see without a powerful electron microscope.

In 1973, Iijima began working for geologist Peter Buseck as a postdoctoral researcher at ASU. In 1974, Iijima formally resigned from Tohoku University to concentrate on his work at ASU. By 1976, Iijima and Buseck had published together seven breakthrough papers on electron microscopy of minerals. In 1977, Iijima became a senior research associate at ASU, a position he held until 1982.

Returning to Japan, from 1982 to 1987, Iijima was group leader and research scientist at the Exploratory Research for Advanced Technology (ERATO) of the Research Development Corporation of Japan. On December 11, 1984, he released a video, *Living Gold Crystals*, that showed his micrograph images of coalescing gold particles and real-life images of the motion of surface atoms on gold particles. No other scientist had looked so deep into the atomic structure of gold before.

In 1987, Iijima joined NEC Corporation in Japan, where he has remained as a senior research fellow. It was at NEC's Fundamental Research Laboratories in Tsukuba that Iijima made his most outstanding discovery. Since their detection in 1985, carbon-60 molecules, also called fullerenes, were the focus of the emerging field of nanoscience. Iijima was less interested in the fullerenes themselves than in the way in which they formed in the sooty carbon remains after electricity passed through two carbon electrodes and vaporized them. In the summer of 1991, utilizing a standard transmission electron microscope, Iijima looked at the tip of the negative carbon electrode after he had brought it so close to the positive electrode that they were joined by an electric arc spark. To his surprise, Iijima could take microscope images of what he determined were multiwalled carbon nanotubes. Iijima's images showed twist-

Single-Walled Carbon Nanotubes

After Sumio Iijima's successful 1991 microscoping of multiwalled carbon nanotubes that revealed these microscopic graphite needles to the larger scientific community, Iijima and his colleague Toshinari Ichihashi turned to the idea of creating and observing single-walled carbon nanotubes. Iijima believed that only the observation of single-walled nanotubes would yield full scientific knowledge of the exact characteristics of these tiny structures with a diameter of just about one-billionth of a meter and a length of up to one thousand times their diameter.

The idea of the existence and possible artificial growth of these ultrasmall particles was mentioned first in a U.S. patent of 1889, but there were no technical means in existence then to prove this. Optical microscopes could never go as far into microscopic detail as was necessary to observe these nanostructures. Only with the invention of the transmission electron microscope in 1939 were scientists able to look into the nanoscale realm with gradually increasing power of observation. Unbeknownst in the West during the Cold War, in 1952 two Soviet physicists, L. V. Radushkevich and V. M. Lukyanovich, published micrograph images that they had taken of carbon filaments. In 2006, when these old photos were examined again, it became clear that they actually showed multiwalled carbon nanotubes, making Radushkevich and Lukyanovich the first to discover them. Still, it was Iijima's 1991 observation of multiwalled carbon nanotubes that triggered the great interest in these structures. Moreover, the quest was still open for the discovery of a single-walled carbon nanotube.

To this end, Iijima and Ichihashi decided on a new approach to grow carbon nanotubes, which so far had been observed only in their multiwalled state. In 1993, Iijima set up an experiment at his Fundamental Research Laboratories of the NEC Corporation in Tsukuba, Japan. In an evaporation chamber in their laboratory, two electrodes were set up in a vertical position close to each other. The anode consisted of a graphitic carbon rod with a diameter of 10 millimeters, while the graphitic carbon rod of the cathode had a diameter of 20 millimeters and held a small piece of iron in a hollow at its tip, acting as catalyst. The evaporation chamber was filled with a gas mixture of methane (a source of more carbon) and argon. Next, Iijima and Ichihashi applied a direct current of 200 amperes and 20 volts to run between the two electrodes, creating a carbon discharge arc that vaporized the iron and the carbon, which formed soot together with the methane. The resulting soot that collected over the electrodes was put into an acetone suspension and placed under Iijima's microscopes.

Looking at the carbon soot with both a regular and an ultrahigh-vacuum transmission electron microscope, Iijima took the image of the single-walled carbon nanotubes that the experiment had generated. The discovery of these nanotubes, with diameters from 0.7 to 1.6 nanometers each, triggered further advances in the research of their exact mechanic and electric properties. Iijima and Ichihashi had discovered the basis on which the new field of nanotechnology came to be built.

ing carbon tubes consisting of multiple cylinders. The smallest, innermost cylinders had a diameter of four nanometers, and the largest cylinders forming the outer shell of the multiwalled tube had a diameter of thirty nanometers. (Nanoscale objects are extremely small; one nanometer is equal to one-billionth of a meter, or 3.28 billionths of a foot.) The length of the twisting nanotubes reached up to one micrometer, or 1,000 nanometers.

Describing his findings in the November 6, 1991, issue of *Nature* magazine, Iijima electrified the nanoscience community. On April 23, 1993, Iijima and his colleague Toshinari Ichihashi submitted to *Nature* their paper showing their discovery of single-walled carbon nanotubes. Iijima and Ichihashi successfully grew and then took microscope pictures of carbon nanotubes consisting of only one cylinder. These two papers laid the much-cited foundation for carbon nanotube research.

Having already won five major physics awards for his microscopy discoveries, in 1996 Iijima received the Asahi Award of the Asahi Shinbun Cultural Foundation of Japan, the first science award of many to follow for his discovery of single-walled carbon nanotubes. Iijima continued his microscopic research of carbon nanotubes to discover more about their structure, properties, and potential applications, and in 1998 he was appointed professor in the Department of Materials Science and Engineering of Meijo University in Nagoya, Japan, a position he has since held. After discovering a special form of curved, conical carbon tubes he called nanohorns, in 1998 Iijima became research director of the Nanotubulites Project of the Japan Science and Technology Agency, a position he held until 2002.

Iijima's great status in the avant-garde field of nanoscience was reflected by his ongoing scientific appointments and scientific awards. On April 1, 2001, he became founding director of the Nanotube Research Center of the National Institute of Advanced Industrial Science and Technology, a position he has since held. His receiving the Benjamin Franklin Medal in Physics in 2002 was a special honor. In 2005, Iijima became dean of Sungkyunkwan University's Advanced Institute of Nanotechnology (SAINT) in South Korea. He was named honorary professor of Xi'an Jiaotong University in 2005 and of Peking University in 2006.

On May 28, 2008, the Norwegian Academy of Science and Letters together with the Kavli Foundation of Oxnard, California, announced that Iijima was co-awarded with Louis Brus from Columbia University the first Kavli Prize in Nanoscience. Iijima and Brus shared the one-million-dollar prize for their discoveries in the fields of carbon nanotubes and colloidal semiconductor nanocrystals, commonly called quantum dots. By 2009, at age seventy, Iijima continued his research and hoped for more discoveries in nanoscience.

Impact

Iijima's two papers published in *Nature* in 1991 and 1993 were generally credited with ushering in the era of carbon nanotube research, fueling research in nanoscience and nanotechnology in general. Iijima published his findings at the right time to send scientists on the quest for new nanomaterials. Carbon nanotubes as popularized by Iijima hold great potential applications because of their great strength and flexibility. Even if bent out of shape, they quickly flex back into their original state, making them potentially ideal for auto body parts, for example. Their electrical properties can be metallic (fully conducting), semiconducting, or superconducting, making them suitable for new applications in electrical engineering and computer science.

On the basis of Iijima's fundamental research, which included an impressive body of discoveries in nanoscience, other researchers pursued a great variety of practical nanotechnological applications. Ultrathin nanotube wires could revolutionize the computer chip industry by offering nanotechnological transistors. Already in use by 2009 were applications in microscopy. Attaching a nanotube to the tip of a scanning microscope creates better resolution and lets the probe delve deeper into material. Carbon nanotubes were already being used in composites for industrial fibers and stain-free textiles.

By 2009, scientists still searched for new revolutionary carbon nanotube applications such as superstrong fibers, vastly powerful yet small fuel cells, and nanotube computer circuits. However, by 2008, there were new concerns about the possible toxicity of carbon nanotubes rivaling that of asbestos needles. This meant more research was needed to study this potentially harmful side effect.

KARL G. JANSKY

American physicist, astronomer, and engineer

Jansky is considered by many to be the "father of radio astronomy." While working to reduce radio interference, he discovered the first astronomical radio emissions. In his honor, radio astronomers measure the intensity of celestial radio emissions in units called janskys.

Born: October 22, 1905; Norman, Oklahoma
Died: February 14, 1950; Red Bank, New Jersey
Also known as: Karl Guthe Jansky (full name)
Primary fields: Astronomy; physics
Primary invention: Radio astronomy

EARLY LIFE

Karl Guthe Jansky (kahrl gewth JAN-skee) was born on October 22, 1905, in Norman, Oklahoma, which at the time was a territory rather than a state. His father, Cyril M. Jansky, was a professor and dean of the College of Engineering at the University of Oklahoma. His mother, Nellie Moreau Jansky, was of French and English descent, while his father was the son of Czech immigrants. Karl Jansky was named for physicist Karl Guthe, who was an admired teacher and coworker of Cyril. In 1908, the Jansky family moved to Madison, Wisconsin, when Cyril accepted a position at the University of Wisconsin. Jansky attended Wisconsin public schools and later the University of Wisconsin.

Jansky graduated with a B.S. in physics from the University of Wisconsin in 1927. He was an excellent student, a member of Phi Beta Kappa, and graduated with honors. While in college, his extracurricular activities included playing on the college ice hockey team and playing tennis for recreation. After receiving his bachelor's degree, Jansky stayed an extra year to complete the coursework for his master's degree, but he did not graduate with the degree in 1928 because he had not completed the thesis requirement. The university finally awarded Jansky a master's degree in 1936, when it counted his early work in radio astronomy for his thesis requirement.

While still a college student, Jansky was diagnosed with chronic kidney disease. This affected his life by limiting the types of work he could do; his job assignments could not unduly stress his health. In addition, his illness limited the length of his life: He died when he was only forty-four years old.

LIFE'S WORK

In 1928, Jansky went to work for Bell Labs in New Jersey. He almost did not get the job because of his health. However, one of his brothers, who was ten years older and had previously worked for Bell Labs, intervened on his behalf. Jansky's first assignment at Bell Labs was of a purely applied nature. Bell Labs had a strong interest in radio telecommunications, which requires transmitters and receivers having the lowest possible amount of static or noise. Bell Labs assigned Jansky to work at its Cliffwood, New Jersey, field laboratory. Using and modifying existing equipment, Jansky began to study the static at 14.6-meter radio wavelengths (20.5 megahertz), which is in the shortwave band. In 1930, Bell Labs moved the entire Cliffwood laboratory to Holmdel, New Jersey. The move interrupted Jansky's work, but he rebuilt his rotating antenna and receiving equipment in Holmdel. The fact that Jansky's antenna rotated like a merry-go-round allowed him to study the direction of origin of any radio static he received.

This project required considerable work to design and modify the receiving equipment. By late 1930, Jansky had begun to study the 14-meter wavelength radio static in detail. He began to carefully and laboriously record data on the strength of the radio static in different directions and at different times. Jansky's data showed three sources of radio static: distant and local thunderstorms and a third unidentified source. Jansky published his work, entitled "Directional Studies of Atmospherics at High Frequencies," in late 1932 in the *Proceedings of the Institute of Radio Engineers*. Jansky further investigated this third unknown source of static and concluded from its direction of origin that the radio waves did not originate anywhere on Earth or in the solar system. The signal strength varied with a cycle time equal to Earth's rotational period, which is characteristic of signals originating from outside the solar system. Jansky discussed his work with A. M. Skellet, a coworker who was familiar with astronomy, and they concluded that the source was the Milky Way galaxy. Jansky published his work in the fall, 1933, issues of *Proceedings of the Institute of Radio Engineers* and *Nature*. The papers were titled "Electrical Disturbances Apparently of Extraterrestrial Origin" and "Radio Waves From Outside the Solar System," respectively. These classic papers by Jansky form the foundation of modern radio astronomy. The May 5, 1933, issue of *The New York Times* featured a story about Jansky's work.

After his initial discovery, Jansky suggested that Bell Labs fund the building of a larger, more sensitive antenna. The research organization, however, declined his proposal because it would not have addressed the feasibility of radio telecommunications. Jansky continued to observe the radio static from the Milky Way until 1936 and confirmed his conclusion that the center of the Milky Way galaxy was indeed the source of the radio noise. He published a summary of his results on astronomical radio static in a paper titled "Minimum Noise Levels Obtained on Short-Wave Receiving Systems" in the *Proceedings of the Institute of Radio Engineers* in December, 1937. Having received no encouragement from the astronomical community, Jansky shortly thereafter stopped studying these astronomical radio signals. The astronomical community of the time did not recognize the potential importance of radio astronomy.

Jansky continued to work on applied aspects of radio noise. He performed experimental studies of radio noise and measured the angle at which transatlantic radio signals arrived. In 1940, he also compared possible sites for receiving these signals. When World War II broke out, Bell Labs went into defense-related research, and employees worked overtime on war-related projects such as radar. There was no time for Jansky to pursue radio astronomy. Jansky, like most American scientists and engineers of the era, contributed to the war effort. He did not publish the results of this defense work because it was classified.

After the war, Bell Labs started to concentrate on the possibility of using microwaves, rather than the shortwaves Jansky had previously studied, for communications. Jansky contributed to this work by designing receivers and amplifiers with minimum noise levels. He even started experimenting with transistors, which had recently been invented, in the amplifiers. However, Jansky's chronic kidney disease was worsening, and he was forced to take an extended sick leave in 1945-1946. During 1948, he traveled more than once to Duke University Medical Center in Durham, North Carolina, for treatment. Jansky's health continued to deteriorate, and he died on February 14, 1950.

Radio Astronomy

Most people are familiar with optical astronomy, a subfield that deals with light from stars, planets, galaxies, and other celestial objects. Fewer people are familiar with radio astronomy, which involves the use of large radio antennae to study radio waves coming from a variety of celestial objects. Much of the current knowledge of the universe comes from radio astronomy. As the first person to discover and study radio waves from celestial objects, Karl G. Jansky is rightly considered the "father of radio astronomy."

Large optical telescopes use a large concave mirror, usually combined with a smaller secondary mirror, to reflect the light to a focal point for detailed study. Similarly, radio telescopes use a large concave metal surface to reflect radio waves to a focal point for further study. This reflecting surface resembles the reflecting surface of a receiver for satellite TV signals, but it is much larger. Just as a satellite TV receiver points in a specific direction of the sky containing a satellite, so too a radio telescope points in a specific direction of the sky to locate the source of extraterrestrial radio waves. This directionality allows astronomers to know which celestial object is transmitting the radio signals being studied.

At the focal point of the radio reflector, astronomers place a receiver and amplifier to study the radio signal. The receivers are tunable, so astronomers can study the frequency dependence of radio waves emitted by various celestial objects. Radio astronomers can map an area of the sky at any radio frequency or study a celestial object's signal strength, which varies with the frequency.

Radio waves are not as easily absorbed by interstellar dust as visible light. Therefore, radio astronomy is very useful for studying celestial objects that would normally be obscured by interstellar dust. Though ordinary stars are not very bright at radio wavelengths, other types of celestial objects are. These objects include pulsars, quasars, the core of the Milky Way, and most active galaxies. Radio astronomy has been crucial for understanding these objects and many more.

Impact

Professional astronomers initially ignored Jansky's seminal work on radio astronomy. In the 1930's, astronomers did not think there was much to learn by studying radio waves from space, and during the Great Depression it was difficult to justify the expense of radio telescopes. There were, however, two people who directly built on Jansky's work, Grote Reber and John Kraus. Reber, a ham radio operator and amateur astronomer, built a radio telescope in his backyard in 1937. Reber used about a half year's pay to build his first radio telescope, using it to map the radio sky. Kraus was the first professional astronomer to build on Jansky's work. After World War II, Kraus founded the radio observatory at Ohio State University. After Reber and Kraus demonstrated that it was worth studying celestial radio sources, professional astronomers started doing radio astronomy.

Thanks to Jansky's pioneering discovery, radio astronomy is now a very important branch of observational astronomy. Pulsars and quasars are two of many good examples of unsuspected new types of celestial phenomena that were discovered by radio astronomy. In honor of Jansky's contribution to the development of radio astronomy, astronomers measure the intensity of radio and infrared signals from celestial bodies in units called janskys. One jansky is defined as 10^{-26} watts/meter^2 hertz.

Because he died before radio astronomy became an important subfield, Jansky received few honors in his lifetime. He was made a fellow of the Institute of Radio Engineers in 1948. Some have speculated that if he had lived to see the important discoveries made by radio astronomy, he might have won the Nobel Prize for his seminal work in that subfield.

ZACHARIAS JANSSEN

Dutch lens maker

Janssen was a Dutch optician with a claim to having invented both the telescope and the microscope. With improvements by scientists such as Galileo, Cornelius Drebbel, and Antoni van Leeuwenhoek, the telescope and microscope soon became the most important scientific instruments in astronomy and biology.

Born: c. 1580; The Hague, the Netherlands
Died: c. 1638; Amsterdam, the Netherlands
Also known as: Sacharias Jansen
Primary field: Optics
Primary inventions: Compound microscope; telescope

EARLY LIFE

Zacharias Janssen (zak-a-RI-ehs YAHN-sehn) was born in the Netherlands around 1580, although his birth has been variously placed in the years 1580 to 1590. Holland was besieged by Spain during this period, and in the 1580's Janssen's family fled to Middelburg, located in the Dutch province of Zeeland. His father, Johannes (Hans), was a skilled optician and owned a spectacles shop in Middelburg. Johannes, perhaps with the assistance of Zacharias, experimented fruitfully with the magnification of spectacle lenses. After the death of Johannes around 1592, Zacharias inherited his father's optical shop. He also peddled his optical goods at town fairs and markets. Zacharias was a childhood friend and neighbor of William Boreel, whose father was a director of the Dutch mint; Zacharias apparently observed enough that he could later become a counterfeiter. On November 6, 1610, Zacharias married Catharina de Haene. Their son, Johannes Sachariassen, was born the following September.

LIFE'S WORK

Janssen engaged in two moneymaking ventures in addition to his work as a lens crafter. The first was the making of a telescope and microscope, which would give his name historic recognition; the second was counterfeiting, which would jeopardize his life. The scientific instruments developed from his lens-crafting trade while he was young; his career as a counterfeiter started later.

The precise details of the invention of the telescope and the microscope cannot be definitively ascertained. There were precursors of the telescope in Italy in the 1590's before the first real telescopes appeared in Holland in the 1600's. At least three Dutch lens makers have claims to the invention of the telescope—Janssen, Hans Lippershey, and Jacob Metius. Historians such as Cornelis de Waard and Albert Van Helden have described a scenario crediting Janssen as the first inventor based on circumstantial evidence and informed speculation.

The invention of the telescope resulted from the expertise of Dutch opticians in crafting spectacle lenses. Convex eyeglasses were invented in late thirteenth century Italy to assist elderly people suffering from presbyopia. Concave lenses were invented later for myopia. A convex lens is thick in the middle and curves outward; a concave lens is thinner in the middle and curves inward; a planar lens is flat. The angle of the lens determines the refraction of light and thus the magnification. In the fifteenth and sixteenth centuries, lens-grinding techniques and the quality of glass for both convex and concave lenses steadily improved. As part of his explorations in magnification in the beginning of the seventeenth century, Janssen probably put a stronger concave lens against his eye and a weaker convex lens some distance apart. When he looked through the two lenses, he saw distant objects magnified. Connecting the two lenses with a tube, Janssen was able to make the first telescope, probably in the year 1604. It is also possible that Janssen had heard about or seen a similar instrument that had been made in Italy several years before, perhaps as early as 1590. Because this telescope employed glass lenses to refract light, it would come to be called a refracting telescope. Because an obvious use was for the military to spot enemy forces on land and sea, the telescope was first known as a spyglass.

Over the next few years, Janssen may have worked secretly to increase the magnification of the spyglass, to about three times. Historians believe that Janssen's character was such that when his spyglass had reached a sufficient magnification, he would try to quickly profit from his invention rather than undertake the legal machinations of obtaining a patent. In September of

The Compound Microscope

The first telescopes invented by Zacharias Janssen, Hans Lippershey, and other Dutch opticians in the first decade of the seventeenth century developed directly from their experiences as lens makers. These opticians connected a strong concave lens eyepiece with a weaker convex objective lens. The objective lens and eyepiece work in concert in focusing and magnifying the light from the object. The convex objective lens collects and focuses light from the distant object, and the concave eyepiece lens makes the light rays parallel as they enter the human eye. As a result, distant objects and panoramas are made to appear closer with an increase in size, definition, and brightness. The magnifying power is proportional to the ratio of the focal length of the objective to the focal length of the eyepiece. When Galileo heard of the Dutch discovery, he began making his own refracting telescopes and microscopes in May, 1609. His improved telescopes were soon capable of a magnification of thirty-six times, by which he was quickly able to discover the mountainous surface of Earth's moon, the four moons of Jupiter, the phases of Venus, sunspots, and the stars of the Milky Way. In the following decades, Johannes Kepler, Christiaan Huygens, Isaac Newton, James Gregory, and Guillaume Cassegrain introduced new forms of optical telescopes, including the "reflecting" telescope, which utilizes curved mirrors. By the middle of the seventeenth century, refracting and reflecting telescopes were able to magnify objects one hundred times. In later centuries, radio and other telescopes were developed that reach distant galaxies.

Janssen is usually credited with the invention of the compound microscope. Janssen's microscope, like his telescope, worked by refraction—that is, the bending of light rays. The objective lens collects the image of the miniature object, which is further magnified by the eyepiece. In the Middelburg Museum, there is a primitive compound microscope that was donated in 1866 and may well be one of Janssen's original microscopes. It resembles a telescope and consists of two cylindrical tubes held together by a third tube that acts as a sleeve and enables the microscope to be handheld. At one end is a plano-convex objective lens and at the other the biconvex eyepiece. This microscope could magnify objects up to nine times. Antoni van Leeuwenhoek's sophisticated single-lens microscopes in the 1670's magnified objects 270 times and allowed him to make detailed observations and recordings of microscopic life. As with the optical telescope, the optical microscope has been surpassed. Electron microscopes invented in 1933 are essential to atomic physics.

1608, he was trying to sell a telescope at the Frankfurt Fair among his other optical wares, although a potential customer complained that the glass was cracked and the instrument too expensive. A few weeks later, on October 2, 1608, a neighboring spectacles maker, Hans Lippershey, petitioned the Dutch States-General in The Hague, the governing body of the Dutch Republic, for a patent for a binocular telescope. This patent application was denied because the investigating committee discovered that the art of making a spyglass telescope was already known to a young man. This young man was probably Janssen. Janssen, learning of Lippershey's application, may have gone to The Hague to present himself as the first inventor. Although denied a patent, Lippershey was commissioned to make two more binocular instruments. A few weeks later, yet another Middelburg lens maker, Jacob Metius, applied for a patent for a spyglass and was also denied. One of these early spyglasses was presented to Prince Maurice of Nassau, the Dutch stadtholder, and several others were soon dispersed around Europe.

The best claims for the invention of the telescope by Lippershey or Metius are their documented patent applications; for the claim of Janssen, it is the testimony of his son, Johannes Sachariassen, and of his childhood friend, William Boreel. In 1655, Boreel, serving as Dutch envoy to France, testified that Janssen was the inventor of the telescope. Boreel also claimed that Janssen was the first inventor of the compound microscope. Like the refracting telescope, a compound microscope consists of two lenses: an eyepiece and an objective lens, which refract light to magnify the image. The invention of the compound microscope probably developed from that of the telescope, as they both follow the same principle, except that with the microscope the object is placed on the objective lens. Therefore, it is plausible that the same person who invented one quickly developed the other. It is even possible that the same instrument served as both a rudimentary telescope and microscope. Boreel claimed to have seen one of Janssen's original microscopes in 1619. He described it as a tube one and a half feet long and two inches in diameter. The viewer looked through the glass at the top down to the minute object resting on an ebony disc at the bottom of the tube.

After 1610, Janssen's questionable activities increased. He was in legal trouble for unpaid drinking bills and for assault. In 1613, he was arrested for counterfeiting, but on April 22 the municipal court of Middelburg merely fined him, probably because he was counterfeiting Spanish copper quarters. Relocating to the town of Arnemuiden, he advanced to the more profitable counterfeiting of gold and silver coins. In 1618, Janssen was sentenced to death for counterfeiting. He avoided the capital sentence by escaping to Middelburg. Janssen's wife died in 1624, and he married Anna Couget a year later. After failing to meet a loan obligation on May 1, 1628, he was bankrupt and his property was auctioned. He died about ten years later, probably in Amsterdam.

Impact

The details of the invention of the telescope and microscope are lost to history, but the impact of their invention is clear. The telescope and microscope were invented by skilled Middelburg lens grinders in their workaday shops, without a theoretical knowledge of optics. It was some of history's greatest scientists who used their theoretical knowledge to improve these instruments and make astounding discoveries.

Eyeglasses were invented in Renaissance Italy, giving rise to speculation about the possibility of magnification through the manipulation of glass lenses. By the beginning of the 1600's, the skill of Dutch opticians had reached the point where the discovery of a simple refracting telescope and compound microscope was likely. Janssen may have been the first to invent a telescope in the years 1604 to 1608, but it may well have been Hans Lippershey or even Jacob Metius, or all three simultaneously. Certainly it was Lippershey who recorded and publicized the invention by applying for a patent in October, 1608. Although the States-General denied Lippershey his patent, its examining committee brought the new discoveries to the attention of the Dutch and soon all of Europe. The princes of Europe conceived of the telescope as a spyglass to obtain advantages over military enemies and assist navigation. Galileo had another idea. Relying on his superior knowledge of the theory of optics and refraction, he made an improved telescope within a year of learning of the Dutch discovery and aimed it at the sky. A half century later, the Dutch lens grinder Antoni van Leeuwenhoek and the English scientist Robert Hooke made improved microscopes and observed bacteria swimming in drops of water.

By meticulous, unaided observation, astronomers such as Nicolaus Copernicus, Johann Bayer, and Tycho Brahe had plotted the solar system to a remarkable degree, but with the telescope, scientists such as Galileo, Johannes Kepler, and Isaac Newton were able to reveal the secrets of the planets, Sun, and stars, and of light and gravity that bind them. With the microscope, the fundamental life of microorganisms was revealed. From the commercial grinding and manipulation of lenses by opticians at the dawn of the Dutch Golden Age came the instruments that have transformed science.

Robert Jarvik

American scientist and zoologist

Jarvik's work on artificial hearts resulted in the Jarvik-7, which kept terminally ill heart patients alive for as long as 620 days and encouraged other researchers in their quest to find permanent replacement hearts for the growing number of heart patients.

Born: May 11, 1946; Midland, Michigan
Also known as: Robert Koffler Jarvik (full name)
Primary field: Medicine and medical technology
Primary invention: Jarvik-7 artificial heart

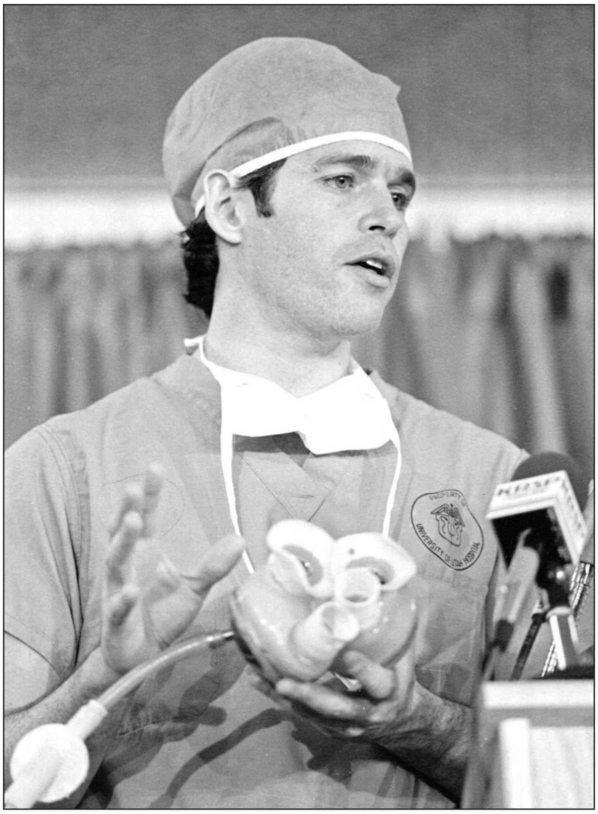
Early Life

Robert Koffler Jarvik was born in Midland, Michigan, but his parents (Norman Eugene Jarvik, a physician, and Edythe Koffler Jarvik) moved to Stamford, Connecticut, where his father became a prominent surgeon. In elementary school, young Jarvik built model airplanes and ships and displayed great manual dexterity. He said that he was always taking things apart and reassembling them in his mind. Before he graduated from high school, Jarvik, who often observed his father's operations, was interested in medicine, but he was even more concerned with building things and solving problems. His first invention, which he patented, was a time-saving automatic surgical stapling machine to replace the slow sewing by hand that was required to bind blood vessels together and to close wounds.

When he enrolled at Syracuse University in 1964, he was not intent on a medical career; but after studying different subjects without making real efforts, he chose zoology for a major. His change of major was caused by his father's near-fatal aortic aneurism. Jarvik then intended to enter medical school in order to solve heart problems. Unfortunately, the weak grades he received before deciding on a medical career prevented him from being accepted to American medical schools. As a result, he studied medicine at the University of Bologna for two years before returning to the United States to again apply to medical schools. When he was rejected again, he studied occupational biomechanics at New York University, where he received his master of arts degree in 1971. He was working at Ethicon, Inc., when his boss presented him with an opportunity to work, for a salary provided by the company, at the University of Utah's Institute for Biomedical Engineering and Division of Artificial Organs, headed by Dr. Willem Kolff. Because working at the institute would improve his chances for medical school admission, Jarvik applied for a job and was hired as a laboratory assistant in 1971.

LIFE'S WORK

Jarvik worked with Kolff, the man who had devised the first working artificial kidney and invented the world's first working kidney dialysis machine. Kolff then began work on creating artificial hearts. In 1957, he constructed an artificial heart that he implanted into a dog, which survived for ninety minutes. After he left the Cleveland, Ohio, clinic for the University of Utah, he began work on an artificial human heart, but progress was slow until Jarvik joined the team.



Robert Jarvik holds the Jarvik-7 artificial heart, which was first implanted in a patient in 1982. (AP/Wide World Photos)

At first, Jarvik worked on devising an artificial heart for a calf and improved on some of the designs of Dr. Clifford Kwan-Gett, a colleague at Utah. By substituting biomer, a Lycra-like elastic, for rubber, he was able to prevent the blood clotting that had caused the deaths of lab animals in earlier experiments. His Jarvik-3 artificial heart (designed in 1972) allowed the calf to live ninety days. He then turned his attention to an artificial human heart and was in competition with the work being done at the Baylor-Rice Artificial Heart Program in Houston, Texas. His Jarvik-7 was still another improvement, and it allowed a calf to live 268 days with the artificial heart in 1976, the same year he finished medical school and became an associate in Kolff's new company, Kolff Associates, later Kolff Medical, Inc. Three years later, he was a research assistant professor of surgery and biomedical engineering at the University of Utah School of Medicine.

Kolff's first request to implant an artificial heart into a human being was denied by the Food and Drug Administration (FDA) in 1979, but he got the necessary approval in 1981. The FDA approval, however, depended on the team using a class IV patient, someone over eighteen years of age who could not live after being taken off a heart-lung machine after open-heart surgery. Barney Clark was the patient, and Dr. William Castle DeVries implanted the Jarvik-7 in him in December, 1982. For his work, Jarvik was named "inventor of the year" by the Intellectual Property Owners Association in 1982 and by the National Inventors Hall of Fame in 1983. During the 1980's, he also received two honorary doctorates, one from his alma mater, Syracuse University, in 1983, and the other from the Hahnemann School of Medicine in 1985.

In the year before the Clark operation, Jarvik persuaded Kolff to name him president of Kolff Medical, Inc., which was renamed Symbion. The attractive, articulate Jarvik was a born fund-raiser, and with businessman W. Edward Massey he began to raise capital. The second operation (1984) was on William Schroeder, who survived for 620 days. Schroeder was the world's longest-surviving recipient of an artificial heart. Two other men died shortly after having Jarvik-7 implants. In 1987, the year Jarvik married Marilyn vos Savant, the brilliant "Ask Marilyn" columnist for *Parade* magazine, Symbion was acquired by a New York firm that subsequently fired Jarvik. The FDA shut the Jarvik-7 experiment down in 1990, and Jarvik moved to Houston, where he worked at the Texas Heart Institute and St. Luke's Episcopal Hospital. His next invention was the Jarvik 2000, a "bridge" between transplants that involves implanting a pump in the patient's left ventricle.

In 2006, Jarvik received a $1.35 million contract to become the television spokesperson for Pfizer's Lipitor, a best-selling drug used to lower cholesterol. His ads, which dramatically increased sales of the drug, came under fire because he wore a physician's uniform and was photographed rowing a boat. A double for Jarvik rowed the boat, and since Jarvik was never licensed to practice medicine (he never completed an internship or a residency, although he did complete medical school), his advice was construed as practicing without a license. Initially, Pfizer defended the ads, and Jarvik noted that he was a doctor and added that he was a medical scientist, not a practical doctor. Pfizer announced in February, 2008, that it was discontinuing the Jarvik ads.

Impact

Although Barney Clark's death was followed by others, none of whom lived more than William Schroeder's 620 days, and although the FDA rescinded its approval of the Jarvik-7 for human implantation in 1990, Jarvik's artificial heart spurred additional research in the use of artificial human hearts. The controversy surrounding the Jarvik-7 was responsible for bringing attention to the ethical, legal, and psychological issues involved in transplants and resulted in closer supervision of FDA approval procedures.

During the 1990's, Jarvik began developing the Jarvik 2000, a heart assist device that is placed in the patient's left ventricle, where its propeller pumps up to 1,500 gallons of blood daily. The device received FDA approval as a "bridge" between heart transplants. In 2006, researchers at Abiomed received FDA approval for their AbioCor replacement heart. Their artificial heart, made of plastic and titanium, is the size of a softball and weighs approximately three pounds. Unlike the Jarvik-7, it has an internal power source that allows it to work for up to thirty minutes. It also has power supplied by batteries that are attached to a belt. The improvements were made possible by the research inspired by Jarvik's work. Other medical advances in artificial hearts may ultimately save thousands of lives.

—Thomas L. Erskine

The Jarvik-7 Artificial Heart

The successor to the Jarvik-3 artificial heart was modeled after the human heart and is approximately the same size as a human's fist-sized heart. It weighs about ten ounces and is designed to replace the human heart. It has two artificial ventricles, which are like the pumping chambers of the heart and which replace the left and right ventricles, which the surgeon has removed. The device is made up of Dacron polyester, aluminum, and plastic. The patient's atria, the upper chambers of the heart that take in blood from the veins, is the anchor to which the Jarvik-7 heart is attached. The power for the device comes from an outside device that is connected to the patient's chest through tubes. As a result, the artificial heart duplicates the functioning of the human heart. The right atrium receives blood from the body, then pushes it down to the right ventricle, which pumps it to the lungs through pulmonary arteries to pick up oxygen. The oxygenated blood goes through the pulmonary arteries to the left atrium and is again pushed down, this time to the left ventricle through the mitral valve. The left ventricle then pumps the blood, after the mitral valve is closed and the aortic opened, to the rest of the body through the aorta. Essentially, the Jarvik-7 consists of the two ventricles, which comprise about two-thirds of the human heart.

Ali Javan

Iranian American physicist

In 1960, Javan and his Bell Labs team built the first gas laser, the helium-neon laser. This invention, the first continuous-light laser, revolutionized telecommunications through fiber-optic technology and became widely used in UPC bar-code scanners, holography, and other applications.

Born: December 26, 1926; Tehran, Iran
Primary fields: Communications; physics
Primary invention: Helium-neon gas laser

Early Life

On December 26, 1926, Ali Javan (AH-lee JAH-von) was born in Tehran, Iran. His parents were Azarbaijanis from Tabriz, the largest city in northwestern Iran. His mother was an artist, and his father was a lawyer and writer interested in human rights. In early childhood, Javan became interested in science. At the age of five, he became fascinated with numbers and mathematics. He also enjoyed playing with gadgets, and at the age of seven Javan attempted his first invention, a camera made from a little box. He imagined many new gadgets that defied the laws of physics and could not possibly be built, but he experimented and tried to invent new devices.

Javan attended excellent schools, including the prestigious Alborz High School in Tehran. His schools had advanced mathematics and physics programs, and his teachers encouraged him to excel. He began studies at Tehran University, the largest university in the country, but in 1948 emigrated to the United States to continue his studies at Columbia University in New York. At Columbia, he studied physics and mathematics, and his doctoral adviser was Charles Hard Townes, who in 1953 invented the maser (microwave amplification by stimulated emission of radiation), the forerunner of the laser. The maser works by generating, focusing, and amplifying electromagnetic radiation, which is typically scattered and chaotic, into a stream that has more energy in the microwave portion of the electromagnetic spectrum. Javan studied microwave spectroscopy with Townes. Javan also took courses in the humanities and arts, such as music classes with the celebrated composer Henry Cowell.

Life's Work

In 1954, Javan received a Ph.D. in physics, but he stayed four more years as a postdoctoral student at Columbia University to work on masers and microwave spectroscopy. During this time, he had the idea for a three-level maser, but Bell Laboratories published its research first. The Radio Corporation of America (RCA) purchased the patent rights to the three-level maser from Javan and battled Bell for the patent. However, RCA decided that this maser was not feasible commercially and Bell could have the patent. In April, 1958, Bell Labs in Murray Hill, New Jersey, hired Javan to be part of their technical staff. In August, 1958, he began research on lasers.

The basic idea of the laser began in 1916 with Albert Einstein's view that atoms could release excess energy as light, either spontaneously or when stimulated by light. In 1917, the concept of stimulated emission appeared, and in 1928 physicist Rudolf Walther Ladenburg was the first to observe stimulated emission.

In 1953, Javan's thesis adviser Charles Hard Townes and associates J. P. Gordon and H. J. Zeiger built the first maser. Since masers had limited applications, Townes and Arthur L. Schawlow at Bell Labs discussed developing an optical maser that would involve the higher-frequency photons (rays of light, or electromagnetic energy moving in oscillating waves of various wavelengths) in the ultraviolet or visible light spectrum. Townes also discussed the subject with Gordon Gould, a graduate student at Columbia University. In the December 15, 1958, issue of *Physical Review*, Townes and Schawlow published a paper proposing an optical maser. In the meantime, Gould had coined the word "laser" (light amplification by stimulated emission of radiation) and applied for a patent. There followed a bitter thirty-year battle over patents and credit for the invention of the laser.

There was intense rivalry among research laboratories and scientists in the race to build the first laser. As 1960 began, no one had been able to build a working laser. Javan had conceived of a gas laser and had assembled a team at Bell Labs to develop a prototype. He had enlisted William R. Bennett, an experimental physicist and expert on gas discharges, and Donald R. Herriott, an optical specialist at Bell Labs, to help on this project. Javan had also published the idea in the *Physical Review Letters* in June, 1959.

On May 16, 1960, Theodore Harold Maiman of Hughes Research Laboratories in Malibu, California, demonstrated the first working laser, the ruby laser, which used a synthetic ruby crystal to produce short pulses of red light. On December 12, Javan, Bennett, and Herriott demonstrated the first gas laser, which generated a continuous infrared beam from a mixture of helium and neon. The next day, Javan's team was able to demonstrate the first telephone conversation transmitted by a laser beam.

In 1961, Javan became an associate professor of physics at the Massachusetts Institute of Technology (MIT), and he became a full professor in 1964. At MIT, he established the preeminent university laser laboratory of the 1960's and 1970's. The research here included significant developments in laser spectroscopy, atomic clocks, the use of lasers to test the special theory of relativity, and other scientific laser applications.

In recognition of his contributions to science, Javan received many honors and awards. These include the Stewart Ballentine Medal of the Franklin Institute (1964), the Fanny and John Hertz Foundation Medal (1966), a Guggenheim Fellowship (1966), and Humboldt Foundation Fellowships (1979 and 1995). In 1975, the Optical Society of America awarded Javan its most prestigious honor, the Fredric Ives Medal, which recognized the significance of the gas laser to scientific research. In 1993, he received the Albert Einstein World Award of Science of the World Cultural Council. On May 6, 2006, Javan was inducted into the National Inventors Hall of Fame.

The Helium-Neon Gas Laser

Theodore Harold Maiman's ruby laser was the first working laser, demonstrated in May, 1960. It emitted pulsating bursts of light. His laser consisted of a synthetic ruby rod containing chromium atoms. Pulses from a photographer's flash lamp excited the atoms, creating pulsating bursts of red laser light.

The second working laser was Ali Javan's helium-neon laser, the first gas laser, demonstrated later that year. It converted electrical energy to a laser light and generated a continuous light beam instead of pulsating bursts of light. Javan's gas laser apparatus had an 80-centimeter-long quartz tube with an inner diameter of 1.5 centimeters. This tube contained a mixture of the inert gases helium and neon, and there were two internal electrodes used to send an electric current through the gas mixture. On both ends of the tube were reflecting and parallel mirrors.

Because inert gases do not easily combine with each other to form molecules, it was possible to isolate the atomic transfer of energy that is used at the first stage of the process, when the electrodes excited the atoms of helium gas with a current. The process began with the electric current stored as an internal energy in an energetic state of helium atoms, which then excited the neon atoms, whose atomic transitions produced the laser light. This light was then bounced between the mirrors and became rapidly amplified, increasing in intensity until a light beam was output from the apparatus. The mirrors could also be used to control the wavelength of the light. The power was low but very constant in this kind of laser, referred to as a continuous-wave laser. The output of Javan's gas laser was near infrared.

In 1962, researchers Alan D. White and J. Dane Rigden created a version of the laser that generated a visible red beam, the now standard 632.8-nanometer (nm) red line. In the mid-1970's, the gas laser was the first laser to be mass-produced, for use in Universal Product Code (UPC) scanners. It also became useful in holography, communications, information handling, construction alignment, surveying, medical technology, and laboratory demonstrations. Up until the late 1990's, the red helium-neon laser was the most common and profitable laser for low-power applications, since it was inexpensive to manufacture and provided a continuous, coherent low-power output at a visible wavelength.

Impact

With the invention of the helium-neon laser, Javan became an internationally acclaimed physicist and pioneer in laser technology. His gas laser was the first laser functioning on the principle of converting electrical energy to a laser light output. It was also the first to operate continuously—that is, to generate a continuous light beam. A significant scientific breakthrough, the gas laser became widely used in research and industrial laboratories, as well as practical applications such as Universal Product Code (UPC) scanners and holography.

It is significant that the day after its invention, the first experiment with a practical application for the gas laser involved a telephone call, because subsequent developments in fiber optics contributed to a revolution in communications, eventually forming the backbone of the Internet as well as telephony and media transmission. Javan's success with the gas laser helped to stimulate a wide range of future developments in laser research, including the use of other kinds of gases and materials such as semiconductor diodes to produce light.

Javan also directly contributed to the development of saturation spectroscopy, which made it possible to achieve unprecedented levels of precision in spectral analysis on the molecular and atomic levels. Ordinarily, lines of resolution at these levels are masked by thermal atomic motion, but the focused laser light can be used to eliminate the extra resonances caused by this motion.

Al-Jazarī

Arab mechanical engineer

Al-Jazarī invented the first suction pump and developed segmental gears, floats, and conical valves, which were essential in the operation of water clocks and water-raising machines for irrigation.

Born: c. 1150; Al-Jazīra, Mesopotamia (now Diyarbakir, Turkey)
Died: c. 1220; probably Mesopotamia
Also known as: Badī ʿal-Zamān Abū al-ʿIzz Isma ʿīl ibn al Razzāz al-Jazarī (full name)
Primary field: Mechanical engineering
Primary inventions: Water-raising machines; water clocks; piston pump

Early Life

Mechanical engineer Badī ʿal-Zamān Abū al-ʿIzz Isma ʿīl ibn al Razzāz al-Jazarī, commonly known as al-Jazarī (ahl-JAH-zah-ree), lived in the city of Diyarbakir in what is now modern Turkey. From his name, it is known that he was born in al-Jazīra, an area between the Tigris and Euphrates rivers in what is now eastern Turkey. His name also reveals that he was unrivaled (Badī ʿal-Zamān). His date of birth, his childhood, and early education are unknown. It is likely that he was trained by his father, who also served as a court engineer.

Life's Work

From 1174 to 1206, al-Jazarī served as court engineer for three rulers of the Turkman Artuqid dynasty centered in Diyarbakir. Some of his ingenious machines, such as water clocks and fountains, served to entertain the young princes and to impress and amuse court visitors. Other devices, such as his phlebotomy measuring basins, had a practical application. Al-Jazarī lived during the flowering of Arab science, a time when advances occurred in optics, hydrology, astronomy, mathematics, and medicine. He was also fortunate to have lived under generous patrons during a period of peace and stability.

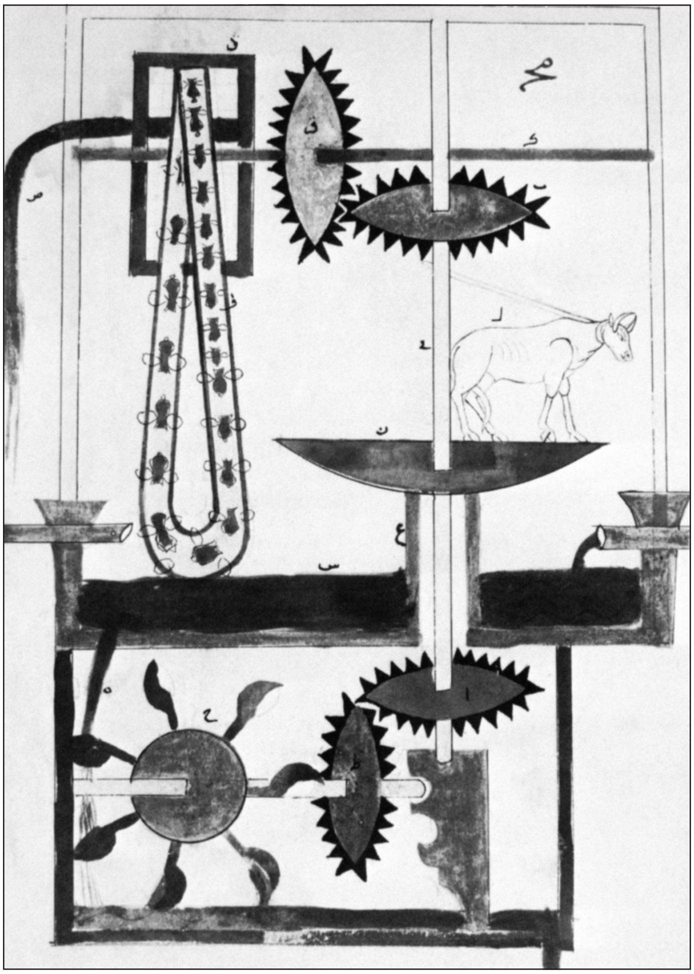
Unlike many engineers of his time, al-Jazarī was literate in written Arabic. He was also a skilled artisan and author. His accomplishments are known because King Nāsir al-Dīn asked him to write and illustrate a book about his machines. On January 16, 1206, al-Jazarī completed his book on theoretical and practical mechanics, *Kitāb fī ma ʿrifaṭ hiyal al-handasiyya*. It was not until 1974 that Donald R. Hill translated this book, *The Book of Knowledge of Ingenious Mechanical Devices*, from Arabic into English. The oldest and most complete copy of the book is at the Topkapi Sarayi Library in Istanbul and was copied by Muhammad ibn Yusuf ibn ʿUthman al-Haskafi on April 10, 1206. Fifteen manuscripts exist. Not all are complete, and some of the pages disappeared into private collections. Some of these copies are now at the Museum of Fine Arts in Boston and the Louvre in Paris. All illustrations are in color, and a school of miniaturists employed by the court illuminated the original manuscript. Other nearly complete copies are at the Bodleian Library at Oxford and the Hagia Sophia Library in Istanbul.

Al-Jazarī's book describes fifty devices, which he groups into six categories: (1) six water clocks and four candle clocks; (2) vessels and figures suited for drinking sessions; (3) ten pitchers and basins for phlebotomy and washing before prayers; (4) ten fountains and machines for the perpetual flute; (5) five water-raising devices; and (6) five miscellaneous devices that include combination locks, an alarm clock, a protractor, and a door for the palace. About 40 percent of the text is devoted to clocks. The instructions are clear and orderly. Each device is first presented with a general explanation of its operation and use. The details of manufacture and assembly are given and followed by a detailed discussion of the operation of the device. Accompanying the descriptions are 174 detailed and labeled drawings. The book summarizes most of the accumulated knowledge of mechanical engineering, and al-Jazarī provides a detailed guide for future artisans to recreate his machines.

Al-Jazarī's machines address practical problems of irrigation and commerce. He focused on water clocks to measure time for religious and commercial purposes. To what extent al-Jazarī had access to Greek scientific works translated under the patronage of the Abbasid dynasty is not known. He was familiar with the work of the ninth century Baghdad scholar Banū Mūsà, who wrote on *hiyal*, or trick vessels, such as fountains and musical automata. Al-Jazarī mentions reading Archimedes' treatise on the construction of water clocks. Much of al-Jazarī's discussion of calibration techniques, cranks, gears, control systems, and methods of casting metals by the use of mold boxes addresses improvements to existing technology. One device, a piston pump for raising water, is clearly a new invention by al-Jazarī.

Al-Jazari describes five water-raising machines. One improves upon the traditional animal-powered *sāqiya* by using water to drive the waterwheel that causes a chain of pots to raise the water. The device appears to be intended for ornamental purposes rather than for actual irrigation. Three other machines are modifications to the *shaduf*, or sweep. These modifications incorporate segmental gears and a machine-driven rather than the usual hand-driven crank. The fifth machine is an invention, a water-driven twin-cylinder pump that raises water to a height of about thirty-three feet, or ten meters. This machine addressed a particular irrigation problem for Upper Mesopotamia: how to raise water cheaply and efficiently from rivers whose beds lay below the surface of the surrounding fields. The important features of the device include the following: a double-acting principle, the conversion of rotary into reciprocating motion, and the use of true suction pipes. These features made possible the development of the steam engine and reciprocating pumps.

Water clocks existed in the ancient civilizations of Babylon and Egypt. Astrolabes and sundials measured only daylight hours, whereas water clocks worked at night. Water clocks measure time by a stopwatch-like function in which the length of a unit of time corresponds to the time that it takes for discharge of a liquid from one container to another. That movement of a liquid, usually water, through a series of tubes powered by gears, weights, and pulleys translates into signals that indicate the passage of time. Water clocks not only tell time but also serve an aesthetic or religious function by simulating the heavens and representing animals and humans that move and make sounds. Al-Jazarī's clocks and fountains feature figures that play musical instruments and falcons that spread their wings and disgorge metal balls from their beaks. These are entertainment robots, which also serve a function in the clock's operation. Some might say that the attention paid to decorative automata was a trivial exercise, but this criticism discounts the contribution made in the areas of delicate mechanisms and scientific instrumentation.



Al-Jazarī's water-powered sāqiya *chain pump.* (The Granger Collection, New York)

Impact

Al-Jazarī created no war machines. All of his machines either delighted the affluent or benefited society as a whole. Al-Jazarī's pumps were more advanced than the suction pumps used in Europe in the fifteenth century. Leonardo da Vinci mentions conical valves. It is not clear that da Vinci read al-Jazarī's book, although it is known that he read some of the translations of Arabic scientific works made in Toledo in the twelfth century. Al-Jazarī is mentioned by the Egyptian Al-Qalqashandī (1355 or 1356-1418) in his fourteen-volume encyclopedia as being preeminent in the science of machines.

Although al-Jazarī's book was copied and preserved in manuscript collections, it did not become a textbook, and no one in the Arabic-speaking world continued his work. The book remained untranslated until 1974. It is valuable as a history of the science and technology of that time. Reproductions of some of al-Jazarī's devices are on exhibit. A working replica of one of his water pumps is at the Institute for the

History of Arabic-Islamic Science at Johann Wolfgang Goethe University in Frankfurt, Germany. A replica of al-Jazarī's elephant clock is on exhibit in the Ibn Battuta Mall in Dubai. The World of Islam Festival in London in 1976 exhibited three reconstructions of his machines: a four-meter-high water clock, a phlebotomy device, and a double-acting pump. The English and Arabic translations and the exhibits of his working devices have stimulated a sense of pride and a desire by scholars to know more about the contributions of Arab scientists, engineers, and inventors.

—*Fran Hassencahl*

Piston Pumps and Water Clocks

Al-Jazarī is unique among his contemporaries because he wrote an illustrated book about his inventions. His major contributions were a piston pump for irrigation and improvements in water clock technology. His pump is driven by a paddle wheel, which drives, through a system of gears, an oscillating slot-rod. Two pistons attach to this rod and work in horizontally opposed cylinders, which connect to valve-operated suction and delivery pipes. As the slot-rod oscillates, one piston is on its delivery stroke and the other is on its suction stroke. The delivery pipes join above the center of the machine and form a single outlet into the irrigation system. The pump differs from conventional Hellenistic pumps that could not be positioned above the water source. Those pumps needed to be immersed in the water, which then could be collected on a suction stroke when the water entered through a hole covered by a plate valve in the bottom of the cylinder.

Al-Jazarī's elephant clock not only incorporates a highly decorated figure of an elephant but also has a receiving tank inside the elephant for the water that flows from a top tank. A sinking float in the bottom tank regulates the water flow. This closed-loop process with a float regulating water flow is analogous to the mechanisms of a flush toilet. The sinking of the float device triggers a ball-release mechanism that then tilts and empties the float. The empty float then rises to the surface of the water, and the process of delineating the rise and fall begins again and marks the passage of time. These valves and feedback mechanisms were essential to the development of the steam engine and automated controls.

Water clocks depend upon careful machining to achieve a constant rate of water discharge because time is measured by the amount of water as it moves through calibrated openings. Al-Jazarī's contributions in water clock technology include the use of carefully cast and fitted conical valves as in-line regulators in water flow systems and the development of float devices. He used emery powder to grind the seats and plugs of the valves to get a more watertight fit than did his predecessors. His casting of bronze and copper parts by using green sand in closed mold boxes did not occur in Europe until the end of the fifteenth century.

There is no evidence that al-Jazarī's mechanical devices transferred to Europe, but the principles of the suction pump and the refinement of conical valves were later incorporated into steam engine technology. His work is one of the efflorescences and declines that characterize the history of scientific discoveries and economic growth.

Thomas Jefferson

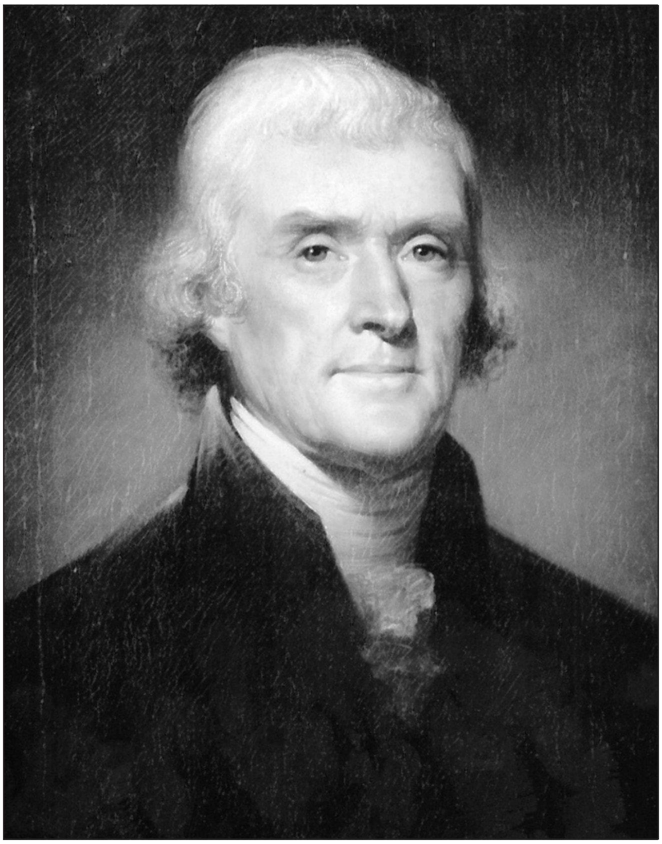
American architect, politician, and agriculturist

Besides serving as the third president of the United States, Jefferson was an architect, agriculturist, and inventor, designing such devices as an improved ox plow, the Great Clock at his self-designed Monticello home, and a lap desk—upon which he wrote the Declaration of Independence.

Born: April 13, 1743; Shadwell, Goochland County (now Albemarle County), Virginia
Died: July 4, 1826; Monticello, Albemarle County, Virginia
Primary fields: Agriculture; architecture
Primary inventions: Great Clock; portable copying press; improved ox plow

Early Life

Thomas Jefferson was the third of eight children born to Peter and Jane Randolph Jefferson. Peter was a surveyor and planter, and the Jeffersons homeschooled young Thomas until he was nine years old, when he began studying Latin, Greek, and French at a local school. Peter died when Thomas was fourteen and left him five thousand acres in Albemarle County on which he eventually built his famous home Monticello. He then attended a school near Gordonsville, Virginia, where he studied history and science. He also learned to play the violin around this time. Jefferson attended the College of William and Mary from 1760 to 1762, where he studied mathematics and philosophy, especially the British empiricists. He boarded in a building named for the British architect Christopher Wren and attended morning and evening prayers in a chapel also named for Wren. Biographers believe it was during this time that Jefferson purchased his first copy of sixteenth century architect Andrea Palladio's *I quattro libri dell' architettura* (1570), a classic architectural textbook that influenced Jefferson's own ideas on architecture. After graduation, he studied law and was admitted to the Virginia bar in 1767. In 1772, he married Martha Wayles Skelton, a widow, and they had six children. Unfortunately, only two daughters survived to adulthood, and Mrs. Jefferson herself died in 1782. He never remarried, although many biographers believe he had more children by his African American slave Sally Hemings.



Thomas Jefferson's official portrait. (White House Historical Society)

Life's Work

Based on a design he saw in James Gibbs's *A Book of Architecture* (1728), Jefferson began building his home Monticello in 1768. He started living in it in 1770, had it torn down and begun again in 1796, substantially completed the second version in 1809, and was still tinkering with it at the time of his death in 1826. Made of brick construction, the second version was influenced by houses Jefferson visited in France. The features of French architecture used at Monticello included a dome and the outward appearance that there was only one story, when in fact there are three. All the public rooms were on the first floor, so Jefferson did not see the need for a grand staircase. (Some visitors, however, complained about the narrow and steep stairways Jefferson designed.) The house also included two wine dumbwaiters to transport wine from the cellar.

"Monticello" means "little hill" in Italian, and building the house on a hill was itself an innovation at the time. Virginia plantation homes in the eighteenth century, such as George Washington's home, Mount Vernon, were normally built close to rivers. However, Jefferson took Palladio's advice that country houses should be built on high ground. In his 1968 book *Great Houses of the Western World*, Nigel Nicholson included Monticello as one of the thirty-six greatest homes in the world.

Jefferson had a second, lesser-known home called Poplar Forest. He inherited the land in 1773 from his father-in-law, John Wayles, and started building the house in 1806. It was the first house in the United States built in the shape of an octagon and included a central room that was twenty feet on each side and porticos on both the north and south sides.

Jefferson became a member of the Virginia House of Burgesses (the state legislature) in 1769 and the Continental Congress in 1775. He then became governor of Virginia in 1779 and served until 1781. He was a mediocre public speaker, especially when compared to his fellow Virginian Patrick Henry, so his main political activity was writing. The need for greater personal productivity inspired Jefferson to design a lap desk so that he could recline while writing. It contained what he considered to be the essentials for a writer, including a thermometer, quills, ink, paper, and a nightcap. He wrote the Declaration of Independence on an early model in 1776.

Jefferson sailed to Europe in 1784 as a diplomat and was the American ambassador to France from 1785 to 1789. During this time, he recruited architect Charles-Louis Clérisseau, author of *Antiquités de la France* (1788), a study of French buildings constructed during the Roman Empire, to provide drawings for the new Virginia state capitol building in Richmond. It was also during this time that he modified his lap desk to add a portable copying press, which could make two hundred copies in forty-five minutes. He invented the press when he found that his travels required a portable version of the copying press originally invented by James Watt. To use Watt's machine, the correspondent wrote with ink on a copper plate that could produce multiple copies. Jefferson's innovation was to reduce the machine's size so that it could fit on his lap desk.

Although Jefferson grew up in the countryside, it was on a trip from Paris to Amsterdam in 1788 that he observed an ox plow, which he could see was extremely inefficient. The problem, he felt, was in the moldboard, the part of the plow that actually makes contact with and tills the soil. Jefferson used mathematical principles to design a new one, which he finally built in 1794. He called it the "moldboard of least resistance." The first version had a square toe, but Jefferson quickly discovered that when the soil was moist, the toe accumulated dirt. He then built a second version with a sharp toe, which solved the prob-

The Great Clock

Clocks fascinated Thomas Jefferson. One of the most striking features of Monticello, Jefferson's home, is the Great Clock, which was designed by Jefferson and constructed by Peter Spruck in 1792. Twenty-first century visitors to Monticello can still see it in operation in the entrance hall. Jefferson was a very organized person, and life at Monticello was as organized as he was. The clock had both an interior and exterior face so that everyone on the plantation was working on the same time. On the outside wall, the clock has only an hour hand, because Jefferson considered this sufficiently accurate for outdoor workers. A copper Chinese gong chimes each hour on the hour. During Jefferson's lifetime, it was loud enough for field hands to hear it anywhere on the plantation and reportedly could be heard as far as the University of Virginia in nearby Charlottesville.

On the inside, the clock displays not only the usual hour and minute hands but also a smaller dial to track the seconds. However, what was truly unusual was the day of the week indicator. Since it is a mechanical clock, it has to be powered by weights, of course. For his Great Clock, Jefferson utilized two sets of eighteen-pound cannon balls, which are suspended on both sides of the front doors. On Sundays, workers have to rewind the clock to raise the cannon balls to the ceiling. As the week goes by, the top ball on the right-hand set of weights shows the day and roughly even the hour as it gradually descends past markers on the wall. On Sunday, the cannon balls are toward the top and by Saturday have descended to the bottom.

There was one problem, however, during the installation process at Monticello. Jefferson originally designed the clock for the home he occupied while living in Philadelphia during his tenure as secretary of state. After Jefferson had the clock transported to Monticello in 1805, it was discovered that the height of Monticello's entrance was shorter than the length of the ropes connected to the cannon balls. Jefferson's solution was to cut square holes in the floor and allow the balls to be lowered until they entered the hole on Saturday and descended into the cellar.

lem. The early versions of the moldboard were made of wood, but Jefferson had an iron one built in 1814. In 1807, the French Society of Agriculture awarded him a gold medal for his achievement.

While serving as secretary of state from 1789 to 1793, one of his duties was supervising the U.S. Patent Office. Jefferson was elected vice president of the United States in 1796 and president in 1800, serving until 1809. One of his most important achievements as president was sending Meriwether Lewis and William Clark on a expedition from St. Louis to the Pacific Coast. He also established the first federal science agency, the Survey of the Coast, in 1807. As the named indicates, the agency surveyed and mapped the Eastern Seaboard. Jefferson's most important postpresidential achievement was the founding of the University of Virginia in Charlottesville in 1825. He died of natural causes in 1826.

Impact

Along with Benjamin Henry Latrobe (1764-1820) and Charles Bulfinch (1763-1844), Jefferson founded what became variously known as the Federal, Classical Revival, or neo-Palladian style of architecture in the United States. They believed that public buildings in the United States should be modeled on the buildings of ancient Greece or Rome, although Jefferson preferred the Roman style of architecture and Latrobe the Greek. While he was president, Jefferson appointed Latrobe to be surveyor of the public buildings of the United States.

Probably Jefferson's greatest impact was not for any one particular invention but for his role in determining the rules and regulations for obtaining a patent in the United States. Although he was only one member of the Board of Arts (the official name for the group that voted on patents) from 1790 to 1793, he dominated it by the force of his personality. He put emphasis on the utility, novelty, and nonobviousness of an invention in the decision of whether to grant a patent. For example, he rejected a 1791 patent application by Jacob Isaacks for a distillation process that converted saltwater to fresh water on the grounds that it was not a significant improvement on techniques already in use. On the other hand, he accepted the application by Eli Whitney for the cotton gin, because he recognized it as a genuine innovation.

Ironically, Jefferson never applied for a patent himself, because he did not agree with the concept of absolute intellectual property rights. He was not opposed to inventors receiving monetary compensation for their inventions, but felt that since patents are government-issued monopolies, they have the potential for abuse by stifling innovation rather than promoting it.

Alec Jeffreys

British geneticist

Jeffreys developed DNA profiling (also known as DNA fingerprinting), a technique used to identify individuals by their unique genetic signature. The technique plays a critical role in forensic scientific analysis and has been used to link suspects to crime scenes, exonerate wrongly convicted individuals, and resolve paternity disputes.

Born: January 9, 1950; Oxford, Oxfordshire, England
Also known as: Sir Alec John Jeffreys
Primary fields: Biology; genetics; medicine and medical technology
Primary invention: DNA profiling

Early Life

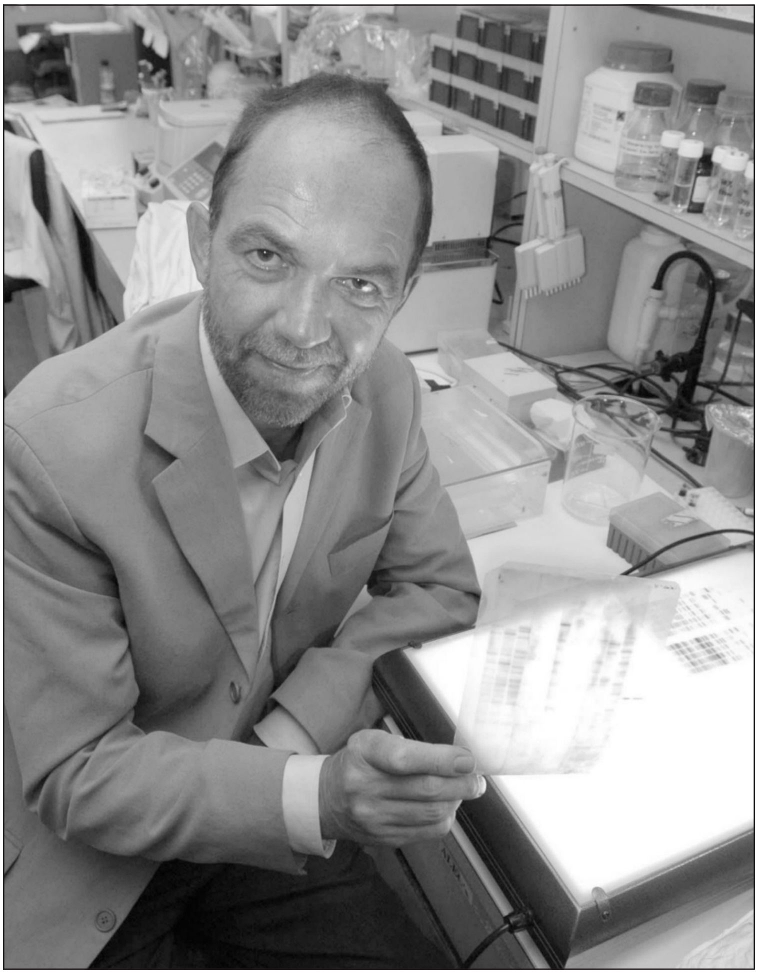
Alec Jeffreys was born into a middle-class British family in Oxford, England, and had one brother and one sister. Jeffreys came from an inventive family; both his father and grandfather had patents. His father encouraged his scientific inquisitiveness, giving Jeffreys a large chemistry set when he was eight years old. The young Jeffreys added to his collection of chemicals over the years, including a large bottle of concentrated sulfuric acid, a very dangerous chemical. His chemistry set was occasionally used to create minor explosions, and one incident left a permanent scar on Jeffreys' chin.

In addition to an early interest in chemistry, Jeffreys was drawn to biology. At about the age of nine, his father bought him a brass telescope. At twelve, Jeffreys made a dissecting kit that he initially used to dissect insects but that was later used to examine larger specimens, including, in one case, a dead cat he found on the road.

Jeffreys' formal education was less adventuresome but equally rewarding. He attended Luton Grammar School and Luton Sixth Form College before entering Merton College, Oxford. He graduated with a degree in biochemistry in 1972. He earned his Ph.D., also from Oxford, in 1975. That year, Jeffreys moved to the University of Amsterdam to work on mammalian genes as a research fellow. In 1977, he transferred to the University of Leicester, where he would develop the field of genetic fingerprinting, or deoxyribonucleic acid (DNA) profiling.

Life's Work

On the morning of Monday, September 10, 1984, Jeffreys was at his laboratory examining an X-ray of his lab technician's family's DNA when he realized that there were similarities and differences in the DNA sample. He quickly recognized the potential broad applications of this kind of DNA analysis, as it could be used to identify specific individuals as well as kinship. Jeffreys



Alec Jeffreys holds a copy of the first DNA profile at the University of Leicester, England. (AP/Wide World Photos)

DNA Profiling

DNA profiling, or genetic fingerprinting, is a scientific process that forensic specialists can use to match the DNA of unknown persons to the DNA of readily identified persons based on a comparison of the similarities and differences in that small percentage of human DNA that differs between human beings.

Almost all human DNA, some 99.9 percent of it, is identical. However, until the morning of September 10, 1984, no one in the scientific community knew that patterns could be detected within the remaining tenth of a percent of human DNA. At 9:05 A.M. that day, British geneticist Alec Jeffreys noticed such patterns in his technician's family's DNA. This simple observation of similarities and differences in this small sample led to the equivalent of an earthquake in the scientific community, with profound consequences for all humankind. Initially, genetic fingerprinting was used to link the DNA of unknown persons to members of their family, or used to link certain unknown individuals to victims of crimes or to crime scenes. Soon it was applied to the remains of deceased persons to link them to certain known persons in order to make an identification.

Obtaining a reference sample from one person is a necessary first step. A sample of saliva, blood, semen, or other bodily fluid or tissue is taken from a living person. That person's unique DNA profile is then prepared and compared to other DNA profiles to see if there is a match. Jeffreys' initial technique used extraction of a restriction enzyme, followed by southern blot analysis. Thereafter, scientists developed a host of other and increasingly improved techniques—all of which flowed from Jeffreys' initial observation of the patterns in the tenth of a percent of human DNA that differs from person to person.

Once it became known that DNA patterns existed, the floodgates opened in nearly all aspects of genetic, as well as forensic, research. The Human Genome Project, which mapped the human genome, and medical research for a wide range of inherited disorders all benefited from Jeffreys' initial discovery. Archaeologists and animal researchers have also made use of DNA fingerprinting to identify remains and fill other gaps in their investigations.

initially called this new form of DNA analysis "genetic fingerprinting," since an individual's genetic profile is unique, like a fingerprint.

DNA profiling was first used to establish the identity of a British boy whose family came from Ghana. The immigration dispute was settled when the DNA results showed that the boy was related to the members of the family whose identity was not in doubt.

The genetic technique was first used in a police investigation to identify the rapist and murderer of two teenage females. The crimes were committed in Narborough, Leicestershire, in 1983 and 1986. British police had identified a suspect, Richard Buckland, whom they were confident would be convicted on circumstantial evidence. However, when his DNA sample was compared to that of the semen samples taken from the dead girls' bodies, the samples did not match. A subsequent investigation led to Colin Pitchfork, whose DNA was a perfect match to the semen samples. Jeffreys' technique had not only identified the rapist and murderer but also exonerated someone who faced the very real prospect of life in prison for a crime he did not commit.

In another case, German prosecutors wanted to be sure that the corpse of the notorious Nazi war criminal Dr. Josef Mengele was indeed him and not a decoy. Mengele was known as the "Angel of Death" at Auschwitz for sending thousands of Jews to their deaths. After the war, he evaded capture and fled to South America, where he died in 1979. In 1990, Jeffreys took DNA samples from the femur of the exhumed skeleton and compared it with the DNA of Mengele's widow and son, determining that the corpse was indeed that of Mengele.

Before genetic fingerprinting was commercialized in 1987, Jeffreys' laboratory was the only center in the world conducting DNA profiling. Since that time, the technique has been refined and used in multiple ways. Jeffreys was knighted in 1994 for his services to the field of genetics. His other honors include the Australia Prize (1998), the Louis-Jeantet Prize for Medicine (2004), and the Heineken Prize (2006).

Impact

Jeffreys' biochemical breakthrough had far-reaching ramifications. Rape and murder cases now routinely use genetic fingerprinting if traces of DNA can be found and connected to the victim or the crime scene. Numerous persons facing execution on death row have been exonerated because of DNA profiling, and criminals have been conclusively identified using this method. DNA fingerprinting has also been used to establish definitive proof of parenthood (paternity or maternity). The identification of long-dead individuals or charred bodies whose identity cannot be determined by conventional means are now resolved through DNA testing.

The field of DNA analysis has received major funding because it has proven to be an invaluable tool in forensic science. The Human Genome Project, begun in 1990, was made possible in part by Jeffreys' breakthrough.

Edward Jenner

English surgeon and scientist

Jenner's discovery and development of smallpox vaccination began the eradication of one of the world's most dreaded diseases in the eighteenth century. He discovered the technique of inoculation with cowpox to prevent smallpox and coined the terms "vaccination" and "vaccine." Immunization saved lives around the world when Jenner's techniques were proven safe and became widely accepted.

Born: May 17, 1749; Berkeley, Gloucestershire, England
Died: January 26, 1823; Berkeley, Gloucestershire, England
Primary field: Medicine and medical technology
Primary invention: Smallpox vaccine

Early Life

Edward Jenner was born to Berkeley's local vicar, the Reverend Stephen Jenner, and his wife, Sarah, their eighth of nine children and their fourth son. Jenner's parents died in 1754, and he was raised by his elder brother Stephen and by an aunt, Deborah Hooper, who lived nearby on Clapton Farm. At the age of eight, Jenner enrolled in the Reverend Clissold's school in Wotton-under-Edge, then the Reverend Dr. Washbourn's school in Cirencester. As a youth, Jenner experienced variolation, whereby he was deliberately inoculated with material from smallpox sores, with the intention of generating a mild but protective case of smallpox. This was a fearful experience he remembered with horror.

At the age of thirteen, Jenner was apprenticed to Dr. Daniel Ludlow, a surgeon-apothecary in Chipping Sodbury, Gloucestershire. Jenner was always interested in nature, and his inquisitiveness and aptitude for the medical sciences was immediately recognized and encouraged. After another medical apprenticeship with George Hardwicke in Sodbury, and with his talents evidenced, he was granted private training in anatomy and surgery with noted surgeon John Hunter from 1770 to 1772 and at St. George's Hospital in London.

After his medical training was completed, Jenner served briefly as an army surgeon, then returned to set up his medical practice in Berkeley in 1772 in the west of England as a local physician. He continued his research and conducted local experiments, carefully recording his case studies and his clinical observations of his patients. Jenner received an offer from Hunter, his mentor, to form a medical partnership, but Jenner decided to remain in Berkeley and assist his community. Nonetheless, Jenner remained friends with and corresponded extensively with Hunter and other members of the Royal Society in London such as Joseph Banks (whose Pacific collection gathered on Captain James Cook's first voyage Jenner had helped catalog), Henry Cline, and Everard Home, both later presidents of the Royal College of Surgeons. Jenner was appreciated in London's highest medical and scientific circles and would be nominated for his Royal Society membership by Hunter.

Successful locally in the Berkeley countryside, Jenner bought his home, The Chantry, in 1785 and in 1788 married Catherine Kingscote. He had met her while conducting a balloon experiment in 1784, landing his hydrogen balloon in her father's park, Kingscote Park. The couple had three children, Edward (1789-1810), Catherine (1794-1833), and Robert Fitzharding (1797-1854). Jenner was awarded a medical degree from the University of St. Andrews in 1792. The early death of his son Edward at age twenty-one from tuberculosis and the frail health of his wife spurred Jenner toward making medical breakthroughs.

Edward Jenner. (Library of Congress)

Life's Work

A major cause of death in the eighteenth century was smallpox, and there had been a virulent outbreak in Gloucestershire in 1788. Jenner's Berkeley community was composed of rural farmers, and he noticed that many milkmaids who had worked with cows and come in contact with cowpox had clear complexions (smallpox survivors were disfigured by pock marks) and did not contract smallpox. He believed that cowpox might offer some form of immunity. A nursery rhyme would prove more than a myth as it affirmed: "'Where are you going, my pretty maid?' 'I'm going a-milking, sir,' she said. . . . 'What is your father, my pretty maid?' 'My father's a farmer,' she said. . . . 'What is your fortune, my pretty maid?' 'My face is my fortune,' she said."

Suspecting that working with cows had something to do with this immunity, Jenner tested his theory in May, 1796, when he vaccinated eight-year-old James Phipps with cowpox. Six weeks later, Jenner exposed Phipps to smallpox and found that the boy had become immune. Jenner's experiment revolutionized the world of medicine and launched the preventive phase of medicine (rather than relying merely on treatment). Jenner would be called the "father of immunology." He published results of his experimental vaccine in *An Inquiry into the Causes and Effects of the Variolae Vaccinae, a Disease Discovered in Some of the Western Counties of England, Particularly Gloucestershire, and Known by the Name of Cow Pox* in 1798. He wrote, "What renders the cowpox virus so extremely singular is that the person who has been thus affected is forever after secure from the infection of the smallpox; neither exposure to the variolous effluvia, nor the insertion of the matter into the skin, producing this distemper." He had replaced variolation with vaccination, using cowpox to prevent smallpox.

Variolation, whereby a patient was inoculated with a small amount of live smallpox virus, had been earlier introduced into English society by Lady Mary Wortley Montagu, who had seen it used in Turkey. Variolation had a mortality rate of about 0.5 percent, however, and variolated persons could infect others. Vaccination with cowpox was much less dangerous and could be inexpensively and widely used. In fact, Jenner opened his own home to dispense free vaccinations once a week. His first treatise was followed by his *Further Observations on the Variolae Vaccinae, or Cow Pox* (1799), *A Continuation of Facts and Observations Relative to the Variolae Vaccinae, or Cow Pox* (1800), and *The Origin of Vaccine Inoculation* (1801). Slowly, Jenner's ideas for inoculation against smallpox became widely accepted. By 1800, most English countrymen had accepted vaccination (in spite of some earlier skeptics who had drawn cartoons of people sprouting parts of cows from their bodies after being vaccinated with cowpox).

Vaccination against smallpox was Jenner's most successful accomplishment, but he enjoyed numerous others. Jenner had earlier formed a medical society in Rodborough that met at the Fleece Inn and another at the Ship Inn in Alveston before which he had read medical treaties on ophthalmia, angina pectoris, and valvular heart disease and presented his cowpox experiments. He was elected to membership in the Royal Society in 1789 based on his findings of the nesting behavior of the cuckoo bird. He discovered through observation (and was later proven right by photography) that the cuckoo bird's mother deposits her eggs in a bird's nest of another species (such as a hedge sparrow) and that the hatched cuckoo nestlings hoist the host eggs or nestlings out the nest by lifting them into the hollow of the cuckoos' backs and pushing them up and out of the nest. The foster parents continue to feed the cuckoo nestlings as their own. Jenner's correct observation of this eviction behavior was published in the *Philosophical Transactions of the Royal Society* in 1788. He was made an honorary member of the Geological Society in 1809, and ten years later he discovered a fossil specimen of a plesiosaurus, the first to be identified in England. In 1823, he read his paper "Some Observations on the Migration of Birds" before the Royal Society that helped to prove that birds did indeed migrate and not merely hibernate during the winter.

Jenner was a true man of the Enlightenment who worked with a number of key scientific ideas. He remained devoted to his work as a doctor all his life and made his house visits by horseback, servicing an area of more than four hundred miles. Most often he received his patients at The Chantry (now the Edward Jenner Museum). He dressed in a blue coat with yellow buttons, wore polished boots, and wore his hair in a club. He remained a member of the landed gentry and established a large clientele among the aristocracy and local gentry, remaining lifelong friends with his in-laws and Lord Berkeley. Jenner established a second home in Cheltenham, near London, and was the founder and president of the Cheltenham Literary and Philosophical Institution, all the while promoting his personal cause of vaccination of the general population. Jenner died of a stroke suffered at his home in Berkeley on January 26, 1823.

Smallpox Vaccine

On May 14, 1796, British physician Edward Jenner performed a vital experiment by making two half-inch scratches on the arm of eight-year-old James Phipps and dabbing cowpox pus into them. The pus had come from the cowpox blisters on the hands of milkmaid Sarah Nelmes, who had milked a cow infected with cowpox, as evidenced by lesions on the teats and udder. Phipps developed symptoms of mild cowpox but suffered no long-term effects. Six weeks later, Jenner exposed Phipps to smallpox virus in the same manner that he had exposed the boy to cowpox, but Phipps did not become ill. When Jenner exposed Phipps to cowpox, the boy's immune system developed antibodies ready to combat the virus, and these same antibodies were capable of fighting off the similar smallpox virus. Jenner realized that his experiment had worked, and the persons he treated with cowpox developed resistance to both cowpox and smallpox.

Vaccination with cowpox fluids helped to contain smallpox, a highly destructive disease that can kill up to one-third of its victims and that permanently scars many survivors. Jenner called his idea "vaccination," from the Latin word *vaccinia*, meaning "cowpox," and coined the word "vaccine," from the Latin *vacca*, meaning "cow." He also introduced the word "virus." The last case of smallpox occurred in 1977, and the World Health Organization (WHO) declared the disease eradicated in December, 1979.

Impact

Vaccination as a means of producing immunity against pathogens was pioneered by Jenner and clearly saved lives. Death from smallpox fell drastically across Europe. Immunology was developed as a science. The British parliament considered Jenner a medical hero, awarding him £30,000 to pursue additional vaccination experiments and the development of preventive treatments. Louis Pasteur adopted the word "vaccination" for immunization against any disease. The British army and navy were vaccinated as early as 1801, and Jenner was awarded a gold medal by British naval officers in recognition. Foreign dignitaries inquired about immunization. By 1803, Jenner had established the Royal Jennerian Institute, which encouraged vaccination to eradicate smallpox, and by 1808 this had grown into the National Vaccine Establishment. In 1805, Jenner became a member of the Medical and Chirurgical Society, further encouraging immunization, and this organization expanded into the Royal Society of Medicine, capitalizing on his prestige and influence in the realm of medical science.

Jenner's vaccination techniques and renown spread worldwide. The empress of Russia even changed the name of the first Russian child vaccinated to "Vaccinoff" to celebrate the accomplishment. So great was Jenner's influence that Napoleon I, in 1805, still at war with England, released British prisoners at Jenner's personal request. Vaccination was first utilized in the United States by Benjamin Waterhouse, Harvard University's first professor of pharmacy. In 1821, Jenner was promoted to physician extraordinary (honorary title) to King George IV. Jenner accepted a fellowship at the Royal College of Physicians of Edinburgh and received honorary doctorates from Oxford and Harvard universities. He was honored by his local community by being named mayor of Berkeley and justice of the peace in recognition of his famed contributions to world health.

Thomas L. Jennings

American businessman

Jennings innovated a dry-cleaning technique to wash stains from garments without using water immersion and agitation. He submitted an application registering that procedure with the U.S. Patent Office, obtaining the earliest-known patent issued to an African American.

Born: 1791; New York, New York
Died: February 11, 1859; New York, New York
Primary field: Chemistry
Primary invention: Dry cleaning

Early Life

Thomas L. Jennings was born during the last decade of the eighteenth century in New York City. Most sources state his birth year as 1791, based on two obituaries written soon after his death in winter, 1859, which say that Jennings was sixty-eight years old. According to the 1850 U.S. Census, Jennings was fifty years old as of August 1, 1850, and he was fifty-five when the New York State census was taken in 1855, suggesting he was born around 1799. Neither record indicates who provided Jennings's age to census enumerators and how they knew that information.

Sources describe Jennings as a free African American without clarifying if he or his parents were ever enslaved and, if so, how Jennings secured his freedom. They do not tell who Jennings's parents were, nor do they specify what name his middle initial represents. In 1790, near the time of Jennings's birth, 1,011 free blacks and 2,369 slaves lived in New York City, composing 9.7 percent of that city's population. Jennings was free in 1820 when he applied for a patent.

Few details about Jennings's childhood are known, except that as a boy he began working as an apprentice to a New York tailor who, sources vaguely commented, was an acclaimed man. Jennings acquired skills to create and modify clothing to meet customers' specifications. No facts confirm that Jennings attended school, but his activities as an adult reveal that he was knowledgeable and literate, writing documents discussing legal issues. During the War of 1812, he dug trenches on Long Island to protect the city.

Jennings married a woman named Elizabeth, who had been born in New Jersey and was five years younger than him. They lived at 167 Church Street in the Fifth Ward of New York County and had two daughters, Elizabeth and Matilda, and two sons, Thomas and William. In addition to earning income from making clothes, Jennings operated a boardinghouse.

Life's Work

Jennings concentrated on a tailoring career after being employed in several other positions. He offered his services to customers who sought alterations for their clothing or desired new garments, which he designed and fitted. The quality of his craftsmanship attracted more clients, both in the city and elsewhere, who traveled to hire Jennings to assist them with their clothes, as people recommended him and promoted his work. Profiting from his sewing talents and entrepreneurial abilities, Jennings invested his income to establish a clothing store located on Church Street that developed into a prominent garment business.

In the late 1810's, Jennings contemplated how to resolve a common complaint his customers voiced regarding their clothing becoming stained. Instead of keeping their dirty clothes, some people replaced them if they could afford to do so, although many customers did not have that option. Jennings sought ways to clean and restore garments, stressing that he wanted to assist less prosperous clients and to prevent people from discarding clothes he had invested his time and skills to make. He realized that regular washing techniques using water might damage fragile materials.

Jennings evaluated the effectiveness of applying chemicals used by tradesmen for cleaning tasks in other professions to remove stains from diverse fabric samples. He mixed chemicals together in varying ratios until he probably determined that turpentine was the most useful cleaning fluid to lift greases and oils from fabrics without harming materials. No available information reveals whether he constructed machinery for his process. Jennings offered his innovative cleaning procedure, referring to it as dry scouring, to his clientele.

Dry Scouring

Thomas L. Jennings developed a practical dry-cleaning technique in response to his customers' demands. Because a fire burned Jennings's patent record, his description of dry scouring and specific information regarding his invention are unavailable. Historians hypothesize Jennings recognized that turpentine, a fluid many craftsmen used for cleaning tasks to remove greases and oils, could be used to launder fabric. Jennings probably evaluated different quantities of turpentine to determine the minimum amounts that would be effective when used on diverse materials. He possibly also combined turpentine with other chemicals to strengthen his cleanser. Jennings's dry-scouring technique might have relied on turpentine evaporating and lifting dirt from fibers.

Histories of dry cleaning do not mention Jennings's patent or acknowledge whether it inspired any other inventors in the United States or elsewhere. Instead, accounts comment that some nineteenth century Europeans used lamp fuels composed of turpentine spirits to clean cloth. After turpentine brushed on stained material dried, grime disappeared. In 1855, a Parisian, Jean Baptiste Jolly—often credited as the founder of commercialized dry cleaning—established a laundry based on using turpentine and chemicals to clean fabrics. Nineteenth century chemists created such solvents as benzene, which dissolved oils and fats that water could not disintegrate. Fibers did not swell when exposed to these solvents, preventing garments from shrinking as they did when laundered in water. Solvents did not damage most materials or alter their colors. Dry cleaners realized that they could expose entire garments, curtains, and other fabric items to solvents instead of just dabbing areas.

Knowledge of dry-cleaning technology and methods extended internationally, and more businesses offered dry-cleaning services to generate income from a process that was not as time-intensive as traditional laundry methods, which appealed to customers. By the early twentieth century, many dry cleaners used petroleum-based solvents, which increased risks of fires and explosions. Professional organizations, including the National Association of Dyers and Cleaners, established standards such as using dry solvents, which were replaced with synthetic solvents developed in the 1970's. Perchloroethylene, a frequently used synthetic solvent, was safer and nonflammable. In the late twentieth century, scientists continued to develop dry-cleaning solvents to be more environmentally sound, such as those patented by GreenEarth Cleaning. The U.S. Patent Office approved patents for dry-cleaning devices, solvents, and techniques from the 1880's through the early twenty-first century, but none, even New York City resident James Baker's 1912 dry-cleaning machine patent (number 1,028,317), reference Jennings's invention.

This early form of dry cleaning pleased Jennings's customers and secured him more business producing clothes and cleaning them.

Aware that customers spread news of his successful dry scouring work, Jennings sought to protect his invention from other people appropriating his techniques without reimbursing him. In 1820, he submitted a patent application to the U.S. Patent Office. Sources do not indicate whether Jennings initiated the patenting process alone or whether he had legal counsel who assisted him, nor do they identify witnesses who signed his application. At the time Jennings applied, patents did not state the race of individuals patenting inventions, and the Patent Office did not discriminate against inventors based on ethnicity. The 1793 patent law in effect at that time permitted both free and enslaved African Americans to secure patents.

Jennings received a U.S. utility patent on March 3, 1821, for his invention entitled "Dry Scouring Clothes." He framed the certificate, which bore the signatures of Secretary of State John Quincy Adams and Attorney General William Wirt. The Patent Office listed Jennings's invention in a contemporary publication noting registered patents. Although most historians credit Jennings as the first African American to receive a patent, there could have been prior African Americans who achieved patents who have not yet been identified. Jennings's patent became well known because Frederick Douglass mentioned it in a eulogy praising Jennings in the April, 1859, issue of *The Anglo-African Magazine*.

The Patent Act of 1836 resulted in patents receiving numbers listed chronologically from the time they had been first issued, assigning patent number 3,306x to Jennings's invention, with the *x* indicating that the patent had been registered before 1836. A December 15, 1836, fire at the U.S. Patent Office burned most patent records stored there, including Jennings's application and any associated materials supporting it. Without that application, specific information and Jennings's description of his invention remain uncertain. His dry scouring invention was the sole U.S. patent he obtained. Sources do not mention if he sought foreign patents or ever attempted inventing any other processes or objects useful to his business.

Jennings generated ample income from his patent, although records do not specify any monetary amounts. Some sources claim that Jennings initially used profits to purchase enslaved relatives, suggesting that perhaps his parents or his wife's family were slaves. In 1820, 10,368 free African Americans and 518 slaves resided in the New York City area. Jennings invested his patent earnings into bettering his community, particularly funding abolition efforts. He promoted suffrage for African Americans and educational opportunities and participated in civic groups devoted to political, economic, and intellectual activities. Jennings helped the Phoenix Literary Society provide clothes to impoverished children so they could attend schools.

After New York ended slavery in 1827, Jennings voiced his opinions regarding issues that many free African Americans experienced, especially prejudices and animosity. *Freedom's Journal*, the first African American newspaper in the United States, printed one of his speeches in its April 4, 1828, issue. He was a delegate to People of Color conventions in the 1830's. In 1837, Jennings took petitions demanding African American suffrage to the state legislature. He organized the Legal Rights Association in 1854, serving as president, to seek equal transportation services for blacks after his daughter experienced discrimination on a public omnibus. When Jennings died at his home on February 11, 1859, his framed patent was displayed by his bed.

Impact

Jennings's inventiveness achieved professional and personal results. In addition to providing a useful cleaning service to his community, Jennings gained financial means to enhance his business and lifestyle and reinforce his efforts to seek legal changes to improve conditions for African Americans. Whether Jennings was aware the process of inventing and patenting would assist him economically and socially is unknown. Sources do not reveal whether Jennings had any access to other inventors who might have motivated him to pursue innovative efforts and suggested potential benefits, both immediate and future.

Although Jennings's contemporaries were aware of his invention, or at least of the novel dry scouring he offered, no records indicate how Jennings might have inspired other African American inventors or convinced skeptics of African Americans' technological and scientific abilities. Other dry cleaners might have appropriated aspects of Jennings's invention for variations they developed but for which they did not seek patents, which might have confirmed his influence.

Many antebellum African American craftsmen and laborers devised objects or methods to resolve problems they encountered. Often, those inventors did not seek patents, or other people, particularly slave owners, claimed patents for those inventions. The U.S. Patent Office first identified an African American inventor thirteen years after Jennings's received his patent when the race of Henry Blair, a free African American, was included on his 1834 and 1836 patents for agricultural tools. No records connect Blair and Jennings or suggest that Jennings inspired Blair to file for patents. Many sources incorrectly identify Blair as the first African American patent holder.

African American congressman George Washington Murray did not include Jennings in his list of African American inventors for the *Congressional Record* in 1894, nor did Henry E. Baker, an African American patent examiner, who published information he compiled regarding African American inventors. Those omissions could have occurred because Jennings's patent was overlooked because of destroyed records, because his race was unknown to those men, or because his invention achievements were no longer publicized after his family, customers, and peers died.

Steve Jobs

American computer engineer

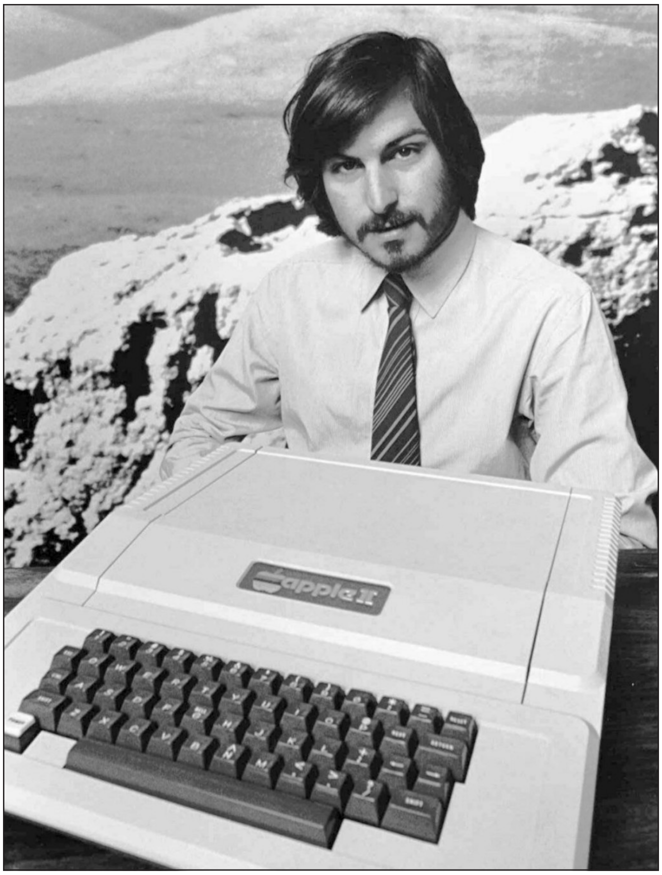
Jobs developed a career based on continuous innovation in the computer and consumer electronics industry, focusing on devices that are simultaneously elegant in design and inviting for ordinary people to use.

Born: February 24, 1955; San Francisco, California
Also known as: Steven Paul Jobs (full name)
Primary field: Computer science
Primary inventions: Apple computer; iPod

Early Life

Steven Paul Jobs was born in San Francisco on February 24, 1955, to a young unwed mother. At that time, an out-of-wedlock birth was considered a disgrace and would have limited the prospects of both mother and child, so she gave him up for adoption. A few weeks later, he entered the home of Paul and Clara Jobs. Young Steve showed his strong-willed side at an early age. He also demonstrated considerable energy and curiosity, traits that constantly got him into trouble. However, his intellectual activities were not confined to exploring the physical world. He had learned to read before he entered school and was frequently bored there. He resisted busywork, and he often focused his formidable intellect on exploiting the weaknesses of any teacher who displeased him. In third grade, he systematically misbehaved until he was expelled from school.

The following year, his teacher realized that she had a



Steve Jobs with the Apple II computer. (AP/Wide World Photos)

bright but unmotivated student on her hands and set out to harness his untapped talent. She quickly discovered that he could be bribed with money to actually turn in good schoolwork. Once she got a measure of his actual talents, she recommended that he be allowed to skip fifth grade and enroll midterm in sixth grade. The school had serious problems with rough students, however, and Steve was so disgusted that he informed his parents he would not be returning for seventh grade.

Rather than force a confrontation, Paul and Clara Jobs relocated to a better district. Steve became increasingly interested in electronics, and an encounter with Bill Hewlett led to a summer job at Hewlett-Packard. Steve also met Steve Wozniak, who was sufficiently impressed with his knowledge of electronics to overlook the difference in their ages.

While a student at Reed College, Jobs became interested in Eastern religions, and in 1974 he took a trip to India. There he dressed in a pilgrim's loincloth and made his way around the country by begging and doing odd jobs while he visited various shrines and learned at the feet of holy men. During his trip, he contracted dysentery and quickly learned the importance of creating a world in which people's physical needs were met so that they could be free to explore their spiritual needs.

Life's Work

Upon returning to the United States, Jobs went back to work for the popular video game manufacturer Atari, which had hired him in 1974. There he became involved in a project to create a new game called *Breakout* and got his old friend Wozniak to do the actual programming. However, Jobs also concealed just how much Atari was paying him, which would later create bitter feelings between the two men. Wozniak introduced Jobs to the Homebrew Computer Club, a group of computer hobbyists. As Jobs helped his friend create what was called the "Cream Soda Computer," he realized how useful a computer could be if it had an easy-to-use interface. He decided that it should also have an inviting appearance and a name that created friendly associations.

On April 1, 1976, Apple Computer was born. Although the original five hundred Apple I computers were kits aimed primarily at the hobbyist market, the Apple II was a complete machine that came in a warm tan case made of plastic with rounded edges and corners. The Apple II was also innovative in using floppy disks rather than magnetic tape to load programs and data into working memory, speeding up access to stored information. This design required more expensive parts than Wozniak and Jobs had capital to purchase. As a result, Jobs had to woo venture capitalists, a process made difficult by his own lack of business experience. However, investor Mike Markkula was open-minded enough to see the potential of these two young men's plans and was willing to work out such fundamentals as a business plan and a formal budget. Satisfied that they could take his advice, Markkula secured them funding and moved them out of their garage workshop into a building in Cupertino, California. On January 3, 1977, formal incorporation papers were signed and Apple Computer, Inc., became a legal entity.

Jobs refused to be satisfied with the success of the Apple II, which still required the user to type commands into a command-line interface. He had become convinced that the personal computer could succeed only if it became an appliance, its inner workings effectively invisible to the end user. During a visit to the Xerox Palo Alto Research Center (PARC), Jobs saw an experimental graphical user interface (GUI). The point-and-click simplicity so impressed him that he decided to base Apple's next generation of computers on them, and thus was born the Macintosh, or Mac, released shortly after the 1984 Super Bowl game.

By 1985, trouble had come to Apple, and Jobs was ousted from his own company by John Sculley, the very man he had brought from PepsiCo to help Apple get through the "adolescent transition" between small business and major corporation. Set adrift, Jobs started another computer company, NeXT, to design a high-powered graphics workstation. However, the market was not yet ripe for that particular niche, and NeXT struggled for several years before getting out of the hardware business entirely and concentrating on the NEXTSTEP operating system (OS). Jobs had more success as the head of Pixar, a company dedicated to graphics processing for the motion-picture industry. Although the earliest versions of *Toy Story* (1995) were rejected by Disney, a revised version proved a box-office runaway.

In 1997, Apple was in bad shape, and there was a serious possibility that it would close its doors altogether. The Macintosh operating system that had been so innovative in 1984 had not received a serious makeover in years, and competition from Microsoft Windows was intense. After trying several stopgap measures, Apple executives finally approached Jobs in order to gain access to the NEXTSTEP OS as the basis of a new version of the Mac OS. After several months of delicate negotiations, Jobs returned to Apple and simplified the company's confused product line. In 1998, he introduced the iMac, a compact computer with innovative universal serial bus (USB) connectors.

By the year 2000, Apple was back on its feet again, and the 2001 introduction of the iPod music player secured its future as a growing company. Throughout the first decade of the twenty-first century, the iPod went through multiple versions, eventually spawning the iPhone, a combination cellular phone, personal digital assistant (PDA), and music player with a slick, sophisticated interface.

IMPACT

Jobs has been a force for ongoing innovation in the computer and personal electronics industry, consistently anticipating consumers' needs and seeking to create products that would fill those needs even before people knew they had them. However, his insistence on technical elegance has often meant that his products have borne a premium price tag that not all users have been willing to pay, leaving his companies vulnerable to being undercut by

THE IPOD

Although digital audio players (usually called MP3 players) had existed before the iPod, they generally had little memory, confusing controls, limited features, and a clunky appearance. MP3 players were not regarded as a serious substitute for a portable cassette or CD player. When Steve Jobs introduced the iPod in 2001, he gave the world an MP3 player that was both elegant and functional. The smooth white plastic surface of its case had a sensuous quality that fairly begged to be handled, and it looked handsome enough that a user would want to wear it on a sleeve or a belt rather than hide the device. (However, as the iPod craze took off, many people found it prudent to keep their iPods out of sight when on the street, lest they have the much-sought-after devices stolen right off their bodies.) In 2007, the iPod became the best-selling digital audio player in history, having sold more than 110 million units worldwide.

In addition, the iPod used a laptop hard drive rather than flash memory as most early MP3 players used. This feature enabled the iPod to provide much more capacity, although at the cost of some battery life and ruggedness. However, carefully designed software allowed songs to be loaded from the hard drive into a buffer. This feature simultaneously reduced battery drain and decreased the chance that a sudden shock could crash the hard drive.

The interface by which the user controlled the iPod was also given careful thought. The menu system was based to some degree on that of the Apple Macintosh operating system. The touch wheel and its successor, the click wheel, enabled the user to move smoothly from one menu to the other, controlling multiple playlists with ease. However, after several versions of the iPod had come out, Apple discovered that many users seldom used the playlist system. Instead they preferred to use the shuffle function to have their iPod play songs at random from their entire music library. As a result, Apple introduced the iPod Shuffle, a thumb-sized device with no screen and with a simplified click-wheel control that was always on shuffle play.

Although many iPod owners stocked their iPods with songs from their existing CD collections, Apple also provided users the option of buying single songs and entire albums in the form of digital downloads from the Apple iTunes online music store.

competitors willing to produce a product of lesser quality that is merely good enough rather than the very best. Nevertheless, Jobs reinvigorated Apple after he returned to the company in 1997 and introduced a simplified product line that included the iMac.

Eldridge R. Johnson

American businessman

Johnson was the technological and industrial forefather of the modern recording industry.

Born: February 18, 1867; Wilmington, Delaware
Died: November 14, 1945; Moorestown, New Jersey
Also known as: Eldridge Reeves Johnson (full name)
Primary fields: Manufacturing; music
Primary inventions: Victrola phonographs; spring-driven motor for phonographs

Early Life

Born in Wilmington, Delaware, in 1867, Eldridge Reeves Johnson was the son of Asa S. Johnson, a home builder, and Caroline Reeves Johnson. When Eldridge was two years old, Caroline died. He was raised by his great-aunt Elizabeth and uncle Dan on a farm in Bethel Church until age eleven, when he returned to live with his father. Johnson then attended Wesley Conference Academy (now Wesley College), graduating in 1882, at age sixteen. A teacher at the academy strongly discouraged him from continuing in higher education because of his poor scholastic record. He found work as an apprentice with Jacob Lodge and Son, which manufactured press equipment. From 1882 to 1886, in Philadelphia, Johnson attended night classes at the Spring Garden Institute that were actually machine shops operating in an eight-hour workday. The apprenticeship proved to be arduous, difficult work and reinforced his desire to start his own business.

Johnson finished his apprenticeship and found employment at the Standard Machine Shop in Camden, New Jersey, in 1886. His partner, John Scull, died suddenly in 1888. Johnson constructed an automatic bookbinder from Scull's records and experiments, his first invention. He formed the New Jersey Wire Stitching Machine Company to promote sales of the bookbinder, which was initially unsuccessful until years later when the demand for stitchers increased.

With eight years of salary savings, Johnson purchased the business from John Scull's father, Captain Andrew Scull, who was the original owner, and renamed it the Eldridge R. Johnson Manufacturing Co. Bookbinding was already a well-established industry, so Johnson's overwhelming curiosity and interest in the talking machine took center stage.

Life's Work

Emile Berliner had invented the disc phonograph as an alternative to Thomas Alva Edison's cylinder phonograph. To play a recording on a gramophone, it was necessary to constantly hand-crank the machine, attempting to maintain 150 revolutions per minute. This proved to be a nearly impossible task, and it caused the needle to skip. In 1895, Berliner approached Johnson about manufacturing a device that could engage the gramophone turntable at a steady speed. Although Johnson was intrigued by the potential of this new music machine, he regarded it as poorly designed, with a scratchy, ill-defined sound. Johnson developed a spring-driven motor that produced a consistent turntable speed. As a result, his company became the gramophone's primary manufacturer. The spring motor proved to be the improvement needed to make the machine more commercially viable.

A Victor record label from 1900 with the dog Nipper and the famous slogan. (Getty Images)

In 1900, Johnson owned the Consolidated Talking Machine Company. He purchased a painting titled *His Master's Voice*, depicting a white fox terrier listening intently to a phonograph's horn. The painting originally showed an Edison-Bell cylinder phonograph, but the dog's owner painted over it to display a Victor machine. The next year, Johnson trademarked the slogan and used it on his machines, recordings, and advertisements. Nipper the dog became famous worldwide. Johnson changed the name of his company to the Victor Talking Machine Company. He was now a millionaire and president of a company encompassing twelve city blocks. At this time, Johnson, wife Elsie, and their only child, Fenimore, were living in Merion, Pennsylvania.

Johnson continued to perfect his machines. Fidelity improved, and records now could be played 125 times rather than only a few. He developed a process to create multiple copies from an original. In 1906, he introduced the Victrola phonograph, with beautifully designed wooden cabinets that owners could proudly display in their homes. The horn was placed inside a large floor cabinet and could be folded downward. Two doors in front covered the horn. Owners could control the volume with the doors by opening or closing them, or leaving them partially open. The patented name Victrola applied to only machines with internal horns, but eventually Victrola was synonymous with any phonograph. In 1913, the first electric motor was introduced; this eliminated all hand-cranking. Although installed on the Victrolas, they were referred to as Electrolas.

Johnson understood that his customers cared what they listened to on recordings. Johnson and partner Leon Douglass signed famed virtuoso and metropolitan opera star Enrico Caruso to a recording contract. The company sold millions of his recordings. More artists recorded, and Johnson and Douglass implemented a royalty system whereby the artists were compensated for each record sold. The company doubled profits between 1901 and 1903. Profits doubled again in 1905, and again in 1907. The emerging recording industry, under Johnson and Douglass's guidance, flourished because of careful attention to manufacturing and marketing. Sales of the Victor Talking Machine Company, particularly the Victrolas, skyrocketed and Johnson and Douglass became enormously wealthy. The company also went global, with operations in Canada, Japan, South America, and England, further extending the influence of the two men.

Johnson realized the impact the newly introduced radio would have before it happened. In 1927, he and Douglass sold the company to investment bankers, the J. and W. Seligman and Company. The firm then sold the company to the new Radio Corporation of America (RCA), which eventually became the RCA Victor Company. Now comfortably retired with about $25 million, Johnson purchased *Caroline*, a plush yacht that launched in Maine in 1931. He also indulged in an expensive art collection.

One of Johnson's most interesting hobbies was collecting memorabilia of Lewis Carroll's 1865 novel *Alice's Adventures in Wonderland*. Johnson acquired several first editions, and he was even photographed with Alice Liddell Hargreaves, who was the author's inspiration for the book. Johnson purchased the original manuscript of *Alice's Adventures Under Ground* (1864), which he proudly displayed in the White House at the invitation of President Calvin Coolidge.

As a wealthy retiree, Johnson continued his philanthropic ways, establishing an $800,000 endowment at Pennsylvania University, the E. R. Johnson Foundation for Medical Physics (now the Department of Biochemistry and Biophysics). Johnson was a benefactor to the Free Library and Deaconess Home in Camden, the Community Church in Dover, Delaware, the Merion War Tribute House, and the Moorestown Community House in New Jersey. In 1932, he donated his yacht to the Smithsonian Institution to conduct marine exploration of the Caribbean region of the West Atlantic Ocean. His crew of forty-two men and an additional $50,000 funding allocation were included. As part of the agreement, Johnson housed his family and friends and their families in the first-class cabins. Former colleague Leon Douglass and his family joined him on the expedition.

Despite his many professional successes, philanthropic contributions, and vast wealth, Johnson suffered from depression. In poor health for many years, he died of a heart attack at his home on November 14, 1945, in Moorestown.

Impact

Johnson epitomized the self-made man. A product of trade schools and apprentice training, he endured great hardships in his

Early Victrola Phonographs

The primary external components of Eldridge R. Johnson's early Victrola phonographs are the cabinet, platter, horn, sound box, sound box tube, pivot, stylus bar and stylus (needle), thumbscrew, and tonearm. The internal, acoustical energy-producing components are the diaphragm, gasket, support springs, and pivot. The stylus apparatus is located just below the gasket and support springs.

Early Johnson machines were based on Emile Berliner's flat-disc concept. The discs revolved at 78 revolutions per minute. The needle moved side to side in a lateral-cut method. The stylus tracks in the grooves, which contain the acoustical signals, and is secured with a thumbscrew. The revolving record, along with the lateral movement of the stylus, sends vibrations consisting of both frequency and amplitude information of the audio signal to the sound box. The sound box consists of a mica diaphragm. In turn, the diaphragm vibrates, moving the air column into the hollow tonearm. Mechanical energy is converted into acoustical energy in the tonearm and flows into the horn, producing sound waves for listeners.

The diaphragm is similar to a membrane that stimulates the air column in the tonearm. The diaphragm is held in place by a gasket around the edges that prevents it from moving very much on the perimeter but allows the center to move freely. Since the motion is not distributed evenly over the surface of the entire diaphragm, the sound waves produce some distortion. A mechanical governor stabilizes the drive system. One spring motor will play an entire side of a twelve-inch disc without further cranking. An external horn is attached. The 1906 Victrola's internal horn, which was housed within the floor cabinet, required inverting the tonearm elbow in order to funnel the sound into the horn.

The early design of the gramophone required the tonearm, sound box, and horn to all move across the disc simultaneously, adversely affecting the sound. After some experimentation, a newer design was implemented using a rigid tonearm and sound box that moved across the record together while the horn remained fixed in place. A pivot joint between the tonearm and the horn separates them. This change produced notable improvements in sound quality. The basic principles of operation remained essentially the same for Victrolas until the electrical pickup arrived in the late 1920's.

The market for Victrolas steadily increased throughout the early 1900's because of Johnson's creative and expensive advertising program. The historic Caruso recordings brought significant recognition to the burgeoning industry of commercial recording. Gradually, competitors began to somewhat limit Victor's hold on the industry, but Johnson's domain remained secure. The introduction of parlor cabinetry to Victrolas signaled the arrival of designer phonographs. Phonographs were now a household necessity.

quest to fulfill his life's ambitions. His invention of the spring-driven motor for gramophones provided the link needed to give birth to the recording industry. His steadfast commitment to product excellence and shrewd business dealings provided the impetus to generate an entire new industry—the recording industry. In a twelve-year period, his small shop encompassing seventeen square feet expanded to a complex of fifteen acres, and the company's income increased from $10 a week to $30 million a year. Perhaps more than any other single individual, Johnson was responsible for establishing and advancing the mass production of entertainment in its early stages, beginning with a limited number of consumers until it transformed into today's multimedia empire. The enormous success of RCA Victor can be attributed to the efforts of Johnson.

Once his fortune was made and his ambitions were satisfied, Johnson used his prosperity to benefit society. He generously donated large sums of money and volunteer time to organizations and his communities. His philanthropic commitments culminated with his gift of the Eldridge R. Johnson Park, a prestigious, cultural state and federal historic landmark in the city of Camden. The park serves as a fine arts center for Rutgers University and the surrounding community and represents the cultural and industrial history of Camden.

Frederick McKinley Jones

American engineer

Of more than sixty patents granted to Jones, forty were related to his system for mobile refrigeration. Other inventions include a ticket-dispensing machine, self-starting gas engine, starter generator, and thermostat and temperature control system.

Born: May 17, 1892; Cincinnati, Ohio
Died: February 21, 1961; Minneapolis, Minnesota
Primary field: Electronics and electrical engineering
Primary invention: Mobile refrigeration

Early Life

On May 17, 1892, Frederick McKinley Jones was born in Cincinnati, Ohio, to John Jones, an Irish American railroad worker, and an African American mother who abandoned the family soon after Frederick's birth. Wanting his son to receive an education, John placed him in the care of the priest at St. Mary's Catholic Church, Father Edward A. Ryan, who gave the boy odd jobs to do and took an interest in helping him develop his amazing mechanical aptitude. Jones was orphaned at age nine.

Jones left the rectory at age eleven to go to Cincinnati and work at the R. C. Crothers Garage. Though Jones was hired to keep the garage clean, his employer noticed his unusual aptitude and allowed him to work full-time as a mechanic when he turned fourteen, the minimum age to work legally in Ohio. Soon, Jones became a foreman. Meanwhile, he developed a keen interest in auto racing and helped build racing cars. He relocated to Minneapolis, Minnesota, where he did janitorial and maintenance work at a hotel. A guest offered him a job maintaining and repairing the machinery and automobiles on a huge farm in the town of Hallock.

When the farm was sold, Jones remained in Hallock for the next eighteen years except for a stint in the U.S. Army's 809th Pioneer Infantry in France during World War I. His unusual mechanical skill was soon noted and his services requested by various military camps. In a short time, he was promoted to sergeant, a rank rarely accorded an African American soldier at that time. Having done some correspondence study in electrical engineering, he taught classes in electrical circuitry. After his discharge, Jones returned to Hallock, where he became actively involved in community affairs, race-car driving, and inventions. In 1946, after Jones had relocated to Minneapolis, he married. He and his wife, Lucille, lived in an apartment over the Thermo King plant.

Life's Work

Despite having a limited formal education, Jones displayed an amazing aptitude for working with all kinds of mechanical things and had an inventive mind. After enlisting in the Army during World War I, he quickly demonstrated his prowess as a mechanic. In addition to repairing military vehicles, he fixed X-ray machines and worked with electrical wiring. After his return to Hallock at the end of the war, Jones wasted no time in further developing his inventive genius. Among the numerous odd jobs that he did, Jones served as a chauffeur for doctors making house calls during the winters. When it became difficult to drive through the snow, he remained undaunted: He attached skis to an old airplane body and attached an airplane propeller to a motor, producing an effective, if unconventional, "snowmobile." In a conversation with a doctor on one occasion, the physician was bemoaning the fact that patients had to come into his office to get X-ray pictures taken, so Jones designed a portable X-ray machine that the doctor could take with him when he made house calls.

Unfortunately, during these earlier years of invention, it did not occur to Jones to have his inventions patented; thus, he saw other inventors become wealthy from their protected versions of various machines and devices. In the late 1920's, he designed a ticket-dispensing machine for movie theaters that would automatically dispense tickets and change. This time, he applied for a patent on the device, which was granted in 1939. About the same time, he found a way to convert silent movie projectors into talking projectors, attracting the attention of his future partner, Joseph A. Numero, who hired him to improve the sound equipment made by his firm, Cinema Supplies, Inc. Amazingly, Jones worked with scrap metal to make the parts needed to deliver a sound track to the video, and he worked with the device to stabilize and improve the quality of the picture.

By the 1930's, Jones was perfecting a system to provide a mechanical refrigeration system for long-haul trucks and railroad cars that would eliminate the risk of food spoilage. This system would later be

The Model A Transport Refrigeration Unit

Frederick McKinley Jones was the first person to invent a workable mechanical refrigeration system for trucks. When Jones heard about a conversation between a farmer and his employer, Joseph A. Numero, in which the farmer recalled how he had suffered great losses of food because of spoilage during long-distance shipping, Jones determined to find a way to end such waste. He began assembling various odds and ends of machinery that would provide refrigeration. When he attached his finished product to a truck and testing showed it to be successful in providing the needed cooling, the first mechanically refrigerated truck was born.

In addition to developing the refrigeration itself, Jones faced the technical challenge of making a structural frame and the necessary refrigerant tubing connections to ensure that the system would be able to withstand the constant vibration on the road. He met the challenge by applying what he had learned years earlier when he designed racing cars to resist shock. A four-cylinder gasoline engine was used to drive the refrigeration compressor, and a starter-generator-flywheel was used for the engine. The unit was controlled by a thermostat that was installed inside the truck trailer. When all the equipment was put into a cabinet that was hung from the floor of the trailer, the unit weighed more than a ton. The trailer remained cool, but the unit was rather inefficient, so Jones redesigned it, reducing the weight by four hundred pounds. When it became evident that moisture and road debris were damaging the under-slung unit, Jones again redesigned the unit, coming up with a 950-pound nose-hung version. The system would be adapted for use in railway cars as well as in ships. After Jones received a patent for the system on July 12, 1940, Numero formed a new company, the U.S. Thermo Control Company, later Thermo King, with Jones as his partner.

Jones's invention of the Model A transport refrigeration system changed Americans' eating habits. No longer did they have to rely on canned foods; the invention ushered in the use of frozen foods. The large supermarket came into being, and the restaurant industry profited from increased availability of fresh foods from anywhere in the country, all year round.

adapted for use in other types of food carriers such as ships. Jones received a patent for his vehicle air-conditioning device in 1940, and Numero established the U.S. Thermo Control Company (later Thermo King) in Minneapolis.

During the 1940's, Jones continued to invent devices related to refrigeration and air-conditioning in addition to other types of devices. In the area of refrigeration technology, he invented a removable cooling unit for compartments in 1943 as well as an air-conditioning unit in 1949. During the early to mid-1940's, he received a patent for a self-starting gas engine. In later years, Jones worked on improving and adapting his inventions. In 1949, he patented a starter generator for cooling gas engines. The next year, he developed another two-cycle engine; in 1958, a combustion engine device.

During World War II, the U.S. government used Jones's portable air conditioner to preserve blood serum and medicines. In 1944, he was inducted into the American Society of Refrigeration Engineers, the first African American to receive such an honor. This honor was especially meaningful in the light of Jones's limited formal education. During the 1950's, the Department of Defense and the Bureau of Standards sought his services as a consultant.

Jones continued to improve on existing items and invent new ones when he saw a need. His final patent was granted on February 23, 1960, almost exactly a year before his death from lung cancer in Minneapolis. In 1991, Jones and his business partner, Joseph Numero, were posthumously awarded one of the highest honors available to an inventor, the National Medal of Technology. President George H. W. Bush presented the medals to their widows in a ceremony held in the Rose Garden of the White House in Washington, D.C. In 2007, Thermo King, which had become a multimillion-dollar international corporation, dedicated a research and development center in Bloomington, Minnesota, in honor of Jones.

Impact

The sheer number and diversity of patents acquired by Jones is astonishing. At least forty of his more than sixty patents were related to refrigeration. His technology literally revolutionized the distribution methods for transporting food and other perishables over long distances. Since his innovations in refrigeration made fresh produce available year-round to people living anywhere in the United States, his work changed the way Americans planned meals, as a wide variety of out-of-season foods were made available in both fresh and frozen form. His work in refrigeration also facilitated the development of international markets and resulted in the creation of frozen-food and fast-food industries as well as container shipping.

Jones's inventions in refrigeration were not limited to food products. During World War II, a modified version of his portable air conditioner allowed the U.S. military to preserve blood serum and medicines so that they could be parachuted to troops behind enemy lines. Nor was the impact of Jones's technological genius limited to the field of refrigeration and air conditioning: The movie industry was forever changed after Jones devised a way to adapt silent movie projectors so that they could play back recorded sound, thus introducing the "talking picture."

PERCY LAVON JULIAN
American chemist

Julian synthesized a number of important drugs from plants, including cortisone, used in the treatment of arthritis, and physostigmine, a glaucoma medicine.

Born: April 11, 1899; Montgomery, Alabama
Died: April 19, 1975; Waukegan, Illinois
Primary field: Chemistry
Primary inventions: Physostigmine sythesis; cortisone sythesis

EARLY LIFE

The grandson of a former slave, Percy Lavon Julian was the son of James Julian, a railway mail carrier, and Elizabeth (née Adams) Julian, a schoolteacher. He and his two brothers and three sisters grew up in a household that valued education. In fact, Julian's two brothers later became physicians, and all his sisters went on to earn master's degrees.

After finishing the eighth grade, Julian enrolled at the State Normal School for Negroes, a private school in Montgomery, Alabama. Upon graduating in 1916 first in his class, he was admitted to DePauw University in Greencastle, Indiana. Julian had to take remedial classes at night for the first two years, but he graduated in 1920 as class valedictorian and a member of Phi Beta Kappa. Julian wished to continue on to graduate school but was discouraged from pursuing that path because of potential racist sentiment. Instead, he taught for the next two years at Fisk University, an African American college in Nashville, Tennessee.

Through an Austin Fellowship, Julian went to Harvard University, where he obtained a master of arts degree in 1923. While his record clearly warranted a teaching fellowship, it was denied, and he spent the next three years in various assistantships seeking the elusive doctoral degree. Finally, in 1926, he began teaching at West Virginia State College. In 1928, he moved to Howard University in Washington, D.C. The following year, he received a Rockefeller Foundation grant, which allowed him to continue his studies at the University of Vienna.

Julian had kept up with the rapidly growing literature concerning the synthesis of natural substances. In Vienna, he studied with the eminent Austrian chemist Ernst Späth, who was conducting fascinating research on the preparation of nitrogen-containing drug molecules called alkaloids. After two wonderful years filled with music and a great deal of serious chemistry, Julian received a Ph.D. in 1931. Späth characterized Julian as "an extraordinary student, the likes of which I have never had before in my career as a teacher."

Percy Lavon Julian, right, and a former student examine a hormone product at the Glidden Company plant in Chicago. (AP/Wide World Photos)

LIFE'S WORK

While Julian was studying in Vienna, he became aware of the great potential of soybeans as a source of steroids. The compounds from this source were to play a central role in his fame as a chemist and inventor. When he returned to Howard University, however, he turned his attention to the synthesis of an alkaloid called physostigmine. This compound is used to treat glaucoma, a condition that can lead to blindness if left untreated. After only two years, Julian left Howard and returned to DePauw.

Over the next three years, Julian

Synthesizing Human Hormones

In 1936—after being rejected for a position with the Institute of Paper Chemistry because he was black—Percy Lavon Julian became director of the Soya Products Division at the Glidden Company in Chicago. He would soon be the first to synthesize physostigmine, a natural product of some plant sterols, which would become a therapeutic drug to treat myasthenia gravis, glaucoma, Alzheimer's disease, and drug overdoses. He also laid a foundation for the synthesis of human hormones—such as progesterone, testosterone, cortisone, and other steroids—from plant sterols. The wide availability of such compounds and their use in pharmaceuticals would revolutionize medicine.

To appreciate Julian's invention, it is essential to understand the challenge faced by a chemist making a synthetic compound. To synthesize a particular molecule, scientists must understand the exact location of each of the atoms in its structure. Physostigmine, for example, is made up of fifteen carbon atoms, along with three nitrogen and two oxygen atoms. Such an array of atoms can have an astronomical number of possible structures. Of the possible arrangements, only one is the desired molecule. Like all scientists, Julian built on the work of earlier researchers. He knew the structure of physostigmine from the work of earlier chemists. Its synthesis, or preparation from simpler molecules, depends on selecting the proper starting material and adding features using reactions known to produce predictable results. A central problem for the chemist wishing to study a naturally occurring molecule is obtaining a large enough supply from which to synthesize the desired molecule. For example, Julian had isolated a minuscule amount of a valuable sterol called stigmasterol, and he had high hopes of converting it to desirable derivatives. The problem was that soybean oil, the most common source of stigmasterol, contains only about 0.2 percent total sterols, and only 18 percent of that is the desired compound. Julian calculated that it would take more than half a ton of soybean oil to produce two pounds of stigmasterol. However, one day when water leaked into a batch of soybean oil, the by-product, a white solid, gave Julian an idea: By spinning the white solid in an industrial-size centrifuge, he laid the foundation for a process that would produce sterols at a greatly reduced price.

Julian's enormous powers of recall, coupled with his uncanny ability to see connections, turned a large loss into a valuable commodity. A series of patents for expansion and improvement of the process followed. Julian went on to invent inexpensive ways of synthesizing male and female hormones (a precursor to birth control pills), cortisone (leading to drugs for arthritis pain), and other steroids. Overcoming racism (his home was set on fire on Thanksgiving Day in 1950), he established his own company, The Julian Laboratories, for the production of synthetic cortisone and other steroids, eventually becoming a millionaire with more than one hundred patents. Even more important, Julian's work made pharmaceutical products available at prices that ordinary people could afford.

and his chief collaborator, Josef Pikl, a friend from Vienna, published a series of articles in the *Journal of the American Chemical Society* describing the synthesis of physostigmine. Their research was the occasion for great drama, because the same compound was being sought by the eminent British chemist Sir Robert Robinson (winner of the 1947 Nobel Prize in Chemistry). Robinson published the results of his research just as Julian was about to submit his own final paper. On close examination, Julian concluded that Robinson's work was in error and added a note to that effect to his article. In a short time, Julian's work was shown to be correct, and he was recognized for his brilliant contribution to pure organic chemistry.

Julian also discovered that an extract from the calabar bean produced crystals of sigmasterol, which is a key sterol for the synthesis of sex hormones. Recognizing the importance of his discovery, in 1936 Julian wrote to the Glidden Company requesting a five-gallon sample of soybean oil, the chief source of sigmasterol. Glidden's vice president, W. J. O'Brien, happened to learn of this talented young man. Instead of a can of soybean oil, Julian received a phone call, an interview, and the position of director of research of the Soya Products Division. The world's most efficient extraction plant was located in Hamburg, Germany, and a second was being built in Chicago. Julian spent more than eighteen years at Glidden. Under his direction, the Soya Products Division became its most profitable unit.

Julian had the keen ability to find talented people and to see their potential. In his years as a manager, he worked with a number of scientists; together they secured more than one hundred patents. It is equally significant that Julian remained an active scientist as well as a manager. During the years that the business was growing and the practical applications were being protected with patents, he was also a regular contributor to pure chemistry. Before Julian left Glidden to found his own company in 1954, he and his collaborators had published twenty-six articles in the *Journal of the American Chemical Society*. Both alkaloids and steroids were investigated in these researches, an accomplishment that compares favorably with the work that might be expected from an academic scientist working in the laboratory of a major university.

Julian took advantage of unexpected, accidental occurrences. When water leaked into a 100,000-gallon tank of purified soybean oil, he turned the expensive mistake into a method of producing one hundred pounds of mixed sterols per day. In 1940, this represented about ten thousand dollars per day for the Glidden Company. Only Julian could imagine what use could be found for such a huge amount of mixture. Soon he was employing ozone, which had been considered far too dangerous for such large-scale use, to devise an efficient synthesis of progesterone, making that compound available in quantity for the first time.

In 1954, Julian left Glidden to found his own Julian Laboratories in Chicago and Laboratorios Julian de Mexico in Mexico City. He had shown that the use of wild yams was the most efficient way to produce cortexolone, or Substance S, a compound that differed from cortisone by one oxygen atom. He and his associates devised a way to introduce the necessary oxygen atom to Substance S to produce cortisone. This synthesis significantly reduced the price of cortisone, making the pain-relieving drug available to arthritis sufferers.

In 1973, Julian was elected a member of the National Academy of Sciences, an honor considered second only to a Nobel Prize. In 1990, Julian and George Washington Carver became the first African Americans elected to the National Inventors Hall of Fame. Julian died on April 19, 1975.

Impact

Julian represents the perfect blend of a serious scientist who explores the details of nature and the practical man of action, who applies those details for the direct benefit of his fellow human beings. His efficient synthesis of cortisone made this important arthritis drug available for the first time to millions of people. The other steroids he prepared in cost-effective processes also had medicinal benefits.

Under Julian's direction, the Glidden Company produced a variety of useful products. Julian created a food supplement that was stabilized against rancidity, edible emulsifiers used in liquid shortening, and animal feeds. His leadership led to the creation of the first plant to isolate and produce pure vegetable protein on a large scale. Just before World War II, Julian devised a soy-derived product called Aero-Foam, used to extinguish oil fires.

As significant as his scientific and industrial accomplishments are, Julian should also be remembered for his extraordinary talent for finding and supporting the very best collaborators. While he was known for his intense work ethic, he would never have been able to accomplish so much without the dedicated support of his fellow scientists.

Bob Kahn

American computer scientist

Kahn, along with Vinton Gray Cerf, developed TCP/IP, the system of protocols used to transmit information over the Internet. With this system, various networks could communicate with one another. For more than twenty-five years, Kahn worked to advance the Internet, helping to transform it into the interactive system it is today.

Born: December 23, 1938; Brooklyn, New York
Also known as: Robert Elliot Kahn (full name)
Primary fields: Communications; computer science
Primary invention: Transmission Control Protocol/Internet Protocol system

Early Life

Robert Elliot Kahn was born in Brooklyn, New York, in 1938. His father was trained as an accountant and a public school administrator in New York City. Kahn was an outstanding student in school, and he participated in sports and played the piano. Nevertheless, he still had a lot of idle time, so he often worked on puzzles. He could look at a puzzle, look away, and solve it in his mind without looking back. Kahn put many of these activities before his studies, as school work seemed easy to him.

Kahn attended Queens College for two years and the City College in Manhattan for three years. He was finally challenged academically in science and mathematics at Queens College. He initially majored in industrial engineering, then chemical engineering, and finally graduated in 1960 with a degree in electrical engineering.

In the summer while he was at the City College, Kahn worked at Bell Laboratories, where he learned about the telephone traffic system. His mathematics background prepared him for telephone engineering, and he also learned a common computer language, FORTRAN, to use on International Business Machines (IBM) mainframe computers. One of the more important parts of his tenure at Bell Labs involved observing how modeling and analysis methods of telephone operations could be used in various other situations.

In 1960, Kahn received a fellowship from the National Science Foundation to attend graduate school at Princeton University. For his Ph.D., he worked on several practical mathematics problems that he applied to understanding sampling signals and using bandwidth in better ways. He received his Ph.D. in 1964. That year, he became an assistant professor at the Massachusetts Institute of Technology (MIT). There he taught courses in probability and information theory for several years.

Life's Work

In 1967, Kahn took a leave from MIT to work at the small consulting firm Bolt Beranek and Newman (BBN). From 1967 to 1971, he helped design and build the first computer network, called the Advanced Research Projects Agency Network (ARPANET), a U.S. Department of Defense network that used packet switching to send data between mainframe computers. Packet switching was a new communications method that transferred information electronically by breaking it up into small pieces called packets. Each packet would travel across a computer network and be reassembled at the receiving end. The implementation of sending data between different mainframe computers (there were no personal computers then) was a completely new approach. First, it required an electronic link between the computers with a way to transfer the data in an orderly manner. Second, a common language had to be used so that different computers could understand one another.

The packet-switching method used by ARPANET (the precursor of the Internet) broke up the message into packets of data using a minicomputer called an Interface Message Processor (IMP). Each packet had the address to where it was being sent and sequence information so that each packet could be reassembled to form the final message when it reached the IMP at its destination. The packets could move through the network using different paths and even reach the destination in the wrong order, so the receiving computer had to assemble the packets in the correct order. A method was devised to have a packet resent if it was not received.

The first four sites on the ARPANET were at three different universities in California and at one university in Utah using IMPs linked with high-speed phone lines. By the early 1970's, the ARPANET had grown to fifteen connected sites, demonstrating that the packet-switching technique was reliable. In 1972, Kahn organized the International Conference on Computer Communications (ICCC), held in Washington, D.C., and encouraged programmers to write applications and documentation for the ARPANET to demonstrate its use. Forty computer terminals were set up at the conference to demonstrate the potential of networking computers. The ICCC excited people about the use of networking for a variety of purposes in such fields as education, medicine, research, and business. ARPANET use surged after the conference, and such networking continued to increase dramatically over the following years. However, in order for a true internetwork to be realized, another step was needed to be able to connect computer networks with different individual hardware and software configurations.

In 1972, Kahn began working for the U.S. Defense Advanced Research Projects Agency (DARPA), where he worked on a satellite packet network. He also established a radio packet network. These networks worked at different speeds and had a different number of packets than did the ARPANET. Kahn was motivated to make these different networks compatible with one another, and he began to work with computer scientist Vinton Gray Cerf on the problem. Together they designed Transmission Control Protocol/Internet Protocol (TCP/IP), a system of protocols that enables computers to communicate with one another. The IP contains the address to identify the host computer and the destination computer. The TCP ensures that the stream of packets are transferred in a reliable way through the network so that no data is lost.

Kahn became the czar of grant giving for computing in the latter part of the 1970's. For instance, he issued grants to Stanford University to develop a large-scale integrated circuit. Such work soon led to the use of the TCP/IP system in UNIX workstations so that smaller networks could more easily be integrated into the Internet. University researchers and students were among the first to use this system.

Kahn left DARPA in 1985 to start the Corporation for National Research Initiatives (CNRI), a nonprofit organization that works to make the Internet more useable. CNRI built some of the first Internet browsers, MCI Mail (the first commercial application on the Internet), and digital libraries. In 1989, CNRI showed how the MCI Mail system worked, allowing other e-mail services to quickly develop and leading to an explosion in e-mail use.

Though at first TCP/IP did not seem very important, it would become the standard protocol suite of the Internet. Both Kahn and Cerf later received numerous awards and honors for this development. Kahn is the recipient of the Presidential Medal of Freedom, the AFIPS Harry Goode Memorial Award, the Alexander Graham Bell Medal, the IEEE Third Millennium Medal, the Secretary of Defense Civilian Service Award, the National Medal of Technology, and the Turing Award. He was inducted into the National Inventors Hall of Fame in 2006.

Transmission Control Protocol/Internet Protocol (TCP/IP)

Bob Kahn worked with Vinton Gray Cerf to create a system whereby computer networks with different individual hardware and software configurations could communicate with one another. Kahn knew very well the overall problems involved with networking, and Cerf was best at implementing the small details into different systems. Kahn and Cerf knew enough about each other's expertise to be able to find problems with each other's logic. They decided that no changes would be made within individual networks in order for them to connect with others. This was reasonable, since changing all networks would be incredibly difficult. Instead, Kahn and Cerf decided to put the Interface Message Processor (IMP) minicomputer (now called a router) between networks to change the size of packets (small pieces of data) or the number of packets that each network needed at the packets' destination. They called this system the Transmission Control Protocol, later known as TCP/IP. In the TCP/IP system, the Internet Protocol (IP) ensures only that the packets arrive at the computer destination. TCP focuses on reliable delivery of data, deals with lost or corrupted packets, and reassembles the packets at the destination. Kahn and Cerf announced their idea for TCP/IP in 1973 and published on the topic in 1974. As Kahn and Cerf worked on their ideas for their paper, Cerf had graduate students at Stanford University implementing these ideas on a minicomputer that could be used, if necessary, to modify Kahn and Cerf's approach to solving this problem.

In 1977, Kahn and Cerf set up a network that transmitted data through three separate networks—Packet Radio Net, ARPANET, and SATNET. The packets of data were transmitted 94,000 miles, from the San Francisco Bay Area to Massachusetts, then to Norway and London, and finally to the University of Southern California's Information Sciences Institute. No information was lost in this transfer. Although this was the first demonstration of the TCP aspect of the new protocols, the landmark event—a pivotal step in the development of the Internet—went largely unnoticed.

Impact

As the coinventor of the TCP/IP system, Kahn helped create the now standard system of protocols used to connect computer networks over the Internet. TCP/IP is the language by which computers around the world "speak" with one another. Indeed, this language has allowed the Internet to develop into the powerful forum it is today.

Kahn had the insight to inspire and organize others to work to build the Internet in the 1970's. He continued to develop the Internet for decades after he helped to establish the TCP/IP system.

Dean Kamen

American entrepreneur

Kamen is best known for his Segway PT (personal transporter), a self-balancing, electric-powered pedestrian scooter. With the invention of such devices as the AutoSyringe, HomeChoice, iBOT, Luke Arm, and the Slingshot—among more than 107 patents—Kamen is said to be one of the most accomplished inventors in the world.

Born: April 5, 1951; Rockville Centre, New York
Primary fields: Electronics and electrical engineering; mechanical engineering; medicine and medical technology
Primary inventions: Segway PT; iBOT

Early Life

Dean Kamen was born in Rockville Centre, New York, on April 5, 1951, to Jack, an illustrator for *Weird Science* and *Mad* magazine, and Evelyn, a high school teacher. As he later recounted, he was interested in gadgetry from an early age. By the time he was five years old, he was devising his first gadget: one that allowed him to make his bed without having to move repeatedly from side to side to do so.

However, the young Kamen was not so interested in school. By the time he was in junior high, he found rote learning distasteful, was averse to traditional conventions of education (and being told what to do), and decided that test-taking was little more than the errand of a fool. He challenged many of his mathematics and physics teachers, heckled others, and opted for reading on his own—such works as Isaac Newton's *Principia* (1687)—rather than doing homework.

Through junior high and high school, Kamen was only an average student, but at home the teen was prodigious. Working with transistorized electronics, he designed, built, and redesigned audiovisual control systems, and at sixteen he began landing contracts to install his works at the Four Seasons Hotel, the Hayden Planetarium in Manhattan, and the Museum of the City of New York. The teenager was also commissioned to automate the New York Times Square ball to drop on New Year's

The Segway PT

Electromechanical engineer Dean Kamen is best known for his Segway PT, which has influenced culture and will likely continue to do so in the future. Kamen's most famous invention had a sketchy start: When he introduced the Segway on ABC's *Good Morning America*, the initial reception was bland at best, one of disappointment and chagrin at worst. This is because of what occurred before Kamen unveiled his machine.

Kamen worked on the Segway for ten years, spending millions of dollars in the process. He also kept it a closely guarded secret. Only a select few technicians and fellow engineers—and one privileged reporter, Steve Kemper, who was called by Kamen to observe and document—were made privy to what was to be "the world's first self-balancing human transporter," one that would be energy-efficient and able to share the sidewalks with pedestrians. The Segway HT that first clocked at 17 miles per hour was code-named "Ginger," but the device was known as "It" to the public. The device was rumored to be a technological marvel that would revolutionize transportation. Intrigue multiplied as word got out that Apple Computer's Steve Jobs had deemed it an invention as important as the personal computer. Segway financial backer John Doerr stated that entire cities would be designed around "It."

When finally unveiled, however, the Segway turned out to be just a scooter—one with the back cut off. It was misrepresented in public relations stints, and it was priced at $4,950. Marketing had projected that 31 million units would sell in the first ten to fifteen years, but only 23,500 sold in the first six years. Recalls were a nightmare: Segway riders could stay on as long as the machine was moving, but users fell off as the batteries wore down. In 2006, a software glitch forced a recall of 24,000 units. Limitations on where Segways were allowed also destroyed the dream of making the device universally accepted: In a number of cities, people were forbidden to use them on sidewalks. In 2004, they were banned from Disney-owned parks.

Doerr recruited a new chief executive officer, James D. Norrod, to do some damage control. Norrod studied the technology and consumers and came up with a decision to increase Segway's utility by going to a second prototype on file and adding two more wheels—though the new version strayed from Kamen's original vision. In response, Kamen brought out a larger, more capacious version, added a price tag of $10,000, and dropped the price of the original Segway to $3,000. Police officers, security guards, postal workers, park rangers, corporate fleet personnel, tour guides, and military personnel and veterans are making more and better use of the Segway. While the jury may still be out, Kamen has said that he will let history determine whether or not his ideas are important.

Eve. Though still in high school, Kamen was taking home earnings that nearly matched those of his mother and father combined: $60,000 a year.

Life's Work

Though he preferred working on inventing, Kamen did finish high school and in the early 1970's went on to study at Worcester Polytechnic Institute (WPI) in Massachusetts. At the same time Kamen was attending WPI, his brother Barton was studying medicine at Harvard. There, Barton discerned the problem of patients who in their need for continuous, twenty-four-hour treatment had to visit the hospital for their medications. Kamen worked on the problem until he came up with the answer: a portable drug infusion pump patients could wear that administered set doses of medication and that freed the people from having to go to the hospital every time they needed a treatment.

By 1976, Kamen had stopped his five-year college studies at WPI and founded his first company, AutoSyringe, after the same name as his infusion pump. AutoSyringe was housed at its birthplace, Kamen's parents' home. There, when the basement got too crowded for production, Kamen took it upon himself to send his parents on a cruise, commission an architect, and hire a crew to raise the house on stilts and expand the basement to accommodate manufacture and sales. Two years later, Kamen demonstrated his first infusion pump to an applauding medical and scientific community. In 1982, the reputed maverick inventor sold the company and product rights for $30 million.

That same year, Kamen founded DEKA Research and Development, to offer inventor-for-hire services. He set up shop in Manchester, New Hampshire, where Kamen moved in 1988. In 2009, the company employed nearly two hundred engineers, technicians, and machinists. In 1989, he founded FIRST (For Inspiration and Recognition of Science and Technology), an organization that sponsors robotics competitions for young people and encourages them to enter careers in science and technology. In 1993, Kamen invented HomeChoice, a portable kidney dialysis machine. In 1995, he invented iBOT, a revolutionary robotic mobility system designed with three pairs of wheels, sensors, gyroscopes, and servomotors that give the "wheelchair" a balance mode function that allows it to raise, as if on its back haunches, enabling the user to virtually stand and climb curbs and stairs. In his eight-year, $50-million designing process for iBOT, Kamen later said that he focused on the nuances of mobility, on restoring not only accessibility but also dignity to disabled people. When the first conventional wheelchair users tried the iBOT, Kamen reported, they were in tears.

Yet what has made Kamen both famous and infamous is his invention introduced in December, 2001: Ten years in the making and costing millions of his own money, the Segway came to the attention of the public by way of national television. The self-balancing, electric-powered personal transporter (PT) device was futuristic, innovative, but a disappointment. The product itself was not a failure, but the hype surrounding the device before its release apparently made out the Segway to be much more than it actually was: a personal scooter powered by computer-controlled electric motors and unique in its self-balancing and other capabilities.

Undaunted, Kamen continued to invent devices that do indeed liberate, accommodate, empower, and even save lives: DEKA was commissioned by the Pentagon's Defense Advanced Research Projects Agency (DARPA), to devise such apparatuses as a "controllable launcher," which can launch an urban fighter from the ground into an arc in the air and onto a building rooftop in 1.2 seconds; PowerSwim fins, which give the combat diver underwater speeds of up to two knots; and the Luke Arm (named for the *Star Wars* character Luke Skywalker), a lightweight, brain-controlled prosthetic arm, which, with its fourteen sensors, enables the user to sense and distinguish temperature and pressure without looking. Most notably, Kamen worked on a project to provide developing countries with clean energy and water. In 2003, Kamen and DEKA produced the Slingshot, a nonpolluting, low-power, relatively cheap water-purifying system. It is easily installed and works on a Stirling engine. Unfortunately, Kamen had difficulty finding a commercial manufacturer for the Slingshot.

The upbeat inventor has been awarded for his innovation and influential efforts. After such accolades as the Kilby Award (1994) and the Hoover Medal (1995), Kamen was named to the National Academy of Engineering in 1997 and was awarded the Heinz Award in Technology, the Economy, and Employment in 1998 and the National Medal of Technology in 2000, for his biomedical inventions that have advanced worldwide medical care and for engaging America in the excitement of science and technology. For his invention of the Segway and the infusion pump for diabetics, Kamen was granted the Lemelson-MIT Prize in 2002. His Slingshot project was runner-up in *Time* magazine's "Coolest Invention of 2003." For his invention of the AutoSyringe, Kamen was inducted into the National Inventors Hall of Fame in 2005. He was honored with the United Nations' Global Humanitarian Action Award in 2006, and in 2007 he was listed as one of fifty outstanding leaders on the *Scientific American* 50 annual list of key contributors in science and technology. Kamen has been awarded honorary doctorates from various universities, including Kettering University, in 2001, and Plymouth State University, in 2008.

Impact

Kamen has affected the world with his avant-garde vision. The Segway, first mocked for its failure to live up to its hype, has become useful in assisting not only police officers and security guards but also people with mobility problems. Kamen's medical inventions—including the AutoSyringe, the wearable infusion pump for diabetics, and the HomeChoice portable dialysis machine—profoundly changed the lives of those who used the devices. Patients no longer had to go to medical facilities every time they needed treatment. The iBOT has also improved the lives of many wheelchair-bound persons, allowing them to go up and down stairs, step onto and off curbs, and navigate rough terrain—to perform actions that perhaps they had never done before. Kamen has reached out to engage young minds in science and technology with his FIRST program, and his Slingshot water-purifying system has the potential to provide clean water at little cost to people in developing countries. His inventions have changed the way people live and even their quality of life.

HEIKE KAMERLINGH ONNES

Dutch physicist

Kamerlingh Onnes was a pioneer in the field of ultra-low-temperature physics. He was the first to liquefy helium, and he discovered superconductivity.

Born: September 21, 1853; Groningen, the Netherlands
Died: February 21, 1926; Leiden, the Netherlands
Primary field: Physics
Primary invention: Helium liquefaction

EARLY LIFE

Heike Kamerlingh Onnes (HI-kuh KAH-mehr-leeng ON-uhs) was the firstborn son of Harm Kamerlingh Onnes, a manufacturer of roofing tiles, and Anna Gerdina Goers. Eventually, Heike had four brothers and two sisters. His maternal grandfather was an architect, and all members of his family were artistically talented. Heike was the only child who was interested in pursuing a career in the sciences, though he maintained a lifelong interest in the arts. His parents were very disciplined and taught him respect for hard work and patience. He was often ill as a child, and he continued to have health problems throughout his life.

Since his father had a stable job in Groningen, Kamerlingh Onnes lived most of his early life in the city of his birth. His secondary education was at the Hoogere Burgerschool in Groningen. Kamerlingh Onnes excelled as a student, particularly in science and mathematics. In 1870, after taking additional classes in classical languages, Kamerlingh Onnes enrolled at the University of Groningen at age seventeen. He was an outstanding student at the university and received an academic gold medal and bachelor's degree in 1871. He also served as student body president there. After two years at Groningen, Kamerlingh Onnes studied for three terms at the University of Heidelberg in Germany, under the direction of Gustav Kirchoff and Robert Wilhelm Bunsen. In 1873, Kamerlingh Onnes returned to Groningen to finish his education. He was appointed as assistant to the director of the Polytechnic School in Delft in 1878, where he began a close professional relationship with Johannes Diderik van der Waals. There Kamerlingh Onnes honed his skills in thermal physics. He received his doctorate with honors in 1879. His dissertation was on "A New Proof of Earth's Rotation."

LIFE'S WORK

In 1881, Kamerlingh Onnes published his first paper dealing with the properties of matter at low temperatures. In 1882, at the age of only twenty-nine, he was appointed professor and chair of experimental physics at the University of Leiden, where he spent the rest of his career. A year later, he was admitted to the Royal Academy of Sciences of Amsterdam. His position made him the director of physics laboratories at Leiden. Kamerlingh Onnes impressed upon all the faculty at Leiden the importance of meticulous measurements, ordering that the motto "Door meten tot weten" (through measurement to knowledge) be placed over each laboratory door. Kamerlingh Onnes also reorganized the physics laboratories into a cooperative venture. Faculty were encouraged to work with one another, and researchers from all over Europe were encouraged to come work at Leiden. Furthermore, he established a central glassblowing shop and machine shop to support research at the institution, rather than each researcher attending to his or her own fabrication needs. Though, being a professor, he was required to teach, Kamerlingh Onnes strongly disliked teaching, preferring his research duties instead. He often persuaded others, especially his friend Hendrik Lorentz, to teach his classes for him.

Five years after coming to Leiden, Kamerlingh Onnes married Maria Adriana Wilhelmina Elisabeth Bijleveld in 1887. Their only child, Albert Harm Kamerlingh Onnes, was born one year later.

In 1892, Kamerlingh Onnes perfected a cascade-type gas liquefaction device to supply his laboratories with liquid nitrogen and oxygen. This device cooled gas in stages, with each stage cooling a different gas to be used in later stages. His gas liquefaction system would be used for decades, and gases are still liquefied today using similar methods.

To further support research efforts at his laboratories and to promote research at other laboratories around the world, in 1901 Kamerlingh Onnes created the Society for the Promotion of the Training of Instrument Makers at Leiden. The training provided by the society taught glassblowers, machinists, and other instrument makers the specialized skills needed to support scientific laboratory research. Leiden-trained instrument makers soon became highly valued throughout all Europe.

By 1906, Kamerlingh Onnes had managed to liquefy hydrogen. James Dewar had liquefied hydrogen eight years earlier, but Kamerlingh Onnes was able to produce liquid hydrogen at a far greater rate than other laboratories at the time. He had been required to create special cryostats capable of keeping the liquefied gas cold. He then turned his sights to helium, the only gas that had not been liquefied. Applying van der Waals's theories to helium, Kamerlingh Onnes calculated that helium could only be liquefied a few degrees above absolute zero. By using techniques similar to those that he used to liquefy hydrogen, he finally succeeded in producing liquid helium, at a temperature of about 4 kelvins, on July 10, 1908. He was the first person ever to liquefy helium. Using his refrigeration technology, Kamerlingh Onnes was eventually able to reach a temperature as low as 0.83 kelvin.

After liquefying helium, he turned his attention to the electrical properties of metals at low temperatures. One theory at the time suggested that electrical conductivity increased steadily as temperature decreased, reaching a maximum value at absolute zero. Another theory, proposed by Lord Kelvin (William Thomson), held that the conductivity would reach a maximum at a temperature above absolute zero, then decrease to zero as the temperature decreased closer to the absolute zero. To investigate which of these theories was correct, Kamerlingh Onnes began experiments with the metal mercury in 1911. To his surprise, he found that the mercury sample's electrical resistance suddenly went to zero at just below the boiling temperature of liquid helium. At first, he suspected an instrumentation short circuit, but repeated experiments repeated his observations. By 1913, he had shown that tin also exhibited a sudden vanishing of resistance at low temperatures. He coined the term "superconductivity" to describe the phenomenon.

The Royal Society of London awarded Kamerlingh Onnes its Rumford Medal in 1912. He was awarded the Nobel Prize in Physics in 1913 for this work in low-temperature physics, including the liquefaction of helium and the discovery of superconductivity. During World War I, Kamerlingh Onnes used his notoriety as a Nobel laureate to work to overcome political differences between scientists and to secure aid for starving children in countries suffering from food shortages.

Kamerlingh Onnes never retired. In the 1920's, he again turned his attention to helium. He observed that its density suddenly increased at a temperature of about 2 kelvins. However, his poor health interfered with his studies. In 1926, after a short illness, he died without completing his work on liquid helium. The phenomenon that he had discovered would later be studied by Pyotr Leonidovich Kapitsa, who would eventually get credit for its discovery and who named it "superfluidity."

Impact

Kamerlingh Onnes was a major figure in the early days of ultra-low-temperature physics. He was the first to liq-

HELIUM LIQUEFACTION

Many gases can be liquefied through refrigeration using other substances as coolants. However, hydrogen and helium have critical temperatures far below even the freezing points of other substances, so another method is needed to liquefy these gases. (The critical temperature of a substance is the temperature at which liquid and gas are indistinguishable.) Near the end of the nineteenth century, two physicists worked to liquefy these gases: Heike Kamerlingh Onnes, in Leiden, and James Dewar, in London. Dewar succeeded in liquefying hydrogen before Kamerlingh Onnes. By 1908, though, Kamerlingh Onnes had extended upon Dewar's methods to devise his own helium liquefaction system, which he called a "helium liquefactor."

In order to cool these gases, both Kamerlingh Onnes and Dewar used Joule-Thomson cooling. James Johnson and William Thomson (also known as Lord Kelvin) had shown in 1852 that certain gases would cool if allowed to expand adiabatically (occurring without loss or gain of heat) through a porous plug under constant enthalpy conditions. The most important condition that must be met is that the gas must start below a critical temperature, called the inversion temperature. Gases above their inversion temperature would warm if they expand under constant enthalpy, but gases below that temperature cool. For most gases, the inversion temperature is quite high, but for hydrogen it is 202 kelvins (–71° Celsius), and even lower, at 51 kelvins (–222° Celsius), for helium, so these gases must first be cooled by some other means below these temperatures before Joule-Thomson cooling can be used. The inversion temperature of helium is lower than the freezing points of nitrogen and oxygen, so Kamerlingh Onnes and Dewar both realized that liquid hydrogen must first be produced to precool the helium.

The helium liquefaction system that Kamerlingh Onnes built was in essence a series of liquefaction systems, with the helium liquefactor being simply the last step. The process started with a standard cascade refrigeration system to liquefy oxygen. The liquid oxygen was used to cool the hydrogen below its inversion temperature. Kamerlingh Onnes used Johannes Diderik van der Waals's principle of corresponding states to show that the critical point of helium was near 5 kelvins, thus a single-stage Joule-Thomson cooling, such as Dewar was using, would not suffice to liquefy helium. Thus, Kamerlingh Onnes built an iterative system. Helium was compressed, cooled with liquid hydrogen, and then allowed to expand, cooling it further. This colder helium was then used to cool more compressed helium, which was then allowed to expand, producing even colder helium. Through a sequence of such steps, the temperature of the helium could be lowered to the point at which it began to condense as a liquid. Using this system, Kamerlingh Onnes succeeded in liquefying helium on July 10, 1908, becoming the first scientist to do so.

uefy helium, and for nearly fifteen years his was the only facility able to produce liquid helium. His careful work and techniques established a pattern for other researchers to follow when studying phenomena at extremely low temperatures. Furthermore, his refrigeration devices became the standard model for reaching such low temperatures.

Superconductivity, which Kamerlingh Onnes discovered, gave rise to a new subfield of ultra-low-temperature physics. The mechanism by which a substance becomes a superconductor would not be known for many years to come, however. The ability of a material to pass electricity without resistance eventually permitted the development of the most powerful magnets ever constructed. Later work on superconductors would lead other physicists to Nobel prizes of their own over the next century. Superconductors have come to have many important applications in modern technology, particularly through their ability to be used to produce extremely powerful electromagnets.

However, Kamerlingh Onnes's impact on physics extended far beyond simply the field of low-temperature research. He foresaw that science had moved beyond the individual scientist working in his laboratory. Scientific research had become more complex, often requiring teams of researchers. Also, the equipment required by the researchers was becoming more complicated than could be fabricated solely by the researchers themselves. His model of a coordinated research facility with shared support staff became the model of every physics laboratory since that time. His work made the physics laboratory facilities at Leiden the best in the world for low-temperature physics. Even today, those facilities, now called the Kamerlingh Onnes Laboratory, make up a first-class research institution.

Pyotr Leonidovich Kapitsa

Russian physicist

Kapitsa was an extraordinary physicist whose research encompassed such diverse areas as extreme magnetic fields, low-temperature physics, and high-power microwave physics. He was the corecipient of the Nobel Prize in Physics in 1978 for his discovery of thesuperfluidity of liquid helium and for his basic inventions in low-temperature physics.

Born: July 8, 1894; Kronshtadt, Russian Empire (now in Russia)
Died: April 8, 1984; Moscow, Soviet Union (now in Russia)
Primary field: Physics
Primary invention: Planotron

Early Life

Pyotr Leonidovich Kapitsa (PYOH-tehr lyi-uh-NYEE-duh-vyich KAH-pyih-tsuh) was born on the Russian island of Kronshtadt on July 8, 1894. His father was Leonid Petrovich Kapitsa, a military engineer, and his mother was Olga Ieronimovna (née Stebnitskaia), a folklore researcher. As a boy, he lived in Tsaritsyn (now Volgograd). Following his early education in Kronshtadt, Kapitsa went to study engineering and the physical sciences at the Petrograd Polytechnical Institute. In 1916, while at the institute, he married Nadeshda Tschernosvitova, and later had two children by her.

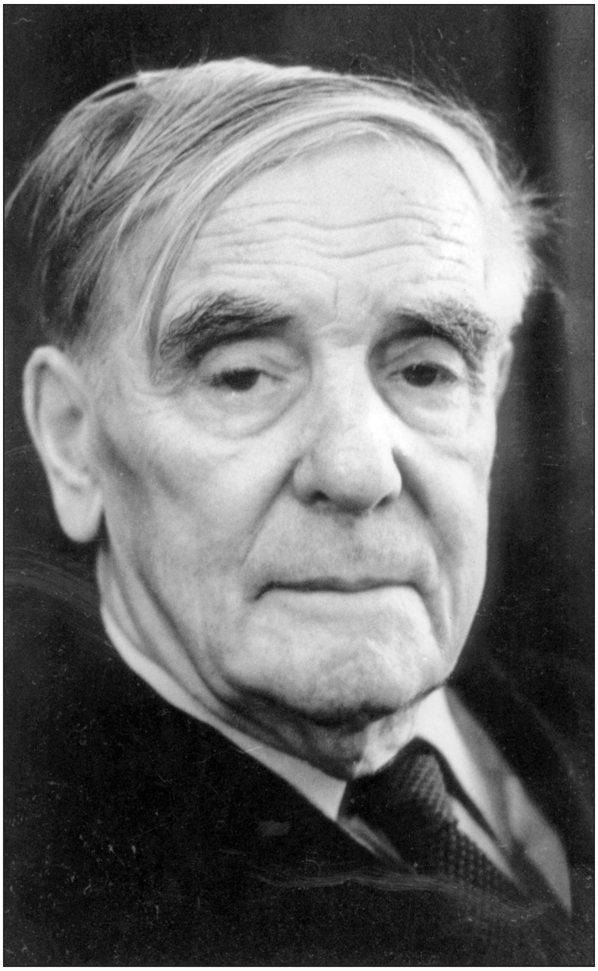
Kapitsa graduated from the Petrograd Polytechnical Institute with an electrical engineering degree in 1918, a year after the Russian Revolution. He then became a lecturer at the institute, which had been renamed the First Polytechnical Institute. Under the new communist control, academicians did not have the same rank, support, and authority as before, and the working environment was strained. Kapitsa's life took a turn for the worse when the 1918-1919 Spanish influenza pandemic swept through Russia. His father, wife, and two children all died. Despite this tragedy, Kapitsa managed to publish several papers during this time. In 1921, he was permitted to leave the country to travel to England as part of a Soviet Academy of Sciences mission. There he met Ernest Rutherford, who persuaded him to stay at Cambridge's Cavendish Laboratory. Kapitsa was awarded a doctorate in physics from Cambridge in 1923.

Life's Work

In 1924, Kapitsa was made the assistant director in charge of magnetic research at the Cavendish Laboratory and was made a fellow of Trinity College in 1925. At Cavendish, he at first continued work begun at the Polytechnical Institute on extremely powerful magnetic fields. Kapitsa helped to discover that alpha radiation consisted of positively charged massive particles by observing their deflection in a cloud chamber placed in a strong magnetic field. He also discovered a relationship between resistance and magnetic field strength of metals placed in strong magnetic fields. Kapitsa's observations that extreme magnetic fields influenced temperature ultimately led him to begin studies of low-temperature physical phenomena. He became particularly interested in the unusual properties of superconductors and the nature of helium at low temperatures.

In 1927, Kapitsa married Anna Alekseevna Krylova, the daughter of a prominent Soviet mathematician. Together, they had two sons, Sergei and Andrei. Anna Kapitsa routinely traveled with her husband on trips to the Soviet Union from their new home in England.

In 1929, Kapitsa was elected a member of the Royal Society and soon thereafter as a corresponding member of the Soviet Academy of Sciences. Kapitsa soon turned his interest fully to low-temperature physics. By 1932, he had designed an improved helium liquefaction system capable of producing more than two liters of liquid helium per hour. With Rutherford's support, the Royal Society built the Mond Laboratory at Cambridge for



Pyotr Leonidovich Kapitsa. (©The Nobel Foundation)

low-temperature physics research. Kapitsa served as the director of the laboratory until 1934. He would have remained at Cambridge indefinitely; however, on a routine trip back to the Soviet Union to visit his mother in 1934, the Soviet government canceled his and his wife's passports, effectively prohibiting his leaving the Soviet Union.

Negotiations between Kapitsa and Joseph Stalin resulted in the former's appointment, in 1935, as director of the newly created Soviet Institute of Physical Problems (now the Kapitsa Institute for Physical Problems). As institute director, Kapitsa worked to secure the equipment built for his low-temperature research at the Mond Laboratory. When his new laboratory was set up using his specially built equipment, Kapitsa once again resumed his low-temperature physics work. In 1938, he announced the discovery of a new state of liquid helium that occurs under conditions colder than 2.17 kelvins. This state of matter is called a superfluid because it is able to flow without viscosity. However, superfluidity is not simply zero-viscosity liquid; rather, it is a different state of matter. For a long time, helium was the only substance known to be capable of undergoing a transition to a superfluid state.

During World War II, Kapitsa's laboratories in Moscow became the primary source for liquid oxygen for the Soviet Union. Kapitsa became head of the Department of Oxygen Industry. Kapitsa's own research turned toward nuclear physics and cosmic rays at this time. At the end of World War II, Stalin appointed Kapitsa to a special research team charged with the development of an atomic bomb for the Soviet Union. However, Kapitsa's personal beliefs and opinions soon put him at odds with the team's political adviser, ultimately resulting in Kapitsa's falling from Stalin's favor. He was removed from the research team, removed as head of the Institute for Physical Problems, and stripped of all his academic rank and privileges. He was placed effectively under house arrest at his home in the Moscow suburb of Zvenigorod from 1946 until after Stalin's death in 1953.

During this time, Kapitsa was unable to continue the research that he had been doing at the institute; however, he was able to construct instruments at his home to study the field of high-energy microwaves. He invented two devices, the planotron and the nigotron, to produce microwaves of far higher intensities than could be easily produced in the laboratory before. Kapitsa also did theoretical work in high-power electronics during this period. Nikita S. Khrushchev, after taking over from Stalin, began to return some of the privileges that Stalin had taken from Kapitsa, though Kapitsa was never fully reinstated to his former positions. Kapitsa continued his studies of high-energy microwaves and plasma physics. From 1955 onward, he served as editor of the *Soviet Journal of Experimental and Theoretical Physics*. In 1957, until his death, Kapitsa was a member of the presidium of the Soviet Academy of Sciences.

In 1964, Kapitsa was permitted to leave the Soviet Union to receive the Niels Bohr International Gold Medal for his work in low-temperature physics. In 1978, he shared the Nobel Prize in Physics with Arno Penzias and Robert Wilson. Kapitsa continued to work until his death, though in his later years his productivity waned. He died in Moscow on April 8, 1984, three months before his ninetieth birthday.

The Planotron

Producing microwaves in a controlled fashion was quite difficult until Albert Wallace Hull's invention of the magnetron in 1921. The magnetron uses crossed electric and magnetic fields in a device that resembles a hollow cylinder with a rod down its center and small cavities spaced around its outside. A magnetron can quite efficiently convert electrical energy into microwaves; however, is has certain limitations. To overcome some of these problems, Pyotr Leonidovich Kapitsa invented a related device that was able to produce microwaves at even higher power and precision. Kapitsa described the device as being much like a magnetron that had been cut open and spread out in a plane. Due to the planar nature of the device, Kapitsa called it a planotron.

The planotron consists of a metal plate kept at a voltage above that of the rest of the apparatus. This is the planotron's cathode. At a fixed distance from the cathode are a series of identical and uniformly spaced anodes (conducting pieces kept at a lower voltage than the cathode). The space between the cathode and the anodes is the working space for the planotron, in which the microwaves are produced. The entire planotron must be operated in a vacuum. When the anodes are heated, electrons will try to flow across the space between the anodes to the cathodes. However, in operation, a magnetic field is established perpendicular to the electric field (hence, parallel to the cathode). Electrons moving in a magnetic field move in a circular path. However, electrons moving in the presence of both electric and magnetic fields move in a trochoidal path (the path drawn by a point at the edge of a rolling circle). An alternating electric field is then established between the anodes, with adjacent anodes being of opposite phase. This causes the electrons to move in a path that resembles an epitrochoid.

As the electrons move in their cyclic motion, they gradually lose energy into electromagnetic radiation. The frequency of radiation is determined by the spacing of the anodes and by the alternating field between them. Typical spacings yield frequencies that are those of microwaves. Like the magnetron, the planotron is extremely efficient at converting electrical energy into microwaves, but it is able to operate at far higher power.

Not only can a planotron efficiently convert electrical energy into microwaves, it can also work in reverse, converting microwaves into electrical energy with similar efficiency. Kapitsa wrote about the possibility of using planotrons for wireless transmission of electrical energy. For terrestrial applications, though, this concept proved not to be commercially practical. However, since Kapitsa's death, there have been proposals to perhaps place giant solar panels into Earth orbit to produce electrical energy. This energy could be beamed to Earth in the form of microwaves, with devices similar to planotrons at each end of the microwave link.

Impact

Throughout his career, Kapitsa demonstrated interest in all aspects of physics. Few other physicists of the twentieth century did such extensive work in so many different areas of physics. His work in low-temperature physics, including his discovery of superfluid helium, was instrumental in the development of that field and led to his winning, with Penzias and Wilson, the 1978 Nobel Prize in Physics. Penzias and Wilson's half of the prize was for their discovery of the cosmic microwave background radiation, which permeates the universe.

Kapitsa spoke out on many social and political issues. He was particularly critical of the Cold War. Though never officially declared a dissident, Kapitsa's outspokenness certainly pushed the limits of what was permitted under totalitarian Soviet control. He was not at all shy about challenging either Stalin or Khrushchev on various matters. That he was able to approach such powerful Soviet leaders and that they tolerated his challenges demonstrated how important he and his work were considered.

John Kay

British machinist and engineer

Kay introduced two significant reforms into the technology of weaving, in advance of the Industrial Revolution, which facilitated the eventual mechanization of textile manufacture. The importance of his innovations became controversial when he was held up posthumously as a key example of the shabby way in which England allegedly treated its inventors.

Born: July 16, 1704; Walmersley, near Bury, Lancashire, England
Died: 1780 or 1781; southern France
Primary field: Manufacturing
Primary invention: Flying shuttle

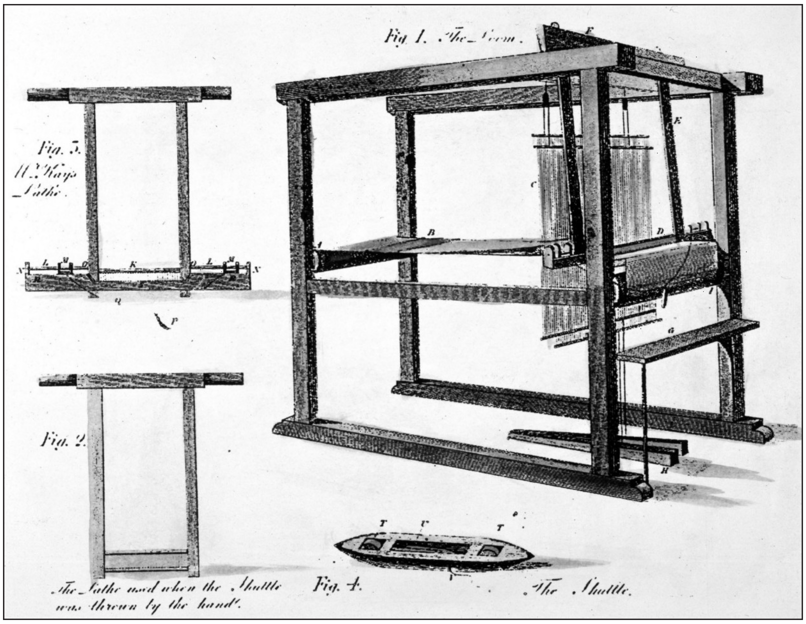
Early Life

John Kay was the fifth and last son of Robert Kay (1651-1704), the owner of Park Farm, and his wife Ellen, née Entwhistle. Robert Kay appears to have been a successful and relatively prosperous farmer, but his death three months before his youngest son's birth inevitably gave rise to difficulties for the family. John was educated locally but left school at fourteen to be apprenticed to a maker of reeds—devices used in weaving, whose function was to separate the threads of the warp and "beat up" the weft after each passage of the shuttle. He reportedly abandoned his master after a month, claiming that he had nothing left to learn. He appears to have been an extremely self-confident person with quarrelsome tendencies.

Anticipating a legacy of £30 from his father, which would come into his possession when he came of age (at twenty-one), Kay married Ann Holt on June 29, 1725. She bore six sons and six daughters before dying in childbirth in 1747. Kay apparently invented a new and improved reed in 1726, which substituted thin wire for the usual slivers of cane or reed, but did not patent it—an omission that he apparently became determined not to repeat. Three years later, he patented a new model of shuttle that was considerably lighter than existing ones, moved on four wheels, and featured a spring-operated "picker"—which is arguably the ancestor of all "mechanical hands." It was initially called a wheel shuttle, spring shuttle, or bobbin shuttle by virtue of its various accoutrements, but it eventually became known as a flying shuttle by virtue of the increased speeds it facilitated. It not only allowed weavers to work faster, enabling them to increase their daily production—or to reduce their working hours—but also made it easier to produce "broad goods" (wide sheets of cloth).

LIFE'S WORK

An improved model of the flying shuttle, launched in 1735, used a larger fitted spool and was widely introduced into the local woolen industry, enabling Kay to set up his own business as a shuttle manufacturer. He tried to charge his clients a "rent" (royalty) on every shuttle they employed, but the manufacturers refused to pay it, considering it extortion. He launched a series of lawsuits against some fifty-two manufacturers between 1737 and 1743, on the grounds of patent infringement, but ultimately failed to collect a penny in royalties and incurred heavy legal costs in the process.



An engraving from 1830 showing John Kay's flying shuttle loom (fig. 1), an unmodified lathe (fig. 2), a lathe modified by Kay (fig. 3), and Kay's shuttle (fig. 4). (The Granger Collection, New York)

Kay's propagandist descendant Thomas Sutcliffe (1791-1849), and others who tried to use Kay as an example of a genius cheated out of his due reward, echoed his own claim to have caused a "yarn famine" by increasing shuttle speeds, which was the direct cause of the development of automated spinning machines by John Wyatt, James Hargreaves, Richard Arkwright, and others, and hence of a key phase of the Industrial Revolution, but there is little hard evidence to support this boast. Opponents of that view suggest that the picking peg required a degree of skill that was quite difficult to master and that this limited the flying shuttle's use by contemporary weavers. Even so, it was a successful innovation, being adapted to numerous different kinds of cloth as the century progressed.

In 1738, Kay patented a wind-powered machine for raising water in mine shafts, but it was never widely employed. In 1745, however, he and Joseph Stell of Keighley obtained a patent for an improved, water-driven swivel loom—better known as a Dutch loom—for the weaving of "narrow goods" (tapes and ribbons). It was the first device to use tappets to control pedals. In the 1738 patent application, Kay described himself as an engineer, but by the time of the 1745 application he termed himself a "gentleman." In 1747, he left England for France. The reasons for the move are not entirely clear. His 1733 patent had expired and he was probably deep in debt, but his family were Jacobites and the failure of the 1745 rebellion was probably also a contributory factor. While he was in France, Kay learned of his wife's death, and that may well have put an end to any immediate plans he had to return to England.

Kay obtained a patent in France giving him a monopoly on the manufacture and sale of the flying shuttle, and in 1749 he was granted a government subsidy and a life pension, on condition that he severed all ties with his native land. He brought over three of his sons to help run his factory: James, John (1740-1791), and Robert (1728-1802)—who became an inventor in his own right, effecting significant improvements to the wheel shuttle. Kay soon found, however, that French weavers were counterfeiting his shuttle just as English manufacturers had. Between 1750 and 1754, he worked hard on improving the process of carding, eventually producing a much-improved carding machine that was widely adopted within the spinning industry, but he could not obtain a patent for it in England and does not seem to have made much money from it even in France. Nor could he bring himself to stay away from England, eventually visiting often enough to have his French pension revoked in 1759. In the meantime, the Kay-Stell Dutch loom was first put into operation in harness with a waterwheel at Keighley in 1750. The version that began operation at Garrett Hall, Manchester, in 1760 was that town's first true factory, anticipating the town's vast development into an important industrial city in the next century.

In 1764, Robert Kay applied to the Society of Arts for a reward for his father's inventions but was refused because of his defection to France; the society eventually consented to award him a bounty of £50 for his carding machine, but not until 1774, and it refused to give him anything for the flying shuttle. By then, however, Kay's French pension had been restored, and he threw himself into further work on behalf of the French government, designing apparatuses for canal excavation, dock cleansing, temperature regulation, and silk manufacture. Étienne Mignot de Montigny was moved in 1779 to declare him a genius, but the statement might have been as much a diplomatic sally aimed at the English as a compliment to Kay's intellect. Kay's actual movements in France remain something of a mystery, and nothing more was heard from him after a letter sent from Sens in Burgundy in 1779. A report that he was living "in credit and affluence" in 1780 might have been a further exercise in diplomacy. At any rate, the exact date, place, and circumstances of his death remain a mystery, although he was definitely deceased by the spring of 1781.

The firm of Robert Hall and Sons erected a statue of Kay in his native town of Bury in 1877, which still exists, although it was moved to Barnsley in 1974. A Kay Memorial was inaugurated in 1908 in Kay Gardens, Bury.

The Flying Shuttle

A weaving loom works by raising up two sets of threads alternately by means of two horizontal bars (known as "heddles") equipped with eyelets, through which the thread is passed. The raising of each individual set of warp threads leaves a space (the "shed") through which a shuttle is passed. The shuttle used prior to John Kay's invention had to be passed from hand to hand, limiting the breadth of the cloth to the length of the weaver's arm. The flying shuttle was mounted on wheels and moved between two shuttle boxes mounted to either side of the loom along a wooden track, or "shuttle race," in response to a jerking action from the weaver, which activated the "picking peg."

The flying shuttle was considerably faster than a hand shuttle and facilitated the weaving of wider bolts of cloth. There is no doubt at all that the flying shuttle was an important technical advance and a crucial first step in the automation of weaving, but historians dispute the speed with which it was actually taken up by manufacturers and the extent of the manufacturers' guilt in refusing to pay royalties for its use. Kay's detractors suggest that his particular model was too awkward to use without considerable modification and that the flying shuttles that achieved dramatic improvements in production owed as much to other improvisers as to him. The basic design-concept was, however, a stroke of brilliance if not of genius, and was certainly a key contribution to the eventual mechanization of the textile industry.

Impact

Kay's posthumous reputation owed much to the propagandizing efforts of his great-grandson Thomas Sutcliffe, who fought at Waterloo before being appointed governor of the Juan Fernández Islands. Sutcliffe followed up *An Exposition of Facts Relating to the Rise and Progress of the Woollen, Linen, and Cotton Manufactures of Great Britain* (1843) with a more specific *A Testimonial in Behalf of Merit Neglected and Genius Unrewarded, and Record of the Services and Sufferings of One of England's Greatest Benefactors* (1847), issued as part of a campaign to obtain state relief for Kay's poorer descendants.

This appeal made Kay a legendary character in the late nineteenth century; Sutcliffe popularized an oft-quoted but highly dubious anecdote relating how Kay was driven to seek refuge in France in 1753 (six years after his actual emigration) when his home was attacked by Luddite machine-breakers intent on his murder. The suggestion was put about that the target of the attack was a new spinning machine invented by Kay in association with one Thomas Hayes, or Highs, who had unwisely bragged about it to Richard Arkwright, who had then made a fortune out of it. The rumor was given extra credence by the fact that Arkwright had commissioned a man named John Kay to build a model of his machine—but that was a clockmaker from Warrington, not John Kay of Bury.

Kay's historical importance was undoubtedly inflated by this legend-mongering, but the flying shuttle was a significant innovation and a key step in the gradual development of a fully automatic loom. His carding machine was also a notable step forward in textile production. Even if Kay's accomplishments were slightly overstated, the fact that he became an exemplary legend is significant in itself, as an admonitory reminder that English technological expertise often did go unremarked and unrewarded for far too long. His own tragedy was compounded by the fact that the nineteenth century campaign mounted on his behalf accomplished little or nothing to ensure that future English engineers would be afforded the status that their contribution to national wealth ought to have entitled them.

John Harvey Kellogg

American physician and surgeon

A health reformer, Kellogg advocated a way of life that included exercise, cleanliness, and a vegetarian diet focused on fruits, nuts, and whole grains. His search for a ready-to-eat form of whole grains led to the invention of flaked breakfast cereal.

Born: February 26, 1852; Tyrone, Michigan
Died: December 14, 1943; Battle Creek, Michigan
Primary field: Food processing
Primary invention: Cereal flakes

Early Life

John Harvey Kellogg was born to John Preston and Ann Stanley Kellogg on their farm near Tyrone, Michigan, in 1852. A few months after his birth, Kellogg's parents embraced the faith of Seventh-day Adventists. When Kellogg was four years old, the family moved to Battle Creek, Michigan. Though he received irregular schooling as a boy, John became an avid reader. He worked in his father's broom shop for a year, until at the age of twelve he first attended school full time. After a year in school, he became acquainted with James and Ellen White, who helped found the Adventist Church. When James White, president of the Review and Herald Press, heard about the boy's impressive performance in school, he offered him a job in 1864. As he worked his way up to typesetter and proofreader, Kellogg became familiar with Ellen White's writings on Seventh-day Adventist health principles, which included vegetarianism.

At the age of sixteen, Kellogg accepted a position in a rural school, but he found the job too taxing on his somewhat delicate health. Eventually, he finished high school. As they hoped to improve the medical foundations of the Seventh-day Adventist's Western Health Reform Institute, the Whites offered Kellogg encouragement and financial support to acquire a medical education. Kellogg completed the six-month course in water therapy at Dr. Russell Trall's Hygieo-Therapeutic College in New Jersey and then attended the University of Michigan Medical School. He completed the first series of lectures but left because of the lack of clinical instruction. James White then lent him money to complete his medical degree at Bellevue Hospital Medical School, which combined classroom and clinical teaching. Kellogg graduated in 1875. In 1878, he married Ella Eaton. They had no biological children, and it is likely that their marriage was never consummated. During their marriage, however, they reared forty-two foster children, seven of whom they adopted.

LIFE'S WORK

Kellogg led an extremely busy life filled with diverse projects. He joined his knowledge of standard medical practice in the performance of surgery with Adventist-inspired health principles that included vegetarianism, sexual continence, exercise, and hydrotherapy. In 1876, the Whites persuaded him to become chief physician of the financially failing Western Health Reform Institute. Within a year, Kellogg had renamed it the Battle Creek Sanitarium and had begun promoting its program of "biogenic" living to remain healthy. From its beginning, the sanitarium had a bakery to produce foods for those with digestive difficulties. As he initiated expansion and modernization of the facility during the 1880's, his control grew and he integrated his health principles and current therapies observed during travels to European medical centers and health spas. In 1892, he reorganized the sanitarium and acquired full control of it.

All of the activities had one goal: the improvement of human health by means of correct living. Kellogg proscribed the consumption of not only meat but also sugar and condiments—foods that Kellogg felt impeded proper digestion and led to sexual excess—as well as stimulants, such as coffee, tea, and chocolate. Tobacco and alcohol were also forbidden. On the positive side, he recommended legumes and nuts for protein, whole grains, and fresh fruits.

John Harvey Kellogg, pictured here in 1942 at the age of ninety. (AP/Wide World Photos)

Kellogg invented a number of grain foods, but not the first cereal. In 1863, James Caleb Jackson, whose ideas had inspired Ellen White, produced granula, a cereal composed of hard wheat-bran nuggets that required overnight soaking to eat. Kellogg conceived of the possibility of the "ready-to-eat" breakfast food during his days at Bellevue. In 1877, he invented a product called granola prepared from a mixture of oatmeal, cornmeal, and wheat baked into a thick biscuit that was then ground up. He had discovered that baking grain at a high temperature turned its starch into dextrin—that is, it completed the first stage of digestion and thus benefited those with digestive disorders. Kellogg started a mail-order business when former patients wanted to purchase his grain products. In 1890, he founded the Sanitarium Food Company. Besides granola, the company produced other healthful foods, such as crackers and a cereal-based coffee substitute. In 1894, Kellogg invented his most famous food, the flaked breakfast cereal, with the help of his brother, Will Keith Kellogg. When the Adventist board of directors refused to finance Kellogg's ongoing research, Kellogg continued at his own expense and with his brother set up the Sanitas Food Company to market the new cereal as Granose.

In 1892, Kellogg invented a peanut butter composed of boiled peanuts mashed into a paste. He developed other vegetarian foods such as Savita Gravy (a bullion made from brewer's yeast), meat substitutes composed of boiled peanut mash combined with wheat gluten or starch and flavored like different meats or salmon, and Bromose, a milk substitute composed of cereals and nuts that he touted in his 1896 book *The Stomach* for its digestibility and efficacy for weight gain. One meat substitute, Nuttose, introduced in 1896, served as the main dish for sanitarium dinners.

In 1902, the Battle Creek Sanitarium burned down, and during the process of rebuilding, the Adventist Church quarreled with Kellogg, both over his use of profits for his projects instead of for the church's programs and over the suspicion that he ascribed to pantheism and not to the church's theology. Though the church severed its relationship with Kellogg in 1907, he nevertheless retained control of the sanitarium and its food companies.

Relations between the Kellogg brothers soured over different business and marketing strategies; after almost a decade of conflict, the courts gave Will exclusive rights to sell corn flakes and to use the Kellogg name. John Kellogg continued to promote his ideas on food and diet. He accepted autointoxication, a theory that viewed the fecal content of the colon as the source of illness. Inspired by the views of microbiologist Ilya Mechnikov that attributed the long lives of Bulgarians to the consumption of beneficial bacteria in yogurt, Kellogg became an advocate of yogurt therapy by the end of the first decade of the twentieth century. At the sanitarium, patients ate yogurt and received yogurt enemas to maintain a healthy colon.

By the end of the second decade, Kellogg had discovered a nutritious meat substitute in the soybean, devoting several pages to soy-based foods in his *The New Dietetics* (1921). He invented foods such as an acidophilus soy milk in 1933, patented the following year, and a soy cheese and sold them through his Battle Creek Food Company. During his life, he received a total of thirty patents for food products, exercise equipment, and even an electric blanket. He also wrote more than fifty books.

At its zenith between 1915 and 1930, the sanitarium attracted many notable visitors such as Edgar Welch of grape juice fame, John D. Rockefeller, Jr., and J. C. Penney. In the early 1930's, the sanitarium experienced severe financial difficulties and was placed in receivership in 1933. After years of negotiations and reorganization, the U.S. government bought several of the main buildings in 1942. Kellogg had hoped to restore the sanitarium, but the ensuing legal and personal troubles adversely affected his health. He died on December 14, 1943, at the age of ninety-one.

Cereal Flakes

During the 1880's and early 1890's, patients at John Harvey Kellogg's Battle Creek Sanitarium (formerly the Western Health Reform Institute), a health retreat operated by the Seventh-day Adventists, began their day by eating dry granola. When an elderly woman complained that her dentures cracked upon eating the hard cereal, Kellogg began a search for ways to make dextrinized cereals that were more soluble. One product already available, shredded wheat, invented in 1893 by Henry D. Perky, did not appeal to his clients. In 1894, Kellogg discovered the process to produce the cereal flake quite by accident. Initially, he attempted to roll out kernels of raw wheat soaked in water, but he obtained only a separation of the starch from the bran. Then he cooked the wheat and forced it between rollers but obtained only a sticky paste. One day after boiling a quantity of wheat, Kellogg was called away before he tried to roll it. When he returned much later, the wheat dough had dried, but he decided to have it rolled out. He obtained flakes that produced a palatable, easily chewed cereal when toasted. With further experimentation, Kellogg and his brother discovered that the cooked wheat had to cool down before being rolled. Further trials determined how fast to pass the dough through the rollers, as well as how best to scrape off the flakes. Kellogg filed a patent on May 31, 1895, for the flaked wheat and its production process. The patent also applied to barley, oats, corn, and other grain flakes.

Kellogg handed over to his brother the management of the Sanitas Food Company that marketed the flaked cereal. During its first year of operation, the company manufactured fifty tons of the flaked wheat cereal that it called Granose. Other manufacturers found ways to infringe on Kellogg's patent, with the result of severe competition. The most famous flake, the corn flake, was not the invention of John Harvey Kellogg but his brother, Will Keith Kellogg. In 1898, Will developed the corn flake and made it more palatable by adding sugar, against his brother's food philosophy. Will introduced corn flakes commercially in 1905 and in the following year acquired exclusive rights to it from his brother. In 1906, he founded the Battle Creek Toasted Corn Flake Company, renamed the Kellogg Toasted Corn Flake Company in 1909, and reincorporated simply as the Kellogg Company in 1922, after it had expanded its product line.

Impact

The development of ready-to-eat cereals revolutionized the breakfast habits of Americans. Before their introduction, a typical American breakfast consisted of ham and fried potatoes. Kellogg's flaked wheat cereal enjoyed sales of more than fifty tons at twelve cents a pound during its first year. A sixty-cent quantity of grain could thus be turned into $12 in sales. This success and the potential for profit inspired a number of competitors, including C. W. Post, who had been a patient at the Battle Creek Sanitarium. Post introduced Grape Nuts in 1897 and in 1908 introduced Elijah's Manna, a corn flake cereal, later sold as Post Toasties. By the first decade of the twentieth century, more that forty companies selling cereals existed in the area around Battle Creek. Almost immediately, the competitors found ways to circumvent the patent taken out by Kellogg by adding ingredients to the flakes, for example. The courts ruled the patent invalid in 1903.

While Kellogg's views on autointoxication soon met with disavowal from the medical profession, some of his products, such as the meat substitutes, did find markets in European countries, notably Germany. Eventually, foods such as soy and yogurt reached the standard market in the United States. Another food introduced by Kellogg, the psyllium seed, is the ingredient in contemporary laxative foods. Ironically, cereal is not highly nutritious unless fortified.

Lord Kelvin

Irish physicist and engineer

Lord Kelvin was the great pioneer of thermodynamics and the architect of the Atlantic cable, but his most significant contribution to the evolution of science was his amazingly prolific development of new measuring devices and his insistence on the crucial significance of accurate and assiduous measurement as the key to success in pure and applied science.

Born: June 26, 1824; Belfast, Ireland (now in Northern Ireland)
Died: December 17, 1907; Netherhall, Ayrshire, Scotland
Also known as: William Thomson (birth name); Baron Kelvin
Primary field: Physics
Primary inventions: Absolute temperature scale; Atlantic cable

Early Life

William Thomson was the second son, among seven children, of James Thomson (1786-1849) and his wife, Margaret, née Gardner (c. 1790-1830). Both his parents were Scottish, but at the time of his birth his father was professor of mathematics at the Royal Belfast Academical Institution in Ireland. In 1832, however, James took the chair of mathematics at what was then Glasgow College (subsequently renamed the University of Glasgow). Thinking that he could educate his children better than any school, James Thomson educated them at home but allowed William and his older brother James to matriculate at the college in 1834, when William was still only ten years old. The two brothers worked very closely together thereafter, although William was broadly interested in natural philosophy, while James was more strictly an engineer.

Thomson became eligible for his Glasgow bachelor's degree in 1839 but did not take it because he wanted to study as an undergraduate at Cambridge University. He entered Peterhouse College on April 6, 1841, where his academic brilliance was soon recognized and rewarded, although he spent a great deal of time rowing and playing the cornet—with the result that he graduated only second in his class, losing the coveted title of "senior wrangler" to a more assiduous rival. Thomson was appointed as a fellow in June, 1845, and immediately took on editorial responsibility for the *Cambridge Mathematical Journal* (*CMJ*), in which he had already published eleven papers; these included the first of his pioneering papers on heat conduction, which drew a mathematical analogy between that process and electrostatic induction.

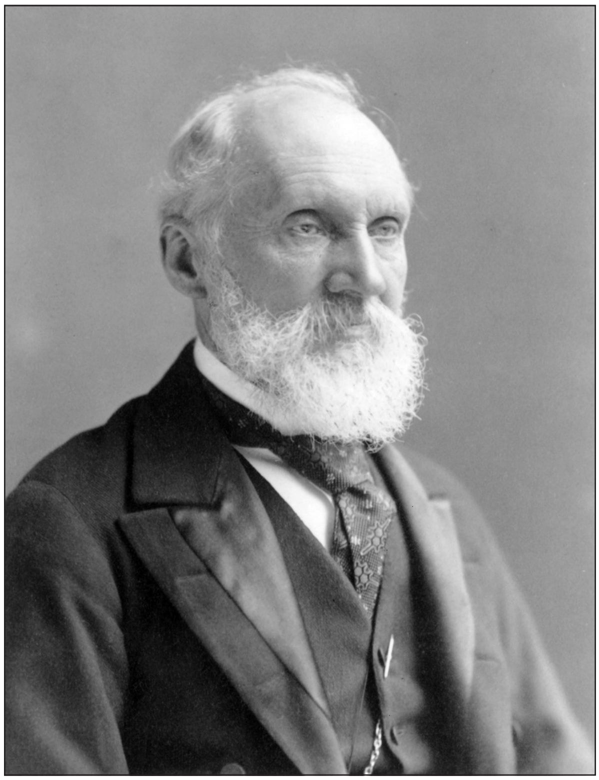
Life's Work

Thomson was, effectively, biding his time in Cambridge while waiting for an opportunity to open up at Glasgow. The death of Professor William Meikleham in May, 1846, vacated the chair of natural philosophy, to which Thomson was unanimously elected on September 11 of that year. Thomson continued to edit the *CMJ* for several more years, however, contributing a further thirty papers to the journal by 1850. He gave up his editorship in 1852 after failing to persuade the journal's owners to broaden the scope of the *CMJ* to take in applications of mathematics to the whole field of natural philosophy. He was initially delighted when the second wrangler of 1854, James Clerk Maxwell, took up his crusade, as well as carrying forward his work in electrostatics. In September, 1852, Thomson married his cousin Margaret Crum, the daughter of a prosperous cotton manufacturer who had a strong interest in industrial chemistry; unfortunately, her health broke down thereafter and she remained an invalid until her death in 1870.

As soon as he had succeeded Meikleham, Thomson, in alliance with other young professors, embarked on a crusade to reequip the university's laboratories, which succeeded so well that Glasgow became one of the leading research centers of the period. He did the same again, much later, when the university moved to a new site in Gilmorehill in 1870, supervising the building and equipment of a state-of-the-art physics laboratory. The necessity of having the best equipment, and constantly improving that equipment, was an obsessive conviction that provided the foundation for all Thomson's discoveries; in order to apply mathematical precision to physical problems, accurate measurement was a fundamental necessity, and it was his talent for refining measuring devices that facilitated his practical discoveries.

Thomson had long been aware of the existence of an extremely rare and esoteric treatise by Nicolas Léonard Sadi Carnot on heat conduction but only managed to lay his hands on a copy in 1849. By that time, Thomson's own research had made significant progress: He had developed the absolute scale of temperature named for him a year earlier, and he was immediately able to fuse his ideas with Sadi Carnot's to develop the initial formulation of the principle of the conservation of energy and the first and second laws of thermodynamics. The word "entropy" was not co-opted until much later, but it was Thomson who realized the importance of the concept and its application to the conversion of energy in various kinds of machines. It was he who popularized the term "energy" as a fundamental concept in physics.

Because he was interested in evolutionary theory—having read Robert Chambers's *Vestiges of the Natural History of Creation* (1844)—Thomson immediately attempted to apply his thermodynamic insights to the question of the age of the Earth in an article for the *Philosophical Magazine*. His argument estimated the time span during which the Sun had been radiating (and would continue to radiate) heat, based on the assumption—borrowed from Hermann von Helmholtz—that its heat must be derived from the energy of gravitational collapse. His conclusion, that the solar system must be millions of years old, helped pave the way for Charles Dar-



William Thomson, Lord Kelvin. (Library of Congress)

The Atlantic Cable

William Thomson's investigations of the transmission of signals in submarine cables, initially carried out in the laboratory, revealed that the crucial technical problem blighting the technology arose from the variations in the quality of supposedly pure copper cables. In order to introduce better quality control, it was necessary to introduce more accurate measuring devices into the production and deployment of such cables; the key invention that facilitated the latter part of this prospectus was Thomson's marine mirror galvanometer, which accompanied him on his expeditions aboard cable-laying ships in 1858.

Thomson eventually took charge of the first attempt to lay an Atlantic cable by the HMS *Agamemnon*; that cable broke, but Thomson was able to prove that the fault lay in the materials, not his calculations. The first cable that Isambard Kingdom Brunel's *Great Eastern* attempted to lay in 1865 also broke, but another was successfully laid the following year and the former was subsequently repaired, launching a new era in transatlantic communication.

Thomson was not as closely involved in the second phase of the operation as he would have wished, because he had broken his leg in 1861 while curling at Largs, and this had restricted his movements. Once the cable was laid, however, he became intensely involved in the practicalities of its usage, in association with Fleeming Jackson and Cromwell Varley, and he was primarily responsible for the refinement of the equipment over the next fifteen years, making the endeavor one of the most triumphant examples of nineteenth century applied science.

win's evolutionary theory, which required some such time span but also suggested that the Earth's future was considerably more limited than its past—an idea that had a considerable influence on the imagery of subsequent futuristic fiction.

Thomson became a fellow of the Royal Society in 1851, and his prestige was such by then that he was asked in 1854 to tackle the thorny problems associated with the transmission of electricity and telegraphic signals in submarine cables. In order to put his mathematical analyses of the problem to the test, in the laboratory and the field, he needed to develop new measuring devices. His association with instrument maker James White, begun in 1845, became crucial to this research. In 1856, Thomson became a director of the Atlantic Telegraph Company, and he accompanied its first expedition in 1857. The eventual fruition of this endeavor won him a knighthood in 1866. He began taking out patents for the new instruments he devised, the first of them being granted in 1865; he had seventy to his credit by the time he died. All the signals transmitted by submarine cables between 1866 and 1883 employed his instruments, and the various electrometers he devised formed the basis of designs used in laboratories and workshops the world over. He also developed conventional depictions of electrical circuits ancestral to those still in use.

The wealth generated by his telegraphic patents allowed Thomson to buy a 126-ton yacht, the *Lalla Rookh*, in 1870, which became a floating laboratory and home-away-from-home. He undertook numerous cruises in the boat, experimenting with sounding devices and compass housings—coming up with improved designs in both instances, which were gladly adopted by the Admiralty. While docked in Madeira on one such expedition, he made the acquaintance of the Blandy family and married Frances Anna Blandy (c. 1838-1916) in June, 1874. In the meantime, his association with James White continued to develop; by 1880, they were joint owners of a major instrument factory, although the partnership was not formally incorporated until 1900.

Thomson began work on an ambitious *Treatise on Natural Philosophy* (1867; expanded 1879) in collaboration with his colleague Peter Guthrie Tait, but the projected later volumes were never completed because he was too busy with his practical endeavors. The core of Thomson's life's work was represented by the vast quantity of his scientific papers. A collection of those on electrostatics and magnetism was issued in 1872, and the remainder was assembled in a six-volume set between 1882 and 1911. In 1871, he became the president of the British Association, and he served several terms as president of the Royal Society of Edinburgh before becoming president of its London parent from 1890 to 1895. He had been awarded its prestigious Copley Medal in 1883. He was elevated to the peerage in 1892. He had begun building a large house at Netherhall in the 1870's, which became his country seat and permanent residence when he eased up on his globetrotting, although he owned a town house in London as well.

Like many other men, Kelvin became increasingly set in his ideas as he grew older, and he became stubbornly hostile to the scientific theorists whose work threatened to render his obsolete, especially James Clerk Maxwell. Kelvin remained a stubborn positivist, deeply antipathetic to Maxwell's tendency to invent unobserved—and sometimes unobservable—entities in response to the mathematical elegance of his theory of electricity. Kelvin also refused to relinquish the theory on which he had based his estimate of the Sun's age when younger men began to favor the hypothesis that the Sun's heart was actually generated by radioactivity. These late lapses could not detract, however, from the enormity of his earlier achievements.

Impact

During his lifetime, Kelvin made a tremendous impact on technological development by virtue of his contributions to instrumentation and telegraphy, and his formulation of the fundamental principles of thermodynamics guaranteed him an important niche in the history of scientific theory. As measuring instruments were further refined and telegraphy became much more sophisticated in the twentieth century, his particular contributions became less noticeable, relegated to the status of a phase in technological evolution, but they were nonetheless crucial—a fine testimony to his unrelenting inquisitiveness and practical genius.

Perhaps ironically, Kelvin's off-the-cuff attempt to calculate the likely life span of the Sun based on the mistaken assumption that its heat was generated by the energy of gravitational collapse continued to be widely quoted long after the discovery that the Sun's heat is actually generated by nuclear fusion. Although it was intended to deliver a killing blow to contemporary creationist accounts, the essay's estimate of the age of the solar system is nowadays frequently cited by creationists avid to challenge more modern and more reliable calculations, which estimate the age of the Earth in billions of years rather than millions. Such mischievous citations have, alas, deflected some attention away from the towering example Kelvin provided in his own day.

—Brian Stableford

Charles F. Kettering

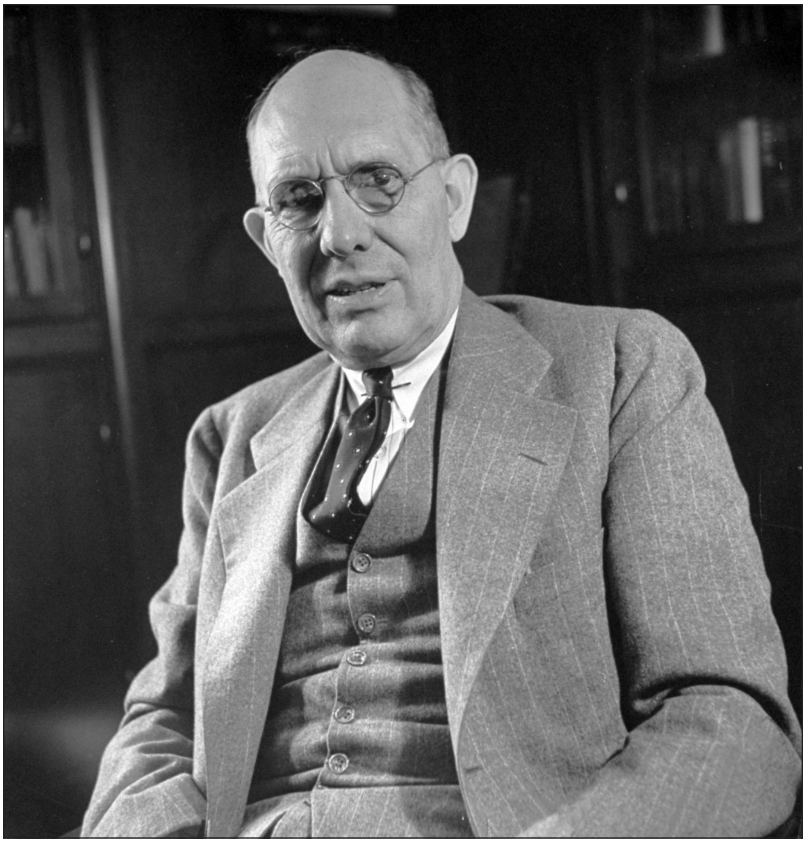
American electrical engineer

Kettering is sometimes referred to as the Thomas Alva Edison of the twentieth century. His numerous inventions contributed to a wide range of fields and included devices that improved railroad engines, automobiles, refrigerators, and airplanes.

Born: August 29, 1876; Loudonville, Ohio
Died: November 25, 1958; Dayton, Ohio
Also known as: Charles Franklin Kettering (full name)
Primary fields: Automotive technology; electronics and electrical engineering
Primary inventions: Freon refrigeration and air conditioning; electric starter; Kettering Aerial Torpedo

Early Life

Charles Franklin Kettering was born on August 29, 1876, in Loudonville, Ohio, where his parents, Jacob and Martha Kettering, owned a farm. As a child, he was educated in a one-room schoolhouse, then attended Loudonville High School on an academic scholarship. Determined to go to college, he taught school for three years to raise the



Charles F. Kettering. (Time & Life Pictures/Getty Images)

necessary funds. He entered Ohio State University in 1898 to study electrical engineering and worked for the Star Telephone Company digging holes for telephone poles.

While Kettering worked for Star, supervisors noted his ability to fix things and discover new ways of solving problems. He showed an aptitude for ascertaining and resolving difficulties that Star engineers could not. For example, when Star was unable to bring service to remote rural areas because of issues with overheating, Kettering resolved the problem by creating a relay system that extended the lines' reach to outlying areas.

A bout of scarlet fever as a child left Kettering very nearsighted. During college, he suffered severe headaches that forced him to leave school in order to save his eyesight. When he returned to Ohio State, his attendance was spotty, as there were months at a time when he was unable to read. Still, with the help of friends who read book assignments to him, he was finally able to graduate with a degree in electrical engineering in 1904 at the age of twenty-eight.

Life's Work

Edward Deeds, chief of research and development for the National Cash Register (NCR) Corporation in Dayton, Ohio, contacted Ohio State seeking an innovative engineer. The engineering department recommended Kettering for the job, and Deeds hired him to work for NCR's research department for $50 per week. Kettering moved to Dayton and on August 8, 1905, married Olive Williams. Their only child, Eugene, was born on April 20, 1908.

The first challenge Kettering tackled at NCR was the issue of obtaining credit approvals for customers in department stores. At the time, the process required a cashier to leave his or her post and go to a separate office to receive approval; this process took a long time and frustrated customers and cashiers alike. Using knowledge acquired from his work with the telephone company, Kettering developed a phone attachment for the cash register. Without leaving their stations, cashiers accessed the credit office through a phone line attached to the register and received quick credit approval for their customers. From their distant office, credit managers had only to push a button at their desk to stamp approval directly onto the customer's receipt at the checkout counter. Next, Kettering replaced spring-powered cash registers with electronic machines by creating a small engine to power the machine. The new electronic register made NCR the leader in its field for many years to come. Kettering also developed an accounting machine for banks that rid them of the need to write account cards for each customer. During Kettering's five years at NCR, he was awarded twenty-three patents.

During evenings and weekends, Kettering worked on improving the automobile, a new invention that was sweeping the nation and that piqued Kettering's curiosity. He tinkered with the idea of a new ignition system for automobiles. The ignition system in use at the time relied on dry-cell batteries that worked well at normal to high speeds but sputtered and frequently died at low speeds. The batteries were expensive and required replacement after only a few hundred miles. Deeds, also fascinated with the idea, loaned Kettering the use of his carriage barn to work on his idea. In 1909, Kettering resigned from NCR to work full-time on his new invention.

Kettering devised a stationary coil that provided a more continuous spark to the ignition. He installed the device on Deeds's car, and Deeds and his wife were able to drive from Dayton to New York City and back without stalling once. The new system also caused less wear and tear on the battery, which now lasted ten times longer. Kettering and Deeds sold the idea to Henry Leland, head of the Cadillac Motor Company, who ordered eight thousand of the new ignitions. With a big order but without a company to subcontract the manufacture of the ignitions, Deeds and Kettering formed the Dayton Engineering Laboratories Company (Delco) in 1909.

Kettering turned his attention to a new way to start the ignition. Early automobiles created the spark that started the ignition by the driver vigorously turning a crank on the front of the car. It took a strong back and a lot of muscle to do so, and sometimes drivers were injured in the process. Using the same principles he employed to electrify the cash register, Kettering developed a small engine that powered a self-starter that required only the turn of a key or push of a button, making the cumbersome crank obsolete. Cadillac Motors ordered twelve thousand electric starters. Unable to subcontract such a large order, Delco opened a factory near downtown Dayton to manufacture the new system. Soon, Delco's self-starting ignition became standard in all automobiles.

During Easter weekend in March, 1913, torrential rains and melting snows combined to threaten Dayton. On March 25, levees holding back the Mad and Miami rivers broke, causing floodwaters to storm into the city. Ninety-seven people and fourteen hundred horses died; $67 million in property was damaged. Fourteen thousand homes were destroyed and fifty thousand residents needed shelter. The Delco factory was under twenty-seven feet of water, and forty-seven men were stranded. Kettering made his way toward the floodwaters and helped establish electrical power to shelters and feed the newly homeless. He set up twenty-five prefab homes for Delco executives left homeless by the disaster and paid to rebuild and refurnish the homes of Delco employees that had been destroyed by floodwaters.

Kettering was also fascinated with the airplane. After learning how to pilot planes himself, he joined with Orville Wright and Edward Deeds to form the Dayton-Wright Company as a research facility in 1917. Plans for development were temporarily put on hold with the United States' entry into World War I in 1917. During the war, Kettering developed a new ignition system for the Liberty airplane, began work on a retractable landing

Kettering's Refrigerator

Charles F. Kettering's inventions were not confined to the transportation industry. Along with Thomas Migley, Jr., the chemist at General Motors (GM) who assisted in the development of a quick-drying automotive paint and ethanol gasoline, Kettering developed an improved cooling system for refrigerators. Refrigerators of the time used dangerous gases such as ammonia, sulfur dioxide, and methyl chloride to generate the rapid evaporation needed to cool the unit. Several people, including more than one hundred people in a Cleveland hospital in 1929, were killed when chemicals leaked from their refrigerators and they breathed in the toxic fumes. Most home refrigerators were iceboxes that used large chunks of ice, delivered by an ice man. Kettering and Migley's version of a refrigerator replaced the cumbersome brine tank and toxic chemicals with a Freon-charged coil compressor. The new chemical compound ran through a compressor, which heated the Freon, then ran through a series of coils, turning it into a cool liquid that absorbed food heat and evaporated a cool vapor. In 1930, Migley demonstrated the safety of Freon by boiling it and breathing in the vapors before a gathering of chemists.

Production of Freon was taken over by DuPont. GM formed a new division to make household refrigerators, and Kettering was named the first vice president of the newly formed Frigidaire Division. The first automobiles with air conditioning were introduced in 1939 by Packard Motor Car Company. Freon was used as a propellant in aerosol cans for items ranging from hairspray and deodorant to insecticides. The manufacture of Freon was banned in 1996 because of concerns over the effects of the chlorofluorocarbon (CFC) on the environment, as CFCs contribute to the breakdown of the Earth's ozone layer.

Kettering expanded on his refrigeration ideas by designing a central air-conditioning system for the home he was building in Dayton, Ohio, Ridgeleigh Terrace. With the addition of ductwork and a fan system, his twenty-room residence became the first home in the United States to be air conditioned. His air-conditioning design was later used for homes, theaters, office buildings, and factories. It is believed that the addition of air conditioning to warehouses and factories contributed to a significant increase in productivity due to the improved comfort level of the workers.

gear, and designed an unmanned aerial vehicle (UAV). The body of his Kettering Aerial Torpedo, also known as the "Kettering Bug," was constructed of wood and papier-mâché. It carried three hundred pounds of explosives fifty miles to a target, then dropped its load on the enemy. The Defense Department ordered forty thousand of the UAVs, but the Armistice was signed before they could be put to use extensively.

Kettering sold his interest in Delco to General Motors (GM) in 1916 for 100,000 shares of stock and became the head of the newly formed General Motors Research Corporation. During his twenty-seven-year tenure at GM, Kettering's research department developed a diesel engine for railroad engines that, within a few years, completely replaced the steam engine. The department developed safety glass to reduce injuries during accidents, oversaw the development of leaded gasoline to reduce engine knocking in automobiles, and created quick-drying automotive paint. Kettering's parents, who still lived on their farm in Loudonville, Ohio, were still without electricity, so Kettering devised a generator system using batteries that brought electricity not only to his parents' farmhouse but also to homes and farms in rural areas throughout the country.

Kettering became a very wealthy man, and his philanthropic spirit had long-term effects. The Virginia Kettering Foundation, the Kettering Family Foundation, and the Kettering Medical Center teaching hospital and foundation continue to offer research, medical, and educational funding. During the 1940's, Kettering's older sister, Emma, died of cancer. In 1945, Kettering joined with Alfred P. Sloan, another GM executive, to form the Sloan-Kettering Cancer Research Institute to investigate causes and cures for the disease. The following year, Kettering's wife, Olive, died of pancreatic cancer. Research, treatment, and education continue today at the research institute. Sloan-Kettering remains one of the top in its field in the areas of research, diagnosis, treatment, and prevention of cancer. Its hospital facility treats tens of thousands of patients annually and disseminates information to thousands online and through publications. Its educational facility provides training for doctors in cancer treatment and research.

Kettering also served as a trustee of and was a major contributor to Antioch University in Yellow Springs, Ohio. In addition to loans and grants to the university, he contributed money for a library and a science building. On June 24, 1955, Van Buren Township incorporated and became the city of Kettering, Ohio, named for its most famous citizen.

Kettering retired from General Motors in 1947 at age seventy-one. While there, he gained the nickname the "Wizard of General Motors" and acquired 140 patents. In retirement, he traveled throughout the country, often flying himself to the destination, to give thousands of speeches. He continued research at his home in Dayton, transforming his basement bowling alley into a research laboratory where he was particularly interested in discovering the way plants transformed sunlight into food energy. Kettering died from a stroke on November 25, 1958. He was survived by his son, Eugene, and wife, Virginia, who continued to oversee his philanthropic organizations.

Impact

Kettering's wide array of inventions added convenience to the American lifestyle: Cars were easier to start and run, and engines knocked less frequently; homes and buildings were made more comfortable with air conditioning, and kitchens had more efficient, roomier refrigerators; rural homes were electrified and provided with telephone service.

Kettering believed that his research in photosynthesis would someday lead to an inexpensive and efficient fuel system for automobiles. By studying how plants transform sunlight into food, Kettering hoped to create automobiles that ran on sunlight. The ideas Kettering first used for the creation of the Kettering Aerial Torpedo led to the development of numerous unmanned air vehicles used for military surveillance and bombing operations.

Some of the implications of Kettering's inventions were unanticipated. When automobiles first hit the road, there were few female drivers. The strong arm and back necessary to start a car frequently required a man's assistance. One of the impacts of Kettering's improvement to ignition systems was an increase in the number of female drivers. Author Rosamond Young theorized that soon after the electric starter became standard in automobiles, women's skirts became shorter and petticoats began to disappear. Long skirts got in the way of automobile brakes and accelerator pedals. Thus, it is possible that Kettering's invention even had an effect on women's fashions.

Al-Khwārizmī

Persian mathematician and astronomer

Al-Khwārizmī was one of a number of scholars from various areas of the ninth century ʿAbbāsid caliphate who, through sponsorship from the caliphs, gathered and developed scientific knowledge pioneered by earlier Indian, Greek, and Roman civilizations. Much of their work, including al-Khwārizmī's famous mathematical treatises, passed on to Europe through medieval translations from Arabic to Latin.

Born: c. 780; probably Khuārizm (now in Khiva, Uzbekistan)
Died: c. 850; possibly Baghdad (now in Iraq)
Also known as: Muḥammad ibn Mūsā al-Khwārizmī (full name)
Primary fields: Astronomy; mathematics
Primary invention: Algebra

Early Life

It is difficult, if not impossible, to reconstruct personal details concerning the early life of al-Khwārizmī (ahl-KWAHR-ihz-mee). A Persian by ethnic origin, al-Khwārizmī was born about 780, probably in Khwārizm (the modern-day region of Khiva, located south of the Aral Sea in Uzbekistan). There is some disagreement about his actual place of birth, in part because Khwārizm in that period was a subregion of the ʿAbbāsid caliphate's vast eastern province of Khorāsān, the borders of which were not clearly defined. He died near the age of seventy possibly in Baghdad, capital of the ʿAbbāsid caliphate. Because so little is known about al-Khwārizmī's life prior to his long stay in Baghdad, it is reasonable to assume that—like so many notable figures whose careers were eventually made in the ʿAbbāsid capital—he probably moved in stages from the quite undeveloped eastern regions of Islam, possibly staying for periods in politically and culturally advanced centers that had developed in Khorāsān, especially in the era of the Samanids, whose ascendancy after 819 in Balkh (now in northern Afghanistan) extended westward into ʿAbbāsid Iran. The fact that most of al-Khwārizmī's scholarly life was passed in Baghdad may have tempted some, including the well-known annalist al-Ṭabarī (c. 839-923), to assume that he was actually born in a region close to the capital.

Life's Work

It was during the caliphate of al-Maʾmūn (r. 813-833) that a very important step was taken to establish Baghdad as a center of learning that would attract scholars from distant places. Building on precedents begun by his famous father, Caliph Hārūn al-Rashīd (r. 786-809), al-Maʾmūn founded an institution known as the Bayt al Hikma (house of wisdom). His goal was to bring to Baghdad Muslim scholars who could advance various fields of knowledge by delving into translations of major Greek and Sanskrit works. It is generally agreed that the Arabic translations of Greek texts that were subsequently lost in the original eventually provided a channel for "recovery" (via translation from Arabic into Latin) of major works in Hellenic philosophy and science. Indeed, several works in Arabic of al-Khwārizmī himself would eventually be saved from oblivion thanks to medieval European scholars translating the Arabic works into Latin. As part of his patronage to knowledge and science, al-Maʾmūn also built several observatories to facilitate astronomical studies, a field which al-Khwārizmī pursued with great interest.

Before turning to al-Khwārizmī's experiences at the Baghdad court and the scientific contributions he made during his career there, it is important to note that—because the Bayt al Hikma possessed a substantial library of manuscripts brought from India—there are a number of links between the work of al-Khwārizmī himself and Indian science and mathematical accomplishments. An outstanding example of this is frequently cited, even though somewhat misleading terminology is used in the general literature. A treatise he wrote when he was about fifty years old explored the attraction of using Hindu numerals, including the invaluable device of the zero, in making mathematical (indeed, even simple arithmetic) calculations. The use of these "Arabic" numerals—which, thanks to the adoption throughout the Arabic-speaking world of al-Khwārizmī's version of what the Hindus had developed originally, spread to Europe by around the twelfth century—greatly simplified methods of calculation by comparison to the unwieldy methods associated with Roman numerals.

Few scholars doubt that it was *Kitāb al-jabr wa al-muqābalah* (c. 820; literally, "the book of integration and equation") that established al-Khwārizmī in the annals of science and mathematics. Indeed, the word "algebra" is derived from the term *al-jabr*, even though that particular branch of mathematics formed only part of al-Khwārizmī's concerns in this very extensive work. The book does, however, stand as a major systematic treatment of what became the subfield of algebra. By the time the book was translated into Latin in the twelfth century, most earlier works exploring what would become the main principles of algebra (ranging from Chinese and Indian studies dating from the first century B.C.E. through the key third century C.E. book *Arithmetica* by Diophantus of Alexandria) had been lost, making al-Khwārizmī's work an absolutely essential source. His intention in this work was more practical than theoretical. He frequently underlined the need for mathematical methods that could facilitate practical projects, such as canal digging and land surveys, and basic social interactions, such as calculation of inheritances and contractual dealings.

Al-Khwārizmī's discussions of the various uses of what would later be called linear and quadratic equations, on the other hand, pioneered what became essentials for modern mathematics. Stated in layman's language applying to modern algebra, each term in a linear equation is either a constant or the product of a constant multiplied by the first power of a variable. Also in modern algebraic language, quadratic equations, which are used widely in solving geometric problems, are referred to as polynomial equations of the second degree.

Partly as a result of the wealth of information contained in Al-Khwārizmī's magnum opus, later students of the Latin translations associated his name with other major landmarks in mathematics. The term "logarithm," or "algorithm," for example, is a corrupted version of his name, as are the Spanish and Portuguese words for "digit," *guarismo* and *algarismo*, respectively.

Al-Khwārizmī's contributions to the field of astronomy—gathered under the title *Sindhind zij*—seem, as the title suggests, to have been the result of his exposure to Indian texts that reached Baghdad some time in the eighth century, together with basics contained in the astronomical tables of Ptolemy (c. 100-c. 178). Although the original versions of this work were lost, a Latin translation by Adelard of Bath of an Arabic tenth century synopsis of the original (plus other more extensive Latin versions) saved his findings for posterity. The main foci of al-Khwārizmī's work took the form of calendars. These were supplemented by calculations establishing the relative positions of the Sun, Moon, and known planets—opening the possibil-

Algebra

Closer examination of the historical record shows that—although the word "algebra" derives from the Arabic word for "balancing" (*al-jabr*) in the title of al-Khwārizmī's major work, *Kitāb al-jabr wa al-muqābalah* (c. 820)—the ninth century Baghdadi scholar did not himself "invent" this important branch of mathematics. Nevertheless, Europeans who drew from Latin translations of his Arabic works could not have made advances in mathematics in the medieval era without his work. It is important to note that a number of issues associated with algebra that were of major concern to al-Khwārizmī drew the attention of other Muslim mathematicians—Persian scholars in particular—in the centuries immediately following his work and well before the "jump" was made linking ninth century Baghdad to the twelfth century Latin translation of *Kitāb al-jabr wa al-muqābalah* by Robert of Chester. This means that the principles of algebra were being refined and expanded within the Islamic world and India (probably drawing on al-Khwārizmī's book) in a more or less continuous way at least into the period of the Seljuk (Turkish) sultanate, which took over Baghdad in the mid-eleventh century. It was the Persian al-Māhānī (820-880), for example, who, confronting problems involving spheres and cylinders contained in the work of Archimedes, pioneered efforts to apply algebraic formulas to solve problems in geometry.

That the promising bases of al-Khwārizmī's work on algebra spread rapidly eastward within the broad cultural borders of the Islamic world (and possibly even farther) before they were "recovered" by Europeans is suggested by the significant number of ninth and tenth century Indian manuscripts citing and expanding on his mathematical theories.

ity of predicting eclipses of the Sun and the Moon. Many experts view the astronomical tables as a sort of composite work drawn from Hindu precedents and, to some degree perhaps, close examination of Ptolemy's second century work *Almagest*.

Al-Khwārizmī's scientific and mathematical involvement in astronomy may have tempted him to speculate on the usefulness of another field, astrology, as a guide to things less scientific. An example of this was a lesser work, essentially political in nature, which offered horoscopes of well-known individuals in the Baghdad court of his time.

Geography may be the area in which al-Khwārizmī's direct debt to Greek predecessors, and to Ptolemy in particular, is most obvious. The full title of his book *Kitāb ṣūrat al-arḍ* (book of the image of the Earth), tentatively dated near 833, actually gives direct credit to Ptolemy as its model. The work attempted to establish an accurate grid of longitudes and latitudes that, although at this early date could not encompass the (not yet known) entire spherical globe, did provide a system of calibration for locating some twenty-five hundred geographical sites. These included mountain regions, seas, and rivers, as well as well-known cities of the day. Al-Khwārizmī was also aware that his system could lay out and distinguish between "weather zones" falling at different latitudinal levels.

Impact

Al-Khwārizmī stands out as the most prominent representative of mathematical science as it was fostered in the court of the Arab ʿAbbāsid caliphs, especially under Caliph al-Maʾmūn. As his name suggests, al-Khwārizmī, like so many scientific and literary figures at the ʿAbbāsid court at that time, was not of specifically Arab origin. However, the Arabic texts he wrote, along with those of the philosopher al-Fārābī (who was also Persian by origin) and others active in Baghdad, filled a very important role. Without these Arabic texts, later European students of science and philosophy in the Middle Ages would have been deprived not only of such valuable original Islamic contributions to these fields of knowledge but also of such scholars' preservation of Greek sources that were subsequently lost.

Jack St. Clair Kilby

American electrical engineer

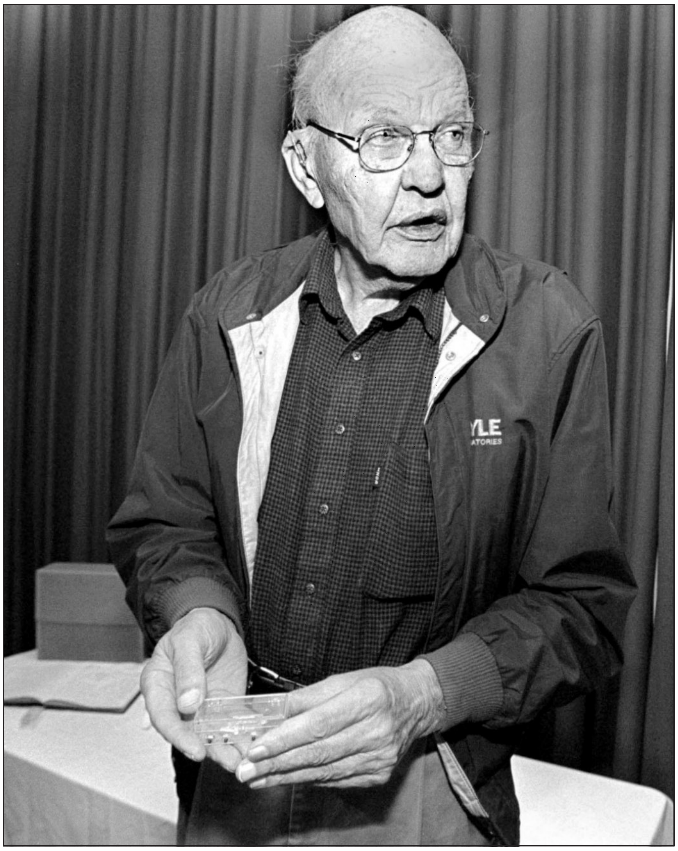
Inventor of the integrated circuit, for which he received the Nobel Prize in Physics in 2000, Kilby also invented many of its applications, such as the calculator, as well as unrelated inventions, such as the thermal printer.

Born: November 8, 1923; Jefferson City, Missouri
Died: June 20, 2005; Dallas, Texas
Primary field: Electronics and electrical engineering
Primary inventions: Integrated circuit (microchip); handheld calculator

Early Life

Jack St. Clair Kilby was born in Jefferson City, Missouri, in 1923. His father, an electrical engineer, moved to western Kansas a few years later, and young Jack often accompanied his father, who eventually became president of the Kansas Power Company, on inspection tours of power stations. Graduating from Great Bend High School in 1941, Kilby applied to Massachusetts Institute of Technology but missed the cutoff on the entrance exam by three points. Scrambling to apply to another school, he was accepted at the University of Illinois at Urbana-Champaign, but four months into his freshman year the United States entered World War II; a few years later, Kilby entered the U.S. Army Signal Corps, and later the Office of Strategic Services (the predecessor of the Central Intelligence Agency), stationed in India and China.

After the war, Kilby finished his bachelor of science degree in engineering at Illinois in 1947. He was hired by Centralab in Milwaukee, and while he worked there Kilby pursued a master's degree in electrical engineering from the University of Wisconsin-Milwaukee, which he received in 1950. At that time, Bell Labs was licensing electronics firms to produce the new transistor, and Kilby was chosen to attend the seminars in New York, a crash course in this cutting-edge technology. In 1958, Kilby joined the engineering team at an electronics firm in Dallas called Texas Instruments (TI). It was a TI tradition that all engineers take the same two weeks in summer for vacation, but because he had just been hired, Kilby was not yet eligible for vacation. Alone in the lab for two weeks, Kilby worked out the idea that would become the microchip.



Jack St. Clair Kilby holds his original design of the integrated circuit at Texas Instruments in Dallas, Texas, in 2000. That year, Kilby was awarded the Nobel Prize in Physics for his invention, which he built about forty years earlier. (AFP/Getty Images)

Life's Work

The problem that Kilby had set out to solve that summer alone in the lab was the single most vexing problem of the electronics industry in the middle of the twentieth century. The appearance of the transistor in 1948 had created unrealizable expectations of miniaturization on the part of the electronics consumer (particularly the military). The popular imagination expected Dick Tracy-type two-way wrist radios and computers that could fit on a desk. Neither was possible because of what engineers called the "interconnection problem," or the "tyranny of numbers." Even though the transistor was smaller, more durable, and cheaper than the vacuum tube it had replaced, it still had to be wired physically to other components in a circuit—which imposed a physical limit on miniaturization. Yet each digit of a digital calculation required a separate wire connection. With literally millions of connections in some complex equipment, hundreds are bound to fail.

Kilby's solution started with the fact that his new employers, Texas Instruments, had invested heavily in silicon, hoping to make transistors out of them. The basic components of electronics that had to be wired together were made of different materials—resistors of carbon, capacitors of metal and porcelain, transistors of germanium crystals. TI had already made transistors out of silicon by doping pure silicon with impurities such as arsenic. Silicon is a semiconductor, which means that on a scale of conductivity it is exactly halfway between conductors and nonconductors, or insulators. In its pure state, silicon will not conduct electricity, but the portion doped with the right impurities (called a "dopant") will become a conductor. One type of dopant will give the silicon a negative charge, another a positive. The doped portions would become the connections, eliminating the need for wires, and the pure silicon sections would be insulators. Kilby's idea did not stop there, however. He realized that resistors, capacitors, and transistors would not have to be manufactured separately and then wired together: A complete circuit could be manufactured together on one slice of silicon.

When the rest of the engineers returned from vacation, Kilby presented his idea to his boss, Willis Adcock. Adcock was interested, but did not think he could divert the company's resources from a U.S. Army contract they were working on, an alternative solution to the tyranny of numbers that Kilby felt (rightly) was doomed to fail. Kilby quietly pushed, and finally Adcock agreed to attempt the solution. If Kilby could produce a working resistor and a working capacitor out of silicon (they had already made workable transistors), TI would go ahead with the project of manufacturing them all in one piece—the solution that Kilby called the "monolithic idea."

The Microchip

Jack St. Clair Kilby's solution to the miniaturization problem that faced the electronics industry in the late 1950's was both elegant and far-reaching. Kilby's role in the development of the integrated circuit, or microchip, is usually presented as conceptual, but he also worked on the prototypes of actual chips at Texas Instruments (TI) in the late 1950's and early 1960's. His starting point was TI's method of making transistors. Early transistors were of the point-contact type: negatively charged and positively charged portions were connected by tiny wires. The silicon transistors developed at TI before Kilby arrived there were of another type, known as "grown-junction," in which the positive and negative areas were made as the silicon crystal was being grown by introducing one type of dopant that would give the silicon a negative (N) charge, then another that would make the silicon positive (P), then another that would produce a negative charge. This NPN "sandwich" would create an electron flow through the crystal—a small, and relatively inexpensive transistor.

Kilby had studied British radar engineer Geoffrey Dummer's unsuccessful attempt just a few years earlier (1956) to create whole circuits out of a single block of material. Kilby's "monolithic idea" was a realization of the same idea, and he was able to do it in the laboratory. The resistance of the pure silicon itself would act as a resistor; the difference in potential at the PN juncture of the doped silicon was essentially a capacitor; the silicon transistor already existed. Kilby first had to prove that working silicon capacitors and resistors could be made. He cut resistors out of pure silicon and ground them to specifications with a dentist's drill. He made and tested capacitors. In September of 1958, he and his team succeeded in producing all three elements—capacitor, resistor, and transistor—in one block. He had produced the first microchip, leading the way to the era of the personal computer.

Kilby produced working resistors and capacitors, but they still had wires. Even though his idea called for wireless and solderless printed or solid-state circuits, the prototype had wires, a fact that caused the U.S. Patent Office to award priority of patent on the microchip to Robert Norton Noyce, who had a similar idea at Fairchild Semiconductor a few months after Kilby. The patent battle had very little effect on the development of the chip, however, or on the profession's acknowledgment of Kilby's role in it. Both Kilby and Noyce became known as coinventors of the microchip, and neither resented the other's role.

In 1965, the chief executive officer of TI, Patrick Haggerty, who had introduced the transistor radio a decade earlier, gave Jack Kilby the task of doing for the adding machine what the transistor had done for the radio—bring it down to pocket size. Kilby assembled a team to work simultaneously on the four components of digital computing—input, memory, processor, and output. Kilby himself worked on the power source and the output. The final product, a two-and-a-half-pound calculator with light-emitting diodes (LEDs) for output, and retailing at $150, appeared by the end of 1966, and sold tremendously.

In 1969, Jack Kilby was awarded the National Medal of Science by President Richard M. Nixon. In 1978, Texas A&M University recognized his stature in the field by naming him Distinguished Professor of Electrical Engineering. He taught at the university until 1985. Kilby was inducted into the National Inventors Hall of Fame in 1982, and he received the National Medal of Technology in 1990. In 2000, forty-two years after he first thought of the microchip, Jack Kilby received the Nobel Prize in Physics—despite the fact that the only physics courses he ever took were in an engineering curriculum.

Impact

There are very few elements of twenty-first century life that are not directly affected by Kilby's inventions—particularly the microchip. Watches (even some analog watches), cell phones, computers—and of course, that other Kilby invention, the electronic calculator—all today bear Kilby's "monolithic" circuits of silicon. Some of the lesser-known spin-offs from the chip are detailed by Kilby himself in his 2000 Nobel Prize lecture. The Internet, of course, is one spin-off he was quick to acknowledge (though he was notoriously slow for an engineer to begin using it), but less obviously, he reminds people that cars are safer and emit fewer pollutants because of devices his invention made possible. Kilby's knack for the less obvious solution might well be another important part of his legacy to engineering. His favorite adjective for his solution to the tyranny of numbers problem was "unobvious." As a sort of elder statesman at Texas Instruments from the late 1960's until his retirement in 1983, Kilby became part of the TI story: His picture and biography will doubtless remain a prominent part of TI's Web site. The company's research facility for the manufacture of silicon was renamed the Kilby Center. In 1990, the Kilby Award Foundation was created in his honor to identify important contributions to electrical engineering.

Mary-Claire King

American geneticist

King discovered the location for a gene that is responsible for some cases of breast and ovarian cancer, thus proving that the disease can be linked to heredity.

Born: February 27, 1946; Evanston, Illinois
Primary fields: Biology; genetics; medicine and medical technology
Primary inventions: *BRCA1* and *BRCA2* cancer gene identification; DNA profiling to identify human remains

Early Life

Mary-Claire King was born in Evanston, Illinois, on February 27, 1946, and grew up in nearby Wilmette, on the North Shore of Lake Michigan near Chicago. Her father, Harvey W. King, was an executive at Standard Oil of Indiana, chiefly responsible for labor relations. Like most other women of that era, Mary-Claire's mother, Clarice, was a homemaker, though she did work for the War Labor Board during World War II.

As a child, King liked puzzles. When she found that puzzle-solving often demanded mathematical skill, she developed an interest in that subject, even though she soon realized that it was considered an area in which only boys excelled. She was not drawn to science, however. At the prestigious New Trier Township High School, which she attended, science was not the exciting subject it became during the Sputnik era, when King's younger brother Paul was there. However, as a teenager, King witnessed her best friend in excruciating pain, dying of a kidney tumor, and that experience later impelled her toward medical research.

After graduating from New Trier, King went to Carleton College in Minnesota, majoring in mathematics. In 1966, when she was nineteen, she received her bachelor's degree, graduating Phi Beta Kappa. King then enrolled in graduate school at the University of California, Berkeley, planning to earn her Ph.D. in biostatistics, which she knew would be useful in medical research. However, a course she took from the famous geneticist Curt Stern aroused her interest in genetics, and she promptly changed her major. During the Vietnam War era, King became involved in the protest movement, finally dropping out of school to work with consumer advocate Ralph Nader. Discouraged because her scientific experiments were not working out, King considered accepting Nader's offer of a job in Washington, D.C. Fortunately, her friend Allan Wilson, a professor of biochemistry and molecular biology, persuaded her that disappointments are inevitable in scientific research, and she joined Wilson in a project comparing the genetic makeup of chimpanzees and humans, which became the subject of her dissertation. Their conclusion, that humans and chimpanzees are 99 percent genetically identical, placed the researchers on the cover of the April, 1995, issue of *Science* magazine.

King was awarded her doctorate in 1973. That same year, she married Robert Colwell, a zoologist, and they went to Santiago, Chile, to teach at the Universidad de Chile. However, following the assassination of President Salvador Allende in a military coup in September of that year in which many of their friends and students were brutally murdered, Colwell and King fled the country. The couple had a daughter, Emily, but they were divorced when she was five. King's subsequent experiences as a working single mother made her an advocate for women in the workplace.

Life's Work

Back in the United States, King spent a year at the University of California, San Francisco. At that time, she began looking for a gene that would account for multiple cases of breast cancer in the same family. In 1976, she joined the epidemiology faculty in the School of Public Health at the Berkeley campus. There, she continued to work on her research project. Finally, in 1990, she announced that she had identified the chromosome involved in the cancer and suggested the approximate location of the gene, which she named *BRCA1*.

In 1983, King was approached by a group of Argentine grandmothers whose sons and daughters had been murdered after the military coup of 1975. The grandmothers needed a geneticist to find their grandchildren, many of whom had been taken by military families and passed off as their own. King was able to find dozens of the children and return them to their families. She was also able to identify the remains of some of the young people who had been killed, thus aiding prosecutors in bringing criminal actions against the murderers.

In the 1990's, King decided to turn her talents to AIDS research. Her goal was to assess the role of genetics in the reaction of different individuals to the same disease. King had also become interested in the genetic causes of deafness. She created a team that included both Israeli and Palestinian scientists, thus demonstrating that political antipathies need not stand in the way of scientific progress.

In 1992 and again in 1999, King received the Susan G. Komen Foundation Award for Distinguished Achievement in Breast Cancer. In 1993, she was named a fellow of the American Association for the Advancement of Science. In 1994, she received the Clowes Award for Basic Research from the American Association for Cancer Research. That year, the American Cancer Society also named her the first recipient of the Walt Disney Research Professorship for Breast Cancer.

In 1995, King moved to the University of Washington in Seattle as a professor of medical genetics and genome sciences. She brought with her not only her own considerable research funds but also twelve assistants from her Berkeley lab, all of whom were supported by federal grants and fellowships. King worked with the Human Genome Project, whose goal was eventually to map all the human genes. Her lab focused on familial breast and ovarian cancer as well as prostate cancer. King also became an active participant in the Human Genome Diversity Project, which involved the study of genetic material from a number of distinct populations. These studies could reveal why certain groups are more susceptible to specific diseases than other groups. The studies will also help scientists to trace migration patterns and understand linguistic variations. Using mitochondrial sequencing, the researchers believe that in time they will be able to trace all humanity back to a common ancestor in Africa, called the "Mitochondrial Eve."

In 2004, King received the Genetics Prize of the Peter Gruber Foundation. In 2005, she was honored by being elected a member of the prestigious National Academy of Sciences. The following year, she received the Heineken Prize for Medicine from the Royal Netherlands Academy of Arts and Sciences for her work on breast cancer and the Weizmann Women and Science Award for her research in genetics. In 2008, she was given an honorary doctorate from Tel Aviv University.

BRCA1

Though her colleagues scoffed at the idea, Mary-Claire King believed that there could be a genetic cause for breast cancer. In 1974, she launched on a painstaking process that would take her two decades to complete. First, she studied the family histories of 1,579 women who were diagnosed with breast cancer, looking for other instances in their immediate families or in prior generations. In some 15 percent of those cases, she found that there were indeed other cases of the disease in the same family. King then collected blood from the families she had identified and started looking at chromosomes. A new technological development in the early 1980's made her work much easier. Deoxyribonucleic acid (DNA) could now be extracted from blood samples, making it possible to spot a marker in one person's DNA that was identical to a marker in the DNA of another family member with cancer. After examining more than 180 markers, King was sure that she had found her pattern. She now knew that the gene she had been seeking was located on chromosome 17. In October, 1990, at the annual meeting of the American Society of Human Genetics in Cincinnati, Ohio, King presented her findings. She named the first breast cancer gene to be discovered "*BRCA1*," which stood for "breast cancer," but privately she liked to think of them as a tribute to Berkeley, the university where she had pursued her research for so many years.

However, though she knew approximately where the gene was located, King had not yet isolated *BRCA1*. Her announcement impelled a number of other research teams into a frantic effort to find the gene. It was finally identified in 1994. Ultimately it was cloned, but not by King. However, by identifying *BRCA1*, King proved that breast cancer could be inherited; thus, King made it possible for individuals at risk to spot symptoms of the disease early in its development and for researchers to find out exactly how genetic breast cancers develop. King's discovery also encouraged geneticists to see whether other diseases that, like breast cancer, had previously been linked primarily to the environment could be inherited. Moreover, by discovering the location of *BRCA1*, King made an important contribution to an area of genetics that could result in revolutionary treatments for various diseases. When scientists know how genes work, gene therapy (the insertion of DNA into an individual's cells to treat a disease) can become a real possibility. Finally, King's pioneering research encouraged scientists, as well as the general public, to focus their attention on breast cancer and to take the necessary steps to defeat it.

Impact

King's three major discoveries in the field of genetics have advanced scientific knowledge and significantly affected human life. By finding that the genomes of human beings and chimpanzees are nearly identical, she bolstered the theory that the two species had a common ancestor and modified the estimate of when the two diverged, thus altering conventional assumptions about evolution.

By discovering *BRCA1*, the gene on chromosome 17 that is linked to breast cancer and also to ovarian cancer, she proved that some of these cancers are inherited. Her work stimulated research into the genetic basis of breast cancer, resulting in the isolation of *BRCA1* and the identification of another breast cancer gene, *BRCA2*. King's discovery not only aroused interest in breast cancer research but also impelled geneticists to initiate studies of other diseases, in the hope that they might find similar familial links; moreover, King and her colleagues could now investigate the possibility that gene therapy, the insertion of DNA into an individual's cells to treat a disease, might be used in the treatment of cancer. King's third contribution to science and to society was her application of DNA technology in human rights causes. She first used DNA sequencing to locate persons "disappeared" during Argentina's "dirty war" in the 1970's and 1980's, and later she also utilized the methods she had developed in order to identify the remains of victims of the repressive regime. King's technique became the standard method of identifying human remains, whether for human rights organizations investigating genocide or for government agencies dealing with disasters. Thus, the work of this dedicated scientist has impacted the lives of countless human beings.

Ewald Georg von Kleist

German physicist

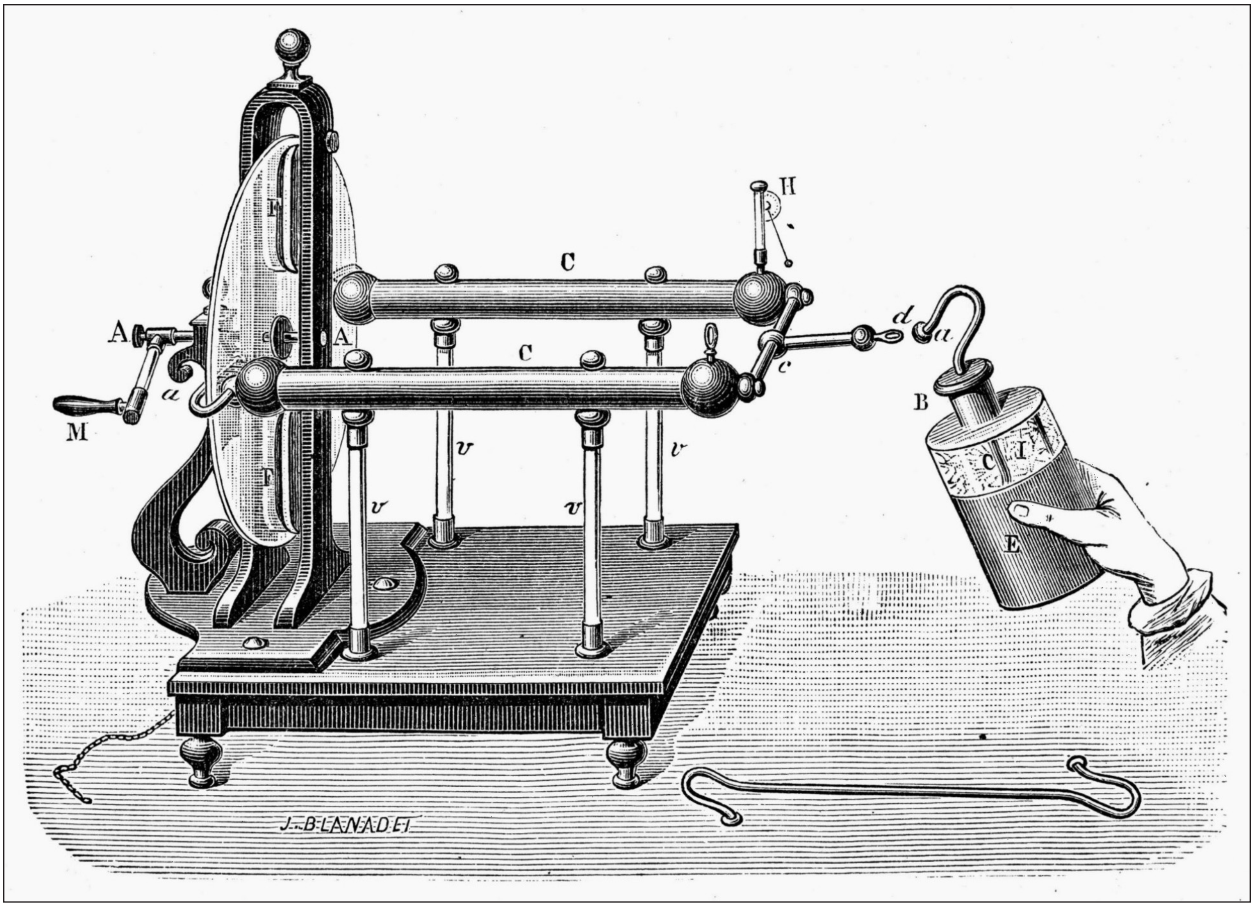
Von Kleist developed the Leiden jar, an early device that stored electricity by accumulating electricity generated by a primitive friction machine in a glass container. This device is the ancestor of the capacitor, which is used in modern electrical and electronic equipment.

Born: June 10, 1700; Vietzow, Farther Pomerania, Prussia (now in Germany)
Died: December 11, 1748; Köslin, Pomerania, Prussia (now Koszalin, Poland)
Also known as: Ewald Jürgen von Kleist
Primary field: Physics
Primary invention: Leiden jar (precursor of the capacitor)

Early Life

Ewald Georg von Kleist (A-vawlt GAY-ohrk fahn klist), a German jurist, Lutheran cleric, and physicist, was born in 1700 in Farther Pomerania, a region in north-central Europe on the Baltic Sea between what is now Poland and Germany. Little is known of his early life beyond the fact that he was born into an upper-class family; his father was a Prussian district manager. Von Kleist enjoyed a reasonably comfortable childhood and youth and was well educated.

In the 1720's, he attended first the University of Leipzig in Germany and then the University of Leiden in the Netherlands, where he studied jurisprudence. His interest in science was stimulated by the experiments of one of the professors in Leipzig, Georg Matthias Bose. Bose, intrigued by electricity, as were many other upper-class



A Leiden jar is charged by a Ramsden electrostatic generator. (The Granger Collection, New York)

Europeans, explored the phenomenon of igniting flammables with sparks generated by electrical friction machines. Much of Europe had become enthralled by the diversions produced with gadgets and the party jokes that used static electricity. However, those more serious-minded individuals saw the potential of electricity to accomplish more worthwhile benefits than mere entertainment and were interested in finding ways to harness its power for practical uses. Von Kleist was one of those who, after observing the demonstrations, developed an interest in serious experimentation. He was particularly interested in those demonstrations in which alcohol, gunpowder, and turpentine were ignited by electrical sparks.

When he completed his education at the University of Leiden, he returned home to Pomerania and became a dean (bishop) of a cathedral chapter of Camin, where he remained from 1722 to 1745. His curiosity about electricity continued, and his aim was to find a way to conserve or accumulate an electrical charge so that it could be used later.

Life's Work

By the 1740's, electricity as a means of entertainment and a scientific phenomenon had captured the interest of large segments of European society. Professor Bose at the University of Leipzig continued conducting experiments that generated considerable interest in electricity's potential. Frederick the Great, king of Prussia, opened the Berlin Academy of Sciences in 1744, where experiments in electricity were conducted. About the time von Kleist was experimenting with capturing electrical charges and attempting to increase their power, a Dutch professor at the University of Leiden named Pieter van Musschenbroek was working on a project with the same goal. Both men would independently arrive at the same discovery. Musschenbroek made his in January, 1746, but von Kleist had made his discovery two months earlier.

Working with knowledge of the experiments of contemporaries such as Bose and Johann Krueger, von Kleist began his attempts to increase the strength and reliability of the electrical flare. His discovery was probably an accident. According to his account of the experiment, he inserted an iron nail into the cork sealing the opening of a handheld glass jar. The jar contained a liquid, variously supposed to be alcohol, mercury, or water. Von Kleist connected the nail to his friction machine to electrify it. He found that the electrical charge could be retained for several hours. Even more astonishing, the charge retained by the jar could be strong enough to ignite wine or other spirits as successfully as the friction machine had done. Von Kleist also received a severe shock when, while holding the glass jar in one hand, he touched the nail with his other hand. He noted that he got a shock only when both hands were on the jar. (This was an example of closed circuitry, a concept unknown at the time.) When his hands touched only the nail, no shock was felt. The shock was strong enough to numb his arm and shoulder. When he touched the nail in the jar to another object, the jar discharged the stored electricity and produced a spark. The device's spark lasted long enough to make a noticeable light in the room.

When he was finally satisfied with the results of his experiment, he wrote to several professors and Berlin Academy members describing the experiment and its effects. They tried to replicate his experiment, but most of them were unsuccessful. Those few who managed to perform the experiment successfully shared the news among themselves but apparently did not widely disseminate the discovery. On the other hand, news of the same discovery by the more famous Musschenbroek quickly reached several countries. Therefore, Musschenbroek's discovery of the Leiden jar and his more thorough investigation of the jar's potential was more widely known for many years. Nevertheless, von Kleist was eventually recognized as the discoverer of this primitive capacitor.

Though the device von Kleist discovered was once called the "Kleistian jar" in his honor, a French scientist, Abbé Nollet, coined the term "Leiden jar," named for Musschenbroek's hometown and the Dutch university where he taught. After its discovery, the Leiden jar was used to put on spectacular demonstrations for spectators. One demonstration that created a particular stir was prepared for the king of France: A regiment of soldiers was lined up, linked together with pieces of wire. Then an electrical charge was sent them, causing them to simultaneously leap into the air, to the amazement of onlookers.

After von Kleist's career as dean of a cathedral chapter at Camin ended in 1745, he went on to become president of the royal court of justice in Köslin. He died there in 1748.

Impact

The Leiden jar was significant to eighteenth century scientists as well as to those who recognized its potential beyond entertainment. By 1752, numerous publications had proclaimed the many uses for the jar in several fields, especially medicine. By 1789, as many as seventy applications in medicine alone had been ascribed to the jar.

Over time, as scientists learned about the concepts of charge, current, and capacitance, the jar became increasingly important for research. It made possible the production of electrical charges that had greater power than any previously produced. As its power was demonstrated to ever more philosophers and scientists, its advantages beyond entertainment were brought to the attention of leaders of different countries, who proceeded to support more research.

Eventually, experimenters used the jar to develop the capacitor, a device with the ability to store unused electrons and ultimately deliver electric power over great distances. The capacitor is an integral element of today's radios, televisions, and other electronic devices. The jar itself is still used today in laboratories for experiments and demonstrations.

—*Jane L. Ball*

Von Kleist's Leiden Jar

Eighteenth century "electricians," searching for ways to increase the electrical charge they could generate from frictional sources, hoped to create a device to conserve significant quantities of electricity to be used at a later time. Ewald Georg von Kleist's Leiden jar accomplished just this. It was a simple device, originally a narrow-necked glass jar half-filled with water (though it was soon found that such thin-necked glasses were easily broken by the powerful electric shocks generated). The inside and outside surfaces of the jar were coated with a conductive metal foil. The glass served as the dielectric (a nonconductive material), though initially it was believed that it was the water that prevented the conduction of electricity. A cork placed in the top of the jar as a stopper had a metal wire or chain and a nail or metal rod driven into the cork in a way that allowed the wire or chain to rest in the water. The nail or metal rod was then hooked to an electrical friction machine, a static generator, cranked by hand to produce and deliver an electrical charge. The jar, thus primed, would hold two equal but opposite charges that, when connected to another wire, would produce a spark or shock.

Von Kleist's account of his Leiden jar experiments states that the device was able to produce an electric charge that lasted long enough for him "to walk sixty paces" around the room where he conducted tests. Anyone holding the device, if touched by another, would receive a shock "so strong . . . [that] both arms and shoulders [would be] shaken thereby." His experiments demonstrated that the electrical charge could be retained even for hours and could be strong enough to ignite wine or other spirits. The Leiden jar's capabilities became so widely appreciated that within a few years, Benjamin Franklin used one in his kite-flying experiment.

The Leiden jar was first a glass vial, but its more familiar form is a coated jar with a brass rod connecting the inner coating with the outer coating. It became useful to experimenters in electrical research because its compact size made it easier to move about than electrostatic generators. In modern times, it is used most often for classroom and laboratory demonstrations and for experimental purposes. It is significant as the forerunner of the capacitor, used in electric lighting and such electronic devices as television sets and radios.

Margaret E. Knight

American mechanical engineer

Credited with about ninety inventions and twenty-two patents, Knight is best known for a machine that made square-bottom paper bags, which continue to be widely used in grocery stores and in homes.

Born: February 14, 1838; York, Maine
Died: October 12, 1914; Framingham, Massachusetts
Also known as: Margaret Ethridge Knight (full name); Lady Edison
Primary fields: Business management; household products; packaging
Primary invention: Paper bag machine

Early Life

Margaret Ethridge Knight was the daughter of James and Hannah Knight. Born in 1838 in York, Maine, Margaret later moved with her family to Manchester, New Hampshire. She always displayed an interest in subjects associated with males and claimed that she would rather have a jackknife than a doll. At a young age, she developed a reputation as a tomboy, and her inventiveness pleased her brothers, for she made kites and other kinds of toys for them, while she devised a foot warmer for her mother. Her father gave her free access to his tools, and when he died, while she was still a child, they were passed on to her. Her mother was left with the task of rearing her and her two brothers in a mill town.

Manchester, which was named for an industrial town in England, in Knight's time employed fifteen thousand people in its factories and produced 360 miles of cotton cloth a day. Her brothers worked in a mill, and Knight, a very serious child, learned about the importance of machinery when she brought her brothers their lunches. She came to realize that manufacturing was a dangerous way of earning a living. At the age of twelve, she witnessed a young working girl injured in the Amoskeag Mill by a shuttle that came loose from a loom. This accident inspired Knight to develop a device that could quickly stop a loom, and eventually all looms in Manchester were provided with them. She also had the experience of working in a cotton mill herself. She was not the first woman to receive a patent, as has sometimes been claimed, but she learned, while still a teenager, about patents and how to prepare them.

Life's Work

Knight's education took her through secondary school; then, like many single young women, she had to find a job. She was a tall and strong young woman with great determination to improve the efficiency and safety of factories. In 1867, while working at Columbia Paper Bag Company in Springfield, Massachusetts, she began to devise a machine that would produce bags with square bottoms so that the user did not need to hold them erect. A man named Charles Annon also was interested in this process, but Knight suspected that Annon was copying her work by spying on the machinist she hired to make her model. Annon argued in his defense that as a woman she could not have understood the complexities of such a machine. Examination of her notebooks and diary proved otherwise, and she won her claim in court in 1870 and earned her patent. Shortly thereafter, she cofounded the Eastern Paper Bag Company in Hartford, Connecticut.

From that time on, Knight invented many items. In 1883, she devised a skirt protector, which was a shield that fit between the outer and inner walls of the elaborate skirts that women wore at the time. It protected the inner surface from rain, snow, and dirt and was secured by a waist belt. The following year, Knight invented a clasp for holding together robes or textile fabrics.

By 1889, Knight was living in South Framingham, Massachusetts, where she would spend the rest of her life, and had turned her attention to machines for cutting shoes. She devised a machine for cutting India rubber and other materials used for the soles of boots and shoes. The machine consisted of an endless apron, or belt, with a series of tablets, or beds, flexibly connected and able to move horizontally beneath a pattern and a blade that had a vertical reciprocating movement. The material would be clamped on an apron, and a complete sole would be cut out on each of the tablets. The apron would carry both the soles and waste material out of the machine. In connection with shoemaking, Knight also patented a numbering mechanism. Working with a man named Charles S. Gooding in 1894, she designed a machine for imprinting or stamping numbers or other characters on products such as boots and shoes.

Also in 1894, Knight filed a patent for a new design of window sash. Realizing the difficulty of cleaning window panes by merely raising and lowering the sashes, she devised a frame whose sashes did not simply operate vertically but would swing horizontally outward. This improved window frame and sash, now very common, seems not to have come into frequent use until a number of decades later.

The Paper Bag Machine

Before Margaret E. Knight's paper bag device, no machine was able to fold a web of paper into a tube and then, by the continuous operation of the machine, so operate upon the leading end of the tube to form automatically the diamond fold, which is the basis of the flat-bottomed bag.

The frame of the machine must be of a suitable shape to sustain the parts. The indefinitely long web of paper from which the bags are made is drawn from a roll so suspended that it can be unwound and supplied to the machine as fast as required. This web is folded about a former with the lap upon the upper side. The pasting is done by another machine. This machine folds a web of paper into a tube and operates on the leading end of the tube, carrying it forward to form the necessary diamond fold.

After a sufficient length of the tube is cut for a bag, the diamond-folded end of the piece of tube is folded transversely and pasted in the form required to produce a satchel-bottom bag. The novel part of Knight's machine she called a "finger," the purpose of which is to open one end of the paper tube, lay it back upon itself, and form the diamond fold. The invention also has a feeding mechanism to move the tube forward so that the finger can enter the open end of the tube as it is being led forward and, by its action within the tube upon one ply thereof, lay the ply back in the opposite direction of the movement of the tube determined by the feeding mechanism. The invention also has a follower that projects beyond the front end of the former and keeps the two plies of the tube separated, so that the leading end of the tube may be readily entered to permit one ply of it to be raised in the formation of the diamond fold.

The machine contains a folder to ensure a straight transverse fold in but one ply of the tube and to determine the line or direction of the fold as that ply is turned outward and back by the finger. The machine also has a blade and a pair of rolls to clear the bag from the machine. The blade rests and moves in a curved guideway that directs the blade to move downward and forward, and then backward and upward, traveling at about the same velocity of the tube-feeding mechanism. Descending upon one end of the diamond fold, it creases it transversely and forces the bag into the bight of the rolls, which carry it away. One of Knight's bag machines may be seen today in the Smithsonian Museum of History and Technology.

By the end of the century, Knight was working on compound rotary steam engines, and in 1902 she patented an improved engine with a new arrangement of cylinders and a new construction of the valve that supplied the steam. She followed this the next year with a new deployment of pistons and their abutments to prevent vibration of the engine. In 1903, along with John M. Benjamin, she patented an automatic tool for boring or planing concave surfaces or the surfaces of cylindrical chambers in rotary engines. She continued to work on improvements in internal combustion engines. In 1910, when she was in her early seventies, she patented a spring wheel with a resilient hub to increase ease of motion in automobile tires.

Knight's working life extended nearly to her death. Called "Lady Edison" by her supporters, she worked in a variety of fields, devising items for women, for households, and for factories. She suffered from pneumonia in 1914 and died on October 12 at the age of seventy-six.

Impact

It is sometimes difficult to determine how long or how well some of Knight's inventions worked. She assigned her improvements on engines to the Knight-Davidson Motor Company in New York. Inventions such as her skirt shield would of course not outlast the full skirts of the late nineteenth century, and steam engines that she worked to improve were rendered obsolete by electrical engines. She turned to the needs of the day over a period of more than forty years while the manufacturing world saw many changes. As someone who had almost reached senior citizen status when automobiles began to appear, she ended her career working on improvements in automobile wheels.

Although it is actually simpler than some of her other machines, the paper bag machine has been Knight's most famous invention. Today, more than seven thousand machines in the world produce flat-bottom paper bags, and despite the fact that many plastic bags are used in grocery stores, customers continue to ask for flat-bottom bags and even to buy them if grocers do not supply them with their orders. People continue to use paper bags around their homes.

Despite the patents that Knight was granted, her labor does not seem to have been well rewarded. When she died in 1914, her estate was valued at less than $300. Her work has not been forgotten, however. In 2006, she was inducted into the Paper Industry International Hall of Fame.

Willem Johan Kolff

Dutch American physician

A visionary in the field of artificial organ engineering whose groundbreaking research led to revolutionary developments in both cardiac and pulmonary treatment, Kolff designed the first artificial kidney, a dialysis machine that cleaned the blood of patients in renal failure.

Born: February 14, 1911; Leiden, the Netherlands
Died: February 11, 2009; Philadelphia, Pennsylvania
Primary fields: Biology; medicine and medical technology
Primary invention: Dialysis machine

Early Life

Willem Johan Kolff (WIHL-uhm YOH-hahn kohlf) was born on Valentine's Day, 1911, in Leiden, the Netherlands. His father, Jacob, was a respected physician who had opened a tuberculosis sanatorium. As a child, Willem loved to watch carpenters, intrigued by their methodical constructions, and he loved animals (he wanted to be a zoo director). He resisted his father's advice to pursue medicine because he did not want to watch people die. In the time before antibiotics, tuberculosis patients often faced agonizing deaths. An average student (he was dyslexic), Willem was accepted for medical studies in 1930 at the prestigious University of Leiden largely through the influence of his father. From 1934 until 1936, Kolff was posted in the university's anatomical pathology department, where he first studied the structural and compositional changes in diseased organs.

After graduating in 1938, Kolff initially went into teaching, joining the medical faculty at the University of Groningen, among the oldest and most respected research universities in Europe. During his stint there, Kolff, after attending a twenty-two-year-old patient who agonized before succumbing to kidney failure, reviewed the specific problems faced by such patients. For these patients, the kidneys could no longer filter liquid wastes from the blood, allowing the accumulation of waste products normally removed in the urine. The resulting accumulation, called uremia, represented a potentially lethal problem for the body. More than twenty years earlier, medical researchers investigating short-term kidney failure had suggested the theoretical workability of blood dialysis as a way to treat these patients, the principle in which the blood would be passed through a semipermeable membrane to a solution with a lower concentration. It would be a way to cleanse the blood, like some kind of external, temporary kidney. After the anticoagulant heparin became available in the mid-1920's, experimental research into dialysis machines began to find success—save that the process in the experimental models was quite slow (sometimes more than an hour) and the availability of the heparin was scarce as Europe moved toward World War II.

Life's Work

Following the Nazi invasion of Holland in spring, 1940, Kolff, a passionate opponent of the occupation, quickly completed his certification as an internist and promptly left Groningen when the hospital was restaffed with Nazi sympathizers. (He would return after the war to complete his Ph.D. in 1946.) Kolff relocated to a small hospital in

Kampen where he was the sole internist. Quickly recognizing the dire circumstances of the war, Kolff went about directing the establishing of what would be Europe's first blood bank to make transfusions safe and available for both soldiers and civilians. He never entirely abandoned dialysis research, however, though materials were in short supply. As early as 1941, he set up a working model (using more than fifty yards of sausage casing to contain and filter the patient's blood). Not entirely surprising, the first patients Kolff worked with died (blood coagulated too quickly). He reworked the design and, in 1945, a woman in a coma from kidney failure was put on the machine and lived. After making refinements in the design, Kolff refused to patent it, believing it unethical for a doctor to make money from such devices. Rather, after the war, he circulated the design freely to researchers around the world. Eager to work with the research resources in the United States, Kolff joined the Cleveland Clinic Foundation in 1950—by then, his dialysis machines were routinely saving hundreds of lives.

First as professor of clinical investigation and later as the science director of the artificial organs program at the Cleveland Clinic, Kolff turned his attention to pulmonary research, specifically problems facing surgeons in heart bypass procedures. Initially, he worked on the team that in 1955 developed the membrane ox ygenator, a kind of artificial lung used to add oxygen to and remove carbon dioxide from the blood, a device that could be used in bypass surgery when the lungs were disabled. Once again, Kolff refused to patent his device.

The experience with pulmonary care caused Kolff to consider the possibility of developing a mechanically efficient implantable artificial heart, a revolutionary idea he conceived nearly two decades before the technology would be available to realize it. However, in 1957, a prototype kept a laboratory dog alive for nearly ninety minutes.

Kolff maintained his appointment at the Cleveland Clinic until 1967. With ambitions to start an entire institute expressly for biomedical engineering, he accepted an appointment at the School of Medicine at the University of Utah. There, as head of the Division of Artificial Organs and the Institute of Biomedical Engineering, he pursued opportunities for significant research monies and, with a massive research team of 175 doctors, surgeons, engineers, and chemists over the next decade, pursued

The Artificial Kidney Machine

Willem Johan Kolff's 1941 prototype of the kidney dialysis machine, crude as it may appear, testifies to the vigor and improvisational resourcefulness of scientific ingenuity applied to a specific problem, how with limited resources a researcher/technician can nevertheless realize an ambitious premise. Although the idea of dialysis had been proposed earlier, few medical researchers before Kolff looked favorably on the idea of actually draining the blood from the body as way to cleanse it of the damaging buildup of toxic materials (principally urea and other salts) that regularly resulted in the death of kidney patients. Kolff maintained that short-term external treatment of the blood could help sustain a patient until the damaged kidneys returned to full effectiveness. Eventually, his design would allow long-term care for patients with renal failure, adding years to their lives. Add to that the fact that Kolff worked under the extreme conditions of an occupied country during wartime with its resources severely curtailed, and the experimental model of the dialysis machine becomes a monumental expression of the research imperative.

Kolff was certain that toxic blood could be filtrated through a semipermeable membrane, agitated in a saline solution to purify it, and then returned to the body. His work establishing the wartime blood bank helped him understand how to handle blood outside the body. In initial attempts, the patient's wrist artery was slit and the blood extracted fifty milliliters at a time. The blood was fed through sterile tubing of sausage casings made of cellophane (a new substance at the time) that served as the semipermeable membrane and then agitated in a large drum that contained a sterile solution of saltwater. In so doing, as the blood passed through, impurities would be filtered out, a process that took about five minutes. The casing's microscopic pores did not allow essential red and white blood cells to fit through. Rather, the agitation in the drum allowed the salts and urea to flow through the membrane and then harmlessly out into the solution, thus removing the impurities much as a functioning kidney would. The problem of returning the treated blood proved tricky, particularly before stronger anticoagulant drugs were readily available. Kolff designed a recovery system by jury-rigging a pump based on the design of the water pump used in Ford motor engines. He implemented his design using two orange juice cans and a pump from an old washing machine. The blood was essentially pumped back into the body gently—and the process then repeated with fifty more milliliters. The process was time-consuming and, at least initially, risky (the first sixteen patients died), but Kolff resolutely set about improvements that made the machine ultimately efficient and safe.

cutting-edge investigations into developing artificial eyes, ears, and arms.

However, it was research into the artificial heart that defined Kolff's career at Utah. On a research team directed jointly with Dr. Robert Jarvik, Kolff pioneered refinements in the mechanical device and experimented on more than two hundred lab animals and dozens of cadavers. Kolff headed the surgical team that successfully implanted the soft-shell mushroom-shaped device into a patient named Barney Clark on December 2, 1982. The so-called Jarvik-7 heart functioned for 112 days before Clark's death from complications from organ failure, although the heart was still working. During the four months after Clark's procedure, amid tremendous international interest in the operation, Kolff was compelled to defend the artificial heart against moral and ethical opposition that saw the procedure as toying with the so-called center of human emotions and personality, upsetting the "natural" order of life and death, and denying the patient any quality of life. Kolff brushed aside such objections, citing the Clark operation as a threshold procedure designed to provide researchers data for long-term cardiac care.

Kolff continued to research artificial organ technology, even after his retirement in 1997 (at the age of eighty-six). He was particularly interested in an artificial lung that would be worn on the outside and a similarly portable kidney to make dialysis convenient. He garnered many international honors for his commitment to bioengineering, most notably the Albert Lasker Award for Clinical Research in 2002. In 1985, he was inducted into the National Inventors Hall of Fame, and in 1990 he was listed among *Life* magazine's most important Americans of the twentieth century. He died on February 11, 2009, at the age of ninety-seven in a retirement home in Newton Square in Philadelphia, Pennsylvania, where he had moved to be near his son.

Impact

It is impossible, of course, even to estimate the number of lives that Kolff's biomedical engineering innovations affected. His dedication to the hands-on work of designing and testing mechanical organ devices was fostered by his early encounters with the human face of suffering that taught him that the responsibility of doctors was not to manage but rather to alleviate that pain. That is his legacy. Since the mid-1950's, dialysis alone has guaranteed a quality of life to millions of patients worldwide struggling with renal end failure who must wait for transplant surgery. Although the technology of the artificial heart and lungs has yet to catch up to Kolff's ambitious vision, his theoretical work, stubborn diligence, and painstaking trial-and-error experimentation on such artificial organs (work done across more than seven decades) position him among the most important medical researchers of his era, remarkable for the sheer reach and variety of fields Kolff tackled.

More than his groundbreaking advances in medical technology, Kolff emerged as a kind of pragmatic conscience of the biomedical engineering field, a field routinely accused of lacking any humanitarian agenda in its rush to mechanize the body and play God. His life has provided an exemplum of a passionate conscience. Not only his courageous resistance to the Nazi threat and his work under inhospitable conditions of war-torn Holland but also his insistence later that his designs be made readily available to the international community without benefiting him financially serve as a striking example of selfless dedication. He pursued the application of engineering ingenuity to medical problems without being distracted into arguments over the ethics of such work—rather, he understood that the role of medical researchers was to solve problems. Not surprisingly, he devoted enormous amounts of time for more than twenty years to campaigning with tireless vigor for a variety of public forum issues from prison reform to public education, certain that solution-thinking could be applied to social issues as well.

Roscoe Koontz

African American health physicist

Koontz was a pioneer in the field of health physics, a discipline concerned with protection from ionizing radiation. Many of the nuclear safety procedures he helped to implement are still used today.

Born: December 16, 1922; St. Louis, Missouri
Died: May 17, 1997; Richland, Washington
Primary fields: Chemistry; medicine and medical technology; physics
Primary invention: Pinhole gamma-ray camera

Early Life

Roscoe Koontz spent his youth in the residentially segregated city of his birth, St. Louis, Missouri. Unlike many of his peers who sought employment upon graduation from Vashon High School, one of the city's racially segregated public schools, Koontz opted to continue his education. With few opportunities available for blacks, Koontz chose to remain close to home as he considered possible career options. He enrolled at Stowes Teachers College in the St. Louis area. Founded in 1890 as a normal school for future black elementary teachers, Stowes offered Koontz the opportunity to consider his future plans. When he made up his mind, Koontz discovered that he wanted something more than the routinized life of an educator.

With one year of college under his belt, Koontz enlisted in the Regular Army Reserve Corps in 1942 and remained on active duty in this capacity until the end of World War II. Military service afforded Koontz the opportunity to travel outside his home state as well as the chance to take advantage of federally funded educational opportunities at West Virginia State College, where he received training in a pre-engineering program. After the war, Koontz attended Tennessee State University, a historically black college, where he graduated with a degree in chemistry.

Life's Work

In 1948, Koontz participated in the University of Rochester's Atomic Energy Health Physics Fellowship Training Program. Koontz flourished under the rigorous training he received at the upstate New York school and soon realized that he possessed considerable aptitude for detailed scientific investigation. While at Rochester, he began researching methods for safely harnessing ionizing radiation, an interest that he would make his life's work.

After completing the Rochester program, Koontz entered the field of health physics, which concerns the safe use of radiation in various settings. Koontz would focus mostly on nuclear reactor safety. Health physics was in its infancy when Koontz entered the field, and many of the professional standards for the discipline were established by Koontz and other early practitioners. A considerable number of the early nuclear safety procedures and much of the early radiation-detecting equipment employed are used to this day.

After receiving rudimentary training in health physics, Koontz relocated to Los Angeles, California, where he began work at Atomics International, a division of North American Aviation, at its Canoga Park nuclear reactor construction and research facility. There with a team of scientists, Koontz conducted a wide array of studies into reactor safety and radiation detection. His employment at the company coincided with the most productive phase of his professional career, during which his research team set the standard by which all nuclear facilities would be judged. From the 1950's to the early 1970's, Koontz coauthored scores of scholarly articles and research projects, including studies on nuclear safety, reports on the characteristics of aerosols produced by sodium fires, examinations of errors in measurements of building leakage due to dynamic temperature effects, assessments that helped to predict and control leakage through cracks and capillaries in reinforced concrete buildings used to house reactors, and assorted items related to liquid-metal fast-breeder reactor accidents. During this period, Koontz regularly attended professional meetings relevant to his field, such as the U.S. Atomic Energy Commission's Air Cleaning Conferences, to learn from his peers and to share his research with others.

In the 1970's, Koontz spent less time researching as he assumed control of all contract work on portions of the massive Clinch River Breeder Reactor project at Oak Ridge, Tennessee, under the direction of the Atomic Energy Commission. Sodium-cooled fast-breeder reactor technology was then in its early stages. In theory, the facility would "breed" more fuel than it consumed, making it a cost-effective energy source. Developers of the Clinch River project hoped that its successful construction would serve as a prototype for other nuclear facilities across the nation. Interest in the project waxed and waned depending on the presidential administration in office and overall public support for nuclear power. Cost overruns and concerns regarding the safety of nuclear energy ultimately undermined the project. Originally fixed with a \$400 million construction cost, the project's price continued to climb over the next decade. By the dawn of the 1980's, more than \$1 billion had been spent on the still-uncompleted Tennessee reactor. In 1983, Congress cut funding for the project, leading to its eventual abandonment.

Despite the setback, Koontz remained with the same employer for most of his career (although North American Aviation had merged with Rockwell-Standard Corporation in 1967). Later in life, Koontz worked at Rockwell's Hanford Operations in Richland, Washington, in the Pacific Northwest. He died in 1997.

Impact

Koontz overcame obstacles of racism to become one of the leading figures in his chosen field, devoting his professional career to harnessing the power of nuclear energy and making it safe for public use. His research helped lay the foundation for the discipline of health physics.

During the 1980's, the U.S. government largely abandoned its support for nuclear power in part because of concerns over reactor safety. Incidents such as the 1979 partial meltdown at the Three Mile Island nuclear facility south of Harrisburg, Pennsylvania, prompted a reassessment of the nation's commitment to nuclear power. In the early twenty-first century, however, the volatile price of oil has encouraged many to reconsider nuclear energy as a viable alternative to fossil fuels. The work of Roscoe Koontz and other nuclear pioneers will no doubt play an integral role in any future U.S. plans to develop nuclear reactors.

—*Keith M. Finley*

The Pinhole Gamma-Ray Camera

Roscoe Koontz and fellow researchers at Atomics International in Canoga Park, California, sought to produce technology that made nuclear reactors safer. As part of his ongoing research in nuclear safety and development, Koontz designed a pinhole gamma-ray camera, an imaging device capable of detecting the distribution of radionuclides (often referred to as radioactive isotopes), atoms with unstable nuclei that emit gamma rays, which make up the ionizing radiation produced by nuclear reactions. Only gamma rays traveling in a parallel direction to the device are filtered through the camera. Although Koontz originally designed his camera to detect radiation in nuclear reactors, such cameras are widely used today by medical professionals to locate tumors and other abnormal growths without exposing patients to toxic levels of radiation. Gamma-ray cameras have been used in other fields as well. The U.S. Department of Homeland Security, for example, has explored using these cameras to identify radiation in shipping containers.

Reactor development and eventual public usage depended on the work of health physicists, who often risked their own safety in pursuit of science. Years after Atomics International was absorbed by Rockwell-Standard Corporation, investigations concerning the increased cancer risk posed to employees at the Canoga Park facility as well as to the surrounding community were conducted. The long-term health effects of nuclear exposure were not fully known at the time Koontz worked, and employees in atomic industries were exposed to dangerous radiation levels.

RAY KURZWEIL

American computer scientist and software engineer

A leading advocate for artificial intelligence, Kurzweil developed several advanced computer-based pattern-recognition technologies, expert systems for finance, music composition, and other fields, as well as electronic musical instruments.

Born: February 12, 1948; Queens, New York
Primary fields: Computer science; mathematics; music
Primary invention: Kurzweil Reading Machine

EARLY LIFE

Ray Kurzweil (KURZ-wil) grew up in Queens, New York. His parents, a well-educated secular Jewish couple involved in the arts, had escaped from Europe during the years of the Holocaust. His father, a musician, and his mother, a visual artist, encouraged his creativity, and his uncle, an engineer at Bell Labs, shared his knowledge of computers with Kurzweil. As a child, Kurzweil enjoyed reading science fiction, learned about diverse spiritual traditions, and also developed a deep concern for social justice. He loved programming, and in high school he created music composition software that could analyze the style of a given piece and generate music in the same style. Word of this achievement spread, and in 1965 he appeared on national television as a guest on Steve Allen's program *I've Got a Secret*. Following the format of the program, Kurzweil played a composition on the piano, and it was eventually revealed that his computer program had composed the piece. His project won first prize in the International Science Fair, and as a winner in the Westinghouse Talent Search, he and thirty-nine other students were honored at the White House, where they were greeted by President Lyndon B. Johnson.

Kurzweil continued to distinguish himself as a college student at Massachusetts Institute of Technology (MIT), where he earned a bachelor of science degree in computer science and literature in 1970. One of his most important teachers at MIT was Marvin Minsky, a pioneer in artificial intelligence (AI). During Kurzweil's sophomore year, he created the Select College Consulting Program, which matched high school students with colleges using a database with two million items of information about three thousand colleges. Kurzweil ran this as a business, renting time on a mainframe computer to perform the calculations, and his program was highly successful. He sold it to the publisher Harcourt Brace Jovanovich for $100,000.

LIFE'S WORK

After graduating, Kurzweil continued his work in pattern recognition, applied to the problem of enabling a computer program to recognize printed letters. This task, know as optical character recognition (OCR), had only been partially solved, because existing programs could recognize characters, but only in a few fonts. This placed severe limitations on the practical value of such systems, since text is printed in a great variety of fonts. Kurzweil founded Kurzweil Computer Products in 1974 to work on this and other technologies, and he soon succeeded in developing the first omnifont optical character recognition program. After a conversation with a blind man who was a fellow passenger on an airplane, Kurzweil realized that his OCR program could be combined with other innovations to create a useful assistive technology for the visually impaired. Working with his team, Kurzweil supervised the development of the first charge-coupled device (CCD) flat-bed scanner, which organized signals from groups of photoelectric light sensors and improved the quality and speed of text-to-speech synthesis, incorporating all of these features into the Kurzweil Reading Machine, announced in 1976.

A discussion with musician Stevie Wonder, who was the first individual to purchase a Kurzweil Reading Machine, reignited Kurzweil's interest in using computers for music. In this case, Kurzweil responded to Wonder's interest in using keyboard synthesizers to imitate natural instruments more realistically. In 1982, Kurzweil founded Kurzweil Music Systems, with Wonder as the music adviser. After two years of research and development, the K250 (Kurzweil 250) was released. It was one of the first electronic synthesizers to successfully emulate an acoustic grand piano and other instruments.

During the same period, Kurzweil turned his attention to the development of speech-recognition software. In 1982, he founded another company, Kurzweil Applied Intelligence, to focus on this area. He took advantage of advances in computer memory and architecture to drastically increase the vocabulary of his system, competing with earlier products developed by researchers from Carnegie Mellon University. Realizing that specialized fields such as medicine make use of their own extensive vocabularies, Kurzweil developed systems such as Kurzweil VoiceMED (now Kurzweil Clinical Reporter) so that physicians and other medical professionals could dictate prescriptions, reports, and other kinds of information quickly and less expensively. Further specialization allowed variants of the system to be customized for various branches of medicine.

Ray Kurzweil with speech-recognition technology developed by his company. (Time & Life Pictures/Getty Images)

In the 1990's, Kurzweil started additional ventures, including the Medical Learning Company, which develops computer simulations of the human body for medical training, FatKat financial investment software (1999), and several Web sites, including KurzweilAI.net, promoting discussion and shared research, and KurzweilCyberArt.com, which highlighted machine-generated paintings and poetry. After being diagnosed with type II diabetes, Kurzweil cured himself through diet and nutrition, adding this success to his long list of research topics. Kurzweil also became a prolific author, starting with *The Age of Intelligent Machines* (1990), *The Ten Percent Solution for a Healthy Life* (1993), *The Age of Spiritual Machines* (1998), *Fantastic Voyage: Live Long Enough to Live Forever* (2004; with Terry Grossman, M.D.), and *The Singularity Is Near* (2005). The topics of these books are wide-ranging, but they are unified by an optimistic view of humanity's future.

Kurzweil has been awarded fourteen honorary doctorates and numerous prizes and awards, including Carnegie Mellon University's Dickson Prize (1994), the National Medal of Technology (1999), the Lemelson-MIT Prize (2001), and many others. In 2002, he was inducted into the National Inventors Hall of Fame. He has continued his research and development projects but is also in great demand as a lecturer and inspirational public speaker. *Transcendent Man*, a feature-length documentary film about Kurzweil's life and ideas, was released in 2009.

Impact

Even without counting Kurzweil's influence as an author, humanist, and entrepreneur, his many inventions in assistive technology, medicine, word processing, finance, music, and other fields have expanded and extended intellectual, professional, and artistic horizons for millions of people. Over the course of his career, the rapid rise in the availability and power of computers has made it possible to greatly accelerate and miniaturize Kurzweil's earliest inventions, supporting his observations about trends in technology. Some of Kurzweil's inventions and businesses have continued under other companies, which maintain, refine, and market them. His omnifont OCR was purchased by Xerox in 1980 and is now known as Xerox TextBridge. His electronic musical instrument business was sold in 1990 to a Korean piano company, Young Chang, and is now the Kurzweil Music Systems division of Hyundai. The speech-recognition software developed by Kurzweil Applied Intelligence was sold to become the dictation division of Lernout and Hauspie in 1997.

Although not everyone agrees with his utopian vision of a technological singularity (defined by several authors as the point at which machines become more intelligent than people and at which human history as it is known will cease to exist), he continues to stimulate discussion about the fundamental nature of intelligence and its machine-based counterparts, and technology's expanding impact on human culture.

—*John E. Myers*

The Kurzweil Reading Machine

The Kurzweil Reading Machine, the first print-to-speech reading machine for the blind, has provided unprecedented levels of independence to thousands of blind and visually impaired people throughout the world. As they worked on the invention, Ray Kurzweil and his team were enthusiastically supported by the National Federation of the Blind and its leader, Dr. Kenneth Jernigan, who helped them secure development grants. Completed in 1976, the reading machine is actually a combination of Kurzweil's earlier inventions, the first omnifont optical character recognition (OCR) program and the charge-coupled device (CCD) flat-bed scanner, with his refinement of text-to-speech synthesis. The synergy of these three innovations working together to make an even more powerful tool is in itself a perfect example of the inventor's own law of accelerating returns. A page of printed text is scanned, sent to the OCR program, and then read aloud by the speech synthesizer.

On January 13, 1976, Kurzweil and the National Federation of the Blind jointly announced the invention, and the major news networks covered the story. Walter Cronkite used the machine to deliver his closing words on the *CBS Evening News*. Soon after that, Kurzweil demonstrated it on the *Today* show. This attracted the interest of the popular musician Stevie Wonder, who purchased one of the machines for his own use. He loved the device and became Kurzweil's good friend. Their friendship led to further collaborations in music technology.

The Kurzweil Reading Machine, installed in libraries worldwide as well as in homes and offices for personal use, has undergone continued development since its introduction. Over time, the physical footprint of the hardware has gotten smaller. In 2005, the first pocket-size print-to-speech reading machine for the blind was introduced: the Kurzweil-National Federation of the Blind Reader (K-NFB). Developed as a joint venture between Kurzweil Technologies and the National Federation of the Blind, the software can be operated on a full-featured cell phone. With this handheld device, which can provide continuous feedback so that the user can orient its camera for the proper angle, someone who is visually impaired is able to read almost any text that he or she might encounter without needing to carry it to a special location for scanning and processing.

Stephanie Kwolek

American chemist

During her years as a DuPont chemist, Kwolek discovered a new branch of synthetic materials: liquid crystalline polymers. Her innovations in polymer science led to the development of the high-performance fiber Kevlar.

Born: July 31, 1923; New Kensington, Pennsylvania
Also known as: Stephanie Louise Kwolek (full name)
Primary field: Chemistry
Primary invention: Kevlar

Early Life

Stephanie Louise Kwolek (KWAW-lehk) was born in New Kensington, Pennsylvania, in 1923. Her parents, John and Nellie (Zajdel) Kwolek, immigrated to America from Poland when they were in their teens. John Kwolek was a foundry worker and amateur naturalist, and he encouraged his daughter to take a scientific interest in her surroundings. Together, the two explored the woods near their home, observing wildlife and collecting seeds, leaves, and flowers. At home, they studied and cataloged their botanical samples. The young Stephanie also enjoyed designing fashions, and she spent many hours sketching and making clothes for her dolls.

John Kwolek died when his daughter was ten years old, leaving his wife to raise Stephanie and her younger brother alone. To support the family, Nellie Kwolek found a job as a kitchenware assembly-line worker at the local Alcoa plant. As Stephanie grew older, she developed an interest in becoming an educator. She took to teaching math, reading, and writing to the other children in her neighborhood. She showed an affinity for the sciences during her school years, and by the time she headed for college in 1942 she had plans to become a doctor or a chemist.

Kwolek attended Margaret Morrison Carnegie College in Pittsburgh, the women's college of the Carnegie Institute of Technology (now the coed Carnegie Mellon University). During her studies there, which were funded by scholarships, she realized that she would be unable to afford medical school. She decided that after graduation she would seek work as a chemist to earn money for later graduate studies in medicine. With that goal in mind, she majored in chemistry and minored in biology. Kwolek received her bachelor's degree in 1946.

Life's Work

Job opportunities in scientific and technical fields had opened up for women during World War II, and Kwolek interviewed with several research companies. Ultimately, she found a position with E. I. du Pont de Nemours and Company, which hired her as a research chemist for its textile fibers laboratory in Buffalo, New York.

Kwolek thrived in the intellectually engaging environment at DuPont. She and her colleagues were working to create new synthetic polymers (long-chained molecules), and DuPont's research facility was the site of pioneering work. She and her coworkers helped one another and learned from each other. DuPont maintained a top-notch research library and invited professors to come discuss their latest research with laboratory staff. Kwolek so enjoyed her work as a research chemist that she decided not to pursue a career in medicine after all. She would remain with DuPont for the next forty years.

Although DuPont employed Kwolek and other women in a traditionally male field, women in postwar America generally found it hard to build and advance careers or to gain recognition in scientific or technical areas. Many of Kwolek's female coworkers left the company after a few years to become homemakers and mothers; others,

A DuPont executive holds a spool of Kevlar, best known for its use in body armor. (AP/Wide World Photos)

frustrated with limited opportunities for advancement, moved on to careers in teaching. Kwolek, who never married, stuck with her job despite unequal treatment. She received her first promotion after she had worked for DuPont for fifteen years.

In 1950, Kwolek was one of several employees at the Buffalo plant who earned a transfer to DuPont's newly opened Pioneering Research Laboratory in Wilmington, Delaware. There, in the Textile Fibers Department, the research team created and tested hundreds of thousands of new synthetic polymers.

Kwolek's early work at DuPont focused on discovering polymers that would dissolve at low heat so that they could be spun into fibers at room temperature. Her advances in low-temperature processes for preparing condensation polymers laid the groundwork for the discovery of several of DuPont's commercial products, including Lycra spandex, the flame-resistant material Nomex, and the multipurpose film Kapton.

In 1964, in the face of predicted gasoline shortages, DuPont set a goal to find a strong, lightweight, high-performance fiber for use in automobile tires. Replacing the heavy steel reinforcement in tires with a lightweight, textile-type fiber would improve gas mileage. Other chemists seemed uninterested in piloting the task, so Kwolek took on the challenge. The polymer needed to be stable at high temperatures and resistant to acids and bases. One of her experiments yielded surprising results. After synthesizing two aromatic polymers that subsequently refused to melt, Kwolek decided to use a solvent to dissolve them into liquid. However, when she mixed one of the polymers with the solvent, she did not get the clear, syrupy solution she expected from a flexible polymer chain. Instead, the resulting fluid was thin—almost like water—and hazy. She tried filtering the solution, but it retained its milky appearance.

Kwolek submitted the solution to a coworker who operated the lab's spinneret, a device used to spin polymer solutions into fiber. He initially refused, convinced that the solution was not cohesive enough to spin and fearful that the cloudy liquid was full of suspended particles that would clog his equipment. When she finally persuaded him to try, the solution spun flawlessly. She submitted the resulting fiber to the physical test lab, which found it to be surprisingly strong and stiff. Heat-treating it, she discovered, intensified its properties. Kwolek resynthesized and retested the new fiber repeatedly before she announced her results.

Kwolek had stumbled upon a new branch of synthetics: liquid crystalline polymers. She had also synthesized something new: a para-aramid fiber. DuPont recognized the commercial potential of the new fibers and set out to create one that was right for commercial production. Lab staff went to work experimenting with other liquid crystalline solutions, thinking up applications for the new fibers and developing new equipment for spinning, testing, and cutting them. After more than half a decade of research and refinement, a commercially viable fiber emerged that was less dense than fiberglass but far stronger than steel. Kwolek applied for a patent for the fiber, which DuPont would dub Kevlar, in 1971. The patent was granted in 1974, and bullet-resistant Kevlar vests went on the market a year later.

Kwolek continued to research polymers at DuPont until her retirement in 1986. She is the holder or coholder of seventeen U.S. patents; these include one for the spinning method that made commercial aramid fibers possible and five for the prototype polymer from which Kevlar was developed.

Since retirement, Kwolek has continued to work part-time as a consultant. She has also lectured, mentored, and participated in education outreach activities to encourage young people in science.

Impact

Kwolek revolutionized chemistry with her discovery of liquid crystalline polymers. By laying the technological foundations for Kevlar body armor, she has also saved thousands of lives. However, Kwolek's impact is not limited to her pioneering discoveries. She has dedicated her post-retirement years to mentoring female scientists and encouraging children, particularly girls, to pursue careers in science. She has not only lectured about her life and work but also welcomed curious students into her home and taken phone calls from children needing homework help. Her scientific curiosity, persistence, and determination make her an excellent role model who shows how science can provide opportunities for both intellectual challenges and valuable contributions to society.

Kwolek's work has earned her multiple honorary degrees and several major awards and distinctions. In 1994, she was named a Kilby Laureate for her revolutionary discoveries. In 1995, she was among the first recipients of the U.S. Patent and Trademark Office's newly established American Innovator Award. The following year, President Bill Clinton awarded her the country's highest honor for technological achievement, the National

Kevlar

Kevlar (polyparaphenylene terephthalamide) is the trade name for a strong, lightweight para-aramid synthetic fiber manufactured by DuPont. Weight for weight, it is five times stronger than steel, yet it is 43 percent less dense than fiberglass. It is nonconductive, it does not rust, and it resists wear, fatigue, corrosion, and heat. Its unique properties make it ideal for a wide range of applications. In a liquid crystal solution, such as the one from which Kevlar is made, the molecules are in an orderly, tightly packed formation. When such a solution passes through a spinneret, the aligned molecules remain in parallel as the solvent is forced out. The tightly packed, parallel, rigid molecules create an extremely strong fiber.

Kevlar is best known as the material used in bullet- and knife-resistant protective gear. When a bullet strikes a fabric woven from Kevlar, the fibers at the point of impact stretch instead of breaking and thereby dissipate the energy of impact. Kevlar vests have protected thousands of police officers from gunshot and knife wounds. Kevlar helmets have been standard issue for American combat soldiers since the early 1990's. In war zones, Kevlar body armor protects military personnel and civilians alike.

The U.S. space program employs Kevlar for various uses on the space shuttle and the International Space Station. Closer to Earth, Kevlar is used in containment rings for jet engines. If a piece of an aircraft turbine were to break off in flight, shrapnel would be traveling fast enough to slice through the engine and beyond. Kevlar shielding ensures that metal shards are contained or deflected.

Kevlar cable is used in suspension bridges and in the moorings that anchor oil-drilling platforms to the ocean floor. In the automotive industry, uses for Kevlar include radial tires and transmission belts. The material's durability and heat resistance have made it an ideal replacement for asbestos in brake pads. The high-performance material is also used in sports and recreation equipment such as skis, tennis rackets, hockey sticks, bicycle tires, fishing line, and racing sails. Canoes and kayaks made with Kevlar are strong and lightweight, like carbon-fiber models, but they have more give. Kevlar boots provide hunters with protection from snakebites.

Medal of Technology. In 1997, she became the second woman to receive the American Chemical Society's Perkin Medal for her innovative work in applied chemistry. She was the 1999 recipient of the Lemelson-MIT Lifetime Achievement Award. She is an inductee of the National Inventors Hall of Fame (1995), the Women in Technology International Hall of Fame (1996), and the National Women's Hall of Fame (2003).

RENÉ-THÉOPHILE-HYACINTHE LAËNNEC

French physician

Laënnec revolutionized medicine through his research in pathological anatomy and his work in clinical diagnosis. His invention of the stethoscope made possible accurate diagnosis of chest and heart problems.

Born: February 17, 1781; Quimper, France
Died: August 13, 1826; Kerlouanec, France
Primary field: Medicine and medical technology
Primary invention: Stethoscope

EARLY LIFE

René-Théophile-Hyacinthe Laënnec (ruh-NAY tay-aw-FEEL yah-SAHNT lay-NEHK) was born in Quimper, France, on February 17, 1781. When he was five years old, his mother died of tuberculosis. His father did not feel that he could take care of the boy properly, so René was sent to live with his great uncle the Abbé Laënnec. He was not a healthy child; he suffered from pyrexia and asthma and spent much of his time playing the flute and writing poetry. He also learned Greek and Latin and studied the classics.

The majority of the Laënnec family were lawyers, and many held positions in the parliament of Brittany. However, René's uncle Dr. Guillaume François Laënnec was dean of the medical school at the University of Nantes. René's interest was in medicine, not law, and when he was twelve years old he went to Nantes, where his uncle encouraged him to pursue a medical career. In 1795, when he was only fourteen years old, René was already working at the Hôtel-Dieu in Nantes, assisting with the care of patients, and there he began his medical education with his uncle. At the age of eighteen, René was serving as a third-class surgeon in the Military Hospital of Nantes. A short time later, he was at the Hospice de la Fraternité and then a surgeon at the Hôtel-Dieu. This was an excellent opportunity for the young man to observe a large variety of patient treatment and surgery.

In 1801, Laënnec went to Paris, where he studied medicine at the École Pratique and at the Hôpital de la Charité. He attended lectures given by the most talented physicians of the day: He learned dissection and was introduced to macroscopic pathology in the laboratories of Guillaume Dupuytren; studied heart and pulmonary conditions with Jean-Nicolas Corvisart, Napoleon Bonaparte's doctor; listened to Philippe Pinel, the founder of modern psychiatry, explain his theories of mental illness as a disease; and was a student of anatomy and physiology with Marie François Xavier Bichat, the father of the science of anatomy. Laënnec was especially talented as a diagnostician and as a pathologist. Soon, he started to do research on his own and to publish his findings in medical reviews.

In 1802, at the age of twenty-two, he obtained first place in the Concours Général de Médecine et de Chirurgie (general medicine and surgery exam). That year, he published a number of papers on various medical subjects and served as editor of the *Journal de Médecine*. While preparing his thesis, he gave private classes on pathological anatomy. In June, 1804, he defended his thesis and graduated.

LIFE'S WORK

Laënnec's career in medicine combined the fields of research scientist, practicing physician, and medical jour-

René-Théophile-Hyacinthe Laënnec. (Getty Images)

The Stethoscope

In 1816, a very obese young woman suffering from general symptoms of heart disease consulted René-Théophile-Hyacinthe Laënnec for treatment. Laënnec was perplexed about how to perform a clinical examination on her. Although he often used the technique of percussion, he rejected it in this case, as her extreme fatness would render it ineffective. Given her age and sex, direct auscultation of her heart with his ear placed against her chest was in his opinion inappropriate. While Laënnec happened to be watching some children playing, he noticed that they were holding a piece of wood to their ears and scratching on the other end with a pin. This observation inspired him to roll up a cylinder of paper that he tied with a string and to use it to examine her. He placed one end of the cylinder over her heart and the other end to his ear. The results were excellent; he could clearly hear the sounds made by her heart.

Pleased with the excellent results, Laënnec proceeded to construct a more durable instrument. He used a hollow wooden cylinder that measured 25 by 2.5 centimeters. Later, he improved upon his instrument by adding detachable parts and using brass rings. He created a detachable chestpiece and modified the stethoscope so that the earpiece could be unscrewed.

Wooden stethoscopes remained in use in the middle of the nineteenth century. The development of rubber tubing permitted the construction of different kinds of stethoscopes. In 1850, the modern binaural stethoscope with rubber tubes leading to both ears was developed. Types of stethoscopes include acoustic, electronic, and differential stethoscopes.

nalist. After graduating, he became an associate of the Société de l'École de Médecine and published a considerable number of articles, many of which dealt with pathological anatomy. However, his article on melanoma published in 1806 resulted in a rupture with Dupuytren, who insisted that Laënnec had failed to give him adequate credit for his work in the field. This quarrel, coupled with family problems, his uncle's death from tuberculosis, and financial difficulties, caused Laënnec a number of health problems, and he was forced to return to his native Brittany to recuperate.

Once his health was restored, Laënnec returned to Paris, became an editor-shareholder of the *Journal de Médecine*, and once again established a private practice. In 1808, he founded the Athénée Médical. He received an appointment as personal physician to Cardinal Joseph Fesch, Napoleon's uncle, and also published a number of articles on pathological anatomy. In 1810, Georges Cuvier, the founder of pathological anatomy, praised Laënnec as one of the very best in that field.

During the war years of 1812 and 1813, Laënnec was at the Salpétrière Hospital taking charge of the wounded Breton soldiers. He also taught medical pathology at the Hôpital Necker. During this period after his return to Paris, Laënnec was disappointed that he had not been offered a senior position as a physician in a Paris hospital. The offer finally came in 1816 from the Hôpital Necker. Laënnec immediately accepted and enjoyed a vast celebrity as a doctor. It was while he was at Hôpital Necker that he would make his most significant medical contribution, the stethoscope. In 1819, an obese young woman with symptoms of heart disease became his patient. Due to the impossibility of using percussion and the impropriety of placing his ear to her chest, he searched for another method and invented the stethoscope.

Shortly thereafter, Laënnec received a number of honors. In July, 1822, he was appointed chair and professor of medicine at the Collège de France. In January, 1823, he was accepted as a full member of the French Academy of Medicine. He also received an appointment as a professor at the medical clinic at the Hôpital de la Charité. In 1824, he was awarded the Legion of Honor.

Throughout his life, Laënnec was a devout Catholic and a kind and generous individual. He counted among his patients many famous people such as the author François-René de Chateaubriand, but he also treated many poor patients. Laënnec did not marry until 1824, just shortly before his death from tuberculosis. In May, 1826, suffering from deteriorating health, he left Paris and returned to Brittany, hoping to restore himself to better health. He continued to deny that his illness was tuberculosis until he asked his nephew Mériadec to listen to his chest with a stethoscope and describe his findings. What Mériadec reported left no doubt in Laënnec's mind that he was dying from tuberculosis. He willed all of his scientific papers, his watch, and his ring to this nephew. He also left him his stethoscope. Laënnec truly realized the importance and value of his invention and described it as the best item he was leaving to Mériadec. On August 13, 1826, he died in Kerlouanec, France.

Impact

Laënnec had a most significant impact on medicine both as a researcher and as a practicing physician. Influenced by the teachings of Corvisart, who had reintroduced the usefulness of chest percussion first used by Leopold

Auenbrugger, Laënnec further explored this method and published the results of his work, which became the basis for diagnosing chest disease.

His greatest contribution to diagnosis of chest illness was his invention of the stethoscope, which made accurate diagnosis possible in cases that otherwise remained unclear. In 1818, he appeared before the Academy of Science in Paris with his findings and research on the stethoscope. In 1819, he published his two-volume work on the stethoscope and chest disease, *De l'auscultation médiate* (*On Mediate Auscultation*, 1821). Laënnec's treatise brought a large number of physicians to Paris to see the stethoscope and to consult with him about its use. A revised version of the book, which correlated the sounds heard with the stethoscope with the lesion found at autopsy, was published in 1826.

Laënnec gave the liver disease known as cirrhosis its name. He also made important discoveries about melanoma and distinguished its lesions from those of tuberculosis. He advanced the diagnosis of heart problems through his research. Using his stethoscope, he discovered and described two distinct heart sounds. As a result of his research and active practice as a physician, Laënnec advanced both the knowledge and the methods of diagnosis available to physicians. He perfected the art of clinical diagnosis, which became one of the most valuable tools for the physician in the treatment of diseases, especially those of the chest. His invention of the stethoscope enabled physicians to distinguish and diagnose various chest diseases.

EDWIN HERBERT LAND

American physicist

The two most important achievements in Land's career were the development of effective and inexpensive sheet polarizers in the 1930's and the invention of instant photography in sepia (1947), black and white (1950), and color (1963).

Born: May 7, 1909; Bridgeport, Connecticut
Died: March 1, 1991; Cambridge, Massachusetts
Also known as: Din Land
Primary fields: Chemistry; optics; photography; physics
Primary inventions: Instant photography; sheet polarizers

EARLY LIFE

Edwin Herbert Land was a very private person who devoted himself to his work, so not much is known about his private life or early history. He was the son of an immigrant to the United States from Odessa, Russia, who settled in Bridgeport, Connecticut, and ran a successful scrap metal business. Land's father, Harry, married Matie Goldfaden, and their first child was a girl named Helen. When Helen's little brother was born, she could not pronounce "Edwin" correctly at first, and her approximation, "Din," became his lifelong nickname.

As a child, Edwin was fascinated by kaleidoscopes and magic-lantern shows. He discovered the textbook *Physical Optics* (1905) by Robert W. Wood and read it, he claimed, as if it were the Bible. When the thirteen-year-old Edwin was at summer camp, a counselor used a piece of Iceland spar (crystallized calcium carbonate) to remove the glare from a tabletop, impressing the boy. Again, later that summer, he was in a car that narrowly missed hitting a farm wagon because of poor visibility from headlight glare. Removing glare from headlights became the primary motivation in his research to develop the sheet polarizer, a device for filtering the type and amount of light to pass through.

Edwin Herbert Land, who founded Polaroid in 1937, demonstrates instant photography. (AP/Wide World Photos)

Land entered Harvard College in 1926 but was soon bored and dropped out. After a brief stay in Chicago to indulge a bohemian fantasy of the writer's life, he relocated to New York City and began independent research into light polarization. He succeeded in 1929 and filed for the first of his many patents. In the fall of that year, Land returned to Harvard to resume his studies and married Terre Maislen, who was to be the mother of his two daughters, Jennifer and Valerie.

LIFE'S WORK

The first sheet polarizer was created by electromagnetically aligning tiny crystals of herapathite (iodoquinine sulfate) in solution, then dipping a celluloid strip in the concoction in order to apply a coat of oriented platelets. An improved method involved much tinier crystals that were oriented on the celluloid or plastic strip by radical extension or stretching.

Land began negotiating with General Motors (GM) and other automobile companies in 1931 about instituting a universal system for headlights and windshields (or goggles) to control glare while driving. These discussions continued until the late

1940's but never bore fruit. One probable reason for this was the need to introduce such a system all at once, eliminating the competitive advantage for any one automobile company. Other safety innovations such as dimmers for headlights, improved brakes, seat belts, and airbags could be introduced piecemeal and provide marketing advantages. Polarized headlights would also have to be some fifty times brighter than the ordinary kind and therefore would drain a car's battery that much more.

Other commercial opportunities did develop for Land's invention, however. He began providing Kodak with polarizing filters for cameras marketed as Polascreens, and he signed contracts with American Optical to make polarizing lenses for sunglasses. Metro-Goldwyn-Mayer (MGM) demonstrated three-dimensional (3-D) movies at the New York World's Fair of 1939-1940, and they were viewed with Land's dark, polarizing plastic glasses, which returned briefly for the 3-D movie craze of the early 1950's.

Land founded the Polaroid Corporation in 1937, and he was given total control for the first ten years. Very soon, however, World War II started, and Land put his company at the service of the war effort. Polaroid developed a system for 3-D reconnaissance photography called the Vectrograph for the U.S. military. The company worked on heat-sensitive guidance systems for bombs and proximity fuses that would detonate explosives at a set distance from targets. Polaroid also made machine-gun trainers with simulated tracer bullets, plastic lenses, nonpolarizing filters, and different kinds of gun sights and goggles. Though Polaroid's volume of business increased dramatically, company profits remained about the same during this period.

At the end of 1943, Land found inspiration for the achievement for which he is best known. He took a photo of his daughter Jennifer while they were on vacation in New Mexico, and she asked why she had to wait so long to see the result. The idea of instant photography was thus implanted in the fertile mind of Land. His first system was put on the market in 1948. Land continued to perfect his invention, finally bringing out the classic SX-70 in 1972.

During the Cold War, Land was asked to serve on a number of advisory committees to help the U.S. government take best advantage of the country's scientific potential. He participated in Project Charles, which reported to the president in August of 1951, and then worked on Project Beacon Hill. He was a member of President Dwight D. Eisenhower's Science Advisory Committee, created in 1954, and he served on this committee until it was abolished by President Richard M. Nixon. Land was also involved in developing photographic systems for reconnaissance planes and satellites

Instant Photography

In 1943, while vacationing in New Mexico with his wife, Terre, and daughter, Jennifer, Edwin Herbert Land took a photograph of his daughter, who asked why the picture did not develop immediately. Her question set in motion a momentous chain of events. Land claimed that the essentials of the instant photography system developed in his mind that very day. All the chemical complexities of bringing a photograph to life in a darkroom were to be shrunk to the size of a normal camera and performed in a few seconds.

With Land's process, tiny pods protected the chemical reagents from air until the critical moment. Then, after exposure, small rollers would rupture the pods and press the latent image of the negative and the positive print together for instant, simultaneous development. This new approach was referred to as diffusion transfer. Finally, the development process had to be stabilized and the print dried in a matter of seconds to produce the immediately viewable photo.

The process for instant development of color photos was even more complex, and Land worked closely with Howard Rogers at Polaroid for this purpose. Rogers developed new molecules for the primary colors, each acting both as a developer and image dye. These molecules made the chemical couplers used in Kodachrome and in other color systems unnecessary, and they made possible the required compression of the process. Polacolor was introduced in Florida in January of 1963, and it was an immediate success among vacationers. An important marketing advantage was that this film worked in existing Polaroid cameras.

The ultimate camera for instant color photography, however, was not brought out until 1972. The SX-70 was new in appearance, flash system, viewing-system electronics, and film structure. The design of the SX-70 was so ambitious and sophisticated, however, that problems arose in the manufacturing process after it was introduced. Polaroid had trouble finding subcontractors with the requisite expertise and had to assume more of a manufacturing role than could easily be accomplished. The SX-70 did finally make a profit, but not as much as its cheaper and simpler variations, such as the OneStep. By the end of the century, both would become defunct with the rise of digital photography.

such as the U-2, the Blackbird, and the Corona. He also helped develop a small camera used by Neil Armstrong on the first Moon landing of Apollo 11 in 1969.

Land was a successful businessman who made a fortune in his life and prided himself on fulfilling practical needs of society with his inventions, but he was also interested in pure science. His work in photography led him to question certain assumptions about the nature of light and the phenomenon of color. Land was intrigued that he could not establish a clear connection between the wavelength of light reflecting off objects into the eye of the beholder and the color perceived. His retinex theory eventually showed that there are certain specialized cells in the retina that are sensitive to certain colors: There are other cells in this area and in the cerebral cortex that criticize and compare these basic reactions. Color constancy is now understood as an extremely complex, relative process involving subtle comparisons of the focal area with the background of any given scene. Land began his experiments in this area in 1955, but his ideas were not accepted by neurophysiologists until the early 1980's.

Polaroid Corporation and Land had a long and complicated relationship with the dominant player in the photography business, the Eastman Kodak Company. When he was just starting out, Land supplied Kodak with products and licensed the company to use some of his patents. Later, the companies collaborated, as Polaroid sometimes availed itself of Kodak facilities and its manufacturing capacity. Finally, when Kodak decided to enter the instant photography field, the two became bitter rivals. Polaroid took Kodak to court in 1976 for patent infringement of Polaroid's instant photography products and won the case. Kodak was ordered to stop making those products in 1986 and had to pay Polaroid $900,000 in damages in 1991.

Toward the end of his career, Land seemed to lose a bit of his flexibility. In the final development phase of the SX-70 camera model, he pushed for his own ideas regarding the viewfinder and other aspects of the camera in a way that alienated many people. He was forced to step down as president of the company in 1975, and William J. McCune took over that post. Land's pursuit of instant movies proved to be his one major business mistake. Polavision was a technological marvel, but it was developed with little regard for the bottom line and without appreciation of the advantages of videotape, which became the dominant technology in the field.

After the failure of Polaroid's instant movies in the marketplace, Land was forced to give up his position as chief executive officer in 1980. He resigned as chairman and member of the board in 1982 and had liquidated all of his Polaroid holdings by 1985. He devoted the rest of his life to the research foundation he endowed, called the Rowland Institute.

Impact

Land was a major force in the science of optics. During his lifetime, he held 535 U.S. patents in this and related fields, more patents than anyone except Thomas Alva Edison. Land's genius made possible the creation of two major industries to manufacture and market sheet polarizers and instant photography. Polaroid Corporation dominated both industries for almost half a century under Land's direction.

The Franklin Institute awarded Land the Cresson Medal in 1937. He received the Presidential Medal of Freedom in 1963 and the National Medal of Science in 1968. He was inducted into the National Inventors Hall of Fame in 1977. Land was honored as a foreign member of the Royal Society of London in 1986.

The Rowland Institute for Science, which Land endowed in 1980, merged with Harvard University in 2002 and is now called the Rowland Institute at Harvard. It specializes in interdisciplinary research primarily in chemistry, physics, and biology. The research seminar for Harvard College freshmen is located there, embodying Land's idea of involving students in actual research early in their college education.

Samuel Pierpont Langley

American physicist and astronomer

Langley designed and built the first powered aircraft that could remain aloft in sustained flight.

Born: August 22, 1834; Roxbury, Massachusetts
Died: February 27, 1906; Aiken, South Carolina
Primary fields: Aeronautics and aerospace technology; astronomy
Primary invention: Aerodromes

Early Life

Samuel Pierpont Langley was born in the Boston suburb of Roxbury, Massachusetts, the son of Samuel and May Williams Langley, part of a distinguished old New England family. The elder Langley was a successful Boston businessman with wide interests outside his business, including an active interest in astronomy. When young Samuel was a boy, he was intrigued by his father's telescope and, together with his brother John, used it to explore the heavens. As teenagers, the boys became well grounded in both astronomy and instrument making.

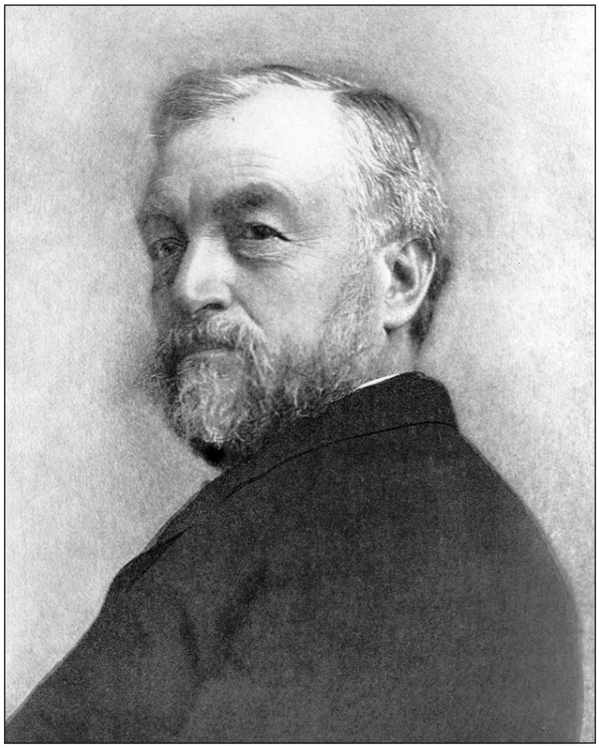
Samuel was sent to Boston Latin School and Boston High School, graduating when he was seventeen. While in school, he excelled in science and math and developed skills in mechanical and engineering fundamentals. Still interested in astronomy, he knew that he would be unlikely to have a career in that field, as there were very few opportunities for employment in what was considered a useless, though interesting, activity.

Although Langley did not attend college, his quick intelligence and skill with mathematics and mechanics led to employment as a civil engineer and architect. His early employment was in Boston, but he eventually moved west to take up positions in Chicago and St. Louis, Missouri. These were important learning experiences, as he became skilled in mechanical drawing and he developed a talent for the design of instruments as well as buildings. However, Langley gave up a career in architecture in 1864 and returned to his boyhood home in Roxbury. He and his brother John were both uncertain about their future but had retained a strong interest in astronomy. Encouraged by a newly developed method of building a reflecting telescope using a glass mirror with a silvered surface, the brothers worked at perfecting the technique, eventually producing an instrument of high quality.

In 1865, the brothers toured Europe, visiting the usual grand tour cities and cultural centers. When they returned to Roxbury, Samuel was thirty-one years old and still seeking a career. Having heard about the expansion of the Harvard College Observatory, located in nearby Cambridge, Massachusetts, Samuel applied to the director, Joseph Whitlock, for a position and was hired as observatory assistant.

Life's Work

Although the world remembers Langley for his experiments with powered flying machines, his career was



Samuel Pierpont Langley. (Library of Congress) mainly in the field of astronomy. Beginning with the position at the Harvard Observatory, he moved with almost unbelievable speed up the ladder of professional science. After only a year at Cambridge, he moved to Annapolis, Maryland, where he became professor of mathematics at the U.S. Naval Academy. His duties while at Annapolis were chiefly concerned with the academy's small observatory.

Further rapid progress in the academic world occurred in 1867, when he was appointed director of the Allegheny Observatory and professor of astronomy of the University of Western Pennsylvania (now the University of Pittsburgh). This observatory had been deeded to the university by a group of amateur astronomers who had lost interest in its use and upkeep. As a professor of astronomy and physics, Langley was expected to teach appropriate courses and care for the observatory as a teaching facility.

The young professor wanted to make the observatory into an active research center, but there were no funds for this, so he sought a method of earning the observatory's support. The instruments could provide one important service: determining the correct time. At that time, there was no standard source of time; each city determined its own time by whatever means it could. Langley arranged with the Pennsylvania Railroad to provide accurate time twice a day to its hundreds of telegraph offices. Soon, others for whom accurate time was important sought this service, too, and the observatory was at last financially supported.

Langley's chief astronomical interest in Pittsburgh was the Sun, and he was particularly concerned with determining the solar constant, which is the rate of solar energy release as measured from the Earth. He experimented with methods of detecting infrared light, for which he developed infrared-sensitive measuring instruments. This work led to his invention of the bolometer, a highly sensitive device used to measure temperatures of radiant bodies like the Sun at various wavelengths.

Another interest that Langley developed in Pittsburgh had little to do with his position as an astronomer. It is said that he was inspired by a talk on avian flight that he heard at a meeting of the American Association for the Advancement of Science. He began to look into how birds can sometimes sustain flight without moving their wings. Langley realized that the secret of avian gliding might be the key to the development of a flying machine. To solve the secret of flight, he experimented with a rotating arm device that allowed him to measure the properties of wings of various shapes moving through air at various velocities. The result was an array of experimental results that formed an important cornerstone in the foundation of the field of aeronautics. These results were published in his book *Experiments in Aerodynamics* (1891).

Langley's reputation as a dynamic and resourceful scientist resulted in his being chosen to be the secre-

AERODROMES

Samuel Pierpoint Langley's unmanned aerodromes were pioneering aircraft in the development of flight. After having decided in 1897 to withdraw from the enterprise of building a craft that could carry a man, Langley had second thoughts almost immediately. War with Spain began in 1898, and President William McKinley persuaded Langley to take up his aeronautics work again so that it might be possible to use manned aircraft in military applications. He agreed to do so and immediately began to construct an aerodrome that would follow the design of Nos. 5 and 6, but that would be large enough to carry the weight of a person. Langley hired a young engineer, Charles Manly, to direct the construction and develop the engine, which would have to be much more powerful than the small steam engines used thus far. This turned out to be very difficult, but by late 1900 Manly had built a gas-powered engine that weighed 124 pounds and delivered 52 horsepower.

After much testing and adjusting, Langley and Manly decided to make a test flight of the new aerodrome from the roof of a houseboat on the Potomac River. On October 7, 1903, with Manly aboard the craft and with the surrounding waters full of the boats of newspaper reporters, the aerodrome was catapulted from its launch vehicle, only to plummet straight down into the river. Afterward, Langley explained that the problem had been a failure of the launching mechanism, not the aerodrome. However, the newsmen, who had been kept waiting for months for this flight, made spectacularly disparaging remarks about the failure.

The damaged craft was quickly rebuilt and again made ready for flight on December 8, 1903. In front of many onlookers and members of the press, Manly again boarded the craft, which was launched over the icy Potomac. This time, something caused part of the tail to drag on the ways, with the result that the aerodrome flew up instead of down, entirely flipping onto its back and falling to the river. Miraculously, Manly was able to free himself from under the ruined craft and come to the surface among the ice floes. Neither he nor Langley attempted to fly the aerodrome again.

tary—that is, the director—of the Smithsonian Institution in 1887. In this post, he continued to carry out solar research, eventually establishing the Smithsonian Astrophysical Observatory, which is now one of the largest astronomical research institutions in the world. His research continued to deal with solar radiation at various wavelengths.

The resources of the Smithsonian Institution also favored continuing research on the physics of flight. Langley used his rotating arm instrument to test various wing designs and even tried it out on actual birds' wings, concluding that a bird, without sensitively controlled muscles to power and to adjust its wings, would not have loft enough to maintain flight. Langley also began experiments with what we would call "model airplanes," powered by rubber bands. Building them with a variety of different designs and wing shapes, Langley flew more than one hundred of these, attaining flights of as much as one hundred feet. These simple experiments showed promise and led to the next stage, the design of a powered flying machine. Langley called these "aerodromes." The first was powered by a small steam engine. Others used carbonic acid gas, compressed air, and, eventually, gasoline engines. The most successful flight was made in 1896 by his Aerodrome No. 6, which flew a distance of forty-eight hundred feet. This was considered to be the first successful flight of a self-propelled machine that kept aloft for a significant amount of time and for a significant distance.

Langley published a review of these experiments in 1897 in which he said that he felt that his task was finished; he had shown that sustained flight by powered flying machines was possible and that others should next try to fly a manned aircraft. However, external events convinced him to carry on, and he eventually made two unsuccessful attempts to fly a manned version of his aerodrome. Langley died in 1906 in Aiken, South Carolina.

Impact

Langley's astronomical work was devoted to the new field of astrophysics, and he was one of the principal developers of the application of physics to the understanding of the stars and planets. His exploration of the spectrum of light into the hitherto unknown infrared region made possible an entirely new way to measure the emission of sunlight and starlight. His invention of the bolometer was an important step in the development of infrared astronomy. His devotion to making science available to the public set an important precedent for his colleagues. Although he considered himself primarily an astronomer, Langley is best known for his experiments in aeronautics, which resulted in the first flight by a self-powered heavier-than-air machine.

Irving Langmuir

American physical chemist

Langmuir's exploration of surface phenomena and thin films led to important practical applications and a Nobel Prize in Chemistry. He is best known for his contributions to the development of the commercially successful incandescent bulb.

Born: January 31, 1881; Brooklyn, New York
Died: August 16, 1959; Falmouth, Massachusetts
Primary fields: Chemistry; physics
Primary invention: Gas-filled incandescent light bulb

Early Life

Irving Langmuir (LAYNG-myoor) was the third of four boys born to Charles and Sadie (née Comings) Langmuir. His early education included schools in both New York and Paris. In 1899, he entered the Columbia University School of Mines for its rigorous curriculum in chemistry, physics, and mathematics. He graduated with a degree in metallurgical engineering in 1903.

Like many aspiring chemists at the beginning of the twentieth century, Langmuir went to Germany for graduate study. At the University of Göttingen, he studied with Walther Nernst, winner of the 1920 Nobel Prize in Chemistry. At first, it appeared that Nernst and Langmuir would not be a good fit as a doctoral research team. Langmuir complained that Nernst spent all his time on his own research and ignored him. There is evidence that Nernst did not see much potential in the American. Nernst was deeply involved in the study of thermodynamics at that time. His work in this field, which combines physics and chemistry through the elegant application of mathematics, contributed to the development of the third law of thermodynamics. These studies dealing with matter at absolute zero were of practical importance for the field of cryogenics.

For a research project, Langmuir was assigned the rather mundane task of studying the chemical reactions of gases near a glowing platinum wire. Despite this unpromising situation, he was able to obtain excellent results. He used this research in his thesis to investigate the chemistry of gases and the transfer of heat from hot surfaces such as platinum wire.

Life's Work

Langmuir struggled trying to decide between a career in research at a university and a career as a chemist in industry. Perhaps by fate, his older brother Herbert wrote him a letter in which he detailed thoughts about this very question. Herbert advised a scholarly, scientific career but only if Irving was satisfied that he had the ability to

Irving Langmuir. (©The Nobel Foundation) make a great success of it. Irving believed in himself and knew his future direction.

After earning his Ph.D. in 1906, Langmuir began teaching chemistry at the new Stevens Institute of Technology in Hoboken, New Jersey. He was often praised for his teaching skills and his interest in the progress of young scientists, but he found the institute to be unbearable. He felt that his students had little interest in learning, his colleagues were lazy, and there was little opportunity for research. After three years, he resigned.

In the summer of 1909, he began working for the General Electric (GE) Research Laboratory in Schenectady, New York, where he would work for the rest of his life. The lab director, Willis R. Whitney, was recently recruited from the Massachusetts Institute of Technology (MIT) and had heard Langmuir at the conference that had brought him to Schenectady. The two men were assigned to work together, and GE's lab was an ideal place. Langmuir was at once taken by the latitude given to the scientists there and the easy rapport they enjoyed with one another.

Whitney had the task of building a great laboratory. He surrounded himself with the best men and allowed them to study whatever they wished without regard to practical outcome. This independence, he believed, would lead to useful product development, and the laboratory setting allowed him to assess new scientists.

Langmuir was drawn to research on gases in close proximity to a heated wire, work that resonated with his doctoral thesis. At that time, his new colleague, William David Coolidge, was working on a tungsten-filament lamp. It seemed logical that tungsten, which could withstand very high temperatures, would be superior to the carbon or tantalum then in use. The problem was that tungsten's brittle nature made it difficult to form into wires. Langmuir was fascinated by the problem and by GE's advanced equipment. He investigated what would happen if the gas in the light bulb was removed, and he discovered that the glowing tungsten wire produced a huge amount of gas inside the bulb. The tungsten-filament bulb blackened over time and the filament was short-lived. He soon discovered that a mixture of argon and nitrogen gases, along with a coiled filament, improved the light bulb's efficiency.

In 1912, Langmuir married Marion Mersereau, and they had two children, Kenneth and Barbara. Langmuir next turned his attention to surface chemistry. As early as 1916, he published in the *Journal of the American Chemical Society* an article concerning the fundamental properties of solids and liquids. A second part appeared in the same journal the next year, and a variety of reports appeared prior to his receiving the Nobel Prize in 1932. In presenting the new Nobel laureate to the audience in Stockholm, the chairman of the Nobel Committee for Chemistry described how Langmuir had radically changed the prevailing view of forces in thin films. Langmuir showed that films that were only one molecule thick behaved much like a two-dimensional gas. This daring point of view opened a new field of exploration.

An Improved Electric Light Bulb

When Irving Langmuir began studying the electric light bulb at General Electric (GE) Research Laboratory, it was universally accepted that producing a vacuum in the bulb would preserve the tungsten filament and thereby prolong the life of the bulb. He had a passion for the extraordinary vacuum equipment available at GE's laboratory, and he designed a still better pumping apparatus. When he proposed to experiment with a light bulb filled with gas, however, even his boss, Willis R. Whitney, was doubtful.

A problem associated with designing a more efficient lamp was its tendency to blacken, or dim, after a period of use. Langmuir discovered that water vapor was the chief cause of the blackening, but only a small amount was required to produce it. After a great deal of effort, he learned just how complicated the process was. When the water vapor molecules come in contact with the hot filament, an oxygen compound of tungsten and atomic hydrogen is produced. The oxide of tungsten, which is easily converted to a gas, moves to the glass, where it is reduced by the atomic hydrogen and is deposited on the glass as metallic tungsten. Before Langmuir, no one had ever produced individual atoms of this highly reactive substance.

Further experiments demonstrated that even in the near absence of water vapor, the glass blackened at the same rate. Langmuir now concluded that a vacuum, no matter how perfect, was not going to improve the quality of the bulb. He turned his attention to other gases, such as nitrogen, in an effort to see if it too could be torn apart. It was not, but the life span of the bulb was markedly increased. It became apparent that the rate of evaporation of the tungsten was retarded by the gas molecules. He discovered that a nitrogen-argon mixture worked best.

In 1913, Langmuir applied for a patent for a gas-filled lamp, and it was granted three years later. Whitney estimated that Langmuir's work saved American consumers more that a million dollars every night on their lighting bills.

Besides the Nobel Prize, Langmuir was awarded fifteen honorary degrees. Both the Royal Society of London and the American Chemical Society recognized his accomplishments with their most prestigious medals. Langmuir died of a heart attack in Falmouth, Massachusetts, in 1957.

Impact

Few scientists have contributed as much to pure research or have made as many practical contributions as Langmuir. He demonstrated an uncanny knack for seeing deeply into nature and understanding how his knowledge could influence real-world needs. Along with Willis R. Whitney, he appreciated both the importance and the joy of fundamental research. His research on the behavior of filaments led to the development of gas-filled incandescent bulbs that were significantly more efficient than other light bulbs, and his work in surface chemistry led to his revolutionary discovery that gases would adsorb onto the surface of a liquid or solid in a layer only one atom or molecule thick.

Lewis Howard Latimer
American draftsman

Latimer's inventions ranged from improvements to the electric light bulb that facilitated its widespread manufacture and use to an advanced toilet system for railroad cars.

Born: September 4, 1848; Chelsea, Massachusetts
Died: December 11, 1928; Flushing, New York
Primary field: Electronics and electrical engineering
Primary invention: Carbon filament for the incandescent light bulb

Early Life

Lewis Howard Latimer was born to George and Rebecca Latimer in Chelsea, Massachusetts, in 1848. His parents had escaped from slavery in Virginia six years before Lewis, their fourth and last child, was born. He had two brothers and one sister. Lewis attended elementary school but was self-educated beyond that. He had great interest in reading, drawing, and learning about new things. By the time he was ten years old, he was working in his father's barbershop and as a paperhanger to help support the family.

In September, 1864, Latimer joined the U.S. Navy at the age of sixteen. He served on the USS *Massasoit* and remained in the Navy until the end of the Civil War, at which time he received an honorable discharge. After returning to the Boston area, he began work as an office boy for the patent law firm Crosby and Gould. While working there, he taught himself mechanical drawing by reading about it and by closely observing the draftsmen at the firm. When his capabilities were recognized, he was promoted to the position of draftsman by the firm. Latimer was married to Mary Wilson on December 10, 1873. The couple had two children—Emma Jeannette, born in 1883, and Louise Rebecca, born in 1890.

Life's Work

Latimer's first patent was for an improved toilet system to be used in railway cars and was called the "Water Closet for Railroad Cars" (U.S. Patent 147,363). The patent was issued to him jointly with Charles W. Brown on February 10, 1874. There is no evidence that he and Brown made serious efforts to market the device or that it came into widespread use. At this time, Latimer was working as a draftsman for Crosby and Gould, patent solicitors. Also while working there, he assisted Alexander Graham Bell by drafting the drawings of and helping in the patent application for his telephone invention. Through their joint efforts, the patent application was filed on February 14, 1876, just a few hours before a competitor. Bell was granted the patent on March 7.

In 1879, Latimer moved to Bridgeport, Connecticut, with his wife, his mother, and his brother William. In 1890, Latimer was hired as assistant manager and draftsman by Hiram Percy Maxim, owner of the U.S. Electric Lighting Company. Maxim was a rival of Thomas Alva Edison. While working for Maxim, Latimer learned quickly about the nascent electrical industry and was awarded three patents for devices and processes that improved the quality and efficiency of manufacturing electric light bulbs. The first patent (number 247,097) was for an "Electric Lamp," issued jointly to Latimer and Joseph V. Nichols on September 13, 1881. This invention was for an improved method of attaching the carbon filament to the wires used to bring electricity into the bulb. The second patent (number 252,386) was for a "Process of Manufacturing Carbons," issued to Latimer on January 17, 1882. This invention was an improved method of manufacturing the carbon filaments used for incandescent bulbs. The improved process produced longer-lasting carbon filaments. The third patent (number 255,212) was for a "Globe Supporter for Electric Lamps," issued to Latimer and John Tregoning on March 21, 1882. This was for an improved method of supporting arc lights. In addition to the three patented inventions, Latimer had many unpatented inventions that improved much of the equipment and many processes used in making electric lamps. In addition to his work in the manufacture of light bulbs, Latimer spent time assisting with installation of Maxim lighting equipment in Philadelphia, New York City, Montreal, and London. He spent nine months in London setting up a factory for producing Maxim electric lamps. His work included teaching the workers all of the processes used in making the lamps.

Latimer left the employ of U.S. Electric Lighting Company late in 1982, after returning from his assignment in London. For the next several years, he worked for several companies in the electrical industry. In 1885, he began a long period of employment with Edison Electric Light Company. He began in the engineering department, and in 1890 he moved to the legal department. He worked as a patent investigator and as an expert witness in cases against those trying to infringe on Edison patents. While working for the company, Latimer authored the book *Incandescent Electric Lighting: A Practical Description of the Edison System* (1890). In easy-to-understand language, the book described the entire system necessary for an incandescent lamp to produce light. There is some confusion about the authorship, however, because the above title by Latimer was published together with a paper by C. J. Field and a paper by John W. Howell, all in the same volume.

When Edison Electric Light Company merged with Thomson-Houston in 1892 to form General Electric, Latimer continued in the legal department of the newly formed company until 1896, when he became chief draftsman for the Board of Patent Control, a joint arrangement between General Electric and Westinghouse Electric Company. He continued in this position until 1911, when he began work for a patent consulting firm headed by Edwin Hammer and Elmer Schwarz. He continued with them until 1922, when he retired because of failing eyesight.

Besides his inventions related to electric light bulbs and their manufacture, Latimer received patents for other devices, including an "Apparatus for Cooling and Disinfecting" (1886), a forerunner of the air conditioner; a device for locking hats, coats, and umbrellas on a hanging rack (1896); a book support (1905); and a lamp fixture (1910). He was a charter member of the Edison Pioneers, an exclusive group formed in 1918 and composed of men who were technical or business affiliates of Edison or one of his companies. The purpose of the group appeared to be primarily social and professional networking. Latimer's wife died in 1924, and he passed away in his home in Flushing, New York, on December 11, 1928.

Impact

While Edison invented the first commercially practical incandescent light bulb (patent issued in 1880), it is less widely known that Latimer made important related inventions shortly afterward that made possible the efficient manufacture of high-quality light bulbs. The three patents Latimer was awarded while working for the U.S. Electric Lighting Company and the unpatented work he did in developing and improving the process of manufacturing electric light bulbs facilitated the widespread use of electric lighting. In addition, Latimer supervised the installation of carbon filament electric lighting in several major cities. He spent most of his career working in the newly developing electrical industry, using his talents as en-

Improved Process for Manufacturing Carbon Filaments

An incandescent light bulb produces light by passing electric current through a thin wire called a filament. The filament has adequate electrical resistance so that it heats to a high temperature when electric current is passed through it. The temperature is high enough to make the filament emit light, hence its glow. In order to be practical for use as a lighting device, the filament must be prevented from oxidizing (burning) and thus wearing out rapidly at the high temperatures. In early light bulbs, a carbon filament was used and a vacuum was drawn in the bulb to prevent oxidation. In modern bulbs, tungsten is used for the filament and the bulb is filled with an inert gas, usually argon, to prevent oxidation. This is done because tungsten would vaporize too rapidly in a vacuum. Also, the filament must be connected to a base with electrical conductors so that an electrical voltage can be applied in such a way that electric current will flow through the filament.

The invention of the incandescent light bulb was actually spread out over many years. In 1802, Sir Humphrey Davy passed enough direct current through a platinum strip to produce incandescent light. In the mid-to-late 1800's, several other inventors experimented with use of some form of carbon for the filament and with drawing a vacuum in the bulb. In 1880, Thomas Alva Edison received a patent for improvements to the light bulb that made it practical to produce. In 1881 and 1882, Lewis Howard Latimer received patents for further improvements to the light bulb, especially the carbon filament. His improved process for manufacturing carbon filaments made them longer lasting and capable of more rapid production. He also made improvements to the light bulb production process. His improvements aided in bringing about production of high-quality bulbs in large numbers.

The incandescent light bulb was a very significant invention. It allowed people to work, travel, and carry out commerce at night. The previous sources of light, such as candles, fire, or oil lamps, made these activities difficult or nearly impossible to do at night. Work could now be done in factories over a twenty-four-hour period rather than in daylight hours only. Stores could stay open longer to do business. With the availability of the light bulb, mining became safer. Previously, lanterns had been used to provide light underground. The flames in lanterns consumed oxygen and added to the carbon dioxide content in the air, making breathing difficult. Also, the use of lanterns with an open flame was an explosion hazard underground.

gineer, draftsman, and patent expert. Latimer was recognized for his work on electric filament manufacturing by his induction into the National Inventors Hall of Fame in 2006.

Ernest Orlando Lawrence

American nuclear physicist

Lawrence was the inventor of the cyclotron, a circular particle accelerator that was widely used by scientists to study nuclear reactions and to produce new radioactive isotopes. During World War II, Lawrence supervised the magnetic separation of fissionable uranium 235 for the atomic bomb project.

Born: August 8, 1901; Canton, South Dakota
Died: August 27, 1958; Palo Alto, California
Primary fields: Military technology and weaponry; physics
Primary invention: Cyclotron

Early Life

Ernest Orlando Lawrence was born in Canton, South Dakota, a small farming community near the Minnesota border. Both his parents were descendants of recent immigrants from Norway. His father was superintendent of Canton City Schools and his mother had been a high school mathematics teacher. As a child, Lawrence showed an early interest in electrical apparatuses. At age nine, he and another boy learned to recharge old batteries, which they used to operate doorbells and electric motors. Later, the two friends built a radio receiver with a roof antenna that enabled them to receive messages from ships at sea. In 1916, Lawrence was the first person in the area to hear the news of Germany's declaration of war against the United States.

Lawrence graduated from high school in 1918. After one year at St. Olaf College in Minnesota, he transferred to the University of South Dakota (USD). At USD, Lawrence approached Professor Lewis Akeley, who taught electrical engineering and physics, about setting up a radio station on campus, which would provide good publicity for the university and give practical experience to engineering students. Lawrence had prepared a proposed budget with several levels of funding to accomplish different levels of operation. With Akeley's approval, Lawrence purchased the needed apparatuses and successfully got the station into operation.

Akeley was amazed that Lawrence knew so much about electricity without ever having taken a class in the subject. He offered to tutor him in physics during the summer, at which time they covered the material for a year's course in just six weeks. In his senior year, Lawrence was the only student to sign up for an advanced physics course. Realizing that this young man had a very special talent, Akeley proposed a novel class format: Lawrence would give all the lectures, while the professor became his student. In later years, Lawrence gave credit to Akeley for teaching him how to study a subject thoroughly. After graduating from USD in 1922, Lawrence obtained a physics fellowship for graduate work at the University of Minnesota.

Life's Work

At Minnesota, Lawrence came under the influence of Professor W. F. G. Swann, a dynamic young physicist who became his thesis adviser. The following year, Swann moved to the University of Chicago, where Lawrence followed him. At Chicago, Lawrence came into contact with world-renowned Nobel Prize laureates such as Albert A. Michelson and Robert Millikan. A year later, Swann accepted a professorship at Yale University, and Lawrence again followed his mentor. Lawrence received the Ph.D. from Yale in 1925 and was given a position as assistant professor.

In the next three years at Yale, Lawrence became recognized as an outstanding experimentalist. He published several notable papers on the interaction of light and electricity, using apparatuses that he designed and built. He did not enjoy teaching undergraduate students who had little interest in physics. In 1928, he was offered a position as associate professor at the University of California, Berkeley, which promised him time for research and teaching duties limited to graduate courses. He accepted enthusiastically. With his infectious optimism, after just one year he had become the thesis adviser for eight students. Through frequent publications and contact with scientists at other universities, he became nationally known. When he received employment offers from two rival universities, Berkeley decided to promote him to full professor at the young age of twenty-nine.

In the early 1930's, physicists were trying to go beyond natural radioactivity to probe the atomic nucleus. One technique was to build a high-voltage device, like an X-ray machine, that would accelerate particles to high energy for bombarding various targets. Lawrence had an alternative idea that many small accelerations at low voltage might overcome the difficulty of using a single stage of high voltage to reach the same final result. It would be like a boy on a swing who is given many small pushes instead of a single big push to pump him up. Using a magnet, Lawrence showed that particles could be forced to go in a circular path and would gain energy repeatedly each time they crossed the same electric acceleration region. In 1931, he was able to produce a circulating beam that reached a final energy equivalent to 1 million electronvolts using fewer than 20,000 electronvolts for each acceleration. Dozens of cyclotrons based on Lawrence's design were built at other universities while he pushed ahead to obtain higher particle energies. With his graduate students, he constructed a machine in 1936 having an electromagnet with a diameter of thirty-seven inches to produce protons with an energy equivalent to 80 million electronvolts. In 1939, Lawrence was awarded the Nobel Prize in Physics for his invention of the cyclotron and the production of new radioactive isotopes.

Ernest Orlando Lawrence makes adjustments to his cyclotron at the University of California, Berkeley, in 1939. (Getty Images)

The fission of uranium was discovered in Germany in 1939. Scientists who recently had come from Europe were greatly alarmed that Germany would try to make an atomic bomb based on fission. The American response was slow at first but eventually became a major war effort called the Manhattan Project. It was determined that only the rare isotope uranium 235, less than one percent of ordinary uranium, was fissionable. In 1941, Lawrence converted the Berkeley cyclotron to a mass separator and showed that a slight enrichment of U-235 could be obtained. Based on rather meager evidence, Lawrence proposed a major scaling up to construct a laboratory dedicated totally to U-235 enrichment. This laboratory, with ninety-six magnetic separators, was built at Oak Ridge, Tennessee, with Lawrence in charge. After some initial problems, the laboratory eventually operated around the clock and by early 1945 had produced several kilograms of U-235 with high enrichment. The material was shipped to Los Alamos, New Mexico, where the atomic bomb design and assembly were carried out.

After the end of World War II, Lawrence's scientific work decreased as he became more involved as a governmental adviser. Along with Edward Teller, he advocated the construction of the powerful hydrogen bomb, which is detonated by a fission bomb. He witnessed several nuclear test explosions in the South Pacific. Lawrence encouraged the Atomic Energy Commission to form a special laboratory for weapons research, now called the Lawrence Livermore National Laboratory. After his death in 1958, the artificially created element 103, first produced at Berkeley, was named Lawrencium in his honor.

The Cyclotron

The cyclotron is a particle accelerator. Most commonly, the particles being accelerated are hydrogen ions, which are hydrogen atoms whose single orbital electron has been stripped off. The hydrogen ions, called protons, have a positive electric charge. When a voltage source is connected to two electrodes, a proton crossing the gap between them would gain kinetic energy. In 1929, Ernest Orlando Lawrence had the unique idea to use a magnetic field to deflect protons back into the acceleration region between two electrodes. By reversing the polarity of the voltage applied to the electrodes, the ions would gain more energy each time they crossed the gap. Lawrence's first experimental model used a magnet with a diameter of just four inches. He was successful in showing that the device, which he called a "proton merry-go-round," operated as intended.

The core of the cyclotron is a pair of D-shaped, hollow, metal electrodes separated by a small gap. To visualize this arrangement, one can imagine a round, flat can cut into halves, each piece having the shape of the letter *D*. When a proton crosses the gap between the two "dees," its kinetic energy increases in proportion to the applied voltage. The dees are placed into a strong magnetic field that curves the protons around in a semicircle, bringing them back to the gap between the dees. The protons gain another burst of kinetic energy if the voltage applied to the dees has been reversed and is synchronized with the arrival time of the protons. As the protons gain energy, they spiral outward because of their greater velocity. The strength and diameter of the magnet limit the maximum particle energy obtainable.

In 1939, construction had started on a sixty-inch model with a two-hundred-ton magnet, and a huge 184-inch-diameter machine was in the design stage. Work on these cyclotrons was discontinued when American scientists were mobilized for the war effort. The 184-inch cyclotron eventually was completed in the late 1940's. For higher energies, it is not practical to increase the magnet size. Modern accelerators are shaped like an enormous doughnut having a circumference up to four miles, using many small magnets along the periphery to produce protons having a final energy of billions of electronvolts. Modern accelerators are the descendants of the early cyclotrons, using magnetic deflection synchronized with repeated electric accelerations.

Impact

In the 1930's, cyclotrons were the primary tool to create new radioactive isotopes, some of which became useful in the medical profession. For example, radioactive iodine can be injected into a patient for cancer therapy of the thyroid gland. Radioactive sodium, calcium, and phosphorus have been widely used as tracers in biological and medical research. Nuclear medicine has become an important department in most large hospitals.

During World War II, many scientists who had prewar experience with nuclear technology were brought into the Manhattan Project. Their expertise with isotope separation, nuclear reactions, and radiation detectors were essential for the atomic bomb development. Lawrence earlier had justified his proposals for research funding from foundations and government agencies in part to provide training of young scientists for their potential future contributions to society.

Lawrence has been recognized as a leader in the development of "big science." He foresaw that only the federal government had the financial resources to fund large projects. The space program to put a man on the Moon, utilizing thousands of personnel and billions of dollars, was modeled after the Manhattan Project. Big accelerators, such as Fermilab near Chicago, typically employ hundreds of scientists and support staff. Research on alternative energy sources to reduce dependence on oil and coal is a current example of big science.

BILL LEAR

American electrical and aeronautical engineer

Lear is best known for his development of the Learjet, a sleek business jet aircraft capable of speeds exceeding 560 miles per hour. In addition, Lear invented the eight-track stereo music system and an autopilot system. He also made significant contributions to automobile radio technology and battery power storage.

Born: June 26, 1902; Hannibal, Missouri
Died: May 14, 1978; Reno, Nevada
Also known as: William Powell Lear (full name)
Primary fields: Aeronautics and aerospace technology; electronics and electrical engineering
Primary invention: Learjet

EARLY LIFE

William Powell Lear was born on June 26, 1902, in Hannibal, Missouri, to Reuben, a carpenter, and Gertrude Lear (Powell), a homemaker. Gertrude left Reuben in 1904 and took young Bill with her to Dubuque, Iowa, where they lived with an aunt. They later moved to Chicago, Illinois, with Otto Kirmse, a family friend. Otto was a hardworking man who had a significant positive influence on Lear.

Lear was educated in the public school system, choosing to leave school in the eighth grade. He spent a couple summers with his father, who had relocated to Oklahoma after separating from Gertrude. These trips often resulted in violent arguments between Lear and his mother. Lear worked odd jobs until joining the Navy as a radioman during World War I. Not unlike another famous Hannibal inhabitant, Mark Twain, Lear was quite the iconoclast. An independent thinker and outspoken individual, Lear did not hesitate to frequently correct his teachers and Navy instructors when they were in error. This habit did not endear him to his instructors and resulted, more than once, in his being asked to leave the class and not return. With the exception of training received in the Navy, the eight years Lear spent in elementary school were the sum of his formal education. Lear was married four times and fathered seven children. He was married to his fourth wife, Moya, for the longest period, staying with her until his death.

LIFE'S WORK

After being discharged from the Navy, Lear worked a short stint in an auto supply store in Quincy, Illinois, representing himself as a radio engineer. While working there, he built his first radio and went into business with a prominent Quincy businessman manufacturing radio receivers. During this time, Lear and his first wife, Ethel, lost a child (William P. Lear, Jr.) to crib death (now called sudden infant death syndrome). The death played a role in Lear's leaving Ethel, moving back to Chicago, and marrying Madeline Murphy in 1926. In Chicago, Lear continued his entrepreneurship, creating a B-battery eliminator, which solved the need for using batteries to supply direct current for commercial radio receivers. He designed a power inverter that converted alternating current to direct current, which in turn supplied the necessary receiver power.

A prototype Learjet 23 on a test flight in February, 1964. (Getty Images)

Lear then began a series of short-lived jobs at ever-increasing salaries. At each job, his clear thinking and innovative approach helped him find ways to maximize electronics performance and simplify associated systems. While working for Galvin Manufacturing Corporation, he designed a car radio called the Motorola. This device became the first major product of the Motorola Corporation (formerly Galvin Manufacturing). Lear was doing well financially, earning a $35,000 salary, an incredible sum in 1931. Some of this money went to flying lessons. After only two and a half hours of flight instruction, Lear made an unauthorized solo flight. Lear's introduction to flying would prove to be auspicious, as it led him to develop an automatic pilot system and ultimately to his crowning life achievement of developing the revolutionary Learjet.

Lear divorced his second wife and moved to New York City with his third wife, Margaret Radel. It was a short-lived marriage. In New York, Lear met Russell King of the Radio Corporation of America (RCA). Lear pitched an idea to King regarding the production of a standardized chassis for "all-wave" (multiband) radio receivers. King jumped at the idea, paying Lear $50,000 cash for it and agreeing to pay him an annual consultancy fee of $25,000 for the next five years. In 1942, Lear met and married the woman who turned out to be the love of his life, Moya Olsen. Bill and Moya would remain married for thirty-six years, the remainder of Lear's life.

Lear had founded an aircraft instrument business, Lear, Inc., in 1939 and begun development and production of airplane autopilot units. The business, based in Grand Rapids, Michigan, filled a number of orders for the Allied effort during World War II. Lear later sold a large portion of the business to the Siegler Corporation, which later became Lear-Siegler. Lear stayed on with the company, and he and Moya relocated to Santa Monica, California. The autopilot that Lear invented resulted in his being awarded the prestigious Collier Trophy in 1950. In 1951, Lear was awarded an honorary engineering degree from the University of Michigan recognizing his innovations and inventions in electronics.

As the 1950's came to a close, Lear proposed to the executives at Lear-Siegler his idea for a radical new business airplane design. The aircraft would be a small private jet capable of flying faster that the most modern airliners. Lear-Siegler immediately struck down the idea, citing the huge financial risk of such a project. Never one to tolerate resistance to his ideas, Lear sold his interest in Lear-Siegler for more than $14 million and took his Learjet idea with him.

Lear established a research and manufacturing facility for the Learjet in Switzerland but then relocated the facility to Wichita, Kansas, in 1962. The Learjet would prove to be a paradigm-altering aircraft that brought the business and entertainment world into the jet age. Capable of cruising at 560 miles per hour at altitudes in excess of 40,000 feet, the Learjet appealed to busy, albeit rich, travelers. One hundred four Learjet 23's were manufactured between 1962 and 1966.

Learjet Aircraft

Bill Lear's early forays into electronic inventions such as the B-battery eliminator, the first practical car radio, and aircraft autopilots were precursors to his crowning invention, the Learjet 23. Lear's devotion to simplicity of design, fueled by his innovative mind, paid off in the design of the Learjet 23. The aircraft was first flown on October 7, 1963, and the first production model was delivered only one year later, on October 13, 1964.

The Learjet 23 was a distinctive presence on airport ramps. With clean, aerodynamic lines, it was powered by two General Electric CJ610-4 turbojet engines. The aircraft was capable of flying 560 miles per hour and achieving a service ceiling of over 44,000 feet. Range was approximately 2,500 statute miles. With an empty weight of 6,151 pounds and a maximum gross takeoff weight of 12,499 pounds, the Learjet could have served as a prototype for the modern very light jet (VLJ). The Learjet design incorporated swept wings, maximizing the aircraft's aerodynamic efficiency. At high, transonic speeds, which the Learjet was capable of achieving, air traveling over the upper surface of the wing accelerates to supersonic speeds, forming a wave of compressed air (shock wave) ahead of the wing. The shock wave causes drag, which must be overcome with additional thrust. Making the wing less curved and as thin as possible reduces the potential of airflow accelerating to supersonic speeds and retards the formation of a shock wave. Unfortunately, thin, flat wings produce significantly reduced lift when compared to thick, curved wings. To overcome this lift deficit, Lear swept the Learjet's wings aft, effectively increasing the wing's area while retaining the thin, flat design that was essential to mitigating shock-wave effects.

One hundred four Learjet 23's were produced between 1962 and 1966. A number of other models were later produced. The Learjet was the ultimate status symbol for the rich and powerful during the 1960's and 1970's. Corporate leaders, actors, government officials, and rock stars traveled in the swift opulence provided by Lear's invention. The timelessness of the Learjet is illustrated by the influence of its design. Both the Canadair CL-600 Challenger Jet and the Canadair Regional Jet (CRJ) owe a great deal of their design heritage to the Lear Star 600, a design derivative of the Learjet 23. Both the Challenger and the CRJ are hugely successful aircraft, the Challenger as a luxury business jet and the CRJ as a workhorse within regional airlines.

Interestingly, the Learjet design and production process led to Lear's invention of the eight-track tape system. Seeking an efficient music delivery system for the Learjet, Lear tweaked the existing four-track system to create the very popular eight-track stereo cartridge and playback system.

In later life, Lear became greatly concerned about air pollution. He made a valiant attempt at reviving the concept of the steam car. Investing millions of dollars in research and production, Lear tried unsuccessfully to produce a cost-effective and efficient steam turbine vehicle. Lear perceived the U.S. government as being obstructionist and unsupportive of his efforts. His frankness and disregard for the standard niceties of addressing government officials did not help his efforts to win government appropriations for his work. Giving up on his quest for steam locomotion, Lear again turned his sights on aviation. During the mid- to late 1970's, Lear worked diligently on his latest aircraft design, the Lear Fan, another new concept aircraft. Utilizing composite construction, the Lear Fan was powered by twin turboshaft engines driving a pusher propeller. The aircraft was capable of being flown by a single pilot, could carry eight passengers, and burned approximately two-thirds less fuel than aircraft with similar capabilities. Sadly, Lear would never see his Lear Fan fly. Diagnosed with leukemia, Lear succumbed to the disease on May 14, 1978, in Reno, Nevada, leaving Moya to run the business.

Impact

Lear ushered in the era of the small business jet. His enthusiasm, innovativeness, and determination to succeed at all costs were remarkable. Many have said that people either loved or hated Lear; there was no middle ground. Although an adherent to the autocratic management style, Lear had an uncanny ability to influence key subordinates who helped steer his projects to success. A lasting testament to Lear's innovativeness and design prowess is the hugely successful Canadair Regional Jet (CRJ), produced by Bombardier. The CRJ is largely based on the design of a later Learjet aircraft, the Lear Star 600.

Hugh Le Caine

Canadian physicist and music composer

Le Caine was one of the founders of the field of electronic music, inventing such instruments as the Electronic Sackbut and the Special Purpose Tape Recorder for composition and performance.

Born: May 27, 1914; Port Arthur (now Thunder Bay), Ontario, Canada
Died: July 3, 1977; Ottawa, Ontario, Canada
Primary fields: Music; physics
Primary invention: Electronic Sackbut

Early Life

Hugh Le Caine (leh KEHN) was born in Port Arthur, Ontario, Canada. From childhood, he was fascinated by both music and science. He studied piano and began to envision the possibility of utilizing techniques used in science to invent musical instruments. Le Caine enrolled at Queen's University in the Department of Applied Science and studied physics. He received his bachelor of science degree in 1938 and his master of science degree in 1939. That year, he was also awarded a National Research Council (NRC) fellowship, which enabled him to remain at Queen's to do additional research. This was the beginning of a long relationship between Le Caine and the NRC, as he worked with the council from 1940 to 1974.

During his graduate studies, Le Caine became involved in atomic physics and made important technical improvements to several of the measuring devices used in the field. He also made significant contributions to the development of the first radar systems. The papers he presented and the articles he published earned him acclaim as a scientist in both fields. In 1948, he received another research grant from the NRC. This grant enabled him to study nuclear physics in England from 1948 to 1952. He received a Ph.D. from the University of Birmingham in 1952.

Life's Work

While studying physics, Le Caine still maintained his interest in music and also developed a fascination with motorcycles, which he enjoyed riding at high speeds. He actually set speed records, though unofficial, for the distance from Montreal to northern Ontario. While these feats impressed his friends and colleagues, his innovative activity in music was of much greater consequence. He tried applying the scientific techniques he was learning to the invention of musical instruments. In 1937, he invented an electronic free reed organ. In 1945, he set up a studio in his home; there he worked on developing electronic instruments, including the Electronic Sackbut, the first synthesizer ever built. He regularly had weekend jam sessions in his studio with his friends Bill Farrow and Mal Clark, his colleagues in physics.

Le Caine also started developing a polyphonic touch-sensitive organ and a device capable of simultaneously playing several tape recordings. His demonstrations of these instruments to the public made such a strong impression that in 1954 the NRC invited him to move his work to its facilities. The NRC provided him with a studio where he could work on his various projects. There he invented the Multi-track (Special Purpose) Tape Recorder. This device had the capability of simultaneously changing the playback speed of several recordings through the use of a keyboard.

Le Caine also composed music using the recorder. His purpose in composing was to understand the needs of the composer and to demonstrate the capabilities of his instruments. In 1955, he composed a piece called "Dripsody." It was created using the sound of a single drop of water falling. Le Caine continued to experiment with a variety of techniques for producing and controlling sound. As a result of his experimental work, he built more than twenty-two new instruments.

Le Caine was instrumental in the creation of Canada's first electronic music studio, which was installed at the University of Toronto in 1959. The studio was equipped with the various components of the Electronic Sackbut; Le Caine made the parts available as individual units.

The Electronic Sackbut

Hugh Le Caine built the first voltage-controlled electronic synthesizer; he called his monophonic instrument the Electronic Sackbut. "Sackbut" was an eighteenth century word for the trombone and comes from the Old French word *sacqueboute* ("pull-push"). It is assumed that Le Caine took the name from this origin. Employed at the time by the Canadian National Research Council as an atomic physicist, Le Caine began working on the Electronic Sackbut in his home studio in 1945. He modified and improved the design from 1945 to 1973. He built his first Sackbut inside a desk. It had a keyboard that enabled the operator to control three aspects of sound: Vertical pressure controlled volume, lateral pressure changed pitch, and timbre was controlled by pressure away from the operator. Since the controls were force-sensitive and changes in pressure caused them to alter the sound, the operator could play the instrument without watching the controls.

Le Caine did not complete a free-standing prototype of his instrument until 1948. This version of the Electronic Sackbut was built on a rather primitive three-legged stand with crosspieces reinforcing it. When playing the instrument, the operator controlled the keyboard with the right hand. One note was played at a time with both vertical pressure and lateral pressure being applied. By 1948, Le Caine had further developed the timbre control, giving the instrument greater complexity and requiring multiple devices for it to function. The left hand was used to control the various aspects of timbre; each finger of the left hand operated a separate pressure-sensitive control. The index finger was used to work a device that continuously altered the waveform. This enabled the operator to produce the sound of six different instruments—oboe, trumpet, clarinet, flute, strings, and organ—as well as organ mutation tones and foundation tones. This Electronic Sackbut is now housed in the Canadian National Museum of Science and Technology.

In 1969, Le Caine started to redesign the 1948 Electronic Sackbut, which he had modified considerably through 1956, and to incorporate modern techniques into the design. He paid special attention to enhancing the pressure-sensitive controls. In 1971, he demonstrated a new prototype that used integrated circuits for the level controls. The octave range had been increased from six to seven. The envelope control had been modified so that it could be played in reverse without any extra adjustment. He also added a device to adjust the wave shape. At this time, Le Caine was already thinking about a Sackbut that would have three oscillators, but he did not live to build it.

While Le Caine performed many public demonstrations of the Electronic Sackbut, it was never commercially marketed, remaining in the realm of academic research and invention. However, the instrument, with its use of adjustable waveforms for timbres and its use of voltage control, is recognized as the predecessor of the electronic synthesizers developed in the 1970's.

These could be used for specific tasks and in varied sequences, thus giving composers a true laboratory in which to experiment. In 1964, Le Caine collaborated on the installation of an electronic music studio at McGill University. It was in Le Caine's laboratory studio at the NRC that the equipment used in both these studios was developed. In 1966, he began teaching at both universities and presented seminars on electronic music.

During his lifetime, Le Caine received many awards and recognitions for his inventions and contributions to the new field of electronic music. In 1971, McGill University awarded him an honorary doctorate of music; in 1974, he received an honorary LL.D. from the University of Toronto. Also in 1974, Queen's University presented him with an honorary doctorate of music and named the Harrison-Le Caine Hall on its campus in his honor. In 1971, Le Caine attempted to commercially market the Electronic Sackbut but met with little success. In 1974, he retired from the National Research Council. On July 4, 1976, he was involved in a serious motorcycle accident; his injuries resulted in his death on July 3, 1977, in Ottawa.

After his death, Le Caine continued to receive honors for his many contributions to electronic music both as an inventor of instruments and as a composer of music. In 1978, the Hugh Le Caine Project was organized by the Canadian Electronic Ensemble to disseminate information about Le Caine. The ensemble began publishing a newsletter in June, 1979, and also played a minimum of one Le Caine composition at each of its concerts during the 1978-1979 season.

Impact

Le Caine was one of the pioneers in electronic music. With the invention of the Electronic Sackbut, he created the first voltage-controlled synthesizer. Using the various components of this instrument, he equipped the first two electronic music studios in Canada and provided the technical equipment needed for early composers of experimental electronic music.

Le Caine also wrote a large number of articles about his work in electronic music and gave numerous public demonstrations of the twenty-two instruments he developed. He also wrote thirty-eight electronic music compositions to demonstrate the capabilities of his instruments. In this way, he disseminated information about this new form of music and the instruments required to compose and perform it.

Through his teaching at the University of Toronto and McGill University, he had a significant impact on an entire generation of electronic-music composers. Le Caine played a significant though indirect role in the development of the first commercially successful electronic synthesizer. Gustav Ciamaga studied composition at the University of Toronto and knew about the filters Le Caine had developed. It was Ciamaga who influenced Robert Moog to invent the voltage-controlled low-pass filter used in his modular Moog synthesizer, and it was the Moog synthesizer that really gave impetus to the field of electronic music.

Robert Steven Ledley

American physicist and radiologist

Ledley's automatic computerized transverse axial (ACTA) X-ray scanner, the first whole-body computed tomography machine, allowed doctors to view three-dimensional X-rays of the body.

Born: June 28, 1926; New York, New York
Primary fields: Computer science; medicine and medical technology
Primary invention: Automatic computerized transverse axial (ACTA) X-ray scanner

Early Life

Born in New York City in 1926, Robert Steven Ledley earned a D.D.S. from New York University in 1948 and an M.A. from Columbia University in 1949. In 1950, he served in the U.S. Army Dental Corps. There he learned to use a Standards Electronic/Eastern Automatic Computer (SEAC) computer for research and befriended the engineers who built it. This was an auspicious beginning for the young doctor, who later pioneered the use of digital computers in medicine.

After serving in the Army, Ledley worked at the National Bureau of Standards (now the National Institute of Standards and Technology) in Washington, D.C. He then worked as a physicist and research analyst for Johns Hopkins University. From 1968 to 1970, he taught electrical engineering at George Washington University. In 1970, he joined the faculty at the School of Medicine at Georgetown University Medical Center as a professor of physiology and biophysics. There he would develop his ideas for the automatic computerized transverse axial (ACTA) X-ray scanner, the invention for which he is best known. In 1974, he became a professor in the Department of Radiology. The following year, he was appointed director of the Medical Computing and Biophysics Division, a position he held for more than thirty years.

Life's Work

Ledley contributed extensively to the field of medical informatics, in which computers and information technology help doctors diagnose and treat patients. Two of his publications laid the groundwork for this field: "Reasoning Foundations of Medical Diagnosis" (1959; published with Lee B. Lusted) and the college textbook *Use of Computers in Biology and Medicine* (1965). During the 1960's, Ledley began to develop genetic databases, another important contribution to medical informatics. In July, 1960, he established the National Biomedical Research Foundation (NBRF), where his first project involved the computerized analysis of human chromosomes. He designed a flying-spot scanner to digitize chromosome images and developed pattern-recognition algorithms to identify the chromosomes. Ledley has been president of the NBRF since its inception.

In 1970, one of Ledley's colleagues referred him to Alfred Luessenhop, chief of neurosurgery at Georgetown University Medical Center, who was interested in buying a brain scanner and had a brochure for a Hounsfield computed tomography (CT) scanner. Ledley read the brochure and was unimpressed with the device's description and design. Inspired by an article on CT scanning by South African physicist Allan M. Cormack, Ledley offered to build an ACTA scanner—the first whole-body CT scanner. Thus, he secured $250,000 from the NBRF to begin work.

Ledley believed that he could build his scanner based on his own design. At the project's outset, he utilized the expertise of mechanical engineers, but in the end he relied on himself to draw the designs. By 1973, his scanner was operational. He delivered lectures on his ACTA scanner, and he received praise for its use in medical diagnoses and its potential to save lives. As demand for the scanner increased, Ledley started his own manufacturing company, called the Digital Information Science Corporation (DISCO). It was difficult for him to fill all of his orders. When he failed to obtain a loan from a bank, he kept himself in business by asking for advances on each of the machines he built.

Ledley focused on teaching, inventing, and writing throughout his career. During his tenure at Georgetown University, he was the editor in chief of four scientific journals. In 1990, he was inducted into the National Inventors Hall of Fame for his invention of the whole-body CT scanner. In 1997, he was awarded the National Medal of Technology by President Bill Clinton for his contribution to radiology. In 1998, the National Institute of Dental Research recognized Ledley's work to improve dentures. After his retirement in the late 1990's, he continued to pursue his passion—inventing machines.

THE ACTA SCANNER

Robert Steven Ledley was the first inventor to develop a digital scanner that could take three-dimensional X rays of the entire human body. On November 25, 1975, Ledley received U.S. Patent number 3,922,552 for his automatic computerized transverse axial (ACTA) diagnostic X-ray scanner. It was first put into clinical operation in 1973. Ledley's scanner was based on the work of South African physicist Allan M. Cormack of Tufts University and English electrical engineer Godfrey Newbold Hounsfield, who had built the first computed tomography (CT), or computerized axial tomography (CAT), scanner. Having read a description of Hounsfield's device, which could scan only the head, Ledley set to work on designing a less expensive, better machine (that could scan any part of the body) for the Georgetown University Medical Center.

Ledley's ACTA scanner revolutionized medicine, providing doctors with an accurate method for diagnosing cancers, soft-tissue irregularities, and other medical conditions. The device works by obtaining cross-sectional X-ray images of a section of the body and piecing together those images using a computer. Whereas a single X-ray presents only a two-dimensional view, a CT scan presents a more detailed, three-dimensional view that allows doctors to see inside organs without surgery. Though noninvasive, the procedure exposes the patient to a high dose of radiation.

IMPACT

Ledley is a retired dentist, physicist, and inventor whose keen ability to visualize and create digital machines for medical purposes has led to significant advances in the field of diagnostic medicine. He spent countless hours in his office laboratory drawing his designs, reflecting on the materials needed to produce his machines, and developing groundbreaking digital programs to produce his inventions. His whole-body CT scanner proved revolutionary in a number of medical fields, including radiology, nursing, and surgery. The CT scan is a noninvasive procedure that allows doctors to see the internal structures of the body to locate tumors and infections. Ledley's work mapping human chromosomes made it possible to scan chromosomes for abnormalities such as Down syndrome. He also developed a three-dimensional fetus scanner that provided clearer images than those of sonograms. Ledley holds more than sixty patents.

Antoni van Leeuwenhoek

Dutch microbiologist

Leeuwenhoek designed and constructed many simple microscopes, perfecting an already existing device and adapting it to scientific use. He used the microscope to discover the existence of microorganisms and introduce them to science.

Born: October 24, 1632; Delft, Holland, United Provinces (now in the Netherlands)
Died: August 26, 1723; Delft, Holland, United Provinces (now in the Netherlands)
Also known as: Thonius Philips van Leeuwenhoek (birth name)
Primary fields: Biology; medicine and medical technology
Primary invention: Simple microscope

Early Life

Antoni van Leeuwenhoek (LAY-vehn-hook) was born to a family of tradespeople. His father, Philips Thonisz, was a basket maker, and his mother, Grietje van den Berch, was the daughter of a brewer. After his father died in 1638, Leeuwenhoek was sent to the town of Warmond to attend school. Upon completion of his basic education, he went to live with his uncle in Benthuizen for further education. When his uncle died in 1648, his mother sent Leeuwenhoek to Amsterdam, where he lived with his mother's brother-in-law and learned the trade of a draper (fabric merchant). While in Amsterdam, Leeuwenhoek saw mounted magnifying glasses that were used by textile merchants to examine the quality of cloth. These were probably the paradigm for the simple microscopes he later made.

In 1654, Leeuwenhoek returned to Delft and married Barbara de Mey, who gave birth to five children. She died in 1666, and Leeuwenhoek remarried in 1671. He bought a house and a shop and launched a fabric busi-

Antoni van Leeuwenhoek. (Library of Congress) ness. In addition to being a fabric merchant, Leeuwenhoek also worked as a surveyor, wine assayer, and a minor city official, which provided him with a permanent income.

Life's Work

Some time before 1668, Leeuwenhoek learned to grind lenses and to use them to make simple microscopes, which he used to observe various objects. The inspiration for Leeuwenhoek's microscopic work seems to have been the research of the English scientist Robert Hooke, who designed and built a compound microscope, which he used to examine a wide variety of living and nonliving specimens. Hooke's illustrated book, *Micrographia* (1665), which contained detailed drawings of his observations, was very popular and heavily influenced Leeuwenhoek.

Leeuwenhoek's scientific investigations were widely read because he reported them to the Royal Society of London. He became known to the Royal Society in 1673 when a brilliant young Delft physician, Regnier de Graaf, wrote to Henry Oldenburg, the secretary of the Royal Society of London, about Leeuwenhoek's observations. Oldenburg was intrigued by de Graaf's reports and initiated contact with Leeuwenhoek, who sent the first of what would be a long series of letters to the Royal Society that described his scientific investigations. Leeuwenhoek's letters were translated from Dutch into English or Latin and published in the *Philosophical Transactions of the Royal Society*. The conversational style of these letters is filled with exacting and careful descriptions of what he observed through his microscope.

As a pioneer in the study of microscopic life, Leeuwenhoek described many new microscopic species. In 1674, he described protozoa from fresh pond water and identified the green alga *Spirogyra* in lake water, and several other free-living protozoa, such as *Vorticella*. He also described the colonial green alga *Volvox* and experimentally showed that it underwent reproduction instead of arising from nonliving matter (spontaneous generation). Leeuwenhoek also was the first to observe and describe the parasitic protozoan *Giardia*, which he incidentally encountered while observing material from his own feces. He also discovered microscopic animals called rotifers and established their unique ability to withstand desiccation.

In 1676, Leeuwenhoek's relationship with the Royal Society experienced some strain when he became the first person to observe and describe bacteria. Leeuwenhoek reported tiny, microscopic organisms in a water preparation of peppercorns. Because the seventeenth century concept of life did not accommodate organisms whose diminutive nature rendered them invisible to the naked eye, the Royal Society viewed his initial report with considerable skepticism. However, after sending representatives to Holland who corroborated Leeuwenhoek's observations, the Royal Society welcomed his reports of microorganisms. The Royal Society rewarded Leeuwenhoek's exacting and reliable observations by electing him to be a full fellow of the society in 1680.

Perhaps Leeuwenhoek's most famous finding was recorded in his September 17, 1683, letter to the Royal Society about observations of the plaque between his own teeth. This whitish material was teeming with swimming bacteria, which he referred to as "animalcules." These bacteria disappeared after drinking hot coffee but reappeared soon thereafter. His descriptions of oral bacteria are so detailed that it is possible to determine which bacterial species he saw.

Leeuwenhoek was a keen observer of nature who had an unusual eye for microscopic detail. He was one of the first people to examine fresh semen and observe living spermatozoa, which led him to propose that fertilization occurred once spermatozoa penetrated the egg. He also discovered lymphatic capillaries in the intestine in 1683 and, in 1688, documented the circulation of red blood cells through blood vessels in the tails of tadpoles. Leeuwenhoek elucidated the fine, microscopic structure of the human spleen (1706), striated (voluntary) muscle (1714), the eye and its optic nerve, and bone (1720). He even described a way to stain transparent muscle fibers with a solution of saffron in brandy.

However, Leeuwenhoek was not just an observer but also a talented experimentalist who developed new techniques and perfected older ones. One such technique extensively used by Leeuwenhoek was microdissection. He used his microscope to guide dissections of very small organisms in order to probe a wide variety of questions. Dissection of aphids, for example, showed that the bodies of adult aphids were filled with young aphids, demonstrating that these tiny insects were born and not spontaneously generated. Microdissections of ovaries from freshwater mussels (*Unio*) revealed spinning mussel embryos, a discovery that called into question Aristotle's idea that mussels and other shellfish are generated from mud or sand at low water. Other microdissections involving plant material not only elucidated the internal structure of plant stems and roots (he described the different structure of the stem of monocotyledonous and dicotyledonous plants) but also provided insights into plant seeds and embryos.

Leeuwenhoek also used his microscopes and microdissection to document parasitism in a wide variety of plants and animals. Beginning in 1695, Leeuwenhoek examined the parasitism of aphids and found empty aphid exoskeletons with small holes bored in them. Leeuwenhoek correctly surmised that the parasite had emerged through this hole. He also microdissected immobile aphids and showed that their entire internal body cavities were filled with larval wasps (Leeuwenhoek referred to them as "ants"). Leeuwenhoek observed the female wasp use her ovipositor "in the manner of a sting" to inject eggs into the host insect. He utilized a confined chamber to isolate infected host insects so he could watch the parasites emerge; in doing so, Leeuwenhoek characterized the life cycle of aphid parasitoid wasps. Leeuwenhoek also examined plant parasites and showed that the larval stages of particular insects were responsible for the formation of galls on the leaves of oak and thistles.

Many distinguished individuals showed interest in Leeuwenhoek's remarkable findings. Heads of state that included Queen Mary of England and Russian czar Peter the Great visited Leeuwenhoek at his home in Holland to view his microscopic images. Leeuwenhoek continued his experiments even until his last days. When Leeuwenhoek died, the pastor of New Church in Delft wrote to the Royal Society, "Antony van Leeuwenhoek considered that what is true in natural philosophy can be most fruitfully investigated by the experimental method."

The Simple Microscope

Simple microscopes use one lens to magnify the specimen, while compound microscopes use a magnifying lens plus an eyepiece lens to multiply the magnification. Compound microscopes were invented around 1595, nearly forty years before Antoni van Leeuwenhoek was born. Two contemporaries of Antoni van Leeuwenhoek, English scientist Robert Hooke and Dutch scientist Jan Swammerdam, built compound microscopes and made important discoveries with them.

Leeuwenhoek made simple microscopes, but his skill as a lens crafter allowed him to make instruments whose magnifying power and clarity were better than the compound microscopes used by other scientists of his time. Therefore, while it is incorrect to designate Leeuwenhoek as the inventor of the microscope, he perfected the simple microscope and was a talented lens grinder and microscope maker. Leeuwenhoek made more than four hundred microscopes, of which fewer than ten survive today, and manufactured more than five hundred microscope lenses.

The microscopes made by Leeuwenhoek had the same basic design as a magnifying glass. Compared to the microscopes of today, they were exceedingly simple. They used one lens mounted in a small hole within a metal plate to which a brace was attached for holding a handle and a specimen mounting device. The specimen was mounted on a sharp point that extended toward the lens and held the specimen in front of it. The position of the specimen could be adjusted by two screws located on the brace, which were also used to focus the image. The whole instrument was quite small—only three to four inches long—and had to be held very close to the eye in order to properly see the magnified image. Because this simple microscope had no built-in light source, candlelight was probably used to illuminate the image. It is clear that the use of this instrument required a great deal of patience.

Technical difficulties prevented compound microscopes from being able to magnify objects more than twenty or thirty times their size. However, Leeuwenhoek's skill as a lens grinder enabled him to make microscopes that magnified objects more than two hundred times their normal size. This technical advantage—combined with his naturally acute eyesight, great care, detail in describing what he saw, and monumental patience—allowed Leeuwenhoek to use his microscope to view just about anything and gain significant insight from it.

Impact

Even though Leeuwenhoek did not invent the microscope, he perfected the simple microscope and also demonstrated the power of microscopy when wielded by an inquisitive investigator. Therefore, it is apt to call Leeuwenhoek "the father of microscopy." However, Leeuwenhoek is best known for his discovery of microorganisms, which introduced science to a world that was previously completely unknown. The discovery of microorganisms initiated the science of microbiology, and this led to the discovery of the germ theory of disease and, eventually, treatments for infectious diseases. Modern medical advances began with Leeuwenhoek's observations of microbes.

Even though his discovery of microbes tends to overshadow his other achievements, Leeuwenhoek was also a pioneer in the field of parasitology. His documentation of parasitism launched a previously unknown field and placed it on firm experimental grounds.

Leeuwenhoek was not only an observational microscopist but also an experimentalist who contributed to the birth of modern science by demonstrating the power of empirical data gathering and the experimental method. Much of his work powerfully refuted the prevailing theory of spontaneous generation. Furthermore, his skills as a section cutter (microtomist) and microdissector distinguish him as a pioneer of eighteenth century experimental biology.

Gottfried Wilhelm Leibniz

German philosopher and mathematician

Leibniz's calculating machine did not have much influence on the subsequent development of computers. His vision of a mechanical way of settling arguments and disputes proved far more influential, even if he could not make much headway himself in translating his vision into reality.

Born: July 1, 1646; Leipzig, Saxony (now in Germany)
Died: November 14, 1716; Hanover (now in Germany)
Primary field: Mathematics
Primary inventions: Calculus; Leibniz's calculator

Early Life

Gottfried Wilhelm Leibniz (GOT-freed VIHL-hehlm LIB-nihts), one of the most wide-ranging intellects in the history of thought, was the son of Friedrich Leibniz and his third wife, Catharina Schmuck. The family was of noble and scholarly ancestry on both sides, and Gottfried's father early saw signs of great talent in his son. Friedrich Leibniz died when his son was six, but the family was financially well enough off to guarantee that Gottfried was able to get the best education. He attended a private school from 1653 to 1661, although he was more influenced during this period by the freedom to range through his late father's library.

In 1661, Leibniz enrolled at the University of Leipzig, where his interests took him in many directions. He studied the traditional discipline of Aristotelian metaphysics, but he also spent time at the University of Jena learning about mathematics. In general, he found mathematics appealing because it provided a degree of certainty that philosophy could not achieve. He pursued further research in philosophy at the same time that he was pursuing the study of law. His original application for a doctorate in law was deferred by the University of Leipzig, which Leibniz claimed to have been based on the legal community's efforts to reduce the flow of new lawyers into the profession. As a result, he transferred to the University of Altdorf in Nuremberg, submitted the same dissertation he had prepared for Leipzig, and had it promptly accepted.

On receiving his degree, Leibniz was offered a position at Nuremberg in the law faculty, but he turned it down, perhaps out of dissatisfaction with the academic life brought on by the rejection at Leipzig. Instead, he took advantage of the interest displayed in his career by Baron Johann Christian von Boineburg to obtain a position as a judge in Mainz in 1671. He saw a future in the scholarly world ahead of him and found that the support of the elector of Mainz would enable him to travel and pursue his research throughout Europe.

Life's Work

In 1672, Leibniz traveled to Paris, ostensibly to take part in diplomatic negotiations related to the conflicts between the Netherlands and France and England. In fact, however, Leibniz used his visit to Paris, which continued until 1676, to make the acquaintance of some of the leading scientists of the time. He learned of the machine for doing arithmetic that had been designed by the French mathematician Blaise Pascal and decided to improve on it. While Pascal's machine had done addition and subtraction, Leibniz designed a machine to handle multiplication and division as well. Although the machine was not built as rapidly as Leibniz had hoped, he was able to display a model of the machine in Paris and in London.

Gottfried Wilhelm Leibniz. (Library of Congress)

On Leibniz's return from London to Paris, he found it necessary to catch up with the state of mathematics. One particular area in which he made rapid progress was the use of techniques initiated by earlier French mathematicians like Pascal and Pierre de Fermat to calculate the areas under curves and to determine the slopes (rates of change) at points on curves. Up until the seventeenth century, questions about curves were investigated using the geometry of Euclid, which was already two thousand years old. By Leibniz's time, algebra had developed to the point that it could be used to replace a strictly geometrical approach to curves. Leibniz was able to use his algebraic expertise to arrive at a new branch of mathematics, called the calculus, putting calculations within reach of a wider audience.

In the decade before Leibniz's invention of the calculus, Sir Isaac Newton had come up with some of the fundamental ideas from which the calculus sprang. Newton himself was disinclined to publish his work until it was fully developed, and in the meantime he had had correspondence with Leibniz about his ideas. The appearance of Leibniz's preliminary work on the calculus created the origins of an argument about priority that stretched on for many decades. While Newton and Leibniz did not start with any personal animosity, both of them had devotees who felt that the issue of the invention of the calculus was a matter of national pride. The resulting schism in the mathematical world (generally between England and the rest of Europe) did not work for the betterment of mathematics on either side of the English Channel.

While Newton certainly developed his calculus before Leibniz, the latter had a notation that was more widely useful and more suggestive. This was part of Leibniz's general approach to science and logic. His hope, expressed often in unpublished fragments, was to create a universal language that would enable all human beings to understand one another. Once that language was in place, he felt that one could create a machinery for judging whether an argument was correct. As a result, he thought that wars could become a thing of the past and that disputes would be settled by calculation. The bitterness of the Thirty Years' War in Germany, which lasted into Leibniz's life, may have made this prospect especially appealing.

Leibniz was also interested in trying to extend the audience for his own philosophy by investigating cultures as remote as the Chinese. He tried to link his logic, his metaphysics, and his physics into a connected chain of reasoning, and he argued that the combination bore a resemblance to Chinese science and philosophy. For example, he saw binary arithmetic as part of Chinese culture. Many of these ideas were expressed in correspondence, which ran to many thousands of pages. While he also took advantage of the scientific journals that had only recently started to appear, the vast bulk of his work remained unpublished.

In the course of his intellectual adventuring, Leibniz also had to earn a living. After the death of the elector of Mainz, Leibniz passed into the service of the government in Hanover, to which he made contributions from economics to genealogy. He had hoped to find permanent employment in Paris after his years there, but he ended up having to return to Hanover. One of the tasks with which he was saddled was writing a history of the ruling house of Hanover, and he used that project to take him into southern Europe. His researches confirmed the hopes of his employer to find himself related to other royal houses in Europe, but this was not the work closest to Leibniz's heart.

In 1714, the elector of Hanover ascended the throne of England as George I. This political promotion did not have the effect on Leibniz's career for which he had hoped. While the monarch went to London, Leibniz was left behind in Hanover, partly because of his being seen as a remnant from an older era, partly because of the animosity with Newton, who was the most visible figure in British science at the time. Leibniz died two years later, neglected even in Hanover.

Leibniz's Calculator

Gottfried Wilhelm Leibniz was struck as a scientist by the amount of time that astronomers and others had to spend carrying out calculations. He had also learned of the calculating machine designed by Blaise Pascal earlier in the century that could carry out addition and subtraction. The Englishman Samuel Morland had built a calculator that could carry out multiplication and division by means of a form of logarithms (which reduce multiplication to addition). While Morland's machine could multiply two numbers together, the answer was only approximate. Leibniz decided to include multiplication and division as operations, but to provide exact answers instead. He also hoped that the machine would be able to extract square roots.

In designing his machine, Leibniz used the same approach for addition and subtraction as Pascal had. Multiplication depended on a piece of equipment called Leibniz's stepped wheel. This really involved rods with teeth in them that interacted with other gears. Each of the stepped wheels had nine teeth of different length, the longest corresponding to the number nine and in decreasing order of size. If the number *A* is to be multiplied by the number *B*, the digits of *A* were entered into the machine via numbered dials, and then a metal peg was placed in a hole corresponding to the number *B*. The peg would then determine how fast the wheels turned (if *B* was four, they would be turning twice as fast as if *B* was two). The results were then transferred to the addition wheels, from which they could be read.

The machine could handle large numbers, but it was not completely automatic, as it required some intervention by the operator in carrying and borrowing. There was nothing faulty in the design of the machine, but the components had to be constructed to a degree of accuracy beyond what the machinists of the time could achieve. The surviving example in Hanover did not work, but there is a working model of the machine in the Science Museum in London. A variant of the machine was used by merchants over the next century, but the design appears to have had little influence on the efforts of Charles Babbage and the subsequent development of the computer in the twentieth century. It was Leibniz's vision of a machine to spare the need for human calculation that proved more influential than his construction.

Impact

At the time of his death, Leibniz's influence looked as though it was limited in science to the creation of the calculus. His calculating machine had not had any great success, although the manufacturer was able to keep producing copies for another century. Even in the area of mathematics, it might have seemed that his work was losing ground in popular esteem compared to Newton's.

As the eighteenth century continued, however, the advantages of Leibniz's notation were widely recognized in Europe, and not merely for political reasons. Leonhard Euler, the greatest mathematician of the time, followed Leibniz's conventions and extended the successes of the calculus in many directions. Perhaps the most decisive moment in determining Leibniz's legacy came in early nineteenth century England, when the generation of young mathematicians being educated at Cambridge University revolted against the Newtonian notation they were being taught and insisted on learning Leibniz's instead. This provided for a reunion of the world of calculus, and both sides were speaking the language of Leibniz.

One of the complaints early urged against the way Leibniz presented calculus was his use of infinitesimals. These seemed like murky sorts of numbers, not quite zero, but not quite ordinary positive numbers. Other means for establishing the foundations of calculus were developed in the nineteenth century, but in the twentieth century Abraham Robinson reintroduced infinitesimals as a way of explaining the basis of calculus. While Robinson's approach used many ideas that would have been unfamiliar to Leibniz, Robinson himself regarded his work as a vindication of Leibniz's ideas.

Leibniz's notion of a universal logic had little influence until his work was rediscovered at the beginning of the twentieth century. Then, mathematicians such as Bertrand Russell began to notice similarities between the development of mathematical logic and Leibniz's dream both of a universal language and of a mechanical way of carrying out reasoning. Just as Robinson's work on calculus could be seen as fulfilling Leibniz's vision in mathematics, so the creation of the modern computer gave physical form to what Leibniz had conceived three centuries earlier.

Emmett Leith

American physicist and electrical engineer

Leith and Juris Upatnieks presented the first three-dimensional hologram at a conference in 1964. Holography has been applied in many fields, including data storage, credit card security, art, and interferometry.

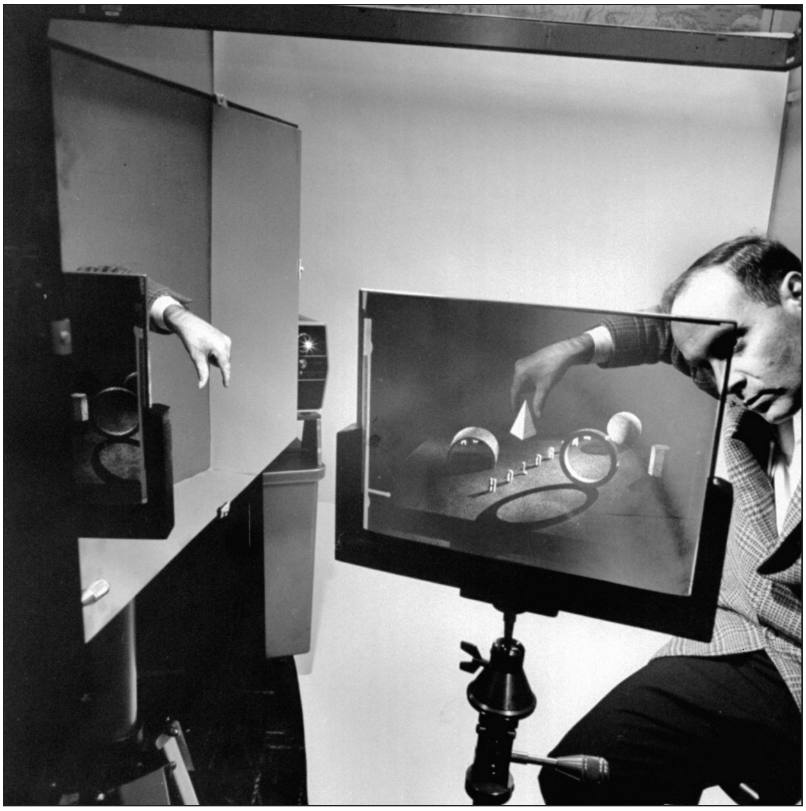
Born: March 12, 1927; Detroit, Michigan
Died: December 23, 2005; Ann Arbor, Michigan
Also known as: Emmett Norman Leith (full name)
Primary fields: Electronics and electrical engineering; optics; physics
Primary invention: Three-dimensional holography

Early Life

Emmett Norman Leith (leeth) was born on March 12, 1927, in Detroit, Michigan. Little is known about his childhood. He attended Wayne State University in Detroit, where he graduated with a bachelor of science degree in physics in 1949 and received his master of science degree in physics in 1952.

Life's Work

After finishing his master's degree, Leith took a job with the University of Michigan's Radar Laboratory, part of its Willow Run facilities. He worked for the university



Emmett Leith demonstrates holography. (Time & Life Pictures/Getty Images)

during his entire fifty-two-year career. The laboratory had an Army contract to develop synthetic aperture radar (SAR), a scanning radar system to be used by aircraft to create topographic maps. Many thought that the project for this high-quality imaging radar system would fail because airplanes could not carry the necessary massive antenna. With SAR, an aircraft could be outfitted with a five-foot antenna, which acted as a much larger one. The antenna would send out a signal that hit objects on the ground and bounced back. The data would then be captured as a line on photographic film, and the lines would produce images when a computer developed the film. The early computers of the early 1950's were not able to handle the volume of data needed for SAR. While other scientists worked on improving computer technology, Leith began working with physical optics solutions.

By 1957, Leith had created a new version of SAR based on his optics research. He later described the system as a "holographic viewpoint." At first, it seemed that Leith's method was valid only in theory; the first eight trials failed. The ninth test flight, however, produced startling results, successfully mapping the Michigan terrain. Leith's work with SAR eventually led to his research in holography. British scientist Dennis Gabor first introduced the idea of holograms in 1947. Gabor's holograms looked fuzzy and had double images, in part because he was working with a mercury lamp. He had hoped that his research would be used to improve the resolution of electron microscopes. By 1955, most scientists felt that holography could not be accomplished successfully and abandoned the field.

Leith began thinking about applying certain optics principles used in SAR to holography. In 1960, Leith told coworker Juris Upatnieks about his theory of how to build holograms. Leith planned to produce an unfocused image on a transparency and use the recorded image to get a clear picture. Upatnieks was not interested at first but was eventually convinced that Leith's idea might work. Leith and Upatnieks used a continuous-wave laser as their light source, a crucial device for creating clear holograms. Based on Gabor's theory, their method—called carrier-frequency, or off-axis, holography—split two beams of light from one coherent beam. One of the beams (the object beam) is shone onto the object to be recorded, and the other (the reference beam) is deflected by a mirror onto the photographic film behind the object. The object beam reflects off the object and converges with the reference beam on the photographic plate, resulting in a negative that looks like a random collection of blobs and specks. This "hodgepodge," as Leith called it, is actually the hologram.

A second step must be taken in order for the hologram to be viewable. In the reconstruction stage, the hologram is illuminated with a replica of the reference beam. The result is two separate images, a virtual one that appears behind the plate and a real one that appears in front of the plate. Together these two images form a hologram. In optics, a real image is produced when the rays of light exiting a lens actually converge at a point. This image can be produced on a screen, such as a movie screen. A virtual image is created when light rays shown through a lens only appear to intersect at a point. This image (such as a reflection seen in a mirror) cannot be produced on a screen.

The two men refined their method in 1961 and published their work in the journal of the *Optical Society of America* the following year. They had proven the critics wrong; holography was possible. In 1963, their work was known as lensless photography, simply because no lens was used. Having successfully found a way to make holograms of any object, Leith and Upatnieks began working on further refining their method. The next goal was to create a three-dimensional (3-D) hologram. In 1964, they presented a paper at an Optical Society of America conference, having successfully created the world's first 3-D hologram. Again, their success was due in part to the newly developed laser, which allowed them to use coherent light to make the hologram three-dimensional. When the two scientists showed their colleagues a hologram of a toy train, the image appeared so real that many of the men thought it was a trick done with mirrors. Leith told *Michigan Engineer* magazine that a few of the scientists even had asked him where the train was. He told them it was back in Ann Arbor. Viewing the hologram was like seeing the toy train in person. It was even possible to look behind the train.

Leith and Upatnieks filed for the first holography patent on April 23, 1964. It was titled "Wavefront Reconstruction Using a Coherent Reference Beam." The term "wavefront reconstruction" had been Gabor's initial name for holography. Leith eventually held more than fourteen patents. During the 1960's, he also played a major role in setting up an optics program for the University of Michigan Physics Department.

The toy train hologram created a lot of buzz within the optics community. News of it spread to nonscientists around the world through press releases, newspapers, and magazines. *Life* magazine covered the story of Leith and the hologram; articles in *Scientific American*, naturally, focused on the science. Holography became a popular field of study for scientists around the world. By 1970, hundreds were working on improving techniques, materials, and applications. Many of these researchers were not optical scientists. Applications for holograms in medical imaging, data storage, and entertainment were being investigated.

In 1978, Leith received his Ph.D. in electrical engineering from Wayne State University. The following year, he was given the National Medal of Science by President Jimmy Carter for his work in holography. Over the course of his career, Leith received several other commendations, including (with Upatnieks) the Inventor of the Year Award (1976).

Leith continued to teach physics, optics, and computer science at the University of Michigan until his death in 2005. He also continued his research in optics and imaging. He suffered a stroke on December 22,

Holography

Hungarian-born electrical engineer Dennis Gabor invented the field of holography in 1947. He was working at a British medical company while working to improve the resolution of electron microscopes. He theorized the need for a strong beam of light having a single color and wavelength. Laser technology, instrumental in Emmett Leith and Juris Upatnieks's success, was not invented until 1960. Gabor did his work with a mercury lamp, resulting in holograms that looked fuzzy. In 1971, Gabor won the Nobel Prize in Physics for his research in holography. The Nobel Committee cited the work of Leith and Upatnieks as support for the importance of his theories. Gabor even mentioned Leith and the SAR holography work during his Nobel lecture.

Russian scientist Yuri Denisyuk produced the first hologram of a three-dimensional object (the hologram itself, however, did not appear three-dimensional) in 1962. One of the common types of holograms is known as the Denisyuk (or reflection) hologram, which is multicolored and uses only a white light reference beam. Leith and Upatnieks's version is known as a transmission hologram. In 1968, Stephen A. Benton invented the rainbow hologram, which is now used as a security feature on credit cards. The rainbow coloring is produced from a white light source instead of a laser.

Holography is also used for data storage (for instance, in Blu-ray discs). In addition to credit cards, holograms are used to secure books, digital video discs (DVDs), and other products. Since holograms are difficult to counterfeit, many countries have put them on their paper currency.

Holography has also had an impact on art and entertainment. The first art show using this technology was held by the Cranbrook Academy of Art in Michigan in 1968. Salvador Dalí was the first artist to use the new art form, at his 1972 New York exhibit. During the 1970's, several art schools were created whose focus was holographic art. None of these remains open. The Massachusetts Institute of Technology Museum has a large collection of holograms and related art.

2005, and died the following day from an internal hemorrhage. Leith was to retire on December 31. He was survived by June, his wife of forty-nine years, and two daughters and three grandchildren.

Impact

Leith's work in optics and holography has had great influence. His early work on the SAR program for the Army helped create a radar system capable of producing high-quality maps of enemy terrain from a safe distance. His work on SAR piqued his interest in optics, which started his career in holography.

Much of his later work dealt with biomedical imaging. Leith and one of his former graduate students, Dr. David Dilworth, collaborated from 1987 to 2005 to create improved biomedical imaging. Together they held a patent related to methods of early detection for breast cancer.

Photon migration, or imaging through human tissue, has become a whole new field of optics. Leith is among the field's pioneers, becoming involved in the research in the late 1980's. His goal was to make human tissue transparent, allowing doctors to look through the tissue to spot tumors. In the 1990's, Leith began working on a joint project with the Michigan Center for Biological Information and the University of Michigan that aimed to produce a virtual 3-D human, visible without 3-D glasses. The image would be used for education, dissections, and virtual surgery.

Leith also influenced a number of students, many of whom pursued fields dealing with optics or holography. Leith was influential in creating the University of Michigan's optics program. His Friday lectures were always filled with demonstrations. Students found themselves drawn in by Leith's enthusiasm for optics.

Jerome H. Lemelson

American engineer

The holder of more than five hundred patents, Lemelson is second only to Thomas Alva Edison as the most prolific American inventor. Lemelson was frequently in conflict with corporations that wanted to avoid crediting him for his inventions, which included components for a host of devices ranging from ATMs to videocassette recorders.

Born: July 18, 1923; Staten Island, New York
Died: October 1, 1997; Incline Village, Nevada
Also known as: Jerome Hal Lemelson (full name)
Primary fields: Computer science; electronics and electrical engineering; household products; manufacturing
Primary invention: Machine vision

Early Life

Jerome Hal Lemelson was born on July 18, 1923, on Staten Island, New York, the oldest of three boys. His father was a medical doctor who studied at Columbia University and worked out of his home. His mother was a schoolteacher trained at the normal school in Trenton, New Jersey.

Lemelson and his younger brothers first attended a small two-room school in which his mother had once taught and later attended public schools on Staten Island. He was fascinated by all things mechanical and was interested in inventing at an early age. As a teenager, he invented a lighted tongue depressor for his father. Lemelson attended New York University (NYU) but left before finishing to join the military in World War II. His engineering skills led to his assignment in the engineering department of the Army Air Corps. After serving in Alaska, he was transferred to Louisiana to teach auto mechanics to African American troops.

After military service, Lemelson returned to NYU, where he made up for lost time participating in a number of joint programs. He graduated in 1951 with a bachelor's degree in aeronautical engineering and two master's degrees, one in aeronautical engineering and the other in industrial engineering. While still in graduate school, Lemelson was employed by the Office of Naval Research to develop pulse jets and rocket engines.

Life's Work

After graduating from NYU, Lemelson was hired by Republic Aviation in New York, where he designed guided missiles. At the time, he was sharing a small apartment with one of his brothers (also an engineer). Lemelson would fill notebooks with his inventive ideas and have his brother sign and date the notes after reading them, a step Lemelson recognized as essential to supporting future patent application claims.

In 1951, Lemelson witnessed the operation of an automatic metal lathe controlled by a punch-card system at a New York factory, inspiring him to create his most important invention: a universal robot that utilized "machine vision" to perform a number of actions, including moving and measuring products and inspecting them for quality control. The machine took him years to build. Between 1951 and 1954, Lemelson wrote patent applications for a flexible manufacturing system, an automated warehousing system, and a number of other inventions for industrial automation. He wrote all these patent applications based on his own legal and industrial research since he could not afford an attorney.

Lemelson also invented toys. He found that toy companies were more inclined to license his ideas and inventions because the companies needed a tremendous number of new products to meet the demands of a growing market. They also found it difficult to maintain their own research and development departments during the 1950's. Lemelson patented a form of a toy cap, a propeller beanie, in October, 1953, and licensed a wheeled toy to the Ideal Toy Company.

The first of Lemelson's many patent infringement cases involved his idea for a cutout face mask that could be printed on a cereal box. He had filed a patent and then presented his idea to a cereal company, which turned Lemelson down but three years later began printing the face masks on its cereal boxes. When he saw that his idea had been stolen, he sued, but the lawsuit was dismissed in district court and on appeal. The cereal company spent upwards of $150,000 on legal fees, whereas licensing fees would have cost about one-tenth that amount. During his career, he was involved in more than twenty patent infringement cases, most of which he lost.

Lemelson was a "workaholic." Even on his return from his honeymoon in the Bahamas in 1954, Lemelson stopped at the U.S. Patent Office to do research. It was a stiflingly hot and muggy summer day in Washington, D.C. A chance comment overheard by Lemelson's new wife, Dorothy, led to an idea for a video-filing system using spools of magnetic tape (later called videotape) to re-

Machine Vision

Jerome H. Lemelson said that his machine-vision technology was the invention of which he was most proud. He began thinking about the concept as early as 1951, the year he graduated from New York University. He was working for Republic Aviation and had the opportunity to visit the Arma factory in Brooklyn. There he observed an automatic metal lathe controlled by a punch-card system, inspiring him to create a revolutionary new industrial procedure.

Lemelson began thinking about inventing a universal robot that could perform multiple functions, such as welding, riveting, transporting, and inspecting for quality control. This robotic system depended on machine-vision technology. With machine vision, a video camera took digital pictures that were analyzed by computers. Developing this invention required more than three years of work and a 150-page application, which he completed by Christmas Eve, 1954. A whole array of inventions—from automobile robotics to bar codes and automated teller machines (ATMs)—depend on Lemelson's basic machine-vision concept.

As difficult as the concept and technology were, the process of patenting the procedure and protecting the patent took years before Lemelson could realize any financial gain. While Lemelson had great difficulty in winning patent infringement lawsuits against U.S. corporations, he had greater success with foreign companies. Eventually, Lemelson won lawsuits against Honda, Toyota, Mazda, and Nissan for his machine-vision technology now used in their sophisticated robotics systems for manufacturing automobiles. This victory led other automakers in Europe and Asia to settle on generous terms without the excessive legal fees.

cord documents. The documents on the tape could be viewed on a television set with a mechanism to freeze frames. Lemelson created the machine to operate the tape, and this machine also became the basis for audio and videocassette recorders.

By the early 1960's, Lemelson had quit his engineering job in order to concentrate solely on his inventions and patent applications. During this period, he invented machines for injection molding, fax transmission, and a target game using Velcro-coated Ping-Pong balls. The cost of the patent applications and legal fees consumed so much of his income that the family was dependent on his wife's income to pay the bills.

In the late 1960's, Lemelson established the Licensing Management Corporation to market his and others' inventions. Prominent among his clients were those seeking to market technologies based on the National Aeronautics and Space Administration (NASA) space program, but opposition from large corporations reduced the profits substantially. This and a few other licensing companies Lemelson created were not very successful at this time. Lemelson had greater success in both licensing and patent infringement cases if the corporations involved were foreign. He successfully licensed his audiocassette-drive mechanism to the Sony Corporation for use in its Walkman (released in 1979).

Lemelson continued to invent until his death from cancer on October 1, 1997. He filed forty patent applications that year. Perhaps it is not surprising that these were for medical devices, as his mind was focused on ways that his own cancer might have been cured. Lemelson died in Incline Village, Nevada, at the age of seventy-four.

Impact

Lemelson invented and patented more than five hundred devices and processes during his lifetime, including toys, computer equipment, photographic storage devices, bar-code technology, an audiocassette-drive mechanism, operational systems for tape and cassette recorders, and a host of other inventions. His machine-vision technology had particularly wide-ranging applications; much of it stimulated other related inventions. Perhaps most important, throughout his life he defended the rights of independent inventors such as himself to be a part of the innovation and entrepreneurship necessary to advance the American economy.

Lemelson was criticized and opposed by major corporations, who had an interest in confining all innovation to their own research and development departments to avoid paying licensing fees. In Lemelson's case, they were sometimes willing to spend more on legal fees than licensing fees simply to be able to drive independent inventors from the marketplace. Lemelson's success in patenting his inventions and defending those patents was an important service for independent inventors. In 1993, he and his wife established the Lemelson Foundation, which funds programs to promote independent inventors around the world.

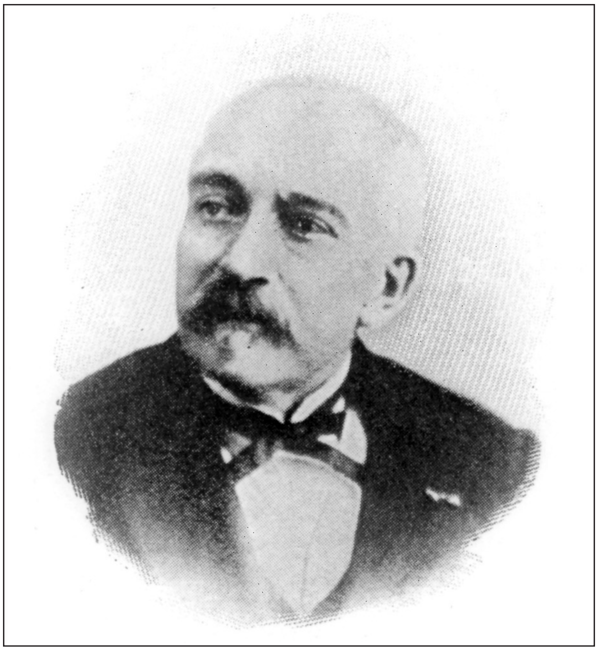
Étienne Lenoir

Belgian French electrical engineer

Lenoir invented the internal combustion engine and the spark plug. His engine led the way to motorized transportation and mechanized farming. The spark plug is still used in many engines today, including the gas-powered automobile.

Born: January 12, 1822; Mussy-la-Ville, Belgium
Died: August 4, 1900; La Varenne-Saint-Hilaire, France
Also known as: Jean-Joseph-Étienne Lenoir (full name)
Primary field: Mechanical engineering
Primary invention: Internal combustion engine



Étienne Lenoir. (Smithsonian Institution)

EARLY LIFE

Jean-Joseph-Étienne Lenoir (zhahn zhoh-ZEHF ay-TYEHN luh-NWAHR) was born in Mussy-la-Ville, Belgium, on January 12, 1822. Little is known about Lenoir's early life except that he taught himself chemistry. In the early 1850's, he moved to Paris to work as an enameller. There he became interested in electroplating. He devised a number of inventions, including a railway telegraph, a railway signaling system, and electric brakes, as well as the first parabolic mirror for use in lighthouses.

THE INTERNAL COMBUSTION ENGINE

Prior to Étienne Lenoir's work, inventors had concentrated on perfecting steam engines, which created pressure and heat outside of the cylinder. The heat then entered the cylinder and moved the piston. Several of these inventors had drawn diagrams of an engine within which the combustion would occur, but no internal combustion engine had actually been built. In 1858, Lenoir invented a two-stroke internal combustion engine that used an electric spark ignition and was fueled by illuminating gas (also known as coal gas). The engine was very similar to a double-acting steam engine; however, Lenoir had made important modifications to the engine, namely, having the combustion occur inside the engine.

Lenoir's internal combustion engine had stemmed valves through which a mixture of coal gas and air entered the engine. The mixture was drawn into the engine by the movement of a piston operated by a flywheel. Once the piston was partially drawn down in the cylinder, an electric spark ignited the gas and air mixture. The combustion then forced the piston the rest of the way down the cylinder. The flywheel then returned the piston to its original firing position. The valves that let the air into the cylinder also provided for the escape of the gas created by the explosion. The single-cylinder two-stroke engine fired on every revolution of the crankshaft. The engine was noisy and produced a considerable amount of pollutants. It was primarily useful for running pumps and small machines.

When Gottlieb Daimler, an inventor who played an instrumental role in later developments of the internal combustion engine, visited Lenoir's factory in Paris, he was not impressed by his engine. It was expensive to use and needed a very high temperature to function. However, Daimler later worked for the Gasmotorenfabrik Deutz, of which Nikolaus August Otto was part owner. It was Lenoir's engine that had inspired Otto to build a four-stroke internal combustion engine.

Lenoir continued to develop his internal combustion engine and successfully adapted it to run on a liquid fuel. This was the engine that he used to power his Hippomobile, a three-wheeled wagon with a passenger compartment and a separate compartment for the engine. He drove the vehicle from Paris to Joinville-le-Pont in a nine-mile trip that took three hours, making him the first to build a functioning vehicle powered by an internal combustion engine.

Lenoir also developed a stationary four-stroke internal combustion engine that he manufactured and sold for agricultural use. This engine was basically the same design as his original except that it produced power once every two revolutions of the crankshaft. Otto, Daimler, and others researched, adapted, and improved on the internal combustion engine to construct a reliable engine that could power an automobile.

LIFE'S WORK

In 1858, having studied the steam engines in use at the time, Lenoir began working on an engine that would produce its power from within. Lenoir envisioned an engine that would create its power by using a combustible gas mixture. In 1859, while he was working as a consulting engineer for Gauthier et Cie, he succeeded in building the first internal combustion engine. Lenoir's engine resembled a double-acting steam engine, but unlike the steam engine, it did not depend on an outside source for its power. It fired an uncompressed charge of air and illuminating (coal) gas with an electric spark ignition that he had designed. This type of ignition was unknown before Lenoir's invention of the spark plug, which is still in use today.

On January 24, 1860, Lenoir obtained a patent for his internal combustion engine. With a capital of two million francs, he established a company that he named Société des moteurs Lenoir. The company was housed in Paris on the Rue de la Roquette in the eleventh arrondissement. The engine that Lenoir built was relatively weak and fairly large in size. It required eighteen liters of the gas mixture to produce a horsepower rating of two. Although his engine had a number of drawbacks, it was very reliable and was particularly suited to run pumps and other small machinery. He succeeded in selling more than five hundred engines in France, Germany, and the United States during a five-year period. A considerable additional number of the engines were built and sold in Germany as a licensed product. By 1865, Reading Gas Works in London had begun producing the engines for Lenoir's company.

Lenoir hoped to use his internal combustion engine to power a vehicle. After making several improvements to his invention, including adding a carburetor and using petroleum for fuel, he attached his engine to a three-wheeled wagon. The vehicle was immediately brought to the attention of the public by *Le Monde Illustré*, a popular nineteenth century illustrated newsmagazine. *Le Monde Illustré* published a plate showing Lenoir's vehicle with a detailed description of how it worked. The writer of the article emphasized the fact that the vehicle was constructed such that the engine was in a separate compartment, leaving ample space for the passengers. He also noted the vehicle's gas reservoir. He described how the wheels were turned by a chain mechanism attached to cogwheels and how the steering mechanism worked, but he gave no details about the engine itself.

Lenoir did not actually make a trip in such a vehicle until 1863, when he drove from Paris to Joinville-le-Pont, a distance of about nine miles. It is not clear as to whether he used the vehicle illustrated in *Le Monde Illustré* or another somewhat improved version. His heavy vehicle, called a Hippomobile, was powered by a 1.5-horsepower engine adapted to run on liquid fuel. The vehicle used a considerable quantity of fuel and was able to attain only a speed of three miles per hour. He experienced several breakdowns and other problems on his journey. The engine not only was fuel inefficient and noisy but also overheated easily and seized up unless a large quantity of cooling water was added to it. Still, the engine was given a good reception by the Paris press, especially by *Cosmos*, and in the United States by *Scientific American*, which repeated the pronouncement made by *Cosmos* that the steam engine had been replaced.

Although he had received a patent on the Hippomobile in 1863, Lenoir apparently did not believe that his vehicle had the potential to be either successful or profitable. He abandoned his work on the road vehicle and shortly thereafter modified his engine for use on boats. However, he kept the vehicle that he had built. That same year, he sold all of his patents except the vehicle patent to the Compagnie Parisienne du gaz (Parisian Gas Company). In 1864, Lenoir sold his vehicle to Czar Alexander II in Russia, where it subsequently disappeared. In 1906, documents verifying the sale and exportation of the vehicle were found in Paris, but the vehicle itself was not to be found anywhere in Russia.

In 1870, Lenoir was given French citizenship for his contributions during the Franco-Prussian War. From 1876 to 1881, Lenoir was involved in a company called Lenoir, Rouart et Mignon, which made a type of four-stroke motor for use in motorboats and in agriculture. Lenoir continued to improve his engine for motorboats. In 1888, he designed a four-stroke boat engine that ran on naphtha fuel. In 1881, Lenoir received the Legion of Honor, awarded for his inventions in telegraphy. Although Lenoir's engine had been commercially successful, he lived in poverty during the last years of his life. He died at La Varenne-Saint-Hilaire on August 4, 1900.

Impact

Lenoir was the first to build an internal combustion engine and to commercially produce the engine. His engine so impressed the German inventor Nikolaus August Otto that Otto did further research and eventually built a four-stroke internal combustion engine that ran on liquid fuel. Otto's engine became the standard engine for all liquid-fueled automobiles. Lenoir made another extremely important contribution to the automobile with his invention of the spark plug, which remains an essential component of the automobile to this day. The Lenoir cycle used to model a pulse jet engine is an idealized thermodynamic cycle based on the operation of the internal combustion engine patented by Lenoir in 1860.

Lenoir's internal combustion engine had a significant impact on agriculture. His four-stroke engine was used to power farm machinery at the end of the nineteenth century. It also provided the basic design for internal combustion engines with improved efficiency, as mechanized agriculture became increasingly important during the twentieth century.

Several of Lenoir's inventions, including the railway signaling system, electric brakes, and parabolic mirror for lighthouses, significantly increased the safety of transportation and travel. His invention of the railway telegraph improved communication.

Louis-Sébastien Lenormand

French aeronautical engineer

Lenormand is credited with making the first successful parachute descent. He brought the parachute principle to the attention of inventors and is also credited with coining the term "parachute." His extensive research, teaching, and publication in the field of parachuting contributed to its acceptance as an important area of study and invention.

Born: 1757; Montpellier, France
Died: 1837; Castres, France
Primary field: Physics
Primary invention: Parachutes

Early Life

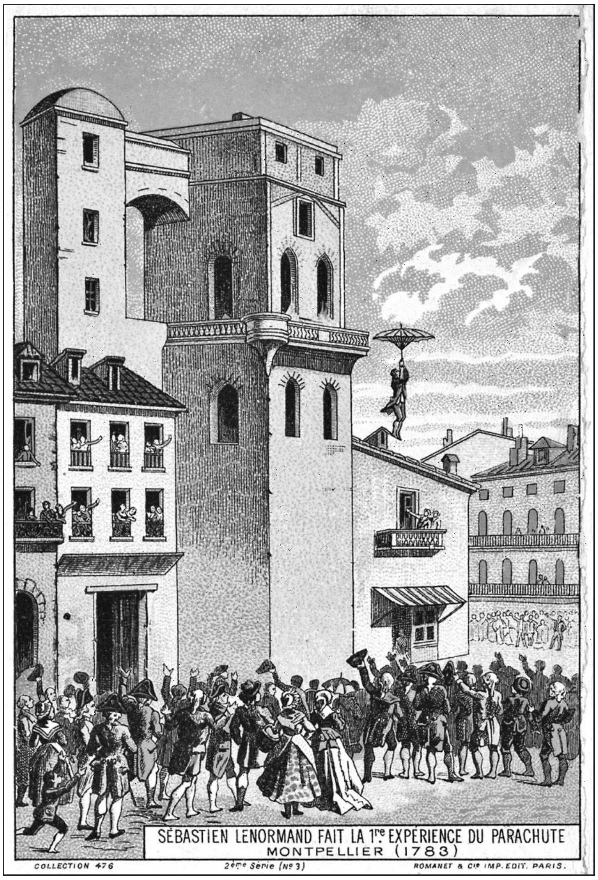
Louis-Sébastien Lenormand (lwee seh-bahs-TYAN leh-nohr-MAHN) was born in Montpellier, France, the son of a clockmaker. He studied chemistry and physics with Antoine Lavoisier and Claude Louis Berthollet in Paris. For a time, he was employed with the administration in charge of saltpeter. In this position, he learned how to make products such as gunpowder.

Lenormand left Paris after a time and returned to his native Montpellier, where he worked in his father's clock shop. During this period of his life, he became actively involved in the intellectual life of Montpellier. Inspired by the performance of a Thai equilibrist and the way in which the man used an umbrella to maintain his balance, Lenormand began conducting experiments in controlled descent, what is today known as parachuting. Before making his own parachute attempts, Lenormand tested his devices using animals. He employed umbrellas or devices based on umbrellas in these experiments.

Life's Work

In his first parachute attempt, Lenormand jumped from a tree; he used two modified umbrellas to control descent. He continued to refine his device and eventually constructed a fourteen-foot-diameter parachute still modeled on the umbrella but with a rigid wooden frame. On December 26, 1783, using this parachute, he jumped from the observatory tower in Montpellier. His safe descent was witnessed by a relatively large crowd of spectators, among whom were other inventors, including Joseph-Michel Montgolfier, who invented the hot-air balloon with his brother Jacques-Étienne that same year. Somewhat curiously, even though he made a successful descent, this concluded Lenormand's interest in parachuting.

Subsequently, Lenormand became interested in what he referred to as the science of "pure technology." He



Louis-Sébastien Lenormand parachutes from the observation tower in Montpellier, France, in 1783. Illustration from the late nineteenth century. (Library of Congress)

Parachutes

The concept of controlled descent can be traced to the ninth century. In Córdoba, Spain, ʿAbbas ibn Firnas developed what might be considered a primitive parachute. Wearing a large cloak resembling wings, he launched himself from a steep natural promontory outside Córdoba. The flight ended with a crash. A conical device resembling a parachute appeared in an Italian manuscript in 1470. Between 1480 and 1483, Leonardo da Vinci sketched a parachute-like device. Leonardo's design used a pyramid of wooden poles that held open a sealed linen cloth measuring twelve yards in height and twelve yards on each side. Leonardo left his device in the realm of ideas, however. More than a century later, the Croatian inventor Faust Vrančić sketched a parachute design that was simpler and more practical than Leonardo's.

By the eighteenth century, inventors had become interested in the parachute as a means to save lives. Louis-Sébastien Lenormand was one of these inventors, intending that his device be used to help people escape from a burning building. He constructed a device resembling a fourteen-foot-diameter umbrella but with a rigid frame. In 1783, he made a successful jump from the observatory tower in Montpellier, France. Although he was not the first to envision the parachute, he is credited as the inventor of the first useful parachute.

In 1793, Jean-Pierre Blanchard invented the first foldable parachute made from silk, lighter in weight and more manageable than linen. André-Jacques Garnerin improved the parachute by venting it (cutting a small opening at the apex of the parachute) to reduce oscillations during descent.

During the nineteenth century, parachutes became associated with carnival acts. Daredevils made astounding jumps from hot-air balloons using parachutes attached to the balloon's equator. When the performer jumped, the parachute broke loose. These feats fascinated spectators until Robert Cocking, using an inverted cone-shaped parachute, plunged to his death in 1837. Horrified, the public lost interest in these performances.

Nevertheless, inventors continued experiments with parachutes. In 1887, Captain Thomas Baldwin invented the parachute harness. In 1890, Paul Letteman and Kathchen Paulus invented the method of packing the parachute in a backpack. Paulus also created the intentional breakaway. With the invention of the airplane, parachutes became more important. The first jumps from an airplane were made in 1911; the first freefall jump in 1918. From World War I to the 1930's, the round solid cloth parachute remained the standard type.

During World War II, different types of parachutes—including the ribbon, ring-slot, and ring-sail parachutes—were designed to meet various military needs. The basic design of the parachute uses a lightweight fabric. Support tapes and suspension lines pass through cloth or metal connectors and are connected to risers (straps), connected to the harness. Military needs have brought about the development of cruciform (square), annular, and pull-down apex parachutes. The modern ram-air (self-inflating) parachute is made of two layers of fabric with air cells between them. All these designs are geared to improve descent control and safety.

Parachutes have been used as a means to deploy troops and to deliver supplies and equipment to soldiers. Parachutes are also used to deliver aid to disaster victims. Starting in the 1960's, parachuting became a recreational sport, known as skydiving.

found a monastery in Saïx, near Castres, where the monks were willing to afford him the opportunity to continue his technological research. Thus, he became a Carthusian monk and joined the brothers. Unfortunately, the French Revolution and its attack on monasticism severely interrupted Lenormand's idyllic life of research. In order to preserve his life, he had to renounce his vows and leave the Church. He married and moved to Albi, where he taught the new science of technology at a college that his father-in-law had established.

In 1803, Lenormand moved once again, this time to Paris. He found a position in the finance ministry working in the excise office. During his free time, he continued his research and experiments in technology. He also started publishing articles in technological journals. He applied for patents for a number of his inventions, including a paddleboat and a lighting system. In addition, he applied for a patent for a clock that was installed at the Paris Opera. This clock was very successful.

In 1815, Lenormand lost his position in the excise office. During the next fifteen years, he spent a vast amount of his time researching, experimenting, and publishing journals and a variety of technical manuals. He founded two very successful journals: *Annales de l'industrie nationale et étrangère* and *Mercure technologique*. He also published a twenty-volume dictionary between 1822 to 1835, appropriately called *Dictionnaire technologique: Ou, Nouveau Dictionnaire universel des arts* *et métiers*. It was a collaborative undertaking with Louis-Benjamin Francoeur, but Lenormand wrote most of the articles. The massive work was the physical manifestation of the academic discipline that he had introduced into the university system.

Lenormand envisioned his dictionary as the compilation of a complete course of study in technology. His intent was to offer a clear and accurate description of every aspect of human industry: agriculture, commerce, manufacturing, and the arts and crafts. He added a five-part classification to this compilation composed of four distinct categories of industrial arts—agriculture, mechanical arts, physical arts, chemical arts—and a fifth category on "pure technology." Lenormand placed in this category the activities usually referred to as the arts and crafts.

In 1830, Lenormand left Paris and returned to Castres. He became estranged from his wife and broke all ties with her family. He then renounced his marriage and returned to the monastery at Saïx. He once again took up his religious life. He died at Castres in 1837.

Impact

Although the parachute was not invented by Lenormand, he reintroduced and demonstrated the principle of the parachute. His interest in the device waned after his successful jump from the observation tower in Montpellier, but other inventors carried on what he had begun. Jean-Pierre Blanchard eliminated the rigid frame used by Lenormand and invented the first foldable parachute, which was made from silk. Blanchard claimed to have used a parachute to jump from a hot-air balloon in 1793; however, there were no witnesses to this event. It is André-Jacques Garnerin who is credited with the first jump using a nonrigid parachute. On October 22, 1797, he jumped from a hot-air balloon. Garnerin made several subsequent jumps from hot-air balloons at various altitudes.

Lenormand helped to create the academic discipline of industrial arts. He was also instrumental in popularizing technology. His journals, articles, and especially his *Dictionnaire technologique* made the processes of technology understandable to a wide audience. *Dictionnaire technologique* carried on the work of Denis Diderot and Jean le Rond d'Alembert, mid-eighteenth century philosophers who had placed the "mechanical arts" on a level equal with artistic, literary, and philosophical creativity in their *Encyclopédie: Ou, Dictionnaire raisonné des sciences, des arts, et des métiers* (1751-1772).

Leonardo da Vinci

Italian engineer and artist

The archetypal Renaissance man, Leonardo da Vinci pursued interests in art, architecture, mathematics, astronomy, anatomy, biology, botany, philosophy, science, and engineering. In thousands of pages of detailed notes and drawings, which included hundreds of inventions, Leonardo examined the physical world around him, leading the world away from the superstitions of the Middle Ages and into the modern era of science and reason.

Born: April 15, 1452; Vinci, Republic of Florence (now in Italy)
Died: May 2, 1519; Cloux (now Clos-Lucé), near Amboise, France
Also known as: Leonardo di ser Piero da Vinci (full name)
Primary fields: Aeronautics and aerospace technology; civil engineering; military technology and weaponry
Primary inventions: Designs for making ropes, lifting columns, threading screws, spinning and weaving machines, flying machines, weaponry, boats, and many other devices

Early Life

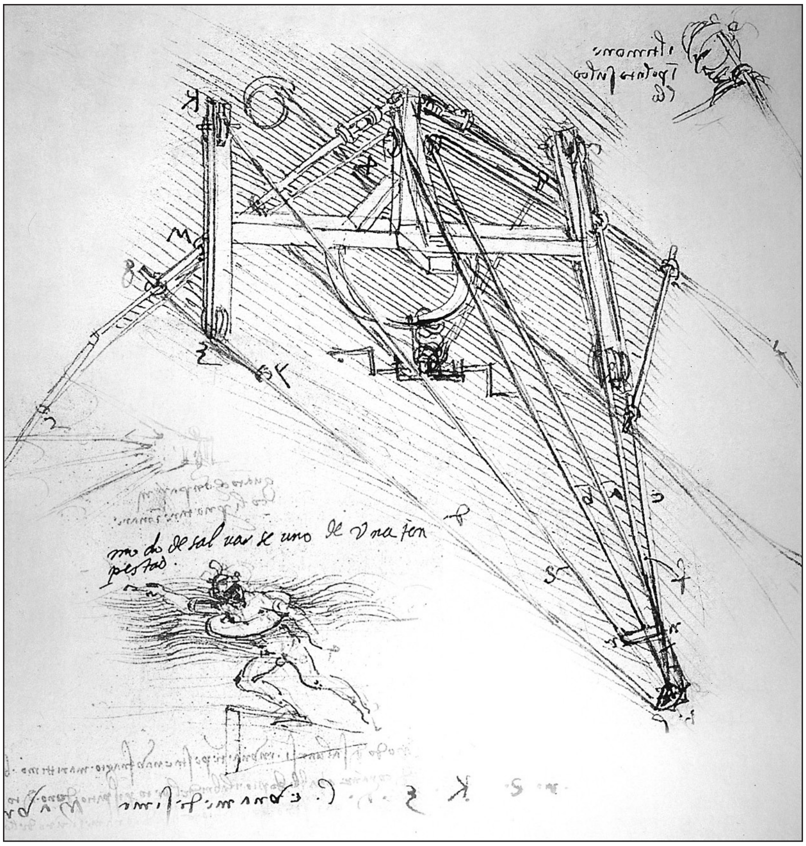
Leonardo da Vinci (lee-uh-NAHR-doh dah VIHN-chee) was born on April 15, 1452, in Vinci, a small town located in the hills above the lower Arno River Valley in the vicinity of Florence. Because he was the illegitimate son of a wealthy notary, Ser Piero, and a local peasant girl, Caterina, few records exist to document Leonardo's early years. In an era in which surnames were not yet in common use, Leonardo's birth name was Leonardo di ser Piero da Vinci, which meant "Leonardo, son of [Mes]ser Piero from Vinci," later shortened to Leonardo da Vinci, or Leonardo from Vinci. Leonardo apparently spent his first five years in Anchiano, a small village just outside Vinci, in the care of his mother, who may have been the first to introduce the young Leonardo to the beauty of the Tuscan countryside and to lay the groundwork for his later insatiable desire to understand the wonders of the natural world.

When Leonardo was age five, Ser Piero brought the boy to live with him and his family in Vinci, where Leonardo was groomed to follow in his father's occupation as a notary. Before long, however, Leonardo's artistic talents were recognized as too impressive to be ignored, and Ser Piero took his son to Florence, the hub of fifteenth century cultural and political activity. In 1466, Ser Piero secured for Leonardo the position of apprentice in the workshop of Verrocchio, one of the foremost artists of the day. There, the young Leonardo met not only important civic leaders and patrons but also other young apprentices such as Perugino, Ghirlandaio, and Botticelli, who, along with Leonardo, would later become some of the greatest artists of their era. In this invigorating atmosphere, Leonardo learned skills that would serve him as an artist and as an inventor and engineer as well, skills such as the vital role of keen observation, the importance of rational investigation, and the need for careful documentation. In 1472, when he was twenty, Leonardo was admitted into the Guild of St. Luke, the organization that oversaw both artists and doctors of medicine, a fortuitous combination for a young man with Leonardo's extraordinary proclivities.

Life's Work

Upon becoming a master, Leonardo established his own workshop, where, in 1473, he created his earliest extant drawing, a view of his beloved Arno River Valley, drawn from a bird's-eye perspective, which reflected his lifelong interest in birds and flight. In 1482, on the advice of Lorenzo de' Medici, Leonardo traveled to Milan to visit the court of Ludovico Sforza, known as Ludovico il Moro. In a letter to Ludovico, Leonardo offered his services as a military engineer, listing the many warfare devices and military benefits he could proffer, including portable bridges, mortars, mines, guns, cannons, covered chariots, and catapults. At the end of the letter, almost as an afterthought, Leonardo mentioned that he could also serve Ludovico as an architect and painter. In an era of intense rivalry, both in cultural status and military prowess, Leonardo's claims appealed to Ludovico, who wisely hired the prodigious young man. Leonardo remained in the Ludovico court from 1482 to 1499, during which time Leonardo worked intensely on mechanisms for both defensive and offensive military purposes.

Whether it was out of his own innate interests or because of the necessity of defending his homeland, Leonardo was always clearly involved in developing machines for warfare. Among his drawings, Leonardo included sketches for both a single sling and a double sling to hurl stones, as well as a giant crossbow. Leonardo also drew designs for a scything wagon, which, when pulled



Leonardo's sketch of an ornithopter with a pilot and a life preserver. (The Granger Collection, New York)

sence, the forerunner of the modern tank. Leonardo proposed the construction of a round, metal-covered enclosure, which, when operated by eight men protected inside, could be turned and moved in any direction by men on the lower level, while men on the upper level of the machine fired through narrow openings in the top.

Leonardo was also interested in innovations at sea. He drew plans for fast boats that could ram and hold the enemy's craft while men protected by shields attacked the enemy with artillery. Leonardo also drew designs for paddle-propulsion boats, with the energy being provided by men in the hull, whose power was increased by a system of cogwheels and gears that multiplied the revolutions of the paddlers. He designed a ship with a double hull that would minimize the water intake if the ship's outer hull were damaged. In order to inflict as much damage as possible on an enemy vessel, Leonardo designed ship bottom breakers to facilitate the sinking of enemy ships. Leonardo was also concerned with spanning bodies of water. He designed fast construction bridges to enable armies to quickly build bridges with a system of wood logs and ropes. Leonardo also designed movable bridges, such as completely revolving bridges that could be turned in case of enemy advances; parabolic bridges, which, secured to one bank, could be turned on vertical hinges; and an impressive design for a single-span bridge with a double support that would permit the bridge to be of sufficient height to permit even vessels with tall masts to sail underneath. If a bridge was not available, Leonardo designed floats so that a man could simply walk across a body of water. Leonardo even drew plans for a diving suit that would allow a man to dive underwater and to breathe through a system of respiration pipes that reached the surface of the water.

The political and military events of the late fifteenth and early sixteenth centuries drove Leonardo from place to place. In 1499, Louis XII of France invaded Milan and defeated the ruling Sforza family. Leonardo was forced to flee to Venice, where he used his talents to invent de-

by horses, moves a system of gears that spin huge scythes protruding from the side of the wagon, capable of cutting down anything in their path. Leonardo missed no opportunity to enlarge and embellish upon current firearms. He multiplied the efficiency of the traditional single-barrel artillery by designing a three-barreled cannon, an eight-barrel machine gun, and even a thirty-three-barrel machine gun. Each of these guns was designed to be mounted on easily movable gun carriages that were adjustable both horizontally and vertically in relation to the desired target. In order to lift heavier artillery, Leonardo devised a winch in which the lifting and lowering was done with a worm screw and a spiral wheel. To improve the accuracy of his artillery, Leonardo explored the use of aerodynamic projectiles to control the trajectory of the ammunition. Concerned with the challenge of rapid ignition of the multiple artillery barrels he was designing, Leonardo drew plans for automated igniting devices and automatic strikers. The covered chariot that Leonardo had promised Ludovico Sforza in his letter of 1482 was, in esvices to defend that city from attacks by sea. The next year found Leonardo back in Florence, where he rejoined his guild and resumed painting. During the ensuing years, Leonardo served as military engineer for Cesare Borgia, traveling between Italian cities devising defensive mechanisms and designing a functioning canal up to the Porto Cesenatico. Only after the Sforzas regained control of Milan in 1506 did Leonardo return once again to that city. In his later years, Leonardo lived and worked in Florence, Rome, and Bologna, making the acquaintance of his younger fellow artists, Michelangelo and Raphael. Leonardo spent his last years in France as the court engineer, architect, and painter to King Francis I. Throughout these tumultuous years, Leonardo recorded his observations, insights, and inventive devices in drawings and notations that filled thousands of notebook pages.

In addition to his copious studies on military matters, Leonardo also turned his attention to civil matters, with special attention to devising labor-saving devices and improving on existing work-related machines. Leonardo drew intricate plans for machines for making ropes, lifting columns, and threading screws. One of his particular interests was the fabrication of textiles, a major industry in Italy at the time. Leonardo drew designs for several spinning and weaving machines and included plans for an automated bobbin winder. He also devised teasing machines that processed cloth by running the cloth over a series of rollers. He designed a winged spindle that would stretch, twist, and wind thread simultaneously. Although most of the textile manufacture in Italy at the time was done with wool, silk was also a coveted material. Leonardo designed a silk-doubling machine that increased silk production output.

Leonardo was always fascinated by the possibility of locomotion, whether on land or in air. It is his experiments with flight for which Leonardo's inventive talents are perhaps best remembered. Leonardo seemed obsessed with enabling humans to fly like the birds. He drew many sketches of wings, both the natural wings of birds and human-made wings that were worked by various mechanisms. To assist the act of flight, Leonardo devised an inclinometer to control the horizontal positioning of the craft and anemometers to show the wind direction. Leonardo's dreams of flight ranged from designs for fly-

The Dream of Flight

To fly like a bird was a lifelong dream for Leonardo da Vinci. Leonardo said that he had a childhood memory of a bird flying down to his cradle and brushing its feathers against his face, and one of Leonardo's earliest drawings was an aerial bird's-eye view of the Arno River Valley. Throughout his life, Leonardo dedicated many in-depth studies to the flight of birds, such as his 1505 *Codex on the Flight of Birds*.

Leonardo's designs for a flying machine progressed over time. His earliest designs consisted of machines in which the human pilot, laying prone in a wooden frame, placed his feet in stirrups and moved his feet together, causing the downstroke of the wings; the pilot's hands directed the upstroke by means of a lever. Over time, Leonardo modified the movement of the pilot's legs, having the legs slide up and down, assisted by the hands, in order to make the wings beat. A still further advance was the addition of a head harness that manipulated a rudder to control direction. Leonardo drew numerous sketches of wing types, from a wing based on that of a bat to adjustable tilt wings, beating wings, and articulated wings, each in an effort to refine his flying machine. The most ambitious of his designs included a large enclosed cabin, capable of holding two pilots who operated the flapping bat wings with a complex system of screws and cranks.

As inspired as Leonardo's designs were for his early flying machines, two factors would have prevented his designs from ever taking off. First, the materials that were available at the time were just too heavy to be manipulated by even multiple human pilots. In addition, Leonardo's understanding of the flight of birds was fundamentally flawed. Leonardo believed that birds flew when the wing was moved down and back, as if the bird were swimming through the air like a swimmer through water. In actuality, the lift required for flight is created when birds move their wing feathers up and forward.

As time progressed, Leonardo replaced the flapping-wing designs with designs for fixed-wing glider crafts. At first, Leonardo did not provide a means for the pilot to control the machine through body movements. Eventually, however, he enabled the pilot to balance the craft by moving the body's extremities, effectively inventing a predecessor to the modern controlled glider.

Leonardo wrote a journal entry in which he stated that a great bird will take flight from Mount Cerceri, a mountain near Leonardo's residence at the time. Legends recount that one of Leonardo's assistants piloted the craft, crashed, and broke his leg. Whether one of Leonardo's great birds ever actually took flight will probably never be known. What is known is that in an era of holdovers of medieval traditionalism and superstition, Leonardo's dream of flight opened up a new vision of possibilities for the future.

ing machines, hang gliders, and parachutes to a complex rendering for an air screw, anticipating the future helicopter.

Impact

Leonardo was one of the foremost visionaries in history. In addition to creating such masterpieces as *The Last Supper* and *Mona Lisa*, Leonardo is credited with being one of the most prolific inventors of all time. His inventions were based on careful observation and copious documentation. Leonardo was unique for his time in that he explained not only the purpose of machines but also how machines actually worked. Leonardo was the first to conceive of machines as both a whole and a sum of its parts, realizing that the parts, such as flywheels, cogs, and gears, could be modified, improved upon, and utilized in innovative new ways. With this realization, Leonardo was able to combine individual parts into hundreds of new machines.

In his designs, Leonardo anticipated many modern inventions. He drew diagrams of a hydrometer that anticipated the modern science of hydraulics. His plans for devices for the canalization of rivers are still in use today. His designs for diving suits, parachutes, flying machines, and helicopters inspired generations of later inventors. In 1903, the Wright brothers achieved Leonardo's dream of heavier-than-air human flight. A few years later, the modern helicopter was developed. His plan for a single-span bridge, conceived in 1502 for the sultan of Istanbul but never realized because it was thought to be impossible, was brought to reality in 2001, when a smaller bridge based on Leonardo's design was constructed in Norway. On May 17, 2006, the Turkish government commenced construction of Leonardo's bridge over the Golden Horn at the mouth of the Bosporus, just as Leonardo had originally planned 504 years earlier.

Recognized now as some of the most farsighted inventions ever devised, Leonardo's achievements are displayed in museums around the world, chief among them the Leonardo da Vinci National Museum of Science and Technology in Milan, Italy, and the Leonardo da Vinci Museum at the Château du Clos Lucé in Amboise, France. His notebooks are the highlights of major collections in the Louvre, the National Library of Spain, the Ambrosian Library of Milan, and the British Library. Only one of Leonardo's notebooks is in a private collection: The Codex Leicester is owned by Bill Gates, an acclaimed inventor of the late twentieth century. Five centuries later, inventors can still draw inspiration from Leonardo da Vinci, the most prodigious of Renaissance men.

Willard F. Libby

American chemist

Libby, a chemist who specialized in the study of radioactive elements, developed the carbon-14 method used to determine the ages of archaeological artifacts. He also pioneered the use of radioactive elements to trace hydrological and geophysical processes.

Born: December 17, 1908; Grand Valley, Colorado
Died: September 8, 1980; Los Angeles, California
Also known as: Willard Frank Libby (full name)
Primary field: Chemistry
Primary invention: Carbon-14 dating

Early Life

Willard Frank Libby was born on a farm in Grand Valley, Colorado, on December 17, 1908. His parents, Ora Edward Libby and Eva May Libby, soon moved to California, where Libby attended grammar school in Sebastopol. There, he received his high school education at Analy High School, where he played on the football team. Libby entered the University of California, Berkeley, in 1927, where he was awarded a B.S. degree in chemistry in 1931. He received his Ph.D. in chemistry in 1933 and was appointed an instructor at the university's Department of Chemistry. Over the next decade, he was promoted to assistant professor and later to associate professor of chemistry. His major research during this period was focused on building sensitive Geiger counters, electronic devices that are used to measure the decay of natural and human-made radioactive elements.

Libby married Leonor Hickey in 1940. Together they had twin daughters, Janet and Susan, in 1945.

Life's Work

In 1941, Libby was awarded a Guggenheim Memorial Foundation fellowship to conduct research at Princeton University. However, the start of World War II interrupted his efforts. Shortly after the attack on Pearl Harbor on December 7, 1941, Libby joined the Division of War Research at Columbia University in New York. He worked on the Manhattan Project to develop the atomic bomb. At Columbia, Libby worked with Harold Urey, who won the Noble Prize in Chemistry in 1934 for isolating deuterium, a heavy isotope of hydrogen. Under Urey's direction, Libby was responsible for developing the gaseous diffusion technique to separate and enrich uranium 235, which was used in the atomic bomb dropped on Hiroshima.

In 1945, at the end of World War II, Libby was appointed professor of chemistry at the University of Chicago, where he worked in the university's Institute for Nuclear Studies. In 1946, Libby showed that when cosmic rays (charged particles moving through space at nearly the speed of light) strike the upper atmosphere of the Earth, they produce trace amounts of tritium, a rare radioactive isotope of hydrogen having an atomic mass of three units, and carbon 14, a rare radioactive isotope of carbon. This tritium can be incorporated into water that is present in the Earth's atmosphere. Since tritium has a half-life (the time required for half of the starting amount of an isotope to decay away) of only twelve years, it can be used to trace the presence of atmospheric water. If water has been isolated underground for many years, all the tritium that was added while the water was in contact with the atmosphere will have decayed. By measuring the tritium concentration, Libby developed a method to determine the last time atmospheric water was added to underground water, such as well water. He applied the same technique to measuring the circulation pattern and

Willard F. Libby. (©The Nobel Foundation)

Carbon-14 Dating

Carbon has two stable isotopes, carbon 12 and carbon 13. A small amount of carbon 14, a radioactive isotope of carbon, is also found on Earth. Since carbon 14 has a half-life of only 5,730 years, any carbon 14 present when the Earth formed has decayed away. However, cosmic rays interact with nitrogen in the Earth's atmosphere, producing carbon 14. If the number of cosmic rays is constant, the ratio of radioactive carbon 14 to stable carbon 12 stays at a constant value, with the production just balancing the decay. The carbon 14 reacts with oxygen in the atmosphere, forming carbon dioxide, which spreads around the world. Plants take in atmospheric carbon dioxide during photosynthesis, so, while plants are alive, their carbon 14-carbon 12 ratio is the same as the atmospheric ratio. Animals ingest carbon 14 by eating plants or other animals, so the carbon 14-carbon 12 ratio in living animals is also the same as the atmospheric ratio. However, as soon as the plant or animal dies, it stops taking in carbon dioxide, and the carbon 14 decays away. The carbon 14-carbon 12 ratio serves as a clock, ticking away the time since the organism died.

A fresh sample of carbon 14 produces about fourteen disintegrations per minute per gram of carbon. When the sample is isolated from new input of carbon 14, the number of disintegrations per minute per gram of carbon decreases exponentially. After 5,730 years, one-half of the original amount of carbon 14 remains, and the carbon-14 decay rate is only about seven disintegrations per minute per gram of carbon. After another 5,730 years, one-fourth of the original amount remains, and after another 5,730 years, only one-eighth of the original amount remains.

Carbon 14 decays by the emission of an electron, which can be detected with instruments such as proportional counters or scintillation counters, electronic devices that detect the individual decay products. However, the cosmic rays produce only a very small amount of carbon 14. In the Earth's atmosphere, there is only one carbon-14 atom for every trillion carbon-12 atoms, so these devices require a relatively large amount of carbon, typically about one gram, to measure a decay rate accurately.

The sensitivity of carbon-14 dating increased with the development of accelerator mass spectrometry. With this technique, the carbon is vaporized and separated into its isotopes, which are counted directly rather than by decay counting. This method allows dating of only a few milligrams of carbon. The carbon-14 dating technique provides reliable ages on samples dating back a few hundred years to about eighty thousand years.

the mixing of water in the ocean, and to determining the age of wines.

In the same research paper that reported the tritium production, Libby noted that the radioactive carbon 14 produced by cosmic rays would be incorporated into living organisms. However, once an animal or plant dies, it takes in no more atmospheric carbon, so the ratio of carbon 14 to the stable carbon 12 decreases. By measuring this ratio, Libby suggested that he could determine how long ago the plant or animal had died. In 1947, Libby and Ernest Anderson performed an experiment demonstrating that Libby's idea was correct. They showed that the methane gas from Baltimore sewage had measurable carbon 14, while methane produced from old petroleum deposits (produced from organisms that lived millions of years ago) did not. In 1949, Libby and James Arnold, a research associate at the Institute for Nuclear Studies, demonstrated that the carbon-14 dating technique worked on archaeological samples: Their carbon-14 technique was as accurate as other dating methods used on objects such as wood from the coffin of an Egyptian mummy.

Libby used the radiocarbon dating technique to determine the ages of linen wrappings from the Dead Sea scrolls, bread from the village of Pompeii buried by the eruption of Mount Vesuvius in 79 C.E., charcoal from a campsite at Stonehenge, and corncobs from a cave in New Mexico. He also used radiocarbon dating to determine that the last North American ice age ended about ten thousand years ago, not twenty-five thousand years ago as had been believed.

Libby remained on the faculty at the University of Chicago until 1954, when President Dwight D. Eisenhower appointed him to the U.S. Atomic Energy Commission (AEC). Libby had previously served as a member of the Committee of Senior Reviewers of the AEC from 1945 to 1952. Libby, the first chemist to serve on the AEC, headed Eisenhower's international "Atoms for Peace" program, which supplied equipment and information on the peaceful uses of atomic energy and radioactive materials to schools, hospitals, and research institutions around the world. Libby also studied the effects of radioactive fallout. He served on the AEC until 1959, when he became professor of chemistry at the University of California, Los Angeles (UCLA). He was appointed director of the Institute of Geophysics and Planetary Physics at UCLA in 1962, a position he held until his death. While serving on the AEC, Libby held a position as a research associate of the Carnegie Institution's Geophysical Laboratory in Washington, D.C., so that he could continue his scientific research.

During the Cold War, Libby opposed efforts to ban testing of nuclear weapons. He proposed that every home should have a fallout shelter in case of nuclear war. In a widely publicized event, Libby built his own fallout shelter in his home. From 1959 to 1961, he served as consultant to the Office of Civil and Defense Mobilization. In 1961, he wrote a twenty-seven-page pamphlet published by the Associated Press titled "You Can Survive an Atomic Attack."

Libby divorced his wife in 1966 and married Leona Woods Marshall. He continued to explore applications of radioactive decay to geological problems. In 1977, he developed a method to monitor the emission of radon gas from earthquake-prone areas, detecting the alpha particle emitted when radon decays by using sensitive film. He suggested that an increase in radon emission might signal an upcoming earthquake. Libby died of a lung illness on September 8, 1980, in Los Angeles.

Impact

In 1960, Libby was awarded the Nobel Prize in Chemistry for his development of carbon-14 dating. Introducing Libby for the award, Professor Arne Westgren said that Libby had "succeeded in developing a method that is indispensable for research work in many fields and in many institutes throughout the world. Archaeologists, geologists, geophysicists, and other scientists are greatly indebted to you for the valuable support you have given them in their work."

Although archaeologists and geologists had other methods to determine the ages of certain types of samples, the carbon-14 method quickly proved more rapid and more accurate. Thus, Libby's radiocarbon dating method quickly attracted attention from the scientific community, and more than one hundred carbon-14 analysis laboratories were established around the world.

Archaeologists were able to establish time lines for human development and settlement that preceded the written record. Egyptologists, for example, employed Libby's technique to create a chronology of Egyptian rulers dating back to about 5000 B.C.E. The charcoal from campfires in Iraq was dated, showing that people lived in Iraq twenty-five thousand years ago. "Ötzi the Iceman," a frozen body found in the mountains of northern Italy in 1991, was also dated using Libby's technique. Samples of the iceman's bones, boot, leather, and hair show that he lived about fifty-five hundred years ago.

The most famous object dated using the radiocarbon technique is the Shroud of Turin—believed by some to be the burial cloth of Jesus Christ. Records of the shroud date back to the mid-fourteenth century. The presence of pollen spores from Israel on the cloth suggested that it might be a genuine relic. However, in the 1980's, small samples of the cloth were dated independently by three laboratories in Tucson, Oxford, and Zurich. Their results showed the cloth was made around 1300 C.E. and could not be a burial shroud from the time of Jesus Christ.

Monitoring the radiocarbon age of the water in a well system can aid in determining if overuse is depleting a region's water supply before the problem becomes so severe that there is a shortage. Oceanographers employ the carbon-14 method to date recent sea sediments. Carbon-14 dating has made accurate determinations of the rate of turnover of the deep water of the Earth's oceans. These results play an important role in studying one of the central problems of physical oceanography: determining how water circulates in the oceans.

Carl von Linde

German engineer

Linde was a key developer of modern refrigeration technology and of a technique for the liquefaction of large quantities of air to extract pure liquid oxygen and nitrogen.

Born: June 11, 1842; Berndorf, Bavaria (now in Germany)
Died: November 16, 1934; Munich, Germany
Also known as: Carl Paul Gottfried von Linde (full name)
Primary fields: Chemistry; mechanical engineering
Primary invention: Ammonia-compressor refrigerator

Early Life

Carl von Linde (kahrl von lihnd) was born June 11, 1842, in Berndorf, Bavaria. His father was a Lutheran minister. Linde first became interested in engineering when he attended high school in the town of Kempten. The father of one of his friends was the director of the local cotton-spinning mill, and Linde became a frequent visitor, fascinated by the mill's complex machinery. These experiences fueled his desire to pursue an education in the field. He received his father's permission to study mechanical engineering at the Federal Polytechnic in Zurich, Switzerland. Although he never officially graduated, he did receive letters of recommendation from some of the Federal Polytechnic's well-known professors.

Linde began his professional career in mechanical engineering at the workshop of the Kottern cotton-spinning mill near Kempten, and in 1865 he became an engineer in the drawing office of the Borsig company in Berlin. In 1866, he accepted the position of head of the technical office of a new Munich locomotive manufacturing factory, Krauss and Company. He married Helene Grimm on September 17 of that same year. The couple would eventually have six children: Maria, Franziska, Friedrich, Anna, Richard, Elisabeth. Linde had developed many research interests in addition to his business interests, and he entered the teaching profession as a result. In 1868, he received an associate professorship at the Polytechnic in Munich. By 1872, he had achieved the rank of full professor of mechanical engineering.

Life's Work

The first phase of Linde's teaching career would last from 1868 to 1879. After he became a full professor, the Bavarian government funded a machine laboratory at the Polytechnic for Linde and his students, the first such laboratory to be established in Germany. It was here that he began conducting his research experiments on heat theory and refrigeration. An 1871 Linde essay on improved refrigeration techniques had sparked interest in his work among breweries in Germany and other parts of Europe. Refrigeration machines would allow for year-round rather than seasonal brewing. Breweries' requests for his refrigeration machines spurred his research into ways to further improve them. By 1874, Linde had developed a methyl-ether refrigerator, and by 1876 he had developed an ammonia-compressor refrigerator. His refrigerators relied on a mechanical system of cooling gas. His model greatly improved on earlier models because of its reliability, efficiency, practicality, and portability. He also engineered and built ice factories that utilized his refrigeration techniques. He would distribute cooling throughout the factories through a method of circulating cold saltwater brine in a pipe cooling system mounted on the ceilings.

In 1877, the German Imperial Patent Office awarded Linde a patent for his ammonia-compressor refrigerator and he decided to go into business to market his invention. The following year, he surrendered his professorship and established Linde's Eismaschinen AG (Society for Linde's Ice Machines), later known as Linde AG, headquartered in Wiesbaden. His company became an international success, selling its product to breweries, slaughterhouses, and cold-storage companies. Linde was actively involved in various technical associations while also running his company. In 1894, after receiving a request to develop a new cooling method from the Guinness brewery in Dublin, Ireland, Linde decided to withdraw from his active role in managing his company to once again focus on research.

Linde's new research conducted during the 1890's would lead to his next major discovery, a process for liquefying air (and later other gases) by cooling it in stages that came to be known as the Linde technique. By 1894-1895, Linde was able to liquefy air by compressing a small quantity in a machine, and then allowing it to expand rapidly, which cooled the air. The already-cooled air would then be used to cool additional air that would enter the machine. Additional repetition of the process would eventually result in liquefaction. The method was based on the Joule-Thompson effect pioneered by James Prescott Joule and William Thomson (Lord Kelvin) and

The Ammonia-Compressor Refrigeration Machine

Carl von Linde's early research career sprang from his desire to improve the refrigeration technology of his day. He set out to build upon the earlier work of scientists such as Dr. William Cullen, Dr. John Gorrie, and Michael Faraday. He developed his first refrigeration machine in 1874 at his newly built machine laboratory at the Munich Polytechnic, utilizing the principle of cooling gas, a compressor-based technology, and methyl ether as his refrigerant. Linde was not happy with the first machine, however, because its mercury seal did not work properly and methyl ether leaked from the compressor. He then built a second machine, with the help of his student assistant Friedrich Schipper. The new machine featured a new compressor design with a more effective seal and used ammonia as a refrigerant. Ammonia proved to be more efficient, and the second machine had the added benefits of being half the cost and weight of his first machine. Linde received a Bavarian patent for his new ammonia-compressor refrigeration machine in 1876 and a German Reichspatent in 1877. A third design featured gas pumps and a horizontal rather than vertical structure.

Linde not only conducted groundbreaking research into the basic laws of physics but also proved to be an astute businessman who knew how to get his invention onto the commercial market. He pioneered both the technology behind the machine and the engineering of the machine itself in addition to forming his own company to market the machines. Linde's company served as a model for science-based industry and grew to become a worldwide corporation, which is still in existence under the name Linde AG. Linde's work on his refrigerator also spurred his later pioneering work in air liquefaction, when the Guinness brewery of Dublin, Ireland, asked him to develop a new cooling technique in the 1890's. The result would be the Linde technique for liquefying air.

Modern refrigerators use a similar process of evaporation utilized by Linde's ammonia-compressor refrigeration machine, using a substance known as a refrigerant to displace heat from the inside to the outside. Standard parts include the compressor, which compresses the refrigerant, raising the pressure and temperature inside the refrigerator; the heat-exchanging pipes located outside the refrigerator, which dissipate the heat inside the refrigerator; and the liquid refrigerant. The refrigerant cools down, condenses, and absorbs the heat to cool the refrigerator, becoming warmer and expanding before continuously repeating the cycle. Early refrigerators used a gas flame to heat the ether or ammonia, while more current models use a safer electric heating unit. Ammonia is not in common use today because of the discovery of less toxic refrigerants. Refrigerators became mass-produced in the 1940's and are now present in most households.

the countercurrent technique. Linde also returned to academia during this period, first as an honorary professor, and later, in 1900, as a full professor without teaching duties.

By 1902, Linde had utilized his method to separate pure liquid oxygen and nitrogen from liquefied air. In 1903, he received patents in the United States for the Linde oxygen process and the machine used in producing the liquid oxygen. Linde achieved worldwide recognition for his work. His honors included three honorary doctorates, the Bavarian Crown Achievement Medal, and his elevation to personal nobility status. During this period, Linde did not completely abandon his outside and business interests. The Linde company continued to flourish, also launching a number of subsidiaries around the world. Linde personally served on the supervisory boards of some of his company's subsidiaries as well as the boards of outside companies, including the locomotive manufacturer Knauss and Company, where he had once worked.

He was also one of the founders of both the Bavarian Boiler Review Association, where he served as chairman for a time, and the Munich Thermal Testing Station. He examined Bavarian patent applications and served on a Berlin commission that reformed German patent law. He was appointed to the board of trustees of the German Physical-Technical Institute in 1895. He was appointed to the Bavarian Academy of Science in 1896 and was appointed Bavarian district chairman of the Association of German Engineers (VDI) in 1892 and its president in 1904. In 1898, he joined the Göttingen Association for Applied Physics and Mathematics, a forerunner of the Kaiser Wilhelm and Max Planck societies. In 1903, he cofounded the Deutsches Museum in Munich, serving on its board for many years. Linde also found time to write a memoir entitled *Aus meinem Leben und von meiner Arbeit* (1916; from my life and about my work). Carl von Linde died on November 16, 1934, in Munich at the age of ninety-two.

Impact

The Linde technique for the liquefaction of air made possible for the first time the timely and cost-effective production of commercial quantities of liquid air. His process for separating oxygen from the liquid air through the apparatus he invented made oxygen a common commodity in both the medical and industrial worlds. Uses for his liquid air products include the oxyacetylene torch, which revolutionized metal cutting and welding, rocket fuel, and the manufacture of steel. Variations of his methods have remained in use long after his passing, as other scientists have utilized them to liquefy gases such as hydrogen. His work also proved to be an important basis for research in the area of low-temperature, high-vacuum physics.

His process of liquefying gases in large quantities also allowed the development of modern refrigeration technology, of which his refrigeration machines were a pioneering example. Although Linde was not the first scientist to use condensed ammonia in a refrigeration machine, he developed the first practical and portable refrigeration systems. Modern refrigeration has vastly improved the ability to produce, store, and handle food safely because of its inhibition of the growth of dangerous bacteria, mold, and yeast that can sicken consumers. Linde AG grew into an international company that has worked in a variety of areas, including the manufacture of refrigeration and air-conditioning systems, the production of rare gases, and the construction of industrial plants of various types. Carl von Linde's lasting impact was his ability to follow an invention from the idea, to the design, to the production and marketing of that design.

Edwin Albert Link

American underwater archaeologist and aviator

Link invented the flight simulator—a training device that allows pilots to develop the skill of flying using flight instruments while they remained on the ground—as well as several devices for undersea exploration.

Born: July 26, 1904; Huntington, Indiana
Died: September 7, 1981; Binghamton, New York
Also known as: Edwin Albert Link, Jr. (full name)
Primary fields: Aeronautics and aerospace technology; naval engineering
Primary inventions: Link Trainer (flight simulator); submersible decompression chamber

Early Life

Edwin Albert Link, Jr., was born on July 26, 1904, in Huntington, Indiana. He was the youngest son of Katherine (Martin) and Edwin A. Link, Sr. His father worked at the Schaff Brothers Piano Company in Chicago, Illinois. In 1910, the family moved to Binghamton, New York, when the senior Edwin bought the Binghamton Automatic Music Corporation, which he renamed the Link Piano and Organ Company. The company manufactured player pianos, nickelodeons, and theater organs.

At an early age, Link showed great mechanical ability, but he was not interested in academic subjects. His parents separated in 1918, and Link moved frequently, attending the Rockford Training High School in Illinois, Los Angeles Polytechnic High School, Bellefonte Academy in Pennsylvania, and the Lindsley Institute in West Virginia.

News accounts of aircraft fighting in World War I stimulated Link's interest in aviation. He took his first flight in 1920. Link returned to Binghamton in 1922, attending Binghamton Central High School while working at his father's piano company. He learned about mechanical devices and the principles of compressed air, and he quickly developed the skill to repair and rebuild organs. Link kept his creative mind busy, thinking about devices he might build to accomplish specific tasks. In 1924, he filed his first patent application, for a device that removed lint from player piano rolls.

Link's interest in flying continued, but he could not take lessons very often because of the cost of the plane rental. Frequently, he could only afford to taxi a friend's plane along the airport runway, learning how to move his hands and feet on the aircraft controls, without actually flying. Link flew whenever he could afford lessons. He made his first solo flight in 1926.

Life's Work

In 1928, Link convinced his mother to help him buy a small Cessna airplane. By that time, he had received his pilot's license and wanted to pursue a career in aviation. He worked on a device designed to make flight training less expensive and safer. He built the prototype of his flight simulator, the Link Trainer, in the basement of the organ factory using parts from an organ. After a year and a half, he succeeded in getting his simulator to mimic the response to control movements that he experienced in his own airplane. He filed a patent application for the Link Trainer in March, 1930, and established the Link Aeronautical Corporation in Binghamton to build and sell his aviation trainer.

Much to Link's surprise, his trainer was a success with amusement park operators, who used it as a coin-operated ride, but aroused little interest at flight-training schools. Link established the Link Flying School in 1930. Using the Link Trainer as the major training device, he guaranteed each student could learn to fly for only $85. However, the Depression made flying too expensive for most people, so Link worked at airports, managing the operations, refueling airplanes, and piloting. Link designed an illuminated sign, which he suspended below his airplane, selling advertising to local shop owners. His "electric sky sign" was only visible at night, and night flying requires more extensive use of the aircraft instruments. He quickly realized that the Link Trainer, equipped with more advanced instruments, could provide night and bad-weather flight training.

In 1931, Link married Marion Clayton, a reporter for a Binghamton newspaper. She took over managing

The Link Trainer

The first flight simulator was designed and built by Edwin Albert Link in 1929 to allow pilots to practice flight maneuvers while they were on the ground. Link used the knowledge of mechanical devices and the operation of bellows, knowledge gained while working in his father's organ company, to construct a mechanical device that responded to control movements in the same way that an airplane responded, simulating the motions experienced during airplane flight. The Link Trainer had two basic components, the training compartment and the instructor's station.

The training compartment, which looked like a large toy airplane, was built from parts available in the organ factory. It was simply a wooden box shaped like the cockpit of an airplane and attached to short wooden wings. The box sat on a universal joint, a device that allows the cockpit to tilt in any direction, mounted on a turntable. The cockpit contained a pilot's seat, a set of aircraft controls, and flight instruments. The motion of the cockpit was driven by several bellows, which were controlled by valves that regulated their pressure in response to the movement of the control wheel or stick and the rudder pedals. This combination allowed the cockpit to move around any of the three axes. The cockpit pitched up and down and rolled side to side as it simulated the movement of an actual airplane in response to the flight controls.

The instructor sat at a table outside the cockpit. He had a display that repeated the flight instruments in the cockpit, a large map, and a marker, called a "crab," that moved across the map tracking the course of the simulated flight. The pilot and instructor talked to each other using headphones and microphones to simulate radio communications.

The student had to rely on the readings on the instruments to fly the simulator through a series of maneuvers directed by the instructor, who followed the progress on the map. Advanced versions of the Link Trainer included simulation of the effects of air passing over the controls, making them more difficult to move as the speed increased, and a generator that simulated turbulence.

Link's businesses. They had two sons—William, born in 1938, and Edwin Clayton, born in 1941.

In the mid-1930's, aviation began to grow. The U.S. Army Air Corps took over transporting airmail for the post office in February, 1934, but within six weeks twelve pilots were killed. Many of them were inexperienced at flying in bad weather, so the Army Air Corps ordered six instrument trainers from Link's company. Japan bought ten Link Trainers, and orders from several European nations followed quickly. An improved instrument flying trainer was introduced in 1936.

In 1937, the company set up a production facility in Canada because a British contract required that the Link Trainers be manufactured in the British Commonwealth. Link's company expanded to other forms of aviation training. In 1939, with a contract from the British military, the company developed the Celestial Navigation Trainer, used to train aircraft navigators. In December, 1941, when the United States entered World War II, there was an immediate effort to produce military aircraft and to train pilots. Link's company, now called Link Aviation Devices, Inc., expanded rapidly.

The end of World War II resulted in cuts to the military budget and cancellation of orders for flight trainers. Link had anticipated this problem and established a marine division of his company that built boats and canoes for the newly emerging recreation market. In the early 1950's, the expansion of commercial airline activity around the world created a new demand for flight trainers, and the outbreak of the Korean War increased the military demand, so Link's company prospered.

Link sold his company to General Precision Equipment Corporation in 1954 and retired to pursue sailing and underwater exploration, particularly underwater archaeology. Documents showed that wrecks from the "Spanish treasure fleet," ships that carried gold, silver, and gems collected by the Spanish armies from the Americas, were undiscovered along the Florida Keys and eastern coast. Finding the wrecks and recovering their treasure posed new engineering challenges.

Link bought a shrimp trawler in May, 1952, and converted it into an expedition ship, which he named the *Sea Diver*. Link began organizing expeditions to find the treasures, ultimately developing systematic search and archaeological exploration procedures and inventing complex machinery to assist the divers. Link designed the *Reef Diver*, a shallow draft search boat; an airlift, a device that carefully moved sand away from the wrecks; and a magnetometer that was towed behind a boat to search for metal on the ocean floor.

Link and his wife spent the summer of 1955 searching for the wreck of the *Santa María*—the ship Christopher Columbus lost on his voyage to the Americas—off the coast of Haiti. They found an anchor that dated from the correct era but could not determine whether it came from the *Santa María*. They found no sign of the ship itself. Later that summer, the couple visited the Bahamas, trying to trace the route Columbus sailed to the New World. Using translations from Columbus's journal and his own on-scene exploration, Link suspected that Columbus landed first on the Caicos Islands, then the Bahamas, and eventually Cuba. He described his idea in "A New Theory on Columbus's Voyage Through the Bahamas," which was published in 1958 by the Smithsonian Institution.

Link ended his retirement in 1957, assuming the presidency of General Precision Equipment Corporation, a position he held for two years. During that period, he developed the submersible decompression chamber, a combination diving bell and decompression chamber that allowed divers to work in deep water. With Link's device, the air pressure and gases could be controlled to prevent nitrogen narcosis, an illness caused by the absorption of too much nitrogen in the body. He also had a new ship built—the *Sea Diver II*, designed and equipped for archaeological research.

Link headed a group of civilian specialists assisting the U.S. Navy in the search for the nuclear submarine *Thresher*, which sank in April, 1963. In 1965, he designed a submersible exploration vehicle with a special compartment, based on his submersible decompression chamber, for divers. The *Sea Diver*, launched in January, 1966, and later renamed *Deep Diver*, allowed researchers to view marine life in its natural environment at depths up to 1,250 feet. His later design, the *Johnson-Sea-Link*, weighed eighteen thousand pounds and could operate to a depth of 3,000 feet, letting divers out down to 1,500 feet.

Link's son Clayton and another diver, Albert Stover, died during a routine dive when the *Johnson-Sea-Link* became tangled in the wreckage of a destroyer sunk off the Florida coast. This personal tragedy resulted in Link's effort to develop the Cabled Observation and Rescue Device (CORD). Link died on September 7, 1981. A few days before he passed away, the city of Binghamton renamed its airport Edwin A. Link Field.

Impact

During his career, Link patented more than two dozen inventions, mostly for flight training or deep-sea exploration. The Link Trainer decreased the cost and increased the safety of pilot training. By 1940, Link Trainers had been sold to more than thirty-five countries. During World War II, Link Trainers became standard training equipment at all pilot-training facilities in the United States. More than ten thousand trainers were delivered, and more than 500,000 military pilots were trained in them.

When Link's interest turned to undersea exploration, his inventions had a similar impact. Link's submersible decompression chamber became a major part of his Man-in-Sea project, funded by the National Geographic Society, to permit divers to work for sustained periods at ocean depths up to one thousand feet. This joint effort with the French undersea pioneer Jacques Cousteau used Link's submersible decompression chamber as the transport to and from an underwater home designed by Cousteau. Link's submersible decompression chamber and later his submersible exploration vehicle allowed the divers to adapt to the pressure during the descent and to begin decompression as soon as they returned to the vehicle, saving valuable time for undersea activities.

Hans Lippershey

Dutch spectacle maker

Lippershey was the first person with good documentary evidence for his discovery of what later came to be called the refracting telescope. He made several monocular and binocular telescopes for the Dutch government and military.

Born: c. 1570; Wesel, Westphalia (now in Germany)
Died: September, 1619; Middelburg, Zeeland, United Provinces (now in the Netherlands)
Also known as: Hans *or* Jan Lippersheim
Primary fields: Military technology and weaponry; optics
Primary invention: Refracting telescope

Early Life

Hans Lippershey (hahnz LIHP-pur-shay) was born in Wesel, a small town in present-day western Germany, only sixteen miles south of the border of the United Provinces (now in the Netherlands). Uncertainty exists about the date of his birth, though most sources give 1570 as the year. He probably received little formal schooling, since the astronomer Christiaan Huygens later described him as an "illiterate mechanick." Religious conflict between Roman Catholics and Protestants may have played a role in the family's move to Zeeland in the southwestern United Provinces, since many Protestants fled across the border after the Spanish forces took Antwerp in 1585. The Lippersheys settled in Middelburg, the capital of Zeeland, which had become a flourishing city as a result of the many Protestant artisans who founded businesses there. Italians introduced new glassmaking techniques to Zeeland in the 1590's, and the making of spectacles became a profitable trade.

It is likely that the adolescent Hans was apprenticed to a master lens maker for the usual period of seven years. In later documents, he is described as "pious and God-fearing," and this religiosity and his accomplishments

Hans Lippershey. (Library of Congress)

as a lens maker indicate that he must have been a dutiful apprentice. If he followed the traditional course of the apprenticeship system, he must have become a journeyman and saved enough money to go into business in Middelburg as a maker of spectacles. He felt secure enough financially to marry in 1594. Middelburg proved to be an excellent location for Lippershey's business. The city had the only glass factory in Zeeland, and high-quality Venetian glass often was shipped there. Because of his skills as an artisan and because of his commercial good sense, his business prospered, and he became a Dutch citizen in 1602.

Life's Work

As a master lens maker and spectacles maker, Lippershey was able to take on apprentices and hire journeymen, both of whom aided in the expansion of his business. He might have remained an instance of those artisans who performed valuable services in their communities but who did nothing that would be noted by historians. However, historians have credited him with the discovery of the telescope, and this has raised many questions: Was he the first? Did he do it alone or with others? Was his discovery accidental or planned? Because of the paucity of evidence, stories have gathered about this pivotal discovery. In one story, which has several variants, in 1608 two children were playing with glass lenses that had been shaped and polished for use in Lippershey's shop (some accounts state that they were his own children, others that it was a single apprentice, and still others that it was Lippershey alone). When one of the children (or an apprentice) held one lens close to an eye and the other at arm's length, and then looked through them, a distant church steeple appeared nearer and larger. The child or apprentice showed this phenomenon to Lippershey, either immediately or when he returned to his shop. After verifying this finding for himself, Lippershey quickly grasped its importance.

Having ascertained the best distance between the lenses for a focused image, he preserved this orientation in a metal or wooden tube, thus creating what would later be called a telescope. Lippershey named it a *kijker* (Dutch for "looker"), but other terms later proliferated, including "optic tube," "perspective glass," and "Dutch trunk." ("Telescope" was coined by the Greek scientist Giovanni Demisiani.) Varied accounts also exist about what lenses were actually in Lippershey's tube. Some interpreters state that both the ocular lens (near the eye) and the objective lens (near the object) were convex—that is, thicker in the middle than at the edges, in which case the image would be upside down. The more common interpretation is that the ocular lens was a short-focal-length concave lens and the objective was a long-focal-length convex lens, in which case the observed image would have been right side up. Whatever the details of his discovery and the design of his device, Lippershey, an astute businessman, recognized its potential military and commercial (though not astronomical) applications. Holland was at war, while it was also extending its trade throughout Europe and even to the Far East, so generals and captains would certainly find Lippershey's "looker" advantageous in their endeavors.

The first clear documentary evidence for the invention of a telescope was a letter, dated September 25, 1608, in which Zeeland's Committee of Councilors, in writing to their delegation at the states-general in The Hague, stated that this letter's "bearer" (Lippershey) claimed to have invented a device by which things at a distance appear as if they were nearby. A week later, Lippershey applied for a thirty-year patent or a pension for his invention. He demonstrated his device to Prince Maurice of Nassau, the stadtholder of the states-general and the commander in chief of the Dutch armed forces. Within a short time, other claimants appeared, stating that they had already invented this device or made superior models. Although Dutch officials wanted to keep this invention secret, and enjoined Lippershey to do so while he worked on a binocular version of his device, knowledge of his discovery spread rapidly, not only through the Low Countries but also to France, Germany, and Italy.

The states-general formed a committee to study Lippershey's (and others') claims, and Lippershey was requested to construct binocular versions of his device, for which he was paid three hundred guilders on October 4, with a stipulation of further payment of six hundred guilders when he completed his task. On December 11, Lippershey delivered the first of his binocular telescopes, with lenses made of rock crystal instead of glass. Committee members inspected and tested the device and found it satisfactory. Four days later, Lippershey received a payment of three hundred guilders, with the promise of another three-hundred-guilder installment when he produced two other binocular telescopes. To his disappointment, he also learned that his patent had been denied because others had shown that they had knowledge of the invention. Nevertheless, he completed his task, received his final payment, and returned to Middelburg.

In the years following his discovery, Lippershey experimented with improved lenses, the spacing of the lenses within the tube, and tube lengths. He was able to interest the Dutch army and navy in these instruments because they allowed enemy combatants to be seen before the enemy was able to see the Dutch forces. Lippershey lived for more than a decade after his discovery of the telescope, and he must have received information on its diffusion throughout

Who Discovered the Telescope?

The idea of the telescope long antedates its realization. Archeologists have found lenses from 2,000 b.c.e., and ancient Greeks and Romans knew of the magnifying power of certain lenses—though for near, not distant, objects. Spectacles were a medieval invention, and in the thirteenth century Roger Bacon, an English Franciscan friar, wrote extensively on the optical properties of lenses and mirrors, and he may have combined lenses to enlarge distant objects. During the sixteenth century, the number of persons who may have developed telescopic devices increased. For example, Thomas Digges claimed that his father had used "angled glasses" to see far-off things. In his writings on optics, the English mathematician William Bourne reported how certain ground lenses gave distant objects the appearance of a "marvellous bigness." In a work published in 1589, the Italian philosopher Giambattista della Porta wrote that a combination of convex and concave lenses would permit the observer to see distant objects larger than they would otherwise appear. However, scholars have pointed out that none of these early claims resulted in concrete instruments that were tested and then influenced the course of developments.

Because of this lack of instruments or unambiguous documentary evidence, most scholars assign the telescope's origin to Hans Lippershey in 1608, since he actually made telescopes, and documents exist to support his claims. However, counterclaims appeared soon after Lippershey's application for a patent. For example, an instrument maker from Alkmaar, Jacob Adriaanzoon, more commonly known as Jacob (or James) Metius, petitioned the states-general for a patent, but he was never able to produce his device. Zacharias Janssen, who lived in Lippershey's city of Middelburg, was later brought into the controversy over the telescope's origin by his son and daughter. After Janssen's death, his son claimed that Janssen had invented the telescope, but estimates of the father's birth date make the son's claim unlikely. In fact, the daughter believed that her father had invented the telescope in 1611, years after Lippershey's documented invention. Galileo is also sometimes stated to be the inventor of the telescope, but he always denied this appellation, reserving that honor for Lippershey.

Because it is relatively easy to combine lenses into a telescope, people before Lippershey may well have used two lenses to magnify distant objects, but since documentation does not exist to verify this, these claims have been largely dismissed. The certitude that does exist over Newton's invention of the reflecting telescope will never exist for Lippershey's invention of the refracting telescope, but Lippershey's is the telescope that historical evidence shows was the start of this instrument's evolution, and so scholars continue to trace its origin to Lippershey.

Europe. Since he was illiterate, he could not have read Galileo's *Sidereus nuncius* (starry messenger) when it was published in 1610, but he may have heard from others about Galileo's wonderful astronomical discoveries, when the Italian astronomer turned his telescope to the heavens. After February 13, 1609, when documentary evidence states that Lippershey fulfilled his agreement on binocular telescopes, nothing certain is known about his life, until the notice of his burial in Middelburg on September 29, 1619.

IMPACT

Although no instrument has had a greater influence on astronomy than the telescope, Lippershey thought that his invention would be important for armies and navies, and, indeed, military personnel did use telescopes for the surveillance of enemy forces. However, most historians of science date the start of modern astronomy to 1609, when Galileo used his telescope, based on Lippershey's conception, to resolve the Milky Way into its thousands of stars, to observe the craters and mountains on the Moon, and to discover four satellites of Jupiter (now called Galilean moons). He later discovered telescopically that Venus, like the Moon, passes through phases and that the Sun has black spots on its surface. In his book on these discoveries, *Sidereus nuncius*, Galileo mentioned that he learned of Lippershey's invention through correspondence with a French scientist.

Lippershey's invention of the refracting telescope was important during the early history of astronomy, but this telescope's unfortunate tendency toward spherical and chromatic aberration meant that images were often fuzzy and distorted. Isaac Newton's invention of the reflecting telescope mitigated these problems, and during the eighteenth, nineteenth, and twentieth centuries reflecting telescopes were the prime conduit for astronomical observations and discoveries. For example, Edwin Hubble in the twentieth century was able to use the hundred-inch reflecting telescope on Mount Wilson in California to resolve galaxies into individual stars. The Hubble Space Telescope, named in his honor, has continued the long and fruitful history of the telescope by discovering distant galaxies and other wonders that bring us close to the origins of the universe. Earlier telescopes had mapped the crater on the Moon and discovered the asteroid that have been named in Lippershey's honor.

Gabriel Lippmann

French physicist

Lippmann is best known for the innovation that won him the 1908 Nobel Prize in Physics: a revolutionary color-photography process based on the interference phenomenon. His other inventions include the capillary electrometer and the coelostat.

Born: August 16, 1845; Hollerich, Luxembourg
Died: July 13, 1921; At sea, en route to France from Canada
Also known as: Gabriel Jonas Lippmann (full name)
Primary fields: Astronomy; photography; physics
Primary invention: Color photography plate (Lippman plate)

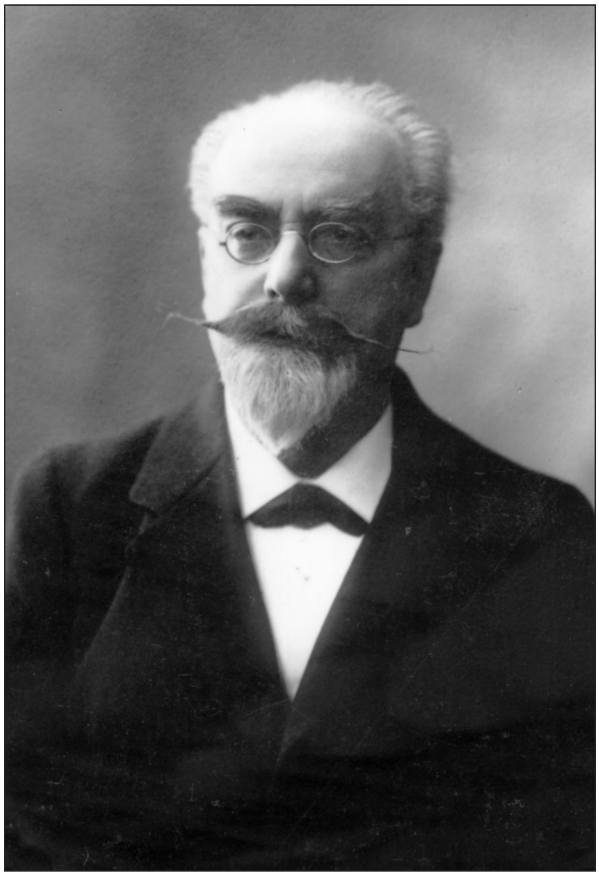
Early Life

Gabriel Jonas Lippmann (gah-bree-ehl joh-nahs lihp-mahn) was born in 1845 in Hollerich, Luxembourg, to French parents. His mother was from Alsace, and his father, who ran a tannery and glove factory, hailed from Lorraine. When Lippmann was a small boy, his parents moved the family to France and settled in Paris. He received his early education at home from his mother. In 1858, the thirteen-year-old Lippmann began studies at the Lycée Napoléon. He continued his studies at the École Normale, which he entered a decade later. While highly intelligent, Lippmann did not excel at school, as he focused only on the subjects that piqued his interest. When he took the government qualifying examination to become a teacher, he failed it.

While at the École Normale, he summarized articles originally written in German for the French chemistry and physics publication *Annales de Chimie et de Physique*. His translation work kept him abreast of the latest experimental work in electricity. Because of his linguistic skill and scientific knowledge, the French government appointed him to travel to Germany in 1873 as part of a mission to study methods of teaching science. In Heidelberg, Lippmann worked in the laboratory of physicist Gustav Kirchhoff, who was known for his research into electrical circuits, spectroscopy, and black-body radiation. There, Lippmann also worked with physiologist Wilhelm Kühne, who introduced him to an experiment in which a drop of mercury coated with sulfuric acid contracted when it was touched with an iron wire and recovered its original shape when the wire was removed. In 1874, the University of Heidelberg awarded Lippmann a doctorate in philosophy. While in Germany, Lippmann did additional work with Hermann von Helmholtz, a physics professor conducting research in electromagnetism at the University of Berlin.

Life's Work

During his time abroad, Lippmann experimented with the mercury phenomenon Kühne had shown him. Lippman theorized that the observed behavior was the result of a connection between electric polarization and surface tension. From his research, he created a capillary electrometer. This exceptionally sensitive instrument, capable of detecting differences in electrical potential as small as one one-thousandth of a volt, measured potential using changes in the surface tension between mercury and dilute sulfuric acid within a small-diameter tube. In 1875, the Sorbonne in Paris awarded him a doctorate for his work. The following year, Lippmann pub-



Gabriel Lippmann. (©The Nobel Foundation)

Color Photography

Gabriel Lippmann based his color photography method on the phenomenon of interference. Interference colors are produced when light waves combine to intensify one another or cancel one another out. The colors seen in soap bubbles, peacock feathers, butterfly wings, mother-of-pearl, and oil slicks on wet roads are all produced by interference.

Lippmann's method involved coating a glass plate with a fine-grain, light-sensitive emulsion. The plate was placed emulsion side down in a holder that contained a layer of mercury, and the holder was introduced into a camera with the emulsion side facing away from the lens. The mercury that was in contact with the emulsion acted as a liquid mirror. Light waves that entered the camera through the lens were reflected back on themselves by this mirror. Interference between the oncoming and reflected light waves created standing waves in the emulsion, and the emulsion formed a recording of the standing wave pattern in thin layers of silver. After the plate was processed, it was viewed in white light. The layers of silver reflected the light, with every point on the plate selectively reflecting the color that was imprinted on it during exposure.

Lippmann's breakthrough, Nobel-winning process produced permanent, true-color images; there were no dyes or pigments to fade over time, and the color seen in the image was the actual spectral color of the subject photographed. However, while Lippmann photographs were beautiful and lasting, his method was too problematic for it to retain a foothold as a commercially viable process. Only a high-quality, very fine grain emulsion would work, but the fine grain meant long exposure times of several minutes, or even hours. The final image could not be copied, and it had to be viewed at the correct angle and under proper lighting conditions.

Nevertheless, the method intrigued other researchers in the field. Between 1891 and 1910, the Lumière brothers, Hans Lehmann, and others experimented with the process, making their own refinements. The Lumières cut exposure time down to a minute with their use of a very fine grain silver-halide gelatin emulsion; this became the standard emulsion for Lippmann photography. Later, Lehmann perfected an emulsion upon which the producers of commercial Lippmann plates based their formulas.

While Lippmann photography could not gain ascendancy as a commercial method, researchers and hobbyists continued to explore and refine it. To date, it remains the only method for correctly imaging spectra. The fact that Lippmann images cannot be reproduced may have security applications, and their long-term stability may make them useful for archiving purposes. The process has been of special interest to those working in holography, as both holograms and Lippmann photographs involve encoding an image using interference, recording the interference structure on a photographic plate, and reconstructing the image through the diffraction of light. High-resolution panchromatic recording materials commercially available for holography have been adopted for modern Lippmann photography.

Lippmann's color photographs are housed at the Musée de l'Elysée in Lausanne, France.

lished his findings that the phenomenon worked in reverse: Mechanically altering a drop of mercury coated in sulfuric acid affected the electrical charge between the two liquids.

In 1878, Lippmann joined the Faculté des Sciences, a laboratory in Paris. There, he became professor of mathematical physics in 1883. In 1886, the year he was admitted as a member of France's prestigious Académie des Sciences, he became professor of experimental physics at the Faculté. He was subsequently appointed director of the laboratory, a position he held for the rest of his life. As director, he oversaw the transfer of the Faculté des Sciences when it became incorporated into the Sorbonne.

In 1891, in a short communication to the Académie des Sciences, Lippmann presented his process for the photographic reproduction of color based on the phenomenon of interference. He had developed the theory of the process as early as 1886 but had struggled with successful execution for years. He was still working to resolve problems with the photographic film's variable sensitivity to different parts of the spectrum. In 1893, he was able to show the Académie photographs taken by Auguste and Louis Lumière that reproduced natural color using Lippmann's method. In 1894, he published his complete theory.

In 1895, Lippmann made a valuable contribution to astronomy with the invention of the coelostat, a device used in photographing stars. At the time, instruments called siderostats were commonly employed to keep the image of a single star stationary despite the movement of the star itself; however, images of surrounding stars would rotate around a single point. Lippmann's coelostat, which involved the use of a mirror and a machine that reproduced the Earth's rotation, held the image of an entire area of sky immobile long enough for photographic exposure. Lippmann also invented a related device, the uranograph, which produced a photographic sky map with longitudes automatically printed on it.

Also in 1895, Lippmann proposed a method to eliminate the personal equation (an individual's observational bias) in measuring time through photographic registration (the creation of visual records on rotating rolls of photographic paper). Two years later, he published on the use of the stroboscopic method to compare the oscillations of two pendulums. In 1901, he wrote of a new form of galvanometer (an instrument for measuring the intensity of an electric current). Lippmann would later write on another field, seismology. He proposed the use of telegraphy to detect and measure earthquakes, and he devised a new form of seismograph that would measure acceleration.

In 1908, Lippmann was elected as a Foreign Member of the Royal Society of London. That same year, he was awarded the Nobel Prize in Physics for his method of reproducing colors in photography based on the interference phenomenon. In 1912, he was elected president of the Académie des Sciences. Other organizations with which he was associated during his career include France's Institut d'Optique Théorique et Appliquée, of which he was a founding member, the Bureau des Longitudes, and the Grand Ducal Institute.

In the summer of 1921, Lippmann and his wife (novelist Victor Cherbuliez's daughter, whom he married in 1888) visited North America. Lippmann made the trip as a member of an official commission traveling to Canada to express France's gratitude for aid during World War I. On the return trip to Europe aboard the steamer *France*, Lippmann died at sea. He was seventy-five.

Impact

Lippmann is most often remembered as the Nobel Prize winner who invented interference color photography. Yet his accomplishments extended far beyond a single discipline or intellectual pursuit. During his career of almost half a century, the physicist made significant contributions to nineteenth century studies of electricity, thermodynamics, optics, astronomy, seismology, photochemistry, and more—as a theoretician, an academician, and an inventor.

One of Lippmann's earliest inventions played a vital part in the first recordings of the electrical activity of the heart. In 1876, French researcher E. J. Marey employed the Lippmann capillary electrometer in measuring electrical variations in the exposed muscles and heart of a frog. British physiologist Augustus Desiré Waller used the instrument in 1887 to record the first human electrocardiogram. An 1889 demonstration that Waller conducted influenced Dutch physiologist Willem Einthoven, who went on to conduct groundbreaking electrocardiogram research of his own. These early experiments, made possible by Lippmann's invention, are the forerunners of modern electrocardiography.

Lippmann influenced the scientific world not only through his own work but also through that of the students whom he taught and mentored. Notable among these are Pierre Curie, whose doctoral thesis Lippmann approved, and Marie Sklodowska, who did her thesis work in Lippmann's laboratory and reported to him as an advisee. In 1898, after she had become Marie Curie, her first paper before the Académie des Sciences was delivered on her behalf by Lippmann.

M. Stanley Livingston

American nuclear physicist

Livingston, working with Ernest Orlando Lawrence, built the world's first cyclotron for the study of the atomic nucleus. Later, he designed and built many other particle accelerators that made possible the modern very high-energy accelerators used in nuclear research.

Born: May 25, 1905; Broadhead, Wisconsin
Died: August 25, 1986; Santa Fe, New Mexico
Also known as: Milton Stanley Livingston (full name)
Primary field: Physics
Primary invention: Cyclotron

Early Life

Milton Stanley Livingston was born in Broadhead, Wisconsin, on May 25, 1905, to Milton McWhorter Livingston and his wife, Sarah Jane. His father was a divinity student who later became pastor of the local church. The church paid so little that Livingston's father decided to take a job as a schoolteacher in Southern California, where the family bought a ten-acre orange grove and ranch. As the only son, Stanley Livingston did most of the ranch chores. Through his work with the farm machinery and automobile engines, he became very interested in machines and technology and became expert in their uses and operations.

After graduating from high school, Livingston entered Pomona College in Claremont, California, to study chemistry, but later he switched to physics. He graduated from Pomona in 1926 and then went on to Dartmouth College, where he obtained his master's degree. After a further year at Dartmouth as an instructor, he moved to the University of California at Berkeley to study for a Ph.D.

At Berkeley, Livingston became interested in nuclear physics and asked a young physics professor, Ernest Orlando Lawrence, for a thesis project. Lawrence suggested that Livingston build a new type of cyclical charged particle accelerator for nuclear research. Livingston built the hardware for this new machine, now called a cyclotron, and showed that it could accelerate hydrogen ions. He obtained his Ph.D. in 1931 after producing a thesis titled "Acceleration of Particles to High Energies Without the Use of High Voltage."

Life's Work

The first proton accelerator for nuclear research was built in Cambridge, England, in 1930 by John Douglas Cockcroft and Ernest Thomas Sinton Walton. They built an electrostatic machine that was able to accelerate protons to 500,000 electronvolts, but the device was limited by the breakdown of the voltage on the high-voltage electrode, creating huge sparks to ground. Ernest Lawrence saw that, to obtain higher energies, one could build a cyclical accelerator by putting the charged particles between the poles of a magnet, making them turn in circles. Then a hollow electrode driven by an oscillating voltage in resonance with the circular motion of the particles would add energy each time the particles passed through the electrode.

Livingston built the first accelerator to apply this principle, using a hollow D-shaped electrode in a vacuum chamber that fit between the poles of a magnet. With an oscillating voltage of only 1,000 volts, the machine accelerated protons to energies of 80,000 electronvolts. Lawrence was impressed by Livingston's work on the accelerator and offered him an instructorship so that he could stay on at Berkeley to continue the development of cyclotrons. Livingston, who was recently married, readily accepted the offer and began work on a new machine with an eleven-inch magnet. After overcoming severe focusing problems that drove the charged particles into the magnet, he obtained a focused beam of just over one million electronvolts (MeV) in January, 1932. In the next two years, Livingston authored or coauthored more than a dozen papers on the cyclotron and its application to nuclear physics.

After four years in Berkeley, Livingston decided it was time to move on. He felt that his contributions were overshadowed by Lawrence, and he needed to be more independent. He saw an opportunity at Cornell University to work with two well-known physicists, Hans Albrecht Bethe and Robert Bacher, to establish a major research program in nuclear physics. At Cornell, Livingston built a two MeV cyclotron that was the first cyclotron constructed outside Berkeley. In 1936-1937, Bethe, Bacher, and Livingston published a three-part series in the journal *Reviews of Modern Physics* that constituted the most significant review of what was then known of nuclear physics.

In 1938, Livingston moved to the Massachusetts Institute of Technology (MIT) to build a cyclotron for nuclear and medical research. The cyclotron was finished by 1940, and Livingston, finding that he enjoyed teaching and research, stayed on at MIT to use the cyclotron to produce radioactive isotopes for medical use as part of the U.S. effort in World War II. In 1944 he took a leave of absence to go to Washington, D.C., to work with the Navy Department on radar countermeasures for submarines.

After the war, Livingston went back to his position at MIT, but in 1948 he was asked to take another temporary leave to build a large accelerator for the new Brookhaven National Laboratory. The cyclotron had given way to the synchrotron, which uses a ring of magnets (in place of the solid round cyclotron magnets) and magnetic fields and accelerating voltages that vary to counteract relativistic effects. Livingston saw that with this synchrotron idea, he could design a machine for energies above one billion electronvolts. He helped design the accelerator for Brookhaven, but he had to return to MIT before it was completed. The Brookhaven synchrotron, known as the Cosmotron, reached its full design energy in January, 1953: 3.3 gigaelectronvolts (GeV).

Still higher energies were needed to study the fundamental particles within the atomic nucleus, and this would take a huge increase in magnet size and cost because of the defocusing of the beam that had been found with the Cosmotron. After reviewing the Cosmotron magnet design, Livingston suggested that if the gradients in the magnet fields around the ring were alternated, some gradients facing in and others out, the beam would be focused both vertically and horizontally. Cornell, Brookhaven, and the European Nuclear Research Center all built successful proton synchrotrons of about 30 GeV, proving the alternating-gradient principle.

In 1962, Livingston designed, for Harvard and MIT, an alternating-gradient electron synchrotron that accelerated electrons to 6 GeV. This synchrotron, the Cambridge Electron Accelerator, held the record for high-energy electrons until the Stanford Linear Accelerator was built four years later.

Designing the Cyclotron

In 1930, M. Stanley Livingston built the world's first cyclotron at the University of California, Berkeley, under the direction of Ernest Orlando Lawrence. The beam of charged particles was initially too unfocused to be useful, but Livingston solved this problem by removing grids that Lawrence had thought necessary and adding shims to the magnet. He obtained a focused beam of hydrogen ions in 1931 and began using the cyclotron for nuclear research in 1932.

Livingston became expert in designing and building particle accelerators and in solving their problems. In 1948, he designed the magnets for what was then the largest accelerator to be built, the Brookhaven Cosmotron. His design, following the experience with cyclotrons, reduced the magnetic fields outward from the center of the ring for a stable orbit. These gradients kept the beam centered between the poles of the magnets, but they also caused defocusing in the horizontal direction. Livingston saw that at the energies needed to probe deeper into the atomic nucleus, the defocusing of the beam would become extremely large, and the weight and cost of the magnets needed to confine the beam would became exorbitant. He suggested that if alternating sectors of the magnets in the ring had the magnetic gradients reversed, the result would be focusing in both vertical and horizontal directions. Calculations by the theoretician Ernest Courant found that the scheme worked even better than Livingston had estimated. Both horizontal and vertical focusing were improved at all energies.

Livingston found that if the alternating-gradient sectors were spaced evenly around the ring of the accelerator, the beam would oscillate around the central orbit. If the magnetic gradients were made stronger and the sectors were spaced more closely, the size of the oscillations would be reduced, and a tighter beam could be obtained. The size of the apertures in the magnets could then be reduced, resulting in a large reduction in the size of the magnets and thus a reduction in cost. This was a revolution in accelerator design. In an alternating-gradient machine ten times the energy of a conventional weak-focusing accelerator such as the Cosmotron, only twice the amount of iron would be needed for the magnets. In larger rings of alternating-gradient magnets, higher energies could be attained without limit. All high-energy accelerators now use alternating-gradient focusing.

In 1966, the U.S. Department of Energy decided to build a national accelerator laboratory outside Chicago. Livingston was recruited to be an associate director to help set up the Fermi National Accelerator Laboratory (known as Fermilab) and to design a 200 GeV proton synchrotron. The machine was completed successfully after Livingston's retirement from the lab, and its energy has been continually upgraded since that time. It became the highest-energy proton accelerator in the world.

Livingston retired from Fermilab in 1970, and he and his wife Lois moved to Santa Fe, New Mexico, where they built an adobe house that they designed themselves. In retirement, Livingston consulted occasionally for the Los Alamos Scientific Laboratory and became increasingly involved in promoting international scientific cooperation through the Federation of American Scientists. He received many honors during his career, including election to the National Academy of Sciences in 1970. He was a recipient of the U.S. Department of Energy's Enrico Fermi Award in 1986, but after an unsuccessful operation for cancer, he died on the day the award was to be presented to him.

Impact

The inventions of the cyclotron and the alternating-gradient synchrotron had revolutionary impacts on modern science and medicine. Livingston became the world's expert in designing and building high-energy charged particle accelerators, and from his first project, building the pioneering cyclotron with Ernest Lawrence, he systematically added improvements and built higher-energy machines.

The first cyclotrons were built for research on the atomic nucleus, but these devices came to be used for many other purposes as well. The more than two hundred cyclotrons in use worldwide are employed in atomic and solid-state research, in studies of radiation damage, and in the radiocarbon dating of archaeological materials. In the field of medicine, cyclotrons are used for the production of radioactive isotopes for imaging and diagnosing cancers as well as for the direct treatment of cancer by radiation.

In high-energy physics research, Livingston's invention of alternating-gradient focusing and the accelerators that were designed and built using this principle have been the main tools used by scientists seeking to understand the atomic nucleus and the subnuclear particles within it. Without these accelerators, little would be known of the primary building blocks of the universe, the quarks and nuclear forces.

Lawrence and Livingston's pioneering work with particle accelerators opened the era of big science. Prior to their work, nuclear research was tabletop science carried out by a few people using naturally occurring radioactive sources. The huge accelerators that have been built since Livingston's work began are staffed by hundreds of people and are used by experimenters from around the world.

Auguste and Louis Lumière

French photographers and filmmakers

Auguste and Louis Lumière invented the cinématographe, a portable camera that also printed and projected films; established several film conventions; and by charging admission for their screenings effectively began the motion-picture business.

Auguste Lumière

Born: October 19, 1862; Besançon, France
Died: April 10, 1954; Lyon, France
Also known as: Auguste Marie Louis Lumière (full name)

Louis Lumière

Born: October 5, 1864; Besançon, France
Died: June 6, 1948; Bandol, France
Also known as: Louise Jean Lumière (full name)
Primary field: Photography
Primary invention: Cinématographe motion-picture camera

Early Lives

Auguste Marie Louis and Louis Jean Lumière (loo-myehr) were the sons of Antoine Lumière, a sign painter who progressed to painting portraits and then to producing photographic supplies. His two sons attended La Martinière, Lyon's largest technical school, and they went to work for their father while they were still in their teens. In 1881, when he was only seventeen, Louis, the more creative of the brothers, produced a high-quality photographic plate that became so popular that it enabled him to build his own factory to manufacture the plates. His was the second-largest photographic company in the world; only Eastman Kodak was larger.

Lives' Work

Although the Lumières are credited with inventing the motion-picture camera, their invention built upon the work of many other inventors. Ever since the first photograph was taken in 1826 by another Frenchman, Nicéphore Niépce, inventors tried to find ways to show pictures in motion. Eadweard Muybridge was one of the first, and his photographs of horses in motion provide a milestone in film history. Étienne-Jules Marey's chronophotograph was another step, as was the camera invented by Louis Le Prince, whose invention was a forerunner of the Lumières' camera. However, before Le Prince could market his camera, he mysteriously disappeared. Thomas Alva Edison, who had invented the phonograph, and William Dickson, one of his employees, invented the first movie camera and the first projector.

Hoping to capitalize on the success of their popular and profitable kinetoscope, Edison and his firm took their product to Paris, where Antoine Lumière saw a demonstration. He told his sons that a fortune could be made if they could devise a less bulky and improved movie camera. Auguste tried but was unsuccessful. After several attempts, Louis was successful, and the cinématographe was born. The camera, which also served as the printer and projector, was smaller than Edison's massive kinetograph so that it was portable enough to be carried to any place the brothers wanted to shoot a film.

Auguste (left) and Louis Lumière. (Time & Life Pictures/Getty Images)

The Cinématographe

According to film historians, Louis Lumière, who was an insomniac, got the idea for the cinématographe one sleepless night when he was pondering how to make the film in a camera advance. The operation of the sewing machine provided him with a model. The sewing machine holds the fabric still while the needle and thread make a stitch, then advances the fabric and holds it while the next stitch is made. In like manner, the shutter of a still camera opens, admitting light onto the film behind the lens, then closes to prevent additional light from overexposing the film. The problem of how to advance the film for successive images was solved by putting perforations on the edges of the film and by having claws or gears engage the perforations. After the film moved, the claws released, holding the film still for the next shot. After the shutter closed, the claws reengaged the film, moving it forward and then releasing it for the next shot. The shots or frames were separated by black bands that occurred because of the lack of light. When the film was played, the frames appeared in quick succession, so quickly that the human eye could not distinguish between the individual frames and perceived the slight differences as motion. The stop-and-go sequence, or intermittent motion, remains one of the basic principles of cinematography. Auguste and Louis Lumière used the negatives to print a film, which consisted of images interspersed with black bands.

The same camera could also be used to project the film, a real advantage over Thomas Alva Edison's kinetoscope, which required an additional projector and provided a film that could only be used by one person at a time. Intermittent motion was also used in projecting the brothers' films. They had a light source behind the projector lens. As a frame appeared in front of the projector lens, it was held for a moment while the shutter opened, then closed as the film advanced to the next frame, when the shutter would open again. The opening and shutting occurred at the rate of sixteen times per second, just as the film had been shot at sixteen frames per second. The light, which went on and off as the images and bands alternated, produced a flickering effect. (Occasionally, people refer to films as "flickers" or, more frequently, as "flicks.") Technical improvements have since almost entirely eliminated the flickering. The brothers' motion-picture camera, which also could print and project film, represented the most important advance in film history because the projection of a film to paying audiences has made the motion-picture industry what it is today.

The other advantage the cinématographe had over the kinetoscope was that Edison's machine only allowed for one viewer at a time; the brothers' machine could be shown to an audience. They patented their machine on February 13, 1895, and only a month later shot their first film, *La Sortie des usines Lumière* (*Workers Leaving the Lumière Factory*).

Interested in marketing their machine, they took it to Paris, where they gave private screenings to members of the Society for the Encouragement of National Industry and to the French Photographic Society. The brothers quickly saw that they could benefit not only by selling their machines but also from holding public exhibitions and charging admission. Louis shot most of the films; Auguste, who was more of a manager, probably shot just one. Once they had shot ten films—including the factory film, *Le Repas de Bébé* (1895; *Feeding the Baby*), and *Le Jardinier* (1895; *The Gardener*), also known as *L'Arroseur Arrosé* (*The Waterer Watered*)—the first public showing (admission was one franc) occurred at the Grand Café, which Auguste had rented for the occasion. Although the first audience was small—some thirty-five people—word spread rapidly, and soon the brothers were taking in two thousand francs a week from multiple showings of the ten films. Lumière cameramen were recruited to shoot additional films all over the world. (Eventually, there were more than fourteen thousand films in the catalog they published in 1898. Fewer than fifty were shot by the brothers.) The films were home movies, travelogues, and "soft news," recording events such as floods or fires.

The Lumières' biggest market became the United States, but Edison's influence with the U.S. government caused legal problems for the brothers, and there were many other competitors as well. By the fall of 1897, Lumière cameramen had left the United States, and after 1900, the year the Lumières sold their movie rights to Pathé, the brothers were out of the movie exhibition business. In 1900, they did design a huge screen (99 by 79 feet) for the Universal Exhibition in Paris and screen some of their films. Three years later, they patented Autochrome Lumière, a kind of color film for still photography, and in 1907 they created the autochrome plate, the first practical color photography process, one that was used until the 1930's, when it was replaced by a subtractive color process. Louis was awarded the Progress Medal of the Royal Photographic Society in 1909 and stayed with the photography business, while Auguste turned his energies to biology and medicine. Auguste was a pioneer in the treatment of wounds and held more than one hundred patents, one of which was for the homonoid forceps. In 1915, he created tulle gras, a sterilized treatment bandage.

Impact

Although the Lumières' invention was certainly not the first movie camera, theirs was the first to become commercially viable, due to the fact that the brothers' company had the financial support to make the machines, to send crews around the world to make their films, and to screen the films (the same cameras shot and screened the films). The Lumières are regarded by most film historians as the fathers of the nonfiction film or the documentary, just as Thomas Edison is the father of the fiction film. Moreover, the Lumière films established the motion-picture camera as a still camera with an emphasis on composition and possessed a sense of a story line with beginning, middle, and end. Despite the rivalry between the Lumière and Edison filmmakers, the two companies did borrow from each other—the most celebrated case being Edison's *Washday Troubles* (1898), a takeoff of the Lumières' *L'Arroseur Arrosé*.

The success of the brothers' films made them the most important men in the film world. By making films all over the globe, they enabled their film patrons to "visit" places they could never visit. Their films also were the first to be screened in India, Japan, and other countries, and, of course, the Japanese and the Indians have become major players in the film industry. Gerald Mast and Bruce Kawin have called the Lumière brothers the "Johnny Appleseeds" of the film world. The practices and conventions they established became the standards for the industry: the film width at 35mm; the exposure rate of sixteen frames per second (speeded up for better sound only when the "talkies" were introduced), which Edison switched to; and the name of their machine, the cinématographe, which persists in the form of "the cinema" and "cinematography" (shooting the film).

JOHN LOUDON MCADAM

Scottish businessman

McAdam's method of road construction and maintenance vastly improved roads and highways at the start of the nineteenth century, facilitating the transport of both goods and people and making a decisive contribution to the Industrial Revolution.

Born: September 21, 1756; Ayr, Ayrshire, Scotland
Died: November 26, 1836; Moffat, Scotland
Primary field: Civil engineering
Primary invention: Macadamization

EARLY LIFE

John Loudon McAdam was born in Ayr, in southwest Scotland, on September 21, 1756, the second son and youngest of ten children of James McAdam, baron of Waterhead, and Susanna Cochrane, niece of the earl of Dundonald. Through his parents, young McAdam was connected to many of the leading Scottish families of his time and was considered a gentleman. He greatly valued this social standing in later life, as it imparted respect upon his somewhat modest occupation as a road surveyor. For much of his childhood, like many boys of his age, his winters were spent attending the parochial school in nearby Maybole and his summers were filled with explorations of the surrounding countryside.

Following his father's death in 1770, McAdam, at the age of fourteen, was sent to New York to the care of his uncle, William McAdam, a powerful merchant and Loyalist who had prospered in the New World. Uncle William first employed his nephew in his counting house, but soon the young McAdam went into business for himself. Despite his youth he accumulated a small fortune. In March, 1778, McAdam married Glorianna Nicoll, the daughter of a prominent and wealthy landowner whose family also was loyal to the British. Because McAdam had served in the British reserve forces during the American War of Independence, the victory of the colonies gave him no choice but to return to Scotland in 1783. He returned as a wealthy man and was accompanied by his wife and two children. The family would grow in the following years and settle in Ayrshire, where McAdam spent his childhood, on an estate purchased at Sauchrie in 1785.

Beginning in 1787, McAdam was a trustee of the Ayrshire turnpike roads system. In later life, he revealed that it was as a trustee that he was first exposed to the wasteful expenditure of public funds for maintaining the road system. He had soon determined to improve road construction, administration, and repair.

LIFE'S WORK

During his period at Sauchrie, McAdam again went into business, this time with his eccentric cousin, Archibald Cochrane, whose interest in extracting tar from coal led him to found the British Tar Company. Cochrane hoped to supply tar for the shipping industry, which needed the product to seal ships' hulls. McAdam held interests in local mills and iron works, became a plant manager, and ultimately bought the tar company. Several of his other business ventures went awry, however, and McAdam was almost ruined financially.

In 1798, McAdam sold his estate, settled with his creditors, and left Scotland for England. Settled in Bristol in 1801 with his family, McAdam began his first investigations into road construction and administration. He later claimed (in evidence presented to the British parliament in 1823) that between 1798 and 1814 he had traveled approximately thirty thousand miles in examining almost every major road in Britain. He inspected their condition and construction and questioned those who worked and traveled on the roads. (Because this project was conducted at his own expense, McAdam had sought some recompense from public funds.) By 1811, McAdam realized that the problem of road construction and maintenance was not about making vehicles adapt to roads but about making roads suitable for all vehicles. Furthermore, multiple laws regulated the manufacture of vehicles, but no laws regulated road construction and maintenance.

Although McAdam believed that road-makers and road-repairers were responsible for many of the failings of the roads system, largely from ignorance, he professed particular contempt for road surveyors. He was so adamant about change that in 1816 he become a surveyor himself. At the age of sixty, he became general surveyor of the Bristol roads system. His first goal was to eliminate corruption and waste (Bristol Turnpike Trust, the largest in the country, had debts of thousands of pounds) and restructure the workforce. McAdam mistrusted many of those then employed as surveyors, so he removed those he considered most incompetent and raised the salaries of those he retained.

Prior to McAdam's intervention, the typical method of repairing a road was to dump large stones on a road's surface to fill holes and ruts; it was believed that the weight of passing traffic would flatten the stones into some kind of consistent surface. McAdam, however, knew that these stones would not be forced together by a passing carriage wheel; instead, the stones would be displaced. McAdam's idea was to break the surface stones to a size smaller than the average vehicle wheel's width (typically about one inch). These smaller stones would consolidate to form a smooth, hard, and durable surface. The materials needed were already at hand, in the form of the oversized rocks of the previous repairs.

Soon, "macadamization," as McAdam's method became known, afforded better roads for less cost. Turnpike trusts in other areas were keen to implement the system. McAdam was consulted extensively and ultimately held seventeen other surveyorships from southwest England to Perthshire in the heart of Scotland. He often recommended his sons for these surveyor positions; eventually, eleven individuals from three generations of his family were employed in a similar capacity over subsequent decades. The family consultancy grew, and much of England, Wales, and Scotland would reap the benefits of improved roadways. The success of the McAdams was partly facilitated by powerful aristocratic patrons, many of whom were friends of the family. Nevertheless, McAdam encountered much resistance to change, professional jealousy, and even ridicule throughout his career.

The last years of McAdam's life were no less eventful than earlier decades. His wife died in 1825; he was remarried in 1827, to his wife's cousin, Anne De Lancey. They settled in Hoddeston, Hertfordshire, close to his friend, George Allen, whose factory made many of the implements used on the turnpike roads. McAdam remained active and engaged in the activities of the various trusts that retained his services. He spent the summers of these years in his native Scotland, returning south in late fall. He died on November 26, 1836, at Moffat in Ayrshire, following an illness.

Macadamization

John Loudon McAdam realized that small, suitably sized pieces of broken stone could form the base of a strong and durable roadway because so much natural friction and interlocking occurs between individual pieces of such stones. His roads consisted of a base eight to twelve inches thick, applied in two layers, and composed of angular, hand-broken stones no larger than three inches each. A third, surface layer comprised even smaller stones, no bigger than one inch, to a maximum depth of around two inches. All of this was laid on the natural formation, which was cambered and had side ditches for drainage. Ensuring that the ground was well drained was crucial. A properly maintained and drained road, McAdam asserted, could support any load: indeed, his roads could support over one hundred pounds per inch of tire width—around twice what his contemporaries could achieve.

McAdam's methods were not entirely new. Pierre-Marie-Jérôme Trésaguet in France and Thomas Telford in Britain had built many miles of roads on the basis of similar techniques, but they demanded small surface stones placed on a base of large, hand-crafted blocks. There is no suggestion that McAdam copied these earlier methods, but rather that he simply observed empirically that his system of smaller stones was the best and certainly the most cost-effective. Telford's roads, for example, were claimed to be more robust and durable than those of McAdam, but they also were far more expensive.

McAdam's method of road construction substantially advanced road transportation in Britain before the coming of the railway age. Indeed, the noun "macadam" and the verb "macadamize" had entered the British vocabulary by around 1825, as more and more miles of roadway were improved to his specifications. McAdam's reputation grew as both employers and the public saw the benefits of his system. Later, when fast-moving motor vehicles appeared, they produced large amounts of dust from such roads and ultimately could cause the surface stones to separate. An alternative means of surface binding using tar was developed, creating "tar-bound macadam" ("tarmacadam" or "tarmac"), very similar to modern asphalt surfaces. Although many roads have now been resurfaced with asphalt or concrete, McAdam's name and work survive today, and the word "tarmac" is still used to describe the paved area of airports.

Impact

McAdam, a key player in improving British highways, was instrumental to the dramatic advances of the Industrial Revolution. With the dawn of the Industrial Revolution in the late eighteenth century, it became increasingly evident that good transport routes were essential to the movement of raw materials and manufactured goods, as well as people and services. Most of Britain at the time was poorly served by the road network, and much of Scotland was effectively isolated by lack of infrastructure. With the new roads, journey times were dramatically reduced (often more than halved), increasing the flow of goods and services, including the mail, at a time when better communication was becoming vital to progress.

McAdam's system had both human and humane benefits. Although manual work on the roads was a despised form of labor, unemployment was high at the time. The labor-intensive breaking of stone required many workers, providing much-needed employment, particularly for the poor. Horses also benefited from the new roads: No longer required to drag coaches over crude, rutted roadways, horses suffered fewer short- and long-term injuries and hence would often live longer than the earlier average of only four years.

Given that his methods also relied upon careful oversight and the management of day-to-day expenses, McAdam can be considered one of the earliest modern professional managers. His early business ventures with the British Tar Company also make him a pioneer of modern chemical manufacturing.

McAdam was an advocate as well as an engineer, actively promoting his methods before Parliament and in several publications. In pressing his belief that there should be more centralized control over roads, he was not only seeking civic consolidation but also endorsing public policy. His plans would not be widely realized for several decades, by which time macadamization was common practice, not only in Britain but also around the world.

Cyrus Hall McCormick

American machinist and agriculturist

McCormick invented the first successful reaping machine, which combined all the steps that earlier harvesting machines had performed separately. His invention led to increased crop production, lower labor costs, the development of the Western frontier in the United States, and the country's evolution from an agrarian to an industrial society.

Born: February 15, 1809; Rockbridge County, Virginia
Died: May 13, 1884; Chicago, Illinois
Primary fields: Agriculture; manufacturing
Primary invention: Mechanical reaper

Early Life

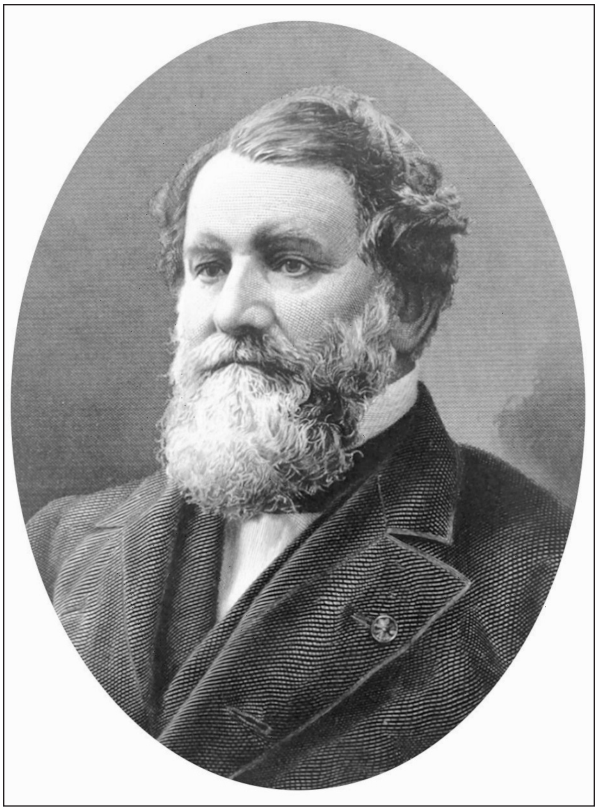
Cyrus Hall McCormick was born to Mary Ann Hall and Robert Hall McCormick in Rockbridge County, Virginia, on the family farm in 1809. At the time of his birth, he was presented with a two-year-old slave named Jo Anderson. Jo would be with him throughout his childhood, but McCormick would have few other close friends growing up. He worked on the family farm, known as Woodbridge, and attended a rural school when time permitted. At school, he learned the basics of reading, writing, geography, and religion. He may have had a special tutor for surveying and mathematics.

Although McCormick became known as an innovator, his childhood environment was traditional. The farm and the church were two focal points, and he was raised in a strict Presbyterian home with daily Scripture readings. He was religiously active throughout his life, including involvement with local churches and making contributions to Presbyterian churches and seminaries. Coming from a slave-owning family, he also strongly defended the institution of slavery up to and throughout the American Civil War. He would use his ownership of the *Chicago Times* to promote pro-Southern ideas.

McCormick's father, Robert, was interested in the innovative and mechanical side of farming. Like his father, the younger McCormick was drawn to the workshop more than the fields. Around the age of fifteen, McCormick invented a lightweight grain cradle and a hillside plow. His father built mills on his and his three sons' adjoining farms and three other sawmills and two flour mills. He made a hemp brake, a clover sheller, a thresher, and a plow in his workshop. He also had worked intermittently in the farm's blacksmith shop on a horse-drawn reaper but was unable to produce a practical machine. A successful reaper had to separate, cut, and deposit stalks to avoid any shelling of kernels. It had to prevent entanglement and ensure the stalks stayed parallel for curing. It also had to cut parallel with the ground, even if that ground was irregular. Robert abandoned the project in 1831. McCormick picked up the project that same year and succeeded with his own invention, the first practical mechanical reaper. He was just twenty-two years old.

Life's Work

Cyrus Hall McCormick's invention addressed a longstanding problem in farming and agriculture: the need to harvest at just the right time. This need to pinpoint a harvest time made it difficult to cultivate large crops, which had to be gathered en masse by many laborers. At harvest time, labor became scarce and expensive. Before the invention of the reaper, only three acres per day could be



Cyrus Hall McCormick. (Library of Congress)

The Mechanical Reaper

In the early nineteenth century, harvesting required a large amount of labor to get everything harvested in time. The often scarce labor was expensive as well. The reaper offered the hope that production would no longer be limited by the amount of labor available. Several people, including Cyrus Hall McCormick's own father, had tried unsuccessfully to invent a working harvest machine.

The essential elements in McCormick's reaper included a reciprocating knife (which moved back and forth), against which the grain stalks fell; fingers or guards for the knife to hold the stalks during the cutting action; a horizontal and adjustable rotating reel to pull the stalks into the machine; a master or main wheel that turned directly behind the horse and supplied power to the reel and knife; a forward side draft (the horse walked in front of the wheel and to the side of the machine so the knife could cut the standing grain); a divider to separate the grain to be cut from that to be left standing; and a platform or grain deck flexibly attached to the master wheel to accommodate irregular ground. The machine required two workers to operate and incorporated all the mechanical principles of modern harvesting machinery.

McCormick's reaper could cut as much as in one day as four to five laborers with cradles or twelve to sixteen laborers with reaping hooks. His early machines required only two people to operate (one to ride the horse and one to rake the cut grain from the platform to the ground). Other workers could gather the cut grain into bundles and tie them with twists of grain. The reaper also lessened waste. It could save one bushel of wheat per acre, ordinarily lost by shelling when workers used the cradle. Eventually, McCormick would eliminate the need for the additional workers to bind the grain when he invented a self-binder in 1876 and a twine binder in 1881. A farmer could now complete the harvest on his own by driving the reaper (with a driver's seat that McCormick added) and taking care of the horse or horse team.

harvested. With the reaper, farmers could harvest fifteen acres per day with just two people to operate the machine.

McCormick's first machine was rudimentary, but he developed it more fully after the first test showed that it worked. He conceived plans for the reaper, built and tested it, and then improved it for public trial. He immediately began to demonstrate his reaper with practical tests in the field. However, he did not seek a patent until 1834. This allowed him to use the reaper in three successive harvests under a variety of conditions and then try to perfect it. Word about the machine spread, however, and its success was noted in agricultural publications as early as 1832. McCormick continued to make several experimental machines in his shop. The machines were not manufactured commercially until 1840.

From 1837, the year a family business failed, until his death in 1884, McCormick focused on the reaper—its improvement, manufacture, and marketing. He had little capital to begin his work, but he produced his machines nonetheless; he sold his first two reapers in 1840. All materials and completed machines had to be transported over land because there were no railroads or canals nearby.

To market the machine, McCormick began to travel and do field trials. He showed that while the reaper was helpful in Virginia, it was essential in Ohio, Illinois, and the plains. In 1847, the McCormick Harvesting Machine Company moved to Chicago. Within one year, the company had 120 employees and produced 450 machines, making it Chicago's largest employer.

McCormick continued to work on improvements to the reaper. His success brought rivals, such as Obed Hussey, who had patented a reaper before McCormick. However, McCormick had successfully demonstrated his machine two years before Hussey demonstrated his in 1833. When McCormick's basic patent expired in 1848, he applied for an extension. However, rival companies blocked the extension, even though the U.S. patent commissioner testified to the U.S. Congress that the invention of the reaper was as important to agriculture as the spinning jenny and power loom had been to the textile industry. In the 1850's, McCormick sued another rival, John Manny, for patent infringement but lost his lawsuit. In 1860, McCormick once again unsuccessfully applied for an extension of the patent.

The loss of the suit and the denial of patent extensions cost McCormick's company much money, but not its competitiveness. McCormick received new patents as he continued to improve the machine, developing combined machinery for reaping and mowing, seats for the driver and raker, and an all-metal main wheel. His later machines also cut wider swaths. He demonstrated his mechanical reaper at the 1851 Crystal Palace Exhibition in London. He was awarded for his invention, the first of many European awards and gold medals. In 1858, he patented his "Automatic Self-Rake Reaper," which needed one person to operate.

Despite many setbacks during the years, including more legal battles and the destruction of his factories in the Chicago fire of 1871, McCormick continued to invent new equipment. His "Marsh Type Harvester" had an elevator and binding platforms. His 1876 "Harvester and Binder" was the first practical self-binder built. It cut and bound grain in a single operation. The last major improvement came in 1881 with the "Harvester and Twine Binder," which bundled with twine rather than wire.

McCormick died in Chicago in 1884. The town was sixty times the size it had been when he moved there in 1847. His factories had produced several million harvesting machines. In 1902, the McCormick Harvesting Machine Company, under the direction of McCormick's grandson, merged with four smaller harvesting-machine manufacturers to form the International Harvester Company.

Impact

McCormick's Virginia reaper, as his invention was first known, and the mechanical revolution it sparked transformed American agriculture by requiring fewer and fewer people to produce more and more crops. The reaper also helped form the Western frontier, and many claim it had a part in the outcome of the Civil War. The reaper, which allowed farmers to fight without causing a severe drop in agricultural production, may have contributed to the success of the Union army.

U.S. secretary of state William H. Seward claimed that the reaper extended the frontier thirty miles per year, making it possible for agricultural production to keep pace with urban growth in the West. The U.S. population doubled between 1840 and 1870. Farms had to produce more to meet the demands of the new populations. In 1831, 90 percent of the population farmed to meet the nation's needs. At the end of the twentieth century, less than 2 percent of the population was directly involved in farming, which meant high demand for the remaining farmlands.

McCormick's invention of the reaper also encouraged the invention of other agricultural machinery that reduced labor while increasing production. His company offered easy credit to enable farmers to pay for machines from increased harvests. Its salesmen also made door-to-door sales calls. The company was one of the first to offer a fixed price and performance guarantees. The company's success in Europe after 1851 helped to push the United States to export manufactured goods as well as raw materials, and it helped to transform the country from an agrarian society into an industrial world power.

Elijah McCoy

Canadian American mechanical engineer

McCoy invented more than fifty different devices, most of which improved the operation of locomotives. Many of his inventions automatically dispensed oil to lubricate the moving parts of the locomotive, reducing friction and helping the train run more smoothly.

Born: March 27, 1843; Colchester, Ontario, Canada
Died: October 10, 1929; Eloise, Michigan
Primary field: Railway engineering
Primary invention: Automatic lubricator

Early Life

Elijah McCoy (ee-LI-juh mih-KOY) was born in 1843 to George McCoy and Mildred Goins McCoy. Many sources give his birth date as May 2, 1844, but the date of March 27, 1843, appears on his death certificate. He was the third child of the McCoys; they had nine more children.

George and Mildred McCoy had lived in slavery in Kentucky until 1837. That year, they escaped to freedom on the Underground Railroad, the network of hidden paths and safe houses that allowed African Americans to flee to free soil. Like many slaves who had escaped along this system, they settled in Canada, which had no slavery. George McCoy joined the Canadian army and, after completing his service, was rewarded with 160 acres of land in Colchester, a village southeast of Windsor and on the shores of Lake Erie.

While helping out on his parents' farm, Elijah McCoy completed his elementary schooling and also attended a mechanical school. He apparently showed some aptitude for mechanics, and at age fifteen he was sent to Edinburgh, Scotland, to work as an apprentice to a mechanical engineer. McCoy's apprenticeship lasted five years. He returned to North America in the mid-1860's, trained as a master mechanic.

The family returned to the United States, settling in Ypsilanti, Michigan, a small city near Detroit. The Michigan Central Railroad was based in that city. McCoy, with his training as a mechanic, hoped to find work with it.

McCoy was hired by the railroad, but neither as a mechanic nor as an engineer. He was hired as a fireman, whose task it was to shovel coal into the firebox of the locomotive, fueling the fire that produced the energy to move the train. Racial prejudice might well have played a role in McCoy's being thus underemployed.

Life's Work

In a steam-powered locomotive, steam produced by the train's boiler enters large cylinders. The buildup and loss of steam pressure drives pistons to move in and out of the cylinders, and that motion moves the wheels of the train. These moving parts operate under extremely high temperatures. They must be lubricated to prevent the high temperatures and friction from destroying them.

As early as 1850, British inventors had created devices to provide a steady stream of oil to lubricate these parts as they moved. At least one of these devices was used not only in railways there but also elsewhere in Europe and in the United States. It is not clear if such devices were part of the locomotives on which McCoy labored. That is likely, however, as he called his first invention an "improvement in lubricators for steam-engines."

Working in a makeshift shop when he could find the time, McCoy spent two years developing a system that would regularly distribute oil onto the moving parts to lubricate them. He completed his work in the summer of 1872 and submitted his first patent application to the U.S. Patent Office. On July 23, 1872, he was awarded the patent. As he would do with many of his later inventions, McCoy assigned the rights of patent to both himself and another person who was, perhaps, an official of the railroad. (Companies often require employees who obtain a patent to assign the rights to the company.)

McCoy's new lubricator was the first of more than fifty patents he would eventually hold. The second came just two months after the first, when McCoy patented an improved model of his self-regulating lubricator. In all, nearly three dozen of McCoy's patents were lubricators that could be used on trains. His lubricating devices also had applications in other steam engines, such as those driving steamships. Among his few nonrailroad inventions were an ironing board (patented in 1874), a lawn sprinkler (1899), and treads for tires (1915).

As railroad technology advanced, McCoy kept abreast of the changes and invented new devices suited to the newer equipment. In 1872, George Westinghouse invented a new railroad braking system called the air brake. More reliable than earlier railroad brakes, the air brake made it easier to stop trains that were larger and heavier, and that ran faster, than before. McCoy invented several lubricating devices that oiled these powerful brakes, helping them operate smoothly.

Another change came in the early 1900's, when engineers developed so-called superheater steam engines. In these engines, the steam produced by the boiler is heated again, which enables it to deliver even more energy when released. Superheater locomotives generated much higher temperatures, which made lubricating them both more important and more difficult. McCoy worked on developing a graphite lubricator to help meet this challenge. Graphite—the same material found in pencils—is a solid lubricant that works very well at high temperatures. McCoy's device suspended graphite in lubricating oil so that the solid would not cause clogs in the machinery. McCoy patented his first graphite lubricator in 1915. He followed over the next few years with improved versions.

McCoy left the Michigan Central Railroad in 1882 and moved to Detroit. There, he worked on his inventions and as a consulting engineer for a company that made lubricators. In 1920, when McCoy was in his mid-seventies, he launched his own company, the Elijah McCoy Manufacturing Company, based in Detroit. The company made lubricators and other devices of McCoy's design. He patented his last four lubricators during the 1920's.

The remaining years of McCoy's life were marred by tragedy. He had married his first wife, Ann Elizabeth Stewart, in 1868, but she had died in 1872—the year of McCoy's first patent. He married Mary Eleanor Delaney the following year, and they lived more than fifty years together. Soon after the McCoy company was founded, however, McCoy and his wife were in an auto accident. Mary McCoy never fully recovered from her injuries and died in 1923. McCoy himself weakened, in part because of injuries incurred in the accident. In addition, he suffered from high blood pressure and, eventually, senile dementia. In 1928, as a result of senility, he was placed in an asylum in what is now Westland, Michigan. The following year, he died.

Impact

McCoy was a trained engineer and mechanic who invented several lubricating devices. Some popular writers call him the "father of lubrication," but other sources dismiss that claim. Still, McCoy can be credited with creating valuable devices that helped railroad locomotives and air brakes function well.

McCoy is often credited in popular literature as the origin of the term "the real McCoy," said to be a tribute to the reliability of the device he first invented. That claim appears unjustified. Sources do not offer documented evidence of its truth. Also, language scholars say that the origin of the term is unknown. It is variously ascribed to a boxer, a liquor distiller, and several other characters. Also, the phrase appears to predate McCoy and his invention.

The lack of justification for these claims does not diminish McCoy's achievement. That he was an African American living in a predominantly white society that often showed little respect or regard for blacks makes his accomplishments the more notable. Late in his life, he held more patents than any other African American inventor.

—*Dale Anderson*

McCoy's First Lubricator

In the late nineteenth and early twentieth centuries, before air and automobile technology, trains transported goods and people across the United States, and their smooth operation was key to keeping the U.S. economy running. Elijah McCoy's first invention was a type of automatic lubricator that used the steam produced by the train's engine to force oil from a holding cup through a channel to the cylinder. This device is called a hydrostatic lubricator because it relies on pressure to maintain the lubricant in place between the working parts.

The lubricator is in the form of a lidded cup that sits on top of a cylinder near one end. At the bottom of the cup is a stem, which is the piece that attaches to the cylinder. Running through the center of the cup and into this stem is a tube with valves at the top and bottom. The tube does not fill the stem completely. When steam pushes the piston forward in the cylinder, some steam escapes around the piston to the head of the cylinder. Some of this steam, in turn, enters the tube of McCoy's lubricator. That steam pushes open the valve as it rises into the cup. Since the valve is open, oil flows through its opening into the stem. It fills the space between the outside of the tube and the inside of the stem and flows down into the cylinder, where it can keep the piston lubricated.

The steam entering the lubricator cup collects and condenses, or cools. As it changes to water, the oil remaining in the cup rises above it, since water is denser than oil. As a result, the oil is always high enough that it is in contact with the top of the stem and tube apparatus.

McCoy placed a faucet with another valve at the bottom of the lubricating cup. When the cup was filled with water, the operator could simply open the faucet to drain this liquid. A thumbscrew on the cup's lid could then be turned to remove the lid and refill the cup with oil. The lubricator was then ready to dispense oil automatically again once the steam engine of the locomotive got under way.

Paul B. MacCready

American aeronautical engineer

MacCready made human-powered flight a reality with his Gossamer Condor and Gossamer Albatross aircraft. Although many of his inventions were not commercially viable, they advanced environmentally responsible technologies while serving as symbols of what can be achieved through creative thinking.

Born: September 29, 1925; New Haven, Connecticut
Died: August 28, 2007; Pasadena, California
Also known as: Paul Beattie MacCready, Jr. (full name)
Primary field: Aeronautics and aerospace technology
Primary inventions: Gossamer Condor; Gossamer Albatross

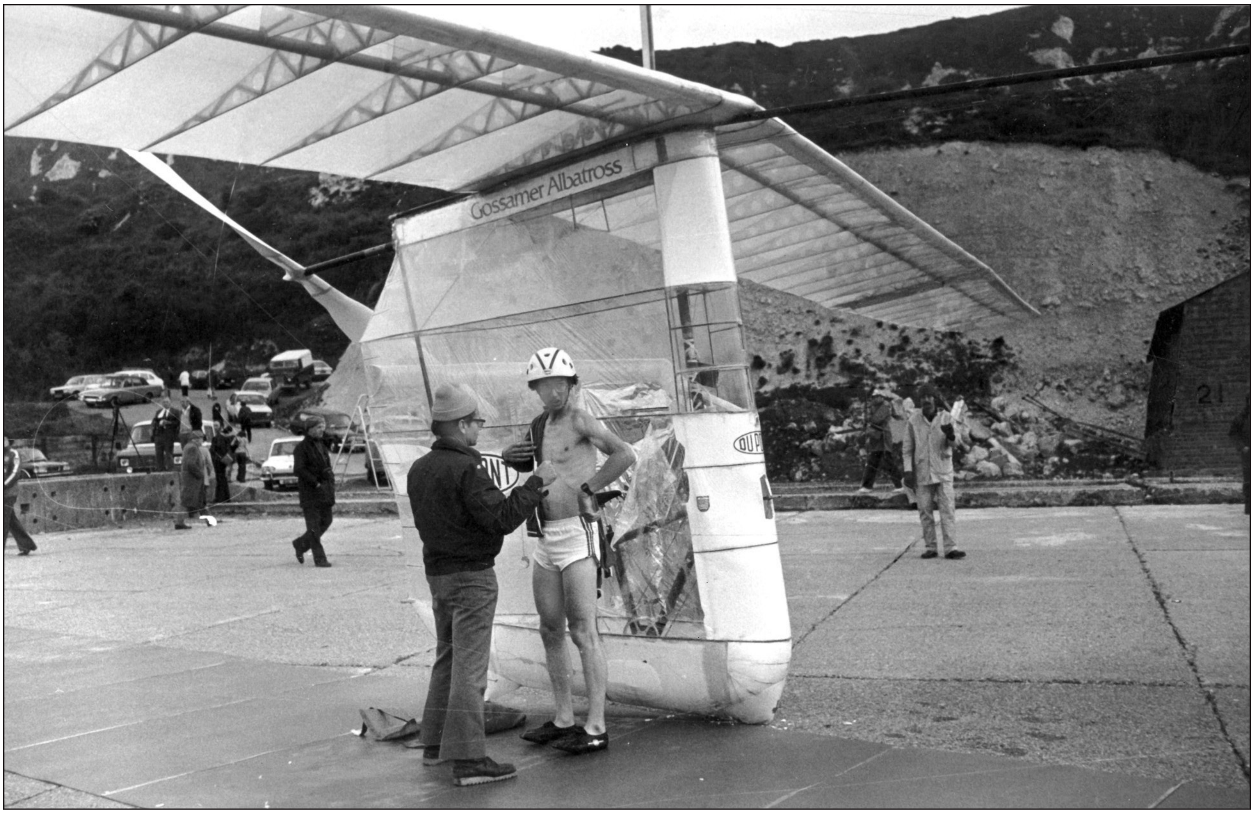
Early Life

Paul Beattie MacCready, Jr., was born in 1925 in New Haven, Connecticut. The youngest of three children and the only son of a successful doctor, MacCready showed an early intellectual curiosity and creativity. A boyhood interest in butterflies and moths grew into a love for building and flying model aircraft, a passion that would remain with him throughout his adult life.

After creating his first model airplanes from kits, he began designing his own aircraft models from scratch. Curious about unconventional designs, he experimented with model helicopters, ornithopters (which employ flapping wings to support and propel them in flight), and autogyros (which use a motor-powered propeller for thrust and an autorotating rotor for lift). He built indoor models, outdoor models, and models that could take off from water, propelling his creations with everything from rubber bands and small gas engines to beetles and flies that he glued to his aircraft.

Small, shy, physically awkward, and mildly dyslexic, MacCready tended to daydream and had to work hard to keep up in school. When it came to model aircraft, though, his focus and determination were forces to be reckoned with. At the age of fourteen, he set a world record by building a model autogyro that could remain aloft for thirteen minutes. Two years later, he was named the overall junior national champion in model building.

His interest in models led to piloting real aircraft, and at sixteen he made his first solo flight in a light plane. After graduating from Hopkins School in 1943, he enrolled at Yale. Halfway through his studies, he began training to become a Navy pilot, but World War II ended before he could fly in combat. He returned to Yale, switching majors from mechanical engineering to physics, and received a B.S. in 1947.



Bryan Allen stands in front of Paul B. MacCready's pedal-powered Gossamer Albatross in Folkstone, England, on June 12, 1979. That day, Allen successfully pedaled the plane over the English Channel, winning a £100,000 prize. (AP/Wide World Photos)

Life's Work

MacCready earned an M.S. in physics (1948) and a Ph.D. in aeronautics (1952) from the California Institute of Technology (Caltech). During his graduate studies, he continued to pilot sailplanes (a pastime he took up shortly after the war ended), winning multiple U.S. soaring championships and setting an international soaring record. His piloting experience and studies led him to develop the MacCready speed ring, an instrument used by sailplane pilots in selecting the optimum flight speed between thermal columns (now often called the MacCready speed). He also worked on sailplane development and soaring techniques. In 1956, he became the first American to win the international soaring championship.

In the early 1950's, he started a small weather modification company, Meteorology Research Inc. (MRI). The firm seeded clouds to produce rain and conducted pioneering research in atmospheric science. MacCready was the pilot on many of the company's research flights inside storm systems. In the mid-1960's, he sold MRI to Cohu Electronics, staying on as MRI's president and a member of Cohu's board until his resignation in 1970.

In 1971, MacCready founded a new company, AeroVironment, to tackle projects in solar and wind energy and in pollution monitoring and control. Although the company fared well, by the mid-1970's MacCready was facing financial difficulties. He had cosigned a bank note for a relative's business venture, which had failed. This $100,000 debt proved to be a catalyst for innovation.

In 1976, several disparate elements came together in MacCready's mind—the differing flight techniques of hawks and vultures he observed during a vacation; the amount of money he owed; the value of the British pound, then almost exactly two American dollars; and the Henry Kremer Prize, a long-standing British monetary award for the first person to fly a mile-long figure-eight course in a human-powered aircraft. The purse for the prize had recently risen to £50,000, or roughly $100,000. MacCready realized that achieving human-powered flight would be not only a way to make aviation history but also a means to erase his debt.

MacCready led a team in a yearlong effort to develop a lightweight, slow-flying, cyclist-powered craft with a large wingspan, employing flight principles he had observed in turkey vultures. His fragile creation, dubbed the Gossamer Condor, won the first Kremer Prize on August 23, 1977. Motivated by their first success (and the fact that developing the Condor had cost more than half the prize money), the team moved on to the next challenge: winning a newly established Kremer Prize for human-powered flight across the English Channel. MacCready reworked the Condor design to decrease weight and improve aerodynamic efficiency. The resulting aircraft, the Gossamer Albatross, had an increased aspect ratio (ratio of wing length to width), more ribs in its wings, and spars made from strong carbon-fiber composites instead of aluminum. The Albatross made its successful flight across the English Channel on June 12, 1979, winning a purse of £100,000 (over $200,000).

Next, MacCready and his AeroVironment team turned their attention to solar-powered flight. A scaled-down version of the Albatross was fitted with an electric motor and an adjustable solar panel. In a media demonstration held on August 7, 1980, the Gossamer Penguin flew approximately 1.95 miles at altitudes of up to 15 feet. This first sustained flight of a piloted, direct-solar-power aircraft laid the groundwork for a sturdier, more controllable solar-powered aircraft. The Penguin's successor, the Solar Challenger, could reach altitudes of up to 14,300 feet, and on July 7, 1981, it made the 163-mile trek from Paris to London in five hours, twenty-three minutes.

Perhaps the quirkiest of MacCready's winged projects was a 1984 commission from the Smithsonian Institution's National Air and Space Museum to create a flying, remote-controlled model pterodactyl. The lifelike, half-scale model (its 18-foot wingspan made it the largest known working ornithopter) appeared in *On the Wing*, an IMAX movie about the evolution of natural and manned flight. While temperamental and ungainly, the replica of *Quetzalcoatlus northropi* performed exceptionally well during filming in early 1986, although it crashed during a subsequent media event publicizing the movie's opening.

The Gossamer Condor

The Gossamer Condor was essentially a flying wing with a gondola suspended underneath to accommodate a pilot and a horizontal stabilizer, or canard, extending in front. Construction materials were thin aluminum tubes, Mylar plastic sheeting, stainless steel wire, and countless yards of industrial-grade Scotch tape. The Condor's wingspan was 96 feet, the maximum width the hangar that was used during early testing could accommodate. At seventy pounds, the aircraft weighed less than its slender pilot, cyclist and hang-gliding enthusiast Bryan Allen. Its single, rear-mounted propeller was powered by a drive chain fashioned largely from scavenged bicycle parts. Allen, who served as the Condor's engine as well as its pilot, kept the aircraft aloft through constant pedaling.

Unlike other contenders for the first Kremer Prize, the Gossamer Condor was not built to be fast, elegant, aerodynamic, aesthetically appealing, or even safe to fly. Instead, Paul B. MacCready and his team designed an aircraft that could win the prize by taking maximum advantage of the power available to it—nothing more, nothing less. The Condor had to be able to take off under its own power, fly a 1.15-mile figure-eight course, and clear ten-foot hurdles at the beginning and end of the course. By keeping the aircraft's weight low and maximizing wingspan, MacCready minimized the power required to keep it aloft. Because it traveled so slowly (its prizewinning flight took 7 minutes, 2.7 seconds), parasitic drag from its exposed wire bracing was negligible. Its slow speed and low-altitude flight also meant that the Condor did not need to be weighed down with safety equipment. Crashes (plentiful during the many test flights) were gentle enough that the pilot could walk away from them, albeit with occasional scrapes and bruises. More likely to sustain serious damage during a crash was the aircraft itself, but its simple design and low-cost construction materials meant repairs could be made quickly, easily, and inexpensively.

The Gossamer Condor's Kremer Prize win garnered international attention and accolades and was the subject of an Academy Award-winning documentary, *The Flight of the Gossamer Condor* (1978). The aircraft is hung on permanent display in the Smithsonian National Air and Space Museum in Washington, D.C.

The Condor—bulky, fragile, and needing a serious athlete to power it for more than a few minutes—is hardly a practical invention. The Condor's value lies not in its marketability or its immediate applications. Rather, it stands as a symbol of the power of creative thinking. MacCready disregarded preconceptions about what a modern, record-breaking aircraft should be, choosing a more unorthodox approach. In so doing, he achieved a goal that had tantalized and eluded humanity for thousands of years: human-powered flight.

In the late 1980's, MacCready and AeroVironment created their first ground vehicle, the Sunraycer. A collaborative effort of AeroVironment, General Motors (GM), and Hughes Aircraft, this solar-powered car won the first World Solar Challenge Race, held in Australia in November, 1987. The Sunraycer clocked the fastest speed of all the twenty-four contestants (65 miles per hour) and remained in first place for the duration of the 1,950-mile race, coming in two days ahead of the second-place vehicle.

MacCready won multiple awards and honors during his career and was a popular lecturer on creativity, thinking skills, and environmental responsibility. He died from advanced melanoma in 2007, a month before his eighty-second birthday.

Impact

Beginning with the Gossamer Condor in 1977, MacCready's inventions captured the public imagination and attracted worldwide attention through media stories, documentaries, and museum exhibits. (The Gossamer Condor, Gossamer Albatross, Solar Challenger, *Quetzalcoatlus northropi* model, and Sunraycer are all among the Smithsonian Institution's collections.) Never intended for mass production or widespread use, these inventions instead serve as inspiring object lessons in what creative problem-solving can accomplish. Furthermore, they showcase nonpolluting, renewable energy sources and demonstrate how using lightweight materials in vehicle construction can reduce energy demands.

Much of MacCready's seemingly impractical work paved the way for practical technologies. Using lessons learned from the Gossamer Penguin and Solar Challenger (which in turn evolved from the Gossamer Condor and Albatross projects), MacCready and AeroVironment worked first with the U.S. Department of Defense and later with the National Aeronautics and Space Administration (NASA) to develop a series of remote-controlled, solar-powered flying wing prototypes. The high-altitude, long-endurance Pathfinder (1981-1997) and Pathfinder Plus (1998) were succeeded by Helios (1998-2003), which had a 247-foot wingspan and fourteen electric motors. Helios could achieve an altitude of more than 96,000 feet and had the capability to remain aloft for months at a time. Demonstration missions proved that unmanned stratospheric aircraft like these are viable, environmentally friendly platforms for scientific observation and communications relays.

Similarly, the commercially impractical Sunraycer solar car laid the groundwork for later AeroVironment-GM work on a battery-powered production vehicle. Ultimately, GM determined that its EV1 electric car (available for lease between 1997 and 2003) was not commercially viable and discontinued the project. However, the EV1 influenced air-quality standards and the development of other manufacturers' alternative-fuel vehicles.

MacCready's impact was reflected in his many awards and honors, including the Spirit of St. Louis Medal (1978), the Collier Trophy (1979), the Ingenieur of the Century Gold Medal (1980), and the Lindbergh Award (1982). He was a National Aviation Hall of Fame inductee, and in 1999 he was named by *Time* magazine as one of "the century's greatest minds."

Charles Macintosh

Scottish chemist

In 1823, Macintosh patented a waterproof fabric produced by spreading soluble rubber between two pieces of cloth. Using this fabric, he made mackintosh raincoats, an enterprise that continues today.

Born: December 29, 1766; Glasgow, Scotland
Died: July 25, 1843; Dunchattan, near Glasgow, Scotland
Primary field: Chemistry
Primary invention: Waterproof fabric

Early Life

Charles Macintosh (MAK-ihn-tosh) was born to the innovative Glasgow dye manufacturer George Macintosh and his wife, Mary Moore. Initially Macintosh worked as an accountant while he studied chemistry, first in Glasgow and later in Edinburgh under Joseph Black, a leader in practical, quantitative chemical analysis and a friend to James Watt, whose refinements to the steam engine had in 1769 inaugurated the Industrial Revolution. In 1786, at the age of nineteen, Macintosh abandoned accounting to devote his career to chemistry, chiefly in its application to the textile industry.

In his first year as a full-time chemist, Macintosh manufactured sal ammoniac (ammonium chloride) out of soot distilled from by-products of Glasgow's new coal-gas works. This compound was used to produce alum, the mordant or astringent salt that made dyes color-fast for Glasgow's expanding calico industry. Macintosh imported another mordant, sugar of lead (lead acetate), from the Netherlands, but he soon produced enough of that compound to export it to Rotterdam. He invented a chemical process for separating a third mordant, sulphate of alumina, from sulphate of lead. In 1790, he married Mary Fisher of Glasgow.

In 1792, Macintosh abandoned the sal ammoniac business, but the next year he developed a process of dyeing fancy muslin for the brand-new sewn-muslin industry in nearby Ayrshire. In 1795, Charles Tennant, a twenty-seven-year-old Ayrshire textile chemist, joined Macintosh to establish Scotland's first alum works, using the aluminous shale readily available from coal waste in abandoned mines near Glasgow. Together, they invented a bleaching powder (chloride of lime), which Tennant patented in 1799. As a weaver, Tennant had noted how inefficient it was to bleach fabric by exposing it to stale urine under sunlight for months. Bleaching powder reduced the process to mere days, dramatically reducing the price of cloth and financially rewarding its inventors.

Life's Work

In 1800, Tennant, Macintosh, and two additional partners established a chemical factory north of Glasgow, and Macintosh remained with the firm until 1814. His continued improvements to dyes included refinements of Prussian blue, a cheap substitute for indigo that produced a deep, durable shade, later called royal blue and associated with uniforms. Macintosh's interests expanded beyond textiles. In 1809, he opened a yeast factory, although opposition from London brewers soon forced him to close it. In 1825, he patented a process for making steel by using a rush of coal gas to heat iron to a white hot, a technique that led Glasgow engineer James Beaumont Neilson to develop the hot blast furnace in 1828. Though Macintosh and Neilson's invention proved essential to Scotland's iron industry, fifteen years of patent litigation deprived both men of their profits. For his many contributions to British chemistry, Macintosh was elected a Fellow of the Royal Society in 1823, the year he patented his most famous product, waterproof fabric.

By his father's death in 1807, Macintosh was running the family factory, manufacturing cudbear, a deep-red dye, from lichens soaked in ammonia water, and a decade later, he was experimenting with inexpensive ways to make Amazonian rubber soluble for practical use. Meanwhile, another Scottish-born inventor, William Murdoch, had employed coal gas for cheap artificial lighting. Piped through cities, the gas illuminated factories, theaters, and street lamps, but its production left two waste products: ammonia water and sticky, black coal tar oil. In 1819, Macintosh contracted with the Glasgow Gas

Works to buy both. The ammonia supplied his cudbear operation, and from the coal tar oil, Macintosh distilled naphtha, which made rubber soluble. He brushed the rubber adhesive onto fabric and before the naphtha evaporated, fixed a second layer of fabric over it, thus making it repel water.

To produce waterproof garments on a commercial scale, Macintosh formed Charles Macintosh and Company in partnership with three leading cotton manufacturers in Manchester, England, where the company's factory opened in 1825, powered by steam and lighted by coal gas. By supplying rainproof garments to the military as well as the public, the company succeeded despite problems with the product. Naphtha gave the fabric a disagreeable odor, and even in Britain's temperate climate, rubberized fabrics turned stiff in the cold and soft in the heat. Moreover, water penetrated the holes left by tailors' needles, and fitted rubberized garments did not allow their wearers' perspiration to escape. The man to solve these difficulties was a Londoner, Thomas Hancock.

Twenty years younger than Macintosh, Hancock had also begun in 1819 to experiment with rubber garments and in 1820 had patented elastic wristbands and garters. Around 1821, he perfected the masticator, a machine that tore and heated rubber scraps into a solid mass that could be rolled to specified thicknesses. In 1825, licensed by Macintosh to manufacture rainwear, he reduced the naphtha odor, and his brisk sales threatened Macintosh's dominance of the industry. By 1830, Macintosh had negotiated with Hancock to supply his company with rubberized fabric, and in 1834, Hancock became a partner in the company and assumed control. He replaced irregular rubber application brushes with a uniform mechanical spreader, designed loosely fitted raincoats for comfortable air circulation, and hired company tailors, supervising their stitching and replacing those who pierced cloth excessively.

In 1838, a fatal fire swept the Manchester factory while Hancock was visiting Macintosh in his Glasgow retirement. Hancock hurried south to supervise the

A Waterproof Raincoat

Charles Macintosh was the first to develop and manufacture rubberized textiles that repelled water on a commercial scale. His 1823 Glasgow invention made use of the resources of the Industrial Revolution, including textile production, coal mining, and steam shipping, as well as the growing market for his goods produced by the wealth created by industrialization.

Familiar with the growing industry of cloth manufacture from his father's business of developing dyes, Macintosh was a prosperous inventor of bleaching agents when he researched the properties of latex, still a rare and mysterious Amazonian export. Eventually he thought of dissolving it in naphtha, which he found in coal tar, a troublesome byproduct of the Glasgow Gas Works, newly built on the discovery that compressed coal gas could produce cheap artificial light. Macintosh's invention supplanted the work of Samuel Peal, who in 1791 had patented a process for coating cloth with rubber liquefied in turpentine. By substituting the more cost-effective naphtha and building a large-scale production plant in England, Macintosh's company dominated the British rubber business by mid-century, while it continued to improve the product and guard its patents.

Initially tailors resented the new fabric, which lost its special properties when their stitches pierced it or when they fashioned it into streamlined styles, so the management of Charles Macintosh and Company hired and closely supervised new tailors while redesigning a baggy garment that allowed for air circulation to combat the tendency for the wearer to perspire. The single greatest improvement to the Macintosh raincoat was vulcanization, a process of pressure-heating rubber with sulfur. Though Charles Goodyear had patented this invention in the United States in 1839, the company developed it shortly after Macintosh's death in 1843, when his partner, Thomas Hancock, secured the English patent. Named for the Roman god of the forge, vulcanization cured rubber of its propensity to soften in heat and grow brittle in cold. Airtight as well as waterproof, the improved product proved reliable not only for raincoats and boots but also for water safety, flexible surgical instruments, and industrial hoses.

Macintosh was not only an inquisitive inventor but also a skilled collaborator and a thrifty recycler. Born in Glasgow, in the second generation of the Industrial Revolution, which began in that city, he was ideally situated to market his inventions to growing local industries, particularly textile manufacturers. His successive partnerships with Charles Tennant in industrial bleaches and Hancock in rubber, as well as his financial backing from Manchester cloth producers, made most of his inventions practical and profitable. Using chemistry to discover large-scale uses for toxic industrial wastes, Macintosh both nurtured the environment and made his industry prosper. Spelled "mackintosh," his name has meant "raincoat" since 1836.

cleanup, and by 1840, an expanded Manchester operation was producing more than three thousand square yards of rubberized fabric a day. Shortly after Macintosh's death in 1843, Hancock solved the last problem with rubberized cloth when he patented the vulcanization process, which weatherproofed rubber by pressure-heating it with sulfur. Although Hancock scrupulously documented his chemical research, he concealed the source of the vulcanized rubber samples that had inspired him, the American inventor Charles Goodyear, who had held the U.S. patent since 1839.

Macintosh died in 1843 at home at Dunchattan, the estate his father had built near Glasgow for his cudbear factory. Hancock expanded Charles Macintosh and Company into the world's largest manufacturer of rubber goods while he immortalized—and altered the spelling of—the founder's name as a synonym for raingear.

Impact

Under Hancock's management, Macintosh and Company expanded its product line to include almost all modern uses for vulcanized rubber except inflated tires. Inflatable beds, pillows, and cushions assisted invalids and rail travelers. Surgeons used rubber tubes, sheeting, and bandages. Brewers and distillers used rubberized hose after learning how to preserve the flavors of their goods. The company supplied the military with not only waterproof capes, saddle covers, and cartridge covers but also tubes for sea divers. Pontoon boats, life preservers, hot-water bottles, and rubber boots served military and civilian needs. Inflexible rubber, called ebonite, anticipated plastic.

Charles Macintosh and Company staged award-winning displays of useful rubberized inventions at London's Great Exhibition of 1851 and the Paris Exhibition of 1855.

In 1857, Hancock noted that between 1842 and 1855, rubber imports in the United Kingdom rose from 140 tons to 2,235 tons. These exports, however, came at a cost to the native rubber workers in South America and in the new plantations of colonial Malaysia and the Congo. Modern historians estimate that in the years before World War I, the Amazon rubber industry claimed a native life for every 330 pounds of rubber it produced, while in the Congo, a native died for every 22 pounds of rubber. Public outcry and the invention of synthetic rubber have dramatically decreased the death count, even as rubber production continues to rise. In 2005, world production was 6.5 million tons of natural rubber and 8.7 million tons of synthetic rubber.

The company started by Macintosh has become Mackintosh Ltd., a Glasgow-based global company, with distributors across Europe and in North America and Japan. It markets high-end rainwear in traditional and fashionable styles to men and women using technological innovation and brand loyalty.

Theodore Harold Maiman

American physicist

Using a synthetic ruby rod that was silvered at both ends to reflect light, Maiman invented, demonstrated, and patented the world's first operable laser. He foresaw many of the applications of laser technology in medicine, industry, electronics, communications, and scientific research. Known as the "father of the electro-optics industry," Maiman was an inventive genius whose work led to the development and manufacture of lasers and video display systems powered by lasers.

Born: July 11, 1927; Los Angeles, California
Died: May 5, 2007; Vancouver, British Columbia, Canada
Primary fields: Optics; physics
Primary invention: Laser

Early Life

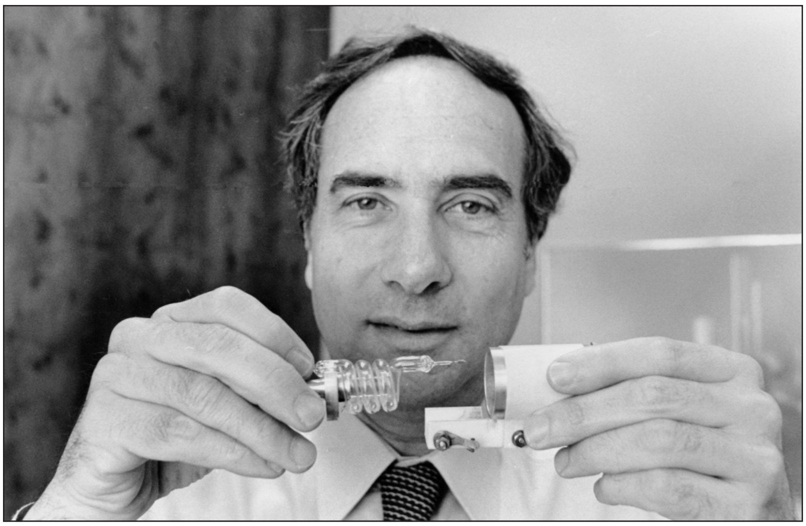
Inspired by his father, who was an electronics engineer and inventor, Theodore Harold Maiman (MAY-muhn) developed a great love for electronics and applied science at an early age. His father was very creative and was totally convinced that science should be used to better the world. He invented what was probably the first electronic stethoscope and did his best to apply electronics in the medical field and instill that same goal in his son. By the age of twelve, the younger Maiman had a job repairing mechanical valve devices. By the time he was fourteen, he ran the company's shop.

Maiman attended the University of Colorado and earned his bachelor's degree in engineering physics in 1949. After applying to do graduate work in physics at Stanford University and being rejected, Maiman attended Columbia University, but he was unhappy there. Once again, he applied to Stanford, but he was rejected a second time. Showing his tenacity, he decided to apply to the Electronics Engineering Department at Stanford and was accepted. After earning a master's degree in electrical engineering in 1951 and taking several physics electives along the way, he was finally admitted into the Stanford physics graduate program.

At Stanford, Maiman pursued his graduate research in spectroscopy under the direction of Nobel laureate Willis Lamb. His work involved making measurements of the fine-structure energy differences between particular energy levels in excited helium atoms, which were caused by the interaction of quantized electromagnetic fields with matter. Maiman built much of the electronic lab equipment necessary for making the measurements. In the process, he learned the makeup and operation of optical and electronic instrumentation that would be critical in his future work on the laser. Maiman received his doctoral degree in physics from Stanford in 1955. In a mutual agreement with Lamb prior to leaving Stanford, Maiman trained another of Lamb's graduate students, Irwin Weider, in how to use the sophisticated lab equipment to make the very precise scientific measurements that were needed to determine fine-structure energy differences in atoms.

Life's Work

During the latter part of 1955, Maiman began working at the Hughes Research Laboratories in Malibu, California. His initial work involved making improvements to the maser (microwave amplification by stimulated emission of radiation) that was invented by Charles Hard Townes in 1953. After becoming a section leader at Hughes, Maiman carefully studied a paper published by Townes



Theodore Harold Maiman holds the original laser, which he invented and patented in 1960. (AP/Wide World Photos)

Lasers

"Laser" is an acronym for "light amplification by stimulated emission of radiation." The fundamental operating principle of lasers, as demonstrated by Theodore Harold Maiman, is population inversion, a process by which energy is added to the atoms or molecules of the laser medium so that there are more atoms or molecules in a high-energy ("excited") state than in a lower-energy state. When this condition is established by optical pumping, light waves passing through the medium stimulate more radiation from the excited states than they lose by absorption to atoms or molecules in the lower-energy states.

In his laser, Maiman used a cylindrical, synthetic ruby crystal, composed of aluminum oxide doped with chromium atoms, with parallel, silver-coated ends. The crystal, or optical gain medium, was about the size of the palm of Maiman's hand. The coating on one end was semitransparent to allow emission of the amplified light. A burst of intense white light from a xenon strobe lamp acted as the optical pump to produce a population inversion in the ruby crystal and stimulate the chromium atoms in the ruby to emit incoherent red light. This red light was reflected back and forth by the silvered ends of the ruby rod until some of the light had enough energy to eventually emerge as an intense, amplified beam of coherent red light, with a wavelength of 694.3 nanometers. Because of the energy states in chromium, Maiman's laser generated pulses of laser light. The first laser to continuously emit amplified light was invented in 1961.

Lasers are used in myriad ways in household products, medicine, industry, electronics, data processing, communications, architecture, and scientific research. Lasers have been developed that can generate very high power densities, make very precise measurements of distances, gently pick up and move microscopic objects, and obtain extremely low temperatures. They are invaluable medical and scientific instruments that have developed into a multibillion-dollar industry. The United States National Academy of Engineering selected the use of lasers and fiber optics in communications as one of the twenty most important engineering developments of the twentieth century. In general, laser design still follows the guiding principles established by Maiman.

and Arthur L. Schawlow in 1958 that discussed the theoretical possibility of constructing an optical maser, or laser, that amplified visible light. Beginning in 1959, a race ensued to see who would be the first to invent a working laser. Several prominent physicists, including Townes, Schawlow, and Gordon Gould, submitted designs and sought patents for a light amplifier, but a working device was still not available. At least nine very important labs were pursuing the goal, including General Electric, Westinghouse, Siemens, and Bell Laboratories.

At Hughes, Maiman pursued the invention of an operable light amplifier on a shoestring budget. His initial pursuits involved investigating ruby as a lasing material, since it had been used successfully in making masers. Other scientists ridiculed him for his choice, particularly after Weider, whom Maiman had trained at Stanford, reported that the fluorescence quantum efficiency of ruby was a dismal 1 percent. After investigating other materials and finding no alternative prospects, Maiman recalculated the efficiency of ruby and found it to be about 75 percent. He then returned to experimenting with ruby.

Since other laboratories were trying to invent a continuous-emitting laser instead of a pulsed laser, Maiman pursued the possibilities of inventing a continuous-emitting ruby laser, using for optical gain a continuous arc lamp that had a brightness temperature of about 4,000 kelvins. He found that his margin of safety for success was too minimal to take the risk on his small operating budget. Surveying the literature, he located an article on photographic strobe lamps that could generate brightness temperatures between 8,000 and 9,000 kelvins. After numerous calculations, Maiman decided that the strobe lamp could provide the optical gain necessary to make a ruby rod emit amplified pulses of light.

In late 1959, Maiman requested Union Carbide to manufacture for him an optically finished ruby rod. Using techniques learned earlier during his graduate work and lab research, he silvered both ends of the rod so that light would be reflected inside the rod. One end was half-silvered so that light could escape through it when it reached a large enough amplitude. Maiman surrounded the rod with a high-power, helical-shaped xenon strobe lamp. On May 16, 1960, he tested his invention at Hughes Research Laboratories. As he had predicted, energy released from the strobe lamp excited atoms in the ruby rod to higher energy states, initiating a release of energy inside the rod. The resulting internal chain reaction caused light to bounce back and forth within the ruby. Once the light reached a certain level of amplification, it escaped from the partially silvered end of the ruby rod in the form of intense pulses of coherent, monochromatic light. Maiman had succeeded in inventing the first working laser in the world.

A public announcement about the working laser was reported to the news media by Hughes Research Laboratories on July 7, 1960. In the meantime, Maiman submitted a short paper describing his invention and results to *Physical Review Letters* for publication. To his dismay, the paper was rejected. Eager to have this significant work published, he submitted it to *Nature*, where it was published on August 6, 1960. The rejection by *Physical Review Letters* indicates the limited understanding at the time of the nature and significance of lasers.

Realizing the important applications for lasers, Maiman joined Quantatron in late 1960 and supervised laser research there. In 1962, he formed his own company, Korad Corporation, for the research and production of lasers. After Korad was purchased by Union Carbide in 1968, Maiman established Maiman and Associates, a company devoted to the development and manufacture of lasers and other optical devices. Four years later, he cofounded Laser Video to develop large-screen, laser-driven video display systems. In 1976, he became the vice president for advanced technology of TRW Electronics. He also served as a director of Control Laser Corporation and a member of the advisory board of *Industrial Research Magazine*. Maiman died on May 5, 2007, at the age of seventy-nine.

Impact

During the latter part of his Ph.D. studies, Maiman established a goal that he would be the first in the world to invent a working laser. When he began to pursue this goal, he was a junior employee at Hughes Research Laboratories with little experience. Although he was ridiculed by some of the world's leading scientists for not following their recommendations about how to build a laser, he stuck with his intuition and inventive genius. He believed that too often scientists follow the dictate of the scientific establishment and wind up wasting precious time and effort. Part of his inventive philosophy was to adhere to the principle of Occam's razor: Keep things as simple as possible. By doing so, he felt that he would avoid many pitfalls and blind alleys in his pursuits. He had confidence in his scientific decisions because he had put in the necessary time and hard work to develop a solid foundation in the understanding of electronics and optics, the keys for a working laser.

As Maiman forged ahead with his laser research, Hughes management grew skeptical about whether he would ever succeed. In addition, intense rivalries existed among individuals and scientific laboratories in the race to build the first working laser. By the time that Maiman became the first to succeed, Hughes management had already told him to quit working on the project. Nevertheless, Maiman endured until he succeeded in achieving his goal. His tenacity and competitive spirit earned him the label of being a maverick scientist. In addition to inventing the first working laser, Maiman applied his inventive philosophy to obtain patents for his inventions associated with masers, laser displays, optical scanning instruments, and laser modulation devices.

The significance of Maiman's inventive genius and scientific contributions is manifest by the numerous prestigious awards he received. He was presented the Ballantine Medal of the Franklin Institute (1962), the Buckley Solid State Physics Prize of the American Physical Society (1966), the Fanny and John Hertz Foundation Award for Applied Physical Science (1966), the Wood Prize of the American Optical Society (1976), the Wolf Prize in Physics from Israel's Wolf Foundation (1984), the SPIE (International Society for Optical Engineering) President's Award (1985), and the Japan Prize (1987), the Asian equivalent of the Nobel Prize. He was twice nominated for a Nobel Prize in Physics.

Leopold Mannes

American photographic technician and musician

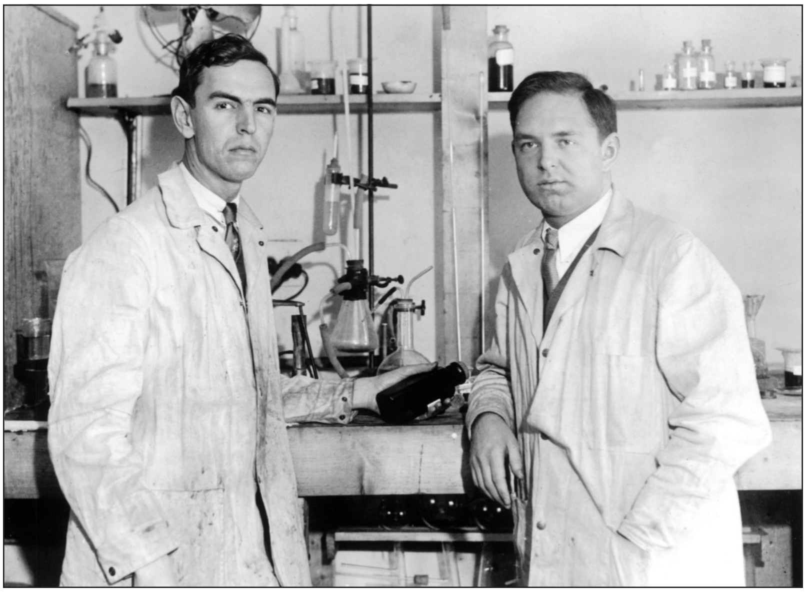
Mannes's boyhood curiosity and infatuation with color photography eventually resulted in an innovative form of superb color film reproduction. Kodachrome was mass-produced and used by amateur and professional photographers for generations.

Born: December 26, 1899; New York, New York
Died: August 11, 1964; Vineyard Haven, Massachussetts
Also known as: Leopold Damrosch Mannes (full name)
Primary field: Photography
Primary invention: Kodachrome color film

Early Life

The Damrosch family settled in New York and successfully launched careers in music as German immigrants. Leopold Damrosch conducted a men's choral ensemble, the Arion Society, and established the Oratorio Society of New York and the Symphony Society of New York. Clara Damrosch, the daughter of Leopold and an accomplished pianist, married David Mannes, violinist and concertmaster of the New York Symphony Orchestra, in 1898. Their son, Leopold Damrosch Mannes (MAN-ihs) was born the following year. At age four, studying piano with Elizabeth Quaile, he was already being compared to Mozart because of his considerable musical talent. At New York City's Riverdale School, Mannes met Leopold Godowsky, Jr., and formed a friendship that eventually led to their collaboration as musicians and inventors.

During his teens, Mannes devoted less time to music and developed a keen interest in photography. In 1917, he and Godowsky, also a highly trained classical musician, watched a movie, *Our Navy*, which was advertised as a color motion picture. Both expressed disappointment with the quality of reproduced color and decided they could improve upon current techniques. The boys constructed a movie camera and projector of their own that utilized three lenses with red, blue, and yellow filters. By projecting black-and-white exposures through the filters, the color hues were greatly enhanced. The system was patented but had little influence on the industry.



Leopold Godowsky, Jr., and Leopold Mannes, nicknamed "God and Man" by their friends, at the laboratory in Rochester, New York, in 1935, the year they invented Kodachrome. (Getty Images)

Life's Work

The two Leopolds went their separate ways. Godowsky studied violin at the University of California, Los Angeles, and became first violinist of the Los Angeles and San Francisco Symphony Orchestras. Mannes graduated from Harvard University

Kodachrome

Colors in a photograph are not actual recorded colors but instead are re-creations. The popularity and success of Kodachrome, the first transparency material, was due to its clear and fine-grain images that retained vivid colors over time. The process developed by Leopold Mannes and introduced to the public in 1935 was the first "tripack" process. Three emulsions with included filters were layered on a piece of film. Most other films required dye couplers embedded in the film, and all three layers were developed simultaneously. With Kodachrome, there were no dyes already embedded in the film. Kodachrome film used three layers of black-and-white film that were sensitive to red, green, or blue light. The dyes were added in the processing, separately for each color, through two specific light reexposures and another step that required chemical fogging. Each emulsion layer was exposed to a colored light and then developed. More dye was transferable to the film because the dye was added separately during each of the three color developments. The result was that colors were more saturated and of finer grain. Importantly, the process stabilized over time and the colors were fade-resistant. Kodachrome slides more than fifty years old maintain precise color and grain. It is estimated that the unstable yellow will lose only 20 percent of its color and grain in 180 years.

The reproduction of color is accomplished by mixing red, green, and blue light in the correct balance, each sensitive to one of the emulsion layers. The layers are so thin, including the gelatin layer between each, that the overall thickness of the film is less than most black-and-white films. Three color records of the film are assembled with blue sensitive (with yellow and yellow filter) at the top, blue-green sensitive (magenta) in the middle, and blue-red sensitive (cyan) on the bottom. The gelatin layer keeps each color record clearly separated. Dye images in each layer regulate the transmission of blue, green, and red light through the negative. For superior color, each dye image must be limited to only one primary color—red to cyan, for example. The red image is capable of transmitting green and blue as well, but those colors disappear when viewed through green and blue filters. The end result is three color records, each paired with the selective dye. Over time, formulas changed but the selective reexposure process remained basically the same.

Kodachrome film and the development process were invented by Mannes and his friend Leopold Godowsky, Jr., two classical musicians with a penchant for color photography. Their discovery expanded the possibilities and capabilities for amateur and professional photographers for decades. As with all improvements in technology, there is a finite time span for usage. However, countless magazine pictures, family vacations, artistic photo shoots, and memoirs are permanently preserved as testaments to the merit and excellence of Kodachrome.

in 1920, then went to Paris to study piano with Alfred Cortot and also won a Pulitzer scholarship in composition in 1925. In 1926, Mannes married Edith Vernon Simonds and received a Guggenheim Fellowship to study composition in Rome for eighteen months. Mannes and Godowsky regularly communicated regarding their plans to improve color photography. Godowsky eventually left his symphony positions to join Mannes in New York, where they both continued their musical careers. The kitchens and bathrooms in their homes served as darkrooms for their photography experiments.

By chance in 1922, Mannes encountered a senior member of Kuhn, Loeb and Co., a prominent investment banking firm. Mannes mentioned their work in color photography, and the firm sent an associate to review the progress. The firm expressed confidence in the developing process and provided $20,000 in financial support to build a photography laboratory in 1924. By 1930, the results of their work were so impressive that the inventors were invited to join the staff of Eastman Kodak in Rochester and were assigned a group of researchers to assist.

Days were spent in the laboratory, while evenings provided opportunities for musical performances at the nearby Eastman School of Music. Since their work in the laboratory required total darkness and they were unable to look at a watch to time film developing, they concocted their own system by singing or whistling classical music compositions such as the final movement of Brahms's C-minor Symphony at two beats per second. This formula was used to determine specific time intervals.

Godowsky and Mannes were affectionately labeled by friends and colleagues with the nicknames "God and Man." God and Man successfully completed their work on a new type of color film within three years of their research. On April 5, 1935, the two inventors announced the arrival of Kodachrome, a revolutionary but practical color photography film that provided excellent results and was also easy to use. At the press conference, there was an announcement of the new product accompanied by sample photographs, and, as usual, unable to separate their music and science careers, the duo performed a violin and piano sonata. In subsequent years, Ektachrome, Ektacolor, and Kodacolor were developed, but Mannes and Godowsky were not participants.

Oddly, after almost twenty years of discussion, testing, and research on improving color photography, Godowsky and Mannes abruptly halted their work in photography. Both decided to resume their music careers. Mannes and Edith had divorced in 1933, and he returned to New York City after 1939 to perform, compose new works, and serve as an adjudicator for music competitions. He judged the first Van Cliburn International Piano Competition. In 1940, he assumed the position of assistant director of the prestigious Mannes School of Music, founded by his father, David Mannes, in 1916. He also served on the faculty, teaching theory and composition. That same year, he married Evelyn Sabin, a dance student of the renowned Martha Graham.

In 1948, Mannes was codirector of the Mannes School and became president in 1950. He continued to perform with the Mannes Trio (piano, violin, and cello), which he had established in 1948. The year 1953 was noteworthy. Under Mannes's leadership, the name of the school changed to the Mannes College of Music, and new degrees were offered. The highly regarded Techniques of Music program was also created.

Leopold Mannes remained as president of the Mannes College of Music until he died at age at age sixty-four at Vineyard Haven in Massachusetts. In 2005, Godowsky and Mannes were inducted into the National Inventors Hall of Fame.

Impact

Critically acclaimed as a concert pianist, university music professor, and administrator, Mannes also invented a product that revolutionized an industry. His lifetime achievements uniquely combined art and science. After a long and prosperous performing career had peaked, Mannes introduced new curriculum tracks at the prestigious Mannes College of Music in his role as director. The new programs continued to evolve and now serve the college students of today. After many years of study and research that essentially began as a hobby, he developed Kodachrome, which became the industry standard for color photography worldwide.

For decades, Kodachrome was the overwhelming choice of photographers due to its characteristic bright colors, striking contrasts, and resistance to fading. It was especially suitable for printing in popular magazines such as *National Geographic* and *Look*. Historic images such as the fiery explosion of the *Hindenburg* zeppelin in 1937 and Sir Edmund Hillary's photo of his climbing partner atop Mount Everest in 1953 are preserved and still revered thanks to Kodachrome.

Remarkably, Mannes's successes in both music and photography were paralleled by those of a childhood friend, Leopold Godowsky, Jr., who accompanied him on his journey and made significant contributions as well. Together, the musical partners dabbled in the science of film and color and helped establish Eastman Kodak as the largest photographic film distributor in the world.

Gradually, the stockpiles of Kodachrome are diminishing as technology inevitably advances. Kodachrome is now available only in 35mm form, 64 ISO speed. In the United States, only one laboratory in Kansas continues to process the film. Even the finest and most trusted products often have a short shelf life. The digital age is taking its toll.

Guglielmo Marconi
Italian physicist

Marconi introduced improvements in sending and receiving wireless telegraph signals, and he developed the first commercial radiotelegraph system. He was also the first to demonstrate long-distance wireless transmission across the Atlantic Ocean.

Born: April 25, 1874; Bologna, Italy
Died: July 20, 1937; Rome, Italy
Primary field: Communications
Primary invention: Wireless telegraph system

Early Life

Guglielmo Marconi (gewl-YEHL-moh mahr-KOH-nee) was born at his father's villa, Palazzo Marescalchi, near Bologna in northern Italy. He was the second son of Giuseppe Marconi, an Italian landowner, and his Irish wife, Annie Jameson, daughter of Andrew Jameson of Daphne Castle in County Wexford, Ireland, and granddaughter of the founder of the Jameson Whiskey distillery. Guglielmo often visited relatives in Great Britain with his mother and learned to speak English as a child, but he did poorly in school because of frequent travels.

Marconi received private education at Bologna, Livorno, and Florence, and took an interest in physical and electrical sciences. After the death of Heinrich Hertz in 1894, Marconi read reports of his discovery of radio waves and about Nikola Tesla's work with radio waves. Through family connections, he was allowed to study for a period of time in Augusto Righi's physics laboratory at the University of Bologna. This began a long relationship with Righi, who had studied the works of Hertz and had developed an improved oscillator and spark gap for generating radio waves.

In 1895, Marconi began his own experiments with radio waves in the attic of his father's country home, Villa Griffone, at Pontecchio, Italy. After assembling his own spark-gap transmitter and using a receiver with a metal-filing coherer in place of a spark gap, as developed by Edouard Branly, he succeeded in transmitting across the length of the attic. After several improvements, he took his equipment outdoors in the summer of 1895 and began to reach greater distances by using longer antennae oriented vertically and grounded at one end. Soon he was able to transmit signals to associates, who received them at distances of a kilometer and a half and even out of sight over a hill, leading him to consider commercial possibilities for a wireless telegraph system.

Life's Work

Early in 1896, Marconi traveled to London with his mother, taking his equipment with him to seek support for developing his idea. Through his cousin, Henry Jameson-Davis, he met William Preece, engineer in chief of the British Post Office, who agreed to observe a test of his equipment and to provide some technical support. Later in 1896, after several demonstrations in London, Marconi was granted the first patent for a wireless telegraph system, even though very little of his equipment was his original invention. His work was introduced to the public in December, 1896, by Preece in a London lecture on "Telegraphy Without Wires," which included a public demonstration by Marconi. This was followed six months later by a second lecture by Preece at the Royal Institution in London on "Signalling Through Space Without Wires."

Marconi continued his demonstrations for the British government, and in March of 1897, he transmitted Morse code signals and received them on a paper tape recorder at a distance of about 6 kilometers across the Salisbury Plain southwest of London. On May 13, 1897, he sent the first wireless signals over water, transmitting the message "So be it, let it be so," across the Bristol Channel in South Wales for a distance of 6 kilometers from Lavernock Point to Flat Holm Island. He then relocated his receiving equipment to Brean Down Fort on the Somerset Coast, extending his transmission range to 16 kilometers.

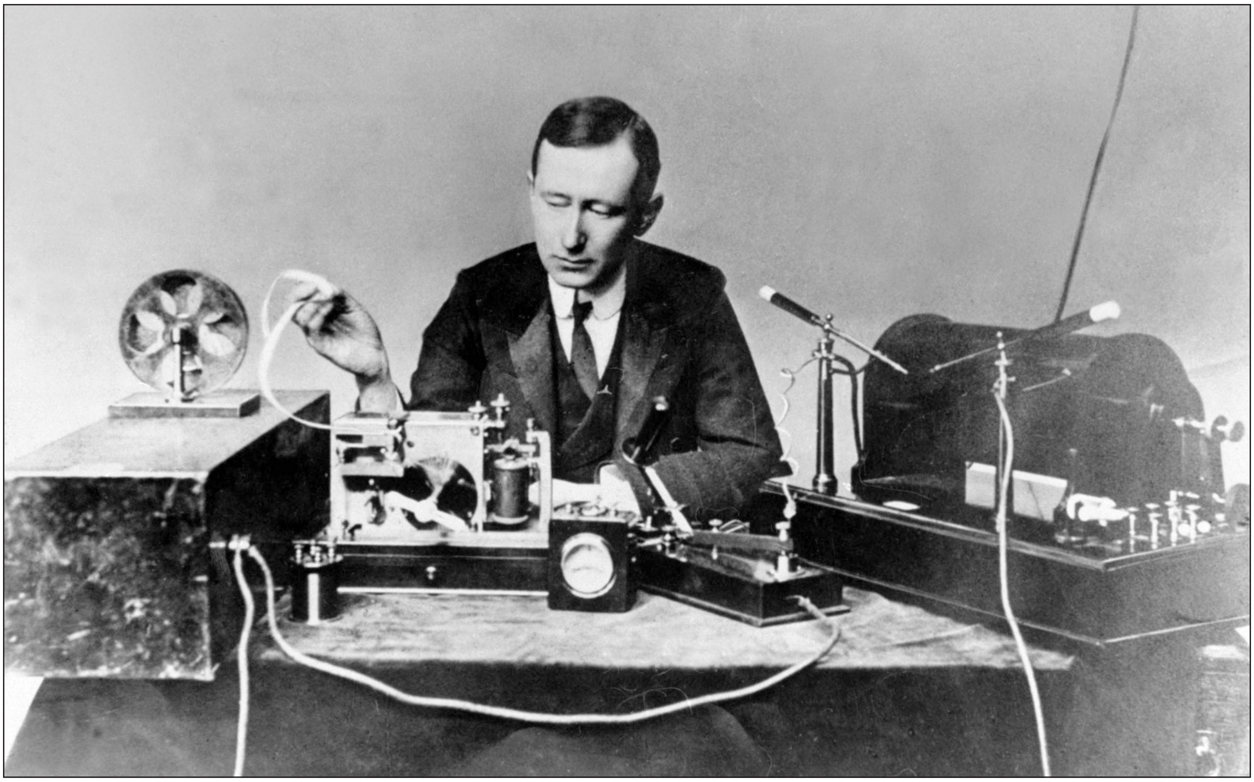
Bypassing the British Post Office, Marconi formed the Wireless Telegraph and Signal Company in July of

1897, with generous financial backing from a syndicate formed by Henry Jameson-Davis. In the same month, he received a U.S. patent and carried out a series of tests for the Italian government at La Spezia, where wireless signals were sent over a distance of about 20 kilometers. By the end of 1897, when he was only twenty-three years old, Marconi's stock holdings in his new company had tripled in value and were worth the equivalent of about $20 million.

In 1898, Marconi opened a radio factory at Chelmsford, England, to produce the equipment needed for permanent wireless stations. A test for Lloyds of London was conducted in July of 1898 between Ballycastle and Rathlin Island, Ireland, leading eventually to a contract to build ten wireless stations for Lloyds. About the same time, Marconi responded to a request from Queen Victoria to provide a wireless service from her royal yacht to her estate at Osborne House in Wales. In March of 1899, he established wireless stations at Wimereux, France, and South Foreland Lighthouse, England, and transmitted the first signals across the English Channel over a distance of some 50 kilometers. In the fall of 1899, the *New York Herald* invited Marconi for his first wireless demonstrations in the United States, reporting the America's Cup yacht races from a station on board the SS *Ponce* that transmitted the results to the mainland.

By the end of the century, Marconi faced increasing competition from other wireless inventors, especially Oliver Lodge, Nevil Maskelyne, and Nikola Tesla. To keep ahead of his competition, he began planning ways to transmit signals across the Atlantic, even though accepted scientific opinion held that radio waves could not bend around the curvature of Earth. With the assistance of John Ambrose Fleming as his scientific adviser, he established a high-power transmitting station on the cliffs near the village of Poldhu in Cornwall, England.

Marconi and his associates then traveled to St. John's, Newfoundland, a British territory at that time, and set up a receiving station on Signal Hill. Using a 150-meter kite-supported antenna, he began to hear prearranged signals from Poldhu, which were too weak to record on tape. On December 12, 1901, he announced his success in receiving signals over some 3,500 kilometers of open water. Although this was hailed as a great achievement,



Guglielmo Marconi with devices similar to those he used to transmit the first transatlantic wireless signals. (Time & Life Pictures/ Getty Images) critics voiced skepticism because there was no physical evidence or independent verification.

To verify and document his claims, Marconi sailed from England on the SS *Philadelphia* in February of 1902 and received tape-recorded signals from the Poldhu station out to 2,500 kilometers, although he could receive signals out to only 1,125 kilometers during the daytime. This daylight effect, limiting the transmission of long radio waves during the day, was explained by Oliver Heaviside's proposed existence of the ionosphere. He suggested that charged particles in the upper atmosphere reflect radio waves around the curvature of Earth, and that they reflect better at night when the Sun does not affect the ionosphere.

Due to threatened legal action by British transatlantic cable interests, Marconi built a new station at Glace Bay, Nova Scotia, Canada. On December 17, 1902, he transmitted the first transatlantic wireless signals from North America. His first transmission from the United States was a message from President Theodore Roosevelt to King Edward VII on January 18, 1903, from his Wellfleet station on Cape Cod in Massachusetts. A regular, but not completely reliable, transatlantic wireless telegraph service began in October of 1907 between Clifden, Ireland, and Glace Bay. Although Marconi was slow to accept continuous-wave radio for audio transmissions, made possible by Fleming's invention of the vacuum tube in 1902, he finally used a vacuum-tube transmitter in 1920 at his Chelmsford factory to transmit the first voice broadcasts in the United Kingdom.

THE WIRELESS TELEGRAPH SYSTEM

Guglielmo Marconi developed and commercialized his wireless telegraph system from known principles, and his innovations were mostly improvements by trial-and-error experiments based on the inventions of others. His system included a transmitter consisting of a simple oscillator with a pulsed power source and an induction coil connected to a wire antenna extending from each side of a spark gap, similar to that used by Heinrich Hertz. He also used a receiver with an antenna and coil, but Hertz's receiving spark gap was replaced by a coherer consisting of metal filings in a glass tube that would conduct current when a signal was received, similar to Edouard Branly's original coherer but modified for improved sensitivity. Messages were sent with a telegraph key to actuate shorter and longer sparks in the transmitter corresponding to the dots and dashes of Morse code. They were received with a telegraph register to record signals on a roll of paper tape when actuated by the coherer.

Marconi used a two-stage circuit to achieve the higher power he needed for long-distance transmission. He connected the first stage to a lower voltage generator, and the second stage operated at a higher voltage for more powerful sparks. Concerns about the extreme power of his Poldhu station led Marconi to investigate methods of tuning the frequency of his transmitter to avoid interference with other stations by adding sheets of metal to the top and bottom of his antenna, based on earlier ideas by Oliver Lodge. This led to a more effective four-circuit design, with two tuned circuits in both the transmitter and receiver, for which he received his famous British patent number 7,777 for "tuned or syntonic telegraphy" in 1900. Six years after Marconi died, the U.S. Supreme Court overturned most of his U.S. patents, based on prior work done by Nikola Tesla, Lodge, and others.

IMPACT

Marconi's main contributions were in showing the feasibility of using radio waves for communication, establishing the first commercial wireless telegraph systems, and demonstrating the first transatlantic wireless transmissions of telegraph signals. His tireless efforts to improve radio transmission and reception led to steady increases in the distance that signals could be sent. His persistence and promotion made it possible to raise the funds for building wireless telegraph stations in several countries and on board many ships. He was able to establish several wireless companies, including a factory for producing radio equipment, and provided the basis for worldwide wireless telegraphy. The use of shipboard telegraphy became crucial in seafaring emergencies, as in the 1912 sinking of the *Titanic* when many lives were saved because of Marconi's radio operators.

Although few of Marconi's inventions were original, his most dramatic achievement was in transmitting wireless signals across the entire Atlantic Ocean, against all scientific opinion of the day. In the process, his success led to the eventual discovery of the ionosphere and of the daylight effect that reduces the ability to reflect long radio waves during daytime. Marconi shared the 1909 Nobel Prize in physics with German physicist Karl Ferdinand Braun, who invented the crystal-diode rectifier for more efficient detection of radio waves, "in recognition of their contributions to the development of wireless telegraphy."

JAN ERNST MATZELIGER

American machinist

Matzeliger's shoe-lasting machine made such a change in the shoemaking industry that shoe production in the United States in particular increased tremendously. Manufacturing costs were cut in half, and the product was made affordable.

Born: September 15, 1852; Paramaribo, Dutch Guiana (now in Suriname)
Died: August 24, 1889; Lynn, Massachusetts
Primary fields: Industrial technology; manufacturing
Primary invention: Shoe-lasting machine

EARLY LIFE

In 1852, the year in which Harriet Beecher Stowe published her scathing exposé of American slavery, *Uncle Tom's Cabin*, in book form, Jan Ernst Matzeliger was born in Dutch Guiana, on the northern coast of South America. He took his name from his father, a Dutch sea captain who was also an engineer. His mother was a black slave. By the time he reached the age of ten, the young Jan was working in machine shops that his father supervised. A smart child with an obvious mechanical aptitude, he was encouraged to develop his mechanical talents and his interest in machinery. At the age of nineteen, he left South America aboard an East Indian merchant ship and spent two years at sea. When his ship made port in Philadelphia, Pennsylvania, he decided to settle in the United States.

Matzeliger arrived in the United States during the early 1870's, a time when the nation was recovering from its devastating Civil War (1861-1865) and its craftsmen were adjusting to changes wrought by the Industrial Revolution. Few jobs were open to black men, much less to a black foreigner who could barely speak English. Having trouble finding gainful employment, Matzeliger took odd jobs to survive while he learned to speak better English. On one job, he was an apprentice shoemaker. Aware of the bustling shoemaking industry in New England, he soon moved to Boston and then to Lynn, Massachusetts, where he found employment at the Harney Brothers shoe factory. There, he learned to use a sole-sewing machine, a heel burnisher, and a buttonhole machine.

Matzeliger had a high regard for learning. When he was not working, he studied English, physics, and other subjects. In addition to his interest in things mechanical, he also had a talent for painting. He gave his paintings to acquaintances and associates and even taught oil-painting classes. However, he seems to have had difficulty making friends and developing a social life, and there is no evidence that he ever courted or married a woman. A religious man, he tried several times to join a church in Lynn but was always refused membership because he was black. Eventually, however, he was allowed to join Lynn's North Congregational Church; he became a devoted member, regularly attending services and even teaching Sunday school.

Life's Work

Meanwhile, Matzeliger's job in the shoe factory made him acutely aware of shortcomings in the shoe manufacturing process. Thanks to the Industrial Revolution, new machines had been devised to cut, sew, and tack shoes. The invention of the sewing machine had ushered in marvelously fast methods of attaching the various upper shoe parts together, but attaching the upper parts to the shoes' soles still had to be done by hand—a slow and expensive process. Shoe lasters, the skilled workers who performed this task, had a strong labor union and could dictate how many shoes they would finish each day and how much they should be paid for their work. Shoe workers who operated the machines could produce upper parts much faster than hand lasters could finish the shoes, but the number of shoes finished in a given day was generally no more than the fifty each laster could sew by hand. Many inventors had tried and failed to mechanize the lasting process, but Matzeliger believed that he could invent a shoe-lasting machine that would do the job faster and more efficiently than human hands could.

Alone and with little financial support from outside sources, Matzeliger worked on the lasting problem. Those who knew what he was trying to do were quick to scoff at him. Nevertheless, he kept at it until he assembled a model of his machine with old cigar boxes and scrap wood that was held together with wire and nails. Though his model was fragile, it clearly demonstrated the feasibility of his invention. After turning down another inventor's offer of $50 for the model, Matzeliger set out to make a metal model of his machine that could be put to a practical test. Knowing how expensive building such a model would be, he switched jobs so that he could have access to a forge at his workplace. Using scrap metal, he finally made a working model of his machine after several years of effort.

After turning down another inventor's offer of $1,500 for his new model, Matzeliger sought investors to put up money for a metal model strong enough for strenuous factory testing. Two men, C. H. Delnow and M. S. Nichols, gave him the money he needed, in exchange for two-thirds of his invention's profits. Matzeliger then joined

A U.S. postage stamp issued in 1991 honors inventor Jan Ernst Matzeliger. (© United States Postal Service)

with them to form the Union Lasting Machine Company and applied for a patent for his machine. His application was several pages long and contained such complicated drawings and descriptions of the machine that the U.S. Patent Office sent an examiner to Lynn to see his machine in action. When Matzeliger demonstrated how the machine held the last, pulled the leather upper shoe parts over it, and nailed the parts together, he was granted a patent.

Matzeliger's machine lived up to its promise, and Matzeliger continually made improvements that eventually enabled each machine to finish from 150 to 700 pairs of shoes per day. Every shoe manufacturer in the country wanted one of his machines. Within two years of the machine's availability, hand-finishing methods had been replaced by the machine that duplicated the movements of the human hand in shoe making.

The Shoe-Lasting Machine

Jan Ernst Matzeliger's hand-lasting machine automated the final step in the shoemaking process, which had long defied all attempts at mechanization. By the 1870's, all the upper parts of shoes—heels, toes, vamps, tongues, counters, and linings—could be assembled and sewed together by machines. Steam-powered sewing machines stitched together all upper parts, but no machine existed that could join those parts with the shoe's soles.

Before he began designing his invention, Matzeliger spent months observing exactly how lasters hand-sewed soles to shoes. After much experimentation, he devised a machine that duplicated their hand motions. His machine held the already-sewn upper parts of a shoe to a last—the foot-shaped wooden form used to shape each shoe to fit a different-sized human foot. As his machine gripped the leather upper, it also pulled it down around the heel and toe and drove nails into the sole, thereby joining the upper and bottom parts. The machine performed the entire process, fitting to the last and stitching the sole while adjusting its edges under the insole, in about one minute. Lasts were shaped approximately like human feet, but early models did not differentiate between left and right feet, so every shoe could be worn on either foot.

Before Matzeliger's invention revolutionized shoe production, most average people could not afford to buy the shoes made mostly by hand. Even shoes made partly by machine but finished by hand-lasters were too expensive for ordinary people. Matzeliger's machine lowered production costs so much that practically every American could buy manufactured shoes, and eventually the cost of shoe production fell all over the world.

Matzeliger continued working on projects to improve his lasting machine and other aspects of the shoemaking process. In 1890, he patented a nailing machine and a mechanism for separating and distributing tacks. In 1891, he patented another lasting machine and in 1899 another tack-and-nail distributing mechanism.

During the years that Matzeliger devoted to his inventions, he led a lonely life. However, his involvement with the Christian Endeavor Society at the North Congregational Church afforded him the solace of his strong Christian faith. He also made friends in the church who joined him in recreational activities, including rock climbing and exploring nearby ponds and islands. After an outdoor excursion in 1886, he came down with what he thought was a cold but what in fact was the onset of tuberculosis. Years of not eating properly and getting insufficient rest while concentrating on his inventions allowed the disease to take hold and eventually confine him to bed. For a while, he continued to work on his projects and paint. However, on August 24, 1889—several weeks before his thirty-seventh birthday—he died. He was buried in Pine Grove Cemetery in Lynn, Massachusetts.

After immigrating to the United States, Matzeliger had had little contact with his family in Dutch Guiana, so he left much of his estate to his Lynn, Massachusetts, church. When the church fell on hard financial times many years later, stock in his company that Matzeliger had left it rescued it.

Impact

Matzeliger's shoe-lasting machine was one of the greatest small inventions of the Industrial Revolution. It enabled manufacturers greatly to increase their production of shoes while cutting production costs in half, and its impact was almost immediate. It freed manufacturers from the tyranny of the hand-lasters who had formerly demanded—and received—high wages that had stifled the industry. With increased production and lower costs, retail prices of shoes fell to levels at which many people who had never before worn commercially produced shoes could afford them.

At the same time, conditions for workers in the shoe industry improved. Inequalities between the wages of high-paid hand-lasters and machine workers were balanced with increased pay for machine workers and modifications for hand-lasters. Hand-lasters became hand-lasting machine workers and produced ever more shoes. Meanwhile, Lynn, Massachusetts, became known as the "shoe capital of the world."

Over the years, the company Matzeliger and his backers had founded merged with other companies to become the United Shoe Machinery Corporation. By 1955, it was worth more than a billion dollars. Even into the twenty-first century, virtually all shoes manufactured by machines were still using machines based on Matzeliger's model. The fact that people all over the world have been able to wear machine-made shoes thanks to the genius of an obscure man from Dutch Guiana was little known for many years. However, long after his death, recognition and honors finally came his way. In 1967, his North Congregational Church had a statue of him erected in downtown Lynn. In 1984, the city of Lynn named one of its bridges after him. Seven years later, the U.S. Postal Service issued a commemorative stamp honoring him.

John William Mauchly

American physicist and engineer

Mauchly, together with John Presper Eckert, designed and built the first general-purpose electronic digital computer, the ENIAC. They later established the Eckert-Mauchly Computer Corporation and built the first commercial computers made in the United States.

Born: August 30, 1907; Cincinnati, Ohio
Died: January 8, 1980; Ambler, Pennsylvania
Primary fields: Computer science; electronics and electrical engineering; physics
Primary invention: Electronic Numerical Integrator and Computer (ENIAC)

Early Life

John William Mauchly (MAHK-lee) was born in Cincinnati, Ohio, in 1907 but grew up in the Maryland suburbs of Washington, D.C. His father, Sebastion Mauchly, was a physicist in the Department of Terrestrial Magnetism of the Carnegie Institution in Washington. Mauchly was a precocious child with an early interest in electricity. When he was five years old, he built a flashlight from a battery and a small bulb in order to explore a dark attic with a friend. While still in grammar school, he earned extra money by wiring electric doorbells and repairing electric wiring for his neighbors.

Mauchly attended a technical high school in downtown Washington where he thrived on mathematics and science. His grades were outstanding, and he still had time for sports and editing the high school paper. He graduated in 1925 and, for his high achievements, obtained an engineering scholarship to Johns Hopkins University. Mauchly entered Johns Hopkins with an electrical engineering major but soon found the courses too mundane and lacking in intellectual excitement. He found physics to be much more interesting, and in his second year he switched his field of study to physics.

Johns Hopkins had a program that allowed outstanding students to skip the final undergraduate years and enter graduate school to work toward a Ph.D. Mauchly took advantage of this and enrolled in graduate school to study physics after only two years as an undergraduate. He received his Ph.D. in 1932 with a thesis on molecular spectroscopy.

At the height of the Depression in 1932, it was very difficult for newly minted physicists to find jobs. Mauchly applied to a number of research institutions without success but finally received an offer from Ursinus College, a small liberal arts college in the outskirts of Philadelphia. Mauchly was the head and only professor of the Physics Department and quickly became an excellent teacher who could make the dull equations of physics come alive. He never lost his desire to do research, however, and in his spare time he became obsessed with predicting the weather. He bought a used desk calculator and, with weather data from friends in Maryland, attempted to predict weather patterns statistically.

Life's Work

Mauchly knew that a mechanical calculator would be far too slow to handle the huge number of variables needed to calculate the weather and that only vacuum tubes were capable of doing the job. He had built some simple electronic circuits at Ursinus, but he was frustrated by his inability to obtain funds and equipment to do research. He found that the nearby Moore School of Electrical Engineering of the University of Pennsylvania was offering a ten-week course in defense electronics and took the course in his spare time in 1941. The assistant in the course was John Presper Eckert, and the two of them found a common interest in computing and building a very high-speed computer. At the end of the course, Mauchly was offered a job as an adjunct professor in the Moore School and gladly accepted. This was the break he needed. With Eckert, he began to outline the plans for a large electronic computing machine.

The Moore School had a contract with the Army's Ballistics Research Laboratory to produce firing tables for the many new field artillery pieces being built. These tables were produced by female "computers" using a large analog computer and mechanical calculators. Mauchly wrote a memo in 1942 outlining a general-purpose electronic digital computer that could calculate the firing tables faster and more accurately than the methods being used. The memo was forgotten until a young mathematician at the Ballistics Research Laboratory became interested in it and encouraged the Moore School to submit a proposal based on the memo. The proposal was submitted in April, 1943, and Project PX, which later became the Electronic Numerical Integrator and Computer (ENIAC), was born.

Eckert was the principal project engineer, and Mauchly, because of his teaching responsibilities, could act only as a consultant to the builders. The computer was a parallel machine with thousands of vacuum tubes that could do several operations simultaneously and calculate one thousand times faster than the methods used at that time. The only drawback of the machine was that to change programs sometimes required up to a day to reset hundreds of patch cords and switches.

The ENIAC was completed in February, 1946, and turned over to the Army. World War II was over by then, but the Cold War with the Soviet Union was heating up and the

The Electronic Digital Computer

John William Mauchly and John Presper Eckert were the first persons to build a workable electronic digital computer that was useful for solving mathematical problems. Mauchly was a physicist who wanted to predict the weather but found that all of the calculators available were orders of magnitude too slow to handle the huge amount of data needed to carry out the task. Others had built computing machines that could solve mathematical problems or operate on large amounts of data, but they were very slow and the results often had high uncertainties. Mauchly teamed up with Eckert, an engineer, and built the first usable electronic digital computer to calculate firing tables for Army artillery.

Their Electronic Numerical Integrator and Computer, ENIAC, consisted of thirty units, twenty of which were essentially ten-digit adding machines. The other units could multiply, divide, take square roots, and perform certain logic functions. The final computer contained 17,468 vacuum tubes and could do five thousand additions or fourteen ten-digit multiplications per second. It was programmed with patch cords and switches, so changing programs was very difficult.

This downtime between operations when the patch cords and switches had to be reset led to the next important invention. While the ENIAC was still under construction, Eckert and Mauchly planned a new computer that would do away with most of the cords and switches by including a memory that could remember the different setups and switch the programs as they were needed. They obtained funding for this stored program computer, which they named the Electronic Discrete Variable Automatic Computer (EDVAC), but did not finish construction before they left the Moore School of Electrical Engineering to set up their own computer company.

It was the development of the Universal Automatic Computer (UNIVAC) by Eckert and Mauchly and its use to successfully forecast Dwight D. Eisenhower's victory in the 1952 presidential election that increased public interest in the electronic digital computer and led to the quick expansion of the industry. Eckert and Mauchly showed that the electronic digital computer was a reality and could be used in dozens of different applications in which high-speed calculation was needed. With the additional inventions of the transistor and the computer chip, powerful computers can now be carried around in a briefcase and used practically anywhere on the planet.

Army had many other uses for the computer. ENIAC was moved to Army facilities in Aberdeen, Maryland, and used in the development of the hydrogen bomb and in other military projects for the next eight years.

As early as 1944, Eckert and Mauchly recognized the difficulty in changing programs on the ENIAC and started to design a second machine with a memory that could take over the functions of many of the patch cords and switches and also store data. In January, 1945, a contract was procured to build a stored-program computer called the Electronic Discrete Variable Automatic Computer, or EDVAC.

Before the EDVAC was completed, Mauchly and Eckert resigned from the Moore School after a dispute over patent policy and established their own company, the Eckert-Mauchly Computer Corporation (EMCC). Unfortunately, the company was undercapitalized and had trouble finding buyers for its computers. Its major sale was of a new computer, the Universal Automatic Computer, or UNIVAC, based on the EDVAC design. The company was sold to Remington Rand in 1950, and Eckert became head of the UNIVAC Division. Mauchly consulted for the company on computer applications but left in 1959 to establish his own consulting company, Mauchly Associates. In the late 1960's, he established another company, Dynatron, which consulted on project planning and management techniques such as the critical path method.

Mauchly's last few years were saddened by the invalidation of his patent for a general-purpose electronic computer. He and Eckert had applied for a patent on the ENIAC in 1947 and it had been granted in 1964, but a physicist from Iowa State College, John Vincent Atanasoff, had come forth and claimed that many of the ideas in the ENIAC were his. Mauchly had visited Iowa State in 1941 and had seen pieces of an electronic computer that Atanasoff was building, but he claimed that the ENIAC was nothing like the pieces he had seen. Although the Atanasoff computer was never completed, a judge ruled in 1973 that John Atanasoff was the inventor of the electronic digital computer and the Eckert-Mauchly patent was not valid.

Mauchly received many honors, including election to the National Academy of Engineering and honorary doctorates from the University of Pennsylvania and Ursinus College. He was also made a life member of the Franklin Institute and the Society for the Advancement of Management. His awards included the Pennsylvania Award, the Emanual R. Piore Award, and the Potts Medal. Mauchly retired to his suburban home in Ambler, Pennsylvania, and lived quietly until his death in 1980 at the age of seventy-two.

Impact

Mauchly and John Presper Eckert will be remembered for their three great contributions—the first all-electronic general-purpose digital computer, the first stored-program computer, and the first commercial computer company. The ENIAC was the forerunner of the millions of electronic computers used in the world today. It was originally designed by Mauchly and Eckert to solve mathematical problems, but it was found to be so versatile, with so many applications, that it changed the world.

Electronic computers are now used in every aspect of communication and control throughout the world. Instead of writing letters with a pen or a typewriter, people type up an e-mail and push the Send button, and the message arrives instantaneously. Instead of doing research by going to the library and reading a book or journal, students often go to Google to find the information they need. By the year 2000, 60 percent of the homes in the United States had one or more computers. Today the percentage is even higher.

The microprocessor, a small, single-purpose computer, has even more applications than a general-purpose computer or a personal computer (PC). It controls the engines of cars, it tells an elevator where to start and stop, and it controls digital cameras and edits pictures before they are printed. A complicated machine such as an airplane or space vehicle has hundreds of microprocessors that navigate and help control its engines. In general, computers have made modern life easier and more fruitful.

Hiram Percy Maxim

American mechanical engineer

Maxim's varied career included work in aviation, the automobile industry, communications, and acoustics, and he is best known for his invention of the silencer. His innovations in automobile design provided the essential structure of the modern automobile, and he was a champion of the rights of amateur radio broadcasters.

Born: September 2, 1869; Brooklyn, New York
Died: February 17, 1936; La Junta, Colorado
Primary fields: Automotive technology; communications; mechanical engineering
Primary inventions: Automobile design; Maxim silencer

Early Life

Born in 1869, Hiram Percy Maxim was the only son of Hiram Stevens Maxim, a pioneer in electrical technology and aviation. The elder Maxim's most famous invention was his Maxim gun, the first portable, fully automatic machine gun. His invention earned him wealth, social standing, and (after he became an English citizen) a knighthood. His brother, Hudson Maxim, was also an inventor, specializing in high explosives.

Growing up in such an inventive household, Hiram Percy Maxim soon developed a great appreciation of the technological arts, and he strove to live up to the family name. Attending public schools in Brooklyn, Maxim was so bright that he skipped several years of schooling and graduated early. He was accepted at the prestigious Massachusetts Institute of Technology (MIT), the leading electrical and mechanical engineering institution in the country. He again engaged in an accelerated program, graduating from MIT in 1886. Unfortunately, his father was not there to celebrate his success. The older Maxim, after losing a patent battle over the light bulb with Thomas Alva Edison, had moved to England and was already perfecting his machine gun designs. Unwilling to move to Europe, despite his father's offer to financially support his projects and education, the younger Maxim chose to stay in the United States. The father and son never saw each other again, but they maintained correspondence until the father died in 1916.

Life's Work

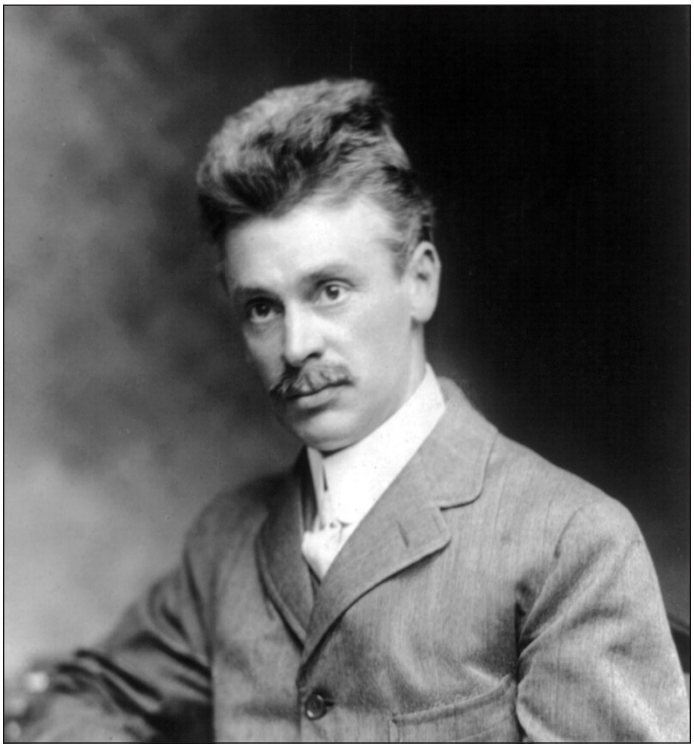
At MIT, Maxim became interested in aviation. He designed and tested several gliders and continued the experiments after he had graduated and moved to Hartford, Connecticut. In 1889, he crashed one of his gliders, badly injuring his right leg. The incident ended his flying days, but not his interest in aviation. Of the fifty-nine patents Maxim received during his career, several were for aircraft navigation and instrumentation devices. He also served on the planning board for construction of Brainard Field (now Hartford-Brainard Airport), one of the first municipal airports in the country.

Maxim also experimented in noise suppression, an interest sparked by his father's work. After years of subjecting his ears to the loud bang of bullet firings, the elder Maxim was almost completely deaf by 1895. Although it was too late for his father, the younger Maxim wanted to prevent hearing loss for others. His solution was the Maxim silencer, a device for reducing the noise of a gun firing. His invention slid onto the end of a firearm and used internal baffles to muffle the sound produced by the combustion of the ammunition propellant. It was not a true silencer, however: It reduced the noise produced by the bullet firing but could not suppress the cracking noise when the bullet passed the sound barrier after leaving the barrel. After demonstrating his concept on firearms, Maxim later adapted his basic design to other applications, such as mufflers for automobiles and sound suppressors for factories. In 1930, Maxim patented a "window silencer," a device that fit into an open window that permitted airflow but blocked exterior noise. Thanks to these inventions, Maxim is considered one of the pioneers of the science of acoustics.

Maxim made some of his greatest contributions in the automotive field. He first became interested in automobiles while at MIT, where several of his colleagues postulated the use of electricity for propulsion. He set aside the issue for several years after he graduated while working at engineering jobs in Indiana and Massachusetts. In 1890, Maxim became the operating superintendent of the American Projectile Company, a maker of munitions for the Army and Navy located in Lynn, Massachusetts. Commuting six miles between Lynn and his home in Salem every day by bicycle soon convinced Maxim that a more efficient mode of transportation would be a good idea, and he began to think again about electrically powered transportation. His plans and experiments brought him into contact with Albert Augustus Pope, a bicycle manufacturer in Hartford interested in getting into the automobile industry. Merging their ambitions, the two men founded the Pope Manufacturing Company in 1895, whose motor vehicle division became the Columbia Automobile Company in 1899. Their first electric car, promoted for its safety compared to the potentially dangerous gasoline-powered cars of the day, was sold in the United States, Canada, France, and the United Kingdom. As gasoline engines became safer, Maxim and Pope changed their designs to accommodate the new technology. Their first gasoline-powered car, introduced in 1900, set the design standard for most automobiles. It was the first automobile with a front-mounted engine (early cars had the engine under the driver's seat) and a steering wheel on the left-hand side of the car (early cars had a centrally mounted tiller).

The Columbia Automobile Company went through several business manifestations as it acquired and merged with rival car companies. The company was able to defeat and acquire its rivals because it possessed the rights to the Selden patent (named for automobile inventor George B. Selden), which allowed Albert Pope to collect royalties from all manufacturers of internal combustion engine vehicles. The Columbia Automobile Company had purchased the rights to the patent and used it to suppress competition. Pope sold his shares in the company in 1903, leaving Maxim as the managing director. Henry Ford was beginning to dominate the automobile industry, however, and in 1911 Maxim also left the company, a few years before the firm went out of business. That year, Ford was able to convince the courts to overturn the Selden patent on the automobile, and his more efficient production systems made him the leading figure in the automobile industry.

Maxim's other great impact was in radio communications. He understood the potential impact of instantaneous communications and received several patents for improved transmitters and receivers. His biggest contribution to radio, however, was his organization in 1914 of the American Radio Relay League (ARRL). With radio in its commercial infancy, Maxim became concerned that government and business might attempt to close the industry to amateur and independent radio transmitters. Maxim and the ARRL defended the rights of independent radio



Hiram Percy Maxim. (Library of Congress) operators to use the airwaves. The ARRL created a network across the country that could relay information rapidly from coast to coast, something that single powerful transmitters of the day could not do. The same relay principle is used today to transmit cellular phone calls.

During the world wars, the U.S. government shut down the ARRL to free the airwaves for military transmissions, but the ARRL reclaimed the right to transmit after each war ended. Maxim created a set of operating guidelines to ensure the professional and ethical standards of the organization. The guidelines made amateur radio respectable, and its high standards ensured that the organization enjoyed a long life.

Automobile Design

Hiram Percy Maxim's solutions to automobile technical problems provided the essential structure of the modern automobile. First, he created the standard exterior appearance. Early automobile makers either made their own chassis or used existing companies', usually wagon or carriage makers. Early cars were called "horseless carriages" because, indeed, they looked like carriages. The engines were located inside the chassis, usually under the driver's seat. This design made the vehicles unstable on rough roads. When Maxim and the Columbia Automobile Company switched from producing electric cars to producing internal combustion engine models, he had the engine placed in front of the chassis. This both lowered and balanced the center of gravity, making the cars more stable and safer to drive.

Maxim also pioneered the left-mounted steering wheel. Early cars had a steering tiller or a wheel centrally mounted on the front axle. This was another holdover from a horse-drawn carriage, in which the driver needed to sit up front to control the horses. However, this arrangement also made it difficult for the driver to look over either shoulder to view other vehicles. By moving the wheel to the left-hand side of the vehicle, Maxim created a safer mode of driving. The left-side steering wheel became the norm when Henry Ford began building only left-side steering automobiles in 1908. Maxim completed the shape of the modern automobile by equipping the vehicle with items that became standard. He installed the first electrically powered headlights, a turn signal, an electric starter, and a muffler to quiet the loud engine. He even installed a seat belt, the first universal safety device in an automobile.

In 1936, Maxim fell ill while returning home by train from a trip to California. He was taken to a hospital in La Junta, Colorado, where he died on February 17. To honor Maxim's role in creating the organization, the ARRL granted him the call sign 1AW, marking him as the first amateur radio operator.

Impact

The son and nephew of famous inventors, Maxim was an important inventor in his own right. His inventive genius touched on many of the early technologies that shaped the twentieth century: flight, electricity, the automobile, and telecommunications. His Maxim silencer brought him fame, and he applied its principle to mufflers for gasoline engines. Through the American Radio Relay League, Maxim championed the rights of amateur radio operators.

Hiram Stevens Maxim

American electrical engineer

Although generally known as an inventor of war machines, Maxim was also an inventive genius whose developments in aerospace might have changed history if he had pursued them.

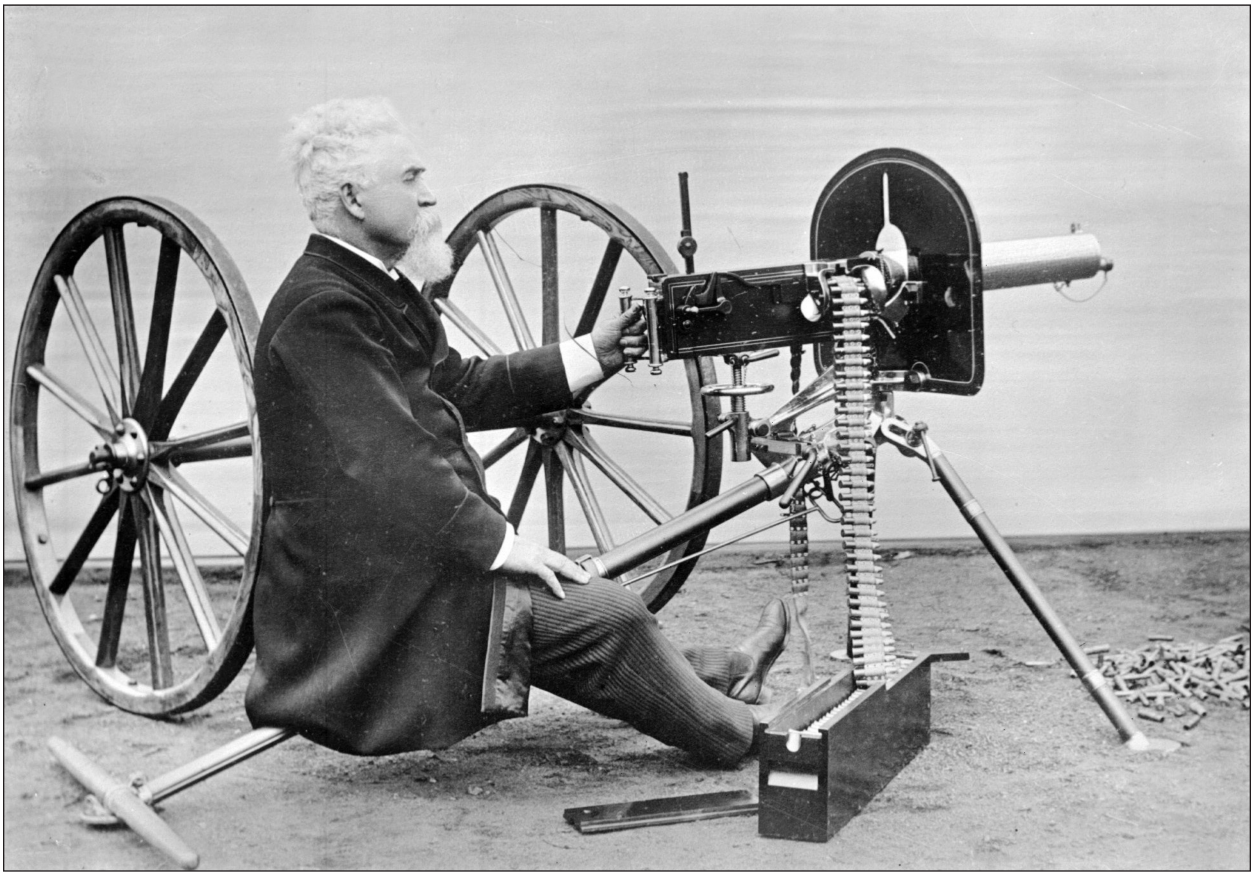
Born: February 5, 1840; Sangerville, Maine
Died: November 24, 1916; London, England
Primary fields: Aeronautics and aerospace technology; military technology and weaponry
Primary invention: Recoil-operated machine gun

Early Life

Born in Maine, Hiram Stevens Maxim was the oldest son of a mechanic employed by the growing railroad industry. Following in his father's footsteps, Maxim apprenticed with a carriage maker until the age of twenty, when he set out to find his own place in the world. Among his early inventions was a spring-loaded mousetrap, the same basic design still used today.

Tinkering with electricity led to other inventions. In 1866, Maxim received a patent for an electrically heated device to curl hair, the curling iron. He also developed products for the railroad industry, including an improved locomotive headlamp. Early lamps used heated gas to produce illumination, and Maxim devised a machine to separate gas elements, allowing for cheaper bulbs and lamps at a time when both were very expensive. These inventions attracted the attention of the United States Electric Lighting Company (USEL), which hired Maxim as its chief engineer. USEL was in the process of developing, patenting, and marketing electric lighting for homes and businesses, and the company set Maxim to create more efficient filaments and bulbs.

By 1880, Maxim had created an improved design, but



Hiram Stevens Maxim with his machine gun in 1880. (Roger Viollet/Getty Images)

The Machine Gun

Hiram Stevens Maxim was the inventor of the first practical machine gun. He recalled when, as a boy, the recoil of a rifle knocked him backward, and he pondered over a way to harness that backward force to power a weapon. Renting a country home outside London, Maxim designed, constructed, and tested a recoil-operated machine gun. The gun used the simple principle of recoil to do a number of complex tasks. When the gun fired, the recoil opened the breech, ejected the spent cartridge, and compressed a spring. The stored energy in the spring then drove the bolt forward again. The forward-moving bolt turned a cog, which drew the next bullet into alignment with the bolt so that the bolt pushed it into the breech when the bolt closed shut. Then the firing pin located in the bolt fired the new bullet, and the process started all over again. Because the gun went through this cycle without human intervention, Maxim had invented the first true machine gun. Like a machine, the gun was turned on when the trigger was pulled, and as long as the trigger remained pulled, the gun would continue to fire. The only way the gun stopped firing was when the operator released the trigger or no more bullets were left.

Maxim's weapon, which improved upon earlier hand-cranked Nordenfelt and Gatling guns, could shoot longer, farther, and with more accuracy than the earlier designs. Using cartridges of his own design, Maxim and his gun could throw out many more bullets than any other gun available at the time. Many armies adopted his weapon, and the machine gun became the centerpiece of infantry forces around the world. The gun first gained infamy when European nations used the Maxim gun to destroy native armies in their push to gain colonies around the world in the late nineteenth century. It became even more infamous when the Europeans used their Maxim guns on each other in World War I, generating massive numbers of dead and wounded over the course of the war.

his work for USEL came into conflict with Thomas Alva Edison. Edison had applied for a patent for the light bulb in 1879, and he believed that Maxim's bulb infringed upon his patent. Edison and Maxim sued and countersued each other for nearly a decade, until the courts ruled in Edison's favor in 1889. With the American patent in Edison's hands, Maxim moved to England to market his electrical system, where Edison's American patent had no leverage. Maxim continued to invent and market electrical devices of his own design, featuring them at technical exhibitions in various European countries.

Life's Work

Maxim was motivated to create his greatest invention while attending one such technical exhibition in Vienna. He ran into an old friend from America, who inquired about Maxim's inventions and business interests. After listening to Maxim's sales pitch on his electrical devices, Maxim's friend instead encouraged him to go into weapons research. The rise of Germany after 1870 was causing a great amount of political tension in Europe, and countries were increasing the size of their armies and spending money on new weapons as the threat of a potential war seemed to grow. Maxim, mired in his patent fight with Edison, decided to take his friend's advice and set about developing a rapid-fire gun. Guns that could fire a large number of bullets very quickly had existed for a couple of decades, but their designs had some drawbacks. The Swedish-designed Nordenfelt gun used four barrels side by side, a clumsy arrangement. The American-designed Gatling gun used six barrels that rotated around a central shaft but had a better arrangement; it was, however, very heavy. Both guns fired when the operator turned a crank that fed rounds by gravity from a hopper, making both guns rapid-firing, but not true machine guns.

At first, Maxim tried to create an electrically driven weapon, but he found that approach to be impractical. Eventually he devised a true machine gun using the principle of recoil. Maxim's design was not only simple; it also was very reliable. Under ideal conditions, the gun could fire six hundred bullets in one minute. The gun did produce a large amount of smoke, but Maxim later redressed this in 1891, when he invented a smokeless powder cartridge for the weapon. Maxim patented the gun in 1885 and formed the Maxim Company in 1886 to market the gun to European armies. After a series of demonstrations—including an impressive demonstration for the Prince of Wales (the future King Edward VII), when Maxim fired the prince's initials into a wooden wall two hundred yards away—the British army adopted the Maxim gun in 1889. Within the next three years, Maxim also saw his gun adopted by a number of armies, including those of Austria, Germany, Italy, Japan, Mexico, and Russia. The United States did not adopt Maxim's gun, instead selecting another model produced by the Colt Firearms Company.

Maxim's company became so lucrative that Vickers & Sons, one of England's largest defense companies, offered to buy him out in 1896. Maxim received a large cash payment for the rights to his patent, a seat on the board of directors, and a fee for every gun sold by Vickers. In honor of the new arrangement, Vickers changed its company name to Vickers, Son & Maxim. Grateful to Great Britain for helping to make his fortune, and still angry that he had lost his patent fight with Edison in America, Maxim became a British citizen in 1899. As a reward for his contributions to the defense of Great Britain, Maxim was knighted in 1901.

While Maxim's machine gun made him famous (or infamous, as all combatants in World War I used copies of his gun to kill each other by the tens of thousands), he was also a pioneer in aviation development. Although Maxim was forced to devote considerable effort to his machine-gun interests over the next years, he began to devote time to aviation in 1889. To test various aircraft designs, most aircraft pioneers relied upon different versions of the wind tunnel, where a model remains stationary and air is blown over the model's control surfaces to see how the aircraft performs. Maxim took a different approach. With his "captive flying machine," he attached models to a suspension rig attached to a spinning frame powered by a steam engine in the center. Maxim could then observe the characteristics of the aircraft model as it moved through the air in the wind tunnel.

The development of this test rig provided another lucrative outlet for Maxim's creativity. He built a larger version of the test rig with cars big enough for people to ride in, creating an amusement ride. Maxim installed his first ride at an exhibition near London at Earl's Court. It was an incredible success, with long lines of patrons willing to spend their money to whiz around in simulated flight. Maxim had made a major contribution to the development of the amusement park, and other inventors soon copied the idea.

Using the aerodynamic information from the test rig, Maxim constructed his first airplane in 1894. It was a massive craft, with two large wings more than 100 feet in length and weighing more than 7,000 pounds. By comparison, the successful Wright brothers aircraft of 1903 had a wingspan of just over 40 feet and a weight of 605 pounds. Maxim had to construct an aircraft that large because of the power plant. His plane was powered by two powerful but bulky steam engines, but these were the best available (lightweight internal combustion engines were still a decade away). On July 31, 1894, Maxim, along with three other men to assist with the flight controls, attempted his first flight. The aircraft surged down an 1,800-foot launch rail, reached an estimated speed of 42 miles per hour, and rose about 15 feet into the air. The craft flew about 200 feet before the engines sputtered and the craft crashed back to earth.

Maxim had to turn his attention to other projects, and he did not return to aviation until 1911, when he partnered in the Grahame-White, Bleriot, and Maxim Company to develop aircraft for military purposes. By that time, however, Maxim was trying to catch up in an existing industry and was no longer the pioneer. The company failed to achieve any technical or commercial success. Later in life, Maxim developed some lesser-known patents that remain in use today, including a pocket menthol inhaler, similar to the pocket inhalers used by asthma sufferers.

Impact

Although a prolific inventor, Maxim remains best known as the inventor of the machine gun. He could not have known what carnage his invention would create in subsequent wars, but he always tried to separate himself from his invention. Unfortunately, the Maxim machine gun, used by all sides during World War I, killed tens of thousands in that conflict, and improved versions of Maxim's design have served in all wars since then. The machine gun remains the dominant infantry weapon in every army's arsenal, and every improvement and development of the machine gun stems from Maxim's pioneering design.

Hudson Maxim

American chemist

The brother of machine-gun inventor Hiram Stevens Maxim, Hudson Maxim invented several types of explosives, the most important of which was smokeless gunpowder, which is now used in all modern firearms.

Born: February 3, 1853; Orneville, Maine
Died: May 6, 1927; Landing, New Jersey
Also known as: Isaac Maxim (birth name)
Primary fields: Chemistry; military technology and weaponry
Primary invention: Smokeless gunpowder

Early Life

One of eight children of a poor family in rural Maine that frequently relocated, Hudson Maxim did not attend school until he was eight years old and did not even wear shoes until he was nine. To earn money for schoolbooks when he was young, he pitched hay on farms, pounded rocks in a granite quarry, and worked in a brickyard. Like his parents, he was exceptionally strong and very hard-working.

At the age of eighteen, Maxim enrolled at Maine Wesleyan Seminary, a coeducational college-preparatory school in Kents Hill that was later renamed Kents Hill School. He attended the school several weeks of each year for seven years, spending the rest of his time earning money to pay for it. When he was twenty, he took a job as a schoolteacher for one term a year and began in a classroom filled with unruly boys who had thrown their last teacher out a window. Maxim later admitted that at that time, he knew little more than his pupils did. However, he learned quickly enough to stay ahead of them and imposed order in the classroom after defeating the toughest boy in a wrestling match.

When he was twenty-two, Maxim hypothesized that all matter is composed of a single type of ultimate atom, and that differences in complex matter are due to the differing arrangements and motions of the atoms' component. In 1889, *Scientific American Supplement* published an article he wrote explaining his theory. When *Scientific American* reprinted the article in 1921, the magazine credited him with anticipating some aspects of Albert Einstein's atomic theory.

Meanwhile, Maxim had moved to Pittsfield, Massachusetts, where he set up a publishing business in 1883. He wrote a self-help book, *The Real Penwork Self-Instructor for Penmanship*, which his own company published. The book sold more than 400,000 copies, and his business grew large enough to employ one hundred people. However, the rise of typewriters and fountain pens killed the market for his book. Maxim also invented a

Hudson Maxim. (Library of Congress)

color-printing process that Pittsfield's *Evening Journal* used to become the first U.S. newspaper with daily color pages.

Life's Work

In 1888, Maxim received a request from his older brother Hiram Stevens Maxim, then living in England, to hire some American workers for his gun company. At that time, Hiram was making a fortune from his automatic machine gun, which became known as the Maxim gun. Hudson took a mechanic and draftsman with him to England, where he went to work for his brother. He and Hiram worked together on many projects, including smokeless gunpowder.

After returning to the United States, Maxim continued his own experiments with explosives and founded the Maxim Powder and Torpedo Company in Squankum, New Jersey—a town that was later renamed Maxim in his honor. Based on nitrocellulose, his smokeless gunpowder became the standard for U.S. Army guns. Maxim's claim that his formula for smokeless gunpowder was his own invention started a bitter feud with his brother. His own formulation was, in fact, different from that of his brother, but neither of them was actually the original inventor of smokeless gunpowder. What they had both done was reverse-engineer a smokeless powder sample that had come from a French government armory.

Maxim next turned his attention to developing smokeless cannon powder. The smokeless cannon powders available at that time were made in the form of flat strips, ribbons, or rods with one perforation. The grains burned when they came into contact with sulfur and charcoal particles, so the powder burned relatively slowly, and pressure decreased significantly as projectiles reached the forward part of the cannons' barrels. Maxim devised a smokeless cannon powder cylinder that was three times as long as it was wide. Each unit was perforated with seven longitudinal holes. These holes allowed the cannon powder to burn evenly and rapidly, producing more ballistic force.

In 1894, Maxim lit a match to test the dryness of a small particle of mercury fulminate compound, forgetting that he was holding another piece of the compound in his left hand. The second piece ignited and blew off his entire hand, leaving the end of his wristbone exposed. His left thumb landed two hundred yards away. He eventually adapted very well to his handicap; he grew

Maximite

Composed of mono-nitro-naphthaline and picric acid, maximite is rated as a high explosive because the velocity at which the detonation propagates through the compound is faster than the speed of sound. Maximite has about 50 percent greater explosive power than an equivalent quantity of dynamite. Even more important, it is extremely stable. Under heat, it simply boils. When it ignited, it burns without exploding.

Maximite's fusion point is below the boiling point of water. Accordingly, it can be safely melted over an open fire and then poured into a projectile. Like water, liquid maximite expands slightly when it solidifies, and it also adheres to the walls of the projectile. These characteristics are among the reasons that it is inexpensive to manufacture.

According to Hudson Maxim's description, after maximite solidifies within a projectile, it remains so stable that it is not disturbed even by the projectile's impact and penetration through an armor plate. It detonates only when a fuse sets it off. Before maximite was used, shells containing high explosives that were fired from cannons had to be fired at relatively low velocities, lest the impulse of the propellants inside the cannon barrels accidentally detonate the explosives within the shells. Maxim promised that using maximite as a high explosive would greatly reduce the risk of accidental detonation. Accordingly, a shell loaded with maximite could be shot with tremendous force, tremendously increasing the shell's range and penetrative power.

Despite the amount of energy that maximite contains, it is a lightweight compound. Accordingly, relatively small cannons firing maximite shells could hit targets at great distances using only small amounts of propellant. The compound's light weight also facilitated the transportation of greater quantities of shells.

When high explosives detonate on hard surfaces—such as armor plates or paved street—much of their energy simply bounces off the surfaces. Thanks to its stability, maximite does not detonate until its shells penetrate the surfaces. Consequently, its explosive energy is directed into the interior of the enemy targets and causes vastly more damage than explosives that detonate on the outside surfaces of ships, buildings, and other armored structures.

At the time Maxim invented maximite, many naval engineers believed that an unsinkable battleship could be built. Maximite made that dream impossible, although many people at the time did not know this. However, despite maximite's many advantages, the U.S. military abandoned its use after a premature detonation of 143 pounds of the compound in a torpedo shell demonstrated that Maxim's formulation was not yet perfected.

skilled at using the hook that replaced his lost hand and was not shy about gesturing with it as one would with a hand.

Meanwhile, Maxim's first marriage, in Pittsfield, ended in divorce after five years. In 1896, he married Lilian Durban, the daughter of a nonconformist London pastor and magazine writer. Like her husband, Lilian had a special interest in poetry, and she worked with him in their home laboratory in Brooklyn, New York. In 1898, Maxim sold his factory and patents to E. I. du Pont de Nemours and Company, for which he worked his remaining years as a consulting engineer.

Another of Maxim's major inventions was maximite, an explosive designed for use in artillery. (His brother Maxim used the same name for his own smokeless gunpowder, an unrelated product.) In 1901, the U.S. Army bought the exclusive right to use maximite from Maxim. Maximite needed delayed-action detonating fuses to work in artillery shells, so it could be activated after the shells penetrated enemy armor. Maxim invented the fuse, which in 1908 the U.S. Navy adopted.

In 1905, Maxim sold stabillite, an improved smokeless gunpowder, to du Pont. Earlier versions of smokeless gunpowder had to be dried for months before they could be used to give the volatile solvents left over from the manufacturing process time to evaporate. Because stabillite used no volatile solvents, it could be used immediately.

Among Maxim's other important inventions was motorite, a fuel for torpedoes and torpedo boats that he called his most difficult invention. Five feet long, seven inches in diameter, and dense and rubbery, each motorite bar was inserted in a steel tube. Each tube was open at one end, which was screwed to a combustion chamber. When a bar was ignited, water was pumped into the chamber and turned to steam by the motorite's heat. A series of baffles directed the steam out the combustion chamber. The combustion of the motorite combined with steam power to propel the torpedo, approximately doubling the amount of energy used by self-propelled torpedoes. In 1912, Maxim gave the rights to motorite to the U.S. Navy for one dollar, but the Navy never used it. Maxim also invented an improved process for producing calcium carbide that was bought by the Union Carbide Company.

After the United States entered World War I in 1916, Maxim chaired the Committee on Ordnance and Explosives for the Naval Consulting Board. He also worked on military inventions, including an underwater mine that was detonated by the magnetic field emitted by submarines that approached within fifty feet. That invention he donated to the U.S. government.

Although Maxim rested only reluctantly, he enjoyed spending time at his country estate at Lake Hopatcong, New Jersey. However, he had a working laboratory at his estate, which was only three miles from his Squankum factory. The loss of his left hand did not dampen his enthusiasm for physically exercise, especially playing tennis. Maxim twice played the role of King Neptune to open the Miss America Pageant in Atlantic City. Sporting a full beard, he rode a seashell barge and was surrounded by mermaids.

Maxim was also a serious lecturer and writer who promoted women's rights and opposed alcohol prohibition, which he called a national calamity. In April, 1926, he testified before a subcommittee of the Senate Judiciary Committee on the harm caused by the Prohibition laws and extolled the benefits of moderate alcohol consumption. He argued that people who abstain from alcohol tend to consume excessive amounts of sugars and starches in unconscious compensation for missing the stimulation and feeling of well-being produced by alcohol. A year later, when he died of cancer, on May 6, 1927, he was lauded by the press and revered by most of the public.

Impact

The importance of Maxim's development of smokeless gunpowder can be seen in its impact on battlefields. For centuries, smoke clouds discharged by black gunpowder revealed the positions of gunners to their enemies and often obscured the gunners' own vision. The creation of smokeless powder was especially important for the Maxim gun, which fired six hundred rounds per minute. It was also a welcome improvement for the Maxim gun's older American competitor, the Gatling gun. Smokeless powder is actually not a true powder; it takes its name from old-fashioned black gunpowder. It later became the standard for virtually all modern firearms. Even in guns with slow firing rates, it is cleaner and produces much less fouling in gun barrels, thereby helping to maintain accuracy and reduce malfunctions.

Maxim's development of a technique for manufacturing powder without use of volatile solvents became especially important during wartime, when rapid production was necessary. However, his own specific process was not used because one of its components, trinitroanisol, damaged human skin when the gunpowder was touched.

During World War I, Maxim's smokeless cannon powder was used extensively by the Allies, including the Russians. It allowed large guns to be fired more accurately and with higher muzzle velocities. It enabled guns to hit targets at greater distances and deliver greater destructive force. Artillery weapons killed more soldiers—on both sides—than did any other weapons in the war. Without Maxim's powder, the Allies would have been at a significant disadvantage.

Dimitry Ivanovich Mendeleyev

Russian chemist

Mendeleyev's periodic table was one of the greatest achievements of chemistry in the nineteenth century. His table provided gaps for future elements, and he accurately predicted the properties of hitherto undiscovered elements.

Born: February 8, 1834; Tobolsk (now Tyumen Oblast), Siberia, Russia
Died: February 2, 1907; St. Petersburg, Russia
Primary field: Chemistry
Primary invention: Periodic table of elements

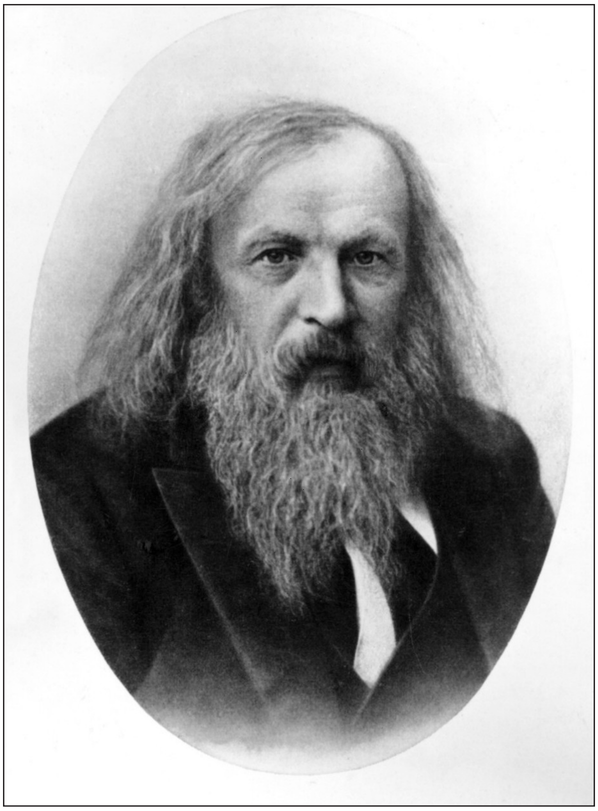
Early Life

Dimitry Ivanovich Mendeleyev (mehn-duhl-AY-uhf) was born on February 8, 1834, in Tobolsk in western Siberia. He was the youngest of fourteen (some sources say seventeen) children. His father, Ivan Pavlovich Mendeleyev, a headmaster of a local school, went blind after Dimitry's birth, so his mother, Maria Dmitrievna Mendeleyeva (born Kornilieva), had to work in their glass factory. Dimitry went to the local school where his father had taught but also received practical education at his mother's glass factory, where he spent hours listening to the chemist and the glassblower talk about glassmaking.

When Mendeleyev was a young teenager, his father died and the glass factory burned down. His mother was determined that Mendeleyev and her daughter Elizabeth (her other remaining dependent child) receive an education, so they traveled to Moscow and then to St. Petersburg. Mendeleyev was refused entry to St. Petersburg University because he was Siberian. In 1850, at age sixteen, he was accepted at the Central Pedagogic Institute of St. Petersburg to study science. Ten weeks later, his beloved mother died from tuberculosis, followed by Elizabeth. Mendeleyev studied diligently despite his personal tragedies. At age twenty, he published his first scientific article, "Chemical Analysis of a Sample from Finland," the first mark of an amazing young scientist. A year later, in 1855, he earned the Student of the Year Award from the institute, a well-deserved honor. After graduation, he obtained an advanced degree in chemistry and in 1857 received his first university appointment.

Life's Work

In the late 1850's, the Russian government tried to keep up with advances in science and technology, paying a number of Russian scientists, including Mendeleyev, to study in Europe. Between 1859 and 1861, he studied at the Universities of Heidelberg and Paris. During this time, he met leading scientists, including chemists Henri Victor Regnault (in Paris), Robert Wilhelm Bunsen, and Stanislao Cannizzaro and physicist Gustav Kirchhoff, learning such things as atomic weight and ways of determining chemical composition of substances, knowledge influential in his later work.



Dimitry Ivanovich Mendeleyev. (Getty Images)

Back in St. Petersburg, Mendeleyev continued to teach and found time to write. In 1861, he published *Organic Chemistry*, a prize-winning textbook that raised his standing in Russian chemistry education. In 1864, he was appointed professor of chemistry at the Technological Institute and married Feozva Leshcheva. They had a son, Vladimir, and a daughter, Olga. Their marriage was unhappy, and he eventually married Anna Ivanova Popova in early 1882, with his divorce finalized one month after remarriage. He had four children with Anna.

In 1867, Mendeleyev was made professor of general chemistry at St. Petersburg University, the institution that had rejected him seventeen years earlier. He was unable to find an appropriate textbook for his classes, so he began writing his own. The result was *The Principles of Chemistry*, volumes 1 and 2, which he wrote between 1868 and 1870. This book provided a framework for modern chemical and physical theory and was a best seller for many years. While writing the textbook, Mendeleyev stumbled on a discovery that would lead to his greatest achievement and ultimately transform the subject of chemistry: the periodic table of elements.

Other chemists had attempted to organize the elements by their properties. In 1803, English chemist John Dalton first developed the idea of atomic weight—the average mass of an atom of an element. Since then, other chemists—including Johann Wolfgang Döbereiner, William Odling, Julius Meyer, and John Alexander Reina Newlands—had tried to arrange the elements by atomic weight and looked for regular patterns in chemical properties of the atoms. In the mid-1860's, Newlands presented his idea of ordering the elements, which he christened the "law of octaves." His idea came very close to Mendeleyev's, but it was greeted with ridicule. Disheartened, Newlands gave it up and eventually retired from chemistry.

Mendeleyev was convinced that the order of the elements lay in their atomic weights. When he arranged the elements in an ascending order by atomic weight, he noticed that the chemical properties of the elements were already grouped into families. He realized that he had to leave gaps in his table for elements yet undiscovered. Further, he believed that he could predict the properties of the elements of those spaces. His predictions were proved right; as the elements gallium, scandium, and germanium were eventually discovered, his periodic table became a breakthrough in chemistry.

In the 1870's, Mendeleyev's periodic table was chal-

The Periodic Table of Elements

Dimitry Ivanovich Mendeleyev's classification of the chemical elements in a logical order was one of the greatest triumphs of chemistry. The periodic law is a fundamental principle in chemistry that enables chemists to understand the array of elements in the table. The law states that chemical elements show repeating ("periodic") properties when arranged in order of increasing atomic number to form the periodic table.

By listing the known elements and using their known atomic weights, Mendeleyev recognized repeating patterns. The elements were charted into rows (periods) and columns (groups) wherein every element had its place and the initial gaps were filled later with newly found elements. On the assumption that there was a pattern to the elements, Mendeleyev left blank spaces where elements seemed to be missing. The patterns in chemical and physical properties were all represented.

On February 17, 1869, Mendeleyev sat with a pack of sixty-three cards, inspired by the card game called patience (solitaire), in which cards are arranged horizontally by suit and vertically by number. He wrote the names and properties of the elements on each card and played "chemical solitaire," arranging the elements in horizontal rows called "periods" and vertical columns called "groups" and placing the elements in groups of seven. He organized them the same way as John Alexander Reina Newlands had arranged his periodic table a few years earlier, with the difference being that Mendeleyev's key property was the element's valency, the chemical-combining power of an element. According to Mendeleyev, the elements ranked from one to four on the valency scale.

As he plotted the valency against atomic weight, Mendeleyev found that the periods fell and rose much like Newlands's "law of octaves." Seven steps, taken in order of atomic weight, covered the elements from lithium (atomic number 3, valency 1) to carbon (atomic number 6, valency 4) and on to fluorine (atomic number 9, valency 1). He ran another seven steps to the next row, from sodium (atomic number 11, valency 1) to silicon (atomic number 14, valency 4) and on to chlorine (atomic number 17, valency 1). Somehow, the succeeding periods fell at each end in the same way as the first two periods, with more elements of the same valency in the middle.

The new system did not win immediate acceptance, but its greatness became apparent with time. In November, 1870, Mendeleyev described the properties of three hitherto unknown elements he named eka-aluminium, eka-boron, and eka-silicon. Within sixteen years, all three were discovered and named respectively as gallium (1875), scandium (1879), and germanium (1886)—conforming closely to his predictions. A half century later, the rationale of Mendeleyev's work gained a firm foundation in the concept of orbits presented by Danish physicist Niels Bohr, who relied on Mendeleyev's periodic table. By the mid-1950's, other discoveries had been made possible through the table's elemental relationships—for example, the discovery by James D. Watson and Francis Crick of deoxyribonucleic acid (DNA), the building block of life.

lenged by the scientific community, but eventually he won international renown. In 1882, he received the Davy Medal from the Royal Society of London. The periodic table paved the way for scientists to discover new elements. By 1898, the periodic table contained the "rare gases" discovered by Lord Rayleigh and William Ramsay, giving it eight groups instead of seven.

Mendeleyev continued to teach at the university after creating the table. He was a dedicated educator and wrote more than 250 science articles that appeared in journals and science magazines. One year before his death, he published "A Project for a School for Teachers" and "Toward Knowledge of Russia." Although he was a scientist, he took interest in politics and the state of Russia. His political activism got him into trouble, and he was forced to resign from his teaching post at St. Petersburg University in August, 1890; however, because Mendeleyev was a popular national figure, the government was obliged to find him other employment. In 1893, he was appointed director of the Bureau of Weights and Measures, a position he held until his death.

In 1905, Mendeleyev received the Copley Medal from the Royal Society of London and other honorary degrees from universities around the world. Two years later, while listening to a reading of Jules Verne's *Les Anglais au Pole Nord* (1866; *A Journey to the North Pole*, 1875), he died peacefully in his home. Today he is remembered as the Russian chemist who discovered the interrelationship between the chemical elements that transformed chemistry into a logical branch of science through his greatest achievement, the periodic table of elements. Though he was not awarded a Nobel Prize, he received a rare distinction when the synthetic element Mendelevium (atomic number 101) was named for him.

Impact

Mendeleyev charted the positions of the elements in what became known as the periodic table of elements, and researchers of the late nineteenth century expanded the principles of chemical knowledge enormously because they had a logical foundation upon which to build their ideas. Before Mendeleyev's periodic table, chemistry as a science was in a fair amount of chaos. Although new elements were being discovered, there was little, if any, consistency in the use of symbols and abbreviations, and no one could work out how to organize the elements in a sensible way. Mendeleyev listed elements according to their known atomic weights and recognized repeating patterns in their behavior. He wisely left gaps in his table, anticipating that they would be filled by future discoveries, and indeed the "missing" elements were discovered. He also predicted the discovery of new elements with extraordinary accuracy, and he set other chemists on the trail for other hidden elements.

By the beginning of the twentieth century, chemistry was progressing as rapidly as physics, and links between them were becoming better understood, so that chemistry could successfully underpin physics, providing a symbiosis that led to faster advances in science. Chemical knowledge and biological insights also began to fuse, giving the world both organic chemistry and biochemistry, whose combination has created some of the most profound developments in both pure and theoretical science. Today, no chemistry classroom or chemical laboratory is complete without a periodic table of elements.

Gerardus Mercator

Flemish cartographer

Mercator was a Flemish engraver, surveyor, scientific instrument maker, and mathematician best known for the map projection bearing his name. He is considered to be the first modern cartographer.

Born: March 5, 1512; Rupelmonde, Flanders (now in Belgium)
Died: December 2, 1594; Duisburg, Duchy of Cleve (now in Germany)
Also known as: Gerhard Kremer (birth name); Gerard de Kremer *or* Cremer
Primary fields: Cartography; geography
Primary invention: Mercator projection map

Early Life

The son of a shoemaker, Gerardus Mercator (gehr-AHR-duhs mur-CAY-tur) was born Gerard Kremer in Rupelmonde, Flanders, near the present-day city of Antwerp, Belgium. His family was not wealthy, so an uncle provided financial support for fifteen-year-old Gerardus to attend Shertogenbosch, a monastic school in the Netherlands. While at Shertogenbosch, Gerardus learned Christian theology and Latin and developed skills in writing with italic script. In 1530, Gerardus enrolled at the University of Leuven (Louvain) to study philosophy and mathematics. Following a common practice among young scholars of the time, Gerardus changed his name from Kremer, meaning "peddler," to the Latinized Mercator, meaning "merchant." While attending the university, Mercator was captivated by lectures from Gemma Frisius (1508-1555), a Dutch astronomer and mathematician who became Mercator's teacher and mentor. In addition to his academic pursuits, Mercator became interested in the design and construction of scientific instruments, including globes and surgical tools. Mercator was awarded a master's degree in philosophy in 1532. At the age of twenty-four, he married Barbara Schellekens, who gave birth to the first of three boys and three girls the following year.

Although Mercator's principal source of income came through the construction of instruments, he maintained a strong interest in mapmaking and engraving. In 1537, he published his first map, a 17-by-39-inch representation of Palestine on six panels intended to be used for illustrating Bible texts. The map was a commercial success, remaining in print for more than forty years. In 1538, Mercator created a world map based on a double cordiform, or heart-shaped, projection. This map was considered innovative at the time because it separated America into separate northern and southern hemispheres and depicted North America as physically separate from Asia.

Life's Work

Mercator's fame expanded with the 1540 publication of his map of Flanders (*Exactissima Flandriae descriptio*) based on field surveys carried out between 1537 and 1540. The map was deemed to be extremely accurate for its time because Mercator used triangulation methods in the field. It was also during this period that Mercator's skills in creating scientific instruments brought him in contact with navigators and cartographers from Portugal and Spain who were associated with the royal court of Holy Roman Emperor Charles V (1500-1558).

Mercator's shift toward Protestantism and growing scholarly reputation made him a target for religious extremists and led to his arrest in 1544 for heresy. After seven months imprisoned in the Rupelmonde Citadel, he was released at the urging of friends, colleagues, and local officials. However, others detained during the same

Gerardus Mercator. (Library of Congress) period were held longer, including four who were executed. In 1552, Mercator moved his family to Duisburg on the Rhine River in Germany to assist in the organization of a new university. Although the university was never realized, Mercator received an appointment as cosmographer to Duke Wilhelm of Cleve (1516-1592).

At his workshop in Duisburg, Mercator remained busy fulfilling requests for maps, globes, and scientific instruments from both royal and private patrons. In 1554, he published a map of Europe in fifteen separate sheets using information from existing maps and field reports. Searching for more accurate geographical representations, Mercator demonstrated a willingness to abandon older theories established by ancient scholars such as Ptolemy. For example Mercator recognized that the Canary Islands were much further west of the Straits of Gibraltar than was accepted at the time. New measurements were incorporated into his European maps, such as a reduction in the length of the Mediterranean Sea by 10 degrees of longitude. In 1564, he printed a map of England, Scotland, and Ireland on eight panels that was considered to be extremely accurate. Although not revealed on Mercator's maps, fieldwork for this map is believed to have been carried out by John Elder, a Scotsman who traveled throughout England and Europe. Cartographic historians believe Elder copied information from secret maps maintained at the British Royal Library.

Mercator's most significant contribution was the map projection bearing his name. A long-standing difficulty in ocean navigation during the 1500's was a discrepancy between compass readings and directions shown on charts, causing seafarers to miss their destinations by hundreds of miles. Created in 1569, the Mercator projection addressed this issue by representing the compass bearing between any two points as a straight line. Maps based on the projection were characterized by parallels and meridians that crossed at right angles. Although useful for navigation, the increasing distance between parallels extending from the equator to each pole resulted in distortions to the sizes of terrestrial regions, especially in higher latitudes.

In addition to compiling and engraving flat maps, Mercator also contributed procedures for the construction of globes. Mercator constructed his first globe in 1537 for his mentor, Frisius. In lieu of time-consuming methods for creating globes by engraving directly to a spherically shaped wood or brass form, Mercator developed a method in which papier-mâché was applied over a wood mold for

The Mercator Projection

Late Renaissance exploration of the world, especially the Americas, brought an increased demand for maps to support navigation at sea. A long-standing problem for seafarers was difficulty holding a line of constant compass bearing, or loxodrome, resulting in navigation errors of hundreds of miles. Flemish cartographer and mathematician Gerardus Mercator is credited with developing the first projection capable of maintaining loxodromes as straight lines. The term "projection" refers to a mathematical system for transferring information from the spherical shape of Earth to a flat surface. Mercator's cylindrical projection featured parallels (lines of latitude) and meridians (lines of longitude) crossing at right angles. Whereas meridians on the spherical Earth converge at the poles, they remain equidistant on the Mercator projection. Likewise, instead of growing progressively shorter with increases in latitude, the lengths of parallels on the Mercator projection remain constant. The resulting map has parallels that are close together near the equator and more widely spaced in higher latitudes.

Despite its advantages, the projection was not used immediately for navigation because Mercator did not release the mathematical formula used in its construction. Others, such as Antwerp mathematician Michiel Coignet (1549-1623) attempted to solve the problem by calculating the length of a loxodrome in small sections. In 1599, mathematical astronomer Edward Wright (1561-1615) published "Certaine Errors in Navigation," which presented the basic mathematical foundation for the projection.

An unfortunate attribute of the Mercator projection is severe distortion to the sizes of areas in high latitudes when compared to regions in the tropics. For example, Mercator's map shows Greenland (840,003 square miles) as larger than Africa (6,870,687 square miles). Because of the increasing space between parallels, world maps based on the Mercator projection must be drawn with high-latitude areas omitted, meaning that Greenland and Antarctica are cut off. Although well-suited to navigation, the popularity of the Mercator projection resulted in inappropriate or poorly conceived applications such as political maps and wall-sized world maps. An equal-area cylindrical projection introduced by Arno Peters (1916-2002) in 1973 attempted to "correct" misconceptions in the relative size of areas that had been promoted by widespread use of the Mercator projection.

each hemisphere. The two halves were then joined and covered with a mixture of thin plaster. Subsequently, Mercator would apply a set of flat maps, called gores, with edges that narrowed near the poles. In 1541, he created a navigator's globe intended for use at sea that measured 16.5 inches in diameter. This was followed in 1551 with a celestial globe.

Mercator dedicated his later years to a project for joining revised versions of Ptolemy's maps with a collection of modern maps he called "Atlas," in honor of the legendary philosopher, scientist, and king of Libya credited with constructing the first terrestrial globe. Published in 1578, the first volume of Atlas included twenty-seven of Ptolemy's maps restored and supplemented with an index of place names. In 1585, Mercator published another volume that included modern maps of Germany, France, and the Netherlands, with a third volume appearing in 1589 that contained additional maps showing the Balkans and Greece. Mercator died in 1594 and was buried inside St. Savior's Church in Duisburg. At the time of his death, he had outlived five of his children. A year after his death, the final volume of his atlas was published by his youngest son. "Atlas sive cosmographicae meditiones de fabrica mundi et fabricati figura" ("Atlas, or Cosmographic Meditations on the Fabric of the World and the Figure of the Fabrick'd") included 107 maps, most representing southern and western Europe. Many of Mercator's original engravings were sold to Dutch cartographer Jodocus Hondius (1563-1612), who continued publishing the maps for many years. Hondius and his sons also published smaller and simplified versions of Mercator's original atlas in several editions, including French, German, and English language translations.

Impact

Mercator's cartographic methods challenged conventional thinking. In addition to producing some of the most accurate maps of his day, he was the first to divide the continent of America into two parts, *Americae pars septentrionalis* (the northern part of America) and *Americae pars meridionalis* (the southern part of America). Mercator is also credited with being the first to use the word "atlas" to describe a book that contained a collection of maps. Mercator is best known for developing the projection named for him that improved the usefulness of charts employed in sea navigation. Maps based on the Mercator projection were used for centuries after Mercator's death by explorers, including Captain James Cook (1728-1779). More recently, Mercator's map projection has fueled controversy among geographers, historians, and others because of its use in creating misleading maps.

Mercator was remarkable among cartographers of his day. Unlike some of his contemporaries, he personally constructed and engraved the majority of maps in his publications. His maps were innovative, accurate, and aesthetically attractive. In addition to his contributions to mapmaking, engraving, and the construction of scientific instruments, Mercator published books on topics ranging from science and mathematics to ancient geography. His versatility as a scholar is further demonstrated by his studies of terrestrial magnetism.

Ottmar Mergenthaler

German American mechanical engineer

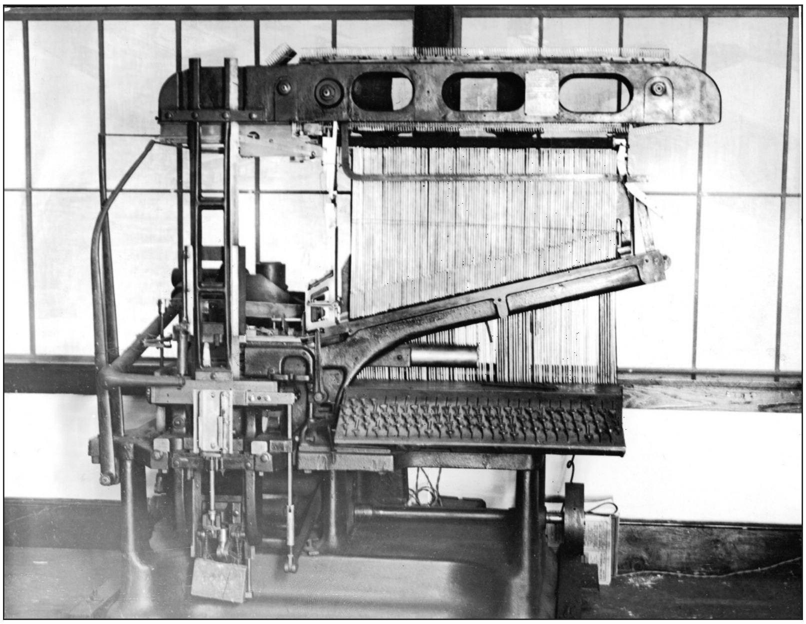
Often called the "second Gutenberg" because of his contributions to the advancement of movable type, Mergenthaler invented a machine that could set type quickly and accurately at the touch of a key.

Born: May 11, 1854; Hachtel, Württemberg (now in Germany)
Died: October 28, 1899; Baltimore, Maryland
Primary field: Printing
Primary invention: Linotype machine

Early Life

Ottmar Mergenthaler (OT-mahr MUR-guhn-thaw-lur) was born in the town of Hachtel in the valley of the Tauber River in Württemberg (now in Germany). Soon after Ottmar's birth, his father, a schoolteacher, moved to Ensingen, where little Ottmar would prove a mechanical prodigy. As a boy at his stepmother's side, he created for her a dough press to make *Springerle*, his favorite Christmas cookie. The town square in the Mergenthalers' new hometown was dominated by a large and beautiful clock, which, however, had not run for years. None of the clockmakers in the region could get it to work. One evening in 1868, however, the people of Ensingen heard the melodic chimes of evensong, and they soon realized that the schoolteacher's thirteen-year-old son had accomplished what the master clockmakers had not been able to do.

When young Ottmar begged to be a watchmaker, his father apprenticed him to a stepuncle named Louis Hahl in Bietigheim. When he heard glowing stories about life in America, however, where Hahl's son August owned a machine shop, the journeyman Mergenthaler wanted to move there. In 1872, when Ottmar turned eighteen, the younger Hahl paid his passage to Baltimore. Mergenthaler made knives and tools, and in two years he had his first patent.



The world's first Linotype machine. Ottmar Mergenthaler's invention revolutionized printing, especially the newspaper publishing industry, with faster, more efficient typesetting. (Getty Images)

Life's Work

On the strength of his inventive genius, Mergenthaler was made a partner in August Hahl's machine shop in 1875. They specialized in building models for other inventors. About ayear later, a man named Charles Moore came to the firm of Hahl and Mergenthaler for help with an invention of his that, like the Ensingen clock, simply did not work. Moore, a printer, wanted to be able to set type mechanically, eliminating the inefficiency of hand-setting. Mergenthaler immediately saw major flaws in Moore's design, and he set about redesigning the "transferable typewriter" (as Moore called it) from scratch.

One aspect of Moore's design captured Mergenthaler's imagination. Instead of placing type directly into a frame for printing, Moore envisioned a brass mold into which molten lead would be poured to make a whole line of type at a time. Moore's description of the mold process sounded precisely like the dough press Mergenthaler had made for his stepmother's cookies. The mold, however, was only one part of the process. In fact, the machine Moore had wanted was really two machines: The process required selecting individual letters from a case of type, framing them a line at a time, pressing them into a mold, pouring molten lead, allowing it to harden, and depositing the line of type in one lead slug, to be placed on the press. So many operations were needed that it took Mergenthaler more than a decade to work out all the bugs.

Each year brought a major setback. Early in the process, a fire in Mergenthaler's shop destroyed all of his plans and models. He was tempted to give up the project, but the thought that his father the schoolteacher had wanted him to be an educator too, and that his invention could drastically reduce the cost of books, made him persevere. In addition, one of the neighboring firms on Mercer Street in Baltimore was that of printer Louis C. Schneidereith, a fellow German American who was professionally interested in Mergenthaler's invention, and he encouraged the inventor not to give up. Another early supporter was Whitelaw Reid, editor of the New York *Herald Tribune*, who wanted his paper to get in on the ground floor of this new technology.

At each step of the development of the Linotype machine, Mergenthaler broke new ground in solving mechanical problems. With each solution, he filed a new patent; more than fifty patents were involved in Mergenthaler's first machine. A major breakthrough was simply thinking of it as a single machine rather than a series of devices, as Moore had envisioned. One day while riding the train, the obvious occurred to Mergenthaler: Unite the processes of casting and stamping in the same machine. Finally, in 1886, Mergenthaler filed his final Linotype patent—for the completed machine, patent number 317,828. On July 3 of that year, Mergenthaler demonstrated the Linotype to the *Herald Tribune*'s compositors, and the paper began converting to machine typesetting immediately. To show that the new technology was not limited to newspapers, Mergenthaler and the

The Linotype Machine

Ottmar Mergenthaler's Linotype machine was the first true innovation in typesetting since Johann Gutenberg had introduced movable type to Europe four centuries earlier. The beauty of the machine is the complexity of the design (with more than five thousand parts in the initial design; by 1892, Mergenthaler had reduced that to thirty-five hundred), combined with the simplicity of operation. The Linotype operator simply types at a keyboard of ninety characters. Like the typewriter keyboard, the Linotype does not use alphabetical order: the characters are arranged according to frequency, from most common (on the left) to least-used (on the right). No shift key is necessary: capital and lowercase letters have separate keys, capitals in white on the left, lowercase in black on the right, and numbers and other characters in blue in the middle.

Striking a key releases a brass mold (matrix) from a magazine, a vertical box divided into ninety columns (channels), each containing a different character. Each matrix has a letter or other figure engraved on it; this becomes the mold for the line of type. For type smaller than twenty-four points, each matrix has two forms of the letter or character, roman on the bottom and italic on the top. To switch to italic, the operator pushes in a rail that raises the matrix, causing the italic form of the letter to be impressed. Each letter is deposited onto a frame called the assembler, side by side in sequence as it is typed. When a space is needed, the operator touches a space-band lever to the left of the keyboard, and a blank matrix (space band) is added. The space band is wedge-shaped so that it can expand to make the space between words wider or narrower as needed to justify (line up left and right) the line.

As soon as a line of type is completed, a reservoir of hot metal (550° Fahrenheit, or 288° Celsius) empties into the matrices, forming a line of metal type called a slug. The molten metal is then water-cooled so that the slug hardens immediately. It then passes to a knife block assembly that trims any excess metal, and the slug is ejected. The matrices are immediately returned to the magazine, so that the process can never exhaust even the most common letter—the lowercase *e*. That letter actually takes up two channels (the first two on the left) so that, while the keyboard has ninety keys, the magazine actually has ninety-one channels. The returning matrices are sorted in the distributor. Each matrix has a unique pattern of teeth, like the wards on a lock and key. As soon as a returning matrix reaches the channel in which it belongs, the cut-away teeth of the distributor bar match the teeth of the matrix, and it falls into the proper channel. The beauty of Mergenthaler's design is that, once each line has been typed, the remaining process is automatic.

Herald Tribune published *The Tribune Book of Open-Air Sports* the following year (1887).

The compositors had mixed feelings about Mergenthaler's machine. On one hand, their union had been pressing the *Herald Tribune* for a nine-hour workday; with the paper's numerous editions, most typesetters had been working twelve or more. The Linotype made the shorter workday possible. Unfortunately, it also led to the loss of many typesetting jobs. Union trouble and complaints of shareholders delayed the implementation of this revolutionary technology. Other newspapers, partly out of rivalry with the *Herald Tribune*, opposed the new machine in editorials. The German press was particularly vicious.

Mergenthaler lived long enough to see his invention triumph, however, and become, by the late 1890's, the standard means of setting type for American newspapers. A decade after his initial demonstration, when Mergenthaler returned to visit his hometown in Germany, the full impact of his invention was finally acknowledged both there and abroad, and he was hailed as a hometown hero. Upon his return to Baltimore, however, Mergenthaler, worn out from the trip, sought medical attention and discovered that he had contracted tuberculosis. Mergenthaler was only forty-five years old when he died in 1899.

Impact

For nearly a century, before the advent of computer typesetting in the 1970's, Mergenthaler's Linotype was virtually the only way text was printed for large press runs in the United States and Europe. The printing industry called the machine "Linotype," but well into the 1970's journalists still called the Linotype machine a "Mergenthaler." Before the summer of 1886, not a single U.S. newspaper had more than eight pages—not even in press-hungry New York City, with its dozens of dailies. A skilled union typesetter could set a line per minute for a pre-Linotype newspaper. With Mergenthaler's machine, the rawest apprentice could set four per minute; with practice, up to seven. Since that labor constituted the major cost of printing a newspaper, Mergenthaler had effected a fourfold reduction in cost. The hefty Sunday paper of one-hundred-plus pages in several sections was now feasible—and it soon appeared. Mergenthaler's influence is also remembered in two legacies in the Baltimore area: The city's major vocational school is named after him (Mergenthaler Vocational High School, known to locals as MERVO), and, on the collegiate level, one of the academic buildings at The Johns Hopkins University is Mergenthaler Hall. Other great inventors of his time—an era rich in inventors—admired his accomplishment. Thomas Alva Edison called Mergenthaler's Linotype the eighth wonder of the world.

Georges de Mestral
Swiss engineer

Mestral revolutionized the fastening industry with his invention of Velcro. The multiuse product totally changed the concept of fastening and made it easy, quick, and adaptable.

Born: June 19, 1907; Colombier, Switzerland
Died: February 8, 1990; Commugny, Switzerland
Primary fields: Household products; manufacturing
Primary invention: Velcro

Early Life

Georges de Mestral (zhohrzh deh meh-STRAHL) was born at Château de Saint-Saphorin-sur-Morges in Colombier, Switzerland, on June 19, 1907. He was the son of Albert de Mestral, an agricultural engineer, and Marthe de Goumoëns. From an early age, Mestral was interested in technology. When he was twelve years old, he designed a toy airplane for which he obtained a patent. He studied at the École Polytechnique Fédérale de Lausanne and graduated in 1930. He then worked in the machine shop of an engineering company. In 1932, he married Jeanne Schnyder; he remarried in 1949, to Monique Panchaud de Bottens; and his third marriage was to Helen Mary Dale. He had two sons, Henri and François.

Mestral enjoyed participating in outdoor activities and was an amateur mountaineer and a hunter. He often took long walks accompanied by his dog. In 1941, while hunting in the Alps near Geneva, he noticed how burdock burrs stuck to his dog's coat and to the wool pants he was wearing. Mestral was fascinated by this phenomenon and began to study the burrs under a microscope. He discovered that the burrs had small hooks that fastened themselves into the fibers of his trousers and also became entangled in his dog's fur. Mestral believed that this configuration of hook and loop could be used to fasten two items together if he could discover a way to make the hooks and loops.

Life's Work

After his discovery of the hook-and-loop concept in 1941, Mestral spent the next eight years searching for the right materials to use to create a fastening system. During most of this time, Mestral met with little encouragement. Most people gave little credence to the practicality of creating fasteners based on the sticking power of burrs. Mestral eventually found a weaver in Lyon, France, who had enough faith in Mestral's idea that he made two cotton strips based on Mestral's theory. The strips worked but were quickly worn out.

Mestral then decided to try various synthetic materials. He discovered that nylon, which was only recently invented, was the best material to use for his fasteners, and he quickly succeeded in making the loops for the fasteners. Creating hooks that would match up and secure into the loops remained a problem. He finally solved his dilemma by making loops and then cutting the loops to

A Velcro hook-and-loop fastener. (Time & Life Pictures/Getty Images)

Velcro

Georges de Mestral's invention of Velcro, a hook-and-loop fastening product, was the result of his keen observation, curiosity, and creativity. After returning home from a hunting trip with his dog, Mestral noticed that his wool trousers were covered with burrs and his dog's fur was matted from them. Inspired to investigate why this was so, Mestral examined a burr under his microscope, discovering that the burr was made up of thousands of stemlike pieces with hooks on the ends. He determined that these very small hooks were capable of attaching to any fabric or item that could be penetrated by the hooks (his trousers) or in which the hooks could become entangled (his dog's fur).

Mestral was convinced that this hook-and-loop concept, which was similar in a general way to the hook and eye already in use, could be used to create a new and superior fastener with great versatility. He conceived of a fastener that would be two strips, one with hooks and the other with loops. Finding the right material, creating the hooks and loops, and developing machinery to make the product became a ten-year-long research project.

Mestral's first hook-and-loop fasteners were made of cotton. They held together but lacked durability and had to be replaced frequently. Mestral next investigated synthetic materials, and he found nylon to be his best choice. Nylon possessed the qualities necessary for making a durable fastener; in addition, when it was produced, the thickness of the threads composing it could be varied. Mestral also discovered that when nylon was sewn under infrared light, it formed the type of hooks that he needed. The loops presented a greater challenge, but he persisted and discovered that nylon sewn in loops and heat-treated made the right loops for his hooks. One problem remained: The loops had to be cut properly to match up to the hooks. To solve this problem, Mestral changed the way he made the hooks. He sewed loops and then cut them; this made the hooks that mated to the loops.

Although Velcro was at first viewed as "funny looking" and was not readily accepted, Mestral soon saw his invention become the way to fasten a wide variety of items, from space suits to children's clothing. It also became a popular attachment fabric in a broad range of important scientific areas as well as in everyday uses. Its contribution to the aerospace industry has been invaluable because of its lightness, durability, and adaptability. Velcro has also enhanced the success of heart surgery procedures.

make the hooks. Next, he had to develop a method for mechanizing the process and finally a loom that not only wove the loops but also cut them properly to make the hooks. Finally, in 1948, he had solved the technical problems and was able to make his fasteners based on the sticking action of burrs. At first, Mestral called his invention "locking tape," but he later combined the first syllables of the French words *velours* (velvet) and *crochet* (hook) to name his invention "Velcro." In 1951, he applied for a Swiss patent, which he received in 1955. In 1952, Mestral started his first Velcro manufacturing company, located in Switzerland, with the support of Gonet and Company.

Mestral quickly obtained patents and opened factories in other countries, including Germany, Great Britain, Italy, Sweden, Belgium, and Canada. In 1957, he obtained a patent in the United States and opened a factory in Manchester, New Hampshire. When he introduced Velcro in these countries, Mestral thought his invention would have immediate and widespread success, but Velcro was very different from anything that had been used in the clothing industry. Although Velcro was actually a miniature version of the traditional hook and eye, the minute size of the hooks and loops gave the impression of an old fuzzy piece of cloth. Furthermore, people were not convinced of Velcro's practicality.

In spite of this initial hesitancy to accept Velcro, Mestral's invention began to conquer one market at a time until it became one of the most successful and widely used commercial products. Mestral enjoyed his first real success with Velcro when it was used to assist astronauts to get in and out of their space suits. Skiers were the next group to see the advantages of Velcro, followed by the makers of scuba gear. Then, led by the manufacturers of children's apparel, the clothing industry began to use it. Mestral's invention became so popular that his company earned millions of dollars.

Mestral insisted that Velcro was the name of his company and that what he produced was a hook-and-loop fastener. He waged a constant battle against the use of the term "Velcro" to identify all hook-and-loop fasteners that resembled his. Mestral eventually sold his company and all of the patent rights. Velcro was not Mestral's only invention. He also invented a hygrometer and an asparagus peeler, which was a very successful commercial product.

In 1966, upon the death of his father, he inherited the family château. He died at the age of eighty-two on February 8, 1990, in Commugny, Switzerland. L'avenue George de Mestral in Commugny is named in his honor.

He was inducted into the National Inventors Hall of Fame in 1999.

Impact

Mestral completely changed the concept of fastening with his invention. He invented a system of attaching one item to another and of fastening two parts of a single item by a means that was not only secure but also exceptionally easy to fasten and unfasten. The hook-and-loop fastener, Velcro, contributed in a significant way to the development of aerospace technology, as the lightweight Velcro provided a simple way to attach items in space. Mestral's easy-to-use invention has given a greater degree of independence to the disabled and the elderly. It also serves as a valuable means of attachment in many fields of surgery, especially heart procedures.

Velcro has become a part of everyday life. It fastens clothing, shoes, lunch boxes, and backpacks, and it holds draperies and car speakers in place. Although Mestral waged a persistent battle against the word "Velcro" replacing "hook-and-loop fastener," he had simply named his invention too well. "Velcro" has become not only the generic noun used for the hook-and-loop fastener but also a verb. Velcro has become a part of popular culture: It has been referenced in films and used in stunts on television shows such as the *Late Show with David Letterman*. Velcro has become as widespread and as much a part of life as the burrs to which it owes its invention.

Robert Metcalfe

American electrical engineer and computer scientist

In the early 1970's, Metcalfe became the coinventor (with his colleague David Boggs) of Ethernet, a system allowing instantaneous communication between computer terminals in a local area network. Like the Internet and the World Wide Web, the Ethernet would become essential to communication technology in all areas of the globe.

Born: April 7, 1946; Brooklyn, New York
Also known as: Robert Melancton Metcalfe (full name)
Primary fields: Communications; computer science
Primary invention: The Ethernet

Early Life

Born in Brooklyn, New York, in 1946, Robert Melancton Metcalfe graduated from Bay Shore High School in Suffolk County on Long Island in 1964. His undergraduate schooling at the Massachusetts Institute of Technology (MIT) led to two degrees in 1969: He earned a B.S. in electrical engineering and a degree in management from MIT's Sloan School of Management. Although it was not immediately apparent, this business-related training (especially where entrepreneurship was concerned) would play an important role in later stages of his career.

After receiving his M.S. in applied mathematics from Harvard in 1970, Metcalfe continued in the doctoral program there, but he continued to cooperate actively with MIT's Project MAC, a program that aimed at linking all the university's computers to the Advanced Research Projects Agency Network (ARPANET). ARPANET was the newly emerging U.S. Department of Defense project that sought to develop "packet-switching" technology in data communication as an improvement over "circuit-switching" methods employed in standard telephonic communication.

LIFE'S WORK

After failing his Ph.D. at Harvard in 1972 (his dissertation topic focused on ARPANET), Metcalfe received his degree in 1973. His ultimately successful research combined his interest in ARPANET with analysis of problems and possible solutions in another system emerging at the time at the University of Hawaii, appropriately named ALOHANET. The technology of both systems and the challenge of overcoming some of their shortcomings (in ALOHANET's case, problems of "collisions" in a system relying on radio waves rather than telephone wires for intrasystem data transmission) would serve as a stepping-stone to Metcalfe's work on the ultimately much more successful Ethernet.

Metcalfe coinvented Ethernet during the first year of his employment at Xerox's Palo Alto Research Center (PARC) in California, in November of 1973. He and colleague David Boggs designed Ethernet to connect the Xerox computers to one another through a local area network (LAN). Although Xerox at this time was concentrating most of its efforts on development of early models of the personal computer (PC), Metcalfe wanted to pursue research related to LANs. While he continued to concentrate on this technology, he accomplished another important assignment at Xerox—helping to develop the Xerox Star workstation, one of the first commercial PCs with a graphical user interface. Other features of the PC included file servers and the new star of the computer world, the mouse.

Six years after his pioneer work at Xerox, and after working out some of the early technical difficulties associated with Ethernet, Metcalfe resigned from PARC to found 3Com, headquartered in Santa Clara, California. 3Com manufactured computer networking equipment, with concentration on Ethernet technology. The firm's name symbolized the integration of three main "coms"—

ETHERNET

Although a full understanding of the Ethernet system demands a sophisticated knowledge of electronic technology, a layperson's understanding can be built on a few essential principles. As a system connecting a transmitting vehicle (in this case, a computer) to a network of receivers, Ethernet shares some characteristics with cable television. The first generation of Ethernet made it possible to transmit "packets" of computer-generated data back and forth along a passive electronic bus (a bus wire with at least two signal transmission wires "tapped" by a number of interconnected circuits, or transceivers) constructed in such a way as to form an annular unit, or "ring." Each Ethernet station, or computer terminal, in the local area network (LAN) is assigned its own 48-bit MAC address, marking both a potential source point and a destination point for any data packets transmitted through the system. In order to control "traffic" and "collisions" (disruptions of transmission that can be compared with radio wave interference) within the intercommunication ring, each Ethernet station is equipped with a computer chip called a network interface card. This device can distinguish between data that is general for the LAN as a whole and more specifically addressed transmissions.

Early Ethernet bus technology used coaxial cables similar to cable television systems. Basic coaxial cables had a limited transmission capacity (expressed in megabits per second, or Mbps). As developing technology discovered ways to build systems that had higher transmission capacity and decreased incidents of collisions when multiple senders and receivers of data "competed" within the LAN loop, Ethernet models progressed from the 10BASE5 (10-Mbps capacity) to the 100BASE-T (100-Mbps capacity, using an improved "twisted-pair" connecting cable) to several succeeding generations of Gigabit Ethernet (transmitting multiples of thousands of megabits per second). Twisted-pair Ethernet technology had the effect of reducing the physical panel space required for setting up a LAN. Also, with time, companies that specialized in network interface card production were able to incorporate Ethernet chips into the electronic package of almost all personal computers, thus contributing to decreasing costs of ever more sophisticated computer systems available on the market.

Along with improving transmission capacity, researchers succeeded in developing technology that would allow both longer "reach" and decreased malfunction vulnerability in LAN networks. In the latter case, a variety of system configurations were devised to achieve higher efficiency compared to stations arranged in a single line. Another, more complicated, feature of evolving Ethernet technology involved development of packet switching to overcome the limitations of circuit switching—a carryover from basic telephone wire technology. Circuit switching involves a dedicated (single and uninterrupted) "busy" signal, whereas packet switching occurs when transmitted data are broken down and assembled into "data graphs" that can be sent simultaneously in a packet, components of which can be distributed to various destinations within the LAN.

computers, communication, and (technological) compatibility. Over several years' time, Metcalfe's company worked, apparently quite successfully, to establish cooperative links between companies such as Intel, Digital Equipment Corporation, and Xerox, which were destined to play major roles in marketing Ethernet technology. By the 1980's, these three companies had joined to form a consortium to develop the 10BASE-T Ethernet standard, which operated at 10 megabits per second (Mbps). This initially impressive accomplishment was followed in the 1990's by the development of three distinct "successor" systems that increased the speed of Ethernet transmission by a factor of ten: the 100BASE-TX and the 100BASE-T4 (1995), and the 100BASE-T2 (1997). Among other highly technical improvements in these and later, even faster versions would be the adoption of different forms of cabling.

In 1990, Metcalfe left 3Com to begin a markedly different stage of his career. Between 1990 and 2001, he was engaged in technology-related publishing and also contributed an Internet column for the internationally known Web site InfoWorld. In the same period, he served as a principal founder of Pop!Tech, a widely recognized conference held yearly in Camden, Maine. Pop!Tech meetings focus on issues of popular culture and the Internet as well as ethical questions relating to Internet technology. Readers of the volume *Beyond Calculation: The Next Fifty Years of Computing* (1997), edited by Metcalfe and his professional associate Peter Denning, can see the diversity of such issues as the new century approached.

By 2001, Metcalfe had entered the arena of venture capitalism, participating as a general partner in Polaris Venture Partners, a company that, since its founding in 1996, has invested seed money in a variety of emerging companies ranging from health care technology companies to financial service companies. Metcalfe has received a number of awards recognizing his contribution to Ethernet technology. Early evidence of his success came in 1980 (just a year after he left PARC), when he received the Grace Murray Hopper Award from the Association for Computing Machinery. By 1996, six years after he resigned from the leadership of 3Com, the Institute of Electrical and Electronics Engineers (IEEE), the most important international professional association for electrical and electronic engineers, presented Metcalfe with the IEEE Medal of Honor. This award was not only for his coinvention of Ethernet but also for the leadership role he continued to play in its development and marketing around the globe. In addition to receiving the National Medal of Technology, awarded by President George W. Bush at a 2003 White House ceremony, Metcalfe was one of seventeen people named in 2007 to the National Inventors Hall of Fame.

Impact

After its introduction in the mid-1970's, Ethernet computer technology first competed with and then came to replace other systems designed to service LANs. Competitors included Token Ring, FDDI, and ARCNET. This success in gaining increasingly important sections of the market guaranteed that 3Com would become a model for a number of other start-up companies engaged in computer technology and the manufacture of computer components. Commercialization of Ethernet grew by the first years of the twenty-first century to handle about 85 percent of LAN-connected personal computers in all areas of the world. One of the main reasons for this success was cost-effectiveness: Installation procedures continued to prove more economical than those of other products on the market. Thus, from a relatively limited sphere of application in largely self-contained academic or business operations, the Ethernet was destined to become an affordable necessity in many different arenas where electronic communication has become a given in the modern world.

—Byron Cannon

André and Édouard Michelin

French industrialists and engineers

The Michelin Tire Company, founded by brothers André and Édouard, is recognized as a pioneer manufacturer of air-inflated tires. Although in later years the highly competitive tire industry witnessed many innovations offered by different companies at a wide range of prices, Michelin continued to enjoy a strong reputation for high-quality products.

André Michelin

Born: January 16, 1853; Paris, France
Died: April 4, 1931; Paris, France
Also known as: André Jules Michelin (full name)

Édouard Michelin

Born: June 23, 1859; Clermont-Ferrand, France
Died: August 25, 1940; Orcines, Puy-de-Dôme, France
Also known as: Édouard Étienne Michelin (full name)
Primary fields: Automotive technology; manufacturing
Primary invention: Rubber automobile tires

Early Lives

In 1852, Jules Michelin (mee-shlan) married Adèle Barbier, daughter of the co-owner of Barbier, Daubrée and Company, an iron and copper foundry in Clermont-Ferrand, France. A year later, their son André Jules was born. André earned his diploma from the School of Arts and Manufacturing in Paris, and the directors of a troubled successor company to Barbier, Daubrée and Company, known as Jean-Gilbert Bideau and Company after 1868 (with the Barbiers still on the board), later called upon André to take part in the firm. In 1886, at the age of thirty-three, André, who had supplemented his training as an engineer with studies in the architectural branch of the Paris School of Fine Arts, accepted this job. He had already launched his own business in the Paris suburb of Bagnolet—a factory producing metal construction girders. André's life work after he took on responsibilities in Clermont-Ferrand would move in a different direction—the incorporation of rubber into different areas of industrial production.

While André seemed to be a logical choice to help rebuild the ailing foundry business, his younger brother Édouard Étienne was less likely to find a niche in manufacturing. Édouard had attended the same School of Fine Arts as André but chose studio painting as his preferred vocation. Only twenty-seven when he joined André, Édouard was destined to fill a very different, but major, complementary role (initially as managing director) of the firm that later bore his family name.

Lives' Work

The Michelin brothers made their first mark in the rubber tire industry in 1889, when they shifted company emphasis toward commercial use of vulcanized rubber: brake shoes with rubber linings. Just one year earlier, a much more important long-term breakthrough had been made in Belfast, Ireland, adopted home of the Scottish veterinarian John Boyd Dunlop, who took out a patent on the first air-filled rubber tire. Realizing how important this new product could be for work and passenger vehicles, the Michelins worked rapidly to improve on Dunlop's inflatable tires.

As the company entered into the market for tires, the brothers used a popular method of attracting attention: The superior performance of their tubular tire in the 1891 Paris-Brest-Paris (PBP) bicycle race and other nationally publicized events launched them on an advertising campaign. This campaign—as it moved into the emergent world of automobile travel—would make the name Michelin a widely recognized symbol, not only for tires but also (once the *Michelin Guide* was launched in 1900) for tourism in general.

The company's popular image grew with the adoption in 1898 of its mascot Bibendum (also known as the Michelin Man)—a rotund cartoon figure made of stacked tires with added human features. The figure's name comes from a Latin slogan originally used by a Munich brewery: *Nunc est bibendum* (now is the time to drink). Michelin would use Bibendum in different ways to draw attention to the company's activities—all commercially connected with the public's growing involvement in automobile tourism. Bibendum's amusing persona began to appear on the cover of and in advertisements in Michelin touring guides. These practical guides were distributed free until much-expanded editions (with details on hotels and restaurants) began to be published after 1920.

The growth of Michelin tire production in Clermont-Ferrand was very rapid. The number of Michelin employees rose from 62 in 1892 to 268 by 1894 (two years before the company introduced its first automobile tires) to 698 by 1898. Thanks to Édouard's skillful management and ever-improving methods of mass production, prices for Michelin tires were affordable for the average buyer. Shortly after the turn of the century, well over half of Paris's four thousand taxis were equipped with Michelin's product.

The Michelin company was an innovative pioneer not only in terms of technology and publicity but also in methods of business management. Many historians focus on the company's attitude toward its workers who came to work in Clermont-Ferrand. Already by 1898, the company had launched a program that rewarded the best employees with business shares that could accumulate—if the recipients kept continuous employment with the company—until the age of retirement. In part, this apparent benevolence was connected with management's desire to avoid inroads by militant labor unions. Similarly, provisions for a variety of social services were always part of Édouard's managerial responsibilities. Starting in 1905, health services, for example, were included in employee benefits. By the interwar years, construction of inexpensive and practical company housing included apartment complexes and multiple- and single-family structures.

At a certain point, it became obvious that Michelin's competitive edge in European continental sales could be extended not only to Dunlop Tyre Company's "home territory" in Great Britain (where an extraordinarily ornate

The Michelin Tire

The earliest versions of what came to be known as tubular tires (reinforced rubber tire casings with tread given durable but flexible shape by means of an air-filled inner tube) were introduced by the Scotsman John Boyd Dunlop in 1888. There was at least one precedent for the idea of air-filled tube tires. In 1845, Scotsman Robert William Thomson produced what he called "aerial wheels" for horse carts. Thomson's tires did not catch on, however, mainly because they were too expensive. Dunlop's model for bicycles and carts forty years later was more economically feasible, but because it (like Thomson's) was glued to the wheel rim, it was difficult to repair. Not only was the task of removal complicated, but regluing the patched tube to the rim also could not be finished "on the spot." The drying process could take hours.

André and Édouard Michelin began by devising an essentially mechanical system to rival Dunlop's. The answer, at least for the next few years, was still awkward: Michelin's method held the tube and tire to the wheel rim using more than thirty nuts and bolts. The next step, which would be adopted by all producers of tubular tires in the next generations, involved redesigning wheel rims so that the "lip" of the tire could be seated very snugly and grip all the way around the rim when inflated.

The Michelin company, however, would continue to make its mark through other technical improvements that went beyond mechanical devices. Important research and development projects aimed at producing higher-quality rubber components at lower prices. A major contributor to the firm's advances in this realm was the Alsatian chemist Maximilien Gerber. Perhaps the most challenging aspect of Gerber's work and that of his successors involved testing different types of tread surfaces not only for durability but also for traction depending on different road surfaces and weather conditions. A notable achievement here was what came to be known as the Michelin Universal Tread. Based on technical principles used in racing tires, even the Michelin Universal Tread seemed to incorporate publicity techniques that could be worked into the patent, as the tread consisted of closely knit rows of *M*'s.

Michelin building was built in London in 1911—replete with dual turrets representing the rotund Bibendum) but also to the United States. By 1910, acting on Édouard's managerial initiative, the company founded a factory in the small town of Milltown, New Jersey. In its heyday, the plant comprised twenty-two buildings and employed two thousand workers plus a number of French engineers and managers. In a U.S. version of what had guided Édouard's policy in Clermont-Ferrand, efforts were made to create a desirable "company town"—including standardized workers' housing and a number of community social organizations.

Around World War I, the Michelin brothers demonstrated interest in producing materials for use in the then-nascent aviation industry—first lightweight fabrics used to cover dirigibles, and then, once war broke out, metallic frames for what came to be known as the Breguet bomber. To protect the plane's landing gear from bullets, the Breguet biplane was equipped with steel wheels produced by Michelin. The company's involvement in the war effort went beyond production of war materials. Not only was its warehouse in Clermont-Ferrand converted into a military hospital, but a program also was introduced for pensions to surviving children of any company employees who died in the war.

Despite the company's dominance, Michelin was not unscathed by the Great Depression. The twenty-year-old plant in Milltown was forced to close down permanently, and in Clermont-Ferrand employment figures dropped from more than sixteen thousand workers in 1929 to half that figure by 1934. Somewhat unexpectedly, the downturn did not deter expansion in European-based operations during the height of the Depression: New plants were opened in Karlsruhe, Germany, in 1931 and in Lasarte in northern Spain in 1933. An even greater sign of the company's intention to weather the storm of depression came in 1935, when Édouard's son Pierre closed a deal with the then-ailing Citroën car company, which initially gave the Michelins a slight voting majority in Citroën even though their capital investment came to less than one quarter of the total. In the post-World War II period, Michelin actually owned Citroën, sharing responsibility for development of the first front-wheel-drive car.

André Michelin, who turned seventy-eight in January, 1931, did not live to witness these important developments. Soon after André died in March, 1931, his brother Édouard declared his intention to retire. His successor was to have been his thirty-three-year-old son Étienne, an amateur pilot who was killed in a plane accident. Édouard, apparently intent on passing the directorship on to one of his sons (thus sidestepping André's son Marcel, who had considerable practical experience in the firm), delayed his retirement so that his own younger son Pierre (who also died prematurely, in 1937) could take over. In his last years, therefore, worries over the future of the company faced the aged company's cofounder. First he was forced out of his intended retirement, then came the onset of the German occupation of France in June, 1940. Édouard died just two months after the Nazi invasion. He was thus spared the wrenching drama of forced service of the very valuable tire company under orders from the Third Reich.

Impact

The last two decades of the Michelin brothers' lives witnessed new developments that continued to expand their company's reputation in France and throughout the world in the twentieth century. One of these was production of tires for trucks. These were not only bigger and heavier tires; Michelin's products in the 1920's were especially designed for what was to become the dual wheel and later the quadruple rear wheel assemblies needed by exceptionally large trucks. In 1929, Michelin also took out a patent for the earliest air-filled tires for use in lightweight passenger trains—an innovation that gave its name to trains serving smaller cities throughout France (the Michelines). The first such train took its trial run in 1931 from Paris to the resort town of Deauville on the Normandy coast, setting a record time for passenger service on that line. Five years later, there would be ninety Michelines servicing regional routes in France. Another notable technological innovation would come just after World War II—development of the first radial tires—further enhancing the company's international reputation.

John Milne

British engineer, geologist, and seismologist

Milne, regarded as the "father of modern seismology," invented the first modern seismograph. He also established the world's first international seismological monitoring network.

Born: December 30, 1850; Liverpool, England
Died: July 31, 1913; Shide, Isle of Wight, England
Primary field: Geology
Primary invention: Seismograph

Early Life

John Milne was born in 1850 in Liverpool, England, to John Milne and Emma Twycross. He grew up in the Greater Manchester towns of Rochdale and Tunshill, Milnrow. He received his early education in Rochdale and at Liverpool Collegiate Institute. Awarded a monetary prize for academic excellence when he was thirteen, he spent the money on a holiday tour of England's Lake District; from there, he decided to cross over to Ireland and continued to Dublin, subsisting largely on apples plucked along the way and whatever he could earn playing the piano at roadside pubs. An adventurer by nature, the adolescent Milne later took to exploring England's waterways by canoe.

At seventeen, he entered King's College, London, where he focused on geology and mechanics. After an expedition to Iceland, he continued his studies at England's Royal School of Mines, earning the credentials to become a mining engineer. He did fieldwork in practical mining engineering in Cornwall and Lancashire, studied mineralogy at the Bergakademie in Freiberg, Germany, and from there visited central Europe's principal mining districts.

After returning home, the twenty-two-year-old Milne was hired for a job overseas, where he spent two years assessing and reporting on the mineral resources of Newfoundland and Labrador. In 1874, he went back to England only to embark on yet another voyage, this time as part of British geographer Charles Tilstone Beke's expedition to Egypt to determine the location of the biblical Mount Sinai.

In 1875, Milne accepted a position in Japan as professor of mining and geology at Tokyo's recently established Imperial College of Engineering. Not fond of sea voyages, Milne made most of the trip over land. The months-long trek across Europe and Asia included one thirty-one-day stretch with no roads, no houses, no change of clothes, and little food. Upon reaching Japan in 1876, the seasoned adventurer had a new experience: On the night of his arrival in Tokyo, he felt his first earthquake.

Life's Work

Milne's appointment to the Imperial College was part of a Japanese program to hire foreign nationals to help the country gain parity with the industrialized West. During his first years there, Milne divided his time between his teaching duties and the various geological attractions his new home offered. He traversed the countryside and made scientific observations, excavated prehistoric shell mounds, and climbed and sketched volcanoes. He also experimented with instruments for monitoring earth motion during seismic activity.

On February 22, 1880, a moderately severe earthquake struck the Tokyo-Yokohama area. Milne was eager to study the quake and its effects, but locating its epicenter and assessing its relative strength and direction of movement proved to be a challenge. Had the quake struck an urban area in Europe, he would have determined its intensity through field observations of damage to structures. However, the commonly used intensity scales (developed in Italy) did not translate easily to Japan because Japanese architecture and construction techniques were so unlike the West's. Where Mediterranean

The Milne Seismograph

The Milne seismograph was a highly sensitive, horizontal-pendulum instrument. It consisted of a horizontal, lightweight aluminum boom with a weight at one end and a universal joint at the other end connecting it to a vertical iron column. Supporting the weighted end of the boom was a thin wire attached to the vertical column. The mass and position of the weight attached to the boom determined the pendulum's sensitivity and its period. Leveling screws in the base of the column allowed it to be tilted slightly, which reduced the gravitational restoring force and thus made it possible to get a long-period response out of the short-period pendulum.

When the earth shook, the vertical pillar moved with it, while inertia caused the heavy mass at the end of the boom to remain stationary in relation to the pillar. Photographic methods were used to create a visual record of the instrument's movements. Light from a lamp was reflected down through a horizontal slit on the weighted boom, passing from there through a fixed horizontal slit perpendicular to the boom's to form a spot of light on a roll of photosensitive paper beneath. The relative motion between the pendulum's slit and the fixed slit caused the spot on the paper to move. A clockwork mechanism rotated the roll slowly, so that it completed a revolution every few hours; the roll also underwent a slow horizontal advancement, allowing a day or two of readout to spool onto it.

Thanks to the worldwide deployment of the Milne seismograph, seismologists in the early twentieth century had access to an accumulated body of reliable, comparable teleseismic data. From these data, researchers began to construct a model of Earth's interior density, pressure, and elasticity, based on what the seismographic data revealed regarding how and how fast seismic waves traveled beneath the planet's surface. By 1906, John Milne had determined that Earth had a surface crust through which seismic waves traveled more slowly and a denser inner region through which they passed more quickly. Richard Oldham posited in 1906 that the planet had a large, dense, and probably fluid core. Andrija Mohorovičić discovered a discontinuity between Earth's crust and its mantle in 1909. In 1912, Beno Gutenberg calculated the depth to the outer boundary of the Earth's core. Almost a quarter of a century later, Inge Lehmann determined that the Earth has a solid inner core within a liquid outer core.

stone and masonry would collapse in a major quake, a wooden structure in Tokyo would sway and jerk violently only to return to its original state once the shaking stopped. To gather data, Milne had to turn to European expatriate communities in Tokyo where Western-style construction predominated. He also sent out questionnaires, surveyed fallen gravestones, and learned what he could from a scattered hodgepodge of seismic monitoring devices created by some of the Western scientists then living in Tokyo.

Milne and two fellow Englishmen also teaching at the Imperial College—Professor of Telegraphy Thomas Gray and Professor of Mechanical Engineering and Physics James Alfred Ewing—collaborated to found an organization that would pool the expertise of Japanese and foreign researchers to collect and systematize information about earthquakes in Japan. That organization, the Seismological Society of Japan, held its inaugural meeting two months after the Tokyo-Yokohama earthquake. With the support of the minister of public works, the society deployed a pendulum-type seismometer codesigned by Ewing, Gray, and Milne in several telegraph offices across the Musashi Plain, the area west of modern-day Tokyo. (The telegraph offices offered the combined conveniences of rapid communications and clocks that were synchronized daily.)

From 1880 on, Milne focused his attentions on earthquakes. He conducted research, wrote extensively (two-thirds of the articles the Seismological Society published were his), and designed monitoring instruments. He investigated small vibratory ground motions using microphones and studied his instruments' response to simulated earthquakes he created by dropping heavy iron weights and setting off gunpowder explosions. His classic *Earthquakes and Other Earth Movements* was published in 1886 and was reprinted numerous times over the next half century. In 1887, he was elected a fellow of the Royal Society, England's prestigious national academy of sciences.

Milne was in Japan during the great Nōbi earthquake of 1891, one of the largest seismic events in the country's history, and he conducted an extended field survey of the damage. When, in 1892, Japan's new Imperial Earthquake Investigation Committee superseded the Seismological Society, Milne began to devote more time to studying and recording teleseisms (distant earthquakes). In 1893, he created the Milne seismograph, a highly sensitive horizontal-pendulum instrument capable of detecting earthquakes occurring at a great distance.

In 1895, Milne's connection with the Japanese government came to an end. He returned to England—along with his wife, Tone Noritsune, and his assistant, Shinobu

Hirota—though not before a house fire destroyed many of his possessions, including instruments he had hoped to deploy in his home country. The Milnes settled on the Isle of Wight, in a location the seismologist chose based on the likelihood that small tremors could be felt there. At his new home, dubbed Shide Hill House, Milne set up a seismological laboratory and a seismograph station for detecting teleseisms and small local seismic events.

In 1897, Milne obtained funding from the Royal Society to establish an international network of earthquake monitoring stations equipped with Milne seismographs. Stations were established in roughly fifty locations, including sites in England and the British Empire, the United States, Canada, Russia, and Antarctica. The stations reported to Milne regularly, and he issued periodic catalogs of the world earthquakes the network detected. Milne used network data to create the first worldwide map of earthquake zones. He also published a second comprehensive text on earthquake science, *Seismology* (1898).

Shide Hill House became an international center for earthquake research. One visitor to Shide, a vacationing amateur scientist named John Johnson Shaw, wound up entering into a long-term collaboration with Milne to improve his eponymous seismograph.

In 1913, the year the Milne-Shaw seismograph was completed, Milne died suddenly from Bright's disease at the age of sixty-two. The seismological network headquartered at Shide continued for another six years before being transferred to Oxford University.

Impact

Milne played a major role in making seismology into a modern, quantitative science. He gave the world its first seismic network and pioneered the development and use of standardized instruments that, in comparison with their predecessors, were remarkably sensitive, reliable, and precise. He also generated a staggering body of observational data.

While later innovations such as electromagnetic seismographs, electronic amplification of signals, and digital recording methods have sidelined mechanical seismographs like Milne's, most of today's seismometers employ the same basic principles that Milne's did: When the ground shakes, the inertia of a weighted pendulum causes the instrument's frame to be displaced in relation to the pendulum; the resulting motion is amplified; and that amplified motion is recorded as a function of time.

The international seismic network Milne created in the early twentieth century was the forerunner of today's array of seismological networks that monitor seismic activity around the globe. Worldwide earthquake observation efforts have enabled seismologists to study global patterns in seismic activity and to form a better picture of how earthquake forces move through the earth. Today's digital networks can provide researchers with real-time data; in addition, they can help emergency response teams determine where to focus their efforts when a large earthquake strikes a populated area and communication systems are down or overloaded. In some regions, these networks can also generate early-warning information for the public, giving people valuable seconds to act before the most severe shaking begins.

Joseph Monier

French landscaper

Around the mid-1800's, Monier began experimenting with ways to make concrete planters that were durable and light. His idea for reinforced concrete influenced the construction of buildings and bridges.

Born: November 8, 1823; Saint Quentin La Poterie, France
Died: March 13, 1906; Paris, France
Primary field: Civil engineering
Primary invention: Reinforced concrete

Early Life

Joseph Monier (mahn-yay) was born into a poor farming family in Saint Quentin La Poterie, near Nîmes in southern France. He was the sixth of ten children. Little is known about his childhood. Joseph and his brothers helped their father in the fields and with landscaping. According to legend, when the local abbey suggested that the fourteen-year-old boy be sent to school, his mother refused, saying that Joseph was too smart for school and would get along fine in life without an education. At nineteen, he was sent to Paris to tend the garden of the duke's palace. He used his evenings to teach himself to read and write.

Life's Work

Around 1846, Monier became a gardener at the Jardin des Tuileries of the Louvre, whose extensive gardens contained various plants and flowers that attracted visitors from around the world. The expensive and exotic flowers needed to be replanted often, and Monier began considering an alternative to wooden flowerpots, which were not durable and were also easily damaged by weather and plant roots. Clay pots were very fragile as well.

Monier started his own landscaping company in 1849 while working for the imperial palace of Luxembourg. Around this time, concrete began to be used for nonbuilding purposes. For example, structures were covered with a layer of concrete to make them fireproof. Planters made of concrete were easily broken, so Monier began to experiment with the material to make sturdier containers. The only way he was able to make the concrete pots stronger was to increase their thickness, which made the flowerpots very heavy and difficult to move. Monier knew that to be useful in landscaping, flowerpots had to be sturdy but light enough to be moved easily.

Monier probably attended the 1855 World's Fair, held in Paris. On display there was a small ship built by Frenchman Joseph Lambot that was constructed with cement mortar that had been reinforced with iron. Lambot is credited with building the world's first concrete boat and inventing ferrocement. By 1861, Monier's landscaping business had grown and was known for his fashionable use of rocks. He had begun experimenting with new methods for making concrete planters, as well as water basins and troughs. Monier used iron mesh to strengthen the material without the weight of extra concrete.

On July 16, 1867, Monier received his first patent for his system of building iron-reinforced concrete troughs used for landscaping. That same year, he showed his invention at the Paris Exposition. Whereas concrete structures had problems with tensile stress fractures, and iron—though strong, readily available as long pipes, and useful for simple jobs—was expensive and difficult to use in more complex projects, Monier's system of adding a steel frame to the concrete slab solved both problems. French engineer François Hennebique saw Monier's horticulture troughs and basins at the 1867 exposition and started his own construction company. In 1892, Hennebique patented his own method for reinforced concrete construction.

In the years following the Paris exposition, Monier filed for five new patents and six patents building on his original one. In 1868, he obtained a patent for iron-reinforced concrete pipes; the following year, he received one for reinforced concrete panels for buildings. Monier continued to work on new applications, and he obtained a patent for reinforced concrete bridges in 1873. He designed the first bridge using this technique in 1875 at the castle of Chazelet. Only 16.5 meters long and 4 meters wide, the bridge spanned the river. His last patent, issued in 1878, was for reinforced concrete beams. Monier's patents do not contain much technical information. It appears that he producd the material without understanding the science behind the techniques.

During the late 1870's and early 1880's, Monier sold his patent rights to various German and Austrian builders. Among them was Gustav Wayss of Berlin. Wayss understood the importance of reinforced concrete to the construction industry, and through a series of business deals he obtained all Monier's patent rights by 1887. Wayss spent years experimenting to understand the science of reinforcing concrete. He published the results, terming the process the "Monier system." Between 1887 and 1899, Wayss's company built 320 bridges throughout Europe using Monier's design of crisscrossed iron rods under a thick layer of concrete.

Critics of the Monier system pointed out a series of potential flaws. They worried that wet cement would rust the bars, making them porous and breakable. It was also speculated that the iron and concrete would not always bond correctly. This would result in a weak structure, capable of breaking as easily as regular concrete. In order to silence the critics, several tests were carried out. Segments of reinforced concrete were excavated and destroyed to examine the iron rods. The rods were intact and looked as though they had just been forged. Tests were also done on slabs of reinforced concrete that were left outside during the winter months. Monier's system held up under these conditions as well. Thanks to Monier, architects and builders finally had a cheaper, stronger, more pliable material that revolutionized the construction industry.

Despite the value of his inventions and patents, Monier filed for bankruptcy in 1888. His business associates from throughout Europe and his many friends petitioned the French president on his behalf. Monier was grateful, saying that he was happy just to have created an inven-

Concrete

Concrete has been a popular building material for more than two thousand years. English engineer John Smeaton developed a cement that hardens under water, called hydraulic cement, around 1756. Portland cement (the dominant type used today), named for its similarity to stone found on the island of Portland, was patented by Joseph Aspdin in 1824. Thirty years later, Englishman William Boutland Wilkinson patented the first reinforced concrete floor slab. It was first used in construction of a home in Newcastle, England, in 1864. Around this time in Paris, Joseph Monier was inventing his method for reinforcing concrete.

In 1878, Thaddeus Hyatt received the first U.S. patent for a reinforced concrete system. After purchasing Monier's patents, the Wayss and Freytag company built 320 bridges throughout Europe by 1899. During the 1890's, François Hennebique began using reinforced concrete for buildings in France. Also at this time, American engineer Ernest Ransome began experimenting with the building material. Ransome developed the twisted square bar system from which many current deformed bar methods evolved. In 1893, a refinery for the Pacific Coast Borax Company in Alameda, California, became the first building in the United States to be constructed with reinforced concrete. In 1906, A. P. Turner of Minneapolis developed the "mushroom slab," a flat slab of concrete that is girderless.

Scientists have since figured out the reasons for reinforced concrete's increased strength. Concrete and steel expand at similar rates when heated and contract similarly when cooled. This means that the two materials do not cause internal cracks when the temperature changes. Second, the lime (calcium carbonate) in the concrete produces a film that coats the steel's surface. The film helps make the steel less susceptible to corrosion. Last, the concrete bonds completely to the surface of the steel. This efficiently transmits the stress and weight between the two materials.

Reinforced concrete does have some flaws. It is easily corroded by salt used to thaw and prevent icing. Using steel that has been specially treated, for example, by a light-green epoxy can slow the corrosion. Certain concrete mixes are also more resistant to the harmful effects of the salt. Poorly made reinforced concrete can be destroyed by freezing and thawing or corrosion. If the steel inside begins to rust, it expands and cracks the concrete.

As technology changes, so does the need for new and better building materials. Hospitals, for example, cannot be reinforced with steel because of the magnets in the magnetic resonance imaging (MRI) machines. Highway tollbooths that use radio signals to read vehicle tags also cannot use steel. A solution to this problem is fabricated plastic that can be as strong as steel. While the plastic version is lighter and often cheaper, it is not fire-resistant.

tion that benefited all civilized people. He died in poverty on March 13, 1906, at the age of eighty-two.

Impact

In addition to garden pots, Monier patented ideas for arches, bridges, pipes, floors, and railroad ties. His invention of reinforced concrete changed the face of cities throughout the world. Most of the large buildings in major cities would not be possible without reinforced concrete. The same can be said for a number of bridges.

Several engineering, construction, and architecture textbooks have been written about reinforced concrete. It lowers the cost of the construction and materials, shortens the schedule, and increases occupancy levels, strength, and durability of the building. When completed in 1910, the Paulinskill Viaduct in Hainesburg, New Jersey, was the world's largest reinforced concrete structure. The bridge, built by the Lackawanna Railroad, is 35 meters high and 335 meters long. Today, the longest reinforced concrete arch bridge is the Wanxian in China, spanning 420 meters. In 1955, only 40 percent of U.S. bridges were made of concrete. By 1995, the percentage was up to 70 and still growing. The National Bridge Institute found that 20 percent of steel bridges built since 1955 were deficient. It also found that only 7 percent of all reinforced concrete bridges ever built were deficient.

Reinforced concrete bridges, roads, and buildings are built to withstand hurricanes, tornadoes, wind, fire, and even terrorism. Reinforced concrete was a key building material used in World War II and Cold War bunkers and bomb shelters. The material is also used to build airport terminals, runways, tunnels, and parking garages. Many homes are built on a slab of reinforced concrete.

Joseph-Michel and Jacques-Étienne Montgolfier

French aeronautical engineers

The Montgolfier brothers are credited with inventing and developing the hot-air balloon, making it possible for the first time for humankind to fly.

Joseph-Michel Montgolfier

Born: August 26, 1740; Vidalon-les-Annonay, France
Died: June 26, 1810; Balaruc-les-Bains, France
Also known as: Joseph-Michel de Montgolfier

Jacques-Étienne Montgolfier

Born: January 6, 1745; Vidalon-les-Annonay, France
Died: August 2, 1799; Serrières, France
Also known as: Étienne-Jacques de Montgolfier
Primary field: Aeronautics and aerospace technology
Primary invention: Hot-air balloon

Early Lives

Joseph-Michel (zhoh-zehf mee-shehl) and Jacques-Étienne Montgolfier (ay-tyehn mahn-gahl-fyay) were two of sixteen children born into a family of prominent paper manufacturers living near the town of Vidalon-les-Annonay in the Ardèche Department of southeastern France. The more imaginative of the two brothers, Joseph was a genial, absentminded tinkerer whose interest in science was at odds with the strict theological curriculum of his Jesuit college in nearby Tournon. He ran away from the school twice, the second time to sell dyes of his own manufacture at fairs and markets. His father sent him for a time to Paris, but he returned to the region of his birth to run competing paper mills in partnership with his brother Augustin. He married his first cousin, Thérèse Filhol, in 1771.

Jacques-Étienne showed more self-discipline than his brother Joseph and, unlike him, gained a solid background in mathematics and mechanics. He was the youngest son of the family and went on to study architecture at the Collège Sainte-Barbe in Paris. With the death of his older brother Raymond, however, he was called home in 1772 to take over the family paper business. It was an unexpected development, but one to which he apparently gladly acquiesced. Soon after his return, he met and fell in love with Adélaïde Bron, a novice nun who had just been released from her vows. The two were married in 1774.

Lives' Work

Joseph was the more creative of the two brothers and seems to have daydreamed for years about traveling through the air. At the same time, he was profiting from the knowledge and experience of others. A cousin who had studied in Paris shared news of the experiments of English scientists Henry Cavendish and Joseph Priestley in isolating and identifying various gases. Cavendish had discovered what is now known as hydrogen, an element far lighter than air, while Priestley had discovered oxygen. Subsequently, Joseph was able to read a translation of Priestley's *Experiments and Observations on Different Kinds of Air* (1774).

Although Joseph experimented first with small hydrogen-filled balloons, he had far greater success using heated air. He was living in the city of Avignon at the time of his first successful experiment, which involved

Brothers Joseph-Michel and Jacques-Étienne Montgolfier. (Library of Congress) lighting a small fire beneath a construction of wood and silk. He promptly rushed home to share his discovery with his family, and in November, 1782, he managed to send a second version of his invention seventy feet into the air and keep it aloft for a minute. His enthusiasm suddenly awakened, the more practical Jacques-Étienne now joined Joseph in constructing a larger version of the invention some nine feet on a side. Launched on December 14, 1782, it rose with such force that it broke its rope and ascended to a height of about six hundred feet. On April 25 of the following year, the brothers released a balloon about thirty-five feet in diameter and watched it rise to a height of about one thousand feet.

Next, the brothers planned a public demonstration of their invention, constructing a balloon of burlap and paper about 110 feet in circumference. Launched on June 4 or 5, 1783, from an open area near the center of Annonay, it reached a height of some six thousand feet and was witnessed by a crowd of onlookers that included the General Council of the region.

Jacques-Étienne now proceeded to Paris to construct a huge balloon fit for a grand public display. It was launched early in the afternoon of September 19, 1783, at the royal palace of Versailles and carried a sheep, a chicken, and a duck beneath it in a wicker basket. Spectators included representatives of the Académie des Sciences as well as King Louis XVI and his wife, Marie Antoinette. The balloon rose to a height of some seventeen hundred feet and eventually landed about two miles away. Subsequently, the king ennobled the Montgolfier family, allowing its members to add "de" to their name.

The next logical step involved human flight, and it was not long in coming. Although he did not speak about it openly, Jacques-Étienne seems to have taken a ten-minute balloon trip on October 12, 1783. Joseph, who had not cared to follow his brother to Paris, apparently made his own flight on November 18 near the city of Lyon. A public display of tethered human flight took place in Paris on October 15, when physician Jean-François Pilâtre de Rozier made several short ascents in one of the Montgolfiers' balloons. Pilâtre de Rozier and his friend François Laurent d'Arlandes made the first untethered flight on November 21 over the roofs of Paris.

In honor of their accomplishments, the Montgolfier brothers were accepted into the Académie des Sciences on December 10, 1783. Jacques-Étienne returned from Paris to manage his father's paper factory in 1784, and during the French Revolution (1789-

THE HOT-AIR BALLOON

Although Joseph-Michel Montgolfier experimented with a number of devices, his most important invention is the hot-air balloon, which he developed with the help of his brother Jacques-Étienne. Many stories have grown up around his early fantasies and observations, but he seems to have experimented first with small constructions of paper and silk filled with hydrogen. He was able to produce the newly discovered gas relatively easily, but he found that it leaked through all the lightweight materials he had available to him.

According to an account he gave later, Joseph was considering unsuccessful French and Spanish attempts to take the fortified peninsula of Gibraltar from the British in 1782 when it occurred to him that the same force carrying smoke up his chimney might be harnessed to invade the peninsula from the air. Accordingly he built a three-by-three-by-four-foot frame from wooden sticks, enclosed all but the bottom of it in silk, and lit a small fire beneath it. Shortly it rose to the ceiling, lifted by the heated air trapped within (although Joseph mistakenly believed that it was the smoke that was creating the force).

Joseph and Jacques-Étienne sometimes employed paper (of which they had an ample supply) in their later models, as well as burlap and silk lined with paper. A small metal stove hanging directly beneath an opening in the bottom of the balloon held the fuel—straw, sticks, and so on—to be burned, while any passengers were carried in a suspended basket.

Although the Montgolfier brothers may not have understood it thoroughly, their balloons operated on the principle of buoyancy, which involves the upward pressure upon an object whose overall density is less than that of the fluid (liquid or gas) in which it is submerged. Like hydrogen, heated air is less dense than the air surrounding it, and it forces the balloon to rise to a level at which its density matches that of the air outside it.

In practice, early balloon flights were limited by the ability to maintain a heat source (without at the same time setting fire to the balloon), although the development of liquid propane as a fuel would eventually provide a practical solution. Balloonists soon learned to carry sand as ballast and to adjust their altitude by releasing it over the side. In addition, designers built adjustable vents in their balloons that could be opened to release hot air as necessary. Because hot-air balloons cannot be steered, they are generally at the mercy of the prevailing winds, but technical advances have made their recreational use common throughout the world.

1799) he worked in favor of the deposed monarchy. He died in the town of Serrières, near Vidalon, in 1799.

Joseph had continued to experiment with other inventions. One was a version of parachute, to which he tied a sheep and dropped it from a tower. He also helped develop the hydraulic ram, an invention for raising water. In 1797, he moved to Paris, where he was given a sinecure with the museum and technical school known as the Conservatoire National des Arts et Métiers. He was also instrumental in founding the Société d'Encouragement pour l'Industrie Nationale, and he was elected to the Institut de France, the parent body of the Académie des Sciences. He died in the southern French town of Balaruc-les-Bains in 1810.

Impact

The principles involved in buoyancy had been recognized since the days of Greek mathematician Archimedes of Syracuse (c. 287-212 B.C.E.), and the ancient Chinese are known to have used small hot-air balloons for signaling purposes during warfare. Brazilian-born priest and scientist Bartolomeu de Gusmão may have employed heated air to raise a small balloon as early as 1709. However, Joseph-Michel Montgolfier and his brother had the knowledge, means, and opportunity to experiment rigorously with the possibilities of lighter-than-air flight, and they are generally and rightly acknowledged as its inventors.

Within less than a year of Joseph's initial modest success in Avignon, the first flights involving humans were made, and other advances came in quick succession. The Montgolfiers' early experiments spurred the efforts of other scientists and inventors and captured the imagination of laypeople around the world. Talk of "aerostats" (balloons) and "aerostatics" (the science involved in launching and flying them) became commonplace, as did images of the colorfully decorated craft floating above cities and the countryside.

Subsequently, hydrogen- and helium-filled balloons were employed in warfare, and eventually much larger craft, known as blimps and dirigibles, were created that were capable of transoceanic flights carrying freight and passengers. Hot-air balloons are still commonly flown by individuals for recreation.

Robert Moog

American electrical engineer

Moog introduced the electronic synthesizer to popular music by creating an electronic keyboard that could be played with the same expressive range as a saxophone or a cello. The Moog synthesizer created an entirely new sound and a number of new genres, changing popular music forever.

Born: May 23, 1934; New York, New York
Died: August 21, 2005; Asheville, North Carolina
Also known as: Robert Arthur Moog (full name)
Primary fields: Electronics and electrical engineering; music
Primary invention: Moog synthesizer

Early Life

Robert Arthur Moog (mohg) was born in New York City in 1934 and raised in Flushing Meadows, New York, by a mother who was insistent that he would become a concert pianist, making him practice for hours each day. Moog described himself as an adolescent "class brain" and a social outcast among his peers. It was with his father that he was able to find some solace. Moog was very interested in his father's passion, electronics, yet it would be a combination of the worlds of music and electronics that would be Moog's key to fame.

In the late 1940's, Moog discovered the theremin, an electronic musical instrument that one plays by waving one's hands around the instrument's two antennae, which control pitch and volume. The tones produced by a theremin were so mysterious and dramatic that the instrument may be best known for its use in the 1951 film *The Day the Earth Stood Still*. In 1949, at the age of fifteen, Moog built his own theremin from plans he found in a magazine. He began modifying his instrument and soon developed a design of his own.

Moog was able to find more of a niche for himself at the prestigious Bronx High School of Science. He continued to pursue his intellectual passion through education as he earned an undergraduate degree in physics from Queens College. From there, he packed up his theremin and headed to Cornell University. In 1954, Moog was a graduate student in physics at Cornell when he published an article in *Radio and Television News* in which he provided the plans for building his version of the theremin. Moog also began selling theremins and theremin kits by mail order for $49.95. The demand was so high that he established the R. A. Moog Company and soon had accumulated more than $13,000 in profit, a tidy sum for that era.

Robert Moog sits in front of his synthesizer, with a keyboard and electronic circuits. (Getty Images)

Life's Work

Moog finished his first doctorate, in engineering physics, from Cornell in 1965, and the R. A. Moog Company had proven profitable. These events led to his work on his second doctorate, in electrical engineering, at Columbia University, where he was beginning to work with a music teacher and composer named Herbert Deutsch on a way of shrinking the room-sized acoustic synthesizers that Radio Corporation of America (RCA) had developed down to an instrument that could be carried onto the stage.

The Moog Synthesizer

In the 1950's, Radio Corporation of America (RCA) constructed a mechanical synthesizer, the telharmonium. The device filled a laboratory and had to be programmed with binary code to make one simple sound. It was not exactly the stuff of which garage bands are made.

Robert Moog's synthesizers were, in 1964, a collection of voltage-controlled electronic music modules. The first module he created was an oscillator that allowed the musician to create a sound wave that varied from the pure and gently pulsing toned sine wave to the grating sound created by sawtooth waves. The next module, called the ADSR (attack, decay, sustain, release) envelope generator, took the wave and defined the way it sounded as it began and ended, its duration and intensity. The third module Moog called the "voltage lowpass filter," and it shaped the texture and color of the wave.

By attaching these modules to others Moog would create, a musician could control the creation and aspects of a sound by turning the appropriate knobs. Moog later added a keyboard as the interface, allowing the musician unprecedented control of the creation of sound. Moog's initial synthesizers were designed as tools for the creation of music in the recording studio, not as performance instruments. The sound that was created was monophonic, not stereo, but the recording techniques of the era were such that entire symphonies could be built from the single notes generated by Moog's early synthesizers.

Moog took the basic synthesizer, which retailed for $10,000, to the 1964 convention of the Audio Engineering Society in New York, where the machine quickly became a sensation among composers. By 1968, Moog had sold dozens of the synthesizers. Early purchasers were Mick Jagger and George Harrison, and the synthesizer began appearing in popular music. However, it was Walter (Wendy) Carlos's hugely popular album *Switched-On Bach* (1968) that both introduced the synthesizer to the general public and, since the album was composed entirely on a Moog synthesizer, alerted the music industry to the musical potential of Moog's invention.

Carlos's success was quickly followed by the Beatles' extensive use of the Moog synthesizer on their final album, *Abbey Road* (1969), and Carlos's venture into cinematic sound tracks with the score to Stanley Kubrick's *A Clockwork Orange* (1971), which featured Moog versions of Ludwig van Beethoven's music. Despite this success, Moog had yet to realize his dream of producing a synthesizer as a stage instrument. Even though some musicians, such as Keith Emerson of Emerson, Lake, and Palmer, would have an entire enormous Moog synthesizer constructed on stage for a performance, Moog wanted a version small enough to be carried by the performer.

In 1970, Moog constructed the first portable synthesizer, the Minimoog, a three-and-one-half-octave electronic keyboard that was small enough for musicians to carry on stage. Even though the digital age and the ability of Asian countries to make cheap knockoffs would soon overtake the Minimoog, the portable analog synthesizer survived long enough to have a permanent impact on popular music and sound recording technology.

Moog had been studying German designer Harald Bode's ideas about transistorized modular synthesizers, and he realized that by using cheap, off-the-shelf voltage-controlled oscillators and amplifiers, he could change the basic tonal characteristics of a sound; that is, one note at a time at least, he could synthesize the sound of any instrument. Moog worked with Deutsch and musician Walter Carlos and began producing synthesizing modules that were connected together via patch cords.

In 1964, Moog was invited to take his analog synthesizer to the convention of the Audio Engineering Society in New York, where his invention garnered a great deal of interest. Moog's first synthesizer cost about one-tenth of RCA's room-sized version, and Moog had made his more user-friendly by adding a keyboard as the user interface. By 1968, Moog had sold dozens of his synthesizers, and his new contribution to music was being heard on the radio in tunes by groups such as the Monkees and the Beatles. Despite this success, the Moog synthesizer had yet to change the face of popular music. That would change with an electronic version of classical works.

In 1968, Walter (who later had a sex-change operation and became Wendy) Carlos released his interpretation of the music of Johann Sebastian Bach, produced entirely on a Moog synthesizer, on an album entitled *Switched-On Bach*. The album was wildly successful and introduced the general public and the recording industry to the potential of Moog's creation.

In 1970, with the release of the Minimoog, Moog achieved his goal of releasing a synthesizer that performers could carry, like an instrument, onto the stage. The now familiar three-octave keyboard freed the musician to take the power of Moog's synthesizer anywhere the musician wished to make music. However, the design of the Minimoog was such that it allowed companies in Asian countries to create cheaper knockoffs. This cut into Moog's profits but spread the gospel of electronic music that eventually led to the Moog sound revolutionizing popular music beginning in the early 1970's. Perhaps the defining moment of the early days of the Moog revolution was the success of Echo and the Bunnymen, a band whose front man, "Echo," was a drum synthesizer.

The Minimoog not only was the synthesizer of choice for the music industry but also brought electronic music to the masses. The Minimoog spread across all musical genres and economic strata. Soon, Minimoogs were appearing in lounge acts at small-town motels. As a result of the success, Moog found himself in a booming business that he was ill-equipped to run. After changing the company's name to Moog Music in 1971, Moog sold the business to rival Norlin Music in 1973.

Moog left Moog Music in 1977 and traveled to the mountains of North Carolina, where he founded Big Briar in 1978. At Big Briar, he went back to his roots: making theremins and developing electronic instruments with unique interfaces. In 2002, Moog was able to recapture the name Moog Music for his company.

While at Big Briar/Moog Music, Moog created such products as the Moogerfooger analog effects modules, which brought the flexibility and creativity of the original Moog modules to all musicians. Moog also brought back the Minimoog Voyager, which incorporated digital features into his original analog design. He died of an inoperable brain tumor on August 21, 2005, in Asheville, North Carolina, at the age of seventy-one.

Impact

From the stylized electronic sound of bands like Devo or Kraftwerk to the expansive digital vistas created by keyboardist Keith Emerson of Emerson, Lake, and Palmer, the signature sounds of these bands would not have been possible without what has become one of the most recognizable instruments in the recording industry: the Moog synthesizer. Robert Moog, the father of the Moog synthesizer, has been compared to Les Paul and Leo Fender, the men who are heralded as the fathers of the electric guitar. Just as the electric guitar forever changed the sound and meaning of popular music, so too did the Moog synthesizer.

The Moog synthesizer led to a wave of new sounds and even new genres in popular music (New Wave and electronica, for instance), and Moog became the leader, through his technology, by introducing the music industry and the music consumer to electronic music and the technology that made it possible. The very name "Moog" became synonymous with synthesizers and electronic music.

Moog also forever changed the way music is made. His technology took music out of the realm of elitist art, which required extensive technical expertise to create, and put it into the hands of the masses. As a result, the Moog synthesizer liberated the music creator from the overwhelming task of orchestration, from hours of scrawling notes, years of practicing numerous instruments, and hours of rehearsal with an ensemble before a single performance. Instead, with a Moog, the performer now simply had to caress a keyboard, thus creating full orchestration with Moog's technology instantaneously. Newer versions of the synthesizer will even allow the synthesizer to be hooked to a computer to compose and print perfectly orchestrated sheet music of whatever the musician is playing on the keyboard.

Garrett Augustus Morgan

American businessman

Morgan is best known for two inventions. His breathing device, or safety hood (a precursor to the modern gas mask), was initially used by fire departments and later modified for military use, and his three-armed traffic signal was a forerunner of the modern tricolor traffic light.

Born: March 4, 1877; Paris, Kentucky
Died: July 27, 1963; Cleveland, Ohio
Primary fields: Civil engineering; fire science
Primary inventions: Automatic traffic signal system; safety hood (gas mask); hair-straightening cream

Early Life

Garrett Augustus Morgan was born in Paris, Kentucky, on March 4, 1877. His father, Sydney Morgan, was the biracial son of a slave and the Confederate colonel John Hunt Morgan, leader of Morgan's Raiders in the Civil War. Garrett's mother, Elizabeth Reed Morgan, was the biethnic daughter of a Native American woman and the black Baptist minister Garrett Reed. Garrett Morgan was the seventh of eleven children.

As a young child, Morgan attended the Branch School located in the African American community of Claysville. By the age of fourteen, he had left school and the family farm and moved north to Cincinnati, Ohio, where he worked as a handyman for a wealthy landowner. To assist him in his efforts to improve his academic skills, Morgan hired a tutor. In 1895, he moved to Cleveland, where he worked for various sewing machine manufacturers and eventually became the only African American sewing machine adjuster, not only making necessary mechanical repairs but also inventing and patenting new machine parts. Among his first inventions were a belt fastener and a zigzag stitching attachment for manually operated sewing machines. In 1896, Morgan married Madge Nelson, but after two years their relationship ended in divorce.

Morgan lived during a period of institutionalized segregation in the United States. As a young man, he realized that even the most talented African Americans had very limited career opportunities. For such individuals, self-employment enabled them to utilize more fully their talents and to earn a worthwhile income. Although African Americans had gained the right to patent inventions, they encountered challenges in manufacturing and marketing them. However, through strong business networks and creative advertising strategies, many minority businessmen were successful in developing, patenting, and marketing their inventions.

Life's Work

In 1907, Morgan opened his first business to sell and repair sewing machines. One year later, he married Mary Anne Hassek, a Bohemian seamstress, with whom he had three sons. That same year, Morgan helped found the Cleveland Association of Colored Men, an offshoot of the National Negro Business League founded by Booker T. Washington. Morgan's commitment to promoting African American businesses and fighting racial prejudice was demonstrated by his active membership and service as an officer. When the Cleveland group merged with the National Association for the Advancement of Colored People (NAACP) in 1914, he became an NAACP member and maintained membership until his death in 1963.

In 1909, Morgan launched a business with thirty-two employees to manufacture coats, dresses, and suits. As a garment manufacturer, he sought a way to reduce fabric damage by reducing friction on the sewing machine needle. While experimenting with a liquid lubricant for the needle, he discovered that the liquid straightened the fibers of a coarse piece of cloth. After further experimenting, he found that the liquid also smoothed human hair, and he developed it into the first hair-straightening cream. In 1913, he started the G. A. Morgan Hair Refining Company to market the cream and additional cosmetics he developed.

Morgan invented a safety hood in 1912 and patented it two years later as a "breathing device." Worn over the head of a person, the canvas hood had two tubes in front that extended downward to encircle the body and join to form a single tube in the back. Hanging close to the ground, the bottom of the single tube was lined with a moist sponge to filter the incoming air. A metal tube inside the hood included a mechanism that prevented smoke from entering as the user inhaled and exhaled air. A nonpressurized air supply was available from a backpack reservoir. Morgan intended the device to be used by firemen, engineers, chemists, and others whose jobs placed them in danger of inhaling toxic fumes or air that contained hazardous dust particles. The National Safety Device Company, with Morgan as its general manager, was established to manufacture and sell the hood. In 1914, at the Second International Exposition of Safety

Traffic Signals

As an inventor and businessman, Garrett Augustus Morgan was financially successful. He was among the privileged Cleveland residents to own an automobile and experience the chaotic road conditions resulting from pedestrians, bicycles, horse-drawn carriages, and automobiles vying for the right of way. After witnessing a terrible accident, Morgan realized that better traffic signals were needed to prevent future catastrophes.

Prior to Morgan's traffic signal, most of the existing signals featured only two positions: stop and go. Manually operated, these two-position traffic signals were an improvement over no signal at all, but because they allowed no interval between the stop and go commands, collisions at busy intersections were common.

Another problem with the two-position traffic signals was the susceptibility to human error. Operator fatigue invariably resulted in erratic timing of the stop and go command changes, which confused both drivers and pedestrians. At night, road conditions were often chaotic because no traffic officers were on duty and motorists simply ignored the signals.

Morgan's mechanical traffic signal was a T-shaped pole unit that featured three positions: stop, go, and an all-directional stop position. The third position halted traffic in all directions before it allowed travel to resume on either of the intersection's perpendicular roads. This feature not only made it safer for motorists to pass through intersections but also allowed pedestrians to cross more safely.

At night, or at other times when traffic was minimal, the lighted Morgan signal could be positioned in a half-mast position, warning approaching motorists to proceed through the intersection with caution. Morgan also included optional bells that could be used as alarms. The half-mast position had the same signaling effect as the flashing red and yellow lights of modern traffic signals. The device made streets safer for pedestrians and was also used at railroad crossings.

Morgan's traffic management technology was used throughout North America until it was replaced by the red-, yellow-, and green-light traffic signals currently used worldwide. Morgan eventually sold the rights to his traffic signal to General Electric for $40,000. Shortly before his death in 1963, Morgan was awarded a government citation for the traffic signal.

and Sanitation in New York City, the device won first prize, Morgan was awarded a gold medal, and sales increased as fire departments of many cities adopted the hood for general use. Morgan received a U.S. Navy contract for the devices one year later. When gas masks were needed by soldiers to protect them from the effects of poisonous gases such as chlorine, a modified Morgan Safety Hood was among the devices tested and used by the British government during World War I.

On July 24, 1916, an explosion occurred in a Cleveland Water Works tunnel 250 feet below Lake Erie. The tunnel quickly filled with smoke, dust, and poisonous gases and trapped thirty-two miners. After several rescue attempts proved futile, Morgan was contacted. With the help of his brother Frank and a neighbor, William Roots, Morgan gathered safety hoods and rushed to the scene of the disaster. At the site, the Morgan brothers, initially unable to convince the discouraged rescue workers to join them, slipped on the hoods and entered the tunnel. Once the brothers began to successfully retrieve bodies, others donned hoods and rejoined the recovery effort. Although the men were unable to save all of the victims, they were able to save many who otherwise would have died. While Morgan's heroism and safety hood were impressive and photographically documented, little mention of his role appeared in Cleveland news reports, and he did not initially get the credit he deserved. Morgan eventually received awards from several civic organizations and honorary membership in the International Association of Fire Engineers. However, he never received the Carnegie Medal for heroism that had been awarded other rescue workers he had assisted and provided with safety hoods.

Morgan lived during the era when automobiles were becoming the preferable mode of transportation. After witnessing a terrible accident between an automobile and a horse-drawn carriage, he sought to develop a way to automatically direct traffic without operator intervention. Morgan was the first inventor to apply for and acquire a U.S. patent for an automatic three-position traffic signal. His device included a position for an all-directional stop and a position that permitted motorists to proceed with caution. The T-shaped signal post also had lights and alarms. The patent was granted on November 20, 1923. Morgan later had the technology patented in Great Britain and Canada. Although he formed the G. A. Morgan Safety System Company to manufacture the traffic signal, he later decided to sell the patent to General Electric.

Morgan was active in Cleveland's African American community. He founded a newspaper, the *Cleveland*

Call, which he published from 1920 to 1923. The newspaper, now known as the *Call and Post*, is published in Cleveland, Columbus, and Cincinnati. Morgan purchased land in Wakeman and founded the Wakeman Country Club, the first African American country club in Ohio. He was awarded an honorary degree from Western Reserve University and helped found a black fraternity, Alpha Phi Alpha, on its campus. In 1931, he ran as an independent candidate for Cleveland's city council but was not elected. Morgan developed glaucoma in 1943 and eventually lost 90 percent of his sight. In spite of the disease, he persisted in working on his inventions. One of his last was a self-extinguishing cigarette. He died in Cleveland on July 27, 1963.

Impact

During his life, Morgan was a respected entrepreneur and inventor. His most notable inventions, the safety hood and the traffic signal, helped to resolve safety issues of his time. The safety hood was adopted for both fire department and military use. Morgan's traffic management technology was used throughout North America until it was replaced by the red-, yellow-, and green-light traffic signals currently used around the world. He served as a catalyst to promote transportation education and the development of intelligent transportation systems (ITS). Morgan received many awards for his contributions to public safety and has been recognized in the United States as the "father of transportation safety technology."

Although he was from a poor family, had little formal education, and lived during an era of overt discrimination in the United States, Morgan was self-taught and steadfast in the pursuit of all of his diverse goals. As an inventor, businessman, newspaper publisher, and politician, he inspired many African Americans to overcome economic, educational, social, and political inequities based on race.

Several public schools in cities around the United States, including Chicago, Cleveland, and New York City, were later named in his honor. The district of Claysville, Kentucky, was renamed Garrett Morgan Place. Garrett A. Morgan Boulevard in Prince Georges County, Maryland, and the Washington Metro Morgan Boulevard Station are also named in his honor.

Samuel F. B. Morse

American painter

Generally considered the inventor of the electric telegraph and the Morse code of dots and dashes, Morse introduced the first practical method of transmitting messages instantaneously over long distances.

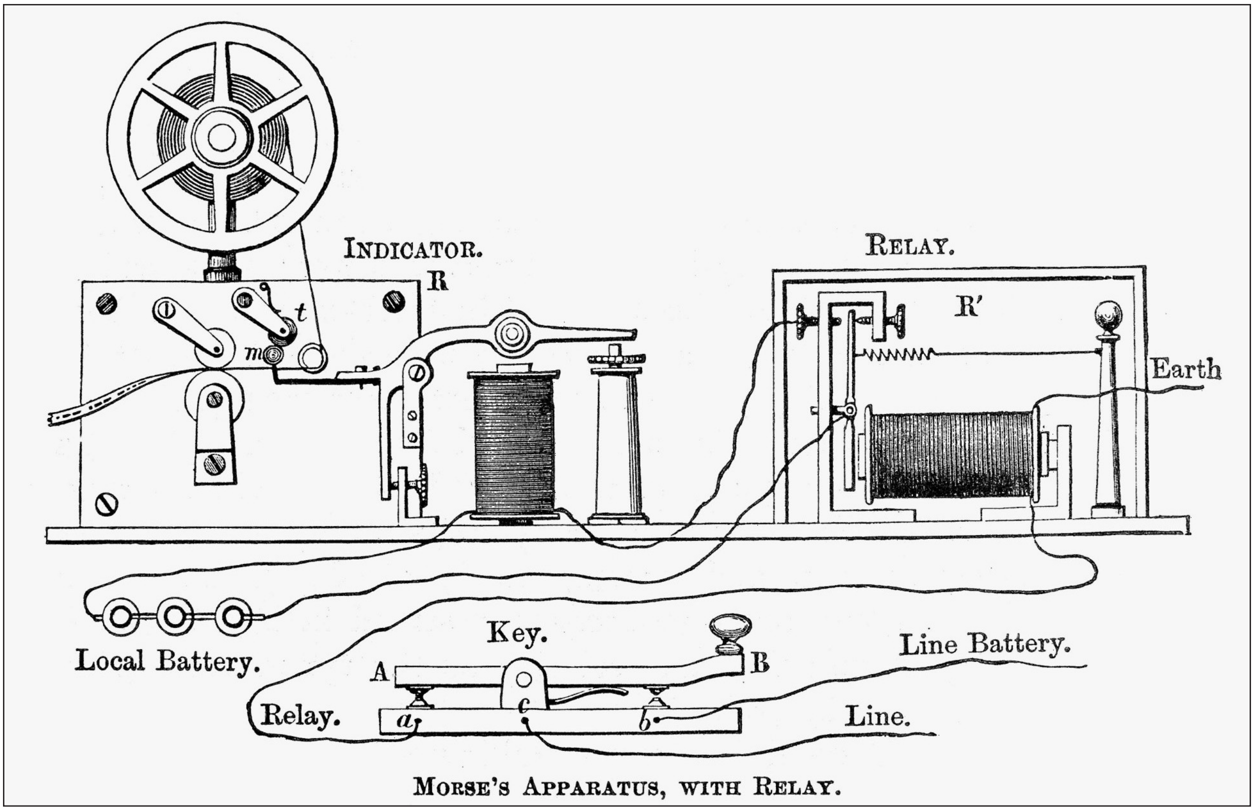
Born: April 27, 1791; Charlestown, Massachusetts
Died: April 2, 1872; New York, New York
Also known as: Samuel Finley Breese Morse (full name)
Primary fields: Communications; electronics and electrical engineering
Primary inventions: Electric telegraph; Morse code

Early Life

Samuel Finley Breese Morse was the eldest son of the Congregationalist minister and noted geographer Jedidiah Morse and Elizabeth Ann Breese. From an early age, he showed a talent for art, drawing miniatures of his classmates at Yale College. By the end of his time at Yale, he was set on becoming a painter, but he also had demonstrated an interest in science, including the new discoveries concerning electricity. In general, he exhibited wide-ranging interests, so much so that his parents were concerned that he was too much of a dilettante, lacking perseverance in any one field.

His parents were also not enthusiastic about his decision to become a painter. His father apprenticed him to a publisher in Boston before relenting and allowing him to go to London to study art with the American painter Washington Allston. The young Morse spent three years in England, developing an interest in painting large historical and mythological subjects and also developing strong patriotic views, speaking up in defense of his homeland during the War of 1812 between the United States and Great Britain.

On his return home, Morse found little market for his grand painting projects and instead became a painter of



Samuel F. B. Morse's experimental telegraph with relay, 1837. (The Granger Collection, New York) portraits, traveling around New England and also to Charleston, South Carolina, to paint pictures of ordinary people. He did, however, embark on a major painting of the House of Representatives in 1821, but it made him little money. Discouraged about his painting career, Morse contemplated other options, including going into the ministry and becoming an architect. He also dabbled in inventions, patenting a pump for fire engines or boats and later devising a machine for carving marble.

In 1826, Morse helped found and became the first president of the National Academy of Design, an organization of young painters formed in opposition to the older, conservative American Academy of Fine Arts. In 1829, feeling the need for more training in art, he returned to Europe to study, coming home again in 1832 on the ship *Sully*. On his return, stimulated in part by what he had seen in Rome, he became an anti-Catholic pamphleteer. He also obtained a position as a professor of fine arts at the new New York University. Most important of all, he came back with an idea for a new invention, the electric telegraph.

The Electric Telegraph

Samuel F. B. Morse's telegraph was not the only one being worked on in the early nineteenth century, but it turned out to be the simplest and most practicable. In England, William Fothergill Cooke and Charles Wheatstone created an electric telegraph that used multiple wires and needles to indicate letters, but this was much more complicated than Morse's invention, a single-wire system that depended simply on the duration of the signal: A short signal meant a dot, a long one a dash. With the dot-dash Morse code, this signaling system allowed messages to be conveyed easily. The original Morse telegraph included a battery to send the electric signals via a port-rule constructed out of printers' materials. At the receiving end, a register activated by an electromagnet recorded the electric signals as marks on a paper tape, using a pencil or, later, a stylus.

At first, Morse wanted to record a series of lines, with the number of lines corresponding to a whole word. This was a cumbersome method requiring a specially constructed dictionary, and he soon abandoned it for Morse code, in which each dot-dash combination corresponded not to a word, but to a letter in the alphabet.

Morse's assistant, Alfred Vail, refined the transmitter by replacing the port-rule with a simple key that, when depressed or lifted, would create or break the circuit, thus sending the dots and dashes. Eventually, it was discovered that telegraph operators could understand messages from the clicking sounds made by the receiver; thus, instead of working from the paper tape, they would transcribe the sounds, handwriting or later typewriting the message as they heard it. To facilitate this process, a device called the sounder was introduced.

Telegraph wires were generally strung overhead on wooden poles, with glass knob insulators where the wire met the wood. At first, copper wires were used, but iron was later found to be more reliable. For underwater transmission across the Atlantic, the wires were placed inside pipes with special insulation.

Life's Work

On the voyage home on the *Sully*, Morse happened to engage in a casual conversation with a shipboard companion, Dr. Charles Jackson, about electricity and the relatively new subject of electromagnetism, two phenomena that did not yet have any practical application. Jackson said that an electric current could continue undiminished through any length of wire, prompting Morse to comment that if this was true, then there could be instantaneous communication over long distances.

Inspired by this notion, Morse began sketching devices that could harness electricity to send messages. Morse had learned a little about electricity at Yale, where one of his professors once sent a current through a class of hand-holding students. He had also been interested enough in the subject to attend lectures on electromagnetism in New York. Jackson and Morse thought they were the first to think of an electric telegraph, but in fact the idea had been suggested decades before, and attempts to produce a working model were under way independently in England and Germany.

When Morse first got home, in 1832, he turned away from the telegraph temporarily to return to his career as an artist and professor, and also to engage in anti-Catholic politics. He became president of the American Protestant Union and twice ran unsuccessfully for mayor of New York on an anti-Catholic and anti-immigrant platform. It was only in 1837, hearing of rival attempts to create a telegraph in Europe, that Morse returned to the project, perhaps also being motivated by being turned down for a commission to do a painting in the Capitol Building. After this date, he essentially abandoned painting for work on the telegraph, and he began using his rooms at New York University for telegraphic experiments.

To assist him, Morse enlisted the aid of Leonard Gale, a chemistry professor at the university, who informed him of the electromagnetic researches of Joseph Henry, which included ringing a bell at a distance through a wire. Based on this information, Morse improved his original telegraph by using a stronger battery and a stronger magnet so that he could send a message ten miles instead of forty feet.

Morse also enlisted the aid of Alfred Vail, a former student of his with mechanical aptitude and a father with money to invest. In 1838, Morse demonstrated his telegraph to the Commerce Committee of the House of Representatives and won the support of its chairman, F. O. J. "Fog" Smith, who became another partner. Smith provided legal, business, and political advice, but Morse was to regret his association with him; most accounts describe him as unscrupulous, and he ended up opposing Morse rather than helping him.

Despite a recommendation from the Commerce Committee in 1838, it was not until 1843 that Congress approved funding for an experimental telegraph line from Baltimore to Washington. Work on this line ran into difficulties because of problems with the underground cable. Morse eventually decided to install the telegraph wires overhead on poles instead. This system worked, and on May 24, 1844, what is known as the first formal telegraph message went out on Morse's telegraph line: "What hath God wrought?" (a Bible quotation). This was not really the first message, for Morse had sent many test messages before this date. Earlier in May, when the Whig Party nominated Henry Clay at its presidential convention in Baltimore, Morse's telegraph was able to get word to Washington an hour and a half before the news could reach there by train.

Besides the telegraph, Morse also worked on the new art of photography, being one of the first to introduce the invention of Jacques Daguerre to the United States and perhaps the first to take a photographic portrait. He also worked with Samuel Colt on using electricity to set off underwater mines. Aside from that, for the rest of Morse's life his main work was his telegraph, which astonished the public and revolutionized communications, business, the military, and the press. His invention brought him many honors both at home and abroad, including an honorary doctorate at Yale and the French Legion of Honor. However, it also involved him in various disputes and lawsuits over the rights to the telegraph, with various former partners and associates claiming to be the true inventor of the device or of the Morse code of dots and dashes that was used to transmit messages.

In 1854, the Supreme Court finally ruled that Morse was the inventor of the telegraph and entitled to patent protection, but disputes continued even after that. For instance, the heirs of Morse's assistant, Alfred Vail, complained to Morse's heirs that it was Vail who had invented Morse code. Most commentators, however, agree that the code was really Morse's invention.

During the Civil War, Morse, though a Northerner, sympathized with the South, wrote in favor of slavery, and became involved with the so-called Delmonico's conspiracy, a failed attempt to overturn the Emancipation Proclamation. Morse originally wanted to sell the rights to the telegraph to the U.S. government but found it was not interested. The result was that private telegraph companies sprang up in which Morse invested and through which he accumulated a substantial fortune, enough to buy a home in New York City and an estate (Locust Grove) near Poughkeepsie, New York. In 1871, the year before he died, a statue of him was erected in New York's Central Park at a ceremony attended by ten thousand people.

Impact

Morse's electric telegraph revolutionized communications in the United States and around the world. Before its introduction, communication at a distance had to be done by transportation, that is, by physically conveying a message by horseback or by train. The only exception was visual signaling, for instance through bonfires, smoke signals, or semaphore systems, but these depended on visibility and good weather and were much slower than electric communication. At first seen by some as magical and by others as a hoax, the telegraph quickly transformed various aspects of American life. News from afar began to be reported within hours instead of days, and the newspapers eventually banded together to form the Associated Press to more efficiently use the telegraph.

Although some hoped that this miraculous form of communication would bring people together and lead to peace and brotherhood, in fact one of the main uses of the telegraph was by the military, for instance during the Civil War. The telegraph was also enthusiastically adopted by business and facilitated the growth of nationwide corporations; in fact, one of the first such corporations was a telegraph company, Western Union, which by 1866 had absorbed all its rivals. Eventually, the telegraph was superseded by the telephone, radio, the Internet, and e-mail, but all those other forms of communication at a distance in a way came out of the telegraph, which was the Internet of its day.

Erwin Wilhelm Müller

German physicist

Müller invented three different microscopes: the field-emission microscope, the field-ion microscope, and the atom-probe field-ion microscope. He was the first person to see an image of an individual atom. His inventions allowed scientists for the first time to view surfaces at an atomic level.

Born: June 13, 1911; Berlin, Germany
Died: May 17, 1977; Washington, D.C.
Primary field: Physics
Primary inventions: Field-emission microscope; field-ion microscope; atom-probe field-ion microscope

Early Life

Erwin Wilhelm Müller (MYOO-lur) was the only child of Wilhelm M. and Käthe Müller (née Teipelke). Wilhelm was a construction worker who specialized in plastering ceilings of houses. Erwin worked part-time as a research assistant (1932-1935) while attending Technische Hochschule in Berlin-Charlottenburg (now Technische Universität Berlin). He received his engineering diploma in 1935 and his doctoral degree with a physics emphasis in 1936. His mentor was the Nobel Prize winner Gustav Hertz.

Being of Jewish descent, Hertz had been forced to resign his university post in 1935. He took Müller with him to the Siemens Research Laboratory, where Müller worked for two years and invented in 1936 the field-emission microscope (FEM), which could achieve near-atomic resolution. In 1937, Müller left Siemens to become the director of research and development at the Stabilovolt Company in Berlin, where he worked from 1937 until 1946. When the Berlin laboratory was destroyed by bombs during World War II, Müller tried to rebuild in Altenburg and in Dresden. Fortunately for science, he was not killed during the firebombing of Dresden in 1945.

Müller was not a member of the National Socialist Party and therefore was not able to obtain a university

The Field-Ion Microscope

It has been said that Erwin Wilhelm Müller's most valuable contribution to science was the invention of the field-ion microscope (FIM), built in 1951. The FIM was developed because it had long been Müller's goal to produce a microscope that would image individual atoms. His first FIM was produced using field-emission microscope (FEM) equipment. A sample in a sharp point form (less than a 50-nanometer-tip radius) was placed in an ultra-high-vacuum container lined with a fluorescent coating. The container was filled with hydrogen gas. The atoms of the gas adsorbed on the sample. When a high positive voltage (5,000-10,000 volts) was applied, the atoms were ionized and repelled by the electric field. The direction of travel was perpendicular to the surface, so the atoms spread out, producing on the fluorescent coating an image of the surface. The hydrogen gas supplied a continuous source of atoms to be ionized. The first image was weak, but rows of individual atoms were discernible. The magnification was in the range of millions.

The first images were only the atoms on edges of protrusions. The images were improved with field-induced surface dissolution (field evaporation). The sample tip was made smooth by a large electric field, and all of the small projections were evaporated off the sample. It was also discovered that helium gas would work better than hydrogen gas, which is flammable. A great improvement involved cooling the sample to a cryogenic temperature. The earlier FEM and FIM had to be placed in a cryogenic chamber to cool the sample, but Müller devised a cold finger to cool it, simplifying the process. FIM could image all of the atoms of a surface of a solid.

Before the invention of the FIM, surface features were only theory. Now studies could be made of individual vacancies, interstitial replacements, dislocations, grain boundaries, surface corrosion, radiation damage, and other surface phenomena. The FIM allowed the study of different planes of crystals. Field-emission energy distributions could more accurately be studied and were found, surprisingly, to have a narrow range of energies.

post until after the war in 1950. Nevertheless, his outstanding research protected him from having to serve in the army. In 1939, he married Klara Thüssing. The couple had one daughter, Jutta, in 1940. The conditions were so bad in Germany immediately after the war that they lived on a nine-hundred-calorie diet. They scavenged food from freshly harvested fields and used marble from a cemetery to make baking powder for bread. During 1946-1947, Müller walked several miles each day to teach physical chemistry at the Technical Institute in Altenburg.

Life's Work

From 1947 to 1951, Müller worked at the Kaiser Wilhelm Institute for Physical Chemistry in Berlin. There he invented in 1951 the field-ion microscope (FIM), which was capable of atomic resolution. He also taught at the Technical University of Berlin, beginning in 1950, when he finally received his habilitation (teacher's certificate). In 1951, he became a professor at the Free University of Berlin. Müller moved his family to Pennsylvania in 1952 and accepted a position at Pennsylvania State University. Conditions were still difficult in Germany, and Pennsylvania reminded Müller and Klara of rural Germany. Müller became an American citizen in 1962. He worked the rest of his career at Pennsylvania State University, becoming a research professor in 1955, the Evan Pugh Professor of Physics in 1968, and professor emeritus in 1976, when he retired.

Müller's doctoral work had been a study of electrons emitted from a material by applying an electric field to the material. His dissertation was on "The Dependence of Field Electron Emission on Work Function" (1936). The work function of a material is the minimum energy required to emit an electron from the surface. During his experiments, Müller developed the field-emission microscope. The FEM holds a sample formed into a sharp point in a vacuum chamber and coated with a fluorescent material. When a negative electric field is applied to the point, electrons are emitted from the surface of the point. The electrons travel perpendicular to the surface, causing the electron current density to be magnified on the fluorescent screen and producing a magnified image of the surface. The electron current densities depend on the electric fields, and the work function depends on the emitter surface.

Müller's first experiments were not successful, as the electron emissions came from any group of atoms protruding from the surface. There had not been a way to produce a truly smooth surface. Müller then changed the sample point so that it could be heated. The heating cleaned the surface of contamination by causing the contaminants to vaporize. More important, the heating smoothed any rough spots. The surface now was imaged on the fluorescent screen. Not only was Müller able to measure electron emission as he varied the work function by causing layers of metal to adhere to the sample point, but he also could view the surface of the material. The FEM was a boon to scientists studying surfaces and surface phenomena.

Müller wanted to be able to identify atoms chemically, so he set out to invent the atom-probe field-ion microscope (APFIM). The microscope had a probe hole to limit the area of study to one atom or to a small group of atoms. A drift tube was added to measure the time of flight of ejected atoms. The APFIM holds a sample formed into a sharp point, situated in an ultra-high-vacuum chamber, and cooled to very low temperatures (20 to 100 kelvins, or –253° to –173° Fahrenheit). A particular atom is selected by moving the tip to place that atom over the hole probe. The atom is ionized by a positive electrical or laser pulse. The electric field provides the momentum for the ion to travel the length of the drift tube to the detector. A measurement of time between the pulse and the arrival of the atom at the detector is used to calculate mass. The composition of a surface can also be accurately determined. Each layer can then be peeled off, producing a three-dimensional map of a solid. The APFIM provided proof of different isotopes, because each isotope could be measured individually.

Besides his work with these microscopes, Müller described the principle of the imaging field-desorption mass spectrometer. He also induced adsorption of noble gases by electric field effects and formed noble gas-metal molecular ions. He studied the patterns of multilayer field desorption, and he published on the precise measurements of the energy distribution of field-emitted electrons.

Müller published some 211 research papers and several books during his career. He was honored with many awards, including those from the Technische Hochschule in Berlin-Charlottenburg (1936), the Instrument Society of America (1960), the Franklin Institute in Philadelphia (1964), the Chemical Society of London (1969), the American Vacuum Society (1970), the city of Philadelphia (1970), and the American Physical Society (1972). He was awarded two honorary doctorates. Near the end of his career, Müller suffered from throat cancer, but after retirement he seemed to be recovering. He died of a stroke in Washington, D.C., at a meeting of the National Academy of Sciences in 1977. He was awarded the National Medal of Science, which was accepted by his daughter at a White House ceremony in November, 1977.

Impact

The field-emission microscope could resolve surface features that were as small as 2 nanometers. With the FEM, scientists could study the surface-layer rearrangement and surface diffusion. For twenty years, FEM was the best tool with which to study surfaces. Information gained from FEM experiments have proven valuable in flat-panel image displays and in vacuum electronics. The field-ion microscope had improved resolution compared to the FEM: one twenty-five-hundredth of a nanometer, the atomic level. The FIM offered visible proof that atoms existed. The magnification was on the order of one million times. The surface could be studied atom by atom, leading to atomic resolution metallurgy and materials research.

In 1967, Müller invented a method to select the atom to be investigated and to measure the mass of that atom by using time-of-flight calculations. Thus, isotopes of the same element could be detected in a surface.

In order to make his microscopes work, Müller had to develop high-vacuum techniques. He was able to produce vacuums of 10^{-12} torr many years before other fields of science reached that vacuum. His use of barium getters and other metal vacuum getters was a valuable step forward for vacuum technology.

Karl Alexander Müller

Swiss physicist

Müller, with J. Georg Bednorz, made the breakthrough discovery of high-temperature superconductivity in a new class of ceramic materials.

Born: April 20, 1927; Basel, Switzerland
Primary field: Physics
Primary invention: High-temperature superconductors

Early Life

Karl Alexander Müller (KAHRL AL-ihg-ZAN-dur MYOO-lur) was born in Basel, Switzerland, in 1927, but the early years of his life were spent in Salzburg, Austria, where his father, Paul Rudolf Müller, was studying music. His mother, Irma (Feigenbaum) Müller later traveled with Karl to Dornach, a few miles south of Basel, where they lived with his grandparents. Since his grandfather had become successful in the chocolate business, mother and child were well provided for. Due to another move, this time to Lugano in an Italian region of Switzerland, Karl began his schooling needing to master not only his courses but also a new language. When his mother died in 1938, he moved with his father to Schiers in eastern Switzerland, where his courses at the Evangelical College were in German. As a teenager, he became interested in science, politics, and sports. His fascination with radio construction and transmission led to a desire to become an electrical engineer, but his achievements in his chemistry and physics courses swayed a respected teacher to steer him in the direction of physics. With Swiss neutrality during World War II, Karl was able to safely pursue his interests in world affairs, while also developing his skill in alpine skiing. He completed his secondary school education just as the war ended.

After completing his mandatory service in the Swiss army, he enrolled in the Physics and Mathematics Department of the Swiss Federal Institute of Technology (ETH) in Zurich. The American use of atomic bombs to end the war with Japan created a worldwide interest in nuclear physics, and Müller's freshman physics course, taught by Paul Scherrer, was three times its traditional size. Scherrer's approach had a profound effect on Müller, but he was so disappointed in his other physics courses that he almost transferred into electrical engineering. He decided to remain a physics major after taking courses from the Nobel laureate Wolfgang Pauli, who communicated the joy that comes with understanding truths about nature. For his undergraduate research project, Müller measured the transverse electric field in gray tin, a semimetal, when it carried an electric current in a magnetic field perpendicular to the current (the so-called Hall effect). Thus began his lifelong interest in solid-state physics.

After receiving his degree, Müller worked on metallic oxides for a year in industrial research and then resumed his graduate studies. His dissertation, done under the supervision of Georg Busch, centered on the synthesis and properties of strontium titanium oxide. This material had a perovskite structure. Perovskite, or calcium titanium trioxide, is a mineral that was discovered by and named for the nineteenth century Russian count and scientist L. A. Perovski. The basic structure of perovskite has the larger titanium atom at the center of a cube with the smaller calcium atoms at the cube's corners, with the oxygen atoms distributed halfway along the cube's edges. A characteristic of this crystal structure is the octahedral arrangement of the six oxygen atoms around each calcium atom. The perovskites would become a career-long fascination for Müller. While working on his dissertation, he courted and married Ingeborg Marie Louise Winkler. His son Eric was born in the summer of 1957, six months before Müller submitted his thesis.

Life's Work

After receiving his doctorate in 1958, Müller joined the Battelle Memorial Institute in Geneva, where he managed a group that was studying layered graphite compounds and where his daughter Silvia was born. At Battelle, he deepened his knowledge of nuclear magnetic resonance (NMR) spectroscopy, and in 1962 he began dividing his time between Geneva and Zurich, where he lectured and helped form an NMR group at the University of Zurich. In 1963, this lectureship led to his accepting a position at the International Business Machines (IBM) Research Laboratory in Rüschlikon, near Zurich, which would become the locus of his work for the rest of his career. As a creative researcher, he believed that he needed not only an agile and rational mind, but also a heart that was driven, in his words, by an "internal fire."

During the 1960's, Müller deepened his understanding of the perovskites. IBM's researchers were interested in these compounds because such synthetic perovskites as barium titanium trioxide played pivotal roles in electronic devices. Walter Beringer was a principal collaborator with Müller in his studies of perovskites and perovskite-related compounds. They added ions to certain perovskites and studied how the doped compounds' chemical, electric, and magnetic properties changed. Publication of their results advanced Müller's reputation, leading to his promotion in 1970 to titular professor at the University of Zurich and, in 1972, to his becoming head of the IBM laboratory's physics group.

As a physics student, Müller had learned of the 1911 discovery of superconductivity by the Dutch physicist Heike Kamerlingh Onnes. Having developed techniques for achieving extremely low temperatures, Kamerlingh Onnes was able to liquefy helium, and he found that, at liquid helium temperatures, such metals as mercury exhibited a total loss of electrical resistance. Since Kamerlingh Onnes's work, scientists had found other metals and alloys that superconducted, including an alloy of tin and germanium that superconducted at 23.2 kelvins. In the early 1970's, Müller, stimulated by certain calculations on metallic hydrogen, investigated the possibility of incorporating hydrogen into a perovskite to create a metallic state that might superconduct, but his calculations led him to conclude that the required density of hydrogen within the structure was unattainable.

From 1968 to 1980, Müller spent eighteen months at IBM's Thomas J. Watson Research Center in Yorktown Heights, New York, where he studied ways in which

The Breakthrough High-Temperature Superconductor

The discovery of a new class of materials that superconducted at a surprisingly high temperature led to such a proliferation of publications that physicists had to reach back to the discovery of nuclear fission to come up with an apt parallel. In the decades before this discovery, searchers for high-temperature superconductors, though not nearly as numerous as they became in the two decades after 1986, were nevertheless numerous enough to study exotic alloys and even complex perovskites. Why, then, did Karl Alexander Müller and J. Georg Bednorz succeed where so many others failed?

In their Nobel lecture, Müller and Bednorz pointed to a series of fortunate circumstances that assisted them in making their breakthrough discovery. Most important, they had the good fortune to meet and decide to collaborate, and their strengths and abilities beautifully complemented each other. Favoring their risky venture was Müller's position as IBM fellow, which permitted him to freely pursue his interests without having to report to company officials. Furthermore, because of their educations, both had an excellent understanding of perovskites. They did run into bad luck when their study of a lanthanum-nickel-oxygen system tested negative for superconductivity, but, by happy accident, they learned of the French work on a barium-lanthanum-copper-oxygen material. They were lucky, too, that the French scientists were interested only in this material's catalytic, not potentially superconductive, property.

When, in January of 1986, Bednorz discovered that a ceramic material he made superconducted at a temperature much higher than any previous material, he and Müller were cautiously optimistic, an optimism that proved fully justified when their discovery ushered in a new era of superconductivity studies. Although Müller and Bednorz did not offer an explanation of the mechanism by which their perovskite superconducted, they did provide clues to other scientists of how future superconductors could be made. Paul Chu and his colleagues in the United States were very successful when they substituted yttrium for lanthanum, and their yttrium-barium-copper-oxygen ceramic was able to superconduct in a liquid nitrogen environment. Within a short time transition, temperatures rose from 35 to more than 120 kelvins. However, *why* these ceramic materials superconducted remained a mystery, and their commercialization has so far been limited to a few restricted markets. Nevertheless, Müller and other scientists in the new field that he helped to create hope that the surprising discovery of high-temperature superconductivity will lead to other, even more fruitful discoveries in the future.

the critical temperature (T_c) at which certain materials superconduct could be increased. He studied the BCS theory, named after its generators, John Bardeen, Leon Cooper, and Robert Schrieffer. To explain superconductivity in certain crystal structures, they used lattice vibrations (phonons) and pairs of electrons with opposite spins (so-called Cooper pairs). The lattice vibrations helped randomize the motion of the electrons, whose Cooper pairs broke apart when the superconducting temperature was reached. Müller's preliminary calculations indicated that superconductivity in perovskite-related materials might be possible.

When, in the fall of 1983, he returned to Zurich, Müller asked J. Georg Bednorz, whose doctoral thesis he had helped to supervise, to collaborate with him in his search for superconductivity in the perovskites. Despite their age difference (more than twenty years), they formed a successful team. Müller was the theoretician who had deep insight into the structures and properties of complex crystal structures, while Bednorz was the skilled experimenter who was able to synthesize these materials and determine their chemical and physical properties. Müller and Bednorz started their search with a lanthanum-nickel-oxygen system, but their nickel-containing perovskites tested negative for superconductivity. A turning point occurred in late 1985 after Bednorz read an article by French chemists describing a compound of barium, lanthanum, copper, and oxygen. Since this material exhibited metallic conductivity over a wide temperature range, it satisfied one of Müller's criteria for superconductive perovskite materials. Bednorz prepared a series of these copper-oxide-containing compounds in which he varied the barium ion concentration. In January, 1986, he found that one of his compounds manifested a sharp drop in resistivity at temperatures as high as 35 kelvins, much higher than any previously studied substance. Because a test of the magnetic properties of their substance was needed to fully establish the true existence of superconductivity, they gave their initial paper, which they submitted in April, a tentative title: "Possible High T_c Superconductivity in the Barium-Lanthanum-Copper-Oxygen System." By the time their paper was published in September, their uncertainty had vanished, since a magnetometer purchased for the IBM laboratory corroborated their discovery of high-temperature superconductivity.

Impact

Initially, because many scientists were skeptical that ceramic materials would manifest high-temperature superconductivity, the discovery of Bednorz and Müller was underappreciated by researchers in the field and underreported in general-interest publications. However, in 1987, when physicists in the United States and around the world began reporting that other ceramic materials superconducted at temperatures near 90 kelvins, scientists, entrepreneurs, politicians, and the public became captivated. Müller and Bednorz were honored with the 1987 Nobel Prize in Physics in what some saw as the Nobel Committee's speediest recognition ever of any scientific achievement. As evidence of the great impact of their discovery, Müller and Bednorz received numerous awards and honorary degrees in the decades that followed.

The new superconductors posed challenges for the BCS theory and several new theories that were proposed to account for this surprising discovery. Not one of these theories has gained wide acceptance. Despite the failure to understand *why* these superconductors work in the way they do, other scientists and inventors have tried to find out *how* they can be used in various applications. They have been used in particle accelerators and other devices, but the hope is that superconductors will make energy generation and transmission more efficient and computers faster and more powerful. Their use in magnetic levitation trains will make transportation smoother and safer. Magnetic resonance imaging (MRI) in medicine will become better and less expensive. These predictions, generated due to the euphoria created by the initial discovery of high-temperature superconductivity, have now been replaced by a pragmatic realization that many difficulties will have to be overcome before any utopia fostered by resistance-free electricity is achieved.

Kary B. Mullis

American biochemist

Mullis conceived and developed the polymerase chain reaction (PCR), which revolutionized the study of the biological and medical sciences. PCR is used in the diagnosis of various infectious and genetic diseases, has been widely used in forensic analysis, and was instrumental in the sequencing of many genomes.

Born: December 28, 1944; Lenoir, North Carolina
Also known as: Kary Banks Mullis (full name)
Primary fields: Biology; chemistry; genetics; medicine and medical technology
Primary invention: Polymerase chain reaction

Early Life

Kary Banks Mullis was born in Lenoir, North Carolina, to Cecil Banks Mullis and Bernice Alberta Barker Mullis. His family moved to Columbia, South Carolina, when he was five years old. Mullis's mother and father were from rural South Carolina. His father sold institutional furniture, and his mother was active in the community and began selling real estate to put her children through college.

Mullis's interest in science developed very early, when he started to play with electricity at the age of six. His interest in chemistry was stimulated when, at the age of seven, he received a chemistry set as a Christmas present. He attended Dreher High School in Columbia, where he was an excellent student. He was vice president of the student council, president of the Junior Engineering Technical Society (JETS), and a National Merit Scholar. At Dreher, his interest in chemistry was further stimulated by his teacher, who let him experiment in the laboratory in the afternoons. The summer after graduation, he worked for Columbia Organic. In 1962, Mullis entered the Georgia Institute of Technology (Georgia Tech), where he received a B.S. in chemistry in 1966. During the summers while at Georgia Tech, he broadened and increased his knowledge of chemistry while synthesizing chemicals for King's Laboratories.

In 1966, Mullis moved to Berkeley, California, to study for a Ph.D. in biochemistry under Allan Wilson. Soon after arriving in Berkeley, Mullis started to work in the laboratory of Joseph B. Neilands. In Neilands's laboratory, his project focused on schizokinen, a molecule involved with the transport of iron in bacteria. While a second-year graduate student in 1968, he published an article in *Nature* titled "The Cosmological Significance of Time Reversal." He received his Ph.D. in 1972 for "Structure and Organic Synthesis of Microbial Iron Transport Agents."

Mullis remained at Berkeley for a year as a lecturer in biochemistry, and then he moved to Kansas. He eventually accepted a postdoctoral fellowship at the University of Kansas, where he worked in pediatric cardiology specializing in pulmonary vascular physiology.

In 1975, Mullis returned to Berkeley and worked in a coffee shop until 1977, when he accepted a postdoctoral fellowship to work in pharmaceutical chemistry at the University of California, San Francisco.

Life's Work

In 1979, Mullis accepted a position as a synthetic chemist specializing in the synthesis of oligonucleotides with the DNA (deoxyribonucleic acid) synthesis unit at Cetus Corporation in Emeryville, California. Although Mullis soon made the process of synthesizing oligonucleotides faster and more efficient, with higher yields, he often clashed over methods with Chander Bahl, who headed the DNA synthesis group. In 1981, Tom White, who had recently been appointed head of Recombinant Molecular Research, appointed Mullis head of the DNA synthesis laboratory to replace Bahl.

One evening in the spring of 1983, while driving to his cottage in Mendocino in Northern California, Mullis conceived the polymerase chain reaction (PCR). He had for some time been attempting to develop a technique that could efficiently amplify the beta-globin gene and screen for the presence of the sickle-cell anemia mutation. The project involved the detection of a single base-pair mutation in the sickle-cell beta-globin gene by seeing if it could be digested with a specific restriction endonuclease. Normal beta-globin DNA would not be digested. Since the technique was hampered by the small amounts of beta-globin DNA available, Mullis was attempting to design a method to amplify beta-globin DNA in order to make the beta-globin project better and the assay more reliable. He realized that if he used two oligonucleotides that bound to opposite sides of sickle-cell beta-globin DNA, the oligonucleotides could be extended by DNA polymerase and make a copy of the sickle-cell beta-globin DNA contained between the two oligonucleotides, resulting in twice the amount of sickle-cell beta-globin DNA. If other rounds were carried out, the increase in the target DNA would be exponential. Although his colleagues at Cetus were not very encouraging of his amplification concept, he made a presentation about the potential method at an August, 1983, Cetus meeting.

Mullis did his first PCR experiment on September 8, 1983. Although his initial attempts to amplify a specific target DNA failed, by June, 1984, he had achieved some success with both plasmid and human DNA targets. By the spring of 1985, DNA amplification by PCR had been perfected by Mullis and his assistant, Fred Faloona, working with Cetus laboratory technicians, namely Stephen Scharf and Randall K. Saiki. Cetus applied for a patent for the PCR procedure on March 28, 1985. Although Mullis's name was on the patent application, all rights were held by Cetus. In the spring of 1986, Mullis received a $10,000 bonus for his invention.

The Polymerase Chain Reaction

Kary B. Mullis not only conceived the concept of the polymerase chain reaction (PCR) but also was instrumental in developing it into a technique that revolutionized the study of genetics, molecular biology, medicine, and forensic science. PCR has three steps: The first step involves denaturation, during which the double-stranded DNA sample is heated to 92°-96° Celsius for about thirty seconds, causing the two DNA strands to separate. The second step involves annealing of single-stranded nucleotide chains, called primers, to opposite ends of the target DNA as the sample is cooled to 55°-65° Celsius for about thirty seconds. The third step involves the extension of those primers by DNA polymerase as the temperature is raised to about 72° Celsius for about one minute. The result is that after one cycle of denaturation, annealing of primers, and extension, one double-stranded target DNA has been replicated into two double-stranded DNA molecules. After thirty cycles of PCR, which takes about three hours, the target DNA is amplified to more than one billion target molecules. The amplified target DNA can easily be detected by electrophoresis. PCR has been fully automated with the use of thermostable DNA polymerases and the development of thermocyclers that can be programmed to incubate the PCR reaction for specific times at specific temperatures.

PCR has widespread application in science. It was instrumental in allowing for DNAs to be amplified, providing enough DNA for sequencing the human and other genomes. PCR is also used extensively in medicine for the rapid diagnosis and screening of genetic diseases such as sickle-cell anemia and cystic fibrosis in fetuses, newborns, and adults, and the detection of pathogenic bacteria, viruses, and parasites such as those that cause acquired immunodeficiency syndrome (AIDS), Lyme disease, pneumonia, and a variety of sexually transmitted diseases. PCR is used to detect the presence of genes that may make one susceptible to certain diseases such as coronary artery disease and cancer. PCR is used extensively by forensic scientists for DNA profiling (formerly referred to as DNA fingerprinting) for use in crime scene analysis, human identification, and paternity testing. Modern adaptations of PCR called real-time PCR and reverse transcriptase PCR (RT-PCR) use fluorescent detection of the amplification products and allow molecular biologists to quantify DNA. By using RT-PCR, molecular biologists study the expression and regulation of specific genes under various conditions. Portable real-time thermocyclers that can be taken into the field allow for the rapid detection of several highly pathogenic organisms, such as *Bacillus anthracis* (anthrax), that could potentially be exploited by terrorists.

The first paper—which was coauthored—describing the applications of PCR, "Enzymatic Amplification of Beta-Globin Genomic Sequences and Restriction Site Analysis for Diagnosis of Sickle Cell Anemia," was published in *Science* on December 20, 1985. Mullis presented his concept of PCR at the May, 1986, Cold Spring Harbor Laboratory Symposium on the Molecular Biology of *Homo sapiens*. Later that year, he published on the concept of PCR and its applications in the *Cold Spring Harbor Symposia on Quantitative Biology*, and in 1987 he published in *Methods in Enzymology* more details of PCR conditions in "Specific Synthesis of DNA in Vitro via a Polymerase-Catalyzed Chain Reaction," after having been previously rejected by *Science* and *Nature*. The first PCR patents were awarded to Cetus in June, 1987. Cetus sold the patent rights to PCR to F. Hoffmann-La Roche in 1991 for $300 million.

In 1986, Mullis left Cetus and joined Xytronyx, a small biotechnology company in San Diego, California, as director of molecular biology. There Mullis worked on DNA technology and photochemistry. He left Xytronyx in 1988 to serve as a consultant for several biotechnology companies.

Mullis has developed an idea that could have significant impact in the field of immunology. He has been working on a method that uses chemical linkers to change the specificity of an antibody from its normal target to a different target. Since humans are naturally immune to many antigens, a linker molecule could be synthesized that would potentially bind to the human antibody at one end and a virus at the other end, resulting in the inactivation of the virus. In this way, antibodies that would normally bind to one antigen could theoretically be diverted to bind to a second antigen. The linker concept has been applied successfully to rodents. Mullis started a small company, Altermune, to coordinate his work on immunology.

Mullis served as Distinguished Researcher at Children's Hospital Institute in Oakland, California. He sat on the board of directors of several companies and organizations. Besides his autobiography, *Dancing Naked in the Mind Field* (1998), he is the author of several scientific publications. He is also the author of several patents, including PCR and one for a plastic that changes color in response to ultraviolet light. He is the recipient of several awards, including the William Allan Memorial Award of the American Society of Human Genetics (1990), the Gairdner Foundation International Award (1991), the National Biotechnology Award (1991), the California Scientist of the Year Award (1992), and the Thomas A. Edison Award and the Japan Prize (both 1993). Mullis won the 1993 Nobel Prize in Chemistry "for contributions to the developments of methods within DNA-based chemistry" and "for his invention of the polymerase chain reaction (PCR) method." Mullis shared the Nobel Prize with Michael Smith. Mullis was a 1998 inductee of the National Inventors Hall of Fame.

Impact

PCR has multiple applications and has had a profound impact on the fields of molecular biology, genetics, medicine, biotechnology, and forensic science. It is a revolutionary technology that precisely copies DNA. In a matter of two or three hours, one DNA molecule can be amplified to billions of copies, making analysis of specific DNA targets possible. The use of PCR technology has accelerated the analysis of the structure and function of genes and the sequencing of several genomes, including that of humans. The technology has been employed to screen and diagnose various viral and bacterial infectious diseases such as HIV/AIDS, tuberculosis, and staphylococcus. In addition, PCR has been used for the prenatal, neonatal, and carrier testing of numerous genetic diseases as well as for sex determination using prenatal cells. PCR has led to the development and employment of DNA-testing methodologies for forensic applications, including human DNA profiling and identification.

WILLIAM MURDOCK

Scottish engineer

Murdock's creative genius brought developments in areas as diverse as steam engine design and chemical dyes and led him to pioneer the use of coal gas for commercial and domestic lighting.

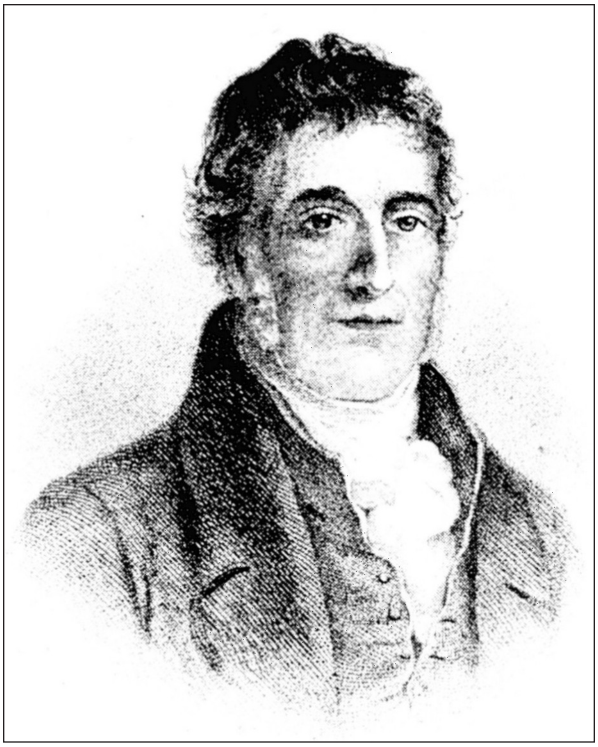
Born: August 21, 1754; Bellow Mill, near Old Cumnock, Ayrshire, Scotland
Died: November 15, 1839; Birmingham, England
Also known as: William Murdoch
Primary field: Civil engineering
Primary inventions: Improved steam engine; coal gas lighting

EARLY LIFE

William Murdock was born near Old Cumnock in Ayrshire, Scotland, on August 21, 1754, the oldest surviving son of Anna and John Murdock's seven children. His father was a miller and wheelwright, from a family that included many other respected technicians, engineers, and clockmakers. John had a reputation for exceptional intelligence, skill, and inventiveness, and young William worked with him on many projects at the mill, on the family farm, even designing and constructing bridges, acquiring great expertise and technical knowledge. John is also said to have invented a "wooden horse," a tricycle predating pedal bicycles by several decades, and young William would certainly have ridden this in his childhood.

William spent many boyhood hours in a small riverbank cave beside the mill and here began simple experiments with steam; he may even have started to investigate producing light by burning the gas produced by heating coal in a kettle. He would certainly have been familiar with the sight of coal burning in the family fireplace on winter evenings, which had the unusual property of hissing and spitting as it emitted spurts of gas that burned brightly at its surface.

William, however, was ambitious to make a name for himself. Through his father's business connections, he heard about the inventions of the great engineer James Watt and became determined to work at the famous Soho Manufactory in Birmingham, England, where Watt was in partnership with Matthew Boulton. Accordingly, in August, 1777, at the age of twenty-three, William left his family to walk the three hundred miles to Birmingham. Boulton was immediately impressed by the young engineer and found him a place at the foundry.



William Murdock. (Library of Congress)

At this time, much of the firm's work was in steam engines, especially for pumping water from mines. Boulton and Watt jointly owned the patent for Watt's separate-condenser engine. Murdock quickly learned the business: By the following year, he was much sought-after in the pattern shop, and within two years (March, 1779) was being sent to manage the erection of engines around the country. On his first such solo job, he rearranged the gears of Watt's engine, greatly improving its performance. Although Watt was very protective of his design, he admired Murdock's ingenuity, and the young mechanic grew in his esteem and trust.

Coal Gas Lighting

When coal is heated in a process that is essentially a destructive distillation, a significant fraction of the coal may be driven off as gas. Depending on the type of coal—its geological source and mineralogical history—the gas evolved will contain principally hydrogen, carbon monoxide, and methane, each in greater or lesser quantities. All three of these gases are highly flammable, burn very efficiently in air, and produce both heat and light as they do so. Even with his relatively primitive apparatus, William Murdock was able to collect and purify this mixture of gases; he introduced quicklime as the best solution for removing the sulfurous gases that contaminated the fuel—their unpleasant odor was one of the main initial drawbacks of using coal gas. His experiments also determined the best way of burning the gas, and what types of apertures would be most effective, ultimately leading to the widespread application of this relatively simple principle to domestic and commercial lighting.

Prior to Murdock's work, oil and tallow were the main fuels used for lighting. They had the great disadvantage that they were considerably less efficient, principally because they did not burn very cleanly. Instead, they produced significant amounts of soot as they burned, and they produced only a very poor quality of light. Coal gas lighting, on the other hand, gave a much brighter and steadier flame, was much cleaner, and was up to 50 percent cheaper. Despite initial skepticism and resistance to change, therefore, Murdock's gaslight was destined to spread rapidly.

Just as the Industrial Revolution was bringing advances and improvements in living standards, gas lighting played its own crucial part. Shops could remain open later, and the lighting of streets made them much safer. At home, people were able to read more easily in this bright new light—and the poor in particular had new worlds opened up to them as newspaper circulation increased. Community gatherings on dark evenings became possible. Profound social changes took place ahead of the twentieth century and the dawn of electric light. There can be no doubt that Murdock's gaslight wrought a change as great as Thomas Alva Edison's light bulb.

Life's Work

Later in 1779, Murdock was sent as manager of the firm's interests to Cornwall in southwest England, which would be his home for almost twenty years. Many of the local copper and tin mines had installed Boulton and Watt pumping engines, and Murdock was to keep them running smoothly. Many times he would modify an engine's design to enhance its performance. Murdock worked so diligently, with such consummate skill, and often without sleep, that he became more valued by his employers, and he achieved great popularity with the mine owners—who, above all, loathed production stoppages.

Murdock also worked on many other projects while in Cornwall. Ways were sought whereby Watt's steam engine could produce rotary motion for the moving machinery of the country's mills, a central part of the Industrial Revolution. Boulton and Watt patented five different methods for generating rotary motion, of which the sun-and-planet gear invented by Murdock was the most widely used. It was patented in February, 1782, less than five years after he joined the firm.

Around the same time, Murdock was beginning to speculate whether the steam engine could also be used to produce locomotion. He already knew, from riding his father's tricycle years earlier, that machines could be made to transport people. However, up to then the wheels were always turned by the strength of a person or an animal. Turning wheels using a machine required a unique mind to recognize the possibility and a talented engineer to make the idea a reality. Murdock combined both of these qualities, and by 1784 he had a working model drawing a small wagon around his living room in Redruth, Cornwall. This was the first working steam locomotive in Great Britain: Nicolas-Joseph Cugnot in France had demonstrated such a vehicle in 1769, but his experiments were curtailed by accidents and its inefficient design.

Unfortunately, neither Boulton nor Watt was enthusiastic about Murdock's "steam carriage," concerned that it would distract him from his other duties within the firm. They believed that all their energies—and Murdock's—should be directed toward maintaining the market superiority of Watt's engine, and they were busy with litigation over steam engine patent infringements. As a result, a great opportunity was missed, and the company failed to benefit from one of Murdock's greatest achievements. It was left to competitors such as Richard Trevithick to produce their own steam locomotives around the beginning of the nineteenth century.

Murdock may have been bitter and puzzled by his employers' behavior, but he remained loyal to them and would soon turn his attentions to fresh innovations. It is a remarkable testament to his strength of character that his professional relationships remained solid, especially as these were also years of great personal upheaval. He had married Anne Paynter, daughter of a mine captain, in 1785, and the following year experienced the loss of twins. Two more sons were born in consecutive years, but he then endured the tragedy of his wife's death in 1788.

Within a few years, Murdock embarked upon new challenges. People knew that gases were given off when coal was heated, and that the gases could be ignited, but Murdock realized the potential of gaslight. He launched a series of experiments at home in Redruth, examining the combustion properties of various materials, comparing the gases produced by coal from different coalfields, and devising means of purifying the gases. He investigated air-gas ratios and the sizes and shapes of apertures giving the most efficient combustion and the best quality of light. Coal gas proved more economical, and provided better illumination, than either oil or tallow, which then were the predominant lighting fuels.

Murdock equipped his house for gas lighting around 1792, the gas being conveyed along pipes from his workshop where coal was heated in a retort. He also devised a portable gas lantern consisting of a gas-filled bladder, with a pipe attached, from which the gas jet could be lit and light his way on dark nights. Bizarrely, Murdock's employers again appeared somewhat indifferent to this momentous advance. The company did not patent the concept, and others would profit from it. However, Murdock was made manager of the new Soho works in 1798 and continued to work on gas lighting. The Soho factory was publicly illuminated in March, 1802, and other premises around the country had gas lighting installed over the next few years. Gas lighting became widespread in cities around the country within two decades, and Baltimore was the first major U.S. city lit by gas in 1817.

The Royal Society of London awarded Murdock the Rumford Medal in 1808 for his achievements. He continued to work on a variety of projects, retiring in his seventy-sixth year. He and Watt remained great friends, and Watt's death in 1819 caused Murdock great grief. In his last years, his own health began to fail, but he remained active until the death of one of his sons, when he deteriorated and died on November 15, 1839, aged eighty-five.

Impact

Murdock came from a family of inventors, so it is no surprise that even as a young man his imagination was working on simple solutions to complex problems. Visitors to the Soho factory observed many of his innovations and special machine tools that "had his genius stamped on them." Murdock contributed significantly to the improvement of the steam engine and steam power, devising notably the oscillating cylinder engine and the bell-crank engine, which was used on steamboats. He also introduced several advancements in rotary motion, including the sun-and-planet gear and the worm wheel.

Murdock also had a fascination with compressed air, steam, and pneumatic devices, and he invented a type of stirrup pump, pneumatic lifting gear, and even a pneumatic doorbell. He also created a system of transmitting letters through pipes using compressed air (used in drive-up banking facilities), and a high-pressure steam gun whose principle was later used to launch planes from aircraft carriers.

Murdock is best remembered for introducing gas lighting, and its attendant benefits, but chemical innovations also came from this. Some of the by-products of coal-gas production became very profitable aspects of gas works business: Coke and coal tar were especially valuable, and some of the other chemicals isolated became aniline dyes—the subject of one of Murdock's own patents (1791). He is also credited with the adventitious discovery of iron cement, and he developed a technique to cheaply produce isinglass for beer clarification.

Murdock was not motivated by fame and fortune; he was simply driven by his work and was content to observe the great benefits that others would derive from his singular achievements. His loyalty to the company even in very difficult circumstances speaks to his remarkable character, and the breadth of his inventiveness belies his extraordinary mind.

Primary invention: Leiden jar

Early Life

Pieter van Musschenbroek (PEE-tur vahn MOO-shehn-brook) was born in 1692 to Johan Joosten van Musschenbroek and Maria van der Straaten. The family history played a significant role in the development of Musschenbroek's career. In the late sixteenth century, the Protestant Musschenbroek family had fled from the Southern Netherlands to Leiden to escape persecution by the Spanish. In Leiden, the family established a brass foundry, producing items such as lamps and weather vanes and gaining a fine reputation for the construction of scientific instruments during the seventeenth century. From 1707 to 1749, Pieter's older brother, Jan, ran the business, where as a boy Pieter helped in the workshop. The Musschenbroek workshop contained a library of more than eight hundred scientific works, including books on physics and electricity, with scientists themselves frequenting the establishment.

Pieter van Musschenbroek studied classical and modern European languages at the Leiden Latin School. In 1708, he matriculated at the University of Leiden, where he earned a doctoral degree in medicine in 1715. In 1717, he traveled to England, where he met Isaac Newton and other scientists in the Newtonian circle. In England, he also attended John Theophilus Desaguliers's lectures on experimental physics. In 1719, he received a second doctorate, in philosophy, with a concentration in physics, at Leiden. There, he studied with Willem Jacob 's Gravesande, author of the first comprehensive book on physics and frequent client of Jan van Musschenbroek.

Life's Work

In 1719, Musschenbroek took a position as professor of mathematics and philosophy at the University of Duisburg; in 1721, he was also appointed professor of medicine. He taught these subjects from 1723 to 1739, and in 1732 he was promoted to the chair of astronomy at the University of Utrecht.

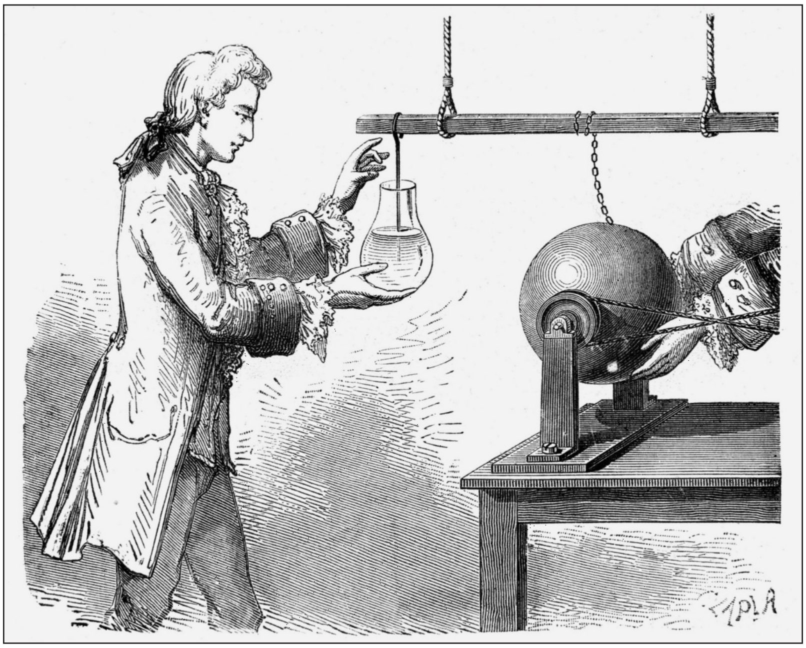
An understanding of Musschenbroek's invention of the Leiden jar requires a brief account of the state of science at that time. Two schools of thought concerning the study of natural phenomena existed then. In setting down the ideas of rationalism, René Descartes had argued that knowledge was found in reason and deduced from first principles. In contrast, Newton asserted that science was grounded in observation and experiment, with the results expressed in terms of mathematics.

While Herman Boerhaave was the first to advocate

Newton's method in the Netherlands in 1715, Musschenbroek, along with 's Gravesande, facilitated the introduction of the Newtonian experimental method in the Netherlands. One of Musschenbroek's earliest works, *Oratio de certa methodo philosophiae experimentalis* (discourse on the most certain method in experimental philosophy), a series of lectures published in 1723, supported the Newtonian method. In 1725, he attacked Cartesian physics directly in a letter to the *Philosophical Transactions of the Royal Society* in London.

A lifetime of teaching and performing experiments reflected Musschenbroek's acceptance of the philosophy of Newton and led to the publication of several important textbooks during his tenure at Utrecht. Among his works is a summary of his lectures, *Epitome elementorum physico-mathematicorum, conscripta in usus academicos* (1726), republished in 1741 under the title *Elementa physicae, conscriptae in usus academicos*. It appeared in an English translation in 1744 as *Elements of Natural Philosophy Chiefly Intended for the Use of Students in Universities*, and in a German translation in 1747. Another work, *Oratio de methodo instituendi experimenta physica* (1730; discourse on the method for performing physical experiments), became a standard textbook. In 1736, he published *Beginselen der natuurkunde* (principles of natural philosophy) in Dutch, translated into French as *Essai de physique*. Although these early works did not contain much about the study of electricity, a science still very much in its infancy, the experimental techniques described in them enabled him to discover a way to store electricity.

Through the efforts of Boerhaave in medicine and chemistry and 's Gravesande in physics, the University of Leiden had gained preeminence in the Newtonian experimental method. After the university's last Cartesian mathematics teacher died in 1739, Musschenbroek accepted an offer to succeed him, and when 's Gravesande died in 1742, Musschenbroek assumed his teaching position in experimental physics. During the early years at Leiden, Musschenbroek became interested in the phenomena of electricity and performed or repeated all the known experiments on it in less than a month. At the end of 1745 and beginning of 1746, Musschenbroek, with Jean Allamand, an assistant from the university, and Andreas Cunaeus, a lawyer who enjoyed visiting the laboratory, discovered that a jar filled with water stored static electricity generated by a friction machine. The entire quantity of electricity discharged when a person touched the wire connecting the source of the electricity and water in the jar. In January, 1746, after confirming the phenomenon, Musschenbroek wrote a letter in Latin to René Réaumur, his contact at the Paris Academy of Sciences, who in turn reproduced the experiment. The popularizer of science Jean-Antoine (Abbé) Nollet translated the letter and published the first drawing of the experiment with the "Leiden jar," as he called the device in his 1746 book *Essai sur l'éléctricité des corps* (essay on the electricity of bodies).



Pieter van Musschenbroek with the Leiden jar, a primitive capacitor. Wood engraving, nineteenth century. (The Granger Collection, New York)

At Leiden, Musschenbroek continued to produce new editions of his textbooks. A final expansion of the *Epitome* resulted in a two-volume work, *Introductio ad philosophiam naturalem* (introduction to natural philosophy), which appeared posthumously in 1762. He taught at the University of Leiden until his death on September 19, 1761. He was buried with his second wife.

IMPACT

Although the historical significance of Musschenbroek's work rests more

Musschenbroek's Leiden Jar

During Pieter van Musschenbroek's time, the only form of electricity known was static electricity. The word "electricity" derives from *elektron*, the Greek word for "amber." Ancient Greeks were aware of static electricity from observing that amber, when rubbed with a woolen cloth, attracted bits of fiber and other light objects. Friction machines invented in the seventeenth century generated static electricity by rubbing a rotating object such as a sulfur ball or glass globe. Francis Hauksbee advanced the theory that minuscule particles of a subtle fluid constituted electricity.

While electricity could be generated, no way to store it existed before the Leiden jar. Ewald Georg von Kleist most likely developed the jar condenser several months before Musschenbroek. However, von Kleist shared his experiment with only a few people, and, as his instructions were inadequate, his correspondents failed to reproduce the results.

Unaware of von Kleist's work, Musschenbroek conducted experiments inspired by the works of Andreas Gordon, who had developed a technique to electrify water, and Georg Matthias Bose, who had attempted to extract electricity from water charged in a glass container. According to the understanding at that time, the electrical effluvia flowed into the water and were stored there. After Musschenbroek repeated the experiment, he clearly described the arrangement. The experiment was set up in this manner: An iron tube suspended by silk cords connected to the friction machine on one end and on the other to a brass wire or nail that passed through a stopper into water inside a glass container. The glass rested on an insulated surface, a practice instituted by Charles François de Cisternay Du Fay. Alone one day, Musschenbroek's student Andreas Cunaeus held the glass in his hand while generating the electricity and received a shock when he attempted to remove the wire. Musschenbroek repeated the experiments many times and realized that the key to obtaining the effect was to ground the jar by holding it in the hand and not to insulate the glass container. In this manner, Musschenbroek and his associates invented a primitive capacitor, a device that stores electrical energy.

Other experimenters made improvements to the Leiden jar. Jean-Antoine Nollet, for example, found that mercury or any liquid other than an oil could be used. Others discovered that the discharge could be increased by using larger glass vessels or by lining the glass inside and outside with metal foil. The foil-lined jar became the standard construction, with the wire or nail connected to inside the foil, sometimes with a small chain. Benjamin Franklin connected several jars together into what he termed a "battery" that gave off a large shock he analogized to a battery of cannons.

Franklin also discovered that the charge was not stored in the liquid and reasoned that it was stored in the glass. More precisely, when a Leiden jar connects with an electrical source, the interior surface acquires a positive charge from the conductors—that is, from either the water or the foil—and the exterior a negative charge. The glass container serves as insulator between the differently charged surfaces. Touching the wire while holding the jar in the hand completes an electrical circuit and results in the shock.

on his promotion of the experimental method and the publication of textbooks than on his role as an inventor, the Leiden jar was the most important electrical invention of the eighteenth century. It spread quickly from the Netherlands to the major countries of Europe and England, as well as to America, and opened a new era in the study of static electricity. Immediately, it became a source of salon demonstrations. Nollet, for example, entertained the king of France with a circle of 180 guards who formed a ring by holding hands, while the first man held the Leiden jar and the last touched the wire. As the electricity discharged, all the men reportedly jumped simultaneously.

The Leiden jar also served as an instrument for serious scientific research. Benjamin Franklin undertook experiments using it in his storied kite experiment, in which the key, wrapped in silk, served to charge the Leiden jar with electricity from the lightning bolt that traveled down the kite's string. This experiment proved that lightning and static electricity were the same phenomenon.

The invention of the Leiden jar inspired research on electricity as a biological phenomenon. Researchers studied the electric eel. Physicians and medical quacks used Leiden jar electricity in attempts to treat paralysis and a multitude of medical disorders. By the end of the century, Luigi Galvani had performed a series of experiments to demonstrate his idea that the nerve impulses were conveyed by electricity, not by fluids as previously thought. He believed that the muscles of frogs' legs acted like a Leiden jar.

As time progressed, the principles of the Leiden jar led to the invention of smaller capacitors that are essential in the operation of electrical devices such as the telegraph, radio, and other communications devices.

Shuji Nakamura

Japanese American electrical engineer

Nakamura's invention of bright blue light-emitting diodes (LEDs) opened up the full light spectrum for this source of solid-state, energy-efficient lighting, including the creation of white LED light. His invention of the blue laser diode paved the way for great advances in optical data storage, while his ultraviolet LED provided inexpensive water purification.

Born: May 22, 1954; Oku, Ehime Prefecture, Japan
Primary fields: Electronics and electrical engineering; physics
Primary invention: Blue light-emitting diodes (LEDs)

Early Life

Shuji Nakamura (shoo-jee nah-kah-moo-rah) was born on May 22, 1954, in the tiny fishing village of Oku on Sadamisaki Peninsula in Ehime Prefecture, Shikoku. His father, Tomokichi Nakamura, worked as a maintenance man for Shikoku Electrical Power and his mother's parents were farmers. He had an older brother and sister, and a younger sister. His father taught him to make movable wooden toys, such as bamboo propellers, and the young Nakamura showed interest and skill. In 1961, when Nakamura was seven years old, his family moved inland to the small town of Ozu.

In high school, Nakamura enjoyed playing volleyball and excelled in math and science, yet he despised the rote learning required to pass the entrance exams to Japan's best universities. In 1973, at age nineteen, he went to local Tokushima University, where he was inspired by semiconductor technology. He earned his degree in electrical engineering in 1975 and decided on graduate work. His thesis adviser, Professor Osamu Tada, strongly emphasized experimental research, which suited Nakamura in his master's studies on the conductivity of barium titanium oxide.

On February 22, 1978, Nakamura married the daughter of a Tokushima banker. The couple's first daughter, Hitomi, was born in August, 1978. To be a married student with a child was very unusual in Japan at this time.

After receiving his master of science degree in electrical engineering in 1979, Nakamura began looking for a job. Faced with the prospects of becoming a typical anonymous salary man researcher at the large company Kyocera in Kyoto, Nakamura asked Professor Tada to find him a job on Shikoku. Tada introduced Nakamura to Nobuo Ogawa, president of Nichia Chemical Industries, a small company a few miles south of Tokushima in the semirural town of Anan. Determined to seize this opportunity, Nakamura secured employment with Nichia in April, 1979.

Life's Work

Nichia specialized in making phosphors for television cathode-ray tubes and fluorescent lamps. Nakamura was asked to invent ways to manufacture base products needed to make red and infrared light-emitting diodes (LEDs), which were invented in 1962 and in high demand by the early 1980's. Nakamura essentially worked alone, and by 1982 he had successfully developed crystals of gallium phosphide. Unfortunately, his crystals were a commercial failure because customers preferred the products of well-known Japanese companies. His next two successful inventions were also commercial failures because of the Japanese preference for brand names. In desperation, Nakamura decided on entirely new research.

Nakamura's greatest challenge was to invent commercially viable bright blue LEDs. Scientists had tried but not succeeded. Late in 1987, Nakamura took the bold step of asking Nichia's president, Ogawa, for permission to pursue the development of a blue LED. Nakamura asked for some $3 million, or about 2 percent of Nichia's sales. Surprisingly, Ogawa granted this.

To learn how to grow the material for a blue LED in a metal-organic chemical vapor deposition reactor (MOCVD), Nakamura was sent on a one-year research sabbatical to the University of Florida in Gainesville in 1988-1989. There, he ended up assembling his own MOCVD. As always in his life as a scientist, Nakamura worked twelve-hour days, from 7:00 a.m. to 7:00 p.m., seven days a week, only taking brief holidays.

Returning to Japan, Nakamura made the crucial decision to focus on gallium nitride (GaN) as source material for his blue LED. He assembled his own MOCVD reactor at Nichia's research lab in Anan and began experiments to grow ultrathin GaN films. At a conference in Japan in 1989, he learned that Isamu Akasaki had developed a dim blue LED based on GaN, but one of inferior quality and too difficult to make commercially.

In early 1990, Nichia's new president, Eiji Ogawa, son-in-law of Nobuo Ogawa, suddenly ordered Nakamura to stop his GaN research, but Nakamura clandestinely refused. In October, 1990, Nakamura invented his two-flow MOCVD reactor, in which hot gases were piped in at right angles to each another, preventing gas convection from interfering with the growing of GaN films. He secretly published a scientific paper about his invention that he also filed as a patent for Nichia. By the end of 1990, Nakamura had produced the purest high-quality gallium nitride ever. He called his invention the most memorable moment in his research life.

On November 12, 1993, in Tokyo, Shuji Nakamura announced Nichia's first bright blue LED. He had won the race for his company, which subsequently prospered immensely. In 1994, he was rewarded a Ph.D. in electrical engineering from Tokushima University. In May, 1994, Nakamura invented a blue-green LED, in 1995 an emerald-green LED, and in September, 1995, a quantum well-based blue-green LED. Nakamura became a star at international scientific conferences. In 1996, he presented his prototype blue laser diode, improved in 1997 and commercially shipped in 1999.

Eiji Ogawa treated Nakamura shabbily and rewarded him poorly. Nakamura's lifetime earnings were close to that of his wife, Hiroko, a kindergarten teacher. In mid-1999, Nakamura consulted with his family, and they agreed for him to become a professor in the United States. On December 27, 1999, Nakamura resigned from Nichia. Because he refused to sign an agreement not to file any patents for three years, Nichia withheld his retirement benefits. On February 19, 2000, Nakamura became a professor in the Materials Department of the College of Engineering at the University of California, Santa Barbara (UCSB).

Nichia sued Nakamura on December 27, 2000, for leaking its trade secrets to Cree, an LED manufacturer. In early 2001, Nakamura became Cree Professor of Solid State Lighting and Display at UCSB. On August 23, 2001, Nakamura sued Nichia for $16.5 million, deemed his share of Nichia's sales of $11.4 billion from Nakamura's patents. In September, 2002, a Tokyo court agreed that Nichia owed Nakamura fair compensation. Nichia had paid him only $180. In October, 2002, Nichia's suit against Nakamura was dismissed. On January 30, 2004, Nakamura won a landmark $190 million award against Nichia, who appealed immediately. On January 11, 2005, Nakamura and Nichia settled for about $8 million, most of which went to pay Nakamura's legal bills and taxes.

At UCSB, Nakamura continued research into blue lasers capable of effec-

The Blue Light-Emitting Diode (LED)

Ever since Nick Holonyak, Jr., invented the first red light-emitting diode in 1962, the race was on to discover a way to make blue light-emitting diodes of a sufficient luminosity and in a commercially viable way. The challenge was to find a suitable compound semiconductor material that could be made to emit blue light. Among other candidates, gallium nitride (GaN) showed promise. In the United States in 1971 and 1972, Jacques Pankove and Herb Maruska created some experimental, but dim, blue LEDs with gallium nitride. In Japan in 1973, Isamu Akasaki developed a dim blue gallium nitride LED, which was improved with the help of his assistant, Hiroshi Amano, at Nagoya University in 1986, but which failed to be commercially viable.

Shuji Nakamura decided to join the race for the first bright blue LED in 1987. His invention of a two-flow metal-organic chemical vapor deposition reactor (MOCVD) provided him the means to grow high-quality gallium nitride of an unmatched quality as a compound semiconductor for blue LEDs. Next, he needed to grow a GaN layer with excess electrons, called a negative type. What had been missing from other experiments was a GaN layer with a deficiency of electrons, called a positive type. Light is emitted by semiconductors if excess electrons from one layer are made to migrate to another layer that lacks electrons, thereby creating the desired light.

In July, 1991, Nakamura created a positive-type GaN layer. This enabled him to make his first blue LED. It lived for one thousand hours but was still too dim. Using a new thermal annealing technique in his reactor, Nakamura created high-quality positive-type GaN in December, 1991. By June, 1992, Nakamura succeeded in growing indium gallium nitride (InGaN) as a third layer, or quantum well, between the negatively and positively charged GaN layers to exponentially increase the brightness of his LED. In September, he created the double heterostructure of his GaN crystal films, and in December his first LED shone with a brilliant blue color. In November, 1993, he announced his invention to a stunned world.

The invention of the bright blue LED made it possible to create all colors of light from LEDs and found immediate applications in large, flat television screens and traffic lights. Computer screens followed, as well as experimental lamps and lighting fixtures. It became conceivable that based on Nakamura's invention, the conventional incandescent light bulb would be replaced in the twenty-first century by a much more energy-efficient alternative.

tive data storage, new white LEDs for everyday lighting, and ultraviolet LEDs for water purification. On June 15, 2006, he was awarded Finland's Millennium Technology Prize of $1.4 million, part of which he donated to LED research projects in developing countries. On June 4, 2008, Nakamura was honored with Spain's Prince of Asturias Award for Technical and Scientific Research.

Impact

Nakamura's invention of the bright blue LED demonstrated that even in the late twentieth century, a single inventor, when working in a supportive environment, could come up with novel, groundbreaking results, outpacing well-funded and well-staffed research teams. Nakamura's bright blue LED meant that for the first time, LEDs covered the full spectrum of the visible light. Thus, LEDs could be used for a broad range of applications requiring more than just red, yellow, or amber light. Immediate uses of his LED technology included large outdoor television screens and traffic lights.

Nakamura's blue laser diode ushered in the next generation of optical storage devices. Because of their shorter wavelength, blue lasers can read 4.6 times more information stored on a compact disc (CD), for example, than red lasers. This meant longer playing times of CDs.

Nakamura's inventions in blue light LEDs and blue lasers also opened up a potentially vast technological advance in lighting, with much more energy-efficient, inexpensive, and long-lasting LEDs replacing the conventional incandescent light bulb or fluorescent tube for all white light needs, from homes to workplaces to consumer entertainment goods. LED lighting based on Nakamura's groundbreaking inventions may save technologically advanced countries billions of dollars in lower energy costs and by lowering the need to build new power plants. Especially important for developing countries, Nakamura's ultraviolet LED can be used as a safe, effective, and affordable means of water purification.

Nakamura's successful countersuit against Nichia changed the way Japanese researchers and scientists are rewarded by the companies that employ them. With Japanese companies legally forced to give adequate compensation to truly outstanding inventors that they employ, these inventors are more inclined to stay in Japan rather than immigrate.

Naomi L. Nakao

Israeli American gastroenterologist

Nakao's invention of a number of devices provided solutions to shortcomings of available medical devices and greatly changed the face of medical technology in gastrointestinal surgery in particular. Some of her products include an endoscopic/laparoscopic stapler, the Nakao Snare line, and the Nakao EndoRetractor.

Born: January 13, 1948; Jerusalem, Israel
Also known as: Naomi Low Nakao (full name)
Primary field: Medicine and medical technology
Primary inventions: Nakao Snare; Nakao EndoRetractor

Early Life

Naomi Low Nakao was born January 13, 1948, in Jerusalem, Israel. She immigrated to the United States when she was a teenager. After completing her secondary education, she attended medical school at the State University of New York (SUNY) at Stony Brook and completed residencies at the Beth Israel Medical Center and at the Veteran Affairs Medical Center in New York.

Life's Work

After becoming a practicing gastroenterologist, Nakao experienced frustration on a number of occasions when available medical devices needed during surgical procedures proved to be inadequate to address certain problems optimally. One such experience occurred in 1989 when she and a colleague were treating a patient for a postoperative leak following gastric bypass surgery. They had to watch the patient's condition deteriorate to the point that surgery was not a viable option. Not content to let the matter drop, they set out to invent a device that would allow a surgeon to close such a leak through an endoscope. Once the device was designed, application for a patent was filed in 1989, and the device was licensed in 2001, the first patent ever issued for a device that would enable surgeons to pass it through a flexible endoscope and staple tissue at the site of a leak.

A passionate inventor, Nakao would continue for the next twenty years to find ways to provide the kinds of devices needed to address specific needs. Early on, she discovered that the life of an inventor is not without its problems. Again, she sought a way to minimize the complicated process of obtaining patents on an invention. This resulted in her cofounding Granit Medical Innovations (GMI) with Moshe Granit in 1989. Granit recognized the value of Nakao's work and provided the financial backing for the company. Free of the encumbrances of bureaucracy, GMI was able to bring new products to the market for a reasonable cost and in a timely manner.

In 1991, the Nakao Snare solved a problem known as "lost polyp syndrome." When colon polyps, precursors to colon cancer, are resected with a cautery snare, they often roll down into the colon, necessitating search and retrieval. This is necessary because treatment for a benign polyp is decidedly different from that of a malignant one. The search to recover the polyp so that it can be examined for malignancy is sometimes as time-consuming as is the entire surgical procedure. In the cases of the polyp not being found, proper management of the patient is uncertain. After the Nakao Snare is used to resect the polyp, a second snare with a net is used for retrieving the specimen so that it may be sent to the pathologist in good condition.

Three years later, in 1994, Nakao, with Dr. John V. Mizzi, devised a way to control the flow rate in an intravenous line (IV), thus saving time on the part of nursing personnel and maintaining an even drip rate in a patient's intravenous infusion.

The invention of the Nakao QuickTrap, licensed for use in 2005, was Nakao's solution to the problem of oxygen deficiency experienced by patients during bronchoscopy. Nakao knew of an incident in which a patient's oxygen saturation was dropping while personnel lost almost a minute in the process of using suction-trap tubing that was standard at that time. A comment by the endoscopist that "someone ought to invent a quick trap" led Nakao to do just that.

An endoscope sheath, known as the Nakao Zip-Sheath, was invented to meet the need to cut down on infection transmission during a flexible endoscopy. Before this sheath was available, the process of ensuring that the elaborate, narrow channels in the endoscope were adequately sterilized between procedures was never a completely sure thing; even when strict protocol was followed, microorganisms could remain in the channels of the endoscope. Furthermore, the cleaning materials employed were toxic and harsh, posing a danger to the nursing staff using them.

Another frustration that Nakao faced was that, unlike the case of general surgeons who had retractors at their disposal to enhance visualization of a surgical field during surgery, the gastroenterologist had to rely on air insufflation to visualize lesions inside the colon, and this provided only fleeting visualization that was often insufficient. Added to the frustration was the fact that the blowing of air into the colon risked colon perforation caused by the abdominal distention associated with the air. Determined to meet the challenge, Nakao invented the Nakao EndoRetractor, a device that is introduced into the intestinal lumen before being inflated, thereby opening the area sufficiently to see and treat a lesion. When the procedure is completed, the retractor is deflated and removed.

Some patents have also been issued for some ejection biopsy forceps, marketed under the trademark Nakao Ejector. Nakao saw the need for this device after a veteran endoscopy nurse was injured by a needle stick in the process of trying to free biopsy tissue from the forceps from a patient who was both HIV- and hepatitis B antigen-positive. The nurse felt that she had done something "stupid," but Nakao was insightful enough to see that the design of the biopsy forceps was the culprit and that this risk was present every time a biopsy was performed. Thus, the idea for the Nakao Ejector forceps was born.

In addition to the numerous inventions that provide devices that address weaknesses of existing surgical instruments, Nakao also designed a software program that could aid the endoscopist in detecting premalignant colonic polyps. This automated endoscopy involves the processing of video endoscopic images during a colonoscopy so as to enhance images and facilitate detection and diagnosis of polyps. When the program is used as an automatic system, the computer alerts the endoscopist when a polyp is detected so that the doctor can return to the site for more thorough examination.

While she has a passion for inventing, Nakao has an impressive record in the medical profession. She is associate professor of medicine at Beth Israel Medical Center and the Albert Einstein College of Medicine. A board-certified gastroenterologist, Nakao is an active member in the American Society for Gastrointestinal Endoscopy (ASGE) and the American College of Gastroenterology (ACG). She has served on the ASGE Technology Committee and the Invention Innovation Special Interest Group (II-SIG), a role that, as chair, has made it possible for her to collaborate with medical innovators worldwide. She is actively involved in cutting-edge research and development of medical technology. Having served on the ACG Women's Committee for six years, she has given evidence of her interest in advancing women's interests in medicine.

The Naomi Nakao Gender-Based Research Award is given annually for the best published research paper in the area of gender-related diseases and their treatment. She is a fellow of the ACG and has written or cowritten fourteen articles based on research; she claims fifty-four U.S. patents and patent-pending applications.

The Nakao Snare Line

The Nakao Snare line may be the best known of Naomi L. Nakao's inventions. Her invention was a direct response to a problem plaguing gastrointestinal surgeons for some time: the problem of losing polyps and risking misdiagnosis, faulty treatment plans, and unnecessary surgery. Since treatment for a malignant polyp differs from that of a benign one, it is essential that the polyp be retrieved in good condition so that an accurate diagnosis can be made.

The Nakao Snare line, which contains three types of snares, was first distributed in 2006. All of the snares function to prevent a severed colon polyp from getting away before it can be collected for pathological testing. The Nakao Snare 1 has a double lumen: one houses a regular cautery snare, the other a retrieval basket. The cautery snare is used to cut away the polyp, after which a second snare with a net is used to hold the specimen. The net is designed in such a way as to slide up and down the snare, cradling the specimen gently so that it can be delivered to the pathology laboratory in perfect condition. The Nakao Cautery Retrieval Snare is designed to both resect and retrieve the polyp in a single maneuver. The net is attached to a larger, outer wire loop, while the smaller, inner wire loop does the cutting. As with the Nakao Snare 1, the polyp is removed without any danger of being lost or damaged. The Nakao Green Net is designed for use in cases in which very large polyps are involved and must be resected in several pieces. As segments of the polyp are removed with a cutting snare, they are caught in the retrieval net, enabling the surgeon to harvest the polyp safely and efficiently.

Nakao is a passionate inventor and a skillful entrepreneur whose goal is to find practical ways of solving medical problems in ways that are efficient and to manufacture her products relatively inexpensively. The Nakao Snare line offers snares that improve vastly on the capabilities of existing ones. Affordability enables physicians to enjoy the benefits of greatly improved methods of removing polyps for pathological testing and enables patients to have confidence that, when they go to surgery, the biopsy samples will be in perfect condition so that accurate laboratory results can ensure that patients will receive appropriate treatment.

Impact

A self-declared "novelty" in the medical industry, Nakao does not stop with inventing devices per se but carries the process on to actually producing them, after getting them licensed, through a company that she cofounded precisely for that purpose. Her insistence on not being content with an idea until it has come to fruition as a product that addresses shortcomings in medical instruments used before her product became available has resulted in a number of important innovations in medicine, especially in the area of interventional gastrointestinal endoscopy.

When Nakao and her colleague Peter Wilk watched a patient's condition decline until surgery was no longer an option, she saw the urgent need for some device that would enable her to close a postoperative leak after gastrointestinal surgery. This idea gave birth to Nakao's endoscopic/laparoscopic stapler, which could be inserted through a channel of an endoscope and used to ligate a blood vessel or to close an opening. While there have been several endoscopic staplers invented since then, Nakao's was the pioneering device that paved the way for others. It is impossible to know how many patients will ultimately benefit from this practical invention.

Finding a way to improve the means of administering IVs to a patient was mutually beneficial to both the patient and nursing personnel. In hospitals, when doctors order IVs for a patient, the orders stipulate, in terms of cubic centimeters per hour, the rate at which the fluid is to flow into a patient's vein, converted into the number of drops per minute. The nurse must adjust the amount of constriction on the tubing until the prescribed number of drops per minute is attained. This process takes time initially, and continues to require time to check the flow frequently, since it is not unusual for the drip rate to decrease or increase. The device not only saved time and ensured increased accuracy but also was inexpensive to manufacture.

Likewise, the impact of the endoscopic cauterization snare (Nakao Snare), the ejection biopsy forceps (Nakao Ejector), the QuickTrap, the endoscopic sheath (Zip-Sheath), and the endoscopy software program is significant in a medical milieu. If a polyp is lost (and the rate of loss is 10-15 percent in the best of hands), surgery that could have been prevented becomes necessary to ascertain whether the patient has a malignancy or not. The biopsy forceps greatly minimize the risk involved in needle pricks that could have disastrous results if a nurse or doctor is working with an AIDS patient. The QuickTrap helps to minimize the amount of time that patients undergoing bronchoscopy have their breathing compromised when the endoscope itself blocks the airway while a tissue specimen is being collected. In view of the fact that two large studies have shown that premalignant adenomas in the colon are missed 25-31 percent of the time and colon cancers are missed 6.2 percent of the time, Nakao's endoscopy software program could play an important role in saving lives.

John Napier

Scottish mathematician

Napier spent twenty years developing his tables of logarithms. Calculations necessary in navigation and astronomy were greatly simplified by this work since difficult multiplication and division problems could be reduced to additions and subtractions.

Born: 1550; Merchiston Castle, near Edinburgh, Scotland
Died: April 4, 1617; Merchiston Castle, near Edinburgh, Scotland
Also known as: John Neper; eighth lord of Merchiston
Primary field: Mathematics
Primary inventions: Logarithms; Napier's bones

Early Life

John Napier was born in Merchiston Castle in Edinburgh, Scotland, in 1550. His father was Archibald Napier, whose family had owned the estate at Merchiston since the early part of the fifteenth century. His mother, the former Janet Bothwell, was the daughter of Sir Francis Bothwell, the provost of Edinburgh. Sources agree that Archibald was only fifteen years old at the time of his marriage to Janet in 1549. There is no uniformity regarding Janet's age, however. It is listed anywhere from fourteen to nineteen at the time of the marriage. In any case, John was born the following year. The family used a variety of spellings for their surname, including Nepair, Neper, and Napare. The modern spelling was not standard until well after John Napier's death.

Napier was educated at home until he enrolled at the University of St. Andrews in 1563. Not long after that, his mother died. No records exist to show that Napier completed a degree at St. Andrews. It is likely that he left the university to study on the Continent, but he later wrote that his time at St. Andrews inspired his first love of theology. It was then that he began to study the book of Revelation. In 1593, he published a tract on that book, which he regarded as the most important intellectual contribution of his life. In his *Plaine Discovery of the Whole Revelation of St. John*, he revealed his pro-Reformist and anti-Catholic sympathies by arguing that the pope is the antichrist.

Napier married Elizabeth Stirling in 1573; together they had a son and a daughter before Elizabeth died at the age of twenty-seven in 1579. In 1582, Napier married again. Agnes Chisholm was to bear him five sons and five daughters.

Life's Work

Napier's opinion that his *Plaine Discovery* was his greatest accomplishment notwithstanding, history has crowned his invention of logarithms as his most notable contribution. As early as 1594, he had begun to work on what he termed "logarithms." He coined this new term from two Greek words: *logos*, meaning "reckon," and *arithmos*, meaning "number." He saw logarithms as "reckoning numbers," that is, as numbers that could be used to facilitate the process of reckoning, or calculating, especially with regard to multiplication, division, and extraction of roots. Although Napier may not have been the first person to entertain the concept of the logarithm, he was the first to put that idea into practice and to develop it so thoroughly.

Napier's conception of the logarithm was kinematic—that is, he used the relationship between two different motions to establish the logarithm. He supposed that he had a line segment of some particular length, AB. Napier chose the length of AB to be 10^7 units. A second segment, actually a ray, begins at point C and extends through D to infinity. At time $t = 0$, a point S begins traveling along CD at a fixed velocity v_0. At the same time $t = 0$, a point R begins traveling along AB beginning at A. Although its initial velocity, like that of S, is v_0, its velocity is always proportional to the distance from R to B. Therefore, its velocity is ever decreasing as R approaches B and will be 0 when R reaches B. At some time t, R is x units away from B and S is y units away from C. Napier defined the logarithm of x to be y. This is sometimes written as "Nap. log $x = y$" for "Napierian logarithm."

Once Napier had his concept in place, he began constructing tables of values. He needed an extensive set of tables in order to be able to represent any number, if not exactly, then at least with a very good approximation. He chose to begin with the number ten million. He then subtracted one ten-millionth (10^{-7}) of 10 million, or one. He repeated this process one hundred times, each time subtracting 10^{-7} of the previous result. After one hundred steps, his last table value was 9,999,900.0004950. By successively reducing the amount to be subtracted, Napier produced the effect of the reduced velocity on segment AB that was described previously. In this table, Napier provides one hundred numbers in close proximity to one another. Multiplying or dividing two of them corresponds to adding or subtracting their logarithm values.

Napier's Bones

Although John Napier is remembered most for his work on logarithms, this is not the only invention that contributed to his fame. In 1617, after he had published his tables of logarithms, he published *Rabdologiae* (study of divining rods). In some circles, Napier is better known for the rods, or "bones," than for his logarithms.

Napier described a set of ivory rods that could be used as a calculating device. These are often referred to as "Napier's bones" since the ivory material gave the rods the appearance of bones. On each rod was written the result of multiplying any of the single digits by zero through nine. For example, the rod for the number 4 might look like this:

A "bone" was really a four-sided rod. It was three-dimensional, with a square cross-section. Each of its four sides contained the digits for one or the other of the rods.

The bones may then be used, for example, in multiplication. As an illustration, if one wanted to multiply 6,754 by 28, one would take the bones for the numbers 6, 7, 5, and 4 and lay them next to each other in order. To multiply this number by 8, the person goes down to the row that represents the multiples of the digits by 8 and reads across, diagonally, from right to left. If necessary, any sum is carried to the next diagonal column, as is similarly done in the usual multiplication algorithm. To multiply by twenty, the same is done in the row containing the multiples of the digits by 2, but a zero is appended at the end since one is actually multiplying by 2 × 10, not just by 2. Adding the two results will produce the final product. The example may be extended to two factors with any number of digits, as long as there are enough bones to represent one of them.

In this way, Napier provided a way to transform a multiplication problem into an addition problem, for no multiplications are performed in the procedure just described, but only additions. His "bones" allowed for a practical implementation of the concept of lattice multiplication, which was introduced in Europe by Leonardo of Pisa (also known as Fibonacci) in the thirteenth century. Napier's device proved to be quite popular throughout Europe. Because of the great interest, the *Rabdologiae* was translated from the Latin into Dutch and Italian.

It should also be noted that in representing the numbers in his table in this way, Napier also revealed a second invention: the decimal point. As with logarithms, it is possible that others may have had a similar concept, but Napier was the first to describe it explicitly and to use it so widely.

After rounding the last number in his table to 9,999,900, Napier began a second table with this rounded number. This table contained fifty values, and the subtractions were by 10^{-5} of the previous result instead of 10^{-7}. Unfortunately, this second table included a mistaken value. The astronomer Johannes Kepler found the error and corrected it when the tables were republished.

The third and final table used a subtraction factor of 0.005 of the previous result. It included sixty-nine columns and almost fifteen hundred numbers. Once this table was in place, Napier proceeded to assign a logarithm to each of the values, using the concept described above. He also developed interpolation procedures for assigning logarithms to numbers not found in the tables. By constructing the second and third tables with larger subtraction factors, Napier was able to produce bigger ranges of values for which to assign logarithms.

Work on this project consumed the better part of twenty years of Napier's life, from 1594 until he published the *Mirifici logarithmorum canonis descriptio* (1614; description of the wonderful canon of logarithms). The tables described above took 90 of the book's 147 pages.

Napier's logarithms are not precisely the same as the logarithms in use today. For example, though it is now understood that $\log_b 1 = 0$ for any base b, this was not the case for Napier. In fact, his logarithms, strictly speaking, are not to any base. In 1615, the English mathematician Henry Briggs began a correspondence with Napier about the logarithms. Briggs also traveled to Edinburgh to meet with Napier to propose that the logarithms be recalculated to what is now called the “common log”: $\log_{10} x$. Napier saw the advantages and agreed, but he revealed that his poor state of health would prevent him from producing the new calculations. Briggs himself completed the project with the publication of *Arithmetica logarithmica* in 1624.

In fact, Napier did not live long past the publication of his tables of logarithms. He died in April of 1617. The nature of his final illness is not certain; however, his lifespan of sixty-seven years was certainly longer than that of most of his contemporaries.

Impact

Unlike so many advances in science and technology, Napier’s invention of logarithms had no known precursor. It seemed to come from nowhere. While it is possible that some others had entertained related ideas, Napier was the one who fully developed logarithms and made them accessible to others. As soon as the tables were published, they were recognized for their utility. For example, navigators often were forced to do many calculations in order to chart their courses, and too often made errors. The East India Company immediately engaged a mathematician to translate the *Mirifici logarithmorum canonis descriptio* into English so that the company could begin to use the logarithms. Likewise, the calculations that astronomers had to perform were greatly simplified through the use of logarithms. In fact, eighteenth century mathematician Pierre-Simon Laplace, who also studied astronomy, once remarked that Napier’s logarithms, “by shortening the labors, doubled the life of the astronomer.”

Almost immediately after the publication of the *Descriptio*, scholars began working to implement Napier’s ideas. For example, by 1630 English mathematician William Oughtred had developed the slide rule. Although the form of the instrument changed over the years, the concept remained the same: The instrument has both a linear scale and a logarithmic one. By sliding one scale against the other, the user may use the principles of logarithms to determine the answer to a multiplication or division problem.

A final indicator of the impact of Napier’s work is that slide rules were not overtaken by calculators as the most common instrument used in education and industry until about the 1970’s. Schoolchildren continued to be taught how to use tables of logarithms in their calculations until the 1980’s, almost four hundred years after Napier first published his work. Handheld calculators have finally made logarithm tables obsolete.

James Nasmyth
Scottish engineer

Nasmyth's steam hammer was a significant metallurgical tool of the budding Industrial Revolution. Developed to forge a shaft for a ship, the steam hammer allowed mechanization of tasks ranging from forging steel to hammering a nail. Nasmyth also invented a planing machine and a punching machine.

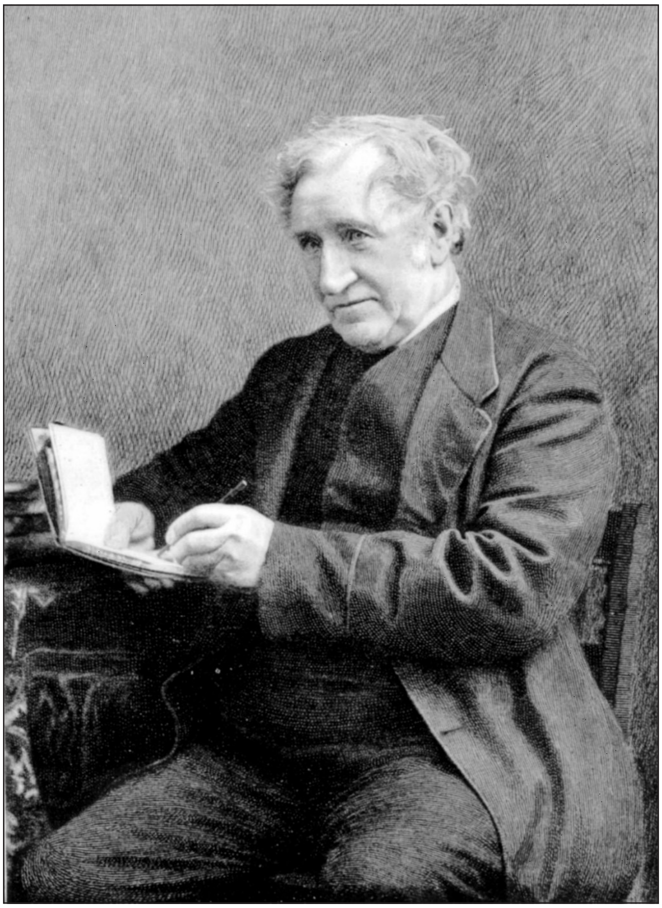
Born: August 19, 1808; Edinburgh, Scotland
Died: May 7, 1890; London, England
Also known as: James Hall Nasmyth (full name)
Primary fields: Civil engineering; naval engineering
Primary invention: Steam hammer

Early Life

James Nasmyth (NAS-mihth) was born in Edinburgh, Scotland, in 1808. His father, Alexander Nasmyth, was an artist by profession, whose hobbies included civil engineering and mechanics. James's oldest sister, Jane, taught him his alphabet and basic reading. He then attended a one-room school to learn English, but his father withdrew him because of the tutor's excessive use of corporal punishment. Young Nasmyth then entered Edinburgh High School in October, 1817, where he studied Latin, much to his chagrin. In high school, Nasmyth befriended Jemmy Patterson, whose father owned an iron foundry where Nasmyth spent much of his free time learning various aspects of metal casting and forging from the foundry's workers. He made small brass cannons and little handguns out of cellar keys for his fellow schoolmates.

Nasmyth left high school in 1820 and began attending private classes on mathematics and geometry, which he found much more to his liking. He continued to learn mechanics from his father, who also taught Nasmyth mechanical drawing. Nasmyth then attended the Edinburgh School of Arts from 1821 to 1826, studying mathematics, chemistry, and mechanical philosophy. He made working models of steam engines in his father's workshop for the teachers to use in their classes. He went on to make and sell steam engines to commercial entities.

In 1837, Nasmyth became intrigued by steam carriages that ran on roads. He constructed a working model that he exhibited to the Royal Scottish Society of Arts. Impressed by his model, the society provided him with funds to build one that could transport four to six people. He completed the carriage in four months and made several runs with it, carrying up to eight passengers per run. The society, however, did not see a commercial application for Nasmyth's carriage, so Nasmyth parted out and sold its components.



James Nasmyth. (Library of Congress)

Life's Work

Nasmyth was determined to secure employment at Henry Maudslay's foundry in London, but Maudslay, disappointed with the performance of previous apprentices, had decided not to accept any more. Nasmyth assembled a portfolio of his drawings, built a working model of a pressure engine, and in 1829 set out for London with his father to plead his case to Maudslay. Maudslay was so impressed by the young man that he took him on, not as an apprentice but as his assistant. On May 30, 1829, Nasmyth began working for Maudslay. His first two designs were a hexagonal nut-cutting machine for Maudslay and an indoor cooking apparatus for himself so he could make his own dinners in his small apartment. Nasmyth worked on such diverse projects as a two-hundred-horsepower steam engine and a telescope for his mentor. Sadly, Maudslay died on February 14, 1831, and Nasmyth continued on with his partner Joshua Field until August when, at age twenty-three, he decided it was time to go into business for himself.

Nasmyth went back to Edinburgh for three years, and he eventually set up his own factory in Manchester, England. He quickly received orders and was able to hire several workmen and to purchase additional machinery. When his business grew, he opened another foundry in Bridgewater and entered into a partnership with Holbrook Gaskell. In 1838, he invented the safety foundry ladle, which allowed workers to pour molten metal from behind the ladle rather than next to it, protecting workers from the danger of being set ablaze from spilled hot metal. He chose not to patent his invention but offered it to the public to help save lives of foundry workers.

The Steam Hammer

Before James Nasmyth invented the steam hammer, the trip hammer was used. These hammers, made of wood or metal, are basically large horizontal shafts attached to a pivot point with a heavy hammer end, raised at the base of the shaft by a cam and then gravity-dropped. The first written description of these hammers came from China in 40 B.C.E., where the hammer was used instead of a mortar and pestle to pound grain. By the first century C.E., China was using a water-powered hammer for pounding metal. Ancient Greece also used water-powered trip hammers for agriculture, and Rome used them for both agriculture and metallurgy. They were used in the Middle Ages in Europe, and Leonardo da Vinci made many sketches of them in use in forges. The problem with the trip hammers is that they could not be raised very high, and they delivered a limited and uniform power blow. Thus, they were suitable only for relatively small projects, such as shaping brass pots, pans, and cutlery or making bar iron out of pig iron.

Nasmyth's steam hammer worked vertically, which allowed it to deliver much greater forces and to work larger and thicker pieces. His hammer was raised vertically by a steam-powered cylinder and then allowed to free-fall. He later modified his design to inject steam into the top side of the cylinder after the hammer had been raised, thus driving the hammer down with steam power and increasing the force of the dropping hammer. By using the steam-powered cylinder to raise and drop the hammer at varying heights, the steam hammer could deliver a hard blow or a gentle pat; Nasmyth enjoyed demonstrating his machine by first dropping the hammer at full force, shaking the building it was in, and then dropping it so gently that it broke an egg in a wine glass without even chipping the glass. Nasmyth immediately saw that his vertical hammer could easily be modified to create a pile driver, which Nasmyth patented the year after he patented the steam hammer.

To give an idea of how large and powerful the steam hammer could be, in 1877 the foundry in Le Creusot, France, built a hammer with legs that were more than ten meters long and a cylinder that was six meters high with a 750-ton anvil. It could deliver a 3.3-million foot-pound force. The hammer is no longer operational but is still on display in Le Creusot.

On May 2, 1838, Nasmyth visited Sheffield; on his way home, he noticed a foundry in Barnsley. He discovered that it belonged to a Mr. Hartop, whom he had met some years earlier, so he stopped to visit. There he met Hartop's twenty-one-year-old daughter Anne and quickly fell in love with her. They were married on June 16, 1840, and remained happily married until his death fifty years later. They had no children.

Nasmyth was awarded a contract to work on the locomotives for the Great Western Railway Company. When the company embarked on construction of its biggest steamship yet, the SS *Great Britain*, it was unable to find anyone with a forge hammer large enough to make the thirty-inch-diameter paddle shaft for the ship. Nasmyth went to work on the problem and sketched out the design of his steam hammer in less than a half hour. The Great Western Railway Company approved his design, but before it could be built the company abandoned the paddle-wheel design in favor of a screw.

The steam hammer remained just a drawing in his "Scheme Book" until one day, while Nasmyth was away, his partner showed Nasmyth's drawing to the proprietor of the ironworks in Le Creusot, France, but did not mention the encounter to Nasmyth. In April, 1842, Nasmyth was astonished to find that the foundry in Le Creusot had built a steam hammer based on his design and that his invention had been used to forge a ship's crank. Nasmyth had not patented his design because of the cost but now rushed to do so, using funds he borrowed from his brother-in-law. Two months later, in June, 1842, he received his patent. He went on to patent the hammer in the

United States as well. He manufactured his hammer in England, and it was used to forge anchors and allowed the die and stamp system to finally be used on a large scale. By the time he retired in 1856, Nasmyth, Gaskell and Company had sold almost five hundred steam hammers, which accounted for 40 percent of the company's profits.

Nasmyth anticipated that his steam hammer could also be used as a pile driver and patented this design in 1843. The Royal Navy commissioned Nasmyth to erect his drivers in Devonport to build a large dock for the navy's ships. On July 3, 1845, he had a good-natured competition with the workers at the docks, pitting his pile driver against a crew using the old, hand-operated one. Nasmyth's device drove a seventy-foot-long, eighteen-inch square pile in 4.5 minutes compared to the old machine, which took twelve hours. His pile driver became an international success.

Nasmyth retired in 1856 to have more time to enjoy astronomy, his longtime hobby. He built a telescope to observe the Moon. He coauthored a book about the Moon that included photographs of models of the Moon that he constructed based on his observations.

Impact

Nasmyth dedicated himself to learning all aspects of engineering, and his tireless dedication to his craft allowed him to invent simple but effective machines. He believed that the ability to perform mechanical drawing was critical to the engineer, because without it the worker is only a hand, but the ability to draw shows he also has a head. He learned from Maudslay's maxims that if one has a clear idea of what one wants to achieve, one will bring it to fruition, that one should avoid the complex and keep designs as simple as possible, and that one should eliminate every ounce of material one can do without. Nasmyth was never without his "Scheme Book," in which he sketched his ideas.

While Nasmyth is known mostly for his development of the steam hammer, which revolutionized large-scale forging, and his pile driver, which expedited bridge, dam, and dock construction, he also built more than one hundred steam engines and other tools that contributed to the Industrial Revolution by accelerating production. He also furthered development of tools and machines by using standardized sizes of machine tools that could be interchangeable and compatible with other machines and tools. He patented some of his creations, but others he left to the public to augment work safety or increase mechanization.

Henri Nestlé

German Swiss pharmacist

Nestlé's most notable invention was devised in response to the infant mortality rate: an infant formula for bottle-fed babies. Nestlé also contributed to the production of absinthe, carbonated mineral water, lemonade, liqueurs, nut oils, rapeseeds, rum, and vinegar. After his death, his company went on to produce milk chocolate, instant coffees, and several other processed foods.

Born: August 10, 1814; Frankfurt am Main (now in Germany)
Died: July 7, 1890; Glion, Vaud, Switzerland
Also known as: Heinrich Nestle (birth name)
Primary field: Food processing
Primary invention: Infant formula

Early Life

The eleventh of fourteen children, Heinrich Nestle (HIN-rihk NEHS-uhl) was born in Frankfurt am Main (now in Germany) on August 10, 1814. His mother was Anna-Maria Catharina Ehemann; his father was Johann Ulrich Matthias Nestle, a glazier in Töngesgasse who had by tradition inherited the business from Heinrich's paternal grandfather.

In his teens, Nestle worked for pharmacist J. E. Stein, completing his apprenticeship in 1834, a few months before he turned twenty. By 1839, at the age of twenty-five, he was officially a pharmacist's assistant, authorized to perform such duties as those of a merchant selling medicines, a pharmacist's assistant making and filling prescriptions, and a small-scale inventor conducting chemical experiments. With such experience, Nestle moved to Vevey, Switzerland, changing his name to Henri Nestlé (then pronounced ahn-REE nehss-LAY; the latter in America now pronounced NEHS-lee)—reportedly a more French-sounding name that would allow him to better fit in with the society.

The inventor-merchant began the next phase of his career by investing, in 1843, in rapeseed production (for manufacture of a variety of foodstuffs such as canola oil) and adding to his repertoire by getting into the production, manufacture, and sales of nut oils, drinking alcohols, vinegar, carbonated mineral water, and lemonade. By 1857, Nestlé had also become involved in gas lighting (as opposed to nut oils used for lighting) and in fertilizers as a resource.

Life's Work

In May of 1860, Nestlé married Anna Clementine Therese Ehemant and soon thereafter adopted a daughter, Emma Seiler, who had been born in 1845. Sometime during these years, Nestlé had begun experimenting with another foodstuff—children's groats. Nestlé created Farine Lactée Henri Nestlé (Henri Nestlé's milk flour), an instant infant formula of powdered cow's milk, malt, sugar, and chemically altered wheat flour (with the acid and starch, difficult for infants to digest, removed), which required only the addition of water.

That year, the first Nestlé product was born, manufactured in the inventor's hometown in the first factories in Vevey. The baby formula was so popular that within four months after its launch, it was sold in five European countries. By 1868, to meet the demands for orders, Nestlé was compelled to open a second office in London. By 1873, the company had expanded even further, exporting the product as far away as Australia, South America, and North America and selling 500,000 boxes worldwide. The following year, Nestlé sold his company to business associates for one million francs and retired. He lived with his family alternately in Montreux and Glion, the latter the location of his home that would be dubbed Villa Nestlé. From his retirement in 1875 until his death in 1890, Nestlé contributed to the financial well-being of Montreux and Glion, making donations to the community and helping individuals with small loans.

The company Nestlé had founded also went on to diversify: In 1905, the company bought out Anglo-Swiss Condensed Milk (where today a second head office sits in Cham, near Zurich); in 1929, Nestlé bought out chocolatiers Peter, Cailler, and Kohler. In 1938, Nestlé introduced another instant marvel—the world's first instant coffee, Nescafé. These successes were followed by the company's 1947 takeover of Maggi, a manufacturer of processed food; the 1950 buyout of Cross and Blackwell; and the 1963 purchase of Findus, a frozen-food conglomerate. Headquartered on the coast of Vevey, Nestlé was Switzerland's largest company by the mid-1960's.

Nestlé was not without its problems. For all the quality innovation that accompanies the Nestlé name, so is there an ironically controversial aspect of its reputation that the Nestlé Company today still works to live down—a controversy beginning with that for which Nestlé was first renowned: the Nestlé infant formula. In the mid-

1970's, the Nestlé Company allegedly ran aggressive marketing campaigns that included hiring graduate nurses in the Philippines to serve as health educators who visit new mothers in their homes and promote the use of Nestlé formula; running Baby World Clubs for the health education of (and product promotion targeting of) pregnant Singapore women; extensive ad campaigns touting bottle-feeding as the more "modern" method to breast-feeding; dispensing formula samples to new mothers; and running extensive advertising campaigns for such infant milk products as "follow-on" (post-breast-feeding) milk. In countries such as the United Kingdom, Nestlé infant formula product was banned for allegedly causing rickets and blindness. In developing countries, great numbers of new mothers were reportedly using the infant formula improperly, adding contaminated water to commercial infant formula, using unsterilized feeding implements, and/or, unable to afford the formula in its purest form, excessively diluting the formula—resulting in diarrhea, malnourishment, and even death in many instances.

Critics maintained that formula companies such as Nestlé were informed of the risks, were denying any culpability, and were increasing the risks by continuing their profit-driven, aggressive marketing to supply products (with labels written only in English and therefore eluding the understanding of users in developing countries) to those women dependent on the products and unable to protect themselves or their babies. U.S. government brochures warning of the dangers of improperly used breast milk substitutes and unsuccessful attempts to convince Nestlé and other companies to alter their practices led several groups—such as the International Nestlé Boycott Committee, the International Baby Food Action Network, and the Baby Milk Action—to call for a boycott of Nestlé products. These efforts resulted in the 1981 adoption by the World Health Assembly of an infant formula marketing code, one imposing tighter restrictions on composition, labeling, and marketing of infant formula products.

Nestlé has likewise changed its policies and practices, stopping all general advertising, halting the promotion of formula by the so-called milk nurses, stopping the dispensing of free samples, and creating infant formula labels and instructions that comply with the World Health Organization (WHO) code requirements. The company that had begun as a one-man vision to produce infant formula had by 1974 purchased the L'Oréal cosmetics company and by 1991 taken over Rowntree's, the British confectioners company, moving into the twenty-first century as a multinational corporation boasting more than two hundred factories around the globe and employing almost a quarter of a million people. Although reportedly still on the defensive with regard to the boycott, today Nestlé carefully instructs company personnel involved in the interpretation and compliant implementation of the WHO code, makes use of an Audit Commission staffed by neutral, non-Nestlé individuals who monitor infant formula practices, and continues to assert the company's ethos begun by Henri Nestlé: that of enduring quality.

The Nestlé Infant Formula

Though his name is associated with delicious chocolate, Henri Nestlé is first and foremost known for his invention of an infant formula that saved lives. In the nineteenth century, mothers who did not, or could not, breast-feed typically opted for either a wet nurse or for dry nursing—making their own infant foods. In the mid-1840's, however, there was a frightening increase in medical issues and mortality rates for infants. Scientists at the time attributed the problems to the dry-nursing habits of mothers who did not breast-feed. Around the same time, Nestlé began working on his own infant formula—his interest in the product attributed to his concerns with the high infant mortality rate in Switzerland and the mortality rate in his own family. (Half of Nestlé's thirteen siblings died before reaching adulthood.) Experimenting with various recipe combinations, he started his formula by mixing cow's milk, sugar, and wheat flour. He then enlisted the aid of colleague and nutritional scientist Jean Schnetzler, who helped him remove the hard-to-digest acids and starches. In 1867, Nestlé fed this "wholesome Swiss milk and cereal component baked by a special process of [his] invention" to a premature baby, saving the infant's life. His formula, Farine Lactée Henri Nestlé (Henri Nestlé's milk flour), was on its way to becoming a household name; within a few short years, it was modified (having the addition of malt) and was selling throughout Europe and the United States.

Nestlé's formula has since changed the lives of adults and infants the world over. Its value has become recognized as "ideal for delicate infants" and lauded for its nutritional beneficence for infants unable to take their mother's breast milk. It has also aided mothers who cannot breast-feed and relieved mothers of the duty of breast-feeding so they can work. Nestlé's formula has been exported to developed and developing countries around the globe as a life-enhancing, even life-saving, product.

Impact

Nestlé invented a baby formula that saved lives and contributed to the lowering of the infant mortality rate in the mid-1800's. Nestlé also inadvertently contributed to the perfecting of the condensed milk-making process and to the industrializing of Daniel Peter's company's milk chocolate. For instance, in 1905, after the death of both Nestlé and Peter, the founders' companies worked together to produce the very sweet Nestlé's milk chocolate, which appealed to the French palette as well as to the tastes of people the world over.

Further, Henri Nestlé was one of the first to make an immediate transition from a home market to a global marketplace. As a pioneer in the food and foodstuff industry, Nestlé instigated one of the earliest global-scale product-cycle patterns—seeing the company into first the local market (Switzerland), then to exporting, then to international production. According to former Nestlé chief executive officer (CEO) Peter Brabeck-Letmathe, it was typical of Swiss food companies' objectives to tend toward the foreign markets in order to cope with the limited size of the domestic market. Other important factors contributing to this trend were the increasingly high import duties, the imperative of remedying rising average costs by increasing plant size, and the ensuring of a steady supply of essential products at the (local) retail level by having a local presence (such as was in the case with the Nestlé Company).

It was because of Henri Nestlé's insightfulness, or visionary aptitude, that the Nestlé Company would come to make such an impressive impact at the global level. He took his company international immediately; established an independent brand by creating his own manufacturer's brand; and created a unique identity, positively exploiting the Nestlé name by using the German origin of the name, "little nest," to secure a memorable, marketable image to inspire trust and confidence in consumers who were reassured by his "seal of quality." This world-renown characteristic of the Nestlé Company has also helped to maintain Switzerland's reputation as a country with a long history of innovation and subsequent high-quality production.

THOMAS NEWCOMEN
English mechanical engineer

Newcomen developed the first successful atmospheric steam engine to do practical work and thereby laid the foundation for the industrial age.

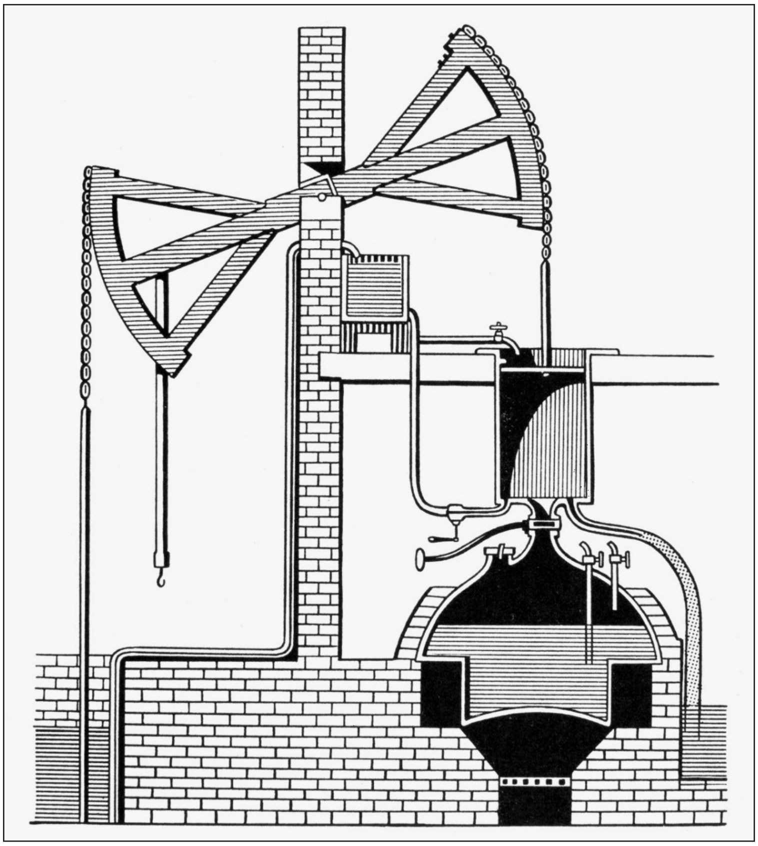
Born: January or February, 1663; Dartmouth, Devon, England
Died: August 5, 1729; London, England
Primary field: Mechanical engineering
Primary invention: Atmospheric steam engine

EARLY LIFE

Thomas Newcomen (new-KUH-muhn) was the second son of Elias and Alice Trenhale Newcomen of Devon, England, born shortly before February 24, 1663, the date of his christening at St. Savior's Church in Devon. He seems to have been apprenticed to an ironmonger in Exeter, for by 1685 he was established in this trade in Devonshire. A popular story has it that he first conceived of the idea of steam doing work as a youth by watching a boiling tea kettle and noticing that the lid would rise and fall once the water was boiling.

He must have enjoyed some success at his trade, because around 1689 he purchased twenty-five tons of iron from a nearby ironworks that he made into various objects and sold in the region. In 1704, he repaired the town clock and so came to acquire the reputation of one talented in ironworking. Also, by this time he had taken on a partner, John Cauley, a plumber and glazer. Both were Baptists; indeed, Newcomen was a lay preacher. This is not especially surprising: Most of the early English industrialists were Dissenters of one sort or another.

In 1705, while in his early forties, Newcomen married Hannah Waymouth of Marlborough, also a Baptist. They leased a house on the high street, which functioned as the home in which they raised their two children, Thomas and Elias. There, Newcomen held religious services and carried on his researches into the steam engine along with his trade. The home came to be known as the Newcomen House until it was demolished in 1864.



A schematic of Thomas Newcomen's steam engine from 1712. (The Granger Collection, New York)

LIFE'S WORK

Newcomen's accomplishment was his steam engine. While relatively costly to operate, it enabled water to be pumped out of mines efficiently at depths hitherto impossible. However, his steam engine was greatly improved upon by James Watt and Matthew Boulton and was not the earliest engine, so the question arises, how important were Newcomen and his engine?

Contemporaries, perhaps blinded by ideas of class, suggested that he received crucial help from Robert Hooke, with whom he corresponded, or perhaps stumbled by accident upon the methods he needed to produce his machine. To these contemporaries, a mere ironmonger could not have been capable of solving a problem that learned academics had failed to solve. Others suggested that his success lay in bringing together ideas that had been developed by other men. Still other scholars, most especially his biographers L. T. C. Rolt and J. S. Allen, insist that the work was his alone. Newcomen may well have been familiar with the efforts of his immediate predecessors, but his engine was his own contrivance. His wife suggested that he worked on his engine in secret in their home for about four years. When curious neighbors asked what he was working on, she always replied that she did not know but, as she knew him to be an honest and upright man, was not at all concerned.

There were two precursors whose failed attempts are indeed reflected in Newcomen's successful engine. The first was Denis Papin, a Huguenot who fled to London to escape religious persecution in France. He was fortunate enough to enjoy the support of Hooke and Robert Boyle and soon gained admittance into the Royal Society. There, he demonstrated a kind of engine that used steam to drive up a piston, generating a vacuum that when cooled would drive down the piston by atmospheric pressure. This is the very principle that Newcomen would apply to great effect in his engine. Papin, on the other hand, did not develop his machine into anything more than a novelty.

The second precursor was Thomas Savery, also of Devonshire, who in 1698 patented a device he called the "Miner's Friend." This device was modeled after one of Edward Somerset's designs and was built to supply water for fountains. It employed two containers alternately filled with steam, then sprayed with cold water to cause condensation and the creation of a partial vacuum into which water would rise from a well. Savery received a royal patent for his device in 1699 that extended the patent until 1733. Unfortunately, despite all his efforts, he was never able to overcome the fact that it could not be used at depths greater than seventy feet. It was useless as a device for extracting water from mine shafts.

It cannot be known with certainty when Newcomen began to work on the problem of lifting water from mine shafts by steam power. His work carried him to tin mines, and he would doubtless have been aware of their problem with water in deep shafts. He very likely was acquainted with Savery, who most certainly knew Papin. However, there is some evidence from the period that suggests that Newcomen owed little or nothing to these two men. A Swedish engineer, Mårten Triewald, who was studying English mining techniques and traveling in Devonshire during this period, along with Stephen Switzer, a writer on hydraulics, both maintained that Newcomen's engine was developed independently of its precursors. Whatever may be the truth, once Newcomen had developed his engine, he decided to go in with Savery to use his patent instead of seeking one of his own, a move advantageous to both men, according to Newcomen's biographers.

The first Newcomen engine seems to have been erected by 1712. It worked by placing a boiler directly above a piston chamber, which was attached via a chain to one side of a rocker arm, the other side of which was attached to a pump rod heavier than the piston. Steam from the boiler was allowed to pass into the chamber, which filled the piston chamber opened up by the weight of the pump rod. Once this chamber filled with steam, it was sealed off and cold water was introduced inside, causing

The Atmospheric Steam Engine

Thomas Newcomen's steam engine went through many iterations, each addressing problems raised by the one that preceded it. The engine employed a boiler, usually of the "haystack" variety, so called because of its shape. This type was larger than those that preceded it and was appropriate only for low-pressure steam systems such as Newcomen used. Because of the low pressure, it was also less likely to explode than earlier versions.

As it was not technically possible to engineer perfectly round objects at that time, Newcomen guaranteed that he had a vacuum by means of a leather ring seal. It was also necessary to keep water on top of the piston. Atop the piston was a water supply that was injected into the bottom to bring about the condensation. As the engine became more sophisticated, it included a secondary pump also attached to the pump side of the fulcrum that supplied water for this water tank from water pumped out by the pump rod.

Most images of the engines show very little of the pumps that were used—most seem to have been deadweight force pumps. These overcame the limitations of Thomas Savery's engine because the suction stroke was only the length of the upward stroke of the piston.

The greatest problem with Newcomen's engine was its inefficiency. James Watt applied new ideas about latent heat to modify a Newcomen engine he had been given to repair. Realizing that it was the heating and cooling of the engine that caused it to wear out, Watt created a separate condenser that allowed the cylinder temperature to remain constant. Other improvements enabled this engine to be connected to a rotary shaft, thus creating an engine with all the features known today.

the steam to condense, creating a vacuum, and allowing the atmospheric pressure above to force the piston down while pulling up the pump, thereby drawing the water out from the mine. Through an elaborate series of secondary pulleys and valves, the process could be repeated twelve to fifteen times per minute, each cycle drawing out about two gallons of water that was then drained off. The machine could run night and day. It is easy to see why it was so popular.

By 1725, there were at least one hundred of the steam engines in use in England and elsewhere. Even after Watt's improved engine was introduced in 1769, Newcomen's continued to be built. Only after Watt's patent expired in the 1790's (significantly lowering his price) did his machine finally replace the Newcomen engine. Still, some Newcomen steam engines continued to be used (and somewhat modified) until the twentieth century.

Not much is known about Newcomen's later life. Business regarding his engine was taken over by an unincorporated company, "Proprietors of the Invention for Raising Water by Fire." Indeed, Newcomen does not seem to have made a lot of money from his invention and apparently was content to spend much of his time preaching and teaching. He died in London in 1729.

Impact

Early in the eighteenth century, Newcomen developed the first atmospheric steam engine that really worked. In so doing, he provided assistance to the mining industries of his era for whom shaft flooding was a serious problem. More important, he demonstrated that steam power could be harnessed to do work. By the end of the century, the Industrial Revolution was taking off in England, and it was largely powered by steam engines of many types rather than the more unpredictable water power. It is fair to say that the industrialization that so transformed the world would have been impossible without Newcomen's work. As it were, he unstopped the dam that was holding back industrial progress and allowed the process to proceed in earnest.

Sir Isaac Newton

English physicist and mathematician

Newton formulated the basic laws for the branch of physics known as mechanics, identified gravitation as the force that controls the motion of bodies in space and expressed it mathematically, and invented calculus independently of Gottfried Wilhelm Leibniz. He also made lasting contributions to optics.

Born: December 25, 1642; Woolsthorpe, Lincolnshire, England
Died: March 20, 1727; London, England
Primary fields: Astronomy; chemistry; mathematics; physics
Primary inventions: Calculus; reflecting telescope

Early Life

Isaac Newton was born three months after his father died. He was born prematurely, and he is believed to have suffered from Asperger's syndrome, a form of autism. His mother, Hannah Ayscough, remarried when Newton was three years old, and she moved in with her new husband, the Reverend Barnabus Smith. The toddler was left to be cared for by his maternal grandmother. Ayscough had three children with her second husband, was widowed for the second time, and returned to Newton's birthplace after eight years.

Newton started school in the hamlet. When he was twelve, he went to King's College in Grantham, where he excelled in his studies. He was removed from school when he was seventeen and returned to Woolsthorpe. His mother wanted him to become a farmer, but Newton did not like farming; in fact, he was not good at it. Henry Stokes, a headmaster at King's College, convinced Newton's mother to send him back to the college to complete his studies. Newton did so, completed his work brilliantly, and was admitted to Trinity College at the age of nineteen, in June, 1661. Newton's mother still wanted him to devote his life to farming, but his maternal uncle, a clergyman who had attended Cambridge University, persuaded her to send Newton to the university. He was granted financial assistance for three years because he was a student with limited means. Such students were known as "sizars"; they earned money by serving the faculty and the wealthy students of the college. In 1664, he was elected a scholar, guaranteeing him four years of financial support. He obtained his degree in August, 1665, but the university was closed for about a year shortly after that because of concerns about the great plague. As a result, Newton went back to Woolsthorpe, where he continued his scientific work on calculus, optics, and universal gravitation.

Life's Work

Newton discovered the generalized binomial theorem and started working on calculus, although he would not publish this work until 1693. On July 5, 1687, he published a three-volume work entitled *Philosophiae naturalis principia mathematica* (*The Mathematical Principles of Natural Philosophy*, 1729). This title is usually abbreviated as *Principia*. The work was prepared during the 1665-1666 period, while Newton was in Woolsthorpe. It contains Newton's laws of motion, the law of universal gravitation, and a derivation of Johannes Kepler's laws for the motion of the planets.

Starting about 1668, Newton studied optics and discovered that the phenomenon of color had mathematical patterns that could be measured. He found that white light was a mixture of colored rays that manifested in the

Sir Isaac Newton. (Library of Congress) color spectrum, as exemplified by the rainbow. He also postulated that light consisted of streams of tiny particles. However, when he expressed his ideas in public in 1672 and 1675, he encountered hostile opposition. The reason was that his views on the nature of light were contradicted by the then accepted notions that considered colors to be modified, but distinct, versions of white light.

Newton formulated a theory of sound, but the speed he derived was too low and did not agree with his experimental results. This discrepancy was due to the fact that the concept of propagation without heat loss, the so-called adiabatic propagation, had not been proposed yet, and, hence, he did not take the heat capacities of air into account. Newton believed that matter consisted of different arrangements of atoms and devoted much time to the study of alchemy later in his life. While his burial place was being moved, exhumation revealed that Newton's remains contained large quantities of mercury. It is speculated that this was due to his alchemical experiments.

Newton was sensitive to criticism of his work and did not want to publish it. Indeed, he had many contemporary critics; among them were Christiaan Huygens (1629-1695) and Edme Mariotte (1620-1684). That may be why he held onto *Principia* for twenty years before publishing it, and why he waited until Huygens and Mariotte were dead before publishing *Opticks* in 1704. Newton's friends recognized his genius, and their persistent support and encouragement made it possible for Newton to publish his work and achieve recognition. His friend and mentor Isaac Barrow helped communicate Newton's discoveries to the mathematics community of London. Another friend, the English astronomer Edmond Halley, was the one who finally persuaded Newton to publish *Principia*.

Despite the criticism and the controversies, Newton's work was well received, even in his lifetime, and he was

Calculus

Sir Isaac Newton invented the method of "fluxions," which is known today as infinitesimal calculus. This mathematical process would prove to have many practical uses. For example, consider an empty bowl on a weight scale in which one drops coins one at a time. The total amount of money collected would not change continuously with time; rather, it would do so in "jumps" that represent the value of the coins added. If one pours water instead of coins into the bowl, the total weight would change continuously.

The mathematical techniques that are needed to determine the rates of changes in these two cases are very different. In the case of coins, the changes are finite; one could use a stopwatch to measure the time increment between two consecutive coin drops and a weight scale to register the change in the weight of the bowl over that time interval. Dividing the change in weight by the increment of time would give an estimate for the time rate of change of the weight over that interval. In the case of water, the changes are infinitesimal, however. Here, to perform a similar operation, one would need to imagine the existence of very small amounts of water being poured into the bowl over very tiny time intervals and subsequently take their ratios. How does one do this? Differential calculus teaches how to determine such ratios, and integral calculus shows how to backtrack. That is, if one knows what the ratio of two infinitesimal quantities is equal to, one can determine one of the quantities in terms of the other. Prior to the invention of calculus by Newton, no one knew how to determine the changes of quantities that vary continuously. Calculus is used extensively in modern science and engineering.

Although Newton did his work on calculus in 1666 and shared it with friends and colleagues, he would not publish it until 1693. The German mathematician Gottfried Wilhelm Leibniz (1646-1716) also worked on calculus and published his work in 1684. This nine-year difference in publication dates led to a bitter dispute between supporters of Newton and those of Leibniz regarding who should get historical credit for the invention of calculus. Members of the Royal Academy, of which Newton was a member, officially accused Leibniz of plagiarism in 1699, claiming, correctly, that Leibniz had seen Newton's papers when the former visited London in 1676. Friends of Leibniz thought it was exactly the opposite, claiming, correctly, that Leibniz had not taken notice of Newton's work on this subject. Leibniz died before the dispute was settled, and these tensions lasted about a century. Today, however, it is agreed that Newton and Leibniz invented calculus independently. However, that does not mean that the agreement led to a tie: Newton is given credit for having invented calculus before Leibniz, and Leibniz is given credit for having published his work before Newton's. Being reticent and late to publish his work caused Newton grief in life, modest loss of credit after death, and considerable stress and strain on his friends and foes alike.

recognized for it. He was elected a fellow of Trinity College in 1667 and Lucasian Professor of Mathematics in 1669. He became a fellow of the Royal Society of London in 1672, its president in 1703, and held that position for twenty-four years (1703-1727). Unfortunately, Newton suffered a mental breakdown between 1675 and 1679. He was appointed warden of the British Mint in 1695 and was knighted by Queen Anne in 1705.

Newton is still being honored for his work today. The Newton crater, a lunar feature, was named for him by American scientists. Rue Newton, located in the sixteenth arrondissement of Paris, is named for him. In physics, the laws of mechanics are named for him, and the standard unit of force is called the Newton: one pound-force is equal to 4.444 Newtons.

Impact

Specialists in the history of science believe that Newton contributed more to the development of science than any other individual in history. His work is thought to have ushered in the Age of Reason. There are three major reasons for this: First, Newton produced a scheme that helped humankind understand how the universe worked; that scheme far surpassed those that preceded it in intuitiveness, consistency, elegance, universality, and mathematical predictability. Second, in the process of devising his scheme, he developed the scientific method by formulating four rules of investigation that were revolutionary, concise, and universal—where "universal" means that, unlike the methods that preceded Newton's, his applied to all branches of science. Last, Newton not only outlined his rules for reasoning but also described how they might be applied to the solution of a given problem, and he actually applied them with great success to formulate some universal laws of nature. The method he invented was more scientifically based than the philosophical approaches of Aristotle (384-322 B.C.E.) and Thomas Aquinas (1225-1274).

When it comes to the development of modern science, Newton is considered to be the most important individual contributor. His ideas form the basis of modern technological civilization. His principles, although originally conceived for the physical sciences, were applied to the social sciences and influenced, for example, the economic theories of Adam Smith (1723-1790).

Nicéphore Niépce

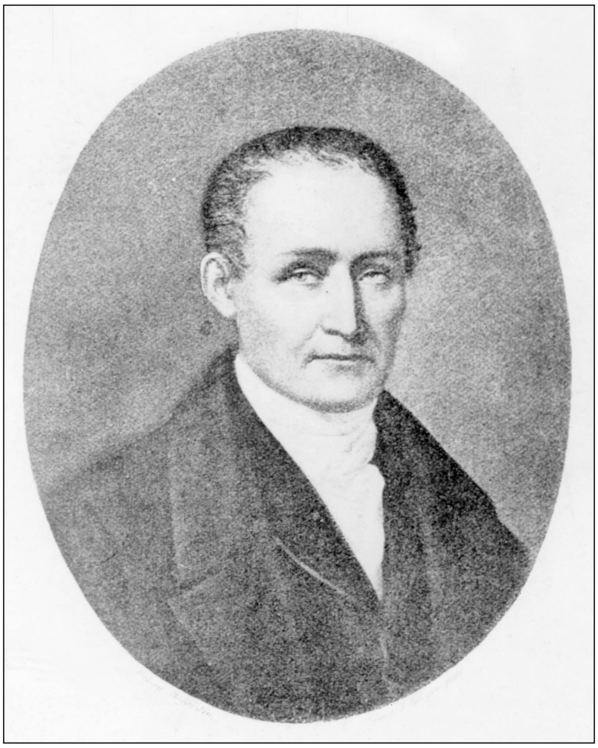
French engineer

The invention of photography by Niépce made possible the pictorial preservation of the life and experiences of the individual regardless of social class. It also enabled people to see actual images of places, events and notable things which they would otherwise never have been able to view.

Born: March 7, 1765; Chalon-sur-Saône, France
Died: July 5, 1833; Chalon-sur-Saône, France
Also known as: Joseph-Nicéphore Niépce (full name)
Primary field: Photography
Primary invention: Photography

Early Life

Joseph-Nicéphore Niépce (zhaw-zehf nee-say-fawr nyehps) was born on March 7, 1765, at Chalon-sur-Saône, France. His father was a lawyer, counsel to the king, and master of the Deposit and Consignment Office for Chalon-sur-Saône. He had one sister and two brothers. As a young man, he developed an interest in chemistry and physics. His father died in 1785, and his mother took charge of the family's business affairs. In 1786, he entered the Church as a member of the Oratorian Brothers at Angers. In 1788, he left the Oratorians and joined the Garde Nationale at Chalon-sur-Saône. At this time, he began to use the surname Nicéphore. In 1792, he enlisted in the French army and participated in campaigns in the south of France and in Sardinia. In 1794, he left the army. He was in Nice at the time, where he stayed and married; his son Isidore was born in 1795. Niépce's older brother Claude joined him there. In 1797, Niépce and his family traveled in Sardinia, and Claude accompanied them. It was during this trip that Niépce and Claude first conceived the idea of photography.



Nicéphore Niépce. (National Library of Medicine)

Life's Work

Upon their return to Nice, the two brothers began to work on inventing; however, it was not photography but rather the invention of an internal combustion engine that occupied them. In 1801, they were called back to Chalon-sur-Saône to take charge of the family's business affairs. They continued to work on their engine, which they named "Pyréolophore." They used it to power a two-meter-long model boat up the Saône. In 1807, they received a patent for it signed by Napoleon I.

In 1807, the government announced a competition for the invention of a new type of machine to replace the pumps at Marly that drew water from the Seine to the Palace of Versailles. From 1807 to 1809, the brothers were occupied with the project. They succeeded in constructing a hydraulic pump to provide the water. Unfortunately, they wished to improve their original pump and redesigned it several times. By the time they had finished it in 1809, Napoleon had commissioned Casimir Périer to build a steam engine for the operation of the pumps at Marly.

In 1811, because of the shortage of indigo caused by the Continental Blockade, Niépce and Claude began to work on the cultivation of woad as a substitute for indigo. Then, Claude left Chalons-sur-Saône, first going to Paris and then to England. The patent on their internal combustion engine was to expire the next year, and they wanted to promote it as much as possible while they still had the patent. Niépce and his brother corresponded by letters during Claude's absence. They were trying to find a different fuel for the internal combustion engine; eventually, by using lamp oil, they developed the principle of fuel injection.

Niépce was left with a lot of time to experiment and invent by himself, and he began to do research and experiments in photography. At the time, a camera obscura was used to create inverted images that were then traced by hand. Niépce did not have a hand steady enough to do this, so he needed to find a way to make the image permanent. He spent a considerable period of time attempting to find the right material to permanently fix the image. He experimented with lithography, then silver chloride, and finally bitumen. His first success came with bitumen. By 1818, he had managed to create an image that was fixed for three months without appreciable fading.

That year, Niépce began working on another type of invention he called a "velocipede," a bicycle without pedals. He made several modifications to it, including an adjustable seat. He was fascinated by his contraption and even thought of adding a motor to it, which he did not. He was often seen riding it on the roads of Saint-Loup-de-Varennes.

Niépce continued his experiments in photography. Starting in 1822, he was able to reproduce images by placing a design in contact with a piece of glass or metal coated with bitumen, then using etching techniques to engrave the image and print it on paper. He continued using and modifying this type of procedure until July of 1827, when he stopped because of repeated failures to engrave images of one color.

In December, 1827, on his way to England, he stopped in Paris for a while. There he made the acquaintance of inventor Louis Jacques Daguerre. Daguerre bought his lenses for his camera oscura from an optician named Vincent Chevalier, who was also Niépce's supplier. Daguerre obtained the address for Niépce from Chevalier and contacted him. Both of the men were experimenting to find a way to fix (keep from fading) the images produced in the camera obscura. They met again in 1828 and began to correspond with letters. In 1829, Niépce proposed that they create a partnership to develop what he called the "heliograph" (sun-drawing). Daguerre agreed, and they signed a contract that very year.

Together, they continued to experiment with bitumen but had little success. Next, they began trying various photosensitive residues. During 1831, Niépce, working alone, experimented with many different residues, but none worked well. Their greatest success came with the residue from essence of lavender. In June of 1832, Daguerre returned to Niépce's residence and together, using the distillate of lavender, they produced an image in less than eight hours of exposure time. Niépce named the process "physautotype."

Photography

Nicéphore Niépce had spent many years working with many different chemical processes in his attempt to fix the images captured in the camera obscura when he met Jacques Daguerre. The men collaborated and attempted to bleach brown bitumen and obtain positive images, but they failed. Then Daguerre discovered distillate of lavender, but he did not realize that it possessed photosensitivity. Niépce experimented with a number of photosensitive residues and distillates, none of which produced the desired results. Once again working with Daguerre, he tried using distillate of lavender oil, which they heated, and they discovered a photographic process that Niépce named "physautotype." Drying the oil turned it into a dark brown, tarlike substance. They put it into alcohol and poured the mixture onto a polished piece of silver. The alcohol evaporated, leaving a residue of white powder. Next, they exposed the piece of silver to light at the end of the camera obscura for approximately eight hours. Finally, the piece of silver was placed over a bowl containing white petroleum or lamp oil. The vapors revealed the image.

After Niépce's sudden death, Daguerre improved on the process and developed a slightly different process that he called the "daguerreotype." When the daguerreotype was revealed to the public, it caused a sensation and made Daguerre famous. The daguerreotype became a success throughout the world and changed the way history and personal memories were preserved.

On July 5, 1833, Niépce died unexpectedly. Isidore replaced his father in the partnership according to the terms of the ten-year contract. However, Isidore did not have the expertise to reproduce Niépce's procedures. Daguerre started working in secret on a new process, using techniques he had learned from Niépce. He eventually developed a new photographic process called the "daguerreotype."

In 1835, Daguerre suggested to Isidore that they make the three photographic processes—heliography, physautotype, and daguerreotype—known publicly. Daguerre knew that only one of the processes could be used successfully in a commercial situation. Isidore was in favor of the proposal. Daguerre then suggested that they change the company name from "Niépce Daguerre" to "Daguerre and Isidore Niépce." In this way, Daguerre began to edge Niépce out and take full credit for the invention of photography. Next, Daguerre showed his procedures to François Arago, the perpetual secretary of the Académie des Sciences. Arago was so impressed with the invention that he insisted that the French government pay and make it available to everyone. His proposal was accepted. Daguerre and Isidore each received an annual stipend of 4,000 francs for life. Daguerre received an additional 2,000 francs for the diorama that he had created for the Paris Opéra in 1822.

On August 19, 1839, Arago revealed the three processes to the public in such a way that only Daguerre was brought to people's attention. Almost no mention was made of Niépce. Subsequently, the daguerreotype process was improved, and it was possible to make portraits. Shops opened all over Paris, then around France, then Europe, and finally the United States. Daguerre became world famous, while Niépce remained unknown.

Isidore was incensed at the neglect of his father and his achievements. In 1841, he published a book, *Historique de la découverte improprement nommée daguerréotype, précédé d'une notice sur son véritable inventeur feu M. Joseph-Nicéphore Niépce* (historical account of the discovery improperly named the daguerreotype, preceded by an account of its true inventor). Isidore gave vent to his anger against Daguerre, put forth a case for his father as the inventor of photography, and started a long suit against Daguerre. Eventually, Nicéphore Niépce was recognized as the inventor of photography.

Impact

Although Niépce and his brother Claude have received little credit for their discoveries and inventions, their contributions have been significant. The two brothers invented an internal combustion engine and a hydraulic pump, and they discovered the principle of fuel injection. The internal combustion engine, which produces a high power-to-weight ratio, plays a very important role in the production of transportation vehicles. It is the main engine used in automobiles, trucks, and boats and with certain modifications in trains and in aircraft. Internal combustion engines also power a wide variety of machinery. Fuel injection has become the primary fuel delivery system used in these engines. Hydraulic pumps, which produce and easily transfer large amounts of power, are widely used in tools and heavy equipment. Thus, although the brothers remain virtually unknown and their inventions have become part of technology by the intermediary of other inventors, their research has been important in the development of the inventions.

Niépce, working alone and then with Daguerre, totally revolutionized the way in which events and individuals were recorded for posterity. Before the discovery of photography, only written accounts or artistic renderings were available to record history and preserve physical images. Artistic reproduction of people and events was affordable for only a small segment of the population, but photography made it possible for everyone to have a pictorial record of his or her life. It also permitted people to see pictures of actual places they had never visited.

Alfred Nobel

Swedish chemist and engineer

The world is reminded in the fall of every year of the legacy of the inventor of dynamite, Alfred Nobel. The international prizes given in his name for achievements in chemistry, economics, physics, medicine, literature, and peace are symbols of the very highest accomplishment in those areas.

Born: October 21, 1833; Stockholm, Sweden
Died: December 10, 1896; San Remo, Italy
Also known as: Alfred Bernhard Nobel (full name)
Primary fields: Chemistry; military technology and weaponry
Primary invention: Dynamite

Early Life

The third of four sons, Alfred Bernhard Nobel (noh-BEHL) was born at a time of economic distress for his family. His father suffered a string of misfortunes as a building contractor, declared bankruptcy, and then was forced to flee creditors. He went to Finland when Alfred was four years old and later to St. Petersburg, Russia, leaving Alfred's mother to support the family in Stockholm by running a small vegetable and dairy product store. Alfred started his education at the poorest neighborhood school. Despite the shaky health that would dog him all his life, he gained distinction there as a promising scholar. The family was finally reunited in St. Petersburg in 1842.

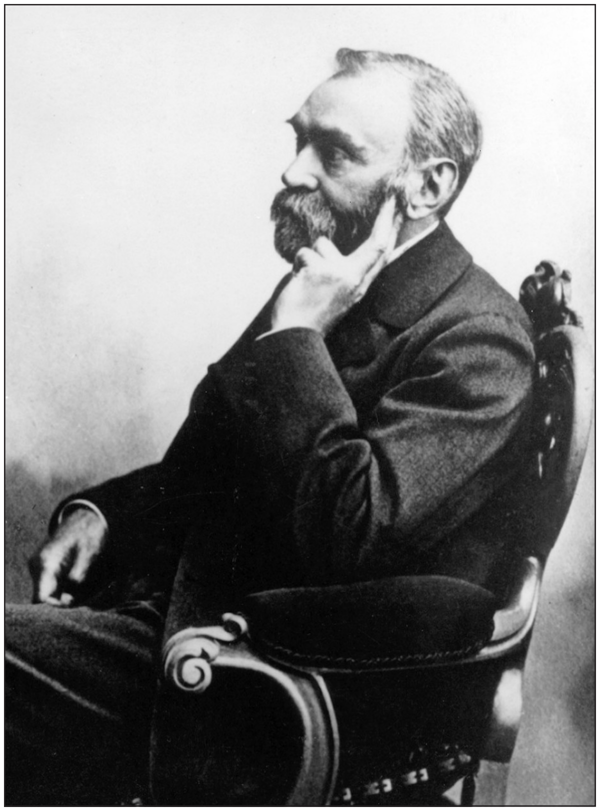
Alfred's father, Immanuel, had managed to reestablish himself in St. Petersburg in the business of manufacturing explosive mines, cannonballs, mortars, and components for steam engines. He had an inventive mind and held a number of patents, including one for the first central-heating system in Russia. His most important products were military, however, which he sold to the Russian war ministry. Business was excellent until Russia lost the Crimean War in 1856. The government defaulted on large debts to Immanuel's company, and he was forced to declare bankruptcy a second time.

The Nobel sons did not attend school in St. Petersburg, but they were provided with first-rate tutors and received an excellent education. Alfred seemed to be equally attracted to science and the arts as a youth. He expressed early interest in becoming a writer and eventually became fluent in five languages. As a kind of bribe to devote himself to more practical pursuits, Immanuel sent Alfred on a grand tour of Germany, France, Italy, and the United States in 1850.

The two crises he had observed in the financial fortunes of his father, however, were probably decisive in turning Alfred away from purely aesthetic endeavors. He devoted himself first to the family business, and then struck out on his own to establish one of the most innovative and successful enterprises in nineteenth century Europe.

Life's Work

Nobel's professional life was distinguished by the rare combination of inventive genius in the physical sciences and an equally remarkable flare for operating effectively in the highly competitive arena of international business. During his life, Nobel secured an amazing 355 patents in different countries in areas as diverse as aerial photography, blood transfusions, and prototypes for manufacturing artificial rubber and silk. The four major innovations for which he is best known, however, and which enabled him to build his immense personal fortune all had to do with explosives.



Alfred Nobel. (©The Nobel Foundation)

DYNAMITE

Black powder, or gunpowder, is a mixture of sulfur, charcoal, and saltpeter. It first appeared in China in the ninth century and arrived in Europe via the Islamic world in the fourteenth century. Few other inventions have had a greater impact on human society, and it was the only explosive in common use until the middle of the nineteenth century.

Alfred Nobel's dynamite began the process of replacing black powder, so that today it has only very limited recreational uses. Dynamite was the first high explosive developed that was safe enough to use for practical purposes. A high explosive does not burn like black power; it detonates and creates a supersonic shock wave. Nobel was able to develop dynamite through two critical breakthroughs in explosive technology.

Nobel's blasting cap was the key to detonating dynamite in a controlled way. He first used the old technology to set off the new one. He filled a small tube with black powder, attached a quick-match fuse, and submerged the device in the nitroglycerin to be detonated. This system worked, but it failed to create a shock wave strong enough to detonate large quantities of the primary explosive. Nobel then developed a blasting cap that was composed of mercury fulminate contained in a small copper capsule, which was more effective.

The precise composition of the primary explosive was the other problem to be solved before dynamite could be used safely. To stabilize it, Nobel tried mixing the nitroglycerin with numerous substances, such as powdered charcoal, sawdust, rock powder, brick dust, coal dust, and gypsum. The best one, however, and the most practical for marketing purposes, proved to be a local diatomaceous clay called kieselguhr. This substance mixed with nitroglycerin at a one-to-three ratio and together with a small amount of sodium carbonate formed Nobel's Safety Powder. This substance was then wrapped with paper into cylinders into which the blasting cap could be planted to become the familiar form of dynamite.

Ascanio Sobrero discovered nitroglycerin in 1846 by slowly pouring glycerol into a chilled mixture of nitric and sulfuric acids. The volatile concoction, which is about seven times more powerful than gunpowder, literally blew up in his face, however, wounding him seriously and scarring him for life. Sobrero decided that nitroglycerin was too dangerous for practical use. Nobel was not so sure. He began experimenting in the late 1850's with various ways to stabilize the liquid and ignite it in a controlled way.

Unfortunately, Nobel solved the ignition problem before the stabilization problem. The blasting cap developed by Nobel in the mid-1860's made possible the first innovation in explosive technology since gunpowder appeared in the fourteenth century in Europe. He began production and sales immediately, but the liquid nitroglycerin was still highly unstable, and many accidents and deaths occurred in the process of manufacturing, transporting, and storing it. One of the worst accidents killed Alfred's younger brother, Emil, and four other people when the Nobel factory in Heleneborg, Sweden, detonated and disappeared in September of 1864. Strict laws were passed in many countries making the transportation and use of this new explosive very difficult.

Nobel was forced to focus his creative intelligence on the stabilization problem and soon came up with a solution. He found a local clay that mixed well with nitroglycerin in a one-to-three ratio. The resulting powder was slightly less powerful than pure nitroglycerin but much more stable. This material was patented under the name of dynamite, or Nobel's Safety Powder, and went into production in 1867. Only eleven tons were produced that year, but by 1874 a number of factories in different countries produced some 3,120 tons. Massive engineering projects soon made possible by dynamite included the Gotthard Tunnel, the Canadian Pacific Railway, the Suez Canal, and the Panama Canal.

Under certain conditions, the liquid nitroglycerin could still separate from the powder and explode unpredictably, however, and dynamite could not be used effectively under water. These problems were solved when Nobel patented gelignite, or blasting gelatin, in 1875. The circumstances of the initial breakthrough illustrate the high level of awareness maintained by a truly inventive mind.

Reportedly, Nobel cut his finger one night while working in his laboratory in Paris and could not sleep because of the pain. He got up, put some collodion on it, and went back to bed. An hour later, he awoke again because the collodion coating had flaked off. He got up to make another application but began thinking about the chemical composition of this substance, which is created by dissolving cellulose nitrate in ether and alcohol. He began adding drops of nitroglycerin to it, and, in a few hours, he had produced gelignite. Three hundred separate experiments later, Nobel had perfected a powerful explosive material with the flexibility of rubber and the durability of leather.

The next major innovation credited to Nobel caused him a great deal of personal anguish because of the political problems that developed. Ballistite, which he patented in 1887, is a smokeless powder for use in large and small firearms. It is a combination of nitroglycerin, nitrocellulose, and camphor. Nobel developed it in his Paris laboratory, where he had been based for twenty years, so he offered the rights for his invention to the French government. The government refused his offer, believing that it already had a comparable product called Sarrau-Vieille, or Poudre B. Two years later, Nobel signed over his Italian patent rights to the Italian government and began supplying it with ballistite.

The French authorities were furious over Nobel's ballistite deal, and he was accused of espionage and treason in the press. His laboratory was searched by the police, and sample stock was seized. He was banned from using the French test ranges and not allowed to manufacture ballistite at his factory in Honfleur. Nobel's well-connected, longtime French partner, Paul Barbe, was unable to help him. In fact, Barbe was soon to be exposed as a swindler and committed suicide. Nobel was forced to leave his beloved Paris and relocate to San Remo, Italy.

Ballistite faired no better in Great Britain. Nobel had been in friendly communication about his work on this invention with Frederick Abel and James Dewar. They made some minor changes and patented a similar product there called cordite. Nobel lost the case in court over patent infringement, but in his opinion the judge referred to Abel as a dwarf standing on the shoulders of a giant.

Added to these disappointments in his professional life, Nobel's older brother died in 1888. He and Ludvig had been close professionally as well as personally. Then, he learned in 1891 that his mistress of fifteen years, Sophie Hess, was carrying the baby of another man, whom she eventually married. All these shocks combined to turn his thinking about the big issues of life in a new direction. He long had had qualms about the military uses of his inventions and the death and destruction they could cause, but in the last years of his life a plan took shape to address this issue concretely.

Impact

When Ludvig died, one of the French newspapers thought the deceased was his better-known brother, Alfred Nobel. The paper ran a scalding obituary calling Nobel a "merchant of death" who got rich on products that "maim and kill." Nobel was deeply hurt, but only slightly less vicious attacks had been coming at him since the early days when accidents with liquid nitroglycerin were common. They had a cumulative effect.

He had been friends for many years with a pioneering European pacifist named Bertha von Suttner, to whom he often expressed regret about the uses to which his inventions were occasionally put. In Paris in 1887, he outlined to her his ultimate defense. Nobel said that he would like to be able to create a substance or a machine with such a horrific capacity for mass annihilation that wars would become impossible forever. Unfortunately, even nuclear weapons so far have not abolished war in the way he envisioned, but perhaps this basic idea will yet prove correct.

To further the cause of peace, as well as science and the arts, which are closely related, Nobel established a foundation in his will for the purpose of awarding international prizes for the most outstanding accomplishments in five areas. The Royal Swedish Academy of Sciences was to decide on the winners in physics and chemistry. The Karolinska Institute would award the prize in medicine. The Swedish Academy would decide on the winner of the prize in literature. Finally, and most surprising, the Norwegian parliament was to make the decision about the winner of the Nobel Peace Prize.

At the time of his death, Nobel had assets in France, England, Germany, Scotland, Italy, Austria, Norway, and Russia, as well as Sweden. When these assets had been liquidated, a total of 31,225,000 Swedish crowns remained. Some of his heirs were not happy to receive only the minimum bequests required by Swedish law, but after settling with them and with Sophie Hess out of court, the Nobel Foundation was established on June 27, 1900. The original capital was invested, and every year the earnings are divided among the recipients of the various Nobel Prizes. The inventor of dynamite would seem to have atoned many times over for the destructive uses to which it sometimes has been put.

In fact, the military applications of dynamite were quite limited. It could not be used to pack ordnance because the heat of launching the shell would detonate the charge in the barrel of the firearm. Propulsion systems utilizing compressed air were developed in the late nineteenth century but never came into common use. Dynamite could only be used effectively for purposes of sabotage and terrorism. For example, there was a violent Irish nationalist paramilitary organization operating out of New York around this time, which was actually called the Dynamite Party. Then, shortly after Nobel's death, trinitrotoluene (TNT) became the gold standard of regular military explosives.

On the other hand, the immense and numerous engineering projects facilitated by the use of dynamite and other nitroglycerin-based explosives stand as monuments to Nobel's genius. They have sped the transportation of people and products around the world and vastly improved the quality of life for virtually everyone living in the twenty-first century. The international prizes awarded every year in his name are by far the most prestigious of their kind. It can only be hoped that these Nobel Prizes will eventually help to realize Nobel's dream of a world in which explosives are only used for constructive and peaceful purposes.

ROBERT NORTON NOYCE

American electrical engineer

Noyce's development of the integrated circuit made possible the mass production of very complex computer circuitry, thus paving the way for the digital revolution. His subsequent leadership of the American semiconductor industry helped consolidate its preeminence.

Born: December 12, 1927; Burlington, Iowa
Died: June 30, 1990; Austin, Texas
Primary fields: Computer science; electronics and electrical engineering
Primary invention: Integrated circuit

EARLY LIFE

Robert Norton Noyce was born in Iowa to a Congregationalist minister. Although the position did not pay an enormous amount of money, the family was well enough off for Mrs. Noyce to be able to have a hospital birth, something still considered unusual at the time. For the next several years, the Noyce family moved from town to town as Reverend Noyce took work with various congregations before settling permanently in Grinnell, a small town west of Des Moines.

Young Robert showed an interest in science and technology from a very early age and was soon working various part-time jobs in order to buy such delights as a crystal radio kit. However, he was not the stereotypical nerd, fascinated with technology to the exclusion of all else. He also showed a striking aptitude for sports, which he turned to good use in some of his more daring and physical mechanical exploits such as building and flying a glider. With his slim, muscular build and good looks, he was also quite successful with the opposite sex.

However, while he was a student at Grinnell College, an adolescent lark nearly wrecked his promising career. Several young men in his dormitory took it upon themselves to throw a genuine Hawaiian luau, complete with a roast pig. It fell upon Robert and another strapping young athlete to acquire the pig, a feat they accomplished by stealing one from a nearby farmer's pen. Although the event was a success, Robert was subsequently struck with pangs of conscience and turned himself in as the thief. Only because of his father's standing as a local minister and the intercession of one of the professors did he avoid criminal proceedings. Instead, he was suspended for a semester; he used that time to work at a local insurance company and gain experience with the practical side of mathematics.

When he returned to Grinnell College, he learned about a fascinating new development, the transistor. Immediately, he perceived the breadth of possibilities represented by solid-state electronics and set his sights on graduate work at the Massachussetts Institute of Technology (MIT). After he completed his Ph.D. there, he took a position with Philco, a well-known manufacturer of radios and televisions.

Life's Work

The job at Philco put Noyce in the position to do real practical science and to become noted in wider circles through monographs and papers in technical journals. This work brought him to the attention of William Shockley, one of the coinventors of the transistor. Shockley had left Bell Laboratories to found his own company, Shockley Semiconductor Laboratory, and he was looking for top-flight talent to implement his new ideas for more sophisticated transistors. Noyce was delighted at the opportunity to work with the prominent physicist.

However, the shine soon wore off the job. Though Shockley was a brilliant physicist, when it came to personnel management he was an utter dunce. When he launched a full-scale sabotage investigation over a fragment of metal that turned out to be a pushpin that had lost its protective glass head, several engineers, including Noyce, decided they had had enough. This group, which Shockley would later condemn as the "Traitorous Eight," found venture capital from Fairchild Camera and Instrument and thus founded Fairchild Semiconductor just down the road from Shockley's company.

However, Fairchild's products were still all discrete transistors, which meant they needed to be soldered onto circuit boards in order to create useful electronic devices. While such transistors were fine for simple devices, in complex circuits it became likely that at least one solder would be faulty, rendering the entire circuit inoperable. This "tyranny of numbers" became the consuming problem for electrical engineers of the 1950's. Noyce hit upon the solution almost by accident, when Fairchild's patent attorney asked him to think of as many possible uses for a new fabrication method. Although the integrated circuit was a major breakthrough, Noyce's corporate bosses at Fairchild Camera and Instrument had little understanding of how to market it. Growing increasingly frustrated with the situation, Noyce and fellow

Robert Norton Noyce at his office at Fairchild Semiconductor with diagrams of semiconductors and microchips. (Time & Life Pictures/Getty Images)

"Traitorous Eight" member Gordon Moore left Fairchild to found Intel.

In founding his own company, however, Noyce left the laboratory behind for good. The integrated circuit would be his last significant invention. Henceforth, he would be primarily an administrator, leading others such as Ted Hoff, who took the integrated circuit to the next step with the microprocessor. Noyce created a new corporate culture at Intel, with a relatively flat hierarchy. Although he was fiercely competitive toward other companies, he wanted to minimize internal competition, emphasizing that everyone at Intel was on the same team with the same goal. There were no executive privileges, even for himself. He had no office, just a cubicle with shoulder-high partitions, and he ate his lunches in the corporate lunchroom rather than in a private executive dining room. He parked in whatever spot happened to be available when he arrived each morning, and if he were to run late one morning, his name would be posted on the "late list" just like any other Intel employee.

By the 1980's, Noyce had largely moved away from

The Integrated Circuit

When the transistor was first developed, it was hailed as a vast improvement over the vacuum tube. Its small size meant that it used much less power and produced much less heat, but its size also made it difficult to wire together into circuits. While a vacuum tube sat in a socket, a transistor had three tiny wire leads that had to be threaded through holes in the circuit board and soldered to the circuit traces with tiny beads of molten metal. This was a difficult, painstaking task, and no matter how careful the workers were, it was inevitable that at least a few solders would be faulty. This was an annoyance in relatively simple circuits such as a radio, but when one was building complex circuitry for telephone switching centers or computers, it became a major problem.

Throughout the 1950's, engineers sought the answer to this "tyranny of numbers." The most common solution was to make the parts even tinier, which only exacerbated the problem. The people assembling circuit boards then had to use tweezers to position the components and peer through magnifying glasses to solder them. Another solution was to make all the components the same size, with identical joining parts, so they would snap together like Tinkertoys.

Two men, Jack St. Clair Kilby of Texas Instruments and Robert Norton Noyce of Fairchild Semiconductor, hit upon the idea of making all the components from a single piece of silicon. Kilby started with the realization that all the necessary components could be made from silicon and need not be cut apart. As a result, when it came time to make a working integrated circuit, he made the necessary electrical connections with tiny wires stuck into the silicon. However, while this worked for a prototype in a proof-of-concept demonstration, as a commercial product that integrated circuit would be no great improvement over discrete transistors.

By contrast, Noyce was trying to think of as many possible ways to use the planar process, a technique by which transistors were deposited on a piece of silicon as flat structures. Fairchild's patent attorney wanted to write the patent as broadly as possible in order to include as many money-making products as possible. While brainstorming, Noyce realized that one could also lay down connections within the transistors and between them. That realization led to the idea of making all the components and connections for an entire circuit from a single piece of silicon and only having leads where it needed to communicate with the outside world.

Since Noyce's idea lent itself to mass reproduction through the photolithographic process, Fairchild was soon producing commercial integrated circuits. Although the earliest integrated circuits had fewer than a dozen components, improvements in etching techniques enabled a rapid increase in the number of transistors on a chip of a given size, and a rapid reduction in the price of existing chip designs, a principle often referred to as Moore's law (named for Noyce's business partner Gordon Moore). The next logical development was to put the circuitry of a computer's central processing unit (CPU) on a single chip, creating the programmable microprocessor.

the day-to-day administration of Intel to address larger issues in the semiconductor industry. Seeing weaknesses in key parts of the industry, he began to push for a consortium that would help draw together the various companies to protect the interests of the industry. Thus, SEMATECH was born. When he was made its head, he had to leave his beloved Silicon Valley and move to Austin, Texas. He lived there for four years, until his sudden death of a heart attack in 1990 at the age of sixty-two. As a result, he missed his opportunity to win his share of a Nobel Prize in Physics alongside Jack St. Clair Kilby in 2000.

Impact

In addition to his work with the integrated circuit, the foundation of the digital revolution, Noyce was critical in the development of California's Santa Clara Valley as a hub of technology innovation. Twice leaving employers to found new companies, he set a pattern that would mark the culture of Silicon Valley, showing that there was little disgrace attached to frequent job changes and that people could easily find venture capital to start their own companies. The culture that Noyce created was absolutely essential to the risk-taking that enabled the rapid growth of the computer industry. In addition, the relatively flat corporate hierarchy he fostered at Intel paved the way for the even more relaxed jeans-and-sneakers culture of the next generation of Silicon Valley companies, including Apple and Google.

Victor Leaton Ochoa

Mexican American engineer

Ochoa invented an airplane with collapsible wings, called the Ochoaplane, and several mechanical and electrical devices, such as an adjustable wrench, a windmill, and an electric brake for streetcars.

Born: 1850; Ojinaga, Mexico
Died: c. 1945; possibly Sinaloa, Mexico
Primary fields: Aeronautics and aerospace technology; mechanical engineering
Primary inventions: Ochoaplane; electricity-generating windmill

Early Life

Victor Leaton Ochoa (oh-CHOH-uh) was born in Ojinaga, Mexico, to Juan and Isabel Leaton Ochoa. His mother was also known as Elizabeth Leaton before her marriage. She was the daughter of Ben Leaton, a prominent figure in the Presidio, Texas, area (across the Rio Grande River from Ojinaga). Ben Leaton remodeled an old Spanish mission, located about three miles east of Presidio, into a fort and trading post. It later became known as Fort Leaton, now a Texas State Historic Site.

Juan and Isabel Ochoa had five children. Victor was the firstborn; the others were Lucia, Esteban, Eduardo, and Enrique. Juan was collector of the Port of Presidio Del Norte. He also owned a large lumber mill in Fort Davis. According to a family story, Juan was attacked by American Indians while he was harvesting timber. His sons Victor and Esteban were with him and managed to get him loaded onto a wagon and taken back to Fort Leaton, where he died. After Juan's death, Isabel married Frank Shirley.

Victor Ochoa lived in the United States in various places for most of his life. He became a U.S. citizen in 1889. Ochoa did not begin inventing until late in his life. He was more than fifty years old when his first U.S. patent was issued in 1903. Before that, he led an active, colorful life in Texas, the New Mexico Territory, and Mexico.

Life's Work

Ochoa married Juana Sanchez and had three children: Sam, Stella, and Isabel. For at least part of Ochoa's married life with Juana, the family lived in Las Vegas, New Mexico Territory, where Juana was murdered by assassins hired to kill her husband, who had been uncovering corruption in the city as a newspaper editor. *New York Times* articles from 1893 and 1895 report that Ochoa was editor of the *Hispano Americano*, a daily newspaper in El Paso, Texas.

In addition to being an inventor and newspaper editor, Ochoa was a Texas Mexican activist and a supporter of the Mexican Revolution against President Porfirio Díaz. In the early 1890's, Ochoa helped organize La Unión Occidental Mexicana, a community-based organization that served as a social and political forum for Texas Mexicans. He was arrested in the United States in April, 1895, for his revolutionary activities, because Mexico was at peace with the United States. He was sentenced to two years in a penitentiary in Brooklyn, New York.

Victor's second wife was Amanda Cole, granddaughter of Thomas Cole, an American painter. Victor and Amanda had two children, Esteban Leaton and Lucia.

Ochoa's earliest U.S. patent was issued on January 13, 1903 (U.S. Patent number 718,508), for a reversible electric motor. Ochoa was residing in Peekskill, New York, at this time. In 1906, he received a patent for a fountain pen and sold the patent to the Waterman Pen Company. In 1907, he was issued three U.S. patents. The first was for a pen and pencil clip, and he sold the patent to the American Pen and Pencil Company. The other two patents were for a magnetic brake for streetcars and an improvement to this brake. Ochoa sold these patents to the American Brake Company in Seattle.

During 1908-1911, Ochoa designed the Ochoaplane, an airplane with collapsible wings that allowed for easy storage in a garage or barn. The machine had a framework of steel spring and steel tubing, put together so that it could be folded by working a lever. It had a canvas covering and was about twenty-six feet wide and six feet long. It was powered by a six-horsepower motor and weighed about 250 pounds. Ochoa had been working on this airplane for more than twenty years. It was never patented in the United States, and there is no evidence of its widespread success. During this time, Ochoa is reported to have been the president of the International Airship Company, based in Paterson, New Jersey.

In 1919, Ochoa was issued a patent for a windmill with a rotor, which rotated on a vertical shaft rather than the typical disk rotating on a horizontal shaft, which was used in water-pumping windmills. A half interest in the patent was assigned to Leigh Clark of El Paso, where Ochoa was residing at the time. Ochoa's last two U.S. patents were issued in 1922 and 1923. They were for an adjustable wrench and an improvement to the invention. The patent of May 8, 1923, was assigned to the Ochoa Tool and Machine Company, a Delaware corporation.

Ochoa is believed to have died in 1945 in Sinaloa, Mexico, but the exact date and details are not known. Included in a Smithsonian Institution collection of Ochoa's papers is a letter he wrote to his son Stephen dated June 7, 1945.

Impact

Ochoa was an active Hispanic American inventor in the early twentieth century. He designed several devices between 1903 and 1923 and sold the rights to several of them to companies. He formed two companies: the International Airship Company, which produced the Ochoaplane, and the Ochoa Tool and Machine Company, which manufactured his adjustable wrench.

Ochoa was a prominent man in his time, having served as editor of at least two Spanish-language newspapers, in Las Vegas and El Paso. He was also active in Hispanic American affairs in the Southwest. He lived part of his life in New York and New Jersey and was said to be a friend of President Theodore Roosevelt.

Ochoa received a patent in 1919 for a simple windmill in which the wind directly turned a vertical shaft. Typical windmills, used for pumping water out of the ground, used a horizontal shaft turned by the wind; the horizontal rotating shaft then had to be converted to up-and-down reciprocating action to drive the pump. Ochoa also proposed use of his windmill to generate electricity, a concept that gained momentum in the early twenty-first century.

—Harlan H. Bengtson

Improvements to the Windmill

Victor Leaton Ochoa's windmill design was simpler than the typical windmills of the early twentieth century, which were used to pump water from the ground. Ochoa claimed that his windmills cost only one-fifth as much as ordinary windmills to put up. He suggested attaching a dynamo and storage batteries to the windmill to provide electric power to a building.

Ochoa was issued a patent on October 21, 1919, for his windmill design. It had a vertical shaft turned directly by the wind, which blew on rectangular vanes mounted at the top of the shaft. His design also included a means of preventing the speed of rotation from becoming excessive in very high winds—by moving some of the vanes into an inoperative position during excessive wind speed.

The most widely used windmill design in Ochoa's time is still in use today for pumping water from the ground in remote locations. This design utilizes a fan-type wheel mounted on a horizontal shaft at the top of the windmill. The wheel turns as a result of wind blowing on it from a direction perpendicular to the plane of the wheel. The wheel is kept facing into the wind by a weathervane mounted perpendicular to the wheel. All of this produces a rotating horizontal shaft. A "windmill motor" mounted at the top of the windmill converts the energy of the rotating shaft to a reciprocating motion, which moves a shaft up and down. This shaft goes from the top of the windmill down into the well at its base. The shaft moves a piston up and down in a pump placed in the water at the bottom of the well. The piston together with a one-way valve brings a column of water up from the bottom of the well to a tank, pond, or some use at the surface.

With Ochoa's simple design, which used a rotating vertical shaft at the base of the windmill to run a dynamo to generate electricity, there would be no need to have the windmill "facing into the wind." The rotation of the vertical shaft would be produced directly without the need for a windmill motor at the top of the windmill. Ochoa stated that one of his windmills with vanes seven feet long could produce enough electrical power to light a building and provide all other necessary power. Of course, "all other necessary power" for a building at that time was significantly less than it would be today.

Ochoa proposed the use of his windmill/generator for areas outside large cities. However, centrally generated electric power eventually became available over most of the United States, and local generation of electric power for homes never came into widespread use. In the early twenty-first century, there has been a resurgence of interest in wind power for both centralized and home-based generation of electricity. Perhaps Ochoa's windmill was ahead of its time.

Hans Joachim Pabst von Ohain

German mechanical engineer

Von Ohain was the first to design and run a turbojet engine as well as the first designer whose engine successfully powered a jet aircraft.

Born: December 14, 1911; Dessau, Germany
Died: March 13, 1998; Melbourne, Florida
Primary fields: Aeronautics and aerospace technology; mechanical engineering
Primary invention: Jet engine

Early Life

Hans Joachim Pabst von Ohain (OH-hayn) was born into an upper-class German family on December 14, 1911. His father, Wolfe Pabst von Ohain, was a career military officer. His mother, Katherina Nagel, came from a wealthy farm family. At an early age, the young man displayed an interest and ability in science. When Hans was thirteen years old, the family moved to Berlin, where he attended Arndt-Gymnasium in Dahlem in preparation for the university. At Arndt, he proved to be only a mediocre student until he was exposed to Albert Einstein's theory of relativity. Einstein's ideas excited him, and he developed an intense interest in mathematics and began to excel in both that subject and physics. He then attended Georg-August University at Göttingen, where he specialized in physics, thermodynamics, and aerodynamics.

He was very successful in his university studies and completed the seven-year doctoral curriculum in four years. His Ph.D. was awarded on November 1, 1935, in physics, with minors in mathematics, aeromechanics, and aerodynamics. His doctoral dissertation concerned "An Interference Light Relay for White Light." At the same time that he was researching and writing his dissertation, he became interested in aircraft propulsion systems. He had flown gliders and was fascinated with what he called the "elegance of flight." When he experienced his first powered flight aboard a Junkers tri-motor aircraft, he was appalled at the noise, vibration, and discomfort associated with powered flight. He felt that the elegance he had experienced in the gliders was destroyed by the engines. It was at this point that he began to examine alternative sources of power, and this led him to design his turbojet engine.

Life's Work

Von Ohain began work on his engine in 1934 largely with money supplied by his maternal grandmother. He received a patent on November 10, 1935, which was classified as secret. He estimated that an aircraft powered by this engine could operate at approximately five hundred miles per hour. One major concern was the excessively high estimated fuel consumption, a problem that was also being addressed by Frank Whittle in England. After a year of calculating and designing, von Ohain was convinced that his design was practical. He decided to construct a test model, and he employed his car mechanic, Max Hahn, to build it. At each setback the team experienced, von Ohain would design an alternative that improved on the original design and Hahn would build it. Interestingly, even though Hahn agreed to build the engine, he was convinced that it would never work. It was this model that von Ohain presented to Ernst Heinkel, who agreed to finance the project. Von Ohain proceeded to build a test engine fueled by hydrogen to minimize combustion problems.

While von Ohain was attending the university, the National Socialist German Workers' Party came to power. Von Ohain was largely apolitical during his university career and avoided involvement as much as was possible. He went so far as to resign his membership in the university soaring club when the National Socialists took it over and politicized it. Ironically, with the success of his proof-of-concept hydrogen engine, his work became known to the Air Ministry. As the newly appointed director of turbine engine development for the Heinkel

Aircraft Company, he was faced with the responsibility of dealing with party officials in the ministry. The aircraft industry was in the center of the military buildup for the approaching World War II. Von Ohain and Heinkel managed to keep most of their work secret, and even the Air Ministry was largely unaware of their progress. Through Heinkel's protection, von Ohain was never forced to join the Nazi Party.

The Heinkel factory designed and built a special test-bed aircraft for a flyable version of von Ohain's engine. This was the Heinkel 178, an experimental design not intended for production. Von Ohain's latest version of his engine, the He S3B, was installed in the aircraft. This new version developed one thousand pounds of thrust and had been test run for ten hours. The first jet-powered aircraft successfully flew on August 27, 1939, only three years after the project was initiated. Von Ohain's next design was shelved in favor of developing a multistage axial-flow engine known as the He S30. This engine proved to be unsuccessful, and von Ohain returned to his centrifugal-flow design and produced the He S8A, which developed thirteen hundred pounds of thrust. Two of the engines were mounted under the wings of the Heinkel He 280 aircraft. This was the world's first jet fighter, and it flew on March 30, 1941.

As the war turned against Germany and the Allied bombing increased, the aircraft factories became prime targets. Materials became scarce, and it was not until April, 1942, that the long-delayed He S30 axial-flow engine first ran. The Air Ministry decided that the Messerschmitt Me 262 powered by the Jumo 004 engine would be the world's first mass-produced jet aircraft, not the Heinkel He 280. Production and development of the He S8 and He S30 series were canceled, and Heinkel was ordered to cease production of jet-powered aircraft. Although Heinkel and von Ohain were again contracted to develop a second-generation turbojet, the He S011, the final collapse of Germany intervened. This engine was the most powerful turbojet engine designed to date, but only nine examples were built and bench-tested. It was never mass-produced. Thus, the advantages gained by developing von Ohain's proven design were lost, and no engine of his was ever put into production.

The Allied occupation resulted in von Ohain being questioned by a team of American intelligence experts. His name appeared on a list of high-priority German scientists who were to be brought to the United States. In 1947, under an operation known as Project Paperclip, von Ohain was invited to emigrate to the United States. He readily accepted and arrived in February of 1947 at Wright-Patterson Air Force Base, where he began work

The Turbojet Engine

The engine that powered the first jet aircraft was Hans Joachim Pabst von Ohain's Heinkel S3B. It operated on the principle of ingesting large quantities of air, compressing that air, and introducing fuel. This fuel-air mixture was then ignited, and the accelerating gases passed through a turbine wheel. The gases not used to drive the turbine-compressor unit were directed rearward in the form of thrust. The S3B incorporated a two-stage centrifugal compressor. The idea of a two-stage compressor reduced the stresses required to increase the air pressure to the desired level because the differential between the inlet and outlet pressure at each of the stages was considerably less than that imposed on a single-stage compressor, which would require a large differential to achieve the same pressure increase. This compressed air was then directed through ducts to the bars where fuel was injected. A spark plug ignited the gases, and these hot gases accelerated past a number of stationary vanes out the single combustion chamber. The gases exiting the combustion chamber were directed into the single-stage turbine wheel, which turned the compressor mounted on the same shaft. The design ensured that only the minimum amount of energy required was used to turn the compressor, thus maximizing the amount used as thrust. Ironically, none of von Ohain's designs reached the production stage, as the German government decided to produce designs by other manufacturers.

Von Ohain's final design under the Heinkel Aircraft Company, the He S011, fell into the hands of the U.S. military during the occupation of Germany. This was a true axial-flow design with five stages of compression and a two-stage turbine. While this engine had never reached the production stage prior to the fall of Germany, it was by far the most advanced turbojet design up to that time and closely resembled many modern turbojet engines. The original engine produced 2,860 pounds of thrust, and von Ohain estimated that it could grow to 3,500 pounds with a potential pressure ratio of eight to one. These were values that had been unachievable up to that time. Von Ohain and this engine design were brought to the United States, where his work continued for many years and resulted in a number of successful innovations in jet-engine technology. Much of the technology used in today's modern jet engines is a result of the genius of von Ohain.

for the Air Force and continued his research for more than thirty years. He continued to develop improvements to the turbine engine and propulsion technology, and he eventually became the chief of the Aerospace Research Laboratory and was chosen as the chief scientist in 1964. He served in that capacity until 1975, when the Aerospace Research Laboratory was disbanded, and he became the chief scientist of the Aero Propulsion Laboratory. He retired in January, 1979, but continued to work part-time for the University of Dayton Research Institute for another ten years. Von Ohain died on March 13, 1998, in Melbourne, Florida.

Impact

Von Ohain was blessed with a very original mind. He was able to analyze a problem and develop a solution based almost entirely on his own insight. He readily admitted that he did not research previous work on the turbojet idea, and he felt that this freed him from the typical limitations and constraints to which most researchers are subject. In his work on the turbojet engine, he identified the problems and then logically addressed them. When one of his concepts proved unworkable or inefficient, he simply altered it or developed an entirely new solution. While he became an outstanding engineer, he really had little experience in the actual manufacturing process. He addressed this shortcoming by surrounding himself with competent assistants to whom he always gave credit for their efforts.

The limitations of piston-powered, propeller-driven aircraft were widely known prior to von Ohain's work. He arrived at what was to become his life work quite by accident. His horror at the discomfort of his first powered aircraft flight led him on a search to reestablish what he termed the "elegance of flight." The idea of a turbine-powered engine that would reduce vibration, operate at higher altitude, and increase cruising speeds was his solution. After leaving Germany, he continued his work to design and improve the turbojet engine for many years. It was not only his ability as an engineer that set him apart but also his leadership skills. He had the talent to match personnel and projects based on the demands of the project and the specific ability of the individual. He and his team were responsible for a number of design improvements to jet engines, and he personally was awarded more than thirty patents ranging from the "Jet Wing with Multiple Thrust Augmentors" to his last, the "Water Craft with a Hydrofoil-Bladed Wheel Assembly." These patents were in addition to the fifty German patents he was awarded under Heinkel Aircraft between 1935 and 1945. Von Ohain was a man of tremendous vision and energy, and the success of modern jet-engine technology can be traced back directly to this vision and energy.

Ransom Eli Olds

American automobile manufacturer

By building his two steam-powered carriages and then a gasoline-powered vehicle, Olds was able to find practical solutions to the problems that stood in the way of the development of the automobile. As a manufacturer, Olds was just as innovative. By outsourcing parts and organizing an assembly line, he revolutionized the production process.

Born: June 3, 1864; Geneva, Ohio
Died: August 26, 1950; Lansing, Michigan
Also known as: R. E. Olds
Primary fields: Automotive technology; manufacturing
Primary invention: Olds horseless carriage

Early Life

Ransom Eli Olds was the fourth son and youngest of five children born to Pliny Fisk Olds—the son of Jason Olds, a Congregational minister who had come from Massachusetts to Ohio as a missionary—and his wife Sarah Whipple Olds. At the time of Ransom's birth, Pliny still owned the blacksmith and machine shop in Geneva, Ohio, that he had established ten years before. Even as a young child, Ransom spent much of his time in the shop, sometimes making toys with the help of his older brothers. Evidently the business was not doing well, for in 1870 Pliny traded it for a house in Cleveland, Ohio, where he became superintendent at an ironworks. Ransom started school in Cleveland. Though he was shy, he must have been appealing, for at the end of the year his teacher presented him with a book. However, the boy's happiest memories were of his visits to the ironworks, which he found fascinating.

After four years in Cleveland, Pliny acquired a farm at nearby Parma. Ransom, now ten, went to a country school a mile from his home. At lunchtime, he avoided the boys his age, whom he found too rough, and played with the girls instead. Though he enjoyed helping his father repair tools in his small blacksmith shop, Ransom developed an aversion to farming and especially to the smell of horses, which he later said motivated him to develop a horseless carriage.

In 1878, Pliny gave up farming and went back to Cleveland to work as a pattern maker, taking Ransom with him so that the boy could go to school there. In 1880, Pliny managed to trade his farm for property in Lansing, Michigan, and the family was reunited. In 1880, Pliny and his son Wallace opened P. F. Olds and Son, where they repaired machinery and manufactured steam engines. Ransom Olds attended high school briefly, dropping out after tenth grade.

Life's Work

From 1882 to 1883, Ransom Olds took courses at Bartlett's Business College so that he could attend to the bookkeeping at his father's shop. In 1885, Olds bought out his brother Wallace and became his father's partner. One of Olds's inventions, a steam engine powered by a gasoline burner, became their most profitable product. Pliny Olds was dubious about his son's next project, a three-wheel horseless carriage powered by a similar device. Nevertheless, it was completed in 1887. A four-wheel horseless carriage followed five years later.

Meanwhile, Olds had begun courting Metta Ursula Woodward, a quiet, high-principled girl from Pinckney, Michigan. On June 5, 1889, they were married. Eventually they had four children, but only the first two, Gladys Marguerite and Bernice Estelle, survived infancy. Metta is credited with persuading Olds to become active in the Baptist Church and involved in community activities.

Like other early automakers, Olds experimented with battery-powered vehicles, but after seeing the internal combustion engines displayed at the Chicago World's Fair in 1893, he decided to switch over to gasoline power. By 1896, Olds had developed his own internal combustion engine, patented it, and turned out a gasoline-powered horseless carriage, which in his patent application he called an automobile. He then divided the family enterprise into the Olds Gasoline Engine Works and the Olds Motor Vehicle Company. It soon became evident that he would need outside financing for his motor vehicle operation, which was seen as a risky venture. In 1899, Olds gave up financial control of his company, renamed his firm the Olds Motor Works, and moved most of the operations to a large, new plant in Detroit. Among the models of what now had the brand name of Oldsmobile was a simple, open vehicle with a curved dash, designed for use as a runabout, that could be sold for the phenomenally low price of $650.

When production on the curved-dash model began in 1901, there were buyers waiting. Then, on March 9, the new plant was destroyed by fire. Fortunately, since he was already obtaining parts from a number of suppliers,

The Olds Horseless Carriage

In 1887, Ransom Eli Olds invented and constructed his first horseless carriage. It resembled a child's tricycle, with two large, steel-tired wheels in the back and a third, smaller one in front, which was attached to a fork. Olds reasoned that this configuration would make the vehicle easier to steer. Behind the front wheel and between the two back wheels was a boxlike structure, with a single seat hollowed out for the driver. Olds used a long rod attached to the front wheel as a tiller. The vehicle was powered by a one-horse-power engine located in a box behind the seat. Though it was often referred to as a gasoline engine, in fact it was a steam engine. A gasoline burner was used to heat water, thus producing the steam that would propel the vehicle. In the summer of 1887, Olds was ready to road-test his invention. Though he had to give it a push to get it onto the street, it then ran a block before the engine showed signs of giving out, and Olds had to enlist the aid of friends to get his horseless carriage back to the shop.

Although other inventors had experimented with the idea of a horseless carriage and some had even tried to build one, Olds was the one who seized the initiative. During the next decade and a half, he worked tirelessly at perfecting the steam car, then applied what he had learned to the development of a gasoline-powered car, and finally used his practical experience to become a pioneer in the manufacture of automobiles. Between 1900 and 1903, there were more Oldsmobiles produced than any other car. Even after Oldsmobile became a part of General Motors in 1908, it continued to be not only a prestigious car but also one that often led the industry—for example, in making available such innovations as hydraulic brakes, an automatic transmission, front-wheel drive, and the air bag. The Oldsmobile was discontinued in 2004. However, the dedication to his craft that R. E. Olds had displayed when he introduced his horseless carriage 117 years before had become an Oldsmobile tradition, making the car bearing his name one of the most highly respected in the industry, and one whose demise is still mourned by automobile enthusiasts.

then using an assembly line to turn out the finished cars, Olds could switch his operation to the smaller plant in Lansing and continue to build cars while the Detroit facilities were being rebuilt. Despite the disaster, from 1900 to 1903 Oldsmobile produced more automobiles than any other American firm.

However, Olds found that he could no longer control the company he had founded. He was willing to let his backers handle financial matters and sales, but by 1904, when it became clear that Frederic Smith, the son of one of his original investors, intended to supervise production as well, Olds sold his stock, left the firm, and founded the R. E. Olds Company. When the Detroit Olds Motor Works threatened legal action because he had used "Olds" in the name of his new firm, he decided to use his initials instead. The first car built by the Reo Motor Car Company was markedly different from those Olds had previously designed. Instead of the curved dash, the Reo had a bonnet, or hood, which held batteries, the gas tank, and the radiator. It also had a running board and a steering wheel. Moreover, it was larger, heavier, and more powerful than the runabout, and it could carry five passengers. Although the company offered several other models, including its own runabout and an even larger touring car, the Reo was its best-selling vehicle. In 1905 and 1906, the new firm sold more cars than Olds Motor Works did, and in 1908 Smith's company was taken over by General Motors.

After 1915, however, Olds became increasingly less involved with automobiles. Instead, he devoted his time to other projects, manufacturing a lawn mower he had invented, for example, and trying his hand at investments and real estate. In 1916, he began building a large community on Tampa Bay in Florida, which he called Oldsmar, but it was not a success.

During the last four decades of his life, Olds enjoyed yachting both on the Great Lakes and in Florida and entertaining friends either at the family home in Lansing or at one of his summer places on the Great Lakes. Olds remained active until July 28, 1950, when he complained of feeling ill and was hospitalized. On August 26, he died of cancer. Metta Olds, who had been in ill health for some time, died of pneumonia on September 2, 1950.

Impact

Although he was actively involved in the development and manufacture of automobiles for only two decades, Olds is ranked as one of the most important figures in automotive history. Other inventors had experimented with horseless carriages, but they did not progress from prototype to plant as rapidly as Olds did. There are several reasons for his success. Olds's experience as a machinist enabled him to work his way through mechanical problems with relative ease. Moreover, he had a rare character trait: the gift of learning from his mistakes. He viewed each new vehicle he built as something that could be improved upon. Finally, he was true to his vision: the elimination of horse-drawn transport, which could only be accomplished if automobiles were inexpensive enough so that everyone could afford them. Olds's inventiveness is indicated by the fact that the thirty-four patents he obtained included such important automotive mechanisms as carburetors, clutches, engines, and tires.

Certainly, Olds's success inspired other talented young men to enter the automotive field. They were influenced by him in many ways, such as his commitment to the internal combustion engine, his body designs, and even the substitution of a steering wheel for a tiller. They utilized his inventions and imitated and refined his production methods; some of them, Henry Ford, for example, built their fortunes upon Olds's vision of an America where everyone could own a car.

Automobile production soon became one of America's largest industries, and Detroit, where Olds had built his large factory, became the center of production. Automobile ownership gave Americans more freedom than ever before, freedom to live where they liked and to travel whenever they pleased, and the development of the trucking industry gave them access to goods from all over the world. Thus, what began as a simple horseless carriage transformed American society.

KEN OLSEN

American computer engineer

Olsen brought the minicomputer to the masses. Under his unique style of leadership, the Digital Equipment Corporation made small computers more efficient and affordable for businesses.

Born: February 20, 1926; Bridgeport, Connecticut
Also known as: Kenneth Harry Olsen (full name)
Primary fields: Computer science; electronics and electrical engineering
Primary invention: Minicomputer

EARLY LIFE

Kenneth Harry Olsen was born to Oswald and Svea (Nordling) Olsen as the second of four children. His father was a machine tool designer with several patents who kept a basement workshop full of tools. Olsen grew up in Stratford, Connecticut, under the strict religious fundamentalism of his parents, and he was almost always a well-behaved young man. After graduating from Stratford High School, Olsen served in the U.S. Navy from 1944 to 1946. There he received his first electronics training. In 1947, he entered the Massachusetts Institute of Technology (MIT) to study electrical engineering. He earned his B.S. in electrical engineering in only three years. With money from a graduation gift, Olsen followed a young lady from Finland who had decided not to finish college in the United States but to return home. Olsen caught up with Eeva-Liisa Aulikki Valve in Sweden, became engaged, courted her while the Cold War red tape generated by both the Finnish and the U.S. governments was settled, and on December 12, 1950, was married to her by her father. They returned to Massachusetts for Olsen to attend graduate school at MIT.

Olsen was able to work on the Whirlwind, a new type of digital computer being developed for the Navy to power a cockpit flight simulator. Whirlwind was different from other computers because it was interactive and worked in real time. A programmer could key in a program and get a seemingly instant response. Whirlwind was the basis for another computer called the Semi-Automatic Ground Environment (SAGE), which was to be used as an early warning system. Olsen directed a group to build a new computer to test the memory banks of the Whirlwind computer, and the task was completed in only nine months. That feat was so impressive that Olsen was rewarded with the task of going to Poughkeepsie, Massachusetts, to facilitate the interaction of MIT and International Business Machines (IBM) in building SAGE. This provided Olsen the opportunity to observe the production techniques of IBM. He was there for two and a half years and hated it. He felt that the company was inefficient and that he could beat IBM at its own game. In 1952, he was awarded his master's degree in electrical engineering.

LIFE'S WORK

In 1957, Olsen and Harlan Anderson, an MIT associate, went to the American Research and Development Company and received a grant of $70,000 to establish Digital Equipment Corporation (DEC). Olsen's younger brother, Stanley, joined the company on the first day. He would stay for more than twenty years. The first year, DEC built only printed-circuit logic modules for engineers to use in testing equipment. The next year, the company began to design and build the Programmed Data Processor-1 (PDP-1), an 18-bit computer that could perform many tasks such as track inventory or monitor scientific experiments, tasks that did not require a room-sized computer. It was successful, and in 1963 the PDP-4 was released, followed by the 12-bit PDP-5. A great breakthrough occurred with the PDP-8, released in 1965. Perhaps the first true minicomputer, it used tiny integrated circuits, which were faster and cheaper than transistors. The uses were uncountable. It could be programmed by a technician to control typesetting, a medical scanner, or even the scoreboard at Fenway Park in Boston. DEC's biggest machine, the mainframe PDP-10, was launched in 1967 to compete with IBM's mainframe computers. The PDP-11 was released in 1970 and became the most popular minicomputer in history. DEC also produced the DECnet software so that a small computer such as the PDP-11 could be attached to a large computer such as the PDP-10. This allowed the smaller computer to use the power of the large computer when the power was needed.

In 1974, DEC released the 32-bit computing architecture Virtual Address eXtension (VAX). VAX machines could be networked to one another so that each had the power of the others. The first superminicomputer, the VAX-11/780, was as powerful as a mainframe but at much less cost. The VAX package accounted for 40 percent of the world minicomputer market.

DEC failed to expand significantly into the microcomputer field in the early 1980's. Olsen did not see that people who had a computer at work might want one at home. Thus, as the microcomputers began to eat into the low end of the minicomputer market and as cheaper mainframes ate into the high-end market, DEC offered three different microcomputers. However, DEC had little retail expertise, and sales were slow. Soon, DEC's stock plunged. Olsen's reaction was to reorganize the company, discard the microcomputers, and push development of the VAX line. Olsen realized that when a person developed expertise on a microcomputer, he or she would eventually want to connect to a more powerful computer. Beginning with VAX clusters in 1983, DEC produced a line of VAX computers of all sizes that could be networked. The MicroVAX II workstation, with the power of the VAX-780 in a desktop-size machine, was hailed at the time as being as important as the IBM Personal Computer (PC) was when it first appeared in 1981. By 1986, the line included a networking system that would allow an IBM PC to retrieve data from any VAX computer. IBM had been unable to network even its own computers. The success of the new line caused many to call Olsen the most successful entrepreneur ever.

The development of more powerful microcomputers ate into DEC's market. The new competition and the recession in the early 1980's caused losses that even Olsen could not overcome before retiring (some say he was forced out) in 1993. He subsequently became chairman of Advanced Modular Systems, and in 1998 DEC was sold to Compaq. Olsen and Aulikki continued to live in a Boston suburb in the same modest home that they moved into when DEC was formed. They had four children, two girls and two boys. Olsen is a deacon in the Park Street Church. Aulikki died on March 2, 2009.

Impact

Before IBM's PC and other microcomputers brought computing to the masses, Olsen brought it to small businesses with the minicomputer. Powerful enough to accomplish innumerable tasks but small enough to be installed anywhere, the DEC minicomputers could be adapted to perform any task. Each company could program its particular software to suit that company's needs. DEC's minicomputers were also interactive. Results were quickly displayed on the cathode-ray tube and could be sent to a printer.

It is reasonable to say that the minicomputer generated the idea for the microcomputer. Once computers were developed for use at work, personal computers in the home soon followed. Also, Olsen and DEC helped establish the foundation for today's computer networking. Now computers are such that people around the world can interact with one another. It is now common for friends to talk long distance by computer or groups to have chat sessions online. Although Olsen did not develop this technology, his work made it possible.

—C. Alton Hassell

The PDP-1 Minicomputer

Released in 1960, the Programmed Data Processor-1 (PDP-1) was the first computer produced by Ken Olsen and the Digital Equipment Corporation (DEC). The PDP-1 was an interactive computer with a cathode-ray tube (CRT) similar to the kind used in televisions. A programmer could type in instructions and receive almost immediate results on the CRT or printer. There were several options for input/output: Besides the typewriter, which acted as a printer, programs could be written on punched tape. Computer cards could be translated to punched tape and inputted into the PDP-1. The CRT also had a light pen that could be used to input, change, or erase data.

The computer was based on microalloy-diffused transistors. It used an 18-bit word (eighteen 0's or 1's per word), and its standard main memory was 4 kilowords—about 9 kilobytes, or 9,000 bytes. The memory could be expanded to 64 kilowords (144 kilobytes). The memory's cycle time was 5 microseconds, which corresponds to a clock speed of 200 kilohertz. Most arithmetic instructions required 10 microseconds (about 100,000 operations per second). In contrast to the PDP-1, a modern computer may have more than 5 gigabytes (5 million kilobytes) of memory and do two billion operations per second.

The PDP-1 was slower and had much less memory than the mainframes, computers that filled entire rooms and required special air conditioning. In 1960, the PDP-1 was the size of a small refrigerator and did not require a sterile, air-conditioned room. It could be placed anywhere and cost $120,000, a fraction of the cost of a mainframe computer. Sales boomed after the International Telephone and Telegraph Company started purchasing the minicomputers to control its message-switching systems. The PDP-1 was powerful enough to do many jobs that did not need a mainframe. Both the Lawrence Livermore National Laboratory and the Atomic Energy of Canada used PDP-1s to control and monitor scientific experiments. Undergraduates at the Massachusetts Institute of Technology (MIT) developed a way to play music on the PDP-1 and produced programs that played the works of Mozart, Chopin, and Bach, among others. The first video game, *Spacewar!*, was developed for the PDP-1.

J. Robert Oppenheimer

American scientist and physicist

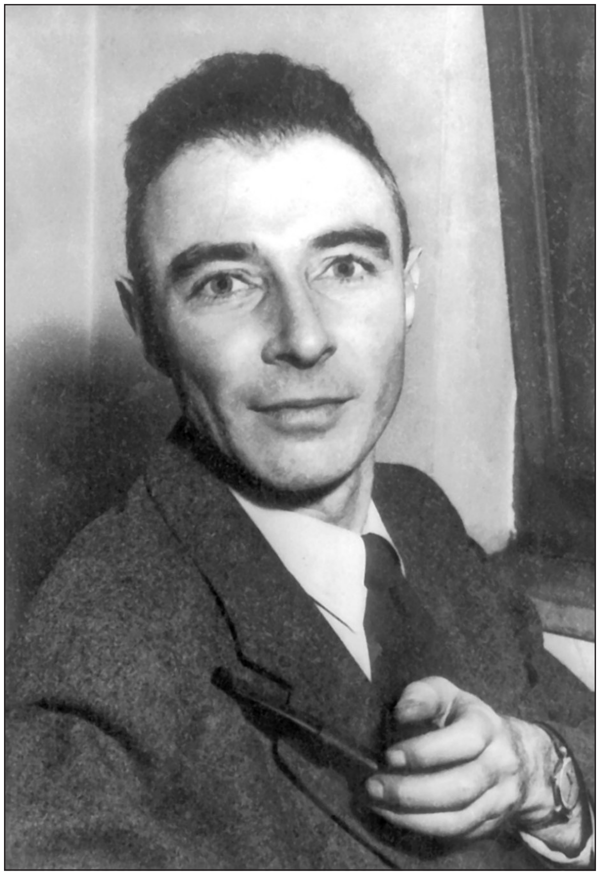
Oppenheimer led the Manhattan Project, which produced the first atomic bomb. He also did some of the earliest studies on subatomic particles, neutron stars, and black holes.

Born: April 22, 1904; New York, New York
Died: February 18, 1967; Princeton, New Jersey
Also known as: Julius Robert Oppenheimer (full name)
Primary fields: Military technology and weaponry; physics
Primary invention: Atomic bomb

Early Life

Julius Robert Oppenheimer (OP-ehn-hi-mur) was born in 1904 in New York City to Julius and Ella Friedman Oppenheimer, both of German-Jewish heritage. Julius was a partner in a successful fabrics company and Ella was a private art teacher, so Oppenheimer grew up in a privileged environment filled with intellectual discussion and the fine arts.

At the age of seven, Oppenheimer enrolled in the Ethical Culture School, a private institution with a progressive philosophy, where Oppenheimer showed an interest in science. In 1916, he wrote to several geologists about Central Park's rock formations. As a result, he was asked to join the New York Mineralogical Club and invited to speak. On the day of the lecture, the members were astonished to discover that Oppenheimer was only twelve years old.



J. Robert Oppenheimer. (NARA)

Upon graduation, Oppenheimer had to delay college because of illness. As part of his convalescence, he spent a summer journeying through New Mexico and fell in love with the state's rugged landscape, a fascination that would later influence the location of the atomic bomb enterprise in Los Alamos. In 1922, Oppenheimer entered Harvard University. Though he majored in chemistry, he discovered that physics was his real interest. Guided by Percy Williams Bridgman, Oppenheimer acquired a foundation in physics, while completing his chemistry degree in three years, summa cum laude. Despite showing little capacity for experimental work, Oppenheimer next went to Cambridge, England, to work with Joseph John Thomson on his electron detection experiments. Again, Oppenheimer demonstrated his incompetence in the laboratory.

However, at Cambridge, Oppenheimer read papers by Werner Heisenberg and met Robert Dirac and Niels Bohr—all of them physicists developing the new field of quantum mechanics. Discovering his calling, Oppenheimer left for the University of Göttingen, then the center of theoretical physics. By 1927, he had completed his Ph.D. and published, with Max Born, his first significant article, "On the Quantum Theory of Molecules." The paper explained the quantum behavior of molecules and would help establish high-energy physics in the 1990's.

Life's Work

After Göttingen, Oppenheimer accepted a dual professorship at the California Institute of Technology and at the University of California, Berkeley, where he and experimental physicist Ernest Orlando Lawrence, the inventor of the cyclotron, made a perfect team. Throughout the 1930's, Oppenheimer published groundbreaking papers on the positron, neutron stars, black holes, and the ability of deuterons to "tunnel" into atomic nuclei, the principle behind the tunneling microscope. It was also in the 1930's that Oppenheimer, concerned about Nazi Germany, became a member of the antifascist left. While he never joined the Communist Party, his brother Frank, his wife Kitty, and a number of his students did.

Just before the irruption of World War II, news emerged of a startling discovery—nuclear fission. Four German scientists—Otto Frisch, Otto Hahn, Lise Meitner, and Fritz Strassmann—found that neutrons can split uranium atoms, thereby releasing more neutrons and energy. There was also the possibility that with a critical

The Atomic Bomb

As the scientific director of the Manhattan Project, J. Robert Oppenheimer led the difficult enterprise of using fission to create a nuclear weapon. The main problems at the Los Alamos National Laboratory were bomb weight, predetonation, and failure to achieve criticality. The Manhattan Project scientists and technicians, with Oppenheimer as their conductor, overcame these issues and invented two types of fission bombs between 1943 and 1945, though only one, the implosion bomb, would be stockpiled for strategic use.

The gun-type bomb, "Little Boy," used uranium 235 as its fissionable material, an isotope of uranium extracted from uranium hexafluoride. Little Boy was a steel cylinder 10.5 feet long and 29 inches in diameter. Its interior consisted of a cordite charge, a U-235 bullet, a set of U-235 target rings, and a steel tamper. When dropped, Little Boy's radar units signaled that the bomb had reached a predetermined height. This signal then set off the primers that lit the cordite. The ignited cordite slammed the bullet into the target rings. The subcritical masses then went critical, resulting in an atomic detonation. This was the bomb used on Hiroshima, Japan, on August 6, 1945. Despite its simplicity, there was only one Little Boy bomb assembled, because of limitations on U-235 production and the superiority of the implosion design in terms of yield.

The other Los Alamos bomb was the "Fat Man," an implosion weapon using plutonium. This design has remained the favored one for fission bombs. Standing at approximately 15 feet, Fat Man was essentially a sphere with fins built from multiple layers cased in steel. The outer layer consisted of wedge-shaped explosive lenses with two layers—an outer, fast-burning layer, and a slow-burning core. These explosive lenses wrapped around a uranium sphere, and within this sphere nestled two nickel-coated hemispheres of plutonium. A final innermost sphere of polonium completed the structure.

When Fat Man was dropped, radar devices signaled perimeter detonators to set off the wedge-shaped charges. The outer layers burned quickly, setting off convex shock waves. The slower burning cores reshaped the shock waves to concave, sending them toward the bomb's center. The uranium layer smoothed out the waves. These waves converged on the plutonium hemispheres, which would crush together, mixing the plutonium with the polonium. The polonium would send initial neutrons into the critical mass of plutonium, sparking a chain reaction and an atomic detonation.

Fat Man was dropped on Nagasaki, Japan, on August 9, 1945. Over the next decade, the Fat Man design improved, and implosion bombs became the triggers for the hydrogen bomb.

mass of uranium, one could create a chain reaction, resulting in a weapon of unimaginable power. This realization radically changed Oppenheimer's life, as well as world history.

Soon after World War II broke out on September 1, 1939, the United States started an atomic bomb project. Fearing that German physicists might be in the lead, Oppenheimer led a team exploring atomic bomb design. However, the American bomb effort was unfocused until September, 1942, when General Leslie Groves took charge and made Oppenheimer scientific director. Oppenheimer called for the project to be centered at an isolated laboratory, and by March, 1943, a former boys' school high in New Mexico's Jemez Mountains became Los Alamos National Laboratory.

Many challenges soon emerged. There were two potential bomb methods. The first, the gun-type bomb, sent a subcritical mass of fissionable material against a plug made of another subcritical mass. When the two subcritical masses met, they would go critical, producing a nuclear detonation. The other method, devised by Seth Neddermeyer, would send an explosive charge inward, crushing a core of fissionable material, thereby producing criticality. There were also two possible bomb materials. The first was uranium 235, an isotope painstakingly separated from uranium gas, an operation executed at Oak Ridge, Tennessee. The other substance was plutonium, an exotic element discovered by Glenn Seaborg. In Hanford, Washington, giant atomic reactors, based on Enrico Fermi's prototype, labored to produce the strange metal.

By mid-1944, it became clear that there would only be enough uranium 235 to produce one gun-type bomb by July, 1945. Thus, the gun-type bomb would not make a viable strategic weapon. On the other hand, Hanford was creating enough plutonium to create a workable atomic arsenal. However, plutonium emits abundant neutrons, and it would predetonate in a gun-style bomb. So, plutonium could only be used in an implosion bomb. For implosion to work, a shock wave must be precisely aimed at the bomb's core. Unfortunately, the implosion team, lead by George Kistiakowsky, had failed to produce this effect. For Oppenheimer, the director of the project, it was a major crisis.

Finally, in the early months of 1945, Kistiakowsky made a breakthrough by using high-explosive lenses to focus the shock wave. On July 16, 1945, the world's first atomic bomb, an implosion device, detonated at Trinity Site, a remote desert basin south of Albuquerque, New Mexico. The force of the blast was equivalent to nearly 19,000 tons of trinitrotoluene (TNT). On August 6, a B-29 bomber dropped the only gun-type uranium bomb on the Japanese city of Hiroshima. Three days later, a second implosion weapon fell on Nagasaki. Both cities were devastated. Death estimates, complicated by the effects of radiation, averaged 150,000 people in each city. On August 14, Japan surrendered.

While many Los Alamos scientists opposed using the bomb on a city, arguing instead for a demonstration followed by a call to surrender, Oppenheimer supported the military use of an atomic weapon, believing that a failed demonstration would only embolden the Japanese. Yet, after the war, Oppenheimer argued vociferously for tight restraints on atomic bomb production, for international control of atomic weaponry, and against hydrogen bomb development. He did not succeed in these goals, and the nuclear proliferation he warned against became a stark reality. When the Soviet Union exploded its first atomic bomb on August 29, 1949, the arms race was in full stride.

In the late 1940's, Oppenheimer became the director of the Institute for Advanced Study in Princeton, New Jersey, and served on committees for the Atomic Energy Commission (AEC). Despite his key role in atomic bomb research, the growing anticommunist atmosphere of the 1950's ultimately engulfed Oppenheimer. In June of 1954, the AEC denied Oppenheimer his security clearance. He was barred from all official connections with the United States government, including the lab at Los Alamos. The AEC cited as reasons Oppenheimer's left-wing past and his opposition to thermonuclear weapons.

After his security hearing, Oppenheimer was bitter and subdued. While he remained the head of the Institute for Advanced Study, he did little research, and he was critical of the burgeoning development of nuclear arsenals. He died of throat cancer on February 18, 1967.

Impact

Oppenheimer's legacy is as multifaceted as the man. He was a complex person, and his contribution of the atomic bomb problematic. He is often viewed as a Faustian figure—a compassionate person filled with scientific zeal who traded his ideals for the destructive illusion of power. However, he is also seen as the brilliant physicist who helped save the world from fascism and attempted to restrain his dangerous invention. Also, as the leader of the world's first large-scale scientific project, he helped formulate the groundwork for later major endeavors like the space program.

The atomic bomb became the major nations' strategic weapon of choice. Oppenheimer watched with trepidation as the Russians detonated their first nuclear weapon, and then the United States and Russia, within nine months of each other, set off the first hydrogen bombs in 1952 and 1953. Since then, the nuclear powers have spent trillions of dollars on tens of thousands of atomic weapons. The delivery systems for nuclear weaponry include bomber jets, intercontinental missiles, and nuclear submarines. In addition to full-out nuclear Armageddon, there have been fears of nuclear terrorism. All of this Oppenheimer warned against and tried to prevent through his pleas for international control.

However, as Oppenheimer had hoped, nuclear weapons, due to their horrible nature, have prevented new world wars. Also, there are peaceful uses of atomic energy—from power generation to medicine—all of which emerge from Trinity's fiery cauldron. Finally, Oppenheimer's work in quantum physics helped produce an amazing outpouring of inventions, for quantum principles are the basis for computer technology, genetic engineering, laser technology, and many other aspects of the modern high-technology era.

Elisha Graves Otis

American mechanical engineer

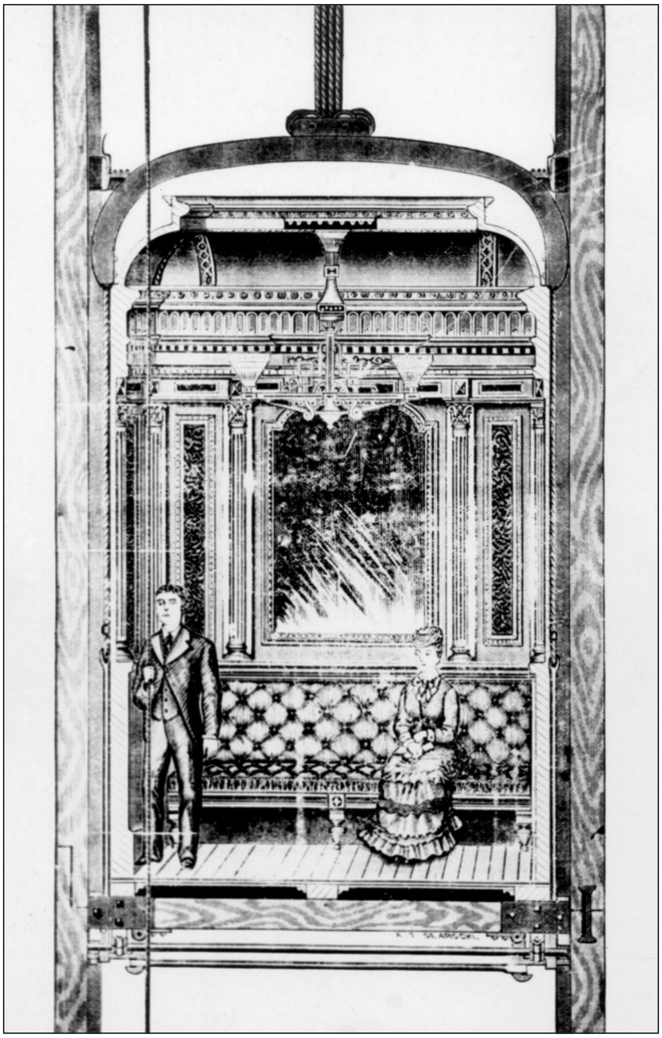
In 1852, Otis invented the first elevator equipped with the sort of safety brake that, without human intervention, would immediately keep it from falling were its cable to break. In 1854, he founded a company to manufacture, install, and maintain elevators with such safety devices.

Born: August 3, 1811; Halifax, Vermont
Died: April 8, 1861; Yonkers, New York
Primary fields: Manufacturing; mechanical engineering
Primary invention: Safety elevator

Early Life

Elisha Graves Otis was the son of Stephen and Phoebe Otis, farmers who lived in Halifax, Vermont, when Vermont was so sparsely populated that all its residents could have fit on a modern city block. Like many farm children, Elisha resisted following in his parents' footsteps. The repetitive seasons and the monotony of the daily chores accompanying this repetitiveness bored the young Otis, who had a fertile mind and a strong imagination. He was among the thousands of young people of his era who forsook their rural birthplaces for urban centers.

Anything mechanical interested the young Elisha.



An Otis hotel elevator, 1881. Wood engraving. (The Granger Collection, New York)

When the farm machinery his parents used broke down or worked inefficiently, Elisha, even before he reached his teens, devised ways of repairing and improving such machinery. Among his favorite haunts was the local blacksmith's shop, where he tinkered with farm implements brought in for repair or upgrading. By age nineteen, Elisha knew for sure that his future was not in farming but in some still undefined occupation where he could sharpen his mechanical skills. Finally, with his father's consent, he left Halifax for Troy, New York, where his brother lived and where he had been offered work.

Troy was a thriving community less than one hundred miles from Halifax and slightly north of Albany, New York. It was located on the Hudson River, a waterway that provided power for the many mills along its course and that also provided a means of transporting materials south to New York City and other ports, using both the river and the Erie Canal for transport. Elisha was intrigued by Troy's small factories and by the mechanical and technological advances that were to usher in America's industrial age.

At that time, most manufacturing operations were small, many of them established by farmers who needed something to keep them busy and to provide extra income during the slack winter months. After he left Halifax, Elisha drifted from job to job in small factories or in other enterprises. He spent five years working in construction for his brother Chandler in Troy. After that, he spent three years hauling freight between Troy and Brattleboro, Vermont, in his own wagon.

Otis began to have family responsibilities. In 1832, he married Susan Houghton. The pair became the parents of four children. When Susan died in 1842, the care of these children fell to Otis. In 1845, he was remarried, this time to Elizabeth Boyd.

In 1838, he established a grist mill in Brattleboro, but it failed within its first year, whereupon Otis converted it into a sawmill and a shop that built wagons and carriages. By 1845, Otis had moved to Albany, where he became a mechanic in a company that made bedsteads, the frames on which a bed's springs and mattress are placed. During this period, he invented an automatic bed turner. In 1848, he opened his own business, Hudson Manufactory, to produce and market his invention.

Life's Work

For his first forty years, Otis seemed to have little direction. He drifted from job to job. He was honest, dependable, and capable of supporting his wife and four children, but he lacked the sort of personal drive and ambition that might have made him a captain of industry.

In 1851, when his Hudson Manufactory failed, he seriously considered joining the legions of adventurers flocking to California during the gold rush that began in 1849. Had he joined this throng, he would likely have arrived too late to be rewarded significantly for taking the risk involved in leaving the eastern United States to relocate three thousand miles across the continent to California's gold fields. Instead, Otis followed his friend Josiah

Maize to Bergen, New Jersey, where Maize opened a factory that made bed frames. In 1852, when Maize moved this factory to Yonkers, New York, Otis again toyed with the prospect of going to California but decided instead to continue his association with Maize, who valued his efficiency and dependability.

The move to Yonkers marked a turning point for Otis. Maize put him in charge of moving his factory from Bergen, a move that required the use of hoists to transport the factory's heavy equipment without damaging it. This requirement was not easy to achieve because the hoists involved had to lift very heavy equipment. These hoists were little more than platforms lifted by thick rope cables. Most hoists then in use fell and crashed to the ground below them when the cable supporting them frayed and broke, which often happened. Such crashes destroyed expensive equipment and frequently resulted in injury or death for those operating them. Otis, a skilled inventor, set about constructing a safe hoist to move Maize's equipment.

Before long, he had constructed a hoist that would not fall precipitously if the cable supporting it broke. Soon, news of Otis's invention spread, and requests for his "safety hoist," as it was initially called, trickled in. Otis began to manufacture his invention, working on it part-time in Maize's facility in Yonkers. In 1854, after Maize went out of business, Otis stayed on and gave his full attention to manufacturing the safety hoists for which there was a growing demand.

As his business grew, Otis became a bit of a showman. He regaled audiences at the American Institute Fair in New York City's Crystal Palace by standing on one of his safety hoists and having it elevated to more than thirty feet. Then he had an employee slash the rope cable that supported the hoist. Audiences gasped because, had the hoist plunged to earth, as many were sure it might, the fall would have killed or seriously injured Otis. Rather than plunging to his death, however, Otis felt a small jolt as the platform's fall was brought to an immediate halt as his invention engaged automatically. These demonstrations, seen by hundreds of people, brought a flood of orders for Otis's invention.

At this point, safety hoists were used exclusively for moving freight. In 1857, however, Otis built an enclosed platform, creating an elevator intended to transport people from floor to floor within buildings, few of which at this time rose to more than five stories. This first passenger elevator, installed in a department store in New York City, rose along toothed guide rails and had a system for stopping the elevator the moment its cable became slack.

By 1861, the year Otis succumbed to diphtheria during an epidemic, he had produced a steam-driven elevator that rose at the rate of five stories per minute, a model that became the standard when Otis's sons, Charles and Norton, took over his corporation following his death.

The Safety Elevator

Hoists have been used in construction since ancient times. The builders of the Egyptian pyramids and the Roman aqueducts had to move heavy construction materials and equipment to considerable heights and used hoists to accomplish this feat. The principle of using hoists was somewhat refined through the years, but their basic design did not change dramatically until the middle of the nineteenth century. In 1857, Elisha Graves Otis installed the first passenger elevator in a New York City department store. Until then, elevators, called hoists, were used primarily to lift heavy equipment above ground level in buildings that ranged in height from two to five stories.

The hoists in common use in the first half of the nineteenth century were platforms set between parallel frames, usually made of wood or metal, and supported by thick rope cables, usually made of hemp. The hoists' guide rails were ratcheted, which limited them to moving in just one direction. When the hoist carried heavy loads, the supporting cables often frayed and eventually broke, dropping their cargoes to the ground below. Current safety devices used in modern elevators are descendants of early devices invented by Otis, who understood fully the dangers that most of the early hoists presented. Otis's safety hoist attracted considerable attention, and demands for it grew quickly.

In Otis's safety hoist, a cable that controls a governor at the top of the structure was attached to the side of the elevator's compartment. If the governor turned faster than it should, it triggered a safety switch automatically, an action that engaged a brake on the drive pulley. The cable of Otis's safety hoist was attached to a spring atop the frame of the hoist. Tension on the rope cable bent the spring and drew back the cams on each side of the frame, which prevented them from engaging the hoists' guide rails. If the cable broke, the spring straightened, which forced the guide rail's cams to engage, thereby keeping the hoist from falling. This action should stop the elevator safely, but the fail-safe system that is used in most modern elevators makes provision for possible brake failure, causing the governor to grab the brake cable, whose safety clamps then wedge against the guide rails on both sides of the frame.

Although the name Otis is generally associated with elevators and gave rise to the Otis Elevator Company that has operated through three centuries, Elisha Otis contributed other inventions to a society rapidly becoming industrial and technological. Among the inventions for which he received patents were a steam plow, an advanced baking oven, and a brake for railcars.

Impact

Before Otis's invention of the modern elevator, cities in the United States were horizontal. It was impractical to erect buildings of more than five stories because of the difficulty of moving people and equipment to greater heights. Otis's invention has had a profound effect on modern architecture because it made possible the construction of the skyscrapers that create the dramatic skylines of most of the world's modern cities.

Otis, almost single-handedly, changed skyscapes throughout the world from horizontal to vertical as buildings soared to new heights, limited primarily by the ability of very lofty buildings to accommodate the banks of elevators necessary to make them usable and practical.

As modern elevators became faster, the buildings that housed them soared to new heights. In some of the major cities of the world, it is possible to dine over one hundred stories above the street. In some cases, as in Chicago's John Hancock Tower, which has 102 stories, people eating in the restaurant on the top floor can look down upon small airplanes as they fly toward the landing strip at Meigs Field. It is doubtful that Otis himself could have envisioned such a scenario.

Nikolaus August Otto

German mechanical engineer

The Otto-Langen atmospheric engine improved Étienne Lenoir's internal combustion engine. Most important, Otto's invention of the four-stroke engine was decisive for the development of the modern internal combustion engine.

Born: June 10, 1832; Holzhausen, Nassau (now in Germany)
Died: January 26, 1891; Cologne, Germany
Primary field: Mechanical engineering
Primary invention: Four-stroke internal combustion engine

Early Life

Nikolaus August Otto was born on June 10, 1832, in Holzhausen, Nassau. Located on the banks of the Rhine, the village was part of Prussia's Rhineland provinces, which became part of the newly created Germany in 1871. All Otto's ancestors were farmers, bakers, and innkeepers who came from this Taunus and Westerwald region. His father, Philipp Wilhelm, was a farmer and innkeeper who also held a position as a postman in Holzhausen. None of Otto's ancestors exhibited any technical or engineering skills.

Otto was the sixth and youngest child in his family.

His father died shortly after his birth, leaving the mother with the responsibility of raising the family. After elementary school, Otto attended secondary school (*Realschule*) in Langenschwalbach between 1846 and 1848. Although his mother wanted Otto to obtain a technical education, because of her financial problems the boy left school and in 1848 started an apprenticeship as a salesman in Nastätten. After completing his training, he spent one year in a general merchandise store in the region. With the help of his brother Wilhelm, he obtained a similar job in Cologne. Between 1851 and 1862, he was a traveling salesman for such items as rice, sugar, coffee, tea, and straw bundles. His customers were primarily small shop and store owners.

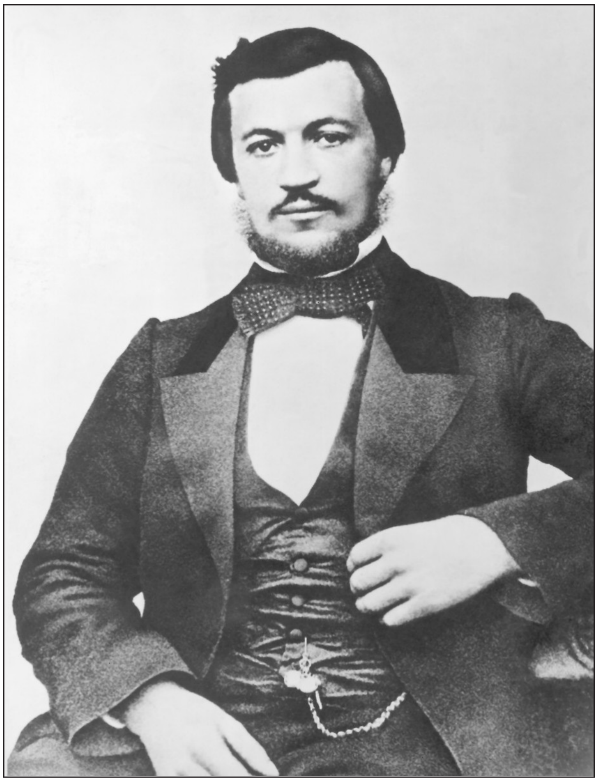
Because Otto left no exact descriptions of his work habits, it is not known when or why he first became interested in motors, particularly since he had no technical education. However, like many other inventors in the mid-nineteenth century who also lacked engineering education, Otto learned by tinkering with machines. According to his unpublished recollections of 1889, in 1860 he read about the construction of a gas engine by Étienne Lenoir, and he studied it carefully. At this time, he lived with Wilhelm, who participated in and financed his brother's early experiments with motors.

Life's Work

Otto wanted to improve the performance and construction of the Lenoir engine. Although that noncompression, internal combustion gas engine was a potential alternative to steam engines, it suffered from serious shortcomings. It consumed an enormous amount of expensive gas and required huge quantities of cooling water. In addition, the bearings had to be constantly lubricated. Otto, who was familiar with the energy needs of small shops and businesses, decided to focus on improving the Lenoir engine and commissioned mechanic Michael Zons to build one in 1861. In 1863, Otto had an atmospheric engine constructed. It used a free piston and one-third less gas than the Lenoir engine; however, it was not commercially viable. By the end of that year, Otto was short of funds, and the state of Prussia had rejected two of his patent applications.

In 1864, Otto's career as an inventor was rescued when he met Eugen Langen, an engineer and prosperous businessman. For the next quarter century, Langen provided the financial support essential for Otto's work, and he also contributed to the improvement of Otto's 1863 engine by designing a workable clutch. The two men formed a company, N. A. Otto and Cie, and their combined efforts produced a successful atmospheric internal combustion engine, the Otto-Langen engine. A mixture of gas and air was ignited to drive a piston up the cylinder, and the piston's weight plus the atmospheric pressure brought the piston back down. In 1866, the firm was granted a patent for the engine, and in 1867 the engine was awarded a gold metal at the Paris Exposition for its fuel economy.

In 1872, the firm was reorganized as the Gasmotorenfabrik Deutz corporation, and it hired Gottlieb Daimler as production manager and Wilhelm Maybach as machine designer. For a time, the Otto-Langen engine was a commercial success. However, it could not meet the demand for more power since it could produce only about three horsepower. Since Otto and Daimler clashed constantly—and spurred on by the dire warnings of Langen's close friend, professor Franz Reuleaux, of competition from more powerful engines—the firm established two company laboratories, one headed by Otto and the other by Daimler. In early 1876, Otto, with the help of the machinist Franz Ring, solved the horsepower problem and returned to one of his previous ideas of



Nikolaus August Otto, inventor of the four-stroke-cycle internal combustion engine. (Getty Images)

The Silent Otto

Nikolaus August Otto's most important invention, the four-stroke-cycle internal combustion engine, was built in 1876 and marketed by the Gasmotorenfabrik Deutz firm as "Otto's new motor," although it soon became known as the "Silent Otto" engine because it was less noisy than the Otto-Langen atmospheric engine. The Silent Otto was patented the following year, based in part on Otto's controversial argument that the special stratification of the gas/air compression he had adapted was the most revolutionary feature of this engine. In fact, it was the four-stroke cycle, allowing for the compression of the gas/air mixture within the working cylinder, that made this engine so innovative. Otto's engine was a horizontal, stationary machine, designed primarily for shops, printing presses, power stations, and other similar facilities. Unlike the Lenoir internal combustion engine, the compression occurred within the working cylinder. Also, the Silent Otto could produce more horsepower than the Otto-Langen atmospheric engine. The Silent Otto established the internal gas combustion engine as the most important new power source for industry and consumers, rivaled only by the massive expansion of the use of electrical power.

Otto's new engine established the basic principles that defined all future four-stroke-cycle internal combustion engines, regardless of size or horsepower. During the first stroke, the piston moves downward toward the crankshaft. Because of the resulting drop in pressure, a fuel and air mixture enters through the intake valve. When the cylinder obtains its maximum volume, the valve closes and the piston returns toward the top of the cylinder, compressing the gas/air mixture. This compressed mixture is then ignited by a spark, and the resulting force creates the third stroke, which forces the piston downward in the direction of the crankshaft and delivers the direct work force. When the piston reaches the bottom, the exhaust valve opens, allowing the gas to exit the cylinder. After the piston returns to the top of the cylinder, the four-stroke process is repeated.

The first Otto engine delivered only three horsepower, but by the time of Otto's death in 1891, his engines were producing as much as one hundred horsepower. Because the first engine weighed 1,450 pounds per horsepower and was dependent on urban gas supply, it was limited to urban stationary use. Otto's engine, however, evolved both in terms of power and size. By increasing the compression ratio, the engine became more powerful and the size and weight of the engine was reduced significantly, allowing it to become mobile. In 1885, Otto's old colleagues Wilhelm Maybach and Gottlieb Daimler produced a petrol gas engine weighing only 88 pounds and producing one-half horsepower. This was only the beginning of a series of developments in the emerging automobile industry. After Otto lost his German patent in 1886, his four-stroke engine became available to all entrepreneurs, helping to launch the automobile revolution in the 1890's.

compressing the gas and air in the cylinder. Otto, who invented this revolutionary four-stroke cycle (four piston strokes for each power stroke), thought that his major contribution was that he used a stratified layer of gas/air mixture that cushioned the shock to the piston.

"Otto's new motor"—nicknamed "Silent Otto" because it operated with much less noise than the atmospheric engine—was first patented in Alsace-Lorraine on June 5, 1876, and then recognized by the newly created German patent system in 1877. Unfortunately for Otto, the patent was challenged in court. Frenchman Alphonse-Eugène Beau de Rochas had patented the four-stroke engine in 1862, but he never built this engine. Even though there is no evidence that Otto knew of Rochas's ideas, in 1886 Otto's patent was rescinded in Germany. It remained valid in Great Britain and Austria. Despite this, he continued his research, receiving a patent in 1887 for his work on an ignition system for stationary petrol motors. Still, the trials took a heavy toll on Otto's health, and he died of heart failure on January 26, 1891. His only son, Gustav, continued his father's interests by becoming an engineer and founding an aircraft company in 1901.

Impact

Otto's pioneering work with engines contributed significantly to the economic and technological modernization of the world. Otto and Langen's firm Gasmotorenfabrik Deutz was the world's first factory devoted to the manufacture of internal combustion engines. It still operates in Germany, producing gas and diesel engines for the world market. Moreover, the Otto-Langen engine was the first internal combustion engine that was a commercial success. The firm and its licensed associates eventually sold five thousand Otto-Langen engines, totaling six thousand horsepower.

Even more important for the world economy was the creation in 1876 of Otto's four-stroke engine, the forerunner of most modern automobile engines. Between 1877 and 1889, the Deutz firm produced 8,308 four-stroke engines, and a firm in Manchester, England, manufactured thousands more. In 1878, at the Paris Exhibition, the Otto engine was judged the best of seventy-five models. Reuleaux called it the greatest discovery of a power machine since the contribution by James Watt. By 1889, only four out of fifty-five engine models exhibited at the Paris Exposition were noncompression gas engines. Also, the introduction of the Otto engine in Philadelphia in 1876 stimulated massive interest in this new source of power in the United States. Fifteen years later, 18,500 Otto-cycle engines were operating in the United States.

After Otto's German patent was revoked in 1886, there was an explosion in car engineering and production that relied on the four-stroke internal combustion engine. In the July, 1894, road race from Paris to Rouen (seventy-eight miles), only seven of the twenty-one cars participating were steamers, and only one of these finished in time. By 1907, the world's largest car producers, the United States and France, had manufactured nearly seventy thousand cars.

STANFORD OVSHINSKY

American machinist and scientist

Ovshinsky pioneered the field of disordered materials research known as ovonics and became a leading developer of hydrogen as an alternate fuel source. His work led to key developments in energy and information technology.

Born: November 24, 1922; Akron, Ohio
Also known as: Stanford Robert Ovshinsky (full name)
Primary fields: Automotive technology; mechanical engineering; physics
Primary invention: Ovonic switch

EARLY LIFE

Stanford Robert Ovshinsky (ov-SHIHN-skee) was born on November 24, 1922, in Akron, Ohio. He was the son of Lithuanian scrap dealer, Benjamin Ovshinsky, and his wife, Bertha Munitz. His parents instilled in him a passion for social causes. Although Ovshinsky was an avid reader with an especially keen interest in science, he never attended college. Instead, he acquired his scientific knowledge by haunting public libraries during his early life. After graduating from high school, he attended trade school to train as a machinist. He married his first wife, Norma Rifkin, and lived for a time in Arizona, where he worked in the tool room of the Goodyear plant in Litchfield. He then opened his own machine shop called the Stanford Roberts Company. In the early 1940's, Ovshinsky invented a popular automated high-speed center-driven lathe known as the Benjamin Center Drive. He later sold his company to the New Britain Machine Company.

In 1951, Ovshinsky moved to Detroit, Michigan, and accepted the position of research director at Hupp Motorcar Company, an automotive parts manufacturer. At Hupp, he was involved in the development of electric power steering. He also developed an interest in human intelligence and its uses in developing machine intelligence as well as in neurophysiology. He formed a new company, named General Automation, in conjunction with his brother Herb. He also received a 1955 invitation from Wayne State University to participate in research on the mammalian cerebellum. His experiments with switches reminded him of research he had done on how neurons functioned within the human brain. He realized that the brain uses and stores energy without the benefit of an ordered structure, and he believed that science could engineer energy information systems that would work the same way. This work began his lifelong interest in what became known as amorphous, or disordered, materials, materials in which atoms are not linked together in a precise order.

LIFE'S WORK

Ovshinsky first had to prove to an often skeptical scientific community that amorphous materials existed. He next learned how to produce thin layers of the materials at a relatively affordable cost. He started with elements such as sulfur, selenium, and tellurium, but later moved on to chalcogenides. At the same time, he continued his studies into the human brain and its relation to his other work. He designed a nerve cell model, which his brother Herb built, to further his understanding. Ovshinsky's research resulted in the discovery of the "Ovshinsky effect," by which thin, glassy films of amorphous materials become superconductors when low voltage is applied to them. He utilized this effect to produce electronic and optical switches that worked at high rates of speed, beginning with his first ovonic switch in 1957. In 1960, Ovshinsky cofounded Energy Conversion Devices (ECD) with his second wife, Iris Dibner. She had a B.A. in zoology, an M.S. in biology, and a Ph.D. in biochemistry and was his lifelong business partner until her death in 2006.

Ovshinsky and his company were interested in using their ovonics technology to further the search for alternative energy sources to fossil fuels. Ovshinsky felt that hydrogen could both produce and store energy through what he termed the "hydrogen loop," whereby water in a fuel cell is converted to hydrogen through solar-powered electrolysis and is then converted back to water, generating electricity in the process. He also achieved fame for his invention of the nickel-metal hydride (NiMH) battery used to power portable electronic devices and hybrid electric cars, including the 1999 model of General Motors' EV1. Ovshinsky utilized his methods to produce thin-film solar cells. He also designed a solar factory in Michigan featuring a shop floor with a flexible, durable, self-adhesive strip of power-generating solar material. In the 1980's, he developed solar roofing materials.

In addition to energy storage and generation, Ovshinsky's ovonics works had applications in the information technology (IT) field. Ovshinsky saw the two fields as compatible, calling information "encoded energy." His patents have been used in computer processes and

Stanford Ovshinsky, middle, at his laboratory, where experiments in ovonics are conducted. (Time & Life Pictures/Getty Images)

nonvolatile memory, rewriteable optical data storage discs, and silverless photography. His optical storage discs allow new data to be written over undeleted old data. In electronics, his work was utilized in the development of flat-panel liquid crystal display (LCD) and high-definition (HD) televisions. Japanese electronics companies licensed his technology in the 1980's to produce digital video discs (DVDs).

Ovshinsky received adjunct professorships in engineering science and physics at Wayne State University and the University of Cincinnati, respectively. He has received a number of awards and professional honors over his lifetime. He is a fellow of both the American Physical Society and the American Association for the Advancement of Science. He received the 1966 Diesel Gold Medal from the German Association of Inventors, the 1988 Coors American Ingenuity Award, the 1991 Toyota Prize for his invention of the hybrid ovonic nickel-metal hydride battery, the 2005 Innovation Award for Energy and the Environment from *The Economist* magazine, several awards for his work in solar energy, and the International Association for Hydrogen Energy Sir William Grove Award.

In 1988, the Public Broadcasting Service (PBS) show *Nova* profiled Ovshinsky in a show titled "Japan's American Genius." His numerous publications have also received recognition, including the 1992 International Symposium for Electric Vehicles award for best article. After the 2006 death of his wife and business partner Iris, Ovshinsky retired from ECD and launched Ovshinsky Innovation, LLC, with his soon-to-be third wife, Rosa Young. He continued to work on photovoltaic energy projects for use in buildings as well as his idea for a cognitive computer with a memory similar to that of the human mind. He has received hundreds of patents over the course of his career.

IMPACT

Although the scientific community greeted many of the self-educated Ovshinsky's ideas with skepticism, he persevered in demonstrating that they had key research and commercial applications and that he could take them from

The Ovonic Switch

Stanford Ovshinsky's research into amorphous, or disordered, materials and phase-change technology led to his development of the first ovonic switch in 1957. ("Ovonic" was coined from the first two letters of his last name and "electronic.") Most scientists at the time did not see the value of amorphous materials, instead working with ordered crystalline solids. Ovshinsky, however, discovered that when amorphous materials such as chalcogenide alloys were charged to a certain voltage with electricity or laser beams, they changed phase, assuming an ordered structure. The materials could then be switched back and forth from the amorphous structural phase, known as "zero" or "off," and the ordered structural phase, known as "one" or "on." The discovery was a direct result of his quest to apply his earlier research on the functioning of mammalian brain cells, in particular neurons that worked like "on/off" switches, into the design of an energy-information system.

Ovshinsky's discovery of the ovonic switch revolutionized semiconductor and phase-change technology. The fast speed at which the ovonic switch could change phases gave it a variety of uses in the fields of energy and information technology (IT). Also valuable was the fact that the ovonic materials on which the switch is based can be custom-made and produced in larger quantities than ordered crystalline materials. Ovshinsky's proof of the existence and value of amorphous materials along with his discovery of the ovonic switch allowed him to overcome the academic skepticism that greeted his early ideas and allowed his company to attract corporate sponsorships and government research grants to further his work.

Ovshinsky developed a number of other ovonic switches based on the first 1957 switch, including the ovonic phase-change memory switch and the ovonic threshold switch. In 1968, Ovshinsky announced that his company Energy Conversion Devices (ECD) had made an ovonic switch out of amorphous silicon. Many of ECD's other subsequent products and innovations were also based on the technology behind amorphous materials and their use in the ovonic switch. In the field of energy, these included his work on hydrogen as an alternative energy source, his development of thin and flexible solar cells, his work on the nickel-metal hydride (NiMH) battery, and the development of new fuel cells. In the field of IT, these included computer processors and memory, flat-screen and high-definition technology, and optical recording technology such as rewriteable CDs and DVDs.

visions to inventions. The new physics field of amorphous materials that he pioneered bears his name, ovonics, a term in common usage. A variety of past and present inventions rely on ovonics technology and his patents, and scientists are studying ovonics materials in a variety of fields, including their use as superconducting materials that allow researchers to work at much higher temperatures than that of conventional superconducting materials. Due to the depth and breadth of his ideas and inventions, he has repeatedly drawn comparisons to renowned scientist Albert Einstein and renowned inventor Thomas Alva Edison. Through his company, he has worked with a number of prominent scientists, including Hellmut Fritzsche, Morrel Cohen, David Adler, Sir Neville Mott, John Bardeen, Arthur Bienenstock, Kenichi Fukui, William Lipscomb, and Linus Pauling.

Ovshinsky's work on the "hydrogen economy" as a potential source for creating and storing energy put him in the forefront of the movement to develop cleaner, more renewable energy sources than fossil fuels and to lessen U.S. dependence on foreign oil imported from regions such as the Middle East. For example, hydrogen fuel cells that rely on his hydrogen-loop technology are a potential replacement for the standard internal combustion engine. Ovshinsky emphasizes the social as well as commercial benefits of clean energy. His work has helped the effort to make the future of electric cars, solar panels, and other green technology more realistic and affordable on a mass scale. For example, he proved that electric cars could travel adequate distances without recharging while driving at normal highway speeds. His company made photovoltaic cells that were used on the Mir space station to generate electricity from sunlight.

Although Ovshinsky's company never achieved steady profitability, his technological developments are finding their way into the commercial market on a greater scale through his company's partnerships with a number of major corporations, including Intel, Samsung, General Electric, and Chevron. For example, ECD partnered with Sharp and Standard Oil to mass-produce solar energy cells made of ovonic materials. Originally used to power calculators, they may someday be cost-effective enough to power homes and businesses.

Larry Page

American computer scientist

Page's development of the PageRank algorithm made it possible to assess more accurately the information content and usefulness of a given page on the World Wide Web and foiled several common methods for tricking search engines into ranking pages more highly than they deserved.

Born: March 26, 1973; East Lansing, Michigan
Also known as: Lawrence Edward Page (full name)
Primary fields: Computer science; mathematics
Primary invention: PageRank algorithm

Early Life

Lawrence Edward Page may well have been destined from birth to become a computer specialist. His father, Carl Victor Page, was one of the first people to receive a computer science degree from the University of Michigan. His mother, Gloria Page, was a database consultant who worked on huge mainframe computers. Larry spent most of his childhood in East Lansing, Michigan, where his father was a professor of computer science at Michigan State University.

Google cofounder Larry Page. (Getty Images)

When Larry was eight, his parents divorced. He and his older brother Carl, Jr., lived with their father, who developed a long-term relationship with another computer science professor, Joyce Wildenthal. However, Larry was also close to his mother, and he came to see both women as mother figures. Interestingly enough, the two women were close friends rather than rivals, and they collaborated to make sure that the boys could have as normal and healthy a childhood as possible.

Although Larry developed his fascination with science and technology early in his life, his inquisitive mind ranged far in the social sciences and politics as well. His family had a history of activism for liberal causes, and Larry would internalize that commitment to socially positive activity.

Larry decided to go to Stanford University for his degree in computer science. During his second year, his father took ill and died. The sense of loss was nearly overwhelming, but Larry determined to stay in school and earn his degree. He subsequently went for a master's degree and started on a doctoral program in computer science.

Life's Work

While working on his doctorate, Page became interested in the World Wide Web, in particular search engines, programs that enable users to find particular information in which they are interested. Early search engines indexed the content of Web pages but had little in the way of determining the value of the information. As a result, techniques such as "keyword stuffing" were frequently used by shady Web designers to inflate the ranking of their pages.

At first, Page was attracted to the problem as an intellectual puzzle, a suitable subject for his doctoral dissertation. Computers dealt best with facts. Making value judgements about information was a matter generally left to human minds. However, the World Wide Web was simply too large to hire enough people to evaluate all the pages to be indexed. Therefore, one had to find some easily recognizable characteristic that would effectively indicate the value of a Web page. Page found his answer in the hypertextual nature of the Web. He realized that each hyperlink to a Web page was in effect a person's judgement that the content to be found there was indeed worthwhile. One needed only count the votes and weight them appropriately to come up with a value for the actual usefulness of the Web page. This was the principle behind the link analysis PageRank algorithm, named for its inventor and its purpose, ranking Web pages.

In order to show that his theory worked, Page developed a model search engine he called BackRub, in reference to its ability to follow hyperlinks back to other pages. At first, it searched a relatively limited number of pages, since it ran on Stanford University servers and as such did not have a great deal of hard drive capacity with which to work in the indexes. Even so, many webmasters did not appreciate the repeated visits by this experimental Web crawler, and some wrote angry letters to Stanford complaining about it. Fortunately, Stanford's computer science department was willing to assist Page.

As he developed the system, Page developed a friendship with fellow computer science student Sergey Brin, a Russian immigrant. Together they realized that this technology had vast commercial potential, and they decided that it was time to strike out on their own. In 1998, they met with Andy Bechtolsheim, one of the cofounders of Sun Microsystems, a major manufacturer of high-end computer workstations. Bechtolsheim was interested enough in their idea to write them a check, but for several weeks they had no company bank account into which to deposit the check. Meanwhile, Brin and Page frantically worked to put together the necessary paperwork to incorporate their company, Google, and put together the rest of the financing they would need to start their company. They moved their business office into a friend's garage in Menlo Park, California, joining a long tradition of garage-based start-ups.

By the end of the year, they were getting more than ten thousand search engine queries a day, and the press was taking notice of their work. The company had also grown to ten employees and was in need of real office space. For a time, they rented various offices in Palo Alto, California, but in 1999 they created a permanent campus in Mountain View, soon named the Googleplex.

The amusing name reflected a corporate culture that believed in the importance of humor. The office area was open, without cubicles to divide the space into little territories. Instead, employees were encouraged to move

PageRank Algorithm

When the World Wide Web was first developed, its critics called it a wonderful library with no catalog and no index. The criticism was not too far off the mark, for there were few ways to find a Web site if one did not already know about it or happen across a link on another page. Indexes and directories arose as people tried to gather links to the pages they found useful, but these were limited to sites their compilers knew about.

To resolve this problem, a number of companies developed search engines, including Web crawlers, programs that periodically searched the Web for new pages and indexed them to be searchable. Most of the early search engines determined the position in which each page appeared on their results by looking at the content of the page. In particular, it looked at description fields in the header, but it also indexed the words within the body text.

As the Web became increasingly commercialized in the second half of the 1990's, webmasters eager to improve their rankings in the search engine (and thus increase their revenue by getting more traffic) found ways to manipulate the search engines into giving them higher rankings than were really merited. Common tricks included repeating one's description multiple times in the header and setting large blocks of text in the same color as the background at the bottom of the body text, where it would be seen by the search engine crawlers but not the page's human audience.

When these questionable tactics led pages to rank high for commonly searched keywords that were in fact unrelated to the actual content of the page, users who arrived at them would often feel frustrated and betrayed, and they would typically blame the search engine. Larry Page, a computer science student at Stanford University, realized that it would be more effective to look not at the page itself but at the pages that had linked to it. Each link from an outside page could be considered a vote for the page's quality and usefulness. This was the principle behind the PageRank algorithm, the patented system behind Page and Sergey Brin's Google search engine. In addition, rewarding pages for obtaining links from other pages rather than solely for their own content would help to increase the hypertextual nature of the Web.

In the natural course of things, many webmasters also set to finding ways to manipulate the PageRank system, creating "link farms" to artificially create the image of a very popular site. However, Google has devoted considerable effort and energy to rapidly defeating such tricks in order to maintain the usefulness of the PageRank system.

around and work with one another in informal groups that might develop and dissolve as projects emerged and were completed. State-of-the-art computers might be perched on desks made of old doors stretched over a pair of two-drawer filing cabinets. Employees could bring their pets to work, and several dogs were regularly seen roaming the campus.

Google focused on a clean site appearance with a minimum of distraction. The brightly colored Google logo above the search box lent it an air of childlike whimsy, and Page and Brin sought to instill a simple ethic upon their company: "Don't be evil." To set themselves apart from the multitudes of corporate executives who demand and collect hefty salaries, Page and Brin gave themselves a token salary of one dollar per year. Instead, for their income they would depend on the dividends derived from their substantial Google stock holdings, a move that reflected a public commitment to live or die by the success of their company.

Google has been quite successful. Although it produces no physical product and sells no advertising on its search pages, it has found a way to commodify the search process without compromising quality through its AdWords system. AdWords allows Web site owners to bid for top placement in various keywords or strings of keywords. Because advertisers want to get the most sales for their advertising dollar, they generally will concentrate their bidding activity on words and phrases that are particularly relevant to their product, rather than keywords that simply happen to be highly searched and thus very expensive.

Impact

Page's PageRank algorithm has made "Google" almost synonymous with "search engine." The search engines that were the mainstays of Internet searching before the rise of Google have shrunk to also-rans or disappeared altogether. The fact that "Google" has become a verb meaning to search the Web using Google is testament to the search engine's dominance.

Charles Parsons

English engineer

Parsons is best known for his invention of the steam turbine. His vessel Turbinia, *the fastest ship in the world in 1897, demonstrated the power of the new technology, which was soon adopted by the Royal Navy and other navies.*

Born: June 13, 1854; London, England
Died: February 11, 1931; Kingston, Jamaica
Also known as: Charles Algernon Parsons (full name)
Primary fields: Mechanical engineering; naval engineering
Primary invention: Steam turbine

Early Life

Born in London, England, in 1854, Charles Algernon Parsons began his scientific training at an early age. His father was the noted astronomer William Parsons, the third earl of Rosse, who provided a comfortable upbringing and a scientific environment for his youngest son. Charles began his education at Trinity College in Dublin and later took a degree in mathematics at Cambridge in 1877. His distinguished father presumed that his son would follow in his footsteps and make a career in the sciences. Upon graduating, however, Parsons determined to step beyond the scientific shadow of his father and establish his own reputation in the scientific community.

Against his father's wishes, Parsons accepted an entry-level position at W. G. Armstrong, a major industrial concern whose products ranged from naval armaments to locomotives. Parsons learned a great deal about industrial construction at Armstrong before moving on to other positions at other industrial firms. He worked at Kitson's, a major locomotive manufacturer attempting to attract military contracts. Parsons helped to design an improved torpedo for the Royal Navy, but Kitson's could not persuade the navy to buy it. In 1884, Parsons became the chief electrical designer at Clarke, Chapman, and Company, a locomotive company that made engines for ships. There Parsons designed and constructed the first steam turbine.

Life's Work

In the late nineteenth century, steam engines were the main power source for most of the world. These engines harnessed steam produced in a boiler to push a series of pistons. Attached to a crankshaft, the pistons provided rotary power for a variety of machines that powered the Industrial Revolution. Steam engines had several problems, however. They were noisy and smoky. They were fuel-inefficient, with only a portion of the energy produced in the boiler used to push the pistons. The rest of the steam went up the smokestack. Steam engines were also bulky. The pistons needed a lot of space to cycle up and down, so the engineering sections on ships took up a large amount of space. The biggest problem, however, was that steam engines were mechanically unreliable. They required many moving parts connected by relatively delicate linkages to turn at thousands of rotations per minute. With such complexity, breakdowns were common and potentially hazardous. When steam engines failed, pieces tended to fly out of the engine. Reliability was also a concern for ship engines. If an engine failed on the high seas, a ship became stranded.

Parsons's new steam turbine solved all these problems. The mechanical device featured a driveshaft with metal blades attached like a huge fan. When steam from the boiler entered the engine, the steam pushed against the blades and turned the driveshaft. The turbine was smaller and lighter than existing steam engines and produced less smoke. Because the turbine spun in place, it took up less area than a typical steam engine, providing room for other things inside the limited space of the ship. It was also more efficient, because the steam could be recycled through the engine before it was released up the smokestack. Most important, the turbine was very reliable. The only moving part was the driveshaft, which meant that the engine could run for a long time without breaking down or requiring extensive maintenance. The turbine had an additional benefit in that an electric dynamo could be attached to the turbine, permitting the turbine to generate electricity as well.

Parsons established two new businesses to promote his inventions: C. A. Parsons and Company to promote his electrical concerns, and the Parsons Marine Steam Turbine Company to develop his new engine. He constructed a small test vessel, the *Turbinia*, to demonstrate the new engine. Parsons initially could not get *Turbinia* up to the speeds he expected because of cavitation—the formation of partial vacuums in water by a swiftly moving solid body—which occurred when propellers spun at high speed. He invented the cavitation tunnel, a device similar to a wind tunnel that allowed him to correct the cavitation problem. Finally operating at top efficiency,

The Steam Turbine

Instead of being bulkier, heavier, and having more parts than its preceding technology, Charles Parsons's steam turbine was smaller, lighter, and simpler than the reciprocating steam engines it replaced. Because the turbine comprised little more than a series of blades arranged radially around a shaft encased in a housing, the engine required relatively few spare parts. The turbine did need a complex ball-bearing mounting to ensure that the shaft rotated smoothly. If the shaft did not rotate axially throughout its length, the momentum of the rapidly spinning shaft would cause a gyroscopic effect, wrenching the shaft out of alignment and causing massive damage to the engine. The risks were worth the effort, however, as the turbine did not totally make existing technology obsolete but instead complemented and improved it. The boilers that generated the steam for ordinary reciprocating engines were entirely sufficient to power the new steam turbines; thus, turbines made traditional types of shipbuilding better without making them obsolete. Because turbines were smaller than the older reciprocating engines, it was economically feasible to retrofit some ships with the turbine instead of rendering the ship obsolete or scrapping it.

The new turbines did require some advanced technology that earlier systems did not need. Turbine blades had to be strong but light, so metallurgical advances were necessary before Parsons's turbines became effective. The blades also needed extremely precise machine tooling, another technology necessary before turbines could exist. Turbines also required complex reduction gearing to transmit power to the propellers. Turbines revolved at thousands of rotations per minute, but the propellers only needed to turn at a few hundred rotations per minute. The reduction gearing transferred the torque of the rapidly spinning turbine shaft through a series of gears until the final gear, attached to the propeller shaft, turned at the required lower number of rotations per minute. The reduction gearing was so complex and required such precise machining that reduction gears failed far more often than the relatively simple turbines.

Turbinia could reach a speed of 34 knots, nearly ten knots faster than the swiftest ships at the time.

Parsons needed something to attract attention to his inventions, and he found it in the 1897 Naval Review. The Royal Navy hosted a gathering of British and foreign ships off the south coast of England every year. This naval review was special, however, because it also celebrated the Diamond Jubilee, the fiftieth year of Queen Victoria's reign, and the queen herself would be present. Parsons arrived without invitation at the naval review in the *Turbinia*. When Royal Navy ships tried to corner him, the *Turbinia* simply zipped away at high speed, and none of the steam engine-powered vessels could catch up. Parsons repeatedly piloted the *Turbinia* up and down the line of ships, and nothing could be done to stop him.

The navy was furious at Parsons's publicity stunt, but his demonstration did get the attention he sought. Two years later, the Royal Navy destroyers HMS *Viper* and *Cobra* were launched as test ships for Parsons's steam turbines. Parsons got an even bigger boost in 1905, when the Royal Navy announced that all of its future battleships would be turbine-powered. A year later, the revolutionary battleship HMS *Dreadnought* was launched. Powered by Parsons turbines, *Dreadnought*'s engines produced 22,000 shaft horsepower, driving the ship to a top speed of 21 knots, making *Dreadnought* the fastest battleship in the world. Following the Royal Navy's lead, other navies adopted the turbine, and Parsons's company profited handsomely from the foreign sales of its products.

Parsons soon had competition for the steam turbine market, however, and he spent much of the next decade defending his patents and firm from rival companies in Europe and the United States. The legal fights kept him away from his scientific research, and he made only relatively minor engineering breakthroughs for the rest of his career. Instead, Parsons purchased the Grubb Telescope Company, the largest manufacturer of large observation instruments, in 1925. The renamed Grubb-Parsons Company built most of the major observatory telescopes for the next thirty years.

For his accomplishments, Parsons received numerous awards. He was awarded the Royal Society's Rumford Medal in 1902, and he was knighted by King George V in 1911. In 1927, Parsons became a member of the Order of Merit, an esteemed honor conferred by the British monarch on citizens who have performed great service to the country. By royal decree, only twenty-four members of the Order of Merit can exist at any one time. Parsons spent his later years concentrating on electrical systems. Sir Charles Parsons died in 1931 at the age of seventy-six.

Impact

Parsons's turbines revolutionized naval warfare. His inventions were particularly vital at the turn of the twentieth century, as Europe was dividing itself into armed camps driven by international rivalry. The tensions in Europe would trigger World War I in 1914, a conflict in which battleships powered by Parsons's turbines played a significant role. The Royal Navy's decision to switch to turbine-powered battleships gave it an advantage over other navies that constructed only a relative few turbine-powered ships. Foreign navies, lagging behind in turbine technology, continued to build ships with the older piston engines that were prone to breaking down. England's turbine-powered ships, on the other hand, not only enjoyed a speed advantage over their rivals but also were more reliable during battle. After the war, the use of turbines in passenger ships made leisure travel safer and more efficient, and cruise ships enjoyed a boom in popularity in the 1920's and 1930's thanks to Parsons's invention.

Blaise Pascal

French physicist and mathematician

Pascal made important contributions to geometry, statistics, and probability theory. His work in physics led to the invention of the hydraulic press and the syringe, and to the modern understanding of the field of hydraulics.

Born: June 19, 1623; Clermont-Ferrand, France
Died: August 19, 1662; Paris, France
Primary fields: Mathematics; physics
Primary inventions: Hydraulic press; syringe

Early Life

Blaise Pascal (blayz pahs-KAHL) was born to Étienne and Antoinette Begon Pascal in Clermont-Ferrand, France. The family was well-to-do; the elder Pascal was a lawyer and judge. When the young Pascal was just three years old, his mother died. He was a frail and sensitive child whose health was always problematic. For this reason, his father insisted on educating the boy at home; by all accounts, Pascal's education was eccentric but resulted in his precocious accomplishments.

Pascal, his two sisters, and his father moved to Paris in 1631. At that time, his father gave up all of his outside work and devoted himself entirely to his intelligent young son's education. Pascal's studies included Latin, Greek, mathematics, and science. Although his father encouraged him to concentrate on Latin and Greek, Pascal proved to be particularly talented in mathematics

Blaise Pascal. (Library of Congress)

and the sciences. An apocryphal story suggests that when he was just twelve years old, Pascal arrived independently at Pythagoras's theorem of right triangles. Pascal's father was closely connected to some of the most important mathematical and scientific minds of his day, including Gilles Roberval, Girard Desargues, and Pierre de Fermat. The young Pascal was permitted to sit in on their discussions, greatly influencing his remarkable gifts in mathematics. Thus, although Pascal did not have any formal schooling, his education was of the highest order.

About 1639, Étienne Pascal unwisely became involved in political intrigue and nearly was sent to prison. Instead, in 1640, he was appointed tax officer in Rouen, and the family moved there. A rebellion among the poor in the area had resulted in the destruction of most of the records, and the senior Pascal was charged with overhauling the entire accounting system. The task was herculean, made even more difficult because French currency was not based on a decimal system. For three years, Blaise Pascal's father toiled away at calculations every day and far into the night. In sympathy, Pascal invented a calculating machine to help him with his work. In 1644, a Rouen artisan produced the first working model of the invention, and Pascal was later granted a patent for the machine. Although ingenious in construction and accurate in computation, the machine never enjoyed widespread use. The cost of construction made it prohibitive for all but the very wealthy.

Although it seemed clear that Pascal would have a lifetime career in mathematics and science, an event in 1646 changed the direction of his life. His father broke his leg in Rouen, and two brothers came to care for him. The brothers stayed with the family for three months and ultimately converted the entire family to Jansenism, a movement within Catholicism at odds with the prevailing Jesuit dogma. As a result of this conversion, and a second, more profound conversion experience in 1654, Pascal ultimately turned away from his scientific work and began instead to write religious and theological essays.

Life's Work

In terms of his scientific and mathematical life's work, Pascal achieved most of his accomplishments when he was quite young, although his most important works were not published until after his death. Pascal's work in physics had far-reaching ramifications for the modern world. About 1644, he became interested in experiments concerning vacuums conducted by the Italian Evangelista Torricelli, who invented the barometer. Pascal built on Torricelli's work by conducting a series of famous experiments with barometers. He constructed mercury barometers and had them taken to the top of a cathedral and to the top of a mountain. The results of his experiment demonstrated what is now known as atmospheric pressure. The same experiment also proved for Pascal that the empty space in the barometer above the mercury was a vacuum, something his contemporaries refused to believe could exist.

Pascal began writing a treatise on vacuums but did not complete the work. Around 1651, however, he completed two short treatises that would prove to be his most important contributions to the field of physics: *Traitez de l'équilibre des liqueurs, et de la pesanteur de la masse de l'air* (*The Physical Treatises of Pascal: The Equilibrium of Liquids and the Weight of the Mass of the Air*, 1937), published in 1663, a year after his death. The first treatise describes a complete system of hydraulics, something that had never been done before. The second demonstrates that nature's so-called abhorrence of a vacuum can be explained through the system of hydraulics. In the process of writing these treatises, he invented the hydraulic press and the syringe.

His work in mathematics is largely documented through correspondence with Fermat in 1654. Most notably, he developed what has come to be known as Pascal's triangle, or the arithmetical triangle, used in algebra and, more commonly, in probability theory. Pascal's triangle can be used to find combinations. In other words, the triangle can help solve the problem, "How many ways can one pick *x* objects from a set of *y* objects?" For example, one could imagine a set of five books. The question might arise, "What is the number of possible combinations of two books taken from this set?" Pascal's triangle quickly reveals the answer to be ten possible combinations. In games of chance, such as dice, the triangle can be used to predict the probabilities of particular throws. Pascal's work with this in mathematics and probability theory also set the scene for later developments in computational science, and ultimately, computers.

In 1656, Pascal had a religious experience that caused him to leave behind his scientific and mathematical work. During the last years of his life, he wrote the philosophical and religious treatises for which he subsequently became most famous. In 1656 and 1657, he published *Lettres provinciales* (*Provincial Letters*, 1657). The work was ostensibly a series of letters written by someone in Paris to a friend living in the country. In fact, it was a highly satiric and tightly written attack on many of the religious views of the day. The work angered the Jesuits and the king of France, who ultimately ordered the book burned. The book, however, enjoyed wide readership. Pascal also planned to write an apology for the Christian religion, a project he undertook beginning about 1657. He was not able to complete this project before his death; however, the section that he did complete, *Pensées* (1670; *Monsieur Pascal's Thoughts, Meditations, and Prayers*, 1688), is a beautiful and well-respected work.

Pascal died on August 19, 1662, after twelve months of painful illness. At the time of his death, he was very well known and highly respected for his mathematical and scientific accomplishments. Ironically, with the passage of time, *Pensées* has become his most famous work, enjoying a large readership well into the twenty-first century.

Impact

It is unusual to find one individual who so deeply influences spiritual and religious thinking as well as shapes the future of mathematical and scientific reasoning. Pascal did both, devoting his young life to scientific discoveries and inventions, and the remainder of his life to God. Because of his early work on vacuums and liquids, he virtually founded the modern study of hydraulics. By demonstrating how hydraulic pressure can multiply force, Pascal made possible such commonplace devices in the modern world as hydraulic brakes on airplanes and trucks, and syringes used in medicine. One of the most important inventions was the hydraulic press, a device that makes much modern manufacturing possible. The hydraulic press is used for forming metals or for any task that requires a great deal of force.

Pascal's memory continues to be honored in several fields. His name is attached to a common computer programming language. A "pascal" is also the name for the metric unit of pressure. Many high school and college mathematics courses discuss Pascal's triangle. Likewise, physics courses teach students about Pascal's law, a principle of hydrostatics. It is difficult to believe that a man

The Hydraulic Press

Blaise Pascal's treatise on the equilibrium of liquids led to the formulation of what became known as Pascal's law. This theory states that a change in pressure on a fluid in a closed container will be carried without loss of pressure to every part of the fluid and to the walls of the container. The pressure is the same throughout the fluid and extends in all directions. Another way of saying this is that pressure throughout a closed system is constant. Further, when there is an increase in pressure on any point of the enclosed liquid, there will be an equal increase on every other point in the container.

This principle makes possible the transmission of force. Just as a lever can be used to move a very heavy object with less force than it would take to move the object without the lever, a hydraulic system uses a liquid, such as water or oil, to transmit force. To illustrate this point, one can imagine two connected cylinders: A one-square-inch cylinder on the left filled with fluid and a ten-square-inch cylinder on the right filled with fluid. Each is fitted with a piston. When a force of one pound is exerted on the smaller piston, it will lower the fluid ten inches. The pressure is then distributed throughout the entire system. That is, the pressure on one square inch on the left is distributed on each one-square-inch segment of the larger cylinder on the right. This pressure will result in lifting a ten-pound weight one inch. This is the principle on which a mechanic's automotive lift works: The transmission of force through liquid allows for a very heavy object (such as an automobile) to be lifted with much less force than it would take to lift the object directly.

who lived only to the age of thirty-nine, and who was sick for most of his life, was able to accomplish so much.

—Diane Andrews Henningfeld

LOUIS PASTEUR

French chemist and microbiologist

A pioneer in the field of microbiology, Pasteur established, on the most general level, what came to be known as the germ theory of disease. His studies of the way germs attacked the body led to important discoveries to prevent or lessen, through immunization, the dangers of many previously fatal diseases.

Born: December 27, 1822; Dôle, Jura, France
Died: September 28, 1895; Villenueve-l'Etang, near Saint-Cloud, France
Primary fields: Biology; chemistry; medicine and medical technology
Primary inventions: Pasteurization; immunization with vaccines for rabies and anthrax

Louis Pasteur. (Library of Congress)

EARLY LIFE

Louis Pasteur (LEW-ee pa-STUR) was born on December 27, 1822, in Dôle, a small city in the historic province of Franche-Comté in eastern France. His family descended from the traditional agricultural peasantry, but his father had shifted from farming to local artisanal work as a tanner. When the young Pasteur was encouraged by his teachers to prepare for examinations that would allow him to study in Paris, he initially hesitated.

Pasteurization

The process known as pasteurization was initially developed in the early 1860's by Louis Pasteur in collaboration with the well-known physiologist Claude Bernard. Today, pasteurization is almost automatically associated with the conservation of milk, cream, and cheeses. Apparently, it was a later German chemist, Franz von Soxhlet (1848-1926), who was responsible for the widespread use of the pasteurization process for commercial dairy products.

When Pasteur carried out his pioneer work, the primary focus of concern was to prevent bacterial spoilage in commercially produced wines. Nonetheless, the principal processes involved are the same, whatever the edible product may be. Essentially, the aim of pasteurization is to reduce significantly the bacterial process associated with spoilage and, very importantly, to kill any pathogenic organisms that can spread diseases to the consumer of tainted dairy products. Two of the most dangerous diseases involved come from *Mycobacterium tuberculosis* and an infection caused by *Coxiella burnetii* commonly called Q fever. Other diseases that can be prevented by pasteurization are diphtheria, scarlet and typhoid fever, and strep throat.

Pasteur discovered that carefully controlled heating for an equally carefully controlled period of time can kill sufficient numbers (not all) of potentially pathogenic microorganisms in the organic substance in question. Pasteur proved that such reduced numbers of surviving bacteria do not constitute a real danger of infection if the product is refrigerated immediately and consumed within a certain period of time—within the expiration date on many commercial products today.

Equipment used to carry out the pasteurization has evolved considerably since the introduction of large vats that had to be heated for as much as thirty minutes. Modern devices have made it possible to treat large quantities with ever-increasing levels of efficiency. There are two widely recognized methods used in today's food processing industry. One process, known as high-temperature, short-time (HTST) pasteurization, involves passing raw milk products through a heating system that creates a uniform temperature of from 57° to upwards of 72° Celsius (about 135° to 162° Fahrenheit), holding that temperature for a period of at least sixteen seconds. Specific temperatures and timing can vary depending on the product being pasteurized. Extreme care must be taken to assure that heated batches do not intermix in any way with liquids coming into the treatment system. A second process, known as ultra-high-temperature (UHT) pasteurization, or asceptic processing, is more common than HTST methods in markets where refrigeration is less easily accessible. In this process, exposure to higher temperatures (91°-146° Celsius, or 195-295° Fahrenheit), which kills more microorganisms, is followed immediately by packaging in hermetically sealed containers. UHT products can be stored for long periods without refrigeration.

However, after his first exposure to a demanding academic environment in Besançon, the capital of Franche-Comté, he succeeded not only in going to Paris but also in gaining admission to France's most highly respected training school for teachers, the École Normale Supérieure. There, he concentrated his studies on chemistry rather than biology.

Life's Work

The professional career of Pasteur spanned nearly half a century. It began with his first rather brief appointment in 1848 in Dijon as a professor of physics at the lycée level. By 1849, he was named professor of chemistry, first at the University of Strasbourg, then at the University of Lille. These posts came after the wider scientific world of the time recognized the importance of his research in the area of crystallography. What he discovered in the mid-1840's was totally new: chiral molecules (that is, molecules that differ from their mirror image and cannot be superimposed as "twins") in the crystals of compounds usually produced from an organic "starter base." When Pasteur passed light through two crystallized compounds—one derived from organic matter, the other from inorganic chemical synthesis—he found that the latter were asymmetric (like right- and left-hand gloves), even though they were chemically identical to organically derived material. This discovery opened the door to a number of new scientific applications involving crystals.

At an early stage in the career that would earn him worldwide recognition, Pasteur's experiments focused on the issue of fermentation and conditions surrounding the genesis of microorganisms. Initially, there was a quite practical side to his work on fermentation, since the economically vital alcoholic beverage industries—both beer and wine—frequently lost a portion of their production when unpredictable souring occurred in their vats. When Pasteur took on the job of explaining this problem, he discovered that samples of bad beer contained both the yeast cells that spark fermentation and unwanted microorganisms that, as they multiplied in the liquid, became dominant, overwhelming the desirable bacteria needed for successful brewing. Pasteur's experiments that aimed at preventing this souring of beers and wines would form the basis of the later work with dairy products that gained him international fame: "pasteurization," or short-term moderate heating to kill off harmful microorganisms without destroying desirable ones.

Later stages of his work to protect key industries from contamination are associated with his years after 1857 as director of the scientific studies program at the École Normale Supérieure, where he had been a student himself in the mid-1840's. He discovered that a near-epidemic disease called pebrine, which prevented the hatching of silkworm eggs or killed young silkworms before they could produce the silk lining of their cocoons, was linked to transmission—via exposure of healthy silkworm eggs to "bad eggs" (often but not always eggs imported from abroad) that were carriers of dangerous microbes.

The key to preventing this presence of unwanted bacteria wherever their presence resulted in spoiling was to combine essential steps for maintaining sanitary conditions at every stage of handling any number of vulnerable organic products with the use of controlled levels of heat to destroy specifically identified bacteria in milk without harming the desired product itself.

Linked to this industrial phenomenon was the growing realization of the importance for medical doctors to use disinfectants to sterilize the entire local surrounding environment in order to prevent sepsis, the spread of bacteria from a point of infection to areas surrounding the infection. Application of disinfectants in hospitals, and particularly at the time of surgical operations, was quickly adopted by doctors. Although early guidelines for such preventive measures were based on Pasteur's findings, the name most often associated with the systematic use of disinfectants in hospitals is that of the Scottish surgeon Joseph Lister (1827-1912).

Pasteur's findings dispelled forever the "spontaneous generation" theory of germs, which held that the source of infection was in the organism from the outset. The extension of Pasteur's discoveries in the practical sphere of food conservation to the different subfields of microbiology would have a major impact on the scientific world's understanding of the transmission of infectious diseases. Most important, his studies of germ theory led him to develop the earliest vaccines, opening the field of immunization that became an important scientific tool for fighting disease in the twentieth century.

Pasteur's discoveries in the area of immunization began when he was studying fatal occurrences of anthrax, a disease that struck herds of both dairy and meat cows in many areas of Europe. He observed what he thought to be different levels of reaction to the disease among different animals in the same herd. He found through experiments that injection of live anthrax bacteria into the bloodstream of cows that had already contracted anthrax but had recovered did not seriously affect survivors. This discovery led to his supposition that injecting light doses of anthrax into healthy animals might lessen the severity of the disease if they contracted it later, or might even prevent infection altogether. Further tests proved his theory correct. Pasteur called the injection of such light doses of infectious bacteria into healthy organisms "vaccination" (from the Latin *vacca*, cow)—a gesture some think represented his recognition of earlier, similar work on cowpox by the British medical doctor and scientist Edward Jenner).

By the mid-1860's, Pasteur had returned to the University of Lille to serve as dean of the recently established faculty of science. His research there began to focus on infectious diseases in humans. A most significant breakthrough that would affect his international reputation came when he laid the basis for a rabies vaccine. His laboratory in Lille received public funds to support rabies research as early as 1867, but—somewhat surprisingly, perhaps, given Pasteur's skills in developing vaccines—his first use of the rabies vaccine with human subjects did not come until 1885, largely because of his collaboration with the medical doctor Pierre-Paul-Émile Roux, one of Pasteur's close colleagues and a major contributor (after 1887) to the newly founded Pasteur Institute in Paris.

Well before he succeeded in treating, and then—once a vaccine could be produced—taking measures for systematic prevention of the effects of rabies in humans, Pasteur spent considerable time experimenting with rabies in animals. Laboratory analysis had already localized the disease in the central nervous system of rabid dogs. Following the procedures he had pioneered in dealing with anthrax, Pasteur first extracted fluids from the spinal column of a rabid dog and produced symptoms of the disease in animals who had received injections of a reduced dosage. As his work progressed, the obvious became apparent: Rabies was transmitted via dog bites when the diseased animal's saliva entered the bloodstream of the victim. When it came to carrying out experiments with human patients, however, great care had to be taken. The first daring application by Pasteur (who was not himself a medical doctor and therefore not professionally qualified to treat patients) of the vaccine produced by Roux came in 1885, when a nine-year-old boy's life was saved after a daring decision to treat him with the rabies vaccine. Before long, news of the unprecedented event spread to many other countries, and requests soon came in for dissemination of Pasteur's findings—not only in the field of immunization but also in other fields—to the broader scientific world.

Various methods would be used to prepare vaccines, beginning in Pasteur's day with the same methods pioneered when he developed anti-anthrax serums: taking samples from the bodies of living infected animals. In the case of rabies, graphic descriptions exist of excruciating and dangerous procedures used to obtain samples from the saliva of rabid dogs. With time and expanding knowledge of chemistry, it became possible to build identical molecular structures of many vaccines in the laboratory, expanding the possibility of supplying medical laboratories all over the world.

A widely recognized monument to Pasteur's accomplishments remains the Pasteur Institute, a private nonprofit research institution with branches in many different cities in France and around the world. Originally founded in 1887, the institute combined closely related fields of specialization in microbiology with the practical concerns of medical doctors. The first such medical doctor was Jacques-Joseph Grancher, who was a specialist in the treatment of rabies. In its early years, the institute not only was involved with research but also established the first formal courses for students in the field of microbiology. Although Pasteur maintained a personal residence outside of Paris, it was a sign of dedication to his work that most of the last seven years of his life were spent in the private apartment within the original institute building. Since 1936, that building has housed a museum dedicated to his life work as well as a separate chapel where he was buried after his death.

From its quite focused beginnings under Pasteur, the institute would expand enormously during the twentieth century. Counted among the twelve research departments operating in the twenty-first century are Ecosystems and Epidemiology of Infectious Diseases, Parasitology, Neuroscience, and Virology.

Impact

Before Pasteur proved that hygienic prophylaxis could prevent diseases from establishing themselves in animals and humans, many biologists continued to subscribe to the idea of "spontaneous generation" of germs. Pasteur not only won this battle against archaic views of disease but also founded entirely new fields of preventive medicine: Pasteurization would obviously become a major procedure for processors of dairy products, and immunization an essential part of modern medical science. Pasteur's early work on vaccines, especially his rabies vaccine, might have been somewhat overshadowed in the twentieth century by vaccines that were developed against very widespread diseases like tuberculosis, diphtheria, tetanus, and yellow fever, but without his basic scientific contributions, such advances would have been delayed considerably.

Ruth Patrick

American botanist and limnologist

Patrick devised a method of assessing environmental pollution in freshwater lakes and rivers by measuring the presence of diatoms, or algae. She also developed a model for determining the health of a body of water; this ecosystem approach would thereafter be used routinely by scientists, environmentalists, and government researchers. Patrick became known worldwide for her pioneering work in limnology, or the study of freshwater biology.

Born: November 26, 1907; Topeka, Kansas
Also known as: Ruth Myrtle Patrick (full name)
Primary field: Biology
Primary invention: Diatometer

Early Life

Ruth Myrtle Patrick was born in Topeka, Kansas, on November 26, 1907, but spent almost all her early life in Kansas City, Missouri. Her father, Frank Patrick, who had majored in botany at Cornell University in Ithaca, New York, had become a lawyer and a banker only because his father was convinced that as a scientist he would not be able to support himself. However, Frank spent his spare time in the nearby woods collecting specimens. Often, he would take Ruth and her older sister, Catherine, along with him. When Ruth was seven, her father gave her a microscope, enabling her to look at the microscopic organisms, which would become her lifelong study. Even though at the time it was generally assumed that only men could be scientists, Frank always encouraged Ruth to pursue her interests. In fact, he would often tell her that she did not need to learn how to cook or sew; since she was going to be a scientist, he said, she could hire others to do those jobs. Ruth's mother, Myrtle Moriah Jetmore Patrick, shared her husband's belief that women should not be trapped in domestic duties. Her own passions were music and French. It is significant that her older daughter, Catherine, eventually earned a Ph.D. in psychology and became a women's rights activist.

After graduating in 1925 from the Sunset Hill School in Kansas City, Ruth took biology courses at the University of Kansas in Lawrence. However, the following year she transferred to Coker College, a small women's college in Hartsville, South Carolina. During summer breaks, her father arranged for her to take courses at Woods Hole Oceanographic Institute in Massachusetts and at Cold Spring Harbor Laboratory on Long Island, New York. In 1929, she received her B.S. degree in biology from Coker College. In 1931, she was awarded an M.S. degree from the University of Virginia. That same year, Patrick married Charles Hodge IV, an entomologist whom she had met at Cold Spring Harbor Laboratory, but at her father's request Patrick continued to use her maiden name. The couple moved to Philadelphia, where Hodge's family had lived for generations. Hodge joined the faculty of Temple University, where he would remain for more than thirty years. Meanwhile, Patrick worked on her own degree, and in 1934 she was granted a Ph.D. in botany by the University of Virginia. Her doctoral thesis was on the diatoms, or microscopic algae, of Southeast Asia.

Life's Work

In 1933, Patrick managed to obtain a position as a researcher at the Academy of Natural Sciences in Philadelphia. At the outset, she was told that because she was a woman, she would not be paid for her work. However, though she would not be put on the payroll until 1945, Patrick soon gained the respect of her male colleagues. In 1937, she was appointed associate curator of the Microscopy Department and curator of the academy's Leidy Microscopical Collection. Immediately, she began work on revitalizing the academy's research on diatoms. She organized the various collections into a Diatom Herbarium; she headed research expeditions that resulted in the addition of new specimens; and she updated both the indices of diatom species and the lists of publications on the subject.

Though Patrick had found the study of diatoms a highly effective way to assess pollution in freshwater, she now envisioned extending such an analysis to other creatures, including not just diatoms but also all the plants and animals living in a particular environment. This ecosystem approach, which became known as the Patrick principle, prompted her in 1947 to found a Limnology Department at the academy, which she chaired, while also serving as curator.

Though Patrick wanted to have a child, she worried that her busy schedule would interfere with parenting. However, she became convinced that it was quality time that was most important. In 1951, Charles Hodge V was born. It soon became obvious that like his parents, he was fascinated by science. When he was seven, his mother presented him with the same microscope her father had given her. Charles Hodge V went to medical school and became a pediatrician, specializing in gastrointestinal problems.

In the late 1940's, William B. Hart, an oil company executive, heard Patrick present a paper on her theories at a scientific conference and immediately hired her to pursue her experiments. One of Patrick's first projects involved applying the Patrick principle to research in the Conestoga River basin near Lancaster, Pennsylvania. The result was a landmark environmental study. Hart's high regard for Patrick helped her to acquire corporate funding for other projects, including a study commissioned by DuPont to assess the impact that the projected Savannah River Nuclear Plant would have on the Savannah River. In 1975, Patrick became the first environmentalist, as well as the first woman, on the DuPont board of directors. She remained a member of the Savannah River Site's Environmental Committee until 1997.

Over the years, Patrick has surveyed all of the rivers in the United States and many in other parts of the world. She estimated that her research has taken her to at least 850 rivers. She reported the conclusions she reached as a result of her studies in over two hundred scientific papers and in a number of books, including the multivolume series *Rivers of the United States*, which began to appear in 1994, and *Groundwater Contamination in the United States* (1987), which was coauthored by Patrick. Her preeminence in her field has brought her numerous honors. In 1973, for example, she was named the first female chair of the board of trustees of the Academy of Natural Sciences of Philadelphia, and in 1976 she was made honorary chairman of that same body. In 1973, she was named to the academy's Francis Boyer Chair of Limnology. She has lectured at Yale University and at the University of Pennsylvania and has received more than twenty honorary degrees and more than forty-five honors and awards. In 1970, she became the twelfth woman to be elected to the National Academy of Sciences. In 1991, the University of South Carolina-Aiken named the Ruth Patrick Science Education Center in her honor. In 1996, she received the National Medal of Science from President Bill Clinton.

Patrick's influence has been felt far beyond the academic community. The friendly relationships she maintained with corporate leaders have enabled her to secure funds for research, and she has managed to convince them that the environment faces real dangers and that as citizens they have a duty to limit or to eliminate damage to it. Patrick has also demonstrated a capacity to work well with government leaders. In 1966, she served on President Lyndon B. Johnson's Science Advisory Committee, Panel on Water Blooms, and in 1982 she was a member of President Ronald Reagan's Advisory Commission on Acid Rain. She also served on numerous other committees at the federal and state levels. In addition, Patrick has been active in environmental groups such as the World Wildlife Fund and the Nature Conservancy.

In 1985, Charles Hodge IV died. Ten years later, Pat-

The Diatometer

Ruth Patrick's theory that water quality could be determined by studying diatoms led her to invent the diatometer. The device enables scientists to collect assemblages of diatoms at specific points in bodies of water so that the specimens can be analyzed for indications of algal responses to pollutants. Generally, the sites chosen are places where there is a considerable discharge of waste water into the larger body of water.

A diatometer is a floating rack with up to six slots in it, each of which will hold a glass microscope slide. Before the diatometer is assembled, the slides to be used are labeled and then cleaned, and from that point on they must not be touched except on the edges. The rack and the slides are then transported to the project site, where the diatometer is assembled. However, before it is installed, it is essential that the flow velocities at the study site are checked, so that the diatometer will be moored firmly enough not to break loose. Sometimes anchors are used to keep the instrument in place; at other times, it is attached by ropes to trees or pilings. There are several other considerations in the placement of a diatometer. It must be in deep enough water so that it can float freely; there must be no danger of it touching bottom; and it should be in direct sunlight, at least for part of each day. A diatometer is usually left in place for about fourteen days, which is a long enough period for the diatoms on the slide to develop fully. In some studies, a series of diatometers is placed at a single location, so that changes over time can be observed; in others, a number of diatometers are positioned near each other and are later removed at the same time.

Researchers throughout the world now use diatometers to check freshwater bodies for pollution. Their conclusions enable government officials to make decisions that will preserve the aquatic ecosystems—for example, by banning the release of certain pollutants into waterways or by setting limits on others.

rick married Lewis H. Van Dusen, Jr., a Philadelphia lawyer and a family friend. On November 17, 2007, the Academy of Natural Sciences held a gala to celebrate Ruth Patrick's upcoming hundredth birthday.

Impact

Patrick devised ways to test the pollution levels of freshwater bodies, notably by inventing the diatometer and by formulating the Patrick principle, both of which became standard tools for researchers. Moreover, through the years she taught her theories and her methods to hundreds of students and mentored many future scientists. Patrick always stressed teamwork, not only making sure that students with a single specialty worked together but also ensuring that every project involved specialists trained in different disciplines—botany and biology, for example—and even chemistry and physics. Thus, she put the Patrick principle into practice, and the success of the Conestoga River study proved how effective her approach was. Necessarily, experts in many different areas made Patrick's Limnology Department their academic home, and soon the department became known for what was then an unusual practice, multidisciplinary research.

Patrick's books and her many scientific papers turned the attention of other scientists to long-neglected dangers to the environment, such as freshwater pollution. However, Patrick's influence did not stop with the academic community. Through her personal contacts with leaders in business and industry and with elected officials, she has played an important role in raising their awareness of ecological issues and in persuading them to develop effective environmental policies.

Les Paul

American guitarist

In addition to inventing the kind of solid-body electric guitar that made rock music possible, Paul developed a number of unusual recording techniques that are now standard in the recording studio, such as sound-on-sound, overdubbing, and tape delay.

Born: June 9, 1915; Waukesha, Wisconsin
Died: August 13, 2009; White Plains, New York
Also known as: Lester William Polfuss (birth name)
Primary field: Music
Primary inventions: Solid-body electric guitar; multitrack recording

Early Life

The father of the modern electric guitar was born Lester William Polfuss in Waukesha, Wisconsin. His father, George, left home when Les was eight, estranged partly by his wife Evelyn's radical communist politics. Evelyn became a doting "stage mother" to young Lester, indulging his passion for music. When he brought home a harmonica given him by a ditch digger, Evelyn boiled it before his son put it to his mouth—unintentionally making the reeds capable of the bluesy sound Les would come to emulate. When he finally picked up the guitar four years later, the twelve-year-old Les was fascinated with WLS radio star Pie Plant Pete, who met Les at a concert and showed him how to finger the guitar. Within weeks, Les had mastered Pete's repertoire and was soon imitating it on rival station WJJD. Calling him "Red Hot Red," Evelyn Polfuss found him gigs at PTA meetings, and he would sneak into speakeasies at night. By the summer of his junior year, 1932, he was on the road with a picker named Sunny Joe Wolverton and left school to play with him on KMOX in St. Louis, then the seventh-largest city in the United States. The partnership only lasted two years, by which time Les was listening to and imitating jazz in Chicago, as well as building pickups for his first experiments in electric guitars.

Paul began playing in Chicago with Jimmy Atkins, older brother of later guitar legend Chet Atkins. In 1938, Paul made the jump to network radio with Fred Waring and his Pennsylvanians, forming a side act with Atkins on acoustic guitar and Ernie Watkins on bass, under the name of the Les Paul Trio. In the midst of traditional studio recording sessions with his trio at that time, Paul experimented at home in his garage studio, recording different parts at different speeds and editing them together. He was on the verge of inventing techniques that would revolutionize the recording industry.

Les Paul with "the Log." (Getty Images)

LIFE'S WORK

While neither of the inventions for which Les Paul is most famous—the solid-body electric guitar and magnetic tape overdubbing—were totally original with him, he was, like most innovators in the electronics field, a creator of something distinctive and influential built on existing technology. In the crudest sense, however, Paul has as early a claim as anyone to the invention of the electric guitar, since he improvised one while playing for tips in the parking lot of Beekman's Barbecue Stand in Waukesha in 1929, at the age of fourteen. Adolph Rickenbacker (1886-1976) is usually credited with the first electric guitar, in 1931, but his was based on the same hollow body as acoustic guitars. By the end of the 1930's, Rickenbacker was also marketing a solid-body electric guitar, and Leo Fender (1909-1991) was experimenting with similar designs when, in 1941, Paul first demonstrated his design. It was nicknamed "the Log" because it was simply a block of wood the width of a fretboard, to which were attached the two halves of a traditional hollow-body guitar. The solid wood core prevented the insides of the body from acting as a sounding chamber.

Paul brought his design to the Gibson Guitar Corporation in Nashville, Tennessee, in hopes of interesting the manufacturer in producing his design. Gibson was not interested—until its rival Leo Fender showed how lucrative the electric guitar market was with the introduction of the Broadcaster (later the Telecaster) solid-body electric in 1950. Hiring Paul as a consultant, Gibson president Ted McCarty designed a solid-body guitar that he named the "Les Paul" and contracted Paul's endorsement. Paul and his fans have often exaggerated his role in the development of the Gibson Les Paul, but at the first meeting between McCarty and Paul in the fall of 1951, McCarty already had a prototype. Paul did, however, contribute one element to the design. His only suggestion regarding the prototype was that it incorporate the sort of tailpiece he had pioneered on the Log that gave him the muting sound Paul had made famous. It had a trapeze-shaped bar below the strings. It was fitted into Gibson's design, and the Gibson Les Paul was born.

There is little mystery about why Gibson wanted Les Paul to be part of its name brand. In 1951, Paul was not only the top guitarist in the world (both in sales and in the *Down Beat* polls) but also one of the top-selling recording artists of any type. The Les Paul-Mary Ford version of "How High the Moon" spent nearly half the year (twenty-five weeks) on the *Billboard* charts, nine weeks of that time in the number one spot. On August 25 of that year, *Billboard* magazine announced that the duo became the first act in history to have four hits simultaneously in the famous Top 40. Paul and Ford (his wife) ended 1951 tied with Patty Page for best-selling recording artists (they even sang some of the same songs). Paul and Ford had more Top 10 hits in 1951 than Bing Crosby, Frank Sinatra, and the Andrews Sisters combined.

One of the keys to the success of those recordings was another series of Les Paul inventions: overdubbing, tape delay effects, and multitrack recording. In 1948, Paul was playing on Bing Crosby's radio show when Crosby bought the first mass-produced tape recorder in America, the Ampex Model 200. Fascinated with Paul's experiments with double-tracking and overdubbing on wax disks, Crosby gave Paul an Ampex 200 and encouraged him to continue. Paul added a second recording head, slightly misaligned, allowing two tracks to be recorded on the same tape. Crosby at the time was recording with the top female harmony recording group, the Andrews Sisters. Paul, who had recorded with the Andrews Sisters, realized that his wife could sing all three harmony parts with his multitracking technique. He had already been using it on multitrack disk to record multiple guitar parts, playing some back at different speeds, allowing his already-fast picking technique to appear superhumanly faster ("Lover," 1947). Putting the two together produced the stunning effects that propelled "How High the Moon" to number one.

Paul understood, more than the marketing executives at Capitol Records did, how much of the appeal of these multitracked recordings was due to their "modern" sound. However, instead of putting this modernity across with hip, modern compositions—these were the waning years of the big band era, and Elvis Presley had not yet appeared—Paul stunned listeners with up-tempo, electrified versions of old-fashioned hits, including covers of the 1918 jazz classic "Tiger Rag" (Paul's first recording with the Gibson Les Paul) and Al Jolson's 1926 hit "I'm Sitting on Top of the World," which *Variety* identified as the thirteenth consecutive Paul-Ford single to sell half a million copies.

THE LOG

In 1941, Les Paul convinced the management of the Epiphone Guitar Company to allow him to use its West 14th Street factory after hours to test some of his theories of guitar construction. The Epiphone he used at the time was one of the first electric guitars, but Paul objected to two of its acoustic qualities: first, the hollow body created a resonance that caused feedback with the amplified sounds; second, it dampened the vibration of the strings so that the guitarist could not sustain a note. In the Epiphone machine shop, he solved both problems by bolting a sheet of metal across the S-shaped holes on the body. Paul realized that he was retrofitting, however: He had learned enough about engineering to understand that even the solid-body guitars of the time, Rickenbacker and Fender, mimicked the shape that the acoustic nature of the traditional guitar required but the electric guitar did not.

Understanding that shape did not affect the sound, which came from the electrical connection, the pickup, Paul took a plain four-inch-square post and attached the neck of a Gibson guitar. The fingerboard came from a Larson Brothers guitar. Two decades before Jimi Hendrix and Jimmy Page achieved amazing vibrato effects with what the sixties called a "whammy bar," Paul designed a similar tremolo arm—in the forties it was called a "vibrola," a lever attached to the tailpiece that allowed him to vary the tension of the strings. Instead of commercial pickups, Paul used coils from an electric clock.

The finished product looked more like a fencepost than a guitar. M. H. Berlin, president of Gibson Guitar's parent company, called it "a broomstick with a pickup" when Paul showed it to him, hoping Gibson would manufacture it. Berlin declined the offer, perhaps postponing by a decade the creation of the Gibson Les Paul guitar. Dubbed "the Log," Paul's invention did not look much like a guitar, though Paul sometimes attached wings fashioned from two halves of an acoustic guitar. The few times he played it in live gigs, however, he removed them for the shock value of the unconventional appearance. In 1990, the Log was donated to Nashville's Country Music Foundation Museum, where it quickly became one of the most popular exhibits.

Impact

No electric guitarist has been more influential on popular music—rock, country, and jazz—than Paul. Furthermore, the recording techniques he pioneered—tape delay, sound-on-sound, multiphasing, and multitracking—became standard in the studio. Multitrack recording, in fact, became virtually universal, even when an artist was not playing multiple instruments. Paul even invented the mechanical means by which multitracking became possible, when he modified an Ampex 200 by adding a second recording head. His design experiments on the solid-body electric guitar were vital to its development, even if his claims as an inventor are not fully granted, because he combined experiments in performance with experiments in guitar construction.

In 2003, *Rolling Stone* magazine rated the top guitarists of all time, and Les Paul was ranked number 46. Many of the top guitarists of the time objected, arguing that his rating should be higher because of his massive influence and sheer longevity. In 2006, at the age of ninety, Paul won two Grammys for his album *Les Paul and Friends*. In the summer of 2008, Discovery World in Milwaukee opened a museum exhibit featuring his contributions to the electric guitar and the recording industry. Paul died on August 13, 2009, at the age of ninety-four.

Gerald Pearson

American physicist

Besides playing a supporting role in the invention and improvement of the transistor, Pearson worked with two other principal researchers at Bell Telephone Laboratories to invent the photovoltaic cell, commonly known as the solar cell, which uses sunlight to generate electricity.

Born: March 31, 1905; Salem, Oregon
Died: October 25, 1987; probably United States
Also known as: Gerald Leondus Pearson (full name)
Primary fields: Electronics and electrical engineering; physics
Primary invention: Photovoltaic cell

Early Life

Gerald Leondus Pearson was born in Salem, Oregon, on March 31, 1905, to David Shafer Pearson and Sarah Allen Pearson. When he finished high school, he stayed in his hometown to enroll at Willamette University, from which he received a bachelor's degree in physics and mathematics in 1926. During the next academic year, he taught at a high school and then, in 1927, enrolled at Stanford University, near Palo Alto, California. At Stanford, he majored in physics, carried out experiments with X rays, and earned a master's degree in 1929. On June 30 of that year, in Rosedale, Oregon, he married Mildred Oneta Cannoy (1906-2000). The newlyweds soon moved to New York City, where Pearson began work for Bell Telephone Laboratories, initially concentrating on reducing electronic noise and then on developing thermistors, which are resistors that show special sensitivity to temperature. During World War II, he carried out research with a friend and fellow physicist at Bell Labs, Walter H. Brattain, on infrared detectors for U.S. military use.

Life's Work

By 1945, Pearson, Brattain, and other scientists and engineers were working at the new Bell Labs campus in Murray Hill, New Jersey. Pearson shared an office with Brattain, who smoked cigars with him, and both men joined the research group for semiconductors when the war ended in August. In October, 1945, John Bardeen, another physicist, joined them. Their supervisor was the physicist William Shockley, brilliant but sometimes abrasive.

In its efforts to develop a solid-state amplifier to replace the commonly used vacuum tube, the research group soon concentrated on the semiconductors germanium and silicon, and through experiments Pearson learned how impurities in crystals of those elements affect the flow of electrons and holes (absences of electrons) in the crystals. In addition, he worked with Brattain to try to produce the electric field effect that Shockley had predicted in April, 1945; that is, Pearson and Brattain tried to use an external electric field to control the flow of holes and electrons in very thin layers of semiconductors.

Early in the spring of 1946, Pearson and Brattain had a slight success in creating a field effect in germanium when they used liquid nitrogen to reduce its temperature drastically. In December, 1947, about the time Brattain and Bardeen invented the point-contact transistor (a solid-state amplifier using point contacts), Pearson had a greater success in creating a field effect by using a suggestion from Shockley. On a plate of quartz, Pearson placed a film of positive-type, or P-type, germanium (germanium in which an impurity has produced an excess of holes). With a wire attached to each end of the germanium-coated plate and a little drop of the electrolyte glycol borate on the germanium, he used a wire touching the drop to apply a small voltage, which

The Photovoltaic Cell

In 1839, Alexandre-Edmond Becquerel discovered the photovoltaic effect in general by exposing a particular solution to light and noticing an electric current, and in 1873 Willoughby Smith discovered the effect for selenium. Beginning with Russell Ohl's discovery in 1940, silicon has proved itself an especially suitable semiconductor for a photovoltaic cell. An individual silicon atom has fourteen protons (each positively charged) in its nucleus, as well as fourteen electrons (each negatively charged) in its electron shells. In the outer shell, there are four electrons and four holes where electrons could be. Within a crystal, each silicon atom bonds with four other silicon atoms, with which it shares electrons.

Boron, with just three electrons in its outer shell, can be used to dope a crystal of pure silicon and, by introducing holes (absences of electrons) into it, turn it into positive-type (P-type) silicon—although in isolation the crystal as a whole remains uncharged because its number of electrons equals its number of protons. Comparably, phosphorus, with five electrons in its outer shell, can be used to dope pure crystalline silicon and, by introducing electrons that do not fit into the crystal lattice, turn it into negative-type (N-type) silicon—although, again, in isolation the crystal as a whole remains uncharged because of the equal number of protons and electrons.

When manufacturers form a PN junction by creating P-type silicon on one side of a wafer and N-type silicon on the other side of the same wafer, electrons flow from the N-type silicon to the P-side of the junction, creating a net negative charge there, and holes flow from the P-type silicon to the N-side of the junction, creating a net positive charge there. When a sufficiently energetic photon (quasiparticle) of light hits an electron on the P-side of the junction, the electron receives energy from the photon. Hardly being able to go farther into the P-side of the junction because of the negative charge there, it returns to the N-side, where it has a significant chance of getting into a conducting channel built into the surface and passing through a circuit, thus helping to provide electric power. While the light shines, the process keeps going with billions upon billions of electrons. Combining photovoltaic cells in series within a frame to form a photovoltaic module (a solar panel), manufacturers have provided a technological means through which the Sun works directly for humankind.

changed the current in the film significantly. He recorded his success in his laboratory notebook with an entry dated December 12.

On the afternoon of December 23, Pearson spoke briefly at the first presentation to high-level Bell Labs executives of Brattain and Bardeen's solid-state amplifier. After his talk and the others were over, Pearson and his fellow researchers witnessed the first formal demonstration of this device, this first transistor. Less than three days later, on the snowy morning of December 26, Pearson achieved the field effect without using glycol borate. Using a thin piece of mica with gold on one side and germanium on the other, he applied a voltage to the gold and thus produced a small change in the current in the germanium.

Regrettably, the invention of the point-contact transistor led to a troublesome situation for researchers, such as Pearson, in the semiconductor group. Shockley was too competitive to be entirely happy that Bardeen and Brattain had invented the device without his own close involvement. Furthermore, the discovery that the little-known physicist Julius Lilienfeld had already patented a device depending upon the electric field effect meant that Shockley's name could not legitimately be on the patent for the point-contact transistor. Pearson avoided taking sides personally in the dispute, but his work pushed him toward Shockley professionally. The issue of *Physical Review* dated July 15, 1948, contained Shockley and Pearson's article "Modulation of Conductance of Thin Films of Semi-Conductors by Surface Charges," which derived from Shockley's theory and Pearson's experiments. The two articles by Bardeen and Brattain in the same issue, however, became more important.

With his laboratory skill, Pearson helped Shockley improve the transistor. Building on an experiment performed at Bell Labs by Richard Haynes, Pearson learned how to make very narrow filaments of germanium. Those filaments would let holes or electrons flow with some ease but would nevertheless control the flow. The intent was to lessen electronic noise by doing away with at least one of the metal points of the point-contact transistor. By the middle of August, 1948, Pearson, Shockley, and Haynes had built a filamentary transistor in which only one point contact remained. In a sign that hard feelings lingered between Brattain and Bardeen, on the one hand, and Shockley, on the other, the two direct inventors of the point-contact transistor did not work on the filamentary one. Furthermore, in a reorganization at Murray Hill in the spring of 1951, Brattain and Bardeen joined the physics of solids research group, while Pearson joined the transistor physics research group, led by Shockley.

Pearson therefore played an important part in the development of Shockley's junction transistor, which Bell Labs announced to the public on July 4, 1951. Depending not at all on point contacts but, in its developed form, on a sandwich-style arrangement with positive-negative junctions, or PN junctions, the junction transistor soon led to the photovoltaic cell, or solar cell, which contains only one PN junction. Actually, Russell Ohl, another Bell Labs colleague, had noticed a strong photovoltaic effect in 1940 when he had shone a flashlight on a silicon rod. Mastery of the manufacture of uniform and pure silicon crystals, however, was necessary for the development of practical photovoltaic cells, as was mastery of doping, the careful contamination of the silicon with certain elements to make it electrically either P-type or N-type.

While researchers at Bell Labs were working successfully at improving techniques for making and doping silicon crystals, Daryl Chapin worked there trying to develop an efficient photovoltaic cell that would use the Sun's energy to power telephones where no other reliable power was available. In 1952, Pearson was working nearby with Calvin Fuller to build a silicon rectifier to convert alternating current to direct current. To increase conductivity, Fuller doped the silicon with gallium. Then Pearson dipped the gallium-doped silicon into heated lithium. Afterward, he found that, when he exposed the treated silicon to light, it produced an electric current, and he quickly told Chapin. After further work by the three researchers improved the efficiency to Chapin's goal of 6-percent efficiency, Bell Labs announced the invention to an appreciative public on April 25, 1954.

Pearson remained at Bell Labs until he retired from the company in 1960. In September of that year, he became a professor of electrical engineering at Stanford, where he worked at his own research, especially on compound semiconductors, and helped his students with theirs. Even after his formal retirement from the faculty in 1970, he remained active in research for years. By the time he died, on October 25, 1987, he had earned numerous honors and the respect of physicists and electrical engineers around the world. His wife and two children survived him, as did grandchildren and great-grandchildren.

Impact

Unlike Shockley, Bardeen, and Brattain, Pearson never received a Nobel Prize. Nevertheless, along with them, Chapin and Fuller, and other researchers at Bell Labs, Pearson contributed enormously to electronic technology. In peace or at war, at home or in the office, or on the road between, people in highly developed countries and often in underdeveloped ones depend on instruments containing descendants of the junction transistor that Pearson helped develop. Complex machines such as automobiles, airplanes, and digital computers, all of which existed before the transistor, have come to rely on what Pearson helped bring into the world. As for the photovoltaic cell, it gained use quickly not only for powering telephones in remote places but also for powering satellites orbiting the Earth. By the early twenty-first century, photovoltaic cells produced the electric current for the transistors within the pocket calculator and, on a larger scale, provided the electric current that powered some houses. In the opinion of numerous engineers and scientists, photovoltaic cells promised to yield environmentally harmless energy for everything from the lamps bordering a driveway to the car in it and the building at the driveway's end.

John Stith Pemberton

American druggist

As an effort to provide Civil War veterans with a commercial pain reliever less addictive than available opiates, Pemberton's formula was not successful. As a soft drink under the name of Coca-Cola, it became the world's best-selling beverage.

Born: July 8, 1831; Knoxville, Georgia
Died: August 16, 1888; Columbus, Georgia
Primary field: Manufacturing
Primary invention: Coca-Cola

Early Life

John Stith Pemberton was born in Knoxville, Georgia, but his family moved to Rome, Georgia, in his childhood. In 1848, Pemberton enrolled in the Southern Botanico-Medical College of Georgia in Macon, and he received his degree in 1850. His training was mostly in herbal cures, and upon graduation he set up a chemical laboratory where he produced patent medicines. He also, at this time, took a degree in pharmacy. In 1853, he married Ann Eliza Clifford Lewis, and together they moved to Columbus, Georgia, where he established a wholesale drug business. On January 19, 1861, as the nation entered the Civil War, Georgia became the fifth state to secede from the Union, and Pemberton enlisted in the Third Georgia Cavalry Regiment, rising to the rank of lieutenant colonel.

On Easter Sunday, 1865, Colonel Pemberton was wounded in the defense of Columbus. It was in the treatment of this wound that Pemberton was given the morphine to which he would remain addicted the rest of his life. Moving his family to Atlanta, Pemberton created what was perhaps the most advanced chemical laboratory of his day, not only producing the patent medicines he had developed in Columbus but also testing soil and chemical fertilizers for the state of Georgia. The lab he established, now a part of the Georgia Department of Agriculture, is still in operation. One of his products, an imitation of French coca wines (wines laced with a distillate of the coca leaf), was promoted as a headache cure. Pemberton used it himself for that purpose. When Atlanta became a “dry” city in 1886, outlawing the consumption and sale of alcohol, Pemberton appealed to the growing temperance movement by replacing the wine in his formula with sugar water. Combining the coca leaf extract (a source of cocaine) with the kola nut (a source of caffeine), Pemberton produced a drink without the slightest trace of alcohol that also functioned as a stimulant.

Life’s Work

The mixture of kola nut and coca leaf was not Pemberton’s invention. Angelo Mariani and Company Vintners of Paris developed a Bordeaux wine with coca and kola known as Vin Mariani. In March of 1885, Pemberton advertised his own version of the laced wine, asserting its superiority to Mariani’s. Coca had been the nineteenth century methadone: Civil War veterans, including Pemberton, injected cocaine in the vain belief that it might cure morphine addiction, which was so common among veterans that it was referred to as “the Army disease.” Some physicians warned, correctly, that the dangers of cocaine addiction were as real as those of morphine, but Pemberton denounced those fears in the press. Even before July 1, 1886, when Atlanta went dry (prohibiting the sale or consumption of alcohol), Pemberton knew that the Reverend Sam Jones’s temperance movement was making wines hard to market in his city. Consequently, he spent that winter and spring experimenting with a “temperance drink” with coca, kola, and an aphrodisiac called “damiana.” He would concoct formulas in his laboratory, then send them to Willis Venable, who operated a soda fountain at Jacob’s Pharmacy, for his customers to try.

As a chemist, Pemberton knew that caffeine was the active ingredient in the kola nut, and that it was more commonly derived from coffee and teas. He was convinced, however, that the caffeine from the kola nut, isolated by Merck laboratories in Darmstadt, Germany, was superior and nonaddictive: He said so in a paper he delivered to the Georgia Pharmaceutical Society in April of 1886. In the same paper (read for him at the convention by a colleague, since Pemberton could not tear himself away from his beverage experiments), Pemberton extolled the virtues of the coca leaf, and he emphasized, as Angelo Mariani had with his coca wines, that the preferred Peruvian coca leaves were those with smaller amounts of cocaine, but with other alkaloids present.

COCA-COLA'S SECRET FORMULA

In a five-page appendix to his book on Coca-Cola, *For God, Country, and Coca-Cola* (2000), Mark Pendergast details the fortuitous coincidence by which he stumbled upon John Stith Pemberton's original recipe, and he gives the world's most secret formula in its entirety. Pemberton's original formula book was apparently kept by his apprentice, John P. Turner, who opened his own pharmacy in Columbus, Georgia. In 1943, Turner's son gave it to the Coca-Cola Company, who carefully removed the page labeled "Coca-Cola."

Pendergast, however, found another page with Pemberton's original formula, which had escaped notice because it was headed only with an *X* at the top of the page. There is no mention of the kola nut, which is surprising considering the emphasis Pemberton placed on that ingredient. The first ingredient listed, however, is "citrate caffein" (1 ounce), which is surely the kola nut extract produced by Merck, which Pemberton lauded in 1886. Next is vanilla extract (1 ounce). The third ingredient is merely listed as "flavoring," but the flavors are listed at the bottom of the recipe: oil orange, oil lemon, oil nutmeg, oil cinnamon, oil coriander, and oil neroli, dissolved in alcohol and left to stand for twenty-four hours. The remaining ingredients are fluid extract of coca (4 ounces), citric acid (3 ounces), lime juice (1 quart), sugar (30 pounds), water (2.5 gallons), and "caramel sufficient"—that is, enough to color the mixture.

The flavoring mixture was the key to the "secret formula" mystique after Pemberton's death. Asa Candler, who bought the Coca-Cola Company in 1892, made this list of essential oils top secret and saw to it that all these items were stripped of their labels as soon as they arrived. Candler code-named the flavoring formula "7X" (for the seven ingredients listed above, including the alcohol in which the mixture is dissolved). By the time this formula was back in the Coca-Cola Company archives in the 1940's, citric acid had been replaced in the mixture by phosphoric acid. Also, because the addictive nature of caffeine was well known, the amount of caffeine was reduced (and caffeine-free coke became available in the 1980's). It is likely that Pemberton's original formula is the one Pendergast found, and it is the one given here.
